I. Introduction to the Cell

1. The Evolution of the Cell

Introduction

All living creatures are made of cells - small membrane-bounded compartments filled with a concentrated aqueous solution of chemicals. The simplest forms of life are solitary cells that propagate by dividing in two. Higher organisms, such as ourselves, are like cellular cities in which groups of cells perform specialized functions and are linked by intricate systems of communication. Cells occupy a halfway point in the scale of biological complexity. We study them to learn, on the one hand, how they are made from molecules and, on the other, how they cooperate to make an organism as complex as a human being.

All organisms, and all of the cells that constitute them, are believed to have descended from a common ancestor cell through *evolution by natural selection.* This involves two essential processes: (1) the occurrence of random *variation* in the genetic information passed from an individual to its descendants and (2) *selection* in favor of genetic information that helps its possessors to survive and propagate. Evolution is the central principle of biology, helping us to make sense of the bewildering variety in the living world.

This chapter, like the book as a whole, is concerned with the progression from molecules to multicellular organisms. It discusses the evolution of the cell, first as a living unit constructed from smaller parts and then as a building block for larger structures. Through evolution, we introduce the cell components and activities that are to be treated in detail, in broadly similar sequence, in the chapters that follow. Beginning with the origins of the first cell on earth, we consider how the properties of certain types of large molecules allow hereditary information to be transmitted and expressed and permit evolution to occur. Enclosed in a membrane, these molecules provide the essentials of a self-replicating cell. Following this, we describe the major transition that occurred in the course of evolution, from small bacteriumlike cells to much larger and more complex cells such as are found in present-day plants and animals. Lastly, we suggest ways in which single free-living cells might have given rise to large multicellular organisms, becoming specialized and cooperating in the formation of such intricate organs as the brain.

Clearly, there are dangers in introducing the cell through its evolution: the large gaps in our knowledge can be filled only by speculations that are liable to be wrong in many details. We cannot go back in time to witness the unique molecular events that took place billions of years ago. But those ancient events have left many traces for us to analyze. Ancestral plants, animals, and even bacteria are preserved as fossils. Even more important, every modern organism provides evidence of the character of living organisms in the past. Present-day biological molecules, in particular, are a rich source of information about the course of evolution, revealing fundamental similarities between the most disparate of living organisms and allowing us to map out the differences between them on an objective universal scale. These molecular similarities and differences present us with a problem like that which confronts the literary scholar who seeks to establish the original text of an ancient author by comparing a mass of variant manuscripts that have been corrupted through repeated copying and editing. The task is hard, and the evidence is incomplete, but it is possible at least to make intelligent guesses about the major stages in the evolution of living cells.

From Molecules to the First Cell[1]

Simple Biological Molecules Can Form Under Prebiotic Conditions[1, 2]

The conditions that existed on the earth in its first billion years are still a matter of dispute. Was the surface initially molten? Did the atmosphere contain ammonia, or methane? Everyone seems to agree, however, that the earth was a violent place with volcanic eruptions, lightning, and torrential rains. There was little if any free oxygen and no layer of ozone to absorb the ultraviolet radiation from the sun. The radiation, by its photochemical action, may have helped to keep the atmosphere rich in reactive molecules and far from chemical equilibrium.

Simple organic molecules (that is, molecules containing carbon) are likely to have been produced under such conditions. The

best evidence for this comes from laboratory experiments. If mixtures of gases such as CO_2, CH_4, NH_3, and H_2 are heated with water and energized by electrical discharge or by ultraviolet radiation, they react to form small organic molecules - usually a rather small selection, each made in large amounts (Figure 1-1). Among these products are compounds, such as hydrogen cyanide (HCN) and formaldehyde (HCHO), that readily undergo further reactions in aqueous solution (Figure 1-2). Most important, representatives of most of the major classes of small organic molecules found in cells are generated, including *amino acids, sugars,* and the *purines* and *pyrimidines* required to make *nucleotides.*

Although such experiments cannot reproduce the early conditions on the earth exactly, they make it plain that the formation of organic molecules is surprisingly easy. And the developing earth had immense advantages over any human experimenter; it was very large and could produce a wide spectrum of conditions. But above all, it had much more time - tens to hundreds of millions of years. In such circumstances it seems very likely that, at some time and place, many of the simple organic molecules found in present-day cells accumulated in high concentrations.

Complex Chemical Systems Can Develop in an Environment That Is Far from Chemical Equilibrium

Simple organic molecules such as amino acids and nucleotides can associate to form *polymers.* One amino acid can join with another by forming a peptide bond, and two nucleotides can join together by a phosphodiester bond. The repetition of these reactions leads to linear polymers known as polypeptides and polynucleotides, respectively. In present-day living cells, large polypeptides - known as proteins - and polynucleotides - in the form of both ribonucleic acids (RNA) and deoxyribonucleic acids (DNA)are commonly viewed as the most important constituents. A restricted set of 20 amino acids constitute the universal building blocks of the proteins, while RNA and DNA molecules are constructed from just four types of nucleotides each. Although it is uncertain why these particular sets of monomers were selected for biosynthesis in preference to others that are chemically similar, we shall see that the chemical properties of the corresponding polymers suit them especially well for their specific roles in the cell.

The earliest polymers may have formed in any of several ways - for example, by the heating of dry organic compounds or by the catalytic activity of high concentrations of inorganic polyphosphates or other crude mineral catalysts. Under laboratory conditions the products of similar reactions are polymers of variable length and random sequence in which the particular amino acid or nucleotide added at any point depends mainly on chance (Figure 1-3). Once a polymer has formed, however, it can itself influence subsequent chemical reactions by acting as a catalyst.

The origin of life requires that in an assortment of such molecules there must have been some possessing, if only to a small extent, a crucial property: the ability to catalyze reactions that lead, directly or indirectly, to production of more molecules of the catalyst itself. Production of catalysts with this special self-promoting property would be favored, and the molecules most efficient in aiding their own production would divert raw materials from the production of other substances. In this way one can envisage the gradual development of an increasingly complex chemical system of organic monomers and polymers that function together to generate more molecules of the same types, fueled by a supply of simple raw materials in the environment. Such an autocatalytic system would have some of the properties we think of as characteristic of living matter: it would comprise a far from random selection of interacting molecules; it would tend to reproduce itself; it would compete with other systems dependent on the same feedstocks; and if deprived of its feedstocks or maintained at a wrong temperature that upsets the balance of reaction rates, it would decay toward chemical equilibrium and "die."

But what molecules could have had such autocatalytic properties? In present-day living cells the most versatile catalysts are polypeptides, composed of many different amino acids with chemically diverse side chains and, consequently, able to adopt diverse three-dimensional forms that bristle with reactive sites. But although polypeptides are versatile as catalysts, there is no known way in which one such molecule can reproduce itself by directly specifying the formation of another of precisely the same sequence.

Polynucleotides Are Capable of Directing Their Own Synthesis3

Polynucleotides have properties that contrast with those of polypeptides. They have more limited capabilities as catalysts, but they can directly guide the formation of exact copies of their own sequence. This capacity depends on complementary pairing of nucleotide subunits, which enables one polynucleotide to act as a template for the formation of another. In the simplest case a polymer composed of one nucleotide (for example, polycytidylic acid, or poly C) can line up the subunits required to make another polynucleotide (in this example, polyguanylic acid, or poly G) along its surface, thereby promoting their polymerization into poly G (Figure 1-4). Because C subunits preferentially bind G subunits, and vice versa, the poly-G molecule in turn can

promote synthesis of more poly C.

Consider now a polynucleotide with a more complex sequence of subunits - specifically, a molecule of RNA strung together from four types of nucleotides, containing the bases uracil (U), adenine (A), cytosine (C), and guanine (G), arranged in some particular sequence. Because of complementary pairing between the bases A and U and between the bases G and C, this molecule, when added to a mixture of activated nucleotides under suitable conditions, will line them up for polymerization in a sequence complementary to its own. The resulting new RNA molecule will be rather like a mold of the original, with each A in the original corresponding to a U in the copy and so on. The sequence of nucleotides in the original RNA strand contains information that is, in essence, preserved in the newly formed complementary strands: a second round of copying, with the complementary strand as a template, restores the original sequence (Figure 1-5).

Such complementary templating mechanisms are elegantly simple, and they lie at the heart of information transfer processes in biological systems. Genetic information contained in every cell is encoded in the sequences of nucleotides in its polynucleotide molecules, and this information is passed on (inherited) from generation to generation by means of complementary base-pairing interactions.

Templating mechanisms, however, require additional catalysts to promote polymerization; without these the process is slow and inefficient and other, competing reactions prevent the formation of accurate replicas. Today, the catalytic functions that polymerize nucleotides are provided by highly specialized catalytic proteinsthat is, by *enzymes*. In the "prebiotic soup" primitive polypeptides might perhaps have provided some catalytic help. But molecules with the appropriate catalytic specificity would have remained rare unless the RNA itself were able somehow to reciprocate and favor *their* production. We shall come back to the reciprocal relationship between RNA synthesis and protein synthesis, which is crucially important in all living cells. But let us first consider what could be done with RNA itself, for RNA molecules can have a variety of catalytic properties, besides serving as templates for their own replication. In particular, an RNA molecule with an appropriate nucleotide sequence can act as catalyst for the accurate replication of another RNA molecule - the template - whose sequence can be arbitrary. The special versatility of RNA molecules is thought to have enabled them to play a central role in the origin of life.

Self-replicating Molecules Undergo Natural Selection[3], [4]

RNA molecules are not just strings of symbols that carry information in an abstract way. They also have chemical personalities that affect their behavior. In particular, the specific sequence of nucleotides governs how the molecule folds up in solution. Just as the nucleotides in a polynucleotide can pair with free complementary nucleotides in their environment to form a new polymer, so they can pair with complementary nucleotide residues within the polymer itself. A sequence GGGG in one part of a polynucleotide chain can form a relatively strong association with a CCCC sequence in another region of the same molecule. Such associations produce complex three-dimensional patterns of folding, and the molecule as a whole takes on a specific shape that depends entirely on the sequence of its nucleotides (Figure 1-6).

The three-dimensional folded structure of a polynucleotide affects its stability, its actions on other molecules, and its ability to replicate, so that not all polynucleotide shapes will be equally successful in a replicating mixture. Moreover, errors inevitably occur in any copying process, and imperfect copies of the originals will be propagated. With repeated replication, therefore, new variant sequences of nucleotides will be continually generated. Thus, in laboratory studies, replicating systems of RNA molecules have been shown to undergo a form of natural selection in which different favorable sequences eventually predominate, depending on the exact conditions. Most important, RNA molecules can be selected for the ability to bind almost any other molecule specifically. This too has been shown, in experiments *in vitro* that begin with a preparation of short RNA molecules with random nucleotide sequences manufactured artificially. These are passed down a column packed with beads to which some chosen substance is bonded. RNA molecules that fail to bind to the chosen substance are washed through the column and discarded; those few that bind are retained and used as templates to direct production of multiple copies of their own sequences. This new RNA preparation, enriched in sequences that bind the chosen substance, is then used as the starting material for a repetition of the procedure. After several such cycles of selection and reproduction, the RNA is found to consist of multiple copies of a relatively small number of sequences, each of which binds the test substance quite specifically.

An RNA molecule therefore has two special characteristics: it carries information encoded in its nucleotide sequence that it can pass on by the process of replication, and it has a specific folded structure that enables it to interact selectively with other molecules and determines how it will respond to the ambient conditions. These two features - one informational, the other functional - are the two properties essential for evolution. The nucleotide sequence of an RNA molecule is analogous to the genotype - the hereditary information - of an organism. The folded three-dimensional structure is analogous to the phenotype -

the expression of the genetic information on which natural selection operates.

Specialized RNA Molecules Can Catalyze Biochemical Reactions[5]

Natural selection depends on the environment, and for a replicating RNA molecule a critical component of the environment is the set of other RNA molecules in the mixture. Besides acting as templates for their own replication, these can catalyze the breakage and formation of covalent bonds between nucleotides. For example, some specialized RNA molecules can catalyze a change in other RNA molecules, cutting the nucleotide sequence at a particular point; and other types of RNA molecules spontaneously cut out a portion of their own nucleotide sequence and rejoin the cut ends (a process known as self-splicing). Each RNA-catalyzed reaction depends on a specific arrangement of atoms that forms on the surface of the catalytic RNA molecule (the *ribozyme*), causing particular chemical groups on one or more of its nucleotides to become highly reactive.

Certain catalytic activities would have had a cardinal importance in the primordial soup. Consider in particular an RNA molecule that helps to catalyze the process of templated polymerization, taking any given RNA molecule as template. (This ribozyme activity has been directly demonstrated *in vitro,* albeit in a rudimentary form.) Such a molecule, by acting on copies of itself, can replicate with heightened speed and efficiency (Figure 1-7A). At the same time, it can promote the replication of any other type of RNA molecules in its neighborhood (Figure 1-7B). Some of these may have catalytic actions that help or hinder the survival or replication of RNA in other ways. If beneficial effects are reciprocated, the different types of RNA molecules, specialized for different activities, may evolve into a cooperative system that replicates with unusually great efficiency.

Information Flows from Polynucleotides to Polypeptides[6]

There are strong suggestions, therefore, that between 3.5 and 4 billion years ago, somewhere on earth, self-replicating systems of RNA molecules, mixed with other organic molecules including simple polypeptides, began the process of evolution. Systems with different sets of polymers competed for the available precursor materials to construct copies of themselves, just as organisms now compete; success depended on the accuracy and the speed with which the copies were made and on the stability of those copies.

However, as we emphasized earlier, while the structure of polynucleotides is well suited for information storage and replication, their catalytic abilities are limited by comparison with those of polypeptides, and efficient replication of polynucleotides in modern cells is absolutely dependent on proteins. At the origin of life any polynucleotide that helped guide the synthesis of a useful polypeptide in its environment would have had a great advantage in the evolutionary struggle for survival.

But how could the information encoded in a polynucleotide specify the sequence of a polymer of a different type? Clearly, the polynucleotides must act as catalysts to join selected amino acids together. In present-day organisms a collaborative system of RNA molecules plays a central part in directing the synthesis of polypeptides - that is, protein synthesis - but the process is aided by other proteins synthesized previously. The biochemical machinery for protein synthesis is remarkably elaborate. One RNA molecule carries the genetic information for a particular polypeptide in the form of a code, while other RNA molecules act as adaptors, each binding a specific amino acid. These two types of RNA molecules form complementary base pairs with one another to enable sequences of nucleotides in the coding RNA molecule to direct the incorporation of specific amino acids held on the adaptor RNAs into a growing polypeptide chain. Precursors to these two types of RNA molecules presumably directed the first protein synthesis without the aid of proteins (Figure 1-7C).

Today, these events in the assembly of new proteins take place on the surface of *ribosomes* - complex particles composed of several large RNA molecules of yet another class, together with more than 50 different types of protein. In Chapter 5 we shall see that the ribosomal RNA in these particles plays a central catalytic role in the process of protein synthesis and forms more than 60% of the ribosome's mass. At least in evolutionary terms, it appears to be the fundamental component of the ribosome.

It seems likely, then, that RNA guided the primordial synthesis of proteins, perhaps in a clumsy and primitive fashion. In this way RNA was able to create tools - in the form of proteins - for more efficient biosynthesis, and some of these could have been put to use in the replication of RNA and in the process of tool production itself.

The synthesis of specific proteins under the guidance of RNA required the evolution of a code by which the polynucleotide sequence specifies the amino acid sequence that makes up the protein. This code - the *genetic code* - is spelled out in a "dictionary" of three-letter words: different triplets of nucleotides encode specific amino acids. The code seems to have been selected arbitrarily (subject to some constraints, perhaps); yet it is virtually the same in all living organisms. This strongly

suggests that all present-day cells have descended from a single line of primitive cells that evolved the mechanism of protein synthesis.

Membranes Defined the First Cell[7]

One of the crucial events leading to the formation of the first cell must have been the development of an outer membrane. For example, the proteins synthesized under the control of a certain species of RNA would not facilitate reproduction of that species of RNA unless they remained in the neighborhood of the RNA; moreover, as long as these proteins were free to diffuse among the population of replicating RNA molecules, they could benefit equally any competing species of RNA that might be present. If a variant RNA arose that made a superior type of enzyme, the new enzyme could not contribute *selectively* to the survival of the variant RNA in its competition with its fellows. Selection of RNA molecules according to the quality of the proteins they generated could not occur efficiently until some form of compartment evolved to contain the proteins made by an RNA molecule and thereby make them available only to the RNA that had generated them (Figure 1-8).

The need for containment is easily fulfilled by another class of molecules that has the simple physicochemical property of being *amphipathic,* that is, consisting of one part that is hydrophobic (water insoluble) and another part that is hydrophilic (water soluble). When such molecules are placed in water, they aggregate, arranging their hydrophobic portions as much in contact with one another as possible and their hydrophilic portions in contact with the water. Amphipathic molecules of appropriate shape spontaneously aggregate to form *bilayers,* creating small closed vesicles whose aqueous contents are isolated from the external medium (Figure 1-9). The phenomenon can be demonstrated in a test tube by simply mixing phospholipids and water together: under appropriate conditions, small vesicles will form. All present-day cells are surrounded by a plasma membrane consisting of amphipathic molecules - mainly phospholipids - in this configuration; in cell membranes, the lipid bilayer also contains amphipathic proteins. In the electron microscope such membranes appear as sheets about 5 nm thick, with a distinctive three-layered appearance due to the tail-to-tail packing of the phospholipid molecules.

Presumably, the first membrane-bounded cells were formed by spontaneous assembly of phospholipid molecules from the prebiotic soup, enclosing a self-replicating mixture of RNA and other molecules. It is not clear at what point in the evolution of biological catalysts and protein synthesis this first occurred. In any case, once RNA molecules were sealed within a closed membrane, they could begin to evolve in earnest as carriers of genetic instructions: they could be selected not merely on the basis of their own structure, but also according to their effect on the other molecules in the same compartment. The nucleotide sequences of the RNA molecules could now be expressed in the character of a unitary living cell.

All Present-Day Cells Use DNA as Their Hereditary Material[3, 6, 8]

The picture we have presented is, of course, speculative: there are no fossil records that trace the origins of the first cell. Nevertheless, there is persuasive evidence from present-day organisms and from experiments that the broad features of this evolutionary story are correct. The prebiotic synthesis of small molecules, the self-replication of catalytic RNA molecules, the translation of RNA sequences into amino acid sequences, and the assembly of lipid molecules to form membrane-bounded compartments - all presumably occurred to generate primitive cells 3.5 to 4 billion years ago.

It is useful to compare these early cells with the simplest and smallest present-day cells, the mycoplasmas. Mycoplasmas are small bacteria of a degenerate type that normally lead a parasitic existence in close association with animal or plant cells (Figure 1-10). Some have a diameter of about 0.3 mm and contain only enough nucleic acid to direct the synthesis of about 400 different proteins. Some of these proteins are enzymes, some are structural; some lie in the cell's interior, others are embedded in its membrane. Together they synthesize essential small molecules that are not available in the environment, redistribute the energy needed to drive biosynthetic reactions, and maintain appropriate conditions inside the cell.

The first cells on the earth were presumably less sophisticated than a mycoplasma and less efficient in reproducing themselves. There was, however, a more fundamental difference between these primitive cells and a mycoplasma, or indeed any other present-day cell: the hereditary information in all cells alive today is stored in DNA rather than in the RNA that is thought to have stored the hereditary information during the earliest stages of evolution. Both types of polynucleotides are found in present-day cells, but they function in a collaborative manner, each having evolved to perform specialized tasks. Small chemical differences fit the two kinds of molecules for distinct functions. DNA acts as the permanent repository of genetic information, and, unlike RNA, it is found in cells principally in a double-stranded form, composed of a pair of complementary polynucleotide molecules. This double-stranded structure makes DNA in cells more robust and stable than RNA; it also makes DNA relatively easy to replicate (as will be explained in Chapter 3) and permits a repair mechanism to operate that uses the intact strand as a

template for the correction or repair of the associated damaged strand. DNA guides the synthesis of specific RNA molecules, again by the principle of complementary base-pairing, though now this pairing is between slightly different types of nucleotides. The resulting single-stranded RNA molecules then perform two primeval functions: they direct protein synthesis both as coding RNA molecules (*messenger* RNAs) and as RNA catalysts (*ribosomal* and other nonmessenger RNAs).

The suggestion, in short, is that RNA preceded DNA in evolution, having both genetic and catalytic properties; eventually, DNA took over the primary genetic function and proteins became the major catalysts, while RNA remained primarily as the intermediary connecting the two (Figure 1-11). With the advent of DNA cells were enabled to become more complex, for they could then carry and transmit an amount of genetic information greater than that which could be stably maintained in RNA molecules.

Summary

Living cells probably arose on earth about 3.5 billion years ago by spontaneous reactions between molecules in an environment that was far from chemical equilibrium. From our knowledge of present-day organisms and the molecules they contain, it seems likely that the development of the directly autocatalytic mechanisms fundamental to living systems began with the evolution of families of RNA molecules that could catalyze their own replication. With time, one of these families of cooperating RNA catalysts developed the ability to direct synthesis of polypeptides. Finally, as the accumulation of additional protein catalysts allowed more efficient and complex cells to evolve, the DNA double helix replaced RNA as a more stable molecule for storing the increased amounts of genetic information required by such cells.

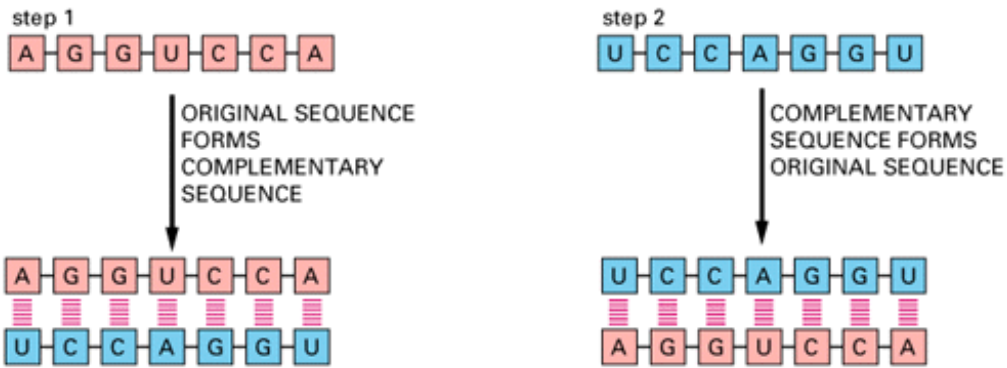
Figure 1-3. Formation of polynucleotides and polypeptides. Nucleotides of four kinds (here represented by the single letters A, U, G, and C) can undergo spontaneous polymerization with the loss of water. The product is a mixture of polynucleotides that are random in length and sequence. Similarly, amino acids of different types, symbolized here by three-letter abbreviated names, can polymerize with one another to form polypeptides. Present-day proteins are built from a standard set of 20 types of amino acids.
Figure 1-4. Polynucleotides as templates. Preferential binding occurs between pairs of nucleotides (G with C and U with A) by relatively weak chemical bonds (*above*). This pairing enables one polynucleotide to act as a template for the synthesis of another (*left*).


Figure 1-5. Replication of a polynucleotide sequence (here an RNA molecule). In step 1 the original RNA molecule acts as a template to form an RNA molecule of complementary sequence. In step 2 this complementary RNA molecule itself acts as a template, forming RNA molecules of the original sequence. Since each templating molecule can produce many copies of the complementary strand, these reactions can result in the "multiplication" of the original sequence.
Figure 1-6. Conformation of an RNA molecule. Nucleotide pairing between different regions of the same polynucleotide (RNA) chain causes the molecule to adopt a distinctive shape.

Figure 1-8. Evolutionary significance of cell-like compartments. In a mixed population of self-replicating RNA molecules

capable of influencing protein synthesis (as illustrated in <u>Figure 1-7</u>), any improved form of RNA that is able to promote formation of a more useful protein must share this protein with its neighboring competitors. However, if the RNA is enclosed within a compartment, such as a lipid membrane, then any protein the RNA causes to be made is retained for its own use; the RNA can therefore be selected on the basis of its guiding production of a better protein.
Figure 1-9. Formation of membranes by phospholipids. Because these molecules have hydrophilic heads and lipophilic tails, they will align themselves at an oil-water interface with their heads in the water and their tails in the oil. In water they will associate to form closed bilayer vesicles in which the lipophilic tails are in contact with one another and the hydrophilic heads are exposed to the water.

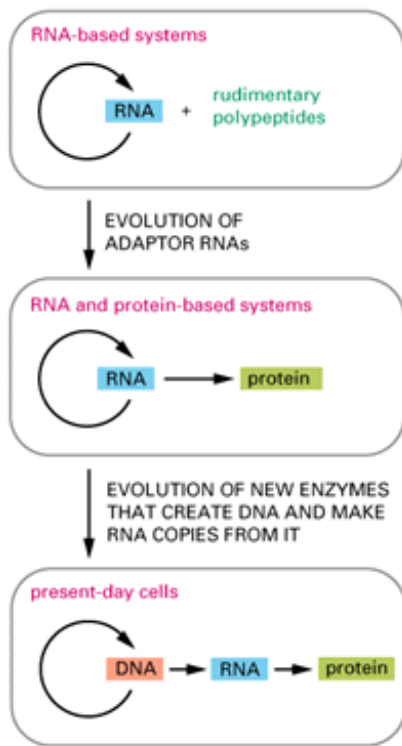

Figure 1-11. Suggested stages of evolution from simple self-replicating systems of RNA molecules to present-day cells.
Today, DNA is the repository of genetic information and RNA acts largely as a go-between to direct protein synthesis.

From Procaryotes to Eucaryotes[9]

Introduction

It is thought that all organisms living now on earth derive from a single primordial cell born more than 3 billion years ago. This cell, out-reproducing its competitors, took the lead in the process of cell division and evolution that eventually covered the earth with green, changed the composition of its atmosphere, and made it the home of intelligent life. The family resemblances among all organisms seem too strong to be explained in any other way. One important landmark along this evolutionary road occurred about 1.5 billion years ago, when there was a transition from small cells with relatively simple internal structures - the so-called procaryotic cells, which include the various types of bacteria - to a flourishing of larger and radically more complex *eucaryotic* cells such as are found in higher animals and plants.

Procaryotic Cells Are Structurally Simple but Biochemically Diverse[10]

Bacteria are the simplest organisms found in most natural environments. They are spherical or rod-shaped cells, commonly several micrometers in linear dimension (Figure 1-12). They often possess a tough protective coat, called a *cell wall,* beneath which a plasma membrane encloses a single cytoplasmic compartment containing DNA, RNA, proteins, and small molecules. In the electron microscope this cell interior appears as a matrix of varying texture without any obvious organized internal structure (see Figure 1-12B).

Bacteria are small and can replicate quickly, simply dividing in two by *binary fission.* When food is plentiful, "survival of the fittest" generally means survival of those that can divide the fastest. Under optimal conditions a single procaryotic cell can divide every 20 minutes and thereby give rise to 5 billion cells (approximately equal to the present human population on earth) in less than 11 hours. The ability to divide quickly enables populations of bacteria to adapt rapidly to changes in their environment. Under laboratory conditions, for example, a population of bacteria maintained in a large vat will evolve within a few weeks by spontaneous mutation and natural selection to utilize new types of sugar molecules as carbon sources.

In nature bacteria live in an enormous variety of ecological niches, and they show a corresponding richness in their underlying biochemical composition. Two distantly related groups can be recognized: the *eubacteria,* which are the commonly encountered forms that inhabit soil, water, and larger living organisms; and the *archaebacteria,* which are found in such incommodious

environments as bogs, ocean depths, salt brines, and hot acid springs (Figure 1-13).

There are species of bacteria that can utilize virtually any type of organic molecule as food, including sugars, amino acids, fats, hydrocarbons, polypeptides, and polysaccharides. Some are even able to obtain their carbon atoms from CO_2 and their nitrogen atoms from N_2. Despite their relative simplicity, bacteria have existed for longer than any other organisms and still are the most abundant type of cell on earth.

Metabolic Reactions Evolve[10], [11]

A bacterium growing in a salt solution containing a single type of carbon source, such as glucose, must carry out a large number of chemical reactions. Not only must it derive from the glucose the chemical energy needed for many vital processes, it must also use the carbon atoms of glucose to synthesize every type of organic molecule that the cell requires. These reactions are catalyzed by hundreds of enzymes working in reaction "chains" so that the product of one reaction is the substrate for the next; such enzymatic chains, called *metabolic pathways,* will be discussed in the following chapter.

Originally, when life began on earth, there was probably little need for such elaborate metabolic reactions. Cells with relatively simple chemistry could survive and grow on the molecules in their surroundings. But as evolution proceeded, competition for these limited natural resources would have become more intense. Organisms that had developed enzymes to manufacture useful organic molecules more efficiently and in new ways would have had a strong selective advantage. In this way the complement of enzymes possessed by cells is thought to have gradually increased, generating the metabolic pathways of present organisms. Two plausible ways in which a metabolic pathway could arise in evolution are illustrated in Figure 1-14.

If metabolic pathways evolved by the sequential addition of new enzymatic reactions to existing ones, the most ancient reactions should, like the oldest rings in a tree trunk, be closest to the center of the "metabolic tree," where the most fundamental of the basic molecular building blocks are synthesized. This position in metabolism is firmly occupied by the chemical processes that involve sugar phosphates, among which the most central of all is probably the sequence of reactions known as glycolysis, by which glucose can be degraded in the absence of oxygen (that is, *anaerobically*). The oldest metabolic pathways would have had to be anaerobic because there was no free oxygen in the atmosphere of the primitive earth. Glycolysis occurs in virtually every living cell and drives the formation of the compound *adenosine triphosphate,* or *ATP,* which is used by all cells as a versatile source of chemical energy. Certain *thioester* compounds play a fundamental role in the energy-transfer reactions of glycolysis and in a host of other basic biochemical processes in which two organic molecules (a thiol and a carboxylic acid) are joined by a high-energy bond involving sulfur (Figure 1-15). It has been argued that this simple but powerful chemical device is a relic of prebiotic processes, reflecting the reactions that occurred in the sulfurous, volcanic environment of the early earth, before even RNA had begun to evolve.

Linked to the core reactions of glycolysis are hundreds of other chemical processes. Some of these are responsible for the synthesis of small molecules, many of which in turn are utilized in further reactions to make the large polymers specific to the organism. Other reactions are used to degrade complex molecules, taken in as food, into simpler chemical units. One of the most striking features of these metabolic reactions is that they take place similarly in all kinds of organisms, suggesting an extremely ancient origin.

Evolutionary Relationships Can Be Deduced by Comparing DNA Sequences[12]

The enzymes that catalyze the fundamental metabolic reactions, while continuing to serve the same essential functions, have undergone progressive modifications as organisms have evolved into divergent forms. For this reason the amino acid sequence of the same type of enzyme in different living species provides a valuable indication of the evolutionary relationship between these species. The evidence obtained closely parallels that from other sources, such as the fossil record. An even richer source of information is locked in the living cell in the sequences of nucleotides in DNA, and modern methods of analysis allow these *DNA sequences* to be determined in large numbers and compared between species. Comparisons of highly conserved sequences, which have a central function and therefore change only slowly during evolution, can reveal relationships between organisms that diverged long ago (Figure 1-16), while very rapidly evolving sequences can be used to determine how more closely related species evolved. It is expected that continued application of these methods will enable the course of evolution to be followed with unprecedented accuracy.

Cyanobacteria Can Fix CO_2 and N_2 [13]

As competition for the raw materials for organic syntheses intensified, a strong selective advantage would have been gained by any organisms able to utilize carbon and nitrogen atoms (in the form of CO_2 and N_2) directly from the atmosphere. But while they are abundantly available, CO_2 and N_2 are also very stable. It therefore requires a large amount of energy as well as a number of complicated chemical reactions to convert them to a usable form - that is, into organic molecules such as simple sugars.

In the case of CO_2 the major mechanism that evolved to achieve this transformation was photosynthesis, in which radiant energy captured from the sun drives the conversion of CO_2 into organic compounds. The interaction of sunlight with a pigment molecule, *chlorophyll,* excites an electron to a more highly energized state. As the electron drops back to a lower energy level, the energy it gives up drives chemical reactions that are facilitated and directed by protein molecules.

One of the first sunlight-driven reactions was probably the generation of "reducing power." The carbon and nitrogen atoms in atmospheric CO_2 and N_2 are in an oxidized and inert state. One way to make them more reactive, so that they participate in biosynthetic reactions, is to reduce them - that is, to give them a larger number of electrons. This is achieved in several steps. In the first step electrons are removed from a poor electron donor and transferred to a strong electron donor by chlorophyll in a reaction that is driven by sunlight. The strong electron donor is then used to reduce CO_2 or N_2. Comparison of the mechanisms of photosynthesis in various present-day bacteria suggests that one of the first sources of electrons was H_2S, from which the primary waste product would have been elemental sulfur. Later the more difficult but ultimately more rewarding process of obtaining electrons from H_2O was accomplished, and O_2 was released in large amounts as a waste product.

Cyanobacteria (also known as blue-green algae) are today a major route by which both carbon and nitrogen are converted into organic molecules and thus enter the *biosphere.* They include the most self-sufficient organisms that now exist. Able to "fix" both CO_2 and N_2 into organic molecules, they are, to a first approximation, able to live on water, air, and sunlight alone; the mechanisms by which they do this have probably remained essentially constant for several billion years. Together with other bacteria that have some of these capabilities, they created the conditions in which more complex types of organisms could evolve: once one set of organisms had succeeded in synthesizing the whole gamut of organic cell components from inorganic raw materials, other organisms could subsist by feeding on the primary synthesizers and on their products.

Bacteria Can Carry Out the Aerobic Oxidation of Food Molecules[13]

Many people today are justly concerned about the environmental consequences of human activities. But in the past other organisms have caused revolutionary changes in the earth's environment (although very much more slowly). Nowhere is this more apparent than in the composition of the earth's atmosphere, which through oxygen-releasing photosynthesis was transformed from a mixture containing practically no molecular oxygen to one in which oxygen constitutes 21% of the total (Figure 1-17).

Since oxygen is an extremely reactive chemical that can interact with most cytoplasmic constituents, it must have been toxic to many early organisms, just as it is to many present-day anaerobic bacteria. However, this reactivity also provides a source of chemical energy, and, not surprisingly, this has been exploited by organisms during the course of evolution. By using oxygen, organisms are able to oxidize more completely the molecules they ingest. For example, in the absence of oxygen glucose can be broken down only to lactic acid or ethanol, the end products of anaerobic glycolysis. But in the presence of oxygen glucose can be completely degraded to CO_2 and H_2O. In this way much more energy can be derived from each gram of glucose. The energy released in respiration - the aerobic oxidation of food molecules - is used to drive the synthesis of ATP in much the same way that photosynthetic organisms produce ATP from the energy of sunlight. In both processes there is a series of electron-transfer reactions that generates an H^+ gradient between the outside and inside of a membrane-bounded compartment; the H^+ gradient then serves to drive the synthesis of the ATP. Today, respiration is used by the great majority of organisms, including most procaryotes.

Eucaryotic Cells Contain Several Distinctive Organelles[14]

As molecular oxygen accumulated in the atmosphere, what happened to the remaining anaerobic organisms with which life had begun? In a world that was rich in oxygen, which they could not use, they were at a severe disadvantage. Some, no doubt, became extinct. Others either developed a capacity for respiration or found niches in which oxygen was largely absent, where

they could continue an anaerobic way of life. Others became predators or parasites on aerobic cells. And some, it seems, hit upon a strategy for survival more cunning and vastly richer in implications for the future: they are believed to have formed an intimate association with an aerobic type of cell, living with it in *symbiosis.* This is the most plausible explanation for the metabolic organization of present-day cells of the eucaryotic type (Panel 1-1, pp. 18-19) with which this book will be chiefly concerned.

Eucaryotic cells, by definition and in contrast to procaryotic cells, have a *nucleus* (*caryon* in Greek), which contains most of the cell's DNA, enclosed by a double layer of membrane (Figure 1-18). The DNA is thereby kept in a compartment separate from the rest of the contents of the cell, the cytoplasm, where most of the cell's metabolic reactions occur. In the cytoplasm, moreover, many distinctive *organelles* can be recognized. Prominent among these are two types of small bodies, the *chloroplasts* and *mitochondria* (Figures 1-19 and 1-20). Each of these is enclosed in its own double layer of membrane, which is chemically different from the membranes surrounding the nucleus. Mitochondria are an almost universal feature of eucaryotic cells, whereas chloroplasts are found only in those eucaryotic cells that are capable of photosynthesis - that is, in plants but not in animals or fungi. Both organelles almost certainly have a symbiotic origin.

Eucaryotic Cells Depend on Mitochondria for Their Oxidative Metabolism[15]

Mitochondria show many similarities to free-living procaryotic organisms: for example, they often resemble bacteria in size and shape, they contain DNA, they make protein, and they reproduce by dividing in two. By breaking up eucaryotic cells and separating their component parts, it is possible to show that mitochondria are responsible for respiration and that this process occurs nowhere else in the eucaryotic cell. Without mitochondria the cells of animals and fungi would be anaerobic organisms, depending on the relatively inefficient and antique process of glycolysis for their energy. Many present-day bacteria respire like mitochondria, and it seems probable that eucaryotic cells are descendants of primitive anaerobic organisms that survived, in a world that had become rich in oxygen, by engulfing aerobic bacteria - keeping them in symbiosis for the sake of their capacity to consume atmospheric oxygen and produce energy. Certain present-day microorganisms offer strong evidence of the feasibility of such an evolutionary sequence. There are several hundred species of single-celled eucaryotes that resemble the hypothetical ancestral eucaryote in that they live in oxygen-poor conditions (in the guts of animals, for example) and lack mitochondria altogether. Comparative nucleotide sequence analyses have revealed that at least two groups of these organisms, the *diplomonads* and the *microsporidia,* diverged very early from the line leading to other eucaryotic cells (Figure 1-21). There is another eucaryote, the amoeba *Pelomyxa palustris,* that, while lacking mitochondria, nevertheless carries out oxidative metabolism by harboring aerobic bacteria in its cytoplasm in a permanent symbiotic relationship. Diplomonads and microsporidia, on the one hand, and *Pelomyxa,* on the other, therefore resemble two proposed stages in the evolution of eucaryotes such as ourselves.

Acquisition of mitochondria must have had many repercussions. The plasma membrane, for example, is heavily committed to energy metabolism in procaryotic cells but not in eucaryotic cells, where this crucial function has been relegated to the mitochondria. It seems likely that the separation of functions left the eucaryotic plasma membrane free to evolve important new features. In particular, because eucaryotic cells need not maintain a large H^+ gradient across their plasma membrane, as required for ATP production in procaryotes, it became possible to use controlled changes in the ion permeability of the plasma membrane for cell-signaling purposes. Thus, a variety of ion channels appeared in the eucaryotic plasma membrane. Today, these channels mediate the elaborate electrical signaling processes in higher organisms - notably in the nervous system -and they control much of the behavior of single-celled free-living eucaryotes such as protozoa (see below).

Chloroplasts Are the Descendants of an Engulfed Procaryotic Cell[16]

Chloroplasts carry out photosynthesis in much the same way as procaryotic cyanobacteria, absorbing sunlight in the chlorophyll attached to their membranes. Some bear a close structural resemblance to the cyanobacteria, being similar in size and in the way that their chlorophyll-bearing membranes are stacked in layers (see Figure 1-20). Moreover, chloroplasts reproduce by dividing, and they contain DNA that is nearly indistinguishable in nucleotide sequence from portions of a bacterial chromosome. All this strongly suggests that chloroplasts share a common ancestry with cyanobacteria and evolved from procaryotes that made their home inside eucaryotic cells. These procaryotes performed photosynthesis for their hosts, who sheltered and nourished them. Symbiosis of photosynthetic cells with other cell types is, in fact, a common phenomenon, and some present-day eucaryotic cells contain authentic cyanobacteria (Figure 1-22).

Figure 1-23 shows the evolutionary origins of the eucaryotes according to the symbiotic theory. It must be stressed, however, that mitochondria and chloroplasts show important differences from, as well as similarities to, present-day aerobic bacteria and

cyanobacteria. Their quantity of DNA is very small, for example, and most of the molecules from which they are constructed are synthesized elsewhere in the eucaryotic cell and imported into the organelle. Although there is good evidence that they originated as symbiotic bacteria, they have undergone large evolutionary changes and have become greatly dependent on - and subject to control by - their host cells.

The major existing eucaryotes have in common both mitochondria and a whole constellation of other features that distinguish them from procaryotes (Table 1-1). These function together to give eucaryotic cells a wealth of different capabilities, and it is debatable which of them evolved first. But the acquisition of mitochondria by an anaerobic eucaryotic cell must have been a crucial step in the success of the eucaryotes, providing them with the means to tap an abundant source of energy to drive all their complex activities.

Eucaryotic Cells Contain a Rich Array of Internal Membranes

Eucaryotic cells are usually much larger in volume than procaryotic cells, commonly by a factor of 1000 or more, and they carry a proportionately larger quantity of most cellular materials; for example, a human cell contains about 1000 times as much DNA as a typical bacterium. This large size creates problems. Since all the raw materials for the biosynthetic reactions occurring in the interior of a cell must ultimately enter and leave by passing through the plasma membrane covering its surface, and since the membrane is also the site of many important reactions, an increase in cell volume requires an increase in cell surface. But it is a fact of geometry that simply scaling up a structure increases the volume as the cube of the linear dimension while the surface area increases only as the square. Therefore, if the large eucaryotic cell is to keep as high a ratio of surface to volume as the procaryotic cell, it must supplement its surface area by means of convolutions, infoldings, and other elaborations of its membrane.

This probably explains in part the complex profusion of internal membranes that is a basic feature of all eucaryotic cells. Membranes surround the nucleus, the mitochondria, and (in plant cells) the chloroplasts. They form a labyrinthine compartment called the endoplasmic reticulum (Figure 1-24), where lipids and proteins of cell membranes, as well as materials destined for export from the cell, are synthesized. They also form stacks of flattened sacs constituting the Golgi apparatus (Figure 1-25), which is involved in the modification and transport of the molecules made in the endoplasmic reticulum. Membranes surround lysosomes, which contain stores of enzymes required for intracellular digestion and so prevent them from attacking the proteins and nucleic acids elsewhere in the cell. In the same way membranes surround peroxisomes, where dangerously reactive hydrogen peroxide is generated and degraded during the oxidation of various molecules by O_2. Membranes also form small vesicles and, in plants, a large liquid-filled *vacuole.* All these membrane-bounded structures correspond to distinct internal compartments within the cytoplasm. In a typical animal cell these compartments (or organelles) occupy nearly half the total cell volume. The remaining compartment of the cytoplasm, which includes everything other than the membrane-bounded organelles, is usually referred to as the cytosol.

All of the aforementioned membranous structures lie in the interior of the cell. How, then, can they help to solve the problem we posed at the outset and provide the cell with a surface area that is adequate to its large volume? The answer is that there is a continual exchange between the internal membrane-bounded compartments and the outside of the cell, achieved by *endocytosis* and *exocytosis,* processes unique to eucaryotic cells. In endocytosis portions of the external surface membrane invaginate and pinch off to form membrane-bounded cytoplasmic vesicles that contain both substances present in the external medium and molecules previously adsorbed on the cell surface. Very large particles or even entire foreign cells can be taken up by *phagocytosis* - a special form of endocytosis. Exocytosis is the reverse process, whereby membrane-bounded vesicles inside the cell fuse with the plasma membrane and release their contents into the external medium. In this way membranes surrounding compartments deep inside the cell serve to increase the effective surface area of the cell for exchanges of matter with the external world.

As we shall see in later chapters, the various membranes and membrane-bounded compartments in eucaryotic cells have become highly specialized - some for secretion, some for absorption, some for specific biosynthetic processes, and so on.

Eucaryotic Cells Have a Cytoskeleton

The larger a cell is, and the more elaborate and specialized its internal structures, the greater is its need to keep these structures in their proper places and to control their movements. All eucaryotic cells have an internal skeleton, the cytoskeleton, that gives the cell its shape, its capacity to move, and its ability to arrange its organelles and transport them from one part of the cell to another. The cytoskeleton is composed of a network of protein filaments, two of the most important of which are *actin filaments*

(Figure 1-26) and *microtubules*. These two must date from a very early epoch in evolution since they are found almostunchanged in all eucaryotes. Both are involved in the generation of cellular movements. Actin filaments enable individual eucaryotic cells to crawl about, for example, and they participate in the contraction of muscle in animals; microtubules are the main structural and force-generating elements in *cilia* and *flagella* - the long projections on some cell surfaces that beat like whips and serve as instruments of propulsion.

Actin filaments and microtubules are also essential for the internal movements that occur in the cytoplasm of all eucaryotic cells. Thus microtubules in the form of a *mitotic spindle* are a vital part of the usual machinery for partitioning DNA equally between the two daughter cells when a eucaryotic cell divides. Without microtubules, therefore, the eucaryotic cell could not reproduce. In this and other examples movement by free diffusion would be either too slow or too haphazard to be useful. In fact, most of the organelles in a eucaryotic cell appear to be attached, directly or indirectly, to the cytoskeleton and, when they move, to be propelled along cytoskeletal tracks.

Protozoa Include the Most Complex Cells Known<u>17</u>

The complexity that can be achieved by a single eucaryotic cell is nowhere better illustrated than in the free-living, single-celled eucaryotes known as *protists* (Figure 1-27). These are evolutionarily diverse (see Figure 1-16) and exhibit a bewildering variety of different forms and behaviors: they can be photosynthetic or carnivorous, motile or sedentary. Their anatomy is often complex and includes such structures as sensory bristles, photoreceptors, flagella, leglike appendages, mouth parts, stinging darts, and musclelike contractile bundles. Although they are single cells, protists, especially the larger and more active types known as protozoa, can be as intricate and versatile as many multicellular organisms. This is particularly well illustrated by the group known as ciliates.

Didinium is a carnivorous ciliate. It has a globular body, about 150 mm in diameter, encircled by two fringes of cilia; its front end is flattened except for a single protrusion rather like a snout (Figure 1-28). *Didinium* swims around in the water at high speed by means of the synchronous beating of its cilia. When it encounters a suitable prey, usually another type of protozoan, such as a *Paramecium,* it releases numerous small paralyzing darts from its snout region. Then the *Didinium* attaches to and devours the *Paramecium,* inverting like a hollow ball to engulf the other cell, which is as large as itself. Most of this complex behavior - swimming, and paralyzing and capturing its prey - is generated by the cytoskeletal structures lying just beneath the plasma membrane. Included in this *cell cortex,* for example, are the parallel bundles of microtubules that form the core of each cilium and enable it to beat.

Predatory behavior of this sort and the set of features on which it depends - large size, the capacity for phagocytosis, and the ability to move in pursuit of prey - are peculiar to eucaryotes. Indeed, it is probable that these features came very early in eucaryotic evolution, making possible the subsequent capture of bacteria and their domestication as mitochondria and chloroplasts.

In Eucaryotic Cells the Genetic Material Is Packaged in Complex Ways

Eucaryotic cells contain a very large quantity of DNA. In human cells, for example, there is about 1000 times more DNA than in typical bacteria. The length of DNA in eucaryotic cells is so great that the risk of entanglement and breakage becomes severe. Probably for this reason, proteins unique to eucaryotes, the *histones,* have evolved to bind to the DNA and wrap it up into compact and manageable chromosomes (Figure 1-29). Tight packaging of the DNA in chromosomes is an essential part of the preparation for cell division in eucaryotes (Figure 1-30). All eucaryotes (with minor exceptions) have histones bound to their DNA, and the importance of these proteins is reflected in their remarkable conservation in evolution: several of the histones of a pea plant are almost exactly the same, amino acid for amino acid, as those of a cow.

The membranes enclosing the nucleus in eucaryotic cells further protect the structure of the DNA and its associated control machinery, sheltering them from entanglement with the moving cytoskeleton and from many of the chemical changes that take place in the cytoplasm. They also allow the segregation of two crucial steps in the expression of genetic information: (1) the copying of DNA sequences into RNA sequences (*DNA transcription*) and (2) the use of these RNA sequences, in turn, to direct the synthesis of specific proteins (*RNA translation*). In procaryotic cells there is no compartmentalization of these processes - the translation of RNA sequences into protein begins as soon as they are transcribed, even before their synthesis is completed. In eucaryotes, however (except in mitochondria and chloroplasts, which in this respect as in others are closer to bacteria), the two steps in the path from gene to protein are kept strictly separate: transcription occurs in the nucleus, translation in the cytoplasm. The RNA has to leave the nucleus before it can be used to guide protein synthesis. While in the nucleus it undergoes elaborate

changes in which some parts of the RNA molecule are discarded and other parts are modified (*RNA processing*).

Because of these complexities, the genetic material of a eucaryotic cell offers many more opportunities for control than are present in bacteria.

Summary

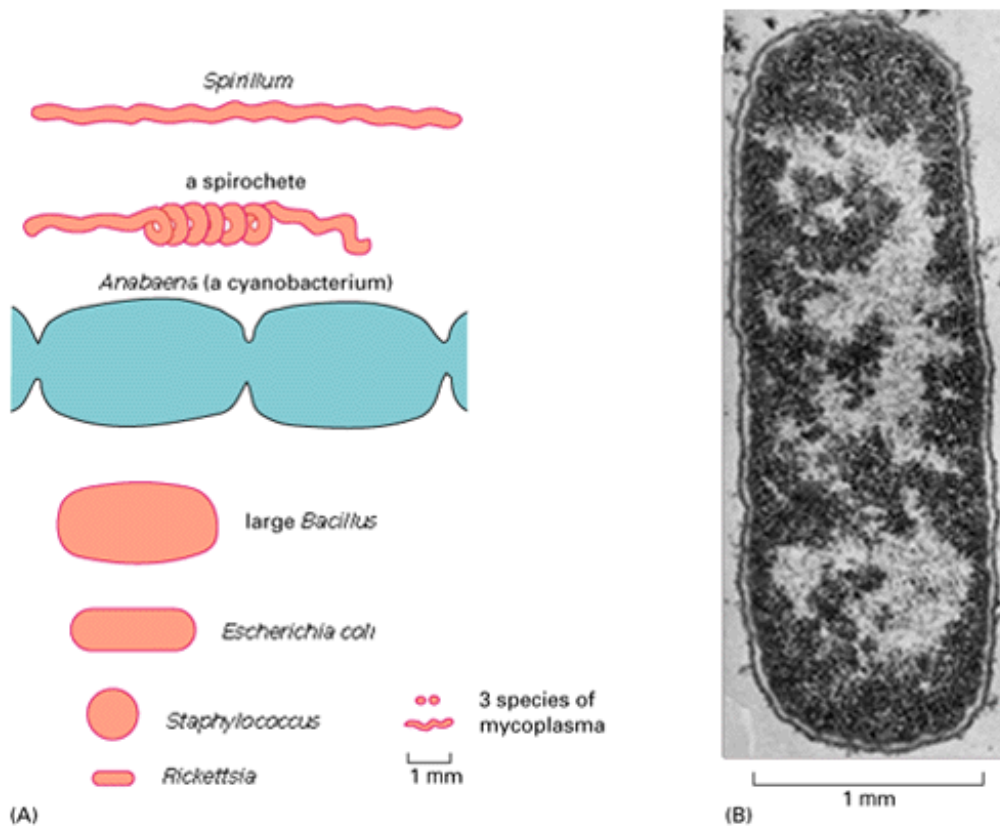
Present-day living cells are classified as procaryotic (bacteria and their close relatives) or eucaryotic. Although they have a relatively simple structure, procaryotic cells are biochemically versatile and diverse: for example, all of the major metabolic pathways can be found in bacteria, including the three principal energy-yielding processes of glycolysis, respiration, and photosynthesis. Eucaryotic cells are larger and more complex than procaryotic cells and contain more DNA, together with components that allow this DNA to be handled in elaborate ways. The DNA of the eucaryotic cell is enclosed in a membrane-bounded nucleus, while the cytoplasm contains many other membrane-bounded organelles, including mitochondria, which carry out the oxidation of food molecules, and, in plant cells, chloroplasts, which carry out photosynthesis. Mitochondria and chloroplasts are almost certainly the descendants of earlier procaryotic cells that established themselves as internal symbionts of a larger anaerobic cell. Eucaryotic cells are also unique in containing a cytoskeleton of protein filaments that helps organize the cytoplasm and provides the machinery for movement.


Figure 1-12. Procaryote sizes and structures. (A) Some procaryotic cells drawn to scale. (B) Electron micrograph of a longitudinal section through a bacterium (*Escherichia coli*); the cell's DNA is concentrated in the palely stained region. (Courtesy of E. Kellenberger.)
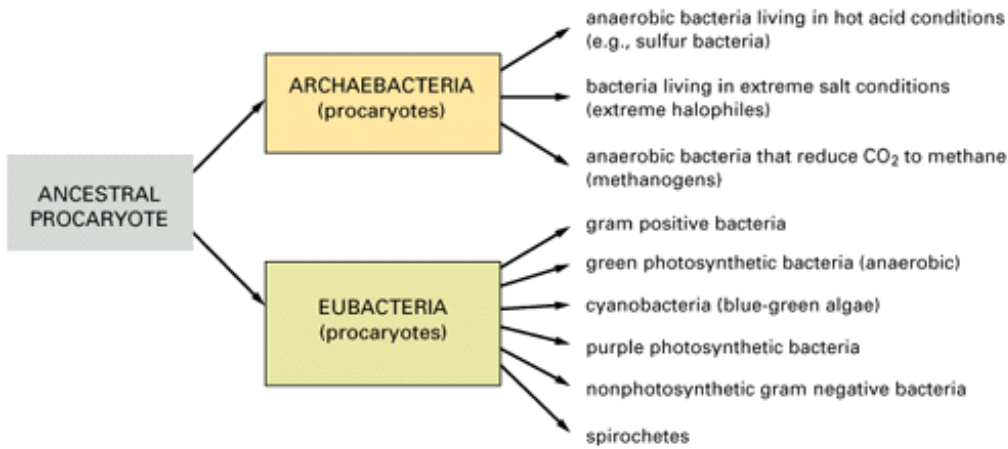

Figure 1-13. Family relationships between present-day bacteria. Arrows indicate probable paths of evolution. The origin of eucaryotic cells is discussed later in the text.
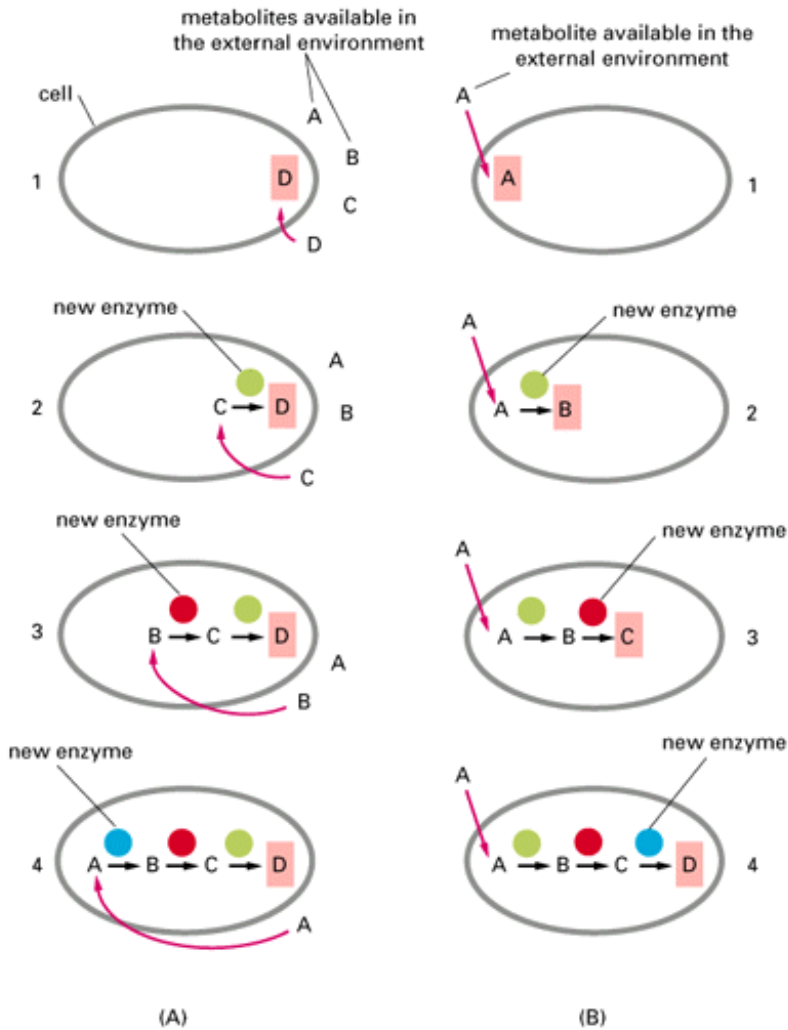

Figure 1-14. Two possible ways in which metabolic pathways might have evolved. (A) The cell on the left is provided with a supply of related substances (A, B, C, and D) produced by prebiotic synthesis. One of these, substance D, is metabolically useful. As the cell exhausts the available supply of D, a selective advantage is obtained by the evolution of a new enzyme that is able to produce D from the closely related substance C. Fundamentally important metabolic pathways may have evolved by a series of similar steps. (B) On the right, a metabolically useful compound A is available in abundance. An enzyme appears in the course of evolution that, by chance, has the ability to convert substance A to substance B. Other changes then occur within the

cell that enable it to make use of the new substance. The appearance of further enzymes can build up a long chain of reactions.

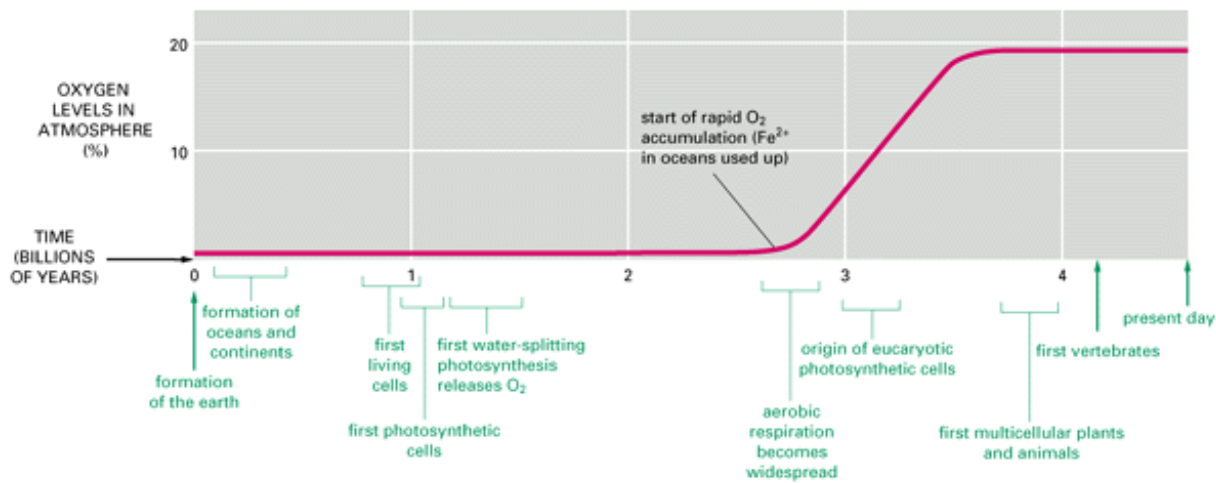

Figure 1-17. Atmospheric oxygen and the course of evolution. The relationship between changes in atmospheric oxygen levels and some of the major stages that are believed to have occurred during the evolution of living organisms on earth. As indicated, geological evidence suggests that there was more than a billion-year delay between the rise of cyanobacteria (thought to be the first organisms to release oxygen) and the time that high oxygen levels began to accumulate in the atmosphere. This delay is thought to have been due largely to the rich supply of dissolved ferrous iron in the oceans, which reacted with the released oxygen to form enormous iron oxide deposits.

Panel 1-1: Eucaryotic cells: a survey of their principal organelles

ANIMAL CELL — thin section of a generalized animal cell

PLANT CELL — thin section of a generalized cell from a higher plant

Labels (center): mitochondria, plasma membrane, endoplasmic reticulum, cytosol, Golgi apparatus, filamentous cytoskeleton, nucleus, lysosomes, peroxisomes

Animal cell labels: centriole

Plant cell labels: cell wall, chloroplast, vacuole

Animal cell scale: 10–30 μm
Plant cell scale: 10–100 μm

THE MEMBRANE SYSTEM OF THE CELL

PLASMA MEMBRANE

The outer boundary of the cell is the plasma membrane, a continuous sheet of phospholipid molecules about 4–5 nm thick in which various proteins are embedded.

EXTRACELLULAR SPACE — pump protein — lipid bilayer

CYTOPLASM — protein — channel protein
Some of these proteins serve as pumps and channels for transporting specific molecules into and out of the cell.

ENDOPLASMIC RETICULUM

Flattened sheets, sacs, and tubes of membrane extend throughout the cytoplasm of eucaryotic cells, enclosing a large intracellular space. The ER membrane is in structural continuity with the outer membrane of the nuclear envelope, and it specializes in the synthesis and transport of lipids and membrane proteins.

The rough endoplasmic reticulum (rough ER) generally occurs as flattened sheets and is studded on its outer face with ribosomes engaged in protein synthesis.

ribosomes — nucleus — lumen
The smooth endoplasmic reticulum (smooth ER) is generally more tubular and lacks attached ribosomes. It has a major function in lipid metabolism.

lumen

GOLGI APPARATUS

A system of stacked, membrane-bounded, flattened sacs involved in modifying, sorting, and packaging macromolecules for secretion or for delivery to other organelles.

lumen
Around the Golgi apparatus are numerous small membrane-bounded vesicles (50 nm and larger) that carry material between the Golgi apparatus and different compartments of the cell.

LYSOSOMES

0.2–0.5 μm

membrane-bounded vesicles that contain hydrolytic enzymes involved in intracellular digestions

PEROXISOMES

0.2–0.5 μm

membrane-bounded vesicles containing oxidative enzymes that generate and destroy hydrogen peroxide

NUCLEUS

The nucleus is the most conspicuous organelle in the cell. It is separated from the cytoplasm by an envelope consisting of two membranes. All of the chromosomal DNA is held in the nucleus, packed into chromatin fibers by its association with an equal mass of histone proteins. The nuclear contents communicate with the cytosol by means of openings in the nuclear envelope called nuclear pores.

3–10 µm

nuclear pores

nucleolus: a factory in the nucleus where the cell's ribosomes are assembled

chromatin

nuclear envelope

CYTOSKELETON

In the cytosol, arrays of protein filaments form networks that give the cell its shape and provide a basis for its movements. Three main kinds of cytoskeletal filaments are

1. microtubules — 25-nm diameter

2. actin filaments — 8-nm diameter

3. intermediate filaments — 10-nm diameter

MITOCHONDRIA

About the size of bacteria, mitochondria are the power plants of all eucaryotic cells, harnessing energy obtained by combining oxygen with food molecules to make ATP.

Figure 1-20. A mitochondrion. Mitochondria carry out the oxidative degradation of nutrient molecules in almost all eucaryotic cells. As seen in this electron micrograph, they possess a smooth outer membrane and a highly convoluted inner mem-brane. (Courtesy of Daniel S. Friend.)

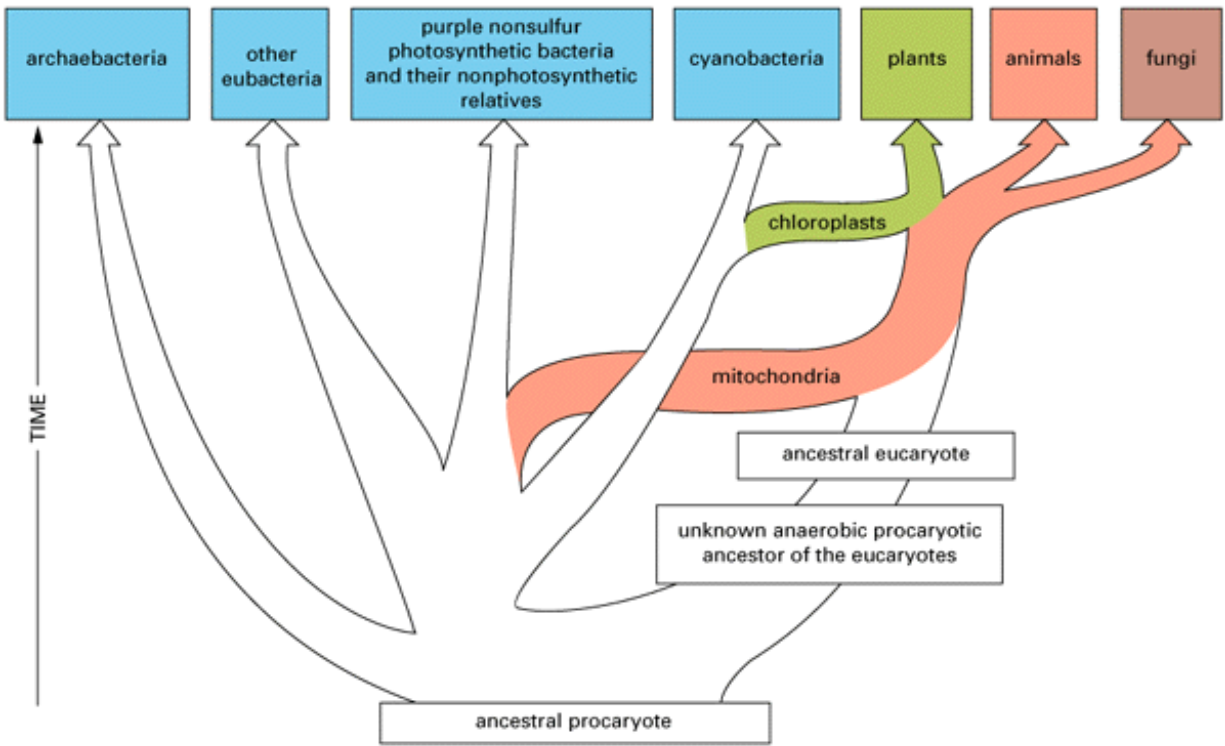
Figure 1-21. The diplomonad *Giardia*. (A) Drawing, as seen in the light microscope. (B) Electron micrograph of a cross-section through the broad, flattened body of the cell. *Giardia* is thought to be one of the most primitive types of eucaryotic cell. It is nucleated (in fact, it has, strangely, two identical nuclei), it possesses a cytoskeleton with actin and tubulin, and it moves by means of typical eucaryotic flagella containing microtubules; but it has no mitochondria or chloroplasts and no normal endoplasmic reticulum or Golgi apparatus. Nucleotide sequencing studies indicate that it is related almost as closely to bacteria as it is to other eucaryotes, from which it must have diverged very early in evolution. *Giardia* lives as a parasite in the gut and can cause disease in humans. (A, after G.D. Schmidt and L.S. Roberts, Foundations of Parasitology, 4th Ed. St Louis: Times Mirror/Mosby, 1989; B, courtesy of Dennis Feely.)
Figure 1-22. A close relative of present-day cyanobacteria that lives in a permanent symbiotic relationship inside another cell. The two organisms are known jointly as *Cyanophora paradoxa*. The "cyano-bacterium" is in the process of dividing. (Courtesy of Jeremy D. Pickett-Heaps.)


Figure 1-23. The postulated origin of present-day eucaryotes by symbiosis of aerobic with anaerobic cells. The time of origin of the eucaryotic nucleus in relation to the time of branching of the eucaryotic lineage from archaebacteria and eubacteria is not known.

Table 1-1. Comparison of Procaryotic and Eucaryotic Organisms

	Procaryotes	**Eucaryotes**
Organisms	bacteria and cyanobacteria	protists, fungi, plants, and animals
Cell size	generally 1 to 10 mm in linear dimension	generally 5 to 100 mm in linear dimension
Metabolism	anaerobic or aerobic	aerobic
Organelles	few or none	nucleus, mitochondria, chloroplasts, endoplasmic reticulum, etc.
DNA	circular DNA in cytoplasm	very long linear DNA molecules containing many noncoding regions; bounded by nuclear envelope
RNA and protein	RNA and protein synthesized in same compartment	RNA synthesized and processed in nucleus; proteins synthesized in cytoplasm
Cytoplasm	no cytoskeleton: cytoplasmic streaming, endocytosis, and exocytosis all absent	cytoskeleton composed of protein filaments; cytoplasmic streaming; endocytosis and exocytosis
Cell division	chromosomes pulled apart by attachments to plasma membrane	chromosomes pulled apart by cytoskeletal spindle apparatus
Cellular organization	mainly unicellular	mainly multicellular, with differentiation of many types

smooth ER   rough ER   ribosomes   mitochondrion   1 µm
Figure 1-24. Endoplasmic reticulum. Electron micrograph of a thin section of a mammalian cell showing both smooth and rough regions of the endoplasmic reticulum (ER). The smooth regions are involved in lipid metabolism; the rough regions, studded with ribosomes, are sites of synthesis of proteins that are destined to leave the cytosol and enter certain other compartments of the cell. Golgi apparatus

1 µm
Figure 1-25. The Golgi apparatus. Electron micrograph of a thin section of a mammalian cell showing the Golgi apparatus, which is composed of flattened sacs of membrane arranged in multiple layers (see also Panel 1-1, pp. 18-19). The Golgi apparatus is involved in the synthesis and packaging of molecules destined to be secreted from the cell, as well as in the routing of newly synthesized proteins to the correct cellular compartments. (Courtesy of Daniel S. Friend.)
Figure 1-26. Actin. A network of actin filaments underlying the plasma membrane of an animal cell is seen in this electron micrograph prepared by the deep-etch technique. (Courtesy of John Heuser.)
Figure 1-27. An assortment of protists, illustrating some of the enormous variety to be found among this class of single-celled organisms. These drawings are done to different scales, but in each case the bar denotes 10 mm. The organisms in (A), (B), (E), (F), and (I) are ciliates; (C) is an euglenoid; (D) is an amoeba; (G) is a dinoflagellate; (H) is a heliozoan. (From M.A. Sleigh, The Biology of Protozoa. London: Edward Arnold, 1973.)
Figure 1-28. One protozoan eating another. Ciliates are single-cell animals that show an amazing diversity of form and behavior. The top micrograph shows *Didinium,* a ciliated protozoan with two circumferential rings of motile cilia and a snoutlike protuberance at its leading end, with which it captures its prey. In the bottom micrograph *Didinium* is shown engulfing another protozoan, *Paramecium.* (Courtesy of D. Barlow.)
Figure 1-29. How the positively charged proteins called histones mediate the folding of DNA in chromosomes.
Figure 1-30. Schematic drawing of eucaryotic cells in mitosis. An animal cell is shown on the left and a plant cell on the right. The nuclear envelope has broken down, and the DNA, having replicated, has condensed into two complete sets of chromosomes. One set is distributed to each of the two newly forming cells by a mitotic spindle composed largely of microtubules.

From Single Cells to Multicellular Organisms[18]

Introduction

Single-cell organisms, such as bacteria and protozoa, have been so successful in adapting to a variety of different environments that they comprise more than half of the total biomass on earth. Unlike animals, many of these unicellular organisms can synthesize all of the substances they need from a few simple nutrients, and some of them divide more than once every hour. What, then, was the selective advantage that led to the evolution of multicellular organisms?

A short answer is that by collaboration and by division of labor it becomes possible to exploit resources that no single cell could utilize so well. This principle, applying at first to simple associations of cells, has been taken to an extreme in the multicellular organisms we see today. Multicellularity enables a plant, for example, to become physically large; to have roots in the ground, where one set of cells can take up water and nutrients; and to have leaves in the air, where another set of cells can efficiently capture radiant energy from the sun. Specialized cells in the stem of the plant form channels for transporting water and nutrients between the roots and the leaves. Yet another set of specialized cells forms a layer of epidermis to prevent water loss and to provide a protected internal environment (see Panel 1-2, pp. 28-29). The plant as a whole does not compete directly with unicellular organisms for its ecological niche; it has found a radically different way to survive and propagate.

As different animals and plants appeared, they changed the environment in which further evolution occurred. Survival in a jungle calls for different talents than survival in the open sea. Innovations in movement, sensory detection, communication, social organization - all enabled eucaryotic organisms to compete, propagate, and survive in ever more complex ways.

Single Cells Can Associate to Form Colonies

It seems likely that an early step in the evolution of multicellular organisms was the association of unicellular organisms to form colonies. The simplest way of achieving this is for daughter cells to remain together after each cell division. Even some procaryotic cells show such social behavior in a primitive form. Myxobacteria, for example, live in the soil and feed on insoluble organic molecules that they break down by secreting degradative enzymes. They stay together in loose colonies in which the digestive enzymes secreted by individual cells are pooled, thus increasing the efficiency of feeding (the "wolf-pack" effect). These cells indeed represent a peak of social sophistication among procaryotes, for when food supplies are exhausted, the cells aggregate tightly together and form a multicellular *fruiting body* (Figure 1-31), within which the bacteria differentiate into spores that can survive even in extremely hostile conditions. When conditions are more favorable, the spores in a fruiting body germinate to produce a new swarm of bacteria.

Green algae (not to be confused with the procaryotic "blue-green algae" or cyanobacteria) are eucaryotes that exist as unicellular, colonial, or multicellular forms (Figure 1-32). Different species of green algae can be arranged in order of complexity, illustrating the kind of progression that probably occurred in the evolution of higher plants and animals. Unicellular green algae, such as *Chlamydomonas,* resemble flagellated protozoa except that they possess chloroplasts, which enable them to carry out photosynthesis. In closely related genera, groups of flagellated cells live in colonies held together by a matrix of extracellular molecules secreted by the cells themselves. The simplest species (those of the genus *Gonium*) have the form of a concave disc made of 4, 8, 16, or 32 cells. Their flagella beat independently, but since they are all oriented in the same direction, they are able to propel the colony through the water. Each cell is equivalent to every other, and each can divide to give rise to an entirely new colony. Larger colonies are found in other genera, the most spectacular being *Volvox,* some of whose species have as many as 50,000 or more cells linked together to form a hollow sphere. In *Volvox* the individual cells forming a colony are connected by fine cytoplasmic bridges so that the beating of their flagella is coordinated to propel the entire colony along like a rolling ball (see Figure 1-32). Within the *Volvox* colony there is some division of labor among cells, with a small number of cells being specialized for reproduction and serving as precursors of new colonies. The other cells are so dependent on one another that they cannot live in isolation, and the organism dies if the colony is disrupted.

The Cells of a Higher Organism Become Specialized and Cooperate

In some ways *Volvox* is more like a multicellular organism than a simple colony. All of its flagella beat in synchrony as it spins through the water, and the colony is structurally and functionally polarized and can swim toward a distant source of light. The reproductive cells are usually confined to one end of the colony, where they divide to form new miniature colonies, which are initially sheltered inside the parent sphere. Thus, in a primitive way, *Volvox* displays the two essential features of all multicellular organisms: its cells become *specialized,* and they *cooperate.* By specialization and cooperation the cells combine to form a coordinated single organism with more capabilities than any of its component parts.

Organized patterns of cell differentiation occur even in some procaryotes. For example, many kinds of cyanobacteria remain together after cell division, forming filamentous chains that can be as much as a meter in length. At regular intervals along the filament, individual cells take on a distinctive character and become able to incorporate atmospheric nitrogen into organic molecules. These few specialized cells perform nitrogen fixation for their neighbors and share the products with them. But eucaryotic cells appear to be very much better at this sort of organized division of labor; they, and not procaryotes, are the living units from which all the more complex multicellular organisms are constructed.

Multicellular Organization Depends on Cohesion Between Cells

To form a multicellular organism, the cells must be somehow bound together, and eucaryotes have evolved a number of different ways to satisfy this need. In *Volvox,* as noted above, the cells do not separate entirely at cell division but remain connected by cytoplasmic bridges. In higher plants the cells not only remain connected by cytoplasmic bridges (called *plasmodesmata*), they also are imprisoned in a rigid honeycomb of chambers walled with cellulose that the cells themselves have secreted (*cell walls*).

The cells of most animals do not have rigid walls, and cytoplasmic bridges are unusual. Instead, the cells are bound together by a relatively loose meshwork of large extracellular organic molecules (called the *extracellular matrix*) and by adhesions between their plasma membranes. Very often, side-to-side attachments between the cells hold them together to form a multicellular sheet, or epithelium.

Epithelial Sheets of Cells Enclose a Sheltered Internal Environment

Of all the ways in which animal cells are woven together into multicellular tissues, the epithelial arrangement is perhaps the most fundamentally important. The epithelial sheet has much the same significance for the evolution of complex multicellular organisms that the cell membrane has for the evolution of complex single cells.

The importance of epithelial sheets is well illustrated in the lowly group of animals known as *coelenterates.* The group includes sea anemones, jellyfish, and corals, as well as the small freshwater organism *Hydra.* Coelenterates are constructed from two layers of epithelium, the outer layer being the *ectoderm,* the inner being the *endoderm.* The endodermal layer surrounds a cavity, the *coelenteron,* in which food is digested (Figure 1-33). Among the endodermal cells are some that secrete digestive enzymes into the coelenteron, while other cells absorb and further digest the nutrient molecules that these enzymes release. By forming a

tightly coherent epithelial sheet that prevents all these molecules from being lost to the exterior, the endodermal cells create for themselves an environment in the coelenteron that is suited to their own digestive tasks. Meanwhile, the ectodermal cells, facing the exterior, remain specialized for encounters with the outside world. In the ectoderm, for example, are cells that contain a poison capsule with a coiled dart that can be unleashed to kill the small animals on which *Hydra* feeds. The majority of other ectodermal and endodermal cells have musclelike properties, enabling *Hydra* to move, as a predator must.

Within the double layer of ectoderm and endoderm is another compartment, separate both from the coelenteron and from the outside world. Here *nerve cells* lie, occupying narrow enclosed spaces between the epithelial cells, below the external surface where the specialized *cell junctions* between the epithelial cells form an impermeable barrier. The animal can change its shape and move by contractions of the musclelike cells in the epithelia, and it is the nerve cells that convey electrical signals to control and coordinate these contractions (Figures 1-33, 1-34, and 1-35). As we shall see later, the concentrations of simple inorganic ions in the medium surrounding a nerve cell are crucial for its function. Most nerve cells - our own included - are designed to operate when bathed in a solution with an ionic composition roughly similar to that of seawater. This may well reflect the conditions under which the first nerve cells evolved. Most coelenterates still live in the sea, but not all. *Hydra,* in particular, lives in fresh water. It has evidently been able to colonize this new habitat only because its nerve cells are contained in a space that is sealed and isolated from the exterior within sheets of epithelial cells that maintain the internal environment necessary for nerve cell function.

Cell-Cell Communication Controls the Spatial Pattern of Multicellular Organisms[19]

The cells of *Hydra* are not only bound together mechanically and connected by junctions that seal off the interior from the exterior environment, they also communicate with one another along the length of the body. If one end of a *Hydra* is cut off, the remaining cells react to the absence of the amputated part by adjusting their characters and rearranging themselves so as to regenerate a complete animal. Evidently, signals pass from one part of the organism to the other, governing the development of its body pattern - with tentacles and a mouth at one end and a foot at the other. Moreover, these signals are independent of the nervous system. If a developing *Hydra* is treated with a drug that prevents nerve cells from forming, the animal is unable to move about, catch prey, or feed itself. Its digestive system still functions normally, however, so that it can be kept alive by anyone with the patience to stuff its normal prey into its mouth. In such force-fed animals the body pattern is maintained, and lost parts are regenerated just as well as in an animal that has an intact nervous system.

The vastly more complex higher animals have evolved from simpler ancestors resembling coelenterates, and these higher animals owe their complexity to more sophisticated exploitation of the same basic principles of cell cooperation that underlie the construction of *Hydra.* Epithelial sheets of cells line all external and internal surfaces in the body, creating sheltered compartments and controlled internal environments in which specialized functions are performed by differentiated cells. Specialized cells interact and communicate with one another, setting up signals to govern the character of each cell according to its place in the structure as a whole. To show how it is possible to generate multicellular organisms of such size, precision, and complexity as a tree, a fly, or a mammal, however, it is necessary to consider more closely the sequence of events in development.

Cell Memory Permits the Development of Complex Patterns

The cells of almost every multicellular organism are generated by repeated division from a single precursor cell; they constitute a *clone.* As proliferation continues and the clone grows, some of the cells, as we have seen, become differentiated from others, adopting a different structure, a different chemistry, and a different function, usually in response to cues from their neighbors. It is remarkable that eucaryotic cells and their progeny will usually persist in their differently specialized states even after the influences that originally directed their differentiation have disappeared - in other words, these cells have a *memory.* Consequently, their final character is not determined simply by their final environment, but rather by the entire sequence of influences to which the cells have been exposed in the course of development. Thus as the body grows and matures, progressively finer details of the adult body pattern become specified, creating an organism of gradually increasing complexity whose ultimate form is the expression of a long developmental history.

Basic Developmental Programs Tend to Be Conserved in Evolution[20]

The final structure of an animal or plant reflects its evolutionary history, which, like development, presents a chronicle of progress from the simple to the complex. What then is the connection between the two perspectives, of evolution on the one hand and development on the other?

During evolution many of the developmental devices that evolved in the simplest multicellular organisms have been conserved as basic principles for the construction of their more complex descendants. We have already mentioned, for example, the organization of cells into epithelia. Some specialized cell types, such as nerve cells, are found throughout nearly the whole of the animal kingdom, from *Hydra* to humans. Molecular studies, to be discussed later in this book, reveal an astonishing number of developmental resemblances at a fundamental genetic level, even between species as remotely related as mammals and insects. In terms of anatomy, furthermore, early developmental stages of animals whose adult forms appear radically different are often surprisingly similar; it takes an expert eye to distinguish, for example, a young chick embryo from a young human embryo (Figure 1-36).

Such observations are not difficult to understand. Consider the process by which a new anatomical feature - say, an elongated beak - appears in the course of evolution. A random mutation occurs that changes the amino acid sequence of a protein or the timing of its synthesis and hence its biological activity. This alteration may, by chance, affect the cells responsible for the formation of the beak in such a way that they make one that is longer. But the mutation must also be compatible with the development of the rest of the organism; only then will it be propagated by natural selection. There would be little selective advantage in forming a longer beak if, in the process, the tongue was lost or the ears failed to develop. A catastrophe of this type is more likely if the mutation affects events occurring early in development than if it affects those near the end. The early cells of an embryo are like cards at the bottom of a house of cards - a great deal depends on them, and even small changes in their properties are likely to result in disaster. Fundamental steps appear to have been "frozen" into developmental processes, just as the genetic code or protein synthesis mechanisms have become frozen into the basic biochemical organization of the cell. In contrast, cells produced near the end of development (or produced early but forming accessory structures such as the placenta that are not incorporated in the adult body) have more freedom to change. It is presumably for this reason that the embryos of different species so often resemble each other in their early stages and, as they develop, seem sometimes to replay the steps of evolution.

The Cells of the Vertebrate Body Exhibit More Than 200 Different Modes of Specialization

The wealth of diverse specializations to be found among the cells of a higher animal is far greater than any procaryote can show. In a vertebrate more than 200 distinct cell types are plainly distinguishable, and many of these types of cells certainly include, under a single name, a large number of more subtly different varieties. Panel 1-3 (pp. 36-37) shows a small selection. In this profusion of specialized behaviors one can see displayed, in a single organism, the astonishing versatility of the eucaryotic cell. Much of our current knowledge of the general properties of eucaryotic cells has depended on the study of such specialized types of cells, because they demonstrate exceptionally well particular features on which all cells depend in some measure. Each feature and each organelle of the prototype that we have outlined in Panel 1-1 (pp. 18-19) is developed to an unusual degree or revealed with special clarity in one cell type or another. To take one arbitrary example, consider the *neuromuscular junction,* where just three types of cells are involved: a muscle cell, a nerve cell, and a Schwann cell. Each has a very different role (Figure 1-37):

1. The muscle cell has made contraction its specialty. Its cytoplasm is packed with organized arrays of protein filaments, including vast numbers of actin filaments. There are also many mitochondria interspersed among the protein filaments, supplying ATP as fuel for the contractile apparatus.

2. The nerve cell stimulates the muscle to contract, conveying an excitatory signal to the muscle from the brain or spinal cord. The nerve cell is therefore extraordinarily elongated: its main body, containing the nucleus, may lie a meter or more from the junction with the muscle. The cytoskeleton is consequently well developed so as to maintain the unusual shape of the cell and to transport materials efficiently from one end of the cell to the other. The most crucial specialization of the nerve cell, however, is its plasma membrane, which contains proteins that act as ion *pumps* and ion *channels,* causing a movement of ions that is equivalent to a flow of electricity. Whereas all cells contain such pumps and channels in their plasma membranes, the nerve cell has exploited them in such a way that a pulse of electricity can propagate in a fraction of a second from one end of the cell to the other, conveying a signal for action.

3. Lastly, Schwann cells are specialists in the mass production of plasma membrane, which they wrap around the elongated portion of the nerve cell, laying down layer upon layer of membrane like a roll of tape, to form a *myelin sheath* that serves as insulation.

Genes Can Be Switched On and Off

The various specialized cell types in a single higher plant or animal appear as different from one another as any cells could be. This seems paradoxical, since all of the cells in a multicellular organism are closely related, having recently descended from the same precursor cell - the fertilized egg. Common lineage implies similar genes; how then do the differences arise? In a few cases cell specialization involves the loss of genetic material. An extreme example is the mammalian red blood cell, which loses its entire nucleus in the course of differentiation. But the overwhelming majority of cells in most plant and animal species retain all of the genetic information contained in the fertilized egg. Specialization depends on changes in *gene expression,* not on the loss or acquisition of genes.

Even bacteria do not make all of their types of protein all of the time but are able to adjust the level of synthesis according to external conditions. Proteins required specifically for the metabolism of lactose, for example, are made by many bacteria only when this sugar is available for use; and when conditions are unfavorable for cell proliferation, some bacteria arrest most of their normal metabolic processes and form *spores,* which have tough, impermeable outer walls and a cytoplasm of altered composition.

Eucaryotic cells have evolved far more sophisticated mechanisms for controlling gene expression, and these affect entire systems of interacting gene products. Groups of genes are activated or repressed in response to both external and internal signals. Membrane composition, cytoskeleton, secretory products, even metabolism - all these and other features must change in a coordinated manner when cells become differentiated. The radical differences of character between cell types reflect stable changes in gene expression. The controls that bring about these changes have evolved in eucaryotes to a degree unmatched in procaryotes, defining the complex rules of cell behavior that can generate an organized multicellular organism from a single egg.

Sequence Comparisons Reveal Hundreds of Families of Homologous Genes[12], [21]

To outward appearances, evolution has transformed the universe of living things to such a degree that they are no longer recognizable as relatives. A human being, a fly, a daisy, a yeast, a bacterium - they seem so different that it scarcely makes sense to compare them. Yet all are descendants of one ancestor, and as we probe their inner workings more and more deeply, we find more and more evidence of their common origins. We now know that the basic molecular machinery of life has been conserved to an extent that would surely have astonished the originators of the theory of evolution. As we have seen, all life forms have essentially the same chemistry, based on amino acids, sugars, fatty acids, and nucleotides; all synthesize these chemical constituents in an essentially similar way; all store their genetic information in DNA and express it through RNA and protein. But the degree of evolutionary conservatism becomes even more striking when we examine the detailed sequences of nucleotides in specific genes and of amino acids in specific proteins. The chances are that the bacterial enzyme catalyzing any particular common reaction, such as the splitting of a six-carbon sugar into two three-carbon sugars in glycolysis, will have an amino acid sequence (and a three-dimensional structure) unmistakably similar to the enzyme catalyzing the same reaction in human beings. The two enzymes - and, equivalently, the genes that specify them - not only have a similar function, but also almost certainly a common evolutionary origin. One can exploit these relationships to trace ancient evolutionary pathways; and by comparing gene sequences and recognizing homologies, one discovers hidden parallels and similarities between different organisms.

Family resemblances are also often found among genes coding for proteins that carry out related functions within a single organism. These genes are also evolutionarily related, and their existence reveals a basic strategy by which increasingly complex organisms have arisen: genes and portions of genes become duplicated, and the new copies then diverge from the old by mutation and recombination to serve new, additional purposes. In this way, starting from a relatively small set of genes in primitive cells, the more complex life forms have been able to evolve the more than 50,000 genes thought to be present in a higher animal or plant. From an understanding of one gene or protein, we consequently gain insight into a whole family of others homologous to it. Thus molecular biology both underscores the unity of the living world and gives us tools to discover the general mechanisms that underlie its endless variety of inventions.

In the next chapter we begin our account of these mechanisms with a discussion of the most basic components of the biological construction kit - the small molecules from which all larger components of living cells are made.

Summary

The evolution of large multicellular organisms depended on the ability of eucaryotic cells to express their hereditary information in many different ways and to function cooperatively in a single collective. In animals one of the earliest developments was

probably the formation of epithelial cell sheets, which separate the internal space of the body from the exterior. In addition to epithelial cells, primitive differentiated cell types would have included nerve cells, muscle cells, and connective tissue cells, all of which can be found in very simple present-day animals. The evolution of higher animals and plants (Figure 1-38) depended on production of an increasing number of specialized cell types and more sophisticated methods of coordination among them, reflecting an increasingly elaborate system of controls over gene expression in the individual component cells.

Panel1-2: The cell types and tissues from which higher plants are constructed

THE PLANT

The young flowering plant shown on the *left* is constructed from three main types of organs: leaves, stems, and roots. Each plant organ in turn is made from three tissue systems: ground, dermal, and vascular.

All three tissue systems derive ultimately from the cell proliferative activity of the shoot or root apical meristems, and each contains a relatively small number of specialized cell types. These three common tissue systems, and the cells that comprise them, are described in this panel.

THE THREE TISSUE SYSTEMS

Cell division, growth, and differentiation give rise to tissue systems with specialized functions.

DERMAL TISSUE (▭): This is the plant's protective outer covering in contact with the environment. It facilitates water and ion uptake in roots and regulates gas exchange in leaves and stems.

VASCULAR TISSUE: Together the phloem (▭) and the xylem (▭) form a continuous vascular system throughout the plant. This tissue conducts water and solutes between organs and also provides mechanical support.

GROUND TISSUE (▭): This packing and supportive tissue accounts for much of the bulk of the young plant. It also functions in food manufacture and storage.

GROUND TISSUE

The ground tissue system contains three main cell types called parenchyma, collenchyma, and sclerenchyma.

Parenchyma cells are found in all tissue systems. They are living cells, generally capable of further division, and have a thin primary cell wall. These cells have a variety of functions. The apical and lateral meristematic cells of shoots and roots provide the new cells required for growth. Food production and storage occur in the photosynthetic cells of the leaf and stem (called mesophyll cells); storage parenchyma cells form the bulk of most fruits and vegetables. Because of their proliferative capacity, parenchyma cells also serve as stem cells for wound healing and regeneration.

Collenchyma are living cells similar to parenchyma cells except that they have much thicker cell walls and are usually elongated and packed into long ropelike fibers. They are capable of stretching and provide mechanical support in the ground tissue system of the elongating regions of the plant. Collenchyma cells are especially common in subepidermal regions of stems.

Sclerenchyma, like collenchyma, have strengthening and supporting functions. However, they are usually dead cells with thick, lignified secondary cell walls that prevent them from stretching as the plant grows. Two common types are fibers, which often form long bundles, and sclereids, which are shorter branched cells found in seed coats and fruit.

A transfer cell, a specialized form of the parenchyma cell, is readily identified by elaborate ingrowths of the primary cell wall. The increase in the area of the plasma membrane beneath these walls facilitates the rapid transport of solutes to and from cells of the vascular system.

DERMAL TISSUE

The epidermis is the primary outer protective covering of the plant body. Cells of the epidermis are also modified to form stomata and hairs of various kinds.

Epidermis

waxy layer

cuticle

The epidermis (usually one layer of cells deep) covers the entire stem, leaf, and root of the young plant. The cells are living, have thick primary cell walls, and are covered on their outer surface by a special cuticle with an outer waxy layer. The cells are tightly interlocked in different patterns.

Stomata

guard cells

air space

5 µm

Stomata are openings in the epidermis, mainly on the lower surface of the leaf, that regulate gas exchange in the plant. They are formed by two specialized epidermal cells called *guard cells*, which regulate the diameter of the pore. Stomata are distributed in a distinct species-specific pattern within each epidermis.

Vascular bundles

Roots usually have a single vascular bundle, but stems have several bundles. These are arranged with strict radial symmetry in dicots, but they are more irregularly dispersed in monocots.

Hairs (or trichomes) are appendages derived from epidermal cells. They exist in a variety of forms and are commonly found in all plant parts. Hairs function in protection, absorption, and secretion; for example,

epidermis   hair   100 µm

young, single-celled hairs in the epidermis of the cotton seed. When these grow, the walls will be secondarily thickened with cellulose to form cotton fibers.

epidermis

root hair

Single-celled root hairs have an important function in water and ion uptake.

VASCULAR TISSUE

The phloem and the xylem together form a continuous vascular system throughout the plant. In young plants they are usually associated with a variety of other cell types in *vascular bundles*. Both phloem and xylem are complex tissues. Their conducting elements are associated with parenchyma cells that maintain and exchange materials with the elements. Also, groups of collenchyma and sclerenchyma cells provide mechanical support.

Phloem

sieve-tube element in cross-section
Phloem is involved in the transport of organic solutes in the plant. The main conducting cells (elements) are aligned to form tubes called *sieve tubes*. The sieve-tube elements at maturity are living cells, interconnected by perforations in their end walls formed from enlarged and modified plasmodesmata (sieve plates). These cells retain their plasma membrane, but they have lost their nuclei and much of their cytoplasm; they therefore rely on associated *companion cells* for their maintenance. These companion cells have the additional function of actively transporting soluble food molecules into and out of sieve-tube elements through porous sieve areas in the wall.

Xylem

Xylem carries water and dissolved ions in the plant. The main conducting cells are the vessel elements shown here, which are dead cells at maturity that lack a plasma membrane. The cell wall has been secondarily thickened and heavily lignified. As shown below, its end wall is largely removed, enabling very long, continuous tubes to be formed.

Panel 1-3: Some of the different types of cells present in the vertebrate body

CELL TYPES

There are over 200 types of cells in the human body. These are assembled into a variety of types of tissue such as

- epithelia
- connective tissue
- muscle
- nervous tissue

Most tissues contain a mixture of cell types.

EPITHELIA

Epithelial cells form coherent cell sheets called epithelia, which line the inner and outer surfaces of the body. There are many specialized types of epithelia.

Absorptive cells have numerous hairlike microvilli projecting from their free surface to increase the area for absorption.

- microvilli
- intercellular junction
- basal lamina
Adjacent epithelial cells are bound together by junctions that give the sheet mechanical strength and also make it impermeable to small molecules. The sheet rests on a basal lamina.

Ciliated cells have cilia on their free surface that beat in synchrony to move substances (such as mucus) over the epithelial sheet.
Secretory cells are found in most epithelial layers. These specialized cells secrete substances onto the surface of the cell sheet.

- cilia
- nucleus

CONNECTIVE TISSUE

The spaces between organs and tissues in the body are filled with connective tissue made principally of a network of tough protein fibers embedded in a polysaccharide gel. This extracellular matrix is secreted mainly by fibroblasts.

Two main types of extracellular protein fiber are collagen and elastin.

fibroblasts in loose connective tissue

Bone is made by cells called osteoblasts. These secrete an extracellular matrix in which crystals of calcium phosphate are later deposited.

Calcium salts are deposited in the extracellular matrix.
- osteoblasts linked together by cell processes
- extracellular matrix
Adipose cells, among the largest cells in the body, are responsible for the production and storage of fat. The nucleus and cytoplasm are squeezed by a large lipid droplet.

lipid   60–120 µm

NERVOUS TISSUE

- dendrites
- OUTPUT
- axon
- INPUTS

The axon conducts electrical signals away from the cell body. These signals are produced by a flux of ions across the nerve cell membrane.

- cell body, or soma
Nerve cells, or neurons, are specialized for communication. The brain and spinal cord, for example, are composed of a network of neurons among supporting glial cells.

Specialized cells, called Schwann cells, or oligodendrocytes, wrap around an axon to form a multilayered membrane sheath.

A synapse is where a neuron forms a specialized junction with another neuron (or with a muscle cell). At synapses, signals pass from one neuron to another (or from a neuron to a muscle cell).

Secretory epithelial cells are often collected together to form a gland that specializes in the secretion of a particular substance. As illustrated, exocrine glands secrete their products (such as tears, mucus, and gastric juices) into ducts. Endocrine glands secrete hormones into the blood.

secreted material

duct of gland

secretory cells of gland
MUSCLE

Muscle cells produce mechanical force by their contraction. In vertebrates there are three main types:

skeletal muscle—this moves joints by its strong and rapid contraction. Each muscle is a bundle of muscle fibers, each of which is an enormous multinucleated cell.

muscle

tendon

nuclei

muscle cell with cross striations
smooth muscle—present in digestive tract, bladder, arteries, and veins. It is composed of thin elongated cells (not striated), each of which has one nucleus.

cardiac muscle—intermediate in character between skeletal and smooth muscle. It produces the heart beat. Adjacent cells are linked by electrically conducting junctions that cause the cells to contract in synchrony.

BLOOD

Erythrocytes (red blood cells) are very small cells, usually with no nucleus or internal membranes, and are stuffed full of the oxygen-binding protein hemoglobin.

1 cm³ of blood contains 5 billion erythrocytes

their normal shape is a biconcave disc

Leucocytes (white blood cells) protect against infections. Blood contains about one leucocyte for every 100 red blood cells. Although leucocytes travel in the circulation, they can pass through the walls of blood vessels to do their work in the surrounding tissues. There are several different kinds, including

lymphocytes—responsible for immune responses such as the production of antibodies.
macrophages and neutrophils—move to sites of infection, where they ingest bacteria and debris.

wall of small blood vessel

bacterial infection in connective tissue
SENSORY CELLS

Among the most strikingly specialized cells in the vertebrate body are those that detect external stimuli. Hair cells of the inner ear are primary detectors of sound. Modified epithelial cells, they carry special microvilli (stereocilia) on their surface. The movement of these in response to sound vibrations causes an electrical signal to pass to the brain.

stereocilia are very rigid because they are packed with actin filaments

hair cell
Rod cells in the retina of the eye are specialized to respond to light. The photosensitive region contains many membanous discs (*red*) in whose membranes the light-sensitive pigment rhodopsin is embedded. Light evokes an electrical signal (*green arrow*), which is transmitted to nerve cells in the eye, which relay the signal to the brain.

GERM CELLS

Both sperm and egg are *haploid*, that is, they carry only one set of chromosomes. A sperm from the male fuses with an egg from the female, which then forms a new diploid organism by successive cell divisions.

2. Small Molecules, Energy, and Biosynthesis

Introduction

"I must tell you that I can prepare urea without requiring a kidney or an animal, either man or dog." This sentence, written 165 years ago by the young German chemist Wöhler, signaled an end to the belief in a special *vital force* that exists in living organisms and gives rise to their distinctive properties and products. But what was a revelation in Wöhler's time is common knowledge today - living creatures are made of chemicals, obedient simply to the laws of chemistry and physics. This is not to say that no mysteries remain in biology: there are many areas of ignorance, as will become apparent in later chapters. But we should begin by emphasizing the enormous amount that is known.

We now have detailed information about the essential molecules of the cell - not just a small number of molecules, but thousands of them. In many cases we know their precise chemical structures and exactly how they are made and broken down. We know in general terms how chemical energy drives the biosynthetic reactions of the cell, how thermodynamic principles operate in cells to create molecular order, and how the myriad chemical changes occurring continuously within cells are controlled and coordinated.

In this and the next chapter we briefly survey the chemistry of the living cell. Here we deal with the processes involving small molecules: those mechanisms by which the cell synthesizes its fundamental chemical ingredients and by which it obtains its energy. Chapter 3 describes the giant molecules of the cell, which are polymers of a subset of the small molecules; these polymers are responsible both for the specificity of biological processes and for the transfer of biological information.

The Chemical Components of a Cell

Cell Chemistry Is Based on Carbon Compounds 1

A living cell is composed of a restricted set of elements, four of which (C, H, N, and O) make up nearly 99% of its weight. This composition differs markedly from that of the earth's crust and is evidence of a distinctive type of chemistry (Figure 2-1). What is this special chemistry, and how did it evolve?

The most abundant substance of the living cell is water. It accounts for about 70% of a cell's weight, and most intracellular reactions occur in an aqueous environment. Life on this planet began in the ocean, and the conditions in that primeval environment put a permanent stamp on the chemistry of living things. All organisms have been designed around the special properties of water, such as its polar character, its ability to form hydrogen bonds, and its high surface tension. Water will completely surround polar molecules, for example, while tending to push nonpolar molecules together into larger assemblies. Some important properties of water are summarized in Panel 2-1 (pp. 48-49).

If we disregard water, nearly all of the molecules in a cell are carbon compounds, which are the subject matter of organic chemistry. Carbon is outstanding among all the elements on earth for its ability to form large molecules; silicon is a poor second. The carbon atom, because of its small size and four outer-shell electrons, can form four strong covalent bonds with other atoms. Most important, it can join to other carbon atoms to form chains and rings and thereby generate large and complex molecules with no obvious upper limit to their size. The other abundant atoms in the cell (H, N, and O) are also small and able to make very strong covalent bonds (Panel 2-2, pp. 50-51).

A typical covalent bond in a biological molecule has an energy of 15 to 170 Kcal/mole, depending on the atoms involved. Since the average thermal energy at body temperature is only 0.6 kcal/mole, even an unusually energetic collision with another molecule will leave a covalent bond intact. Specific catalysts, however, can rapidly break or rearrange covalent bonds. Biology is made possible by the combination of the stability of covalent bonds under physiological conditions and the ability of biological catalysts (called *enzymes*) to break and rearrange these bonds in a controlled way in selected molecules.

In principle, the simple rules of covalent bonding between carbon and other elements permit an infinitely large number of compounds. Although the number of different carbon compounds in a cell is very large, it is only a tiny subset of what is theoretically possible. In some cases we can point to good reasons why this compound or that performs a given biological function; more often it seems that the actual "choice" was one among many reasonable alternatives and therefore something of

an accident (Figure 2-2). Once established in an ancient cell, certain chemical themes and patterns of reaction were preserved, with variations, during billions of years of cellular evolution. Apparently, the development of new classes of compounds was only rarely necessary or useful.

Cells Use Four Basic Types of Small Molecules 2

Certain simple combinations of atoms - such as the methyl ($-CH_3$), hydroxyl ($-OH$), carboxyl ($-COOH$), and amino ($-NH_2$) groups - recur repeatedly in biological molecules. Each such group has distinct chemical and physical properties that influence the behavior of whatever molecule the group occurs in. The main types of chemical groups and some of their salient properties are summarized in Panel 2-2 (pp. 50-51).

The atomic weights of H, C, N, and O are 1, 12, 14, and 16, respectively. The small organic molecules of the cell have molecular weights in the range 100 to 1000 and contain up to 30 or so carbon atoms. They are usually found free in solution, where some of them form a pool of intermediates from which large polymers, called macromolecules, are made. They are also essential intermediates in the chemical reactions that transform energy derived from food into usable forms (discussed below).

The small molecules amount to about one-tenth of the total organic matter in a cell, and (at a rough estimate) only on the order of a thousand different kinds are present (Table 2-1). All biological molecules are synthesized from and broken down to the same simple compounds. Both synthesis and breakdown occur through sequences of chemical changes that are limited in scope and follow definite rules. As a consequence, the compounds in a cell are chemically related and can be classified into a small number of distinct families. Since the macromolecules in a cell, which form the subject of Chapter 3, are assembled from these small molecules, they belong to corresponding families.

Broadly speaking, cells contain just four major families of small organic molecules: the simple sugars, the fatty acids, the amino acids, and the nucleotides. Each of these families contains many different members with common chemical features. Although some cellular compounds do not fit into these categories, the four families, and especially the macromolecules made from them, account for a surprisingly large fraction of the mass of every cell (Table 2-1).

Sugars Are Food Molecules of the Cell 3

The simplest sugars - the monosaccharides - are compounds with the general formula $(CH_2O)_n$, where n is an integer from 3 through 7. *Glucose,* for example, has the formula $C_6H_{12}O_6$ (Figure 2-3). As shown in Figure 2-3, sugars can exist in either a ring or an open-chain form. In their open-chain form sugars contain a number of hydroxyl groups and either one aldehyde ($_H> C=O$) or one ketone ($> C=O$) group. The aldehyde or ketone group plays a special role. First, it can react with a hydroxyl group in the same molecule to convert the molecule into a ring; in the ring form the carbon of the original aldehyde or ketone group can be recognized as the only one that is bonded to two oxygens. Second, once the ring is formed, this carbon can become further linked to one of the carbons bearing a hydroxyl group on another sugar molecule, creating a *disaccharide* (Panel 2-3, pp. 52-53). The addition of more monosaccharides in the same way results in oligosaccharides of increasing length (trisaccharides, tetrasaccharides, and so on) up to very large polysaccharide molecules with thousands of monosaccharide units. Because each monosaccharide has several free hydroxyl groups that can form a link to another monosaccharide (or to some other compound), the number of possible polysaccharide structures is extremely large. Even a simple disaccharide consisting of two glucose residues can exist in eleven different varieties (Figure 2-4), while three different hexoses ($C_6H_{12}O_6$) can join together to make several thousand different trisaccharides. It is very difficult to determine the structure of any particular polysaccharide because one needs to determine the sites of linkage between each sugar unit and its neighbors. With present methods, for instance, it takes longer to determine the arrangement of half a dozen linked sugars (those in a glycoprotein, for example) than to determine the nucleotide sequence of a DNA molecule containing many thousands of nucleotides (where each unit is joined to the next in exactly the same way).

Glucose is the principal food compound of many cells. A series of oxidative reactions (see p. 62) leads from this hexose to various smaller sugar derivatives and eventually to CO_2 and H_2O. The net result can be written

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O + energy$$

In the course of glucose breakdown, energy and "reducing power," both of which are essential in biosynthetic reactions, are

salvaged and stored, mainly in the form of ATP in the case of energy and NADH for reducing power. We discuss the structures and functions of these two crucial molecules later in the chapter.

Simple polysaccharides composed only of glucose residues - principally *glycogen* in animal cells and *starch* in plant cells - are used to store energy for future use. But sugars have functions in addition to the production and storage of energy. Important extracellular structural materials (such as cellulose) are composed of simple polysaccharides, and smaller but more complex chains of sugar molecules are often covalently linked to proteins in *glycoproteins* and to lipids in *glycolipids.*

Fatty Acids Are Components of Cell Membranes <u>4</u>

A fatty acid molecule, such as *palmitic acid* (<u>Figure 2-5</u>), has two distinct regions: a long hydrocarbon chain, which is hydrophobic (water insoluble) and not very reactive chemically, and a carboxylic acid group, which is ionized in solution (COO⁻), extremely hydrophilic (water soluble), and readily reacts with a hydroxyl or an amino group on a second molecule to form esters and amides. In fact, almost all of the fatty acid molecules in a cell are covalently linked to other molecules by their carboxylic acid group. The many different fatty acids found in cells differ in the length of their hydrocarbon chains and the number and position of the carbon-carbon double bonds they contain (<u>Panel 2-4</u>, pp. 54-55).

Fatty acids are a valuable source of food since they can be broken down to produce more than twice as much usable energy, weight for weight, as glucose. They are stored in the cytoplasm of many cells in the form of droplets of *triglyceride* molecules, which consist of three fatty acid chains, each joined to a glycerol molecule (<u>Panel 2-4</u>, pp. 54-55); these molecules are the animal fats familiar from everyday experience. When required to provide energy, the fatty acid chains can be released from triglycerides and broken down into two-carbon units. These two-carbon units, present as the acetyl group in a water-soluble molecule called *acetyl CoA,* are then further degraded in various energy-yielding reactions, which we describe below.

But the most important function of fatty acids is in the construction of cell membranes. These thin, impermeable sheets that enclose all cells and surround their internal organelles are composed largely of phospholipids, which are small molecules that resemble triglycerides in that they are constructed mostly from fatty acids and glycerol. In phospholipids, however, the glycerol is joined to two rather than three fatty acid chains. The remaining site on the glycerol is coupled to a negatively charged phosphate group, which is in turn attached to another small hydrophilic compound, such as *ethanolamine, choline,* or *serine.*

Each phospholipid molecule, therefore, has a hydrophobic tail - composed of the two fatty acid chains - and a hydrophilic polar head group, where the phosphate is located. A small amount of phospholipid will spread over the surface of water to form a *monolayer* of phospholipid molecules; in this thin film, the hydrophobic tail regions pack together very closely facing the air and the hydrophilic head groups are in contact with the water (<u>Panel 2-4</u>, pp. 54-55). Two such films can combine tail to tail in water to make a phospholipid sandwich, or lipid bilayer, an extremely important assembly that is the structural basis of all cell membranes (discussed in <u>Chapter 10</u>).

Amino Acids Are the Subunits of Proteins <u>5</u>

The common amino acids are chemically varied, but they all contain a carboxylic acid group and an amino group, both linked to a single carbon atom (called the alpha-carbon; <u>Figure 2-6</u>). They serve as subunits in the synthesis of proteins, which are long linear polymers of amino acids joined head to tail by a *peptide bond* between the carboxylic acid group of one amino acid and the amino group of the next (<u>Figure 2-7</u>). Although there are many different possible amino acids, only 20 are common in proteins, each with a different *side chain* attached to the alpha-carbon atom (<u>Panel 2-5</u>, pp. 56-57). The same 20 amino acids occur over and over again in all proteins, including those made by bacteria, plants, and animals. Although the choice of these particular 20 amino acids probably occurred by chance in the course of evolution, the chemical versatility they provide is vitally important. For example, 5 of the 20 amino acids have side chains that can carry a charge (<u>Figure 2-8</u>), whereas the others are uncharged but reactive in specific ways (<u>Panel 2-5</u>, pp. 56-57). As we shall see, the properties of the amino acid side chains, in aggregate, determine the properties of the proteins they constitute and underlie all of the diverse and sophisticated functions of proteins.

Nucleotides Are the Subunits of DNA and RNA <u>6</u>

In nucleotides one of several different nitrogen-containing ring compounds (often referred to as *bases* because they can combine with H⁺ in acidic solutions) is linked to a five-carbon sugar (either *ribose* or *deoxyribose*) that carries a phosphate group. There

is a strong family resemblance between the different nitrogen-containing rings found in nucleotides. *Cytosine* (C), *thymine* (T), and *uracil* (U) are called *pyrimidine* compounds because they are all simple derivatives of a six-membered pyrimidine ring; *guanine* (G) and *adenine* (A) are *purine* compounds, with a second five-membered ring fused to the six-membered ring. Each nucleotide is named by reference to the unique base that it contains (Panel 2-6, pp.58-59).

Nucleotides can act as carriers of chemical energy. The triphosphate ester of adenine, ATP (Figure 2-9), above all others, participates in the transfer of energy in hundreds of individual cellular reactions. Its terminal phosphate is added using energy from the oxidation of foodstuffs, and this phosphate can be split off readily by hydrolysis to release energy that drives energetically unfavorable biosynthetic reactions elsewhere in the cell. As we discuss later, other nucleotide derivatives serve as carriers for the transfer of particular chemical groups, such as hydrogen atoms or sugar residues, from one molecule to another. And a cyclic phosphate-containing adenine derivative, *cyclic AMP,* serves as a universal signaling molecule within cells.

The special significance of nucleotides is in the storage of biological information. Nucleotides serve as building blocks for the construction of nucleic acids, long polymers in which nucleotide subunits are covalently linked by the formation of a phosphate ester between the 3'-hydroxyl group on the sugar residue of one nucleotide and the 5'-phosphate group on the next nucleotide (Figure 2-10). There are two main types of nucleic acids, differing in the type of sugar that forms their polymeric backbone. Those based on the sugar *ribose* are known as ribonucleic acids, or RNA, and contain the four bases A, U, G, and C. Those based on *deoxyribose* (in which the hydroxyl at the 2' position of ribose is replaced by a hydrogen) are known as deoxyribonucleic acids, or DNA, and contain the four bases A, T, G, and C. The sequence of bases in a DNA or RNA polymer represents the genetic information of the living cell. The ability of the bases from different nucleic acid molecules to recognize each other by noncovalent interactions (called base-pairing) - G with C, and A with either T (in DNA) or U (in RNA) - underlies all of heredity and evolution, as explained in Chapter 3.

Summary

Living organisms are autonomous, self-propagating chemical systems. They are made from a distinctive and restricted set of small carbon-based molecules that are essentially the same for every living species. The main categories are sugars, fatty acids, amino acids, and nucleotides. Sugars are a primary source of chemical energy for cells and can be incorporated into polysaccharides for energy storage. Fatty acids are also important for energy storage, but their most significant function is in the formation of cell membranes. Polymers consisting of amino acids constitute the remarkably diverse and versatile macromolecules known as proteins. Nucleotides play a central part in energy transfer and also are the subunits from which the informational macromolecules, RNA and DNA, are made.
Figure 2-1. The relative abundance of chemical elements found in the earth's crust (the nonliving world) compared to that in the soft tissues of living organisms. The relative abundance is expressed as a percentage of the total *number* of atoms present. Thus, for example, nearly 50% of the atoms in living organisms are hydrogen atoms.

Panel 2-1: The chemical properties of water and their influence on the behavior of biological molecules

HYDROGEN BONDS

Because they are polarized, two adjacent H₂O molecules can form a linkage known as a hydrogen bond. Hydrogen bonds have only about 1/20 the strength of a covalent bond.

Hydrogen bonds are strongest when the three atoms lie in a straight line.

bond lengths

hydrogen bond
0.28 nm

0.104 nm
covalent bond

WATER

Two atoms, connected by a covalent bond, may exert different attractions for the electrons of the bond. In such cases the bond is dipolar, with one end slightly negatively charged (δ^-) and the other slightly positively charged (δ^+). A bond in which both atoms are the same, or in which they attract electrons equally, is called nonpolar.

electropositive region

electronegative region

Although a water molecule has an overall neutral charge (having the same number of electrons and protons), the electrons are asymmetrically distributed, which makes the molecule polar. The oxygen nucleus draws electrons away from the hydrogen nuclei, leaving these nuclei with a small net positive charge. The excess of electron density on the oxygen atom creates weakly negative regions at the other two corners of an imaginary tetrahedron.

WATER STRUCTURE

Molecules of water join together transiently in a hydrogen-bonded lattice. Even at 37°C, 15% of the water molecules are joined to four others in a short-lived assembly known as a "flickering cluster."

The cohesive nature of water is responsible for many of its unusual properties, such as high surface tension, specific heat, and heat of vaporization.

which makes the molecule polar. The oxygen nucleus draws electrons away from the hydrogen nuclei, leaving these nuclei with a small net positive charge. The excess of electron density on the oxygen atom creates weakly negative regions at the other two corners of an imaginary tetrahedron.
The cohesive nature of water is responsible for many of its unusual properties, such as high surface tension, specific heat, and heat of vaporization.
HYDROPHILIC AND HYDROPHOBIC MOLECULES

Because of the polar nature of water molecules, they will cluster around ions and other polar molecules.

Nonpolar molecules interrupt the H-bonded structure of water without forming favorable interactions with water molecules. They are therefore hydrophobic and quite insoluble in water.

Molecules that can thereby be accommodated in water's hydrogen-bonded structures are hydrophilic and relatively water-soluble.

HYDROPHOBIC MOLECULES AND CLATHRATE WATER STRUCTURES

Molecules that are nonpolar and cannot form hydrogen bonds—such as hydrocarbons— have only limited solubility in water and are called hydrophobic. In water, ordered cages of water molecules are formed around hydrocarbons. These icelike cages, called "clathrate structures," are relatively more ordered than water and cause an entropy decrease of the mixture. Part of a clathrate cage (red) surrounding a hydrocarbon (black) is shown. In the intact cage, each oxygen atom (red circles) would be tetrahedrally coordinated to four others.
ACIDS AND BASES

An acid is a molecule that releases an H^+ ion (proton) in solution. For example,

acid ⇌ base + proton
A base is a molecule that accepts an H^+ ion (proton) in solution. For example,

CH_3-NH_2 + H^+ ⇌ $CH_3-NH_3^+$

base + proton ⇌ acid

Water itself has a slight tendency to ionize and can act both as a weak acid and as a weak base. When it acts as an acid, it releases a proton to form a hydroxyl ion. When it acts as a base, it accepts a proton to form a hydronium ion. Most protons in aqueous solutions exist as hydronium ions.

hydroxyl ion   hydronium ion
pH

The acidity of a solution is defined by the concentration of H^+ ions it possesses. For convenience we use the pH scale where

$pH = -\log_{10}[H^+]$

For pure water

$[H^+] = 10^{-7}$ moles/liter

H^+ conc. moles/liter	pH
10^{-1}	1
10^{-2}	2
10^{-3}	3
10^{-4}	4
10^{-5}	5
10^{-6}	6
10^{-7}	7
10^{-8}	8

ALKALINE
OSMOSIS

If two aqueous solutions are separated by a membrane that allows only water molecules to pass, water will move into the solution containing the greatest concentration of solute molecules by a process known as osmosis.
This movement of water from a hypotonic to a hypertonic solution can cause an increase in hydrostatic pressure in the hypertonic compartment. Two solutions that have identical solute concentrations and are therefore osmotically

For pure water

$[H^+] = 10^{-7}$ moles/liter

ALKALINE

10^{-8}	8
10^{-9}	9
10^{-10}	10
10^{-11}	11
10^{-12}	12
10^{-13}	13
10^{-14}	14

This movement of water from a hypotonic to a hypertonic solution can cause an increase in hydrostatic pressure in the hypertonic compartment. Two solutions that have identical solute concentrations and are therefore osmotically balanced are said to be isotonic.

Panel 2-2: Chemical bonds and groups commonly encountered in biological molecules

CARBON SKELETONS

The unique role of carbon in the cell comes from its ability to form strong covalent bonds with other carbon atoms. Thus carbon atoms can join to form chains.

or branched trees

or rings

also written as

also written as

also written as

COVALENT BONDS

A covalent bond forms when two atoms come very close together and share one or more of their electrons. In a single bond one electron from each of the two atoms is shared; in a double bond a total of four electrons are shared.

Each atom forms a fixed number of covalent bonds in a defined spatial arrangement. For example, carbon forms four single bonds arranged tetrahedrally, whereas nitrogen forms three single bonds and oxygen forms two single bonds arranged as shown below.

Double bonds exist and have a different spatial arrangement.

Atoms joined by two or more covalent bonds cannot rotate freely about the bond axis. This restriction is a major influence on the three-dimensional shape of many macromolecules.

HYDROCARBONS

Carbon and hydrogen together make stable compounds called hydrocarbons. These are nonpolar, do not form hydrogen bonds, and are generally insoluble in water.

RESONANCE AND AROMATICITY

The carbon chain can include double bonds. If these are on alternate carbon atoms, the bonding electrons move within the molecule, stabilizing the structure by a phenomenon called resonance.

the truth is somewhere between these two structures

When resonance occurs throughout a ring compound, an aromatic ring is generated.

often written as

C—O COMPOUNDS

Many biological compounds contain a carbon bonded to an oxygen. For example,

alcohol
The —OH is called a **hydroxyl** group.

aldehyde
ketone
The C=O is called a **carbonyl** group.

carboxylic acid
The —COOH is called a **carboxyl** group. In water this loses an H⁺ ion to become —COO⁻.

esters

Esters are formed by combining an acid and an alcohol.

acid   alcohol   ester
C—N COMPOUNDS

Amines and amides are two important examples of compounds containing a carbon linked to a nitrogen.

Amines in water combine with an H⁺ ion to become positively charged.
They are therefore basic.

Amides are formed by combining an acid and an amine. They are more stable than esters. Unlike amines, they are uncharged in water. An example is the peptide bond.
Nitrogen also occurs in several ring compounds, including important constituents of nucleic acids: purines and pyrimidines.

cytosine (a pyrimidine)
PHOSPHATES

Inorganic phosphate is a stable ion formed from phosphoric acid, H_3PO_4. It is often written as P_i.

Phosphate esters can form between a phosphate and a free hydroxyl group.

also written as
The combination of a phosphate and a carboxyl group, or two or more phosphate groups, gives an acid anhydride.

Figure 2-2. Living organisms synthesize only a small number of the organic molecules that they in principle could make. Of the six amino acids shown, only the top one (tryptophan) is made by cells.

Table 2-1. The Approximate Chemical Composition of a Bacterial Cell

	Percent of Total Cell Weight	Types of Each Molecule
Water	70	1
Inorganic Ions	1	20
Sugars and precursors	1	250
Amino acids and precursors	0.4	100
Nucleotides and precursors	0.4	100
Fatty acids and precursors	1	50
Other small molecules	0.2	~300
Macromolecules (proteins, nucleic acids, and polysaccharides)	26	~3000
Figure 2-3. The structure of the monosaccharide glucose, a common hexose sugar. (A) is the open-chain form of this sugar, which is in equilibrium with the more stable cyclic or ring form in (B). (C) and (D) are space-filling and ball-and-stick models, respectively, of this cyclic form (b-d-glucose). The chair form (E) is an alternative representation of the cyclic form that is frequently used because it more accurately reflects the structure. In (A), (B), and (E) the *red*O denotes the oxygen atom of the aldehyde group. For an outline of sugar structures and chemistry, see Panel 2-3 (pp. 52-53).
Figure 2-4. Eleven disaccharides consisting of two D-glucose units. Although these differ only in the type of linkage between the two glucose units, they are chemically distinct. Since the oligosaccharides associated with proteins and lipids may have six or more different kinds of sugar joined in both linear and branched arrangements through linkages such as those illustrated here, the number of distinct types of oligosaccharides that can be used in cells is extremely large.

Panel 2-3: An outline of some of the types of sugars commonly found in cells

HEXOSES $n = 6$

Two common hexoses are
glucose   fructose

D-glucose (open-chain form)

β-D-glucose   α-D-glucose

STEREOISOMERS

MONOSACCHARIDES

Monosaccharides are aldehydes or ketones

that also have two or more hydroxyl groups. Their general formula is $(CH_2O)_n$. The simplest are trioses ($n = 3$) such as

glyceraldehyde (an aldose)

dihydroxyacetone (a ketose)

RING FORMATION

The aldehyde or ketone group of a sugar can react with a hydroxyl group

For the larger sugars ($n > 4$) this happens within the same molecule to form a 5- or 6-membered ring.

NUMBERING

The carbon atoms of a sugar are numbered from the end closest to the aldehyde or ketone.

PENTOSES $n = 5$

A common pentose is

ribose

D-ribose (open-chain form)

β-D-ribose   α-D-ribose

STEREOISOMERS

ISOMERS

Monosaccharides have many isomers that differ only in the orientation of their hydroxyl groups—e.g., glucose, mannose, and galactose are isomers of each other.

glucose   mannose

galactose

D AND L FORMS

Two isomers that are mirror images of each other have the same chemistry and therefore are given the same name and distinguished by the prefix D or L.

D-glucose

mirror plane

L-glucose

α- AND β-LINKS

The hydroxyl group on the carbon that carries the aldehyde or ketone can rapidly change from one position to another. These two positions are called α- and β-.

β-hydroxyl
α-hydroxyl

As soon as one sugar is linked to another, the α- or β-form is frozen.

SUGAR DERIVATIVES

The hydroxyl groups of a simple monosaccharide can be replaced by other groups. For example,

COOH

CH_2OH

D-glucuronic acid

D-glucosamine

CH_2OH

NH
C=O
CH_3

N-acetyl-D-glucosamine
DISACCHARIDES

The carbon that carries the aldehyde or the ketone can react with any hydroxyl group on a second sugar molecule to form a glycosidic bond. Three common disaccharides are maltose (glucose α1,4 glucose), lactose (galactose β1,4 glucose), and sucrose (glucose α1,2 fructose). Sucrose is shown here.

α-D-glucose
CH_2OH

β-D-fructose
$HOCH_2$

H_2O

CH_2OH

$HOCH_2$

CH_2OH

Panel 2-4: An outline of some of the types of fatty acids commonly encountered in cells and the structures that they form

COMMON FATTY ACIDS

These are carboxylic acids with long hydrocarbon tails.

Hundreds of different kinds of fatty acids exist. Some have one or more double bonds and are said to be unsaturated.

This double bond is rigid and creates a kink in the chain. The rest of the chain is free to rotate about the other C—C bonds.

oleic acid

stearic acid

Figure 2-6. The amino acid alanine. In the cell, where the pH is close to 7, the free amino acid exists in its ionized form; but when it is incorporated into a polypeptide chain, the charges on the amino and carboxyl groups disappear. A ball-and-stick model and a space-filling model are shown to the right of the structural formulas. For alanine, the side chain is a -CH_3 group.
Figure 2-7. A small part of a protein molecule, showing four amino acids. Each amino acid is linked to the next by a covalent *peptide bond,* one of which is shaded *yellow.* A protein is therefore also sometimes referred to as a *polypeptide.* The amino acid *side chains* are shown in *red,* and the atoms of one amino acid (glutamic acid) are outlined by the *gray box.*
Figure 2-8. The charge on amino acid side chains depends on the pH. Carboxylic acids readily lose H^+ in aqueous solution to form a negatively charged ion, which is denoted by the suffix "ate," as in aspart *ate* or glutam *ate*. A comparable situation exists for amines, which in aqueous solution take up H^+ to form a positively charged ion (which does not have a special name). These reactions are rapidly reversible, and the amounts of the two forms, charged and uncharged, depend on the pH of the solution. At a high pH, carboxylic acids tend to be charged and amines uncharged. At a low pH, the opposite is true - the carboxylic acids are uncharged and amines are charged. The pH at which exactly *half* of the carboxylic acid or amine residues are charged is known as the pK of that amino acid side chain. In the cell the pH is close to 7, and almost all carboxylic acids and amines are in their fully charged form.

Panel 2-5: The 20 amino acids involved in the synthesis of proteins

THE AMINO ACID

The general formula of an amino acid is

α-carbon atom

amino group — H₂N—C—COOH — carboxyl group

R — side-chain group

R is commonly one of 20 different side chains. At pH 7 both the amino and carboxyl groups are ionized.

$^{\oplus}H_3N—C—COO^{\ominus}$

R
OPTICAL ISOMERS

The α-carbon atom is asymmetric, which allows for two mirror image (or stereo-) isomers, D and L.

L   D
Proteins consist exclusively of L-amino acids.

PEPTIDE BONDS

Amino acids are commonly joined together by an amide linkage, called a peptide bond.

peptide bond: The four atoms in each *gray box* form a rigid planar unit. There is no freedom of rotation about the C—N bond.

H₂O
Proteins are long polymers of amino acids linked by peptide bonds, and they are always written with the *N*-terminus toward the left. The sequence of this tripeptide is His Cys Val.

amino or *N*-terminus

carboxyl or *C*-terminus
These two single bonds, on either side of the rigid peptide unit, exhibit a high degree of rotational freedom.

FAMILIES OF AMINO ACIDS

The common amino acids are grouped according to whether their side chains are

acidic
basic
uncharged polar
nonpolar

These 20 amino acids are given both three-letter and one-letter abbreviations.

Thus: alanine – Ala – A

BASIC SIDE CHAINS

lysine
(Lys, or K)
This group is very basic because its positive charge is stabilized by resonance.

arginine
(Arg, or R)

histidine
(His, or H)

These nitrogens have a relatively weak affinity for an H⁺ and are only partly positive at neutral pH.

ACIDIC SIDE CHAINS

aspartic acid (Asp, or D)

glutamic acid (Glu, or E)

NONPOLAR SIDE CHAINS

glycine (Gly, or G)

alanine (Ala, or A)
valine (Val, or V)
leucine (Leu, or L)
isoleucine (Ileu, or I)

proline (Pro, or P)
(actually an imino acid)
phenylalanine (Phe, or F)
methionine (Met, or M)
tryptophan (Trp, or W)

cysteine (Cys, or C)

Amino acids with uncharged polar side chains are relatively hydrophilic and are usually on the outside of proteins, while the side chains on nonpolar amino acids tend to cluster together on the inside. Amino acids with basic or acidic side chains are very polar, and they are nearly always found on the outside of protein molecules.

The one letter code in alphabetical order:

A = Ala	G = Gly	M = Met	S = Ser
C = Cys	H = His	N = Asn	T = Thr
D = Asp	I = Ileu	P = Pro	V = Val
E = Glu	K = Lys	Q = Gln	W = Trp
F = Phe	L = Leu	R = Arg	Y = Tyr

UNCHARGED POLAR SIDE CHAINS

asparagine (Asn, or N)

glutamine (Gln, or Q)

Although the amide N is not charged at neutral pH, it is polar.

serine (Ser, or S)

threonine (Thr, or T)

tyrosine (Tyr, or Y)

The —OH group is polar.

Paired cysteines allow disulfide bonds to form in proteins.

$$- -CH_2-S-S-CH_2- -$$

Panel 2-6: A survey of the major types of nucleotides and their derivatives encountered in cells

BASES

The bases are nitrogen-containing ring compounds, either purines or pyrimidines.

uracil
cytosine
thymine
adenine
guanine

PYRIMIDINE
PURINE
PHOSPHATES

The phosphates are normally joined to the C5 hydroxyl of the ribose or deoxyribose sugar. Mono-, di-, and triphosphates are common.

as in AMP

as in ADP

as in ATP
The phosphate makes a nucleotide negatively charged.

NUCLEOTIDES

A nucleotide consists of a nitrogen-containing base, a 5-carbon sugar, and one or more phosphate groups.

BASE

PHOSPHATE

They are the subunits of the nucleic acids.

SUGAR

BASIC SUGAR LINKAGE

N-glycosidic bond

BASE

SUGAR

The base is linked to the same carbon (C1) used in sugar-sugar bonds.
SUGARS

PENTOSE
a 5-carbon sugar

two kinds are used

β-D-RIBOSE
used in ribonucleic acid

β-D-2-DEOXYRIBOSE
used in deoxyribonucleic acid
Each numbered carbon on the sugar of a nucleotide is followed by a prime mark; therefore, one speaks of the "5-prime carbon," etc.
NOMENCLATURE

The names can be confusing, but the abbreviations are clear.

BASE	NUCLEOSIDE	ABBR.
adenine	adenosine	A
guanine	guanosine	G
cytosine	cytidine	C
uracil	uridine	U
thymine	thymidine	T

Nucleotides are abbreviated by three capital letters. Some examples follow:

AMP = adenosine monophosphate
dAMP = deoxyadenosine monophosphate
UDP = uridine diphosphate
ATP = adenosine triphosphate

BASE + SUGAR = NUCLEOSIDE

BASE + SUGAR + PHOSPHATE = NUCLEOTIDE
NUCLEIC ACIDS

Nucleotides are joined together by a phosphodiester linkage between 5' and 3' carbon atoms to form nucleic acids. The linear sequence of nucleotides in a nucleic acid chain is commonly abbreviated by a one-letter code, A—G—C—T—T—A—C—A, with the 5' end of the chain at the left.

phosphodiester linkage

example: DNA
NUCLEOTIDES HAVE MANY OTHER FUNCTIONS

1. They carry chemical energy in their easily hydrolyzed acid-anhydride bonds.

example: ATP (or ATP)
2. They combine with other groups to form enzymes.

example: coenzyme A (CoA)
3. They are used as specific signaling molecules in the cell.

example:
cyclic AMP (cAMP)

(A)

(B)

(C)

triphosphate | ribose | adenine
adenosine

Figure 2-9. Chemical structure of adenosine triphosphate (ATP). A space-filling model (A), a ball-and-stick model (B), and the structural formula (C) are shown. Note the negative charges on each of the three phosphates.
Figure 2-10. A short length of deoxyribonucleic acid (DNA), showing four nucleotides. One of the phosphodiester bonds that link adjacent nucleotides is shaded *yellow*, and one of the nucleotides is enclosed in a *gray box.* DNA and its close relative RNA are the nucleic acids of the cell.

Biological Order and Energy [7]

Introduction

Cells must obey the laws of physics and chemistry. The rules of mechanics and of the conversion of one form of energy to another apply just as much to a cell as to a steam engine. There are, however, puzzling features of a cell that, at first sight, seem to place it in a special category. It is common experience that things left to themselves eventually become disordered: buildings crumble, dead organisms become oxidized, and so on. This general tendency is expressed in the *second law of thermodynamics,* which states that the degree of disorder in the universe (or in any isolated system in the universe) can only increase.

The puzzle is that living organisms maintain, at every level, a very high degree of order; and as they feed, develop, and grow, they appear to create this order out of raw materials that lack it. Order is strikingly apparent in large structures such as a butterfly wing or an octopus eye, in subcellular structures such as a mitochondrion or a cilium, and in the shape and arrangement of molecules from which these structures are built. The constituent atoms have been captured, ultimately, from a relatively

disorganized state in the environment and locked together into a precise structure. Even a nongrowing cell requires constant ordering processes for survival since all of its organized structures are subject to spontaneous accidents and must be repaired continually. How is this possible thermodynamically? The answer is that the cell draws in fuel from its environment and releases heat as a waste product. The cell is therefore not an isolated system in the thermodynamic sense.

Biological Order Is Made Possible by the Release of Heat Energy from Cells <u>8</u>

As already mentioned, the second law of thermodynamics states that the amount of order in the universe (that is, in a cell plus its environment) must always decrease. Therefore, the continuous increase in order inside a living cell must be accompanied by an even greater increase in *dis*order in the cell's environment. Heat is energy in its most disordered form - the random commotion of molecules - and heat is released from the cell by the reactions that order the molecules it contains. The increase in random motion, including bond distortions, of the molecules in the rest of the universe creates a disorder that more than compensates for the increased order in the cell, as required by the laws of thermodynamics for spontaneous processes. In this way the release of heat by a cell to its surroundings allows it to become more highly ordered internally at the same time that the universe as a whole becomes more disordered (<u>Figure 2-11</u>).

It is important to note that the cell will achieve nothing by producing heat unless the heat-generating reactions are directly linked with the processes that generate molecular order in the cell. Such linked reactions are said to be *coupled,* as we explain later. It is the tight coupling of heat production to an increase in order that distinguishes the metabolism of the cell from the wasteful burning of fuel in a fire.

The creation of order inside the cell is at the expense of the degradation of fuel energy. For plants this fuel energy is initially derived from the electromagnetic radiation of the sun; for animals it is derived from the energy stored in the covalent bonds of the organic molecules that animals eat. Since these organic nutrients are themselves produced by photosynthetic organisms such as green plants, however, the sun is in fact the ultimate energy source for animals also.

Photosynthetic Organisms Use Sunlight to Synthesize Organic Compounds <u>9</u>

Solar energy enters the living world (the *biosphere*) by means of the photosynthesis carried out by photosynthetic organisms - either plants or bacteria. In photosynthesis electromagnetic energy is converted into chemical bond energy. At the same time, however, part of the energy of sunlight is converted into heat energy, and the release of this heat to the environment increases the disorder of the universe and thereby drives the photosynthetic process.

The reactions of photosynthesis are described in detail in <u>Chapter 14</u>. In broad terms, they occur in two distinct stages. In the first (the *light-activated reactions*) the visible radiation impinging on a pigment molecule drives the transfer of electrons from water to NADPH and at the same time provides the energy needed for the synthesis of ATP. In the second (the *dark reactions*) the ATP and NADPH are used to drive a series of "carbon-fixation" reactions in which CO_2 from the air is used to form sugar molecules (<u>Figure 2-12</u>).

The *net* result of photosynthesis, so far as the green plant is concerned, can be summarized by the equation

$$\text{energy} + CO_2 + H_2O \rightarrow \text{sugar} + O_2$$
This simple equation hides the complex nature of the reactions, which involve many linked reaction steps. Furthermore, although the initial fixation of CO_2 results in sugars, subsequent metabolic reactions soon convert these into the many other small and large molecules essential to the plant cell.

Chemical Energy Passes from Plants to Animals

Animals and other nonphotosynthetic organisms cannot capture energy from sunlight directly and so have to survive on "secondhand" energy obtained by eating plants or on "thirdhand" energy obtained by eating other animals. The organic molecules made by plant cells provide both building blocks and fuel to the organisms that feed on them. All types of plant molecules can serve this purpose - sugars, proteins, polysaccharides, lipids, and many others.

The transactions between plants and animals are not all one-way. Plants, animals, and microorganisms have existed together on this planet for so long that many of them have become an essential part of the others' environment. The oxygen released by photosynthesis, for example, is consumed in the combustion of organic molecules by nearly all organisms, and some of the CO_2 molecules that are "fixed" today into larger organic molecules by photosynthesis in a green leaf were yesterday released into the atmosphere by the respiration of an animal. Thus, carbon utilization is a cyclic process that involves the biosphere as a whole and crosses boundaries between individual organisms (Figure 2-13). Similarly, atoms of nitrogen, phosphorus, and sulfur can, in principle, be traced from one biological molecule to another in a series of similar cycles.

Cells Obtain Energy by the Oxidation of Biological Molecules 10

The carbon and hydrogen atoms in the molecules taken up as food materials by a cell can serve as fuel because they are not in their most stable form. The earth's atmosphere contains a great deal of oxygen, and in the presence of oxygen the most energetically stable form of carbon is as CO_2 and that of hydrogen is as H_2O. A cell is therefore able to obtain energy from sugars or other organic molecules by allowing their carbon and hydrogen atoms to combine with oxygen to produce CO_2 and H_2O, respectively. The cell, however, does not oxidize organic molecules in one step, as occurs in a fire. Through the use of specific enzyme catalysts, it takes the molecules through a large number of reactions that only rarely involve the direct addition of oxygen. Before we can consider these reactions and the driving force behind them, we need to discuss what is meant by the process of oxidation.

Oxidation, in the sense used above, does not mean only the addition of oxygen atoms; rather, it applies more generally to any reaction in which electrons are transferred from one atom to another. Oxidation in this sense refers to the removal of electrons, and reduction - the converse of oxidation - means the addition of electrons. Thus, Fe^{2+} is oxidized if it loses an electron to become Fe^{3+}, and a chlorine atom is reduced if it gains an electron to become Cl^-. The same terms are used when there is only a partial shift of electrons between atoms linked by a covalent bond (Figure 2-14A). When a carbon atom becomes covalently bonded to an atom with a strong affinity for electrons, such as oxygen, chlorine, or sulfur, for example, it gives up more than its equal share of electrons; it therefore acquires a partial positive charge and is said to be oxidized. Conversely, a carbon atom in a C-H linkage has more than its share of electrons, and so it is said to be reduced (Figure 2-14B).

Often, when a molecule picks up an electron (e^-), it picks up a proton (H^+) at the same time (protons being freely available in an aqueous solution). The net effect in this case is to add a hydrogen atom to the molecule

$$A + e^- + H^+ \rightarrow AH$$

Even though a proton plus an electron is involved (instead of just an electron), such *hydrogenation* reactions are reductions, and the reverse, *dehydrogenation* reactions, are oxidations.

The combustion of food materials in a cell converts the C and H atoms in organic molecules (where they are both in a relatively electron-rich, or reduced, state) to CO_2 and H_2O, where they have given up electrons and are therefore highly oxidized. The shift of electrons from carbon and hydrogen to oxygen allows these atoms to achieve a more stable state and hence is energetically favorable.

The Breakdown of an Organic Molecule Takes Place in a Sequence of Enzyme-catalyzed Reactions 11

Although the most energetically favorable form of carbon is as CO_2 and that of hydrogen is as H_2O, a living organism does not disappear in a puff of smoke for the same reason that the book in your hands does not burst into flame: the molecules of both exist in metastable energy troughs and require activation energy (Figure 2-15) before they can pass to more stable configurations. In the case of the book, the activation energy can be provided by a lighted match. For a living cell the combustion is achieved molecule by molecule in a much more controlled way. The place of the match is taken by an unusually energetic collision of one molecule with another. Moreover, the only molecules that react are those that are bound to the surface of *enzymes.*

As explained in Chapter 3, enzymes are highly specific protein *catalysts*. Like all other types of catalysts, they speed up reactions by reducing the activation energy for a particular chemical change. Enzymes bind tightly to their substrate molecules

and hold them in a way that greatly reduces the activation energy of one particular reaction that rearranges covalent bonds. By selectively lowering the activation energy of only one reaction path for the bound molecule, enzymes determine which of several alternative bond-breaking and bond-forming reactions occurs (Figure 2-16). After the product of one enzyme is released, it can bind to a second enzyme that catalyzes an additional change. In this way each of the many different molecules in a cell moves from enzyme to enzyme along a *specific* reaction pathway, and it is the sum of all of these pathways that determines the cell's chemistry. We discuss a few central pathways of energy metabolism later.

The success of living organisms is attributable to their cells' ability to make enzymes of many different types, each with precisely specified properties. Each enzyme has a unique shape and binds a particular set of other molecules (called *substrates*) in such a way as to speed up a particular chemical reaction enormously, often by a factor of as much as 10^{14}. Like all other catalysts, enzyme molecules themselves are not changed after participating in a reaction and therefore can function over and over again.

Part of the Energy Released in Oxidation Reactions Is Coupled to the Formation of ATP 12

Cells derive useful energy from the "burning" of glucose only because they burn it in a very complex and controlled way. By means of enzyme-directed reaction paths, the synthetic, or *anabolic,* chemical reactions that create biological order are closely coupled to the degradative, or *catabolic,* reactions that provide the energy. The crucial difference between a coupled reaction and an uncoupled reaction is illustrated by the mechanical analogy shown in Figure 2-17, where an energetically favorable chemical reaction is represented by rocks falling from a cliff. The kinetic energy of falling rocks would normally be entirely wasted in the form of heat generated when they hit the ground (section A). But, by careful design, part of the kinetic energy could be used to drive a paddle wheel that lifts a bucket of water (section B). Because the rocks can reach the ground only by moving the paddle wheel, we say that the spontaneous reaction of rock falling has been directly coupled to the nonspontaneous reaction of lifting the bucket of water. Note that because part of the energy is now used to do work in section B, the rocks hit the ground with less velocity than in section A, and therefore correspondingly less energy is wasted as heat.

In cells enzymes play the role of paddle wheels in our analogy and couple the spontaneous burning of foodstuffs to reactions that generate ATP. Just as the energy stored in the elevated bucket of water in Figure 2-17 can be dispensed in small doses to drive a wide variety of hydraulic machines (section C), ATP serves as a convenient and versatile store, or currency, of energy to drive many different chemical reactions that the cell needs (Figure 2-18).

The Hydrolysis of ATP Generates Order in Cells 13

How does ATP act as a carrier of chemical energy? Under the conditions existing in the cytoplasm, the breakdown of ATP by hydrolysis to release inorganic phosphate (P_i) requires catalysis by an enzyme, but whenever it occurs, it releases a great deal of usable energy. A chemical group that is linked by such a reactive bond is readily transferred to another molecule; for this reason the terminal phosphate in ATP can be considered to exist in an *activated* state. The bond broken in this hydrolysis reaction is sometimes described as a *high-energy bond.* There is nothing special about the covalent bond itself, however; it is simply that in aqueous solution the hydrolysis of ATP creates two molecules of much lower energy (ADP and P_i).

Many of the chemical reactions in cells are energetically unfavorable. These reactions are driven by the energy released by ATP hydrolysis through enzymes that directly couple the unfavorable reaction to the favorable reaction of ATP hydrolysis. Among these reactions are those involved in the synthesis of biological molecules, in the active transport of molecules across cell membranes, and in the generation of force and movement. These processes play a vital part in establishing biological order. The macromolecules formed in biosynthetic reactions, for example, carry information, catalyze specific reactions, and are assembled into highly ordered structures. Membrane-bound pumps maintain the special internal composition of cells and permit many signals to pass within and between cells. And the production of force and movement enables the cytoplasmic contents of cells to become organized and the cells themselves to move about and assemble into tissues.

Summary

Living cells are highly ordered and must create order within themselves in order to survive and grow. This is thermodynamically possible only because of a continual input of energy, part of which is released from the cells to their environment as heat. The energy comes ultimately from the electromagnetic radiation of the sun, which drives the formation of organic molecules in photosynthetic organisms such as green plants. Animals obtain their energy by eating these organic molecules and oxidizing

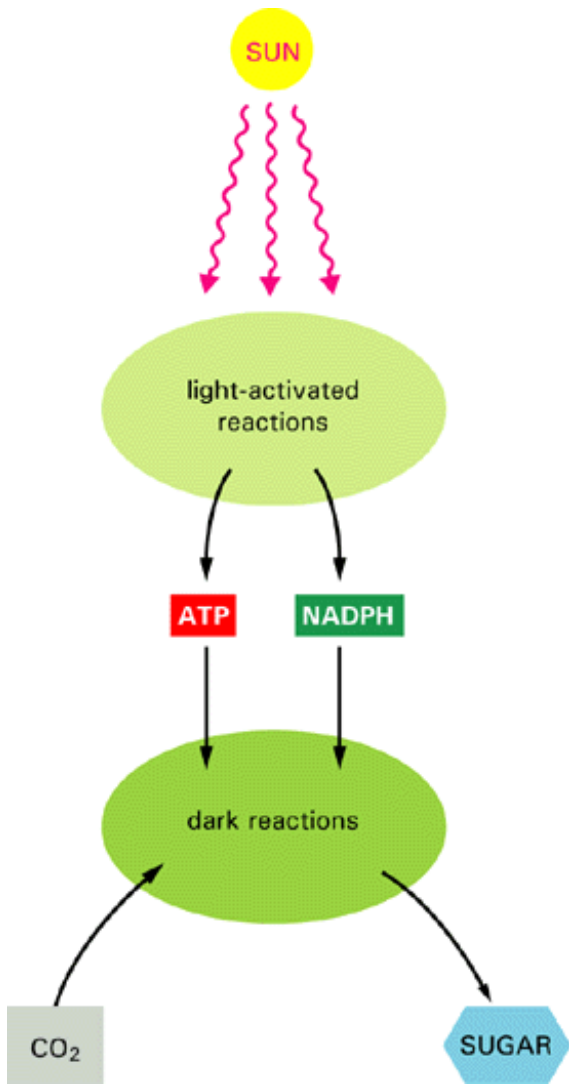
them in a series of enzyme-catalyzed reactions that are coupled to the formation of ATP. ATP is a common currency of energy in all cells, and its energetically favorable hydrolysis is coupled to other reactions to drive a variety of energetically unfavorable processes that create the high degree of order essential for life.
Figure 2-11. A simple thermo-dynamic analysis of a living cell. In the upper diagram, the molecules of both the cell and the rest of the universe (its environment) are depicted in a relatively disordered state. In the lower diagram, heat has been released from the cell by a reaction that orders the molecules that the cell contains (*green*). Because the heat increases the disorder in the environment around the cell, the second law of thermodynamics is satisfied as the cell grows and divides.


Figure 2-12. Photosynthesis. The two stages of photosynthesis in a green plant.
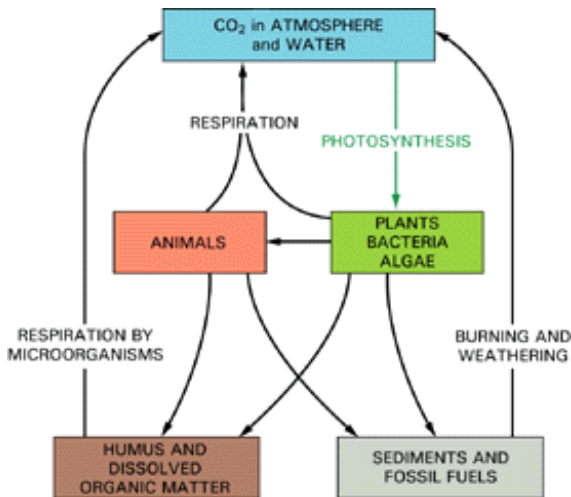

Figure 2-13. The carbon cycle. Individual carbon atoms are incorporated into organic molecules of the living world by the photosynthetic activity of plants, bacteria, and marine algae. They pass to animals, microorganisms, and organic material in soil and oceans in cyclic paths. CO_2 is restored to the atmosphere when organic molecules are oxidized by cells or burned by humans as fossil fuels.
Figure 2-14. Oxidation and reduction. (A) When two atoms form a covalent bond, an atom ending up with a greater share of electrons acquires a partial negative charge and is said to be *reduced,* while the other atom acquires a partial positive charge and is said to be *oxidized.* (B) The carbon atom of methane can be converted to that of carbon dioxide by the successive removal of its hydrogen atoms. With each step, electrons are shifted away from the carbon, and the carbon atom becomes progressively more oxidized. Each of these steps is energetically favorable inside a cell.
Figure 2-15. The principle of activation energy. Compound X is in a metastable state because energy is released when it is converted to compound Y. This transition will not take place, however, unless X can acquire enough *activation energy* from its surroundings (by means of an unusually energetic collision with other molecules) to undergo the reaction.

(A) uncatalyzed   enzyme catalysis of pathway 1

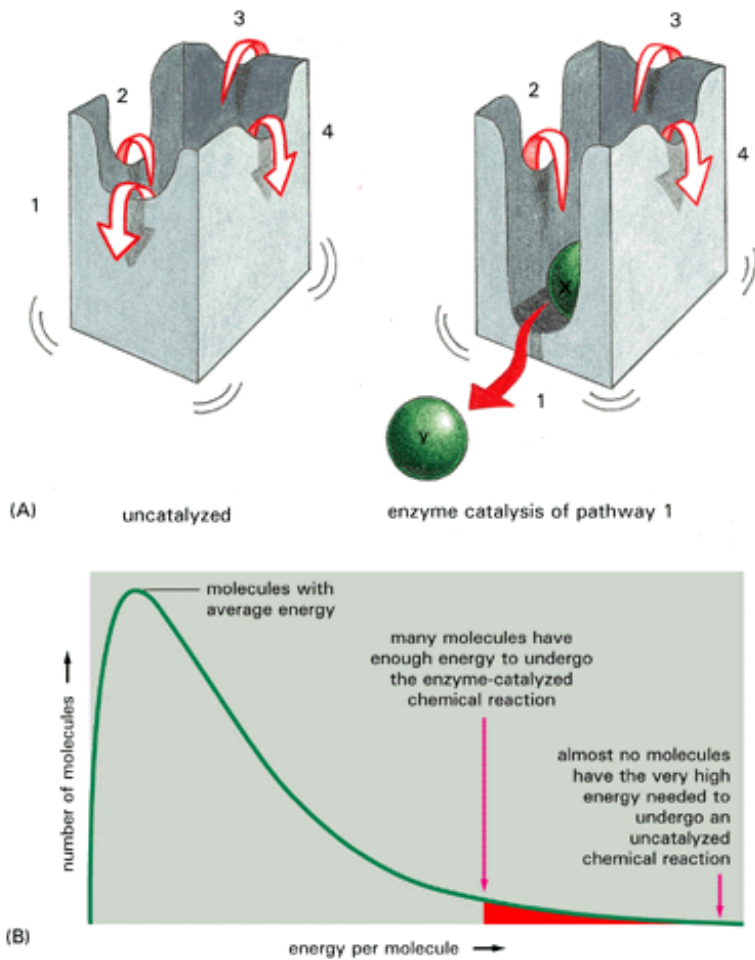
(B)


Figure 2-16. Enzyme catalysis. (A) A "jiggling-box" model illustrates how enzymes direct molecules along desired reaction pathways. In this model the *green ball*represents a potential enzyme substrate (compound X) that is bouncing up and down in energy level due to the constant bombardment of colliding water molecules. The four walls of the box represent the activation energy barriers for four different chemical reactions that are energetically favorable. In the left-hand box none of these reactions occurs because the energy available from even the most energetic collisions is insufficient to surmount any of the energy barriers. In the right-hand box enzyme catalysis lowers the activation energy for reaction number 1 only. It thereby allows this reaction to proceed with available energies, causing compound Y to form from compound X. Compound Y may then bind to a different enzyme that converts it to compound Z, and so on. (B) The distribution of energy in a population of identical molecules. In order to undergo a chemical reaction, the energy of the molecule (as translational, vibrational, and rotational motions) must exceed the activation energy; for most biological reactions, this never happens without enzyme catalysis.
Figure 2-17. A mechanical model illustrating the principle of coupled chemical reactions. The spontaneous reaction shown in (A) might serve as an analogy for the direct oxidation of glucose to CO_2 and H_2O, which produces heat only. In (B) the same reaction is coupled to a second reaction; the second reaction might serve as an analogy for the synthesis of ATP. The more versatile form of energy produced in (B) can be used to drive other cellular processes, as in (C). ATP is the most versatile form of energy in cells.
Figure 2-18. The ATP molecule serves as a convenient energy store in cells. As indicated, the energetically unfavorable formation of ATP from ADP and inorganic phosphate is coupled to the energetically favorable oxidation of foodstuffs (see Figure 2-17B). The hydrolysis of this ATP back to ADP and inorganic phosphate in turn provides the energy needed to drive many important cellular reactions.

Food Molecules Are Broken Down in Three Stages to Give ATP

The proteins, lipids, and polysaccharides that make up the major part of the food we eat must be broken down into smaller molecules before our cells can use them. The enzymatic breakdown, or catabolism, of these molecules may be regarded as proceeding in three stages (<u>Figure 2-19</u>). We shall give a short outline of these stages before discussing the last two of them in more detail.

Stage 1, called digestion, occurs mainly in our intestine. Here, large polymeric molecules are broken down into their monomeric subunits - proteins into amino acids, polysaccharides into sugars, and fats into fatty acids and glycerol - through the action of secreted enzymes. Stage 2 occurs in the cytoplasm after the small molecules generated in stage 1 enter cells, where they are further degraded. Most of the carbon and hydrogen atoms of sugars are converted into *pyruvate,* which then enters mitochondria, where it is converted to the acetyl groups of the chemically reactive compound *acetyl coenzyme A (acetyl CoA)* (<u>Figure 2-20</u>). Major amounts of acetyl CoA are also produced by the oxidation of fatty acids. In stage 3 the acetyl group of acetyl CoA is completely degraded to CO_2 and H_2O in the mitochondrion. It is in this final stage that most of the ATP is generated. Through a series of coupled chemical reactions, about half of the energy theoretically derivable from the combustion of carbohydrates and fats to H_2O and CO_2 is channeled into driving the energetically unfavorable reaction $P_i + ADP \longrightarrow ATP$. Because the rest of the combustion energy is released by the cell as heat, this generation of ATP creates net disorder in the universe, in conformity with the second law of thermodynamics.

Through the production of ATP, the energy originally derived from the combustion of carbohydrates and fats is redistributed as a conveniently packaged form of chemical energy. Roughly 10^9 molecules of ATP are in solution throughout the intracellular space in a typical cell, where their energetically favorable hydrolysis back to ADP and phosphate in coupled reactions provides the driving energy for a very large number of different coupled reactions that would otherwise not occur.

Glycolysis Can Produce ATP Even in the Absence of Oxygen

The most important process in stage 2 of catabolism is the degradation of carbohydrates in a sequence of reactions known as glycolysis - the lysis (splitting) of glucose. Glycolysis can produce ATP in the absence of oxygen, and it probably evolved early in the history of life, before the activities of photosynthetic organisms introduced oxygen into the atmosphere. In the process of glycolysis, a glucose molecule with six carbon atoms is converted into two molecules of pyruvate, each with three carbon atoms. This conversion involves a sequence of nine enzymatic steps that create phosphate-containing intermediates (<u>Figure 2-21</u>). The cell hydrolyzes two molecules of ATP to drive the early steps but produces four molecules of ATP in the later steps, so that there is a net gain of ATP by the end of glycolysis.

Logically, the sequence of reactions that constitute glycolysis can be divided into three parts: (1) in steps 1 to 4, glucose is converted to two molecules of the three-carbon aldehyde *glyceraldehyde 3-phosphate* - a conversion that requires an investment of energy in the form of ATP hydrolysis to provide the two phosphates; (2) in steps 5 and 6, the aldehyde group of each glyceraldehyde 3-phosphate molecule is oxidized to a carboxylic acid, and the energy from this reaction is coupled to the synthesis of ATP from ADP and inorganic phosphate; and (3) in steps 7, 8, and 9, the same two phosphate molecules that were added to sugars in the first reaction sequence are transferred back to ADP to form ATP, thereby repaying the original investment of two ATP molecules hydrolyzed in the first reaction sequence (see <u>Figure 2-21</u>).

At the end of glycolysis, therefore, the ATP balance sheet shows a net profit of the two molecules of ATP (per glucose molecule) that were produced in steps 5 and 6. As the only reactions in the sequence in which a high-energy phosphate linkage is created from inorganic phosphate, these two steps lie at the heart of glycolysis. They also provide an excellent illustration of the way in which reactions in the cell can be coupled together by enzymes to harvest the energy released by oxidations (<u>Figure 2-22</u>). The overall result is that an aldehyde group on a sugar is oxidized to a carboxylic acid and an inorganic phosphate group is transferred to a high-energy linkage on ATP; in addition, a molecule of NAD^+ is reduced to NADH, a molecule with a central role in energy metabolism, as we discuss next. This elegant set of coupled reactions was probably among the earliest metabolic steps to appear in the evolving cell.

For most animal cells glycolysis is only a prelude to stage 3 of catabolism, since the pyruvic acid that is formed at the last step

quickly enters the mitochondria to be completely oxidized to CO_2 and H_2O. In the case of anaerobic organisms (those that do not utilize molecular oxygen), however, and for tissues, such as skeletal muscle, that can function under anaerobic conditions, glycolysis can become a major source of the cell's ATP. Anaerobic energy-yielding reactions of this type are called *fermentations.* Here, instead of being degraded in mitochondria, the pyruvate molecules stay in the cytosol and, depending on the organism, can be converted into ethanol plus CO_2 (as in yeast) or into lactate (as in muscle), which is then excreted from the cell. These further reactions of pyruvate use up the reducing power produced in reaction 5 of glycolysis, thereby regenerating the NAD^+ required for glycolysis to continue, as we discuss in Chapter 14.

NADH Is a Central Intermediate in Oxidative Catabolism

The anaerobic generation of ATP from glucose through the reactions of glycolysis is relatively inefficient. The end products of anaerobic glycolysis still contain a great deal of chemical energy that can be released by further oxidation. The evolution of *oxidative catabolism* (cellular respiration) became possible only after molecular oxygen had accumulated in the earth's atmosphere as a result of photosynthesis by the cyanobacteria. Earlier, anaerobic processes had dominated life on earth. The addition of an oxygen-requiring stage to the catabolic process (stage 3 in Figure 2-19) provided cells with a much more powerful and efficient method for extracting energy from food molecules. This third stage begins with a series of reactions called the *citric acid cycle* (also called the tricarboxylic acid cycle, or the Krebs cycle) and ends with *oxidative phosphorylation,* both of which occur in aerobic bacteria and the mitochondria of eucaryotic cells.

A simplified version of the two central processes of oxidative catabolism is given in Figure 2-23. First, in the citric acid cycle, the acetyl groups from acetyl CoA are oxidized to produce CO_2 and NADH. Next, in the process of oxidative phosphorylation, the NADH generated reacts with molecular oxygen (O_2) to produce ATP and H_2O in a complicated series of steps that relies on electron transport in a membrane.

NADH, which serves as a central intermediate in the above process, was previously encountered as a product of glycolysis (see Figure 2-22). It is an important carrier of reducing power in cells. As illustrated in Figure 2-24, it is formed by the addition of a hydrogen nucleus and two electrons (a hydride ion, H^-) to nicotinamide adenine dinucleotide (NAD). Because this addition occurs in a way that leaves the hydride ion held in a high-energy linkage, NADH acts as a convenient source of readily transferable electrons in cells, in much the same way that ATP acts as a convenient source of readily transferable phosphate groups.

Metabolism Is Dominated by the Citric Acid Cycle 15

The primary function of the citric acid cycle is to oxidize acetyl groups that enter the cycle in the form of acetyl CoA molecules. The reactions form a cycle because the acetyl group is not oxidized directly, but only after it has been covalently added to a larger molecule, *oxaloacetate,*which is regenerated at the end of one turn of the cycle. As illustrated in Figure 2-25, the cycle begins with the reaction between acetyl CoA and oxaloacetate to form the tricarboxylic acid molecule called *citric acid* (or *citrate*). A series of enzymatically catalyzed reactions then occurs in which two of the six carbons of citrate are oxidized to CO_2, forming another molecule of oxaloacetate to repeat the cycle. (Because the two carbons that are newly added in each cycle enter a different part of the citrate molecule from the part oxidized to CO_2, it is only after several cycles that their turn comes to be oxidized.) The CO_2 produced in these reactions then diffuses from the mitochondrion (or from the bacterium) and leaves the cell.

The energy made available when the C - H and C - C bonds in citrate are oxidized is captured in several ways in the course of the citric acid cycle. At one step in the cycle (succinyl CoA to succinate), a high-energy phosphate linkage is created by a mechanism resembling that described for glycolysis above. All of the remaining energy of oxidation that is captured is channeled into the conversion of hydrogen - or hydride ion - carrier molecules to their reduced forms; for each turn of the cycle, three molecules of NAD^+ are converted to NADH and one *flavin adenine nucleotide* (FAD) is converted to $FADH_2$. The energy that is stored in the readily transferred electrons on these carrier molecules will subsequently be harnessed through the reactions of *oxidative phosphorylation* (considered in more detail below), which are the only reactions described here that require molecular oxygen from the atmosphere.

The additional oxygen atoms required to make CO_2 from the acetyl groups entering the citric acid cycle are supplied not by molecular oxygen but by water. Three molecules of water are split in each cycle, and their oxygen atoms are used to make CO_2. Some of their hydrogen atoms enter substrate molecules and, like the hydrogen atoms of the acetyl groups, are ultimately

removed to carrier molecules such as NADH.

In the eucaryotic cell the mitochondrion is the center toward which all catabolic processes lead, whether they begin with sugars, fats, or proteins. For, in addition to pyruvate, fatty acids and some amino acids also pass from the cytosol into mitochondria, where they are converted into acetyl CoA or one of the other intermediates of the citric acid cycle. The mitochondrion also functions as the starting point for some biosynthetic reactions by producing vital carbon-containing intermediates, such as *oxaloacetate* and *alpha-ketoglutarate*. These substances are transferred back from the mitochondrion to the cytosol, where they serve as precursors for the synthesis of essential molecules, such as amino acids.

In Oxidative Phosphorylation the Transfer of Electrons to Oxygen Drives ATP Formation 10, 16

Oxidative phosphorylation is the last step in catabolism and the point at which the major portion of metabolic energy is released. In this process molecules of NADH and $FADH_2$ transfer the electrons that they have gained from the oxidation of food molecules to molecular oxygen, O_2, forming H_2O. The reaction, which is formally equivalent to the burning of hydrogen in air to form water, releases a great deal of chemical energy. Part of this energy is used to make the major portion of the cell's ATP; the rest is liberated as heat.

Although the overall chemistry of NADH and $FADH_2$ oxidation involves a transfer of hydrogen to oxygen, each hydrogen atom is transferred as an *electron* plus a proton (the hydrogen nucleus, H^+). This is possible because a hydrogen atom can be readily dissociated into its constituent electron and proton (H^+). The electron can then be transferred separately to a molecule that accepts only electrons, while the proton remains in aqueous solution. Conversely, if an electron alone is donated to a molecule with a strong affinity for hydrogen, then a hydrogen atom will be reconstituted automatically by the capture of a proton from solution. In the course of oxidative phosphorylation, electrons from NADH and $FADH_2$ pass down a long chain of carrier molecules that are known as the electron-transport chain. The presence or absence of intact hydrogen atoms at each step of the electron-transfer process depends on the nature of the carrier.

In a eucaryotic cell this series of electron transfers along the electron-transport chain takes place on the inner membrane of the mitochondrion, in which all of the electron carrier molecules are embedded. At each step of the transfer, the electrons fall to a lower energy state, until at the end they are transferred to oxygen molecules. Each oxygen molecule (O_2) picks up four electrons from the electron-transport chain plus four protons from aqueous solution to form two molecules of water. Oxygen molecules have a high affinity for electrons, and electrons bound to oxygen are thus in a low energy state.

The electron-transport chain is important for the cell because the energy released as the electrons fall to lower energy states is harnessed in a remarkable way. As described in Chapter 14, particular electron transfers cause protons to be pumped across the membrane from the inner mitochondrial compartment to the outside (Figure 2-26). An *electrochemical proton gradient* is thereby generated across the inner mitochondrial membrane. This gradient in turn drives a flux of protons back through a special enzyme complex in the same membrane, causing the enzyme (*ATP synthase*) to add a phosphate group to ADP and thereby generating ATP inside the mitochondrion. The newly made ATP is then transferred from the mitochondrion to the rest of the cell.

Amino Acids and Nucleotides Are Part of the Nitrogen Cycle

In our discussion so far we have concentrated mainly on carbohydrate metabolism. We have not yet considered the metabolism of nitrogen or sulfur. These two elements are constituents of proteins and nucleic acids, which are the two most important classes of macromolecules in the cell and make up approximately two-thirds of its dry weight. Atoms of nitrogen and sulfur pass from compound to compound and between organisms and their environment in a series of reversible cycles.

Although molecular nitrogen is abundant in the earth's atmosphere, nitrogen is chemically unreactive as a gas. Only a few living species are able to incorporate it into organic molecules, a process called nitrogen fixation. Nitrogen fixation occurs in certain microorganisms and by some geophysical processes, such as lightning discharge. It is essential to the biosphere as a whole, for without it life would not exist on this planet. Only a small fraction of the nitrogenous compounds in today's organisms, however, represents fresh products of nitrogen fixation from the atmosphere. Most organic nitrogen has been in circulation for some time, passing from one living organism to another. Thus present-day nitrogen-fixing reactions can be said to perform a "topping-up" function for the total nitrogen supply.

Vertebrates receive virtually all of their nitrogen in their dietary intake of proteins and nucleic acids. In the body these macromolecules are broken down to component amino acids and nucleotides, which are then repolymerized into new proteins and nucleic acids or utilized to make other molecules. About half of the 20 amino acids found in proteins are *essential amino acids* (Figure 2-27) for vertebrates, which means that they cannot be synthesized from other ingredients of the diet. The others can be so synthesized, using a variety of raw materials, including intermediates of the citric acid cycle. The essential amino acids are made by nonvertebrate organisms, usually by long and energetically expensive pathways that have been lost in the course of vertebrate evolution.

The nucleotides needed to make RNA and DNA can be synthesized using specialized biosynthetic pathways: there are no "essential nucleotides" that must be provided in the diet. All of the nitrogens in the purine and pyrimidine bases (as well as some of the carbons) are derived from the plentiful amino acids glutamine, aspartic acid, and glycine, whereas the ribose and deoxyribose sugars are derived from glucose.

Amino acids that are not utilized in biosynthesis can be oxidized to generate metabolic energy. Most of their carbon and hydrogen atoms eventually form CO_2 or H_2O, whereas their nitrogen atoms are shuttled through various forms and eventually appear as urea, which is excreted. Each amino acid is processed differently, and a whole constellation of enzymatic reactions exists for their catabolism.

Summary

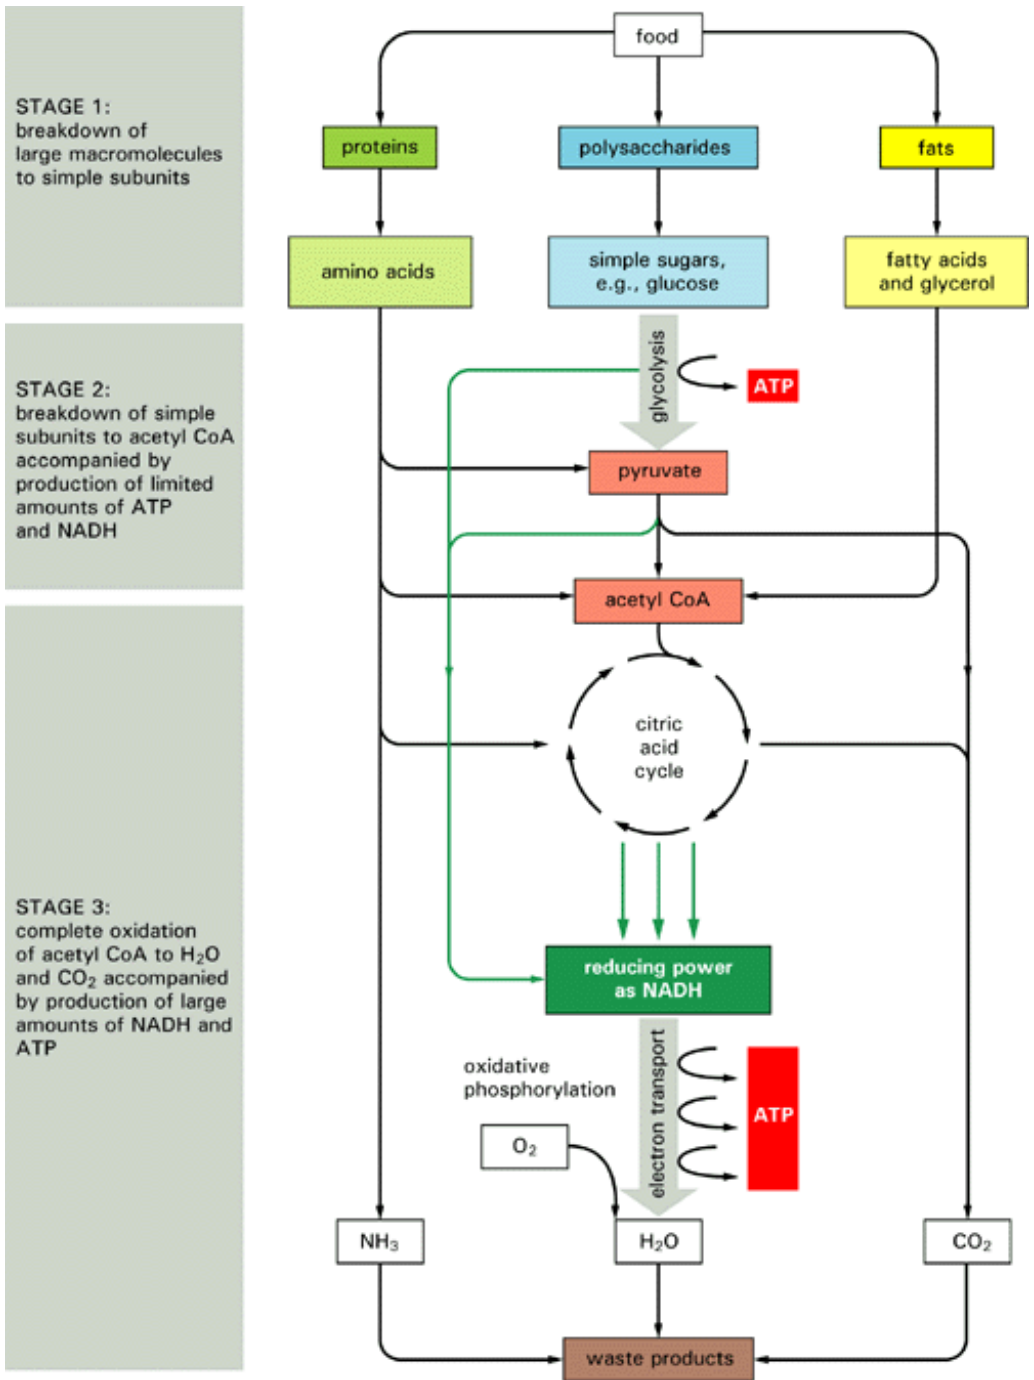
Animal cells derive energy from food in three stages. In stage 1, called digestion, proteins, polysaccharides, and fats are broken down by extracellular reactions to small molecules. In stage 2, these small molecules are degraded within cells to produce acetyl CoA and a limited amount of ATP and NADH. These are the only reactions that can yield energy in the absence of oxygen. In stage 3, the acetyl CoA molecules are degraded in mitochondria to give CO_2 and hydrogen atoms that are linked to carrier molecules such as NADH. Electrons from the hydrogen atoms are passed through a complex chain of membrane-bound carriers, finally being passed to molecular oxygen to form water. Driven by the energy released in these electron-transfer steps, protons (H^+) are transported out of the mitochondria. The resulting electrochemical proton gradient across the inner mitochondrial membrane is harnessed to drive the synthesis of most of the cell's ATP.


Figure 2-19. Simplified diagram of the three stages of catabolism that lead from food to waste products. This series of reactions produces ATP, which is then used to drive biosynthetic reactions and other energy-requiring processes in the cell.
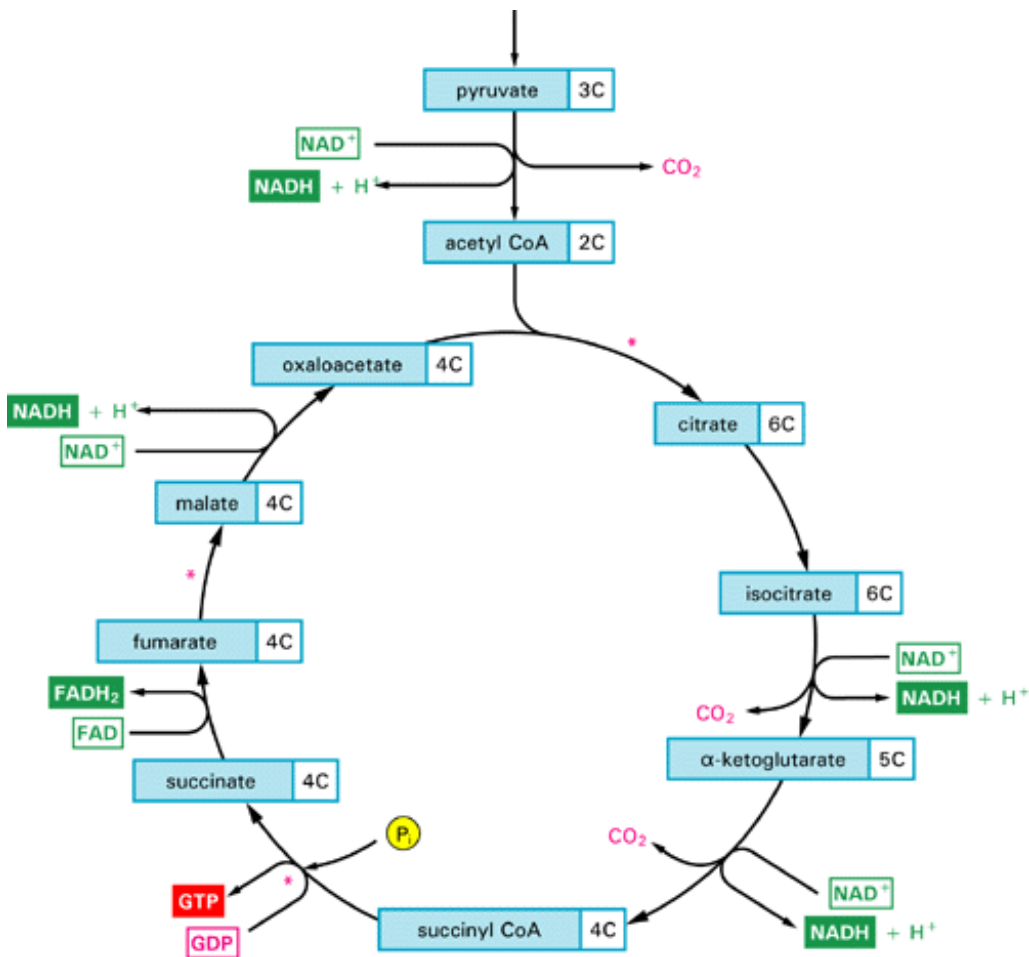
Figure 2-20. Acetyl coenzyme A (acetyl CoA). This crucial metabolic intermediate is generated when acetyl groups, produced in stage 2 of catabolism, are covalently linked to coenzyme A (CoA).
Figure 2-21. Glycolysis. Each reaction shown is catalyzed by a different enzyme. In the series of reactions designated as step 4, a six-carbon sugar is cleaved to give two three-carbon sugars, so that the number of molecules at every step after this is doubled. Steps 5 and 6 (in the *yellow box*) are the reactions responsible for the net synthesis of ATP and NADH molecules (see Figure 2-22).
Figure 2-22. Steps 5 and 6 of glycolysis. In these steps the oxidation of an aldehyde to a carboxylic acid is coupled to the formation of ATP and NADH (see also Figure 2-21). Step 5, shown here as a series of three steps, begins when the enzyme *glyceraldehyde 3-phosphate dehydrogenase* (see Figure 3-42) forms a covalent bond to the carbon carrying the aldehyde group on glyceraldehyde 3-phosphate. Next, hydrogen (as a hydride ion - a proton plus two electrons) is removed from the enzyme-linked aldehyde group in glyceraldehyde 3-phosphate and transferred to the important hydrogen carrier NAD^+ (see Figure 2-24). This oxidation step creates a sugar carbonyl group attached to the enzyme in a high-energy linkage (shown as a *red bond*). This linkage is then broken by a phosphate ion (P_i) from solution, creating a high-energy sugar-phosphate bond instead (*red bond*). In these last two reactions, the enzyme has *coupled* the energetically favorable process of oxidizing an aldehyde to the energetically unfavorable formation of a high-energy phosphate bond, allowing the second step to be driven by the first. Finally, in step 6 of glycolysis, the newly created reactive phosphate group is transferred to ADP to form ATP, leaving a free carboxylic acid group on the oxidized sugar.
Figure 2-23. A simplified outline of stage 3 of catabolism. The process is primarily designed to produce large amounts of ATP from ADP and inorganic phosphate (P_i). NADH is produced by the citric acid cycle and is then used to drive the production of ATP during oxidative phosphorylation. NADH thus serves as a central intermediate in the oxidation of acetyl groups to CO_2 and H_2O (lesser amounts of $FADH_2$ play a similar part).
Figure 2-24. NAD⁺ and NADH. These two molecules are the most important carriers of readily transferable electrons in catabolic reactions. Their structures are shown in (A). NAD is an abbreviation for *nicotinamide adenine dinucleotide,* reflecting the fact that the bottom half of the molecule, as drawn, is adenosine monophosphate (AMP). The part of the NAD⁺ molecule known as the nicotinamide ring (labeled in *gray box*) is able to accept two electrons together with a proton (in sum, a hydride ion, H⁻), forming NADH. In this reduced form, the nicotinamide ring has a reduced stability because it is no longer stabilized by resonance. As a result, the added hydride ion is *activated* in the sense that it can be easily transferred to other molecules. (B) An example of a reaction involving NAD⁺ and NADH. In the biological oxidation of a substrate molecule such as an alcohol, two hydrogen atoms are lost from the substrate. One of these is added as a hydride ion to NAD⁺, producing NADH, while the other is released into solution as a proton (H⁺).


Figure 2-25. The citric acid cycle. In mitochondria and in aerobic bacteria the acetyl groups produced from pyruvate are further oxidized. The carbon atoms of the acetyl groups are converted to CO_2, while the hydrogen atoms are transferred to the carrier molecules NAD^+ and FAD. Additional oxygen and hydrogen atoms enter the cycle in the form of water at the steps marked with an asterisk (*). The number of carbon atoms in each molecule is indicated by a *white box.* For details, see .
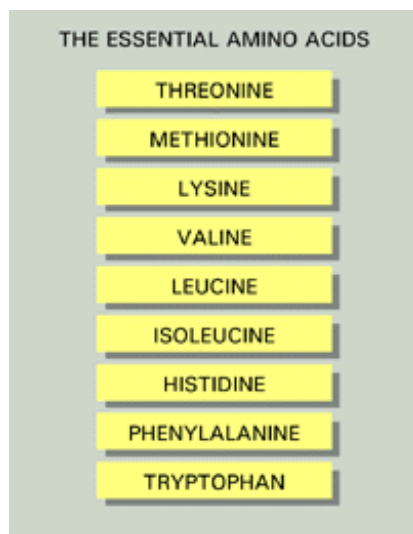
Figure 2-26. The generation of an H⁺ gradient across a membrane by electron-transport reactions. A high-energy electron (derived, for example, from the oxidation of a metabolite) is passed sequentially by carriers A, B, and C to a lower energy state. In this diagram carrier B is arranged in the membrane in such a way that it takes up H^+ from one side and releases it to the other as the electron passes. The resulting H^+ gradient represents a form of stored energy that is harnessed by other membrane proteins in the mitochondrion to drive the formation of ATP, as discussed in Chapter 14.


Figure 2-27. The nine essential amino acids. These cannot be synthesized by human cells and so must be supplied in the diet.

Introduction

Thousands of different chemical reactions are occurring in a cell at any instant of time. The reactions are all linked together in chains and networks in which the product of one reaction becomes the substrate of the next. Most of the chemical reactions in cells can be roughly classified as being concerned either with catabolism or with biosynthesis (anabolism). Having discussed the catabolic reactions, we now turn to the reactions of biosynthesis. These begin with the intermediate products of glycolysis and the citric acid cycle (and closely related compounds) and generate the larger and more complex molecules of the cell.

The Free-Energy Change for a Reaction Determines Whether It Can Occur <u>18</u>

Although enzymes speed up energetically favorable reactions, they cannot force energetically unfavorable reactions to occur. In terms of a water analogy, enzymes by themselves cannot make water run uphill. Cells, however, must do just that in order to grow and divide; they must build highly ordered and energy-rich molecules from small and simple ones. We have seen that, in a general way, this is done through enzymes that directly couple energetically favorable reactions, which consume energy (derived ultimately from the sun) and produce heat, to energetically unfavorable reactions, which produce biological order. Let us examine in greater detail how such coupling is achieved.

First, we must consider more carefully the term "energetically favorable," which we have so far used loosely without giving it a definition. As explained earlier, a chemical reaction can proceed spontaneously only if it results in a net increase in the disorder of the universe. Disorder increases when useful energy (energy that could be harnessed to do work) is dissipated as heat; and the criterion for an increase of disorder can be expressed conveniently in terms of a quantity called the free energy, G . This is defined in such a way that changes in its value, denoted by D- G , measure the amount of disorder created in the universe when a reaction takes place. *Energetically favorable reactions,* by definition, are those that release a large quantity of free energy, or, in other words, have a large *negative* D- G and create much disorder. A familiar example on a macroscopic scale would be the "reaction" by which a compressed spring relaxes to an expanded state, releasing its stored elastic energy as heat to its surroundings. Energetically favorable reactions, with D- $G <$ O, have a strong tendency to occur spontaneously, although their rate will depend on other factors, such as the availability of specific enzymes (discussed below). Conversely, *energetically unfavorable reactions,* with a *positive* D- $G,$ such as those in which two amino acids are joined together to form a peptide bond, by themselves create order in the universe and therefore do not occur spontaneously. Reactions of this kind can take place only if they are coupled to a second reaction with a negative D- G so large that the D- G of the entire process is negative.

The course of most reactions can be predicted quantitatively. A large body of thermodynamic data has been collected that makes it possible to calculate the change in free energy for most of the important metabolic reactions of the cell. The overall free-energy change for a pathway is then simply the sum of the free-energy changes in each of its component steps. Consider, for example, two reactions

$$X \rightarrow Y \text{ and } C \rightarrow D$$
where the D G values are +1 and -13 kcal/mole, respectively. (Recall that a mole is 6 x 10^{23} molecules of a substance.) If these two reactions can be coupled together, the D- G for the coupled reaction will be -12 kcal/mole. Thus, the unfavorable reaction X $\rightarrow$ Y, which will not occur spontaneously, can be driven by the favorable reaction C $\rightarrow$ D, provided that a mechanism exists by which the two reactions can be coupled together.

Biosynthetic Reactions Are Often Directly Coupled to ATP Hydrolysis

Consider a typical biosynthetic reaction in which two monomers, A and B, are to be joined in a dehydration (also called *condensation*) reaction, in which water is released:

$$A\text{-}H + B\text{-}OH \rightarrow A\text{-}B + H_2O$$
Almost invariably the reverse reaction (called hydrolysis), in which water breaks the covalently linked compound A-B, will be the energetically favorable one. This is the case, for example, in the hydrolysis of proteins, nucleic acids, and polysaccharides into their subunits.

The general strategy that allows the cell to make A-B from A-H and B-OH involves a sequence of steps through which the energetically unfavorable synthesis of the desired compound is coupled to an even more energetically favorable reaction (see Figure 2-17). ATP hydrolysis (Figure 2-28) has a large negative D- G, and it is the usual source of the free energy used to drive the biosynthetic reactions in a cell. In the coupled pathway from A-H and B-OH to A-B, energy from ATP hydrolysis is first used to convert B-OH to a higher-energy intermediate compound, which then reacts directly with A-H to give A-B. The simplest mechanism involves the transfer of a phosphate from ATP to B-OH to make $B-OPO_3$ (or BO-Ⓟ), in which case the reaction pathway contains only two steps:

1. B-OH + ATP ⟶ B-O- Ⓟ + ADP

2. A-H + B-O- Ⓟ ⟶ A-B + P_i
Since the intermediate B-O-Ⓟ is formed only transiently, the overall reactions that occur are

$$A\text{-}H + B\text{-}OH \rightarrow A\text{-}B \ \text{ and } \ ATP \rightarrow ADP + P_i$$
The first reaction, which by itself is energetically unfavorable, is forced to occur by being directly coupled to the second energetically favorable reaction (ATP hydrolysis). An example of a coupled biosynthetic reaction of this kind, the synthesis of the amino acid glutamine, is shown in Figure 2-29.

The D- G for the hydrolysis of ATP to ADP and inorganic phosphate (P_i) depends on the concentrations of all of the reactants, and under the usual conditions in a cell it is between -11 and -13 kcal/mole. In principle, this hydrolysis reaction can be used to drive an unfavorable reaction with a D- G of, perhaps, +10 kcal/mole, provided that a suitable reaction path is available. For some biosynthetic reactions, however, even -13 kcal/mole may not be enough. In these cases the path of ATP hydrolysis can be altered so that it initially produces AMP and pyrophosphate (PP_i), which is itself then hydrolyzed in a subsequent step (Figure 2-30). The whole process makes available a total free-energy change of about -26 kcal/mole.

How is the energy of pyrophosphate hydrolysis coupled to a biosynthetic reaction? One way can be illustrated by considering again the synthesis of compound A-B from A-H and B-OH. By an appropriate enzyme, B-OH can be converted to the higher-energy intermediate B-O- Ⓟ - Ⓟ by its reaction with ATP. The complete reaction now contains three steps:

1. B-OH + ATP ⟶ B-O- Ⓟ - Ⓟ + AMP

2. A-H + B-O- Ⓟ - Ⓟ ⟶ A-B + PP_i

3. PP_i + H_2O ⟶ $2P_i$
And the overall reactions are

$$A\text{-}H + B\text{-}OH \rightarrow A\text{-}B \ \text{ and } \ ATP + H_2O \rightarrow AMP + 2P_i$$
Since an enzyme always facilitates equally the forward and backward directions of the reaction it catalyzes, the compound AB can be destroyed by recombining it with pyrophosphate (a reversal of step 2). But the energetically favorable reaction of pyrophosphate hydrolysis (step 3) greatly stabilizes compound A-B by keeping the concentration of pyrophosphate very low, essentially preventing the reversal of step 2. In this way the energy of pyrophosphate hydrolysis is used to drive this reaction in the forward direction. An example of an important biosynthetic reaction of this kind, polynucleotide synthesis, is illustrated in Figure 2-31.

Coenzymes Are Involved in the Transfer of Specific Chemical Groups

Because the terminal phosphate linkage in ATP is easily cleaved, with release of free energy, ATP acts as an efficient donor of a phosphate group in a large number of phosphorylation reactions. A wide variety of other chemically labile linkages also function in this way, and molecules bearing them often bind tightly to the surface of enzymes so that they can be used efficiently as donors of their reactive group in enzymatically catalyzed reactions. Such molecules are called coenzymes because they are essential for the activity of the enzyme; the same coenzyme can participate in many different biosynthetic reactions in which its group is needed.

Some examples of coenzymes are listed in Table 2-2. Among them is acetyl coenzyme A (acetyl CoA), which we encountered earlier. It carries an acetyl group linked to CoA through a reactive thioester bond (see Figure 2-20). This acetyl group is readily transferred to another molecule, such as a growing fatty acid. Other important coenzymes are NADH, which carries a hydride ion (see Figure 2-24), and *biotin,* which transfers a carboxyl group in many biosynthetic reactions (Figure 2-32).

Many coenzymes cannot be synthesized by animals and must be obtained from plants or microorganisms in the diet. *Vitamins* - essential nutritional factors that animals need in trace amounts - are often the precursors of required coenzymes.

The Structure of Coenzymes Suggests That They May Have Originated in an RNA World

As discussed in Chapter 1, the recent discovery that RNA molecules can fold up to form highly specific catalytic surfaces has led to the view that RNAs (or their close relatives) were probably the main catalysts for early life forms and that proteins were a later evolutionary addition. To allow efficient catalysis of the many types of reactions needed in cells, it seems likely that these RNAs would have required a large variety of coenzymes to compensate for their own chemical monotony (being made from only four different nucleotide subunits). Some present-day RNAs contain highly specific binding sites for nucleotides, which utilize non-Watson-Crick, hydrogen-bonded base-base contacts (see Figure 3-21). It is conceivable that coenzymes bound to early RNAs by means of the same type of nucleotide "handle" that is present on the back side of many present-day coenzymes, such as ATP, acetyl CoA, and NADH. According to this view, these molecules evolved with a covalently attached nucleotide because of the nucleotide's earlier usefulness for coenzyme binding in an RNA world.

Biosynthesis Requires Reducing Power

We have seen that oxidation and reduction reactions occur continuously in cells. The chemical energy in food molecules is released by catabolic oxidation reactions, while, in order to make biological molecules, the cell needs (among other things) to carry out a series of reduction reactions that require an input of chemical energy. By using the principle of coupled reactions described previously, cells directly channel chemical energy derived from catabolism into the synthesis of NADH (see Figure 2-22, for example). The high-energy bond between hydrogen and the nicotinamide ring in NADH then provides the energy for otherwise unfavorable enzyme reactions that transfer two electrons plus a proton (as a hydride ion) to another molecule. NADH, and the closely related NADPH to which it can be readily converted, are therefore said to carry "reducing power"; both are used as coenzymes in many types of reduction reactions.

To see how this hydrogen transfer works in practice, consider just one biosynthetic step: the last reaction in a pathway for the synthesis of the lipid molecule *cholesterol.* In this reaction two hydrogen atoms are added to the polycyclic steroid ring in order to reduce a carbon-carbon double bond. As in most biosynthetic reactions, the constituents of the two hydrogen atoms required in this reaction are supplied as a hydride ion from NADPH and a proton (H^+) from the solution ($H^- + H^+ = 2H$) (Figure 2-33). As in NADH, the hydride ion to be transferred from NADPH is part of a nicotinamide ring and is easily lost because the ring can achieve a more stable aromatic state without it (see Figure 2-24). Therefore, NADH and NADPH both hold a hydride ion in a high-energy linkage from which it can be transferred to another molecule when a suitable enzyme is available to catalyze the transfer.

The difference between NADH and NADPH is trivial in chemical terms, but it is crucial for their distinctive functions. The extra phosphate group on NADPH is far from the active region (Figure 2-34) and is of no importance to the hydride ion transfer reaction; but it determines the enzymes to which NADPH can bind as a coenzyme. As a general rule, NADH operates with enzymes catalyzing catabolic reactions, whereas NADPH operates with enzymes that catalyze biosynetic reactions. By having the two coenzymes act in different pathways, the cell can keep NADPH:$NADP^+$ ratios high to provide the reducing power

necessary for biosynthetic pathways, while at the same time it can keep NADH:NAD$^+$ ratios low to provide the NAD$^+$ required to accept electrons during catabolism.

Biological Polymers Are Synthesized by Repetition of Elementary Dehydration Reactions

The principal macromolecules synthesized by cells are polynucleotides (DNA and RNA), polysaccharides, and proteins. They are enormously diverse in structure and include the most complex molecules known. Despite this, they are synthesized from relatively few kinds of small molecules (referred to as either *monomers* or *subunits*) by a restricted repertoire of chemical reactions.

An oversimplified outline of the mechanism of addition of monomers to proteins, polynucleotides, and polysaccharides is shown in Figure 2-35. Although the synthetic reactions for each polymer involve a different kind of covalent bond and different enzymes and cofactors, there are strong underlying similarities. As indicated by the red shading, the addition of subunits in each case occurs by a dehydration reaction, involving the removal of a molecule of water from the two reactants.

As in the general case discussed on page 76, the formation of these polymers requires the input of chemical energy, which is achieved by the standard strategy of coupling the biosynthetic reaction to the energetically favorable hydrolysis of a nucleoside triphosphate. For all three types of macromolecules, at least one nucleoside triphosphate is cleaved to produce pyrophosphate, which is subsequently hydrolyzed so that the driving force for the reaction is large. The mechanism used for polynucleotide synthesis was illustrated earlier in Figure 2-31.

The activated intermediates in the polymerization reactions can be oriented in one of two ways, giving rise to either the head polymerization or the tail polymerization of monomers. In *head polymerization* the reactive bond is carried on the end of the growing polymer and must therefore be regenerated each time a monomer is added. In this case each monomer brings with it the reactive bond that will be used to react with the *next* monomer in the series (Figure 2-36). In *tail polymerization* the reactive bond carried by each monomer is used instead for its own addition. Both types of polymerization are used for the synthesis of biological macromolecules. The synthesis of polynucleotides and some simple polysaccharides occurs by tail polymerization, for example, whereas the synthesis of proteins occurs by head polymerization.

Summary

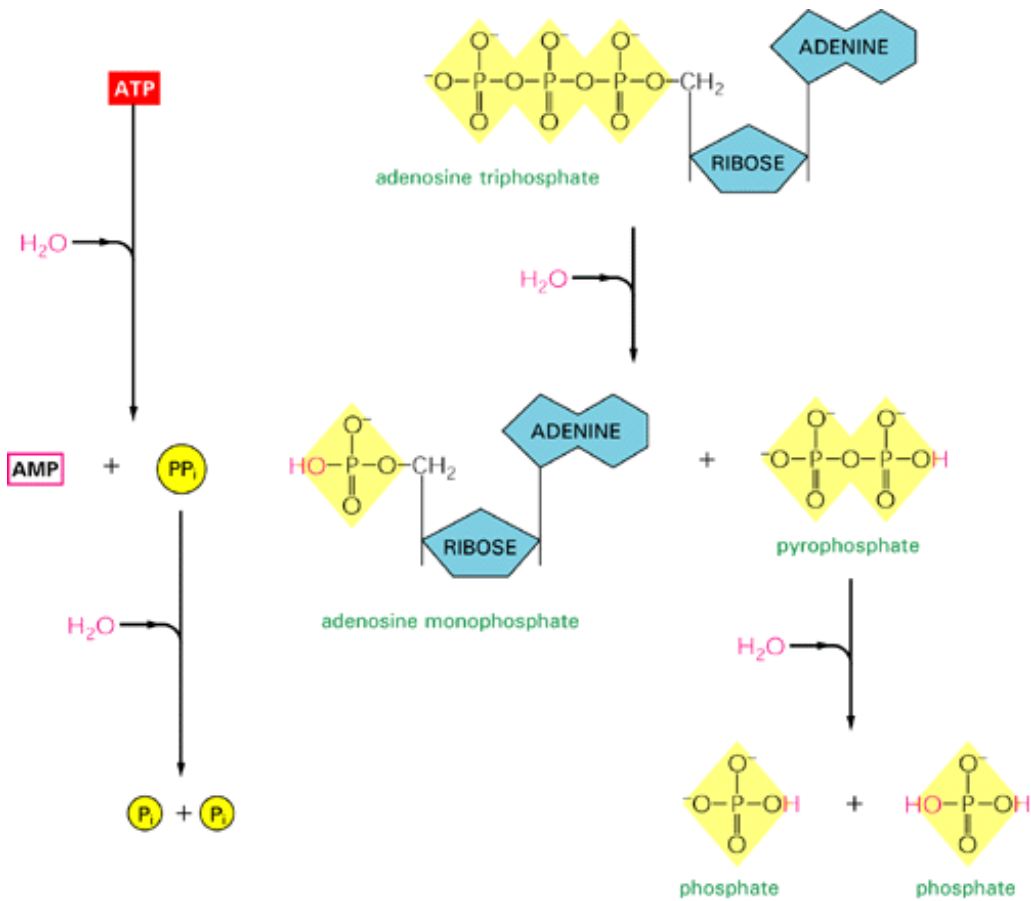
The hydrolysis of ATP is commonly coupled to energetically unfavorable reactions, such as the biosynthesis of macromolecules, by the transfer of phosphate groups to form reactive phosphorylated intermediates. Because the energetically unfavorable reaction now becomes energetically favorable, ATP hydrolysis is said to drive the reaction. Polymeric molecules such as proteins, nucleic acids, and polysaccharides are assembled from small activated precursor molecules by repetitive dehydration reactions that are driven in this way. Other reactive molecules, called coenzymes, transfer other chemical groups in the course of biosynthesis: NADPH transfers hydrogen as a proton plus two electrons (a hydride ion), for example, whereas acetyl CoA transfers acetyl groups.
Figure 2-28. ATP hydrolysis. The hydrolysis of the terminal phosphate of ATP yields between 11 and 13 kcal/mole of usable energy, depending on the intracellular conditions. The large negative D G of this reaction arises from a number of factors. Release of the terminal phosphate group removes an unfavorable repulsion between adjacent negative charges. In addition, the inorganic phosphate ion (P_i) released is stabilized by resonance and by favorable hydrogen bond formation with water.
Figure 2-29. An example of a biosynthetic reaction of the dehydration type driven by ATP hydrolysis. Glutamic acid is first converted to a high-energy phosphorylated intermediate (corresponding to the compound BOR described in the text), which then reacts with ammonia to form glutamine. In this example both steps occur on the surface of the same enzyme, *glutamine synthase*. Note that, for clarity, these molecules are shown in their uncharged forms.


Figure 2-30. An alternative route for the hydrolysis of ATP, in which pyrophosphate is first formed and then hydrolyzed. This route releases about twice as much free energy as the reaction shown in Figure 2-28. The hydrogen atoms derived from water are shown attached to the phosphate groups following hydro-lysis. At the pH of the cytoplasm, however, most of these dissociate to form free hydrogen ions, H^+.
Figure 2-31. Synthesis of a polynucleotide, RNA or DNA, is a multistep process driven by ATP hydrolysis. In the first step a nucleoside monophosphate is activated by the sequential transfer of the terminal phosphate groups from two ATP molecules. The high-energy intermediate formed - a nucleoside triphosphate - exists free in solution until it reacts with the growing end of an RNA or DNA chain with release of pyrophosphate. Hydrolysis of the latter to inorganic phosphate is highly favorable and helps drive the overall reaction in the direction of polynucleotide synthesis.

Table 2-2. Some Coenzymes Involved in Group-Transfer Reactions

Coenzyme*	Group Transferred
ATP	phosphate
NADH, NADPH	hydrogen and electron (hydride ion)
Coenzyme A	acetyl
Biotin	carboxyl
S-Adenosylmethionine	methyl

*. Coenzymes are small molecules that are associated with some enzymes and are essential for their activity. Each one listed is a carrier molecule for a small chemical group, and it participates in various reactions in which that group is transferred to another molecule. Some coenzymes are covalently linked to their enzyme; others are less tightly bound.
Figure 2-32. Transfer of a carboxyl group by the coenzyme biotin. Biotin (shown in *green*) acts as a carrier molecule for the carboxyl group (shown in *red*). In the sequence of reactions shown, biotin is covalently bound to the enzyme pyruvate carboxylase. An activated carboxyl group derived from a bicarbonate ion (HCO_3^-) is coupled to biotin in a reaction that requires an input of energy from the hydrolysis of an ATP molecule. Subsequently, this carboxyl group is transferred to the methyl group of pyruvate to form oxaloacetate.
Figure 2-33. The final stage in one of the biosynthetic routes leading to cholesterol. The reduction of the C=C bond is achieved by the transfer of a hydride ion from the carrier molecule NADPH plus a proton (H^+) from the solution.
Figure 2-34. The structure of NADPH. It differs from NADH (see Figure 2-24) only in the presence of an extra phosphate group that allows it to be recognized selectively by the enzymes involved in biosynthesis.
Figure 2-35. Synthesis of macromolecules. Outline of the polymerization reactions by which three kinds of biological polymer

are synthesized, illustrating that synthesis in every case involves the loss of water (dehydration). Not shown is the consumption of high-energy nucleoside triphosphates that is required to activate each monomer prior to its addition. In contrast, the reverse reactionthe breakdown of all three types of polymeroccurs by the simple addition of water (hydrolysis).
Figure 2-36. Activated intermediates in polymerization reactions. Head growth of polymers is compared to tail growth.

The Coordination of Catabolism and Biosynthesis [19]

Metabolism Is Organized and Regulated

Some idea of how intricate a cell is when viewed as a chemical machine can be obtained from Figure 2-37, which is a chart showing only some of the enzymatic pathways in a cell. All of these reactions occur in a cell that is less than 0.1 mm in diameter, and each requires an enzyme that is itself the product of a whole series of information-transfer and protein-synthesis reactions. For a typical small molecule - the amino acid *serine,* for example - there are half a dozen or more enzymes that can modify it chemically in different ways: it can be linked to AMP (adenylated) in preparation for protein synthesis, or degraded to glycine, or converted to pyruvate in preparation for oxidation; it can be acetylated by acetyl CoA or transferred to a fatty acid to make phosphatidyl serine. All of these different pathways compete for the same serine molecule, and similar competitions for thousands of other small molecules go on at the same time. One might think that the whole system would need to be so finely balanced that any minor upset, such as a temporary change in dietary intake, would be disastrous.

In fact, the cell is amazingly stable. Whenever it is perturbed, the cell reacts so as to restore its initial state. It can adapt and continue to function during starvation or disease. Mutations of many kinds can eliminate particular reaction pathways, and yet - provided that certain minimum requirements are met - the cell survives. It does so because an elaborate network of control mechanisms regulates and coordinates the rates of its reactions. Some of the higher levels of control will be considered in later chapters. Here we are concerned only with the simplest mechanisms that regulate the flow of small molecules through the various metabolic pathways.

Metabolic Pathways Are Regulated by Changes in Enzyme Activity [20]

The concentrations of the various small molecules in a cell are buffered against major changes by a process known as feedback regulation, which fine-tunes the flux of metabolites through a particular pathway by temporarily increasing or decreasing the activity of crucial enzymes. The first enzyme of a series of reactions, for example, is usually inhibited by a *negative feedback* effect of the final product of that pathway: if large quantities of the final product accumulate, further entry of precursors into the reaction pathway is automatically inhibited (Figure 2-38). Where pathways branch or intersect, as they often do, there are usually multiple points of control by different final products. The complexity of such feedback control processes is illustrated in Figure 2-39, which shows the pattern of enzyme regulation observed in a set of related amino acid pathways.

Feedback regulation can work almost instantaneously and is reversible; in addition, a given end product may activate enzymes leading along other pathways, as well as inhibit enzymes that cause its own synthesis. The molecular basis for this type of control in cells is well understood, but since an explanation requires some knowledge of protein structure, it will be deferred until Chapter 5.

Catabolic Reactions Can Be Reversed by an Input of Energy [21]

By regulating a few enzymes at key points in a metabolic network, a cell can effect large-scale changes in its general

metabolism. A special pattern of feedback regulation enables a cell to switch, for example, from glucose degradation to glucose biosynthesis (denoted *gluconeogenesis*). The need for gluconeogenesis is especially acute in periods of violent exercise, when the glucose needed for muscle contraction is generated from lactic acid by liver cells, and also in periods of starvation, when glucose must be formed from the glycerol portion of fats and from amino acids for survival.

The normal breakdown of glucose to pyruvate during glycolysis is catalyzed by a number of enzymes acting in series. The reactions catalyzed by most of these enzymes are readily reversible, but three reaction steps (numbers 1, 3, and 9 in the sequence of Figure 2-21) are effectively irreversible. In fact, it is the large negative free-energy change that occurs in these reactions that normally drives the sequence in the direction of glucose breakdown. For the reactions to proceed in the opposite direction and make glucose from pyruvate, each of these three reactions must be bypassed. This is achieved by substituting three enzyme-catalyzed bypass reactions that are driven in the uphill direction by an input of chemical energy (Figure 2-40). Thus, whereas two ATP molecules are generated as each molecule of glucose is degraded to two molecules of pyruvate, the reverse reaction during gluconeogenesis requires the hydrolysis of four ATP and two GTP molecules. This is equivalent, in total, to the hydrolysis of six molecules of ATP for every molecule of glucose synthesized.

The bypass reactions in Figure 2-40 must be controlled so that glucose is broken down rapidly when energy is needed but synthesized when the cell is nutritionally replete. If both forward and reverse reactions were allowed to proceed at the same time without restraint, they would shuttle large quantities of metabolites backward and forward in futile cycles that would consume large amounts of ATP and generate heat for no purpose.

The elegance of the control mechanisms involved can be illustrated by a single example. Step 3 of glycolysis is one of the reactions that must be bypassed during glucose formation (see Figure 2-40). Normally, this step involves the addition of a second phosphate group to fructose 6-phosphate from ATP and is catalyzed by the enzyme *phosphofructokinase.* This enzyme is activated by AMP, ADP, and inorganic phosphate, whereas it is inhibited by ATP, citrate, and fatty acids. Therefore, the enzyme is activated by the accumulation of the products of ATP hydrolysis when energy supplies are low, and it is inactivated when energy (in the form of ATP) or food supplies such as fatty acids or citrate (derived from amino acids) are abundant. *Fructose bisphosphatase* is the enzyme that catalyzes the reverse bypass reaction (the hydrolysis of fructose 1,6-bisphosphate to fructose 6-phosphate, leading to the formation of glucose); this enzyme is regulated in the opposite way by the same feedback control molecules so that it is stimulated when the phosphofructokinase is inhibited.

Enzymes Can Be Switched On and Off by Covalent Modification 22

The types of feedback control just described permit the rates of reaction sequences to be regulated continuously and automatically in response to second-by-second fluctuations in metabolism. Cells have different devices for regulating enzymes when longer-lasting changes in activity, occurring over minutes or hours, are required. These involve reversible covalent modification of enzymes. This modification is usually, but not always, accomplished by the addition of a phosphate group to a specific serine, threonine, or tyrosine residue in the enzyme. The phosphate comes from ATP, and its transfer is catalyzed by a family of enzymes known as *protein kinases.*

In Chapter 5 we describe how phosphorylation can alter the shape of an enzyme in such a way as to increase or inhibit its activity. The subsequent removal of the phosphate group, which reverses the effect of the phosphorylation, is achieved by a second type of enzyme, called a *protein phosphatase.* Covalent modification of enzymes adds another dimension to metabolic control because it allows specific reaction pathways to be regulated by extracellular signals (such as hormones and growth factors) that are unrelated to the metabolic intermediates themselves.

Reactions Are Compartmentalized Both Within Cells and Within Organisms 23

Not all of a cell's metabolic reactions occur within the same subcellular compartment. Because different enzymes are found in different parts of the cell, the flow of chemical components is channeled physically as well as chemically.

The simplest form of such spatial segregation occurs when two enzymes that catalyze sequential reactions form an enzyme complex and the product of the first enzyme does not have to diffuse through the cytosol to encounter the second enzyme. The second reaction begins as soon as the first is over. Some large enzyme aggregates carry out whole series of reactions without losing contact with the substrate. The conversion of pyruvate to acetyl CoA, for example, proceeds in three chemical steps, all of which take place on the same large enzyme complex (Figure 2-41). In fatty acid synthesis an even longer sequence of reactions is catalyzed by a single enzyme assembly. Not surprisingly, some of the largest enzyme complexes are concerned with the

synthesis of macromolecules such as proteins and DNA.

The next level of spatial segregation in cells involves the confinement of functionally related enzymes within the same membrane or within the aqueous compartment of an organelle that is bounded by a membrane. The oxidative metabolism of glucose is a good example. After glycolysis, pyruvate is actively taken up from the cytosol into the inner compartment of the mitochondrion, which contains all of the enzymes and metabolites involved in the citric acid cycle (Figure 2-42). Moreover, the inner mitochondrial membrane itself contains all of the enzymes that catalyze the subsequent reactions of oxidative phosphorylation, including those involved in the transfer of electrons from NADH to O_2 and in the synthesis of ATP. The entire mitochondrion can therefore be regarded as a small ATP-producing factory. In the same way other cellular organelles, such as the nucleus, the Golgi apparatus, and the lysosomes, can be viewed as specialized compartments where functionally related enzymes are confined to perform a specific task. In a sense, the living cell is like a city, with many specialized services concentrated in different areas that are extensively interconnected by various paths of communication.

Spatial organization in a multicellular organism extends beyond the individual cell. The different tissues of the body have different sets of enzymes and make distinct contributions to the chemistry of the organism as a whole. In addition to differences in specialized products such as hormones or antibodies, there are significant differences in the "common" metabolic pathways among various types of cells in the same organism. Although virtually all cells contain the enzymes of glycolysis, the citric acid cycle, lipid synthesis and breakdown, and amino acid metabolism, the levels of these processes in different tissues are differently regulated. Nerve cells, which are probably the most fastidious cells in the body, maintain almost no reserves of glycogen or fatty acids and rely almost entirely on a supply of glucose from the bloodstream. Liver cells supply glucose to actively contracting muscle cells and recycle the lactic acid produced by muscle cells back into glucose (Figure 2-43). All types of cells have their distinctive metabolic traits and cooperate extensively in the normal state as well as in response to stress and starvation.

Summary

The many thousands of different chemical reactions carried out simultaneously by a cell are closely coordinated. A variety of control mechanisms regulate the activities of key enzymes in response to the changing conditions in the cell. One very common form of regulation is a rapidly reversible feedback inhibition exerted on the first enzyme of a pathway by the final product of that pathway. A longer-lasting form of regulation involves the chemical modification of one enzyme by another, usually by phosphorylation. Combinations of regulatory mechanisms can produce major and long-lasting changes in the metabolism of the cell. Not all cellular reactions occur within the same intracellular compartment, and spatial segregation by internal membranes permits organelles to specialize in their biochemical tasks.

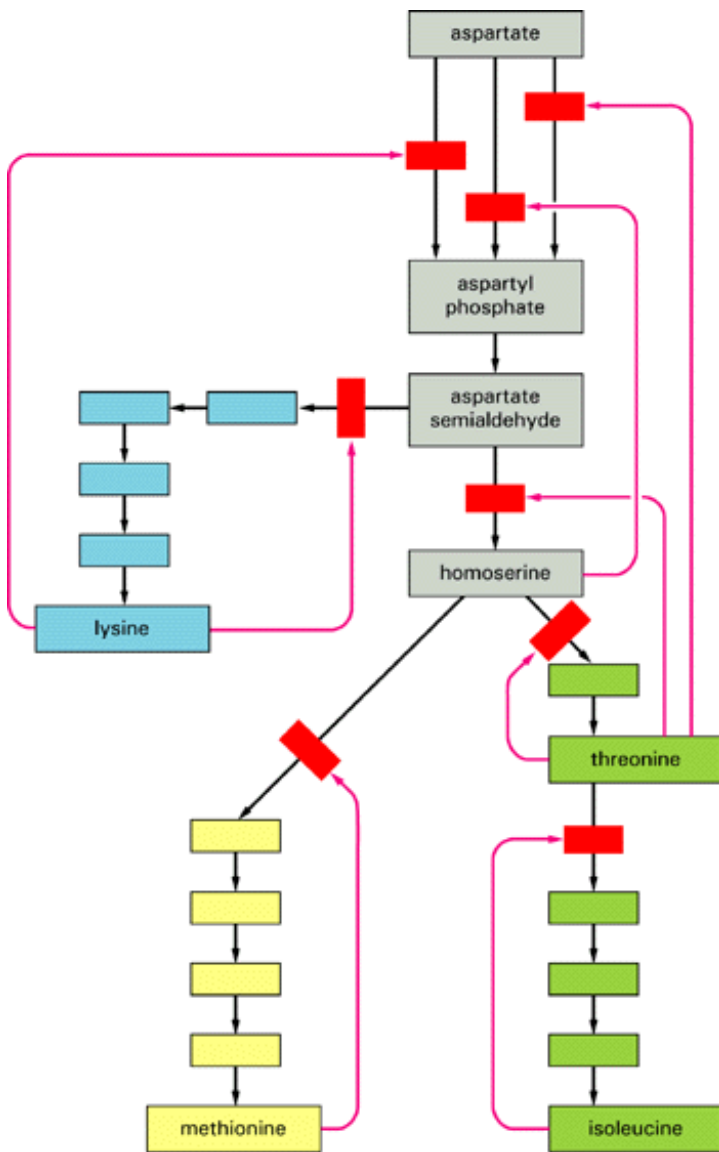
Figure 2-37. Some of the chemical reactions occurring in a cell. (A) About 500 common metabolic reactions are shown diagrammatically, with each chemical species represented by a filled circle. The centrally placed reactions of the glycolytic pathway and the citric acid cycle are shown in *red*. A typical mammalian cell synthesizes more than 10,000 different proteins, a major proportion of which are enzymes. In the arbitrarily selected segment of this metabolic maze (shaded *yellow*), cholesterol is synthesized from acetyl CoA. To the right and below the maze, this segment is shown in detail in an enlargement (B).
Figure 2-38. Feedback inhibition of a single biosynthetic pathway. Each letter represents a different small molecule, and each *black arrow* denotes a reaction catalyzed by a different enzyme. The end product Z inhibits the first enzyme that is unique to its synthesis and thereby controls its own level in the cell. This is an example of *negative feedback*.


Figure 2-39. Feedback inhibition in the synthesis of the amino acids lysine, methionine, threonine, and isoleucine in bacteria. In this diagram, each enzyme-catalyzed reaction is represented by a *black arrow,* whereas the *red arrows* indicate positions at which products "feed back" to inhibit enzymes. Note that three different enzymes (called *isozymes*) catalyze the initial reaction, each inhibited by a different product.
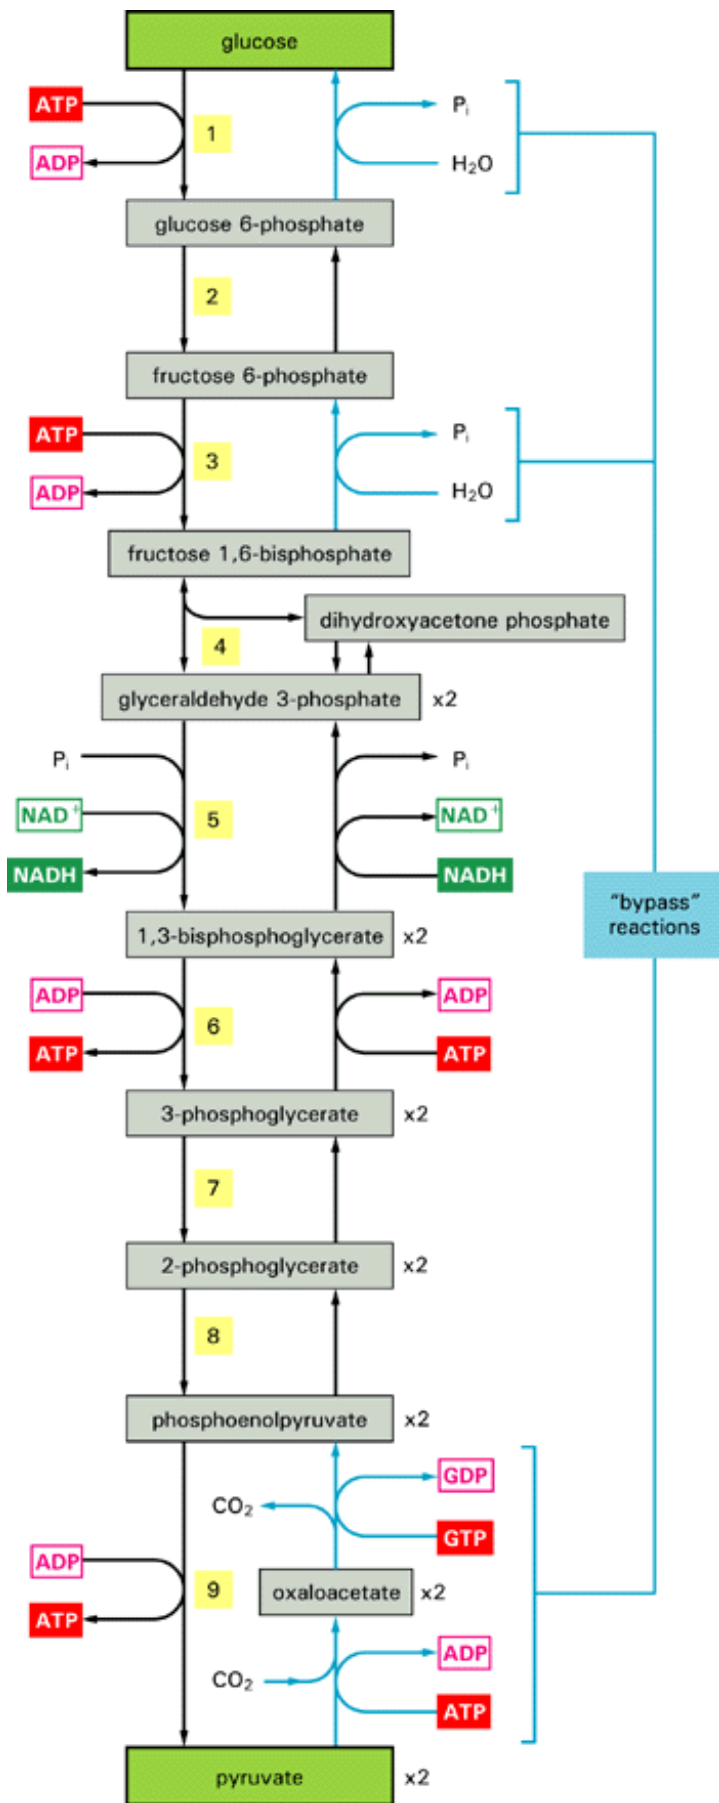

Figure 2-40. Comparison of the reactions that produce glucose during gluconeogenesis with those that degrade glucose during glycolysis. The degradative (glycolytic) reactions are energetically favorable (the free-energy change is less than zero),

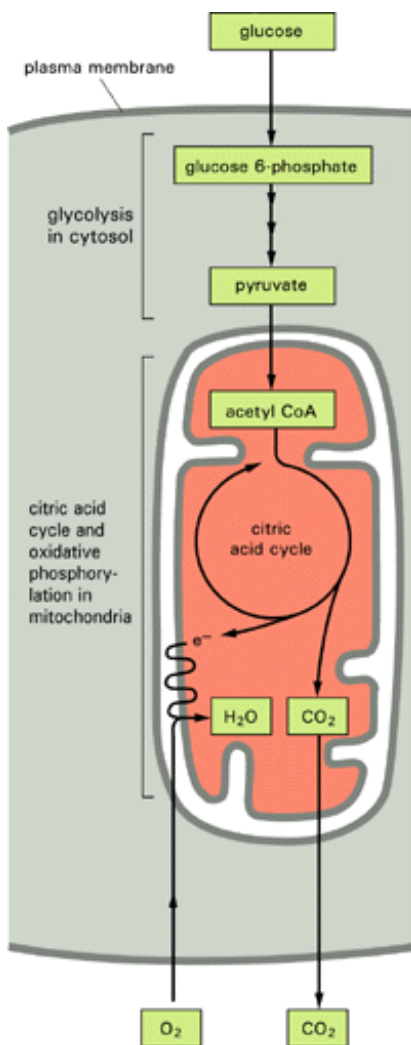
whereas the synthetic reactions require an input of energy. To synthesize glucose, different "bypass enzymes" are needed that bypass reactions 1, 3, and 9 of glycolysis. The overall flux of reactants between glucose and pyruvate is determined by feedback control mechanisms that regulate the enzymes that participate in these three steps.
Figure 2-41. The structure of pyruvate dehydrogenase. This enzyme complex catalyzes the conversion of pyruvate to acetyl CoA. It is an example of a large multienzyme complex in which reaction intermediates are passed directly from one enzyme to another.


Figure 2-42. Segregation of the various steps in the breakdown of glucose in the eucaryotic cell. Glycolysis occurs in the

cytosol, whereas the reactions of the citric acid cycle and oxidative phosphorylation take place only in mitochondria.
Figure 2-43. Schematic view of the metabolic cooperation between liver and muscle cells. The principal fuel of actively contracting muscle cells is glucose, much of which is supplied by liver cells. Lactic acid, the end product of anaerobic glucose breakdown by glycolysis in muscle, is converted back to glucose in the liver by the process of gluconeogenesis.

3. Macromolecules: Structure, Shape, and Information

Introduction

In moving from the small molecules of the cell to the giant macromolecules, we encounter a transition of more than size alone. Even though proteins, nucleic acids, and polysaccharides are made from a limited repertoire of amino acids, nucleotides, and sugars, respectively, they can have unique and truly astounding properties that bear little resemblance to those of their simple chemical precursors. Biological macromolecules are composed of many thousands sometimes millions of atoms linked together in precisely defined spatial arrangements. Each of these macromolecules carries specific information. Incorporated in its structure is a series of biological messages that can be "read" in its interactions with other molecules, enabling it to perform a precise function.

In this chapter we examine the structures of macromolecules, emphasizing proteins and nucleic acids, and explain how they have adapted in the course of evolution to perform specific functions. We consider the principles by which these molecules catalyze chemical transformations, build complex multimolecular structures, generate movement, andmost fundamental of allstore and transmit hereditary information.

Molecular Recognition Processes 1

Introduction

Macromolecules typically have molecular weights between about 10,000 and 1 million and are intermediate in size between the organic molecules of the cell discussed in Chapter 2 and the large macromolecular assemblies and organelles that will be discussed in subsequent chapters (Figure 3-1). One small molecule, water, constitutes 70% of the total mass of a cell; nearly all of the remaining cell mass is due to macromolecules (Table 3-1).

As described in Chapter 2, a macromolecule is assembled from low-molecular-weight subunits that are repeatedly added to one end to form a long, chainlike polymer. Usually only one family of subunits is used to construct each chain: amino acids are linked to other amino acids to form proteins, nucleotides are linked to other nucleotides to form nucleic acids, and sugars are linked to other sugars to form polysaccharides. Because the precise sequence of subunits is crucial to the function of a macromolecule, its biosynthesis requires mechanisms to ensure that the correct subunit goes into the polymer at each position in the chain.

The Specific Interactions of a Macromolecule Depend on Weak, Noncovalent Bonds 2

A macromolecular chain is held together by *covalent* bonds, which are strong enough to preserve the sequence of subunits for long periods of time. Although the sequence of subunits determines the information content of a macromolecule, utilizing that information depends largely on much weaker, *noncovalent* bonds. These weak bonds form between different parts of the same macromolecule and between different macromolecules. They therefore play a major part in determining both the three-dimensional structure of macromolecular chains and how these structures interact with one another.

The noncovalent bonds encountered in biological molecules are usually classified into three types: ionic bonds, hydrogen bonds, and van der Waals attractions. Another important weak force is created by the three-dimensional structure of water, which forces exposed hydrophobic groups together in order to minimize their disruptive effect on the hydrogen-bonded network of water molecules (see Panel 2-1, pp. 48-49). This expulsion from the aqueous solution generates what is sometimes thought of as a fourth kind of weak, noncovalent bond. These four types of weak attractive forces are the subject of Panel 3-1, pages 92-93.

In an aqueous environment each noncovalent bond is 30 to 300 times weaker than the typical covalent bonds that hold biological molecules together (Table 3-2) and only slightly stronger than the average energy of thermal collisions at 37°C (Figure 3-2). A single noncovalent bond - unlike a single covalent bond - is therefore too weak to withstand the thermal motions that tend to pull molecules apart. Large numbers of noncovalent bonds are needed to hold two molecular surfaces together, and these can form between two surfaces only when large numbers of atoms on the surfaces are precisely matched to each other (Figure 3-3). The exacting requirements for matching account for the specificity of biological recognition, such as occurs between an enzyme and its substrate.

As explained at the top of Panel 3-1, atoms behave almost as if they were hard spheres with a definite radius (their van der Waals radius). The requirement that no two atoms overlap limits the possible bond angles in a polypeptide chain (Figure 3-4). These and other steric interactions severely constrain the number of three-dimensional arrangements of atoms (or conformations) that are possible. Nevertheless, a long flexible chain such as a protein can still fold in an enormous number of ways. Each conformation will have a different set of weak intrachain interactions, and it is the total strength of these interactions that determines which conformations will form.

Most proteins in a cell fold stably in only one way: during the course of evolution the sequence of amino acid subunits in each protein has been selected so that one conformation is able to form many more favorable intrachain interactions than any other.

A Helix Is a Common Structural Motif in Biological Structures Made from Repeated Subunits [3]

Biological structures are often formed by linking subunits that are very similar to each other - such as amino acids or nucleotides - into a long, repetitive chain. If all the subunits are identical, neighboring subunits in the chain will often fit together in only one way, adjusting their relative positions so as to minimize the free energy of the contact between them. In this case, each subunit will be positioned in exactly the same way in relation to its neighboring subunits, so that subunit 3 will fit onto subunit 2 in the same way that subunit 2 fits onto subunit 1, and so on. Because it is very rare for subunits to join up in a straight line, this arrangement will generally result in a helix - a regular structure that resembles a spiral staircase, as illustrated in Figure 3-5. Depending on the twist of the staircase, a helix is said to be either right-handed or left-handed (Figure 3-6). Handedness is not affected by turning the helix upside down, but it is reversed if the helix is reflected in a mirror.

Helices occur commonly in biological structures, whether the subunits are small molecules that are covalently linked together (as in DNA) or large protein molecules that are linked by noncovalent forces (as in actin filaments). This is not surprising. A helix is an unexceptional structure, generated simply by placing many similar subunits next to each other, each in the same strictly repeated relationship to the one before.

Diffusion Is the First Step to Molecular Recognition [4]

Before two molecules can bind to each other, they must come into close contact. This is achieved by the thermal motions that cause molecules to wander, or *diffuse,* from their starting positions. As the molecules in a liquid rapidly collide and bounce off one another, an individual molecule moves first one way and then another, its path constituting a "random walk" (Figure 3-7). The average distance that each type of molecule travels from its starting point is proportional to the square root of the time involved: that is, if it takes a particular molecule 1 second on average to go 1 μm, it will go 2 μm in 4 seconds, 10 μm in 100 seconds, and so on. Diffusion is therefore an efficient way for molecules to move limited distances but an inefficient way for molecules to move long distances.

Experiments performed by injecting fluorescent dyes and other labeled molecules into cells show that the diffusion of small molecules through the cytoplasm is nearly as rapid as it is in water. A molecule the size of ATP, for example, requires only about 0.2 second to diffuse an average distance of 10 μm - the diameter of a small animal cell. Large macromolecules, however, move much more slowly. Not only is their diffusion rate intrinsically slower, but their movement is retarded by frequent collisions with many other macromolecules that are held in place by molecular associations in the cytoplasm (Figure 3-8).

Thermal Motions Bring Molecules Together and Then Pull Them Apart [4]

Encounters between two macromolecules or between a macromolecule and a small molecule occur randomly through simple diffusion. An encounter may lead immediately to the formation of a complex between the two molecules, in which case the rate of complex formation is said to be *diffusion-limited.* Alternatively, the rate of complex formation may be slower, requiring some adjustment of the structure of one or both molecules before the interacting surfaces can fit together, so that most often the two colliding molecules will bounce off each other without sticking. In either case once the two interacting surfaces have come sufficiently close together, they will form multiple weak bonds with each other that persist until random thermal motions cause the molecules to dissociate again (see Figure 3-3).

In general, the stronger the binding of the molecules in the complex, the slower their rate of dissociation. At one extreme the total energy of the bonds formed is negligible compared with that of thermal motion, and the two molecules dissociate as rapidly as they came together. At the other extreme the total bond energy is so high that dissociation rarely occurs. Strong interactions

occur in cells whenever a biological function requires that two macromolecules remain tightly associated for a long time - for example, when a gene regulatory protein binds to DNA to turn off a gene. Weaker interactions occur when the function demands a rapid change in the structure of a complex - for example, when two interacting proteins change partners during the movements of a protein machine.

The Equilibrium Constant Is a Measure of the Strength of an Interaction Between Two Molecules [5]

The precise strength of the bonding between two molecules is a useful index of the specificity of their interaction. To illustrate how the binding strength is measured, let us consider a reaction in which molecule A binds to molecule B. The reaction will proceed until it reaches an *equilibrium point,* at which the rates of formation and dissociation are equal (Figure 3-9). The concentrations of A, B, and the complex AB at this point can be used to determine an equilibrium constant (K) for the reaction, as explained in Figure 3-9. This constant is sometimes termed the affinity constant and is commonly employed as a measure of the strength of binding between two molecules: the *stronger* the binding, the *larger* is the value of the affinity constant.

The equilibrium constant of a reaction in which two molecules bind to each other is related directly to the standard free-energy change for the binding (D $G°$) by the equation described in Table 3-3. The table also lists the D $G°$ values corresponding to a range of K values. Affinity constants for simple binding interactions in biological systems often range between 10^3 and 10^{12} liters/mole; this corresponds to binding energies in the range 4-17 kcal/mole, which could arise from 4 to 17 average hydrogen bonds.

Atoms and Molecules Move Very Rapidly [6]

The chemical reactions in a cell occur at amazingly fast rates. A typical enzyme molecule, for example, will catalyze on the order of 1000 reactions per second, and rates of more than 10^6 reactions per second are achieved by some enzymes. Since each reaction requires a separate encounter between an enzyme and a substrate molecule, such rates are possible only because the molecules are moving so rapidly. Molecular motions can be classified broadly into three kinds: (1) the movement of a molecule from one place to another (translational motion), (2) the rapid back-and-forth movement of covalently linked atoms with respect to one another (vibrations), and (3) rotations. All of these motions are important in bringing the surfaces of interacting molecules together.

The rates of molecular motions can be measured by a variety of spectroscopic techniques. These indicate that a large globular protein is constantly tumbling, rotating about its axis about a million times per second. The rates of diffusional encounters due to translational movements are proportional to the concentration of the diffusing molecule. If ATP is present at its typical intracellular concentration of about 1 mM, for instance, each site on a protein molecule will be bombarded by about 10^6 random collisions with ATP molecules per second; for an ATP concentration tenfold lower, the number of collisions would drop to 10^5 per second and so on.

Once two molecules have collided and are in the correct relative orientation, a chemical reaction can occur between them extremely rapidly. When one appreciates how quickly molecules move and react, the observed rates of enzymatic catalysis do not seem so amazing.

Molecular Recognition Processes Can Never Be Perfect [7]

All molecules possess energy - the kinetic energy of their translational movements, vibrations, and rotations and the potential energy stored in their electron distributions. Through molecular collisions this energy is randomly distributed to all of the atoms present, so that most atoms will have energy levels close to the average, with only a small proportion possessing very high energy. Although the favored conformations or states for a molecule will be those of lowest free energy (see p. 75), states of higher energy occur through unusually violent collisions. Given the temperature, it is possible to calculate the probability that an atom or a molecule will be in a particular energy state (see Table 3-3). The probability of a high-energy state becomes smaller relative to a low-energy state as the difference in free energy between the two increases. It reaches zero, however, only when this energy difference becomes infinite.

Because of the random factor in molecular interactions, minor "side reactions" are bound to occur occasionally. As a consequence, a cell continually makes errors. Even reactions that are very energetically unfavorable will take place occasionally. Two atoms joined to each other by a covalent bond, for example, will eventually be subjected to an especially energetic collision

and fall apart. Similarly, the specificity of an enzyme for its substrate cannot be absolute because the recognition of one molecule as distinct from another can never be perfect. Mistakes could be avoided completely only if the cell could evolve mechanisms with infinite energy differences between alternatives. Since this is not possible, cells are forced to tolerate a certain level of failure and have instead evolved a variety of repair reactions to correct those errors that are the most damaging.

On the other hand, errors are essential to life as we know it. If it were not for occasional mistakes in the maintenance of DNA sequences, evolution could not occur.

Summary

The sequence of subunits in a macromolecule contains information that determines the three-dimensional contours of its surface. These contours in turn govern the recognition between one molecule and another, or between different parts of the same molecule, by means of weak, noncovalent bonds. The attractive forces are of four types: ionic bonds, van der Waals attractions, hydrogen bonds, and an interaction between nonpolar groups caused by their hydrophobic expulsion from water. Two molecules will recognize each other by a process in which they meet by random diffusion, stick together for a while, and then dissociate. The strength of this interaction is generally expressed in terms of an equilibrium constant. Since the only way to make recognition infallible is to make the energy of binding infinitely large, living cells constantly make errors; those that are intolerable are corrected by specific repair processes.

Table 3-1. Approximate Chemical Compositions of a Typical Bacterium and a Typical Mammalian Cell

	Percent of Total Cell Weight	
Component	*E. coli* Bacterium	*Mammalian Cell*
H_2O	70	70
Inorganic ions (Na$^+$, K$^+$, Mg^{2+}, Ca^{2+}, Cl$^-$, etc.)	1	1
Miscellaneous small metabolites	3	3
Proteins	15	18
RNA	6	1.1
DNA	1	0.25
Phospholipids	2	3
Other lipids	-	2
Polysaccharides	2	2
Total cell volume:	2×10^{-12} cm^3	4×10^{-9} cm^3
Relative cell volume:	1	2000

Proteins, polysaccharides, DNA, and RNA are macromolecules. Lipids are not generally classed as macromolecules even though they share some of their features; for example, most are synthesized as linear polymers of a smaller molecule (the acetyl group on acetyl CoA), and they self-assemble into larger structures (membranes). Note that water and protein comprise most of the mass of both mammalian and bacterial cells.

sugars, amino acids,
and nucleotides ~0.5-1 nm

globular proteins ~2-10 nm

ribosome ~30 nm

Panel 3-1: The principal types of weak noncovalent forces that hold macromolecules together

VAN DER WAALS FORCES

At very short distances any two atoms show a weak bonding interaction due to their fluctuating electrical charges. This force is known as van der Waals attraction. However, two atoms will very strongly repel each other if they are brought too close together. This van der Waals repulsion plays a major part in limiting the possible conformations of a molecule.

Each type of atom has a radius, known as its van der Waals radius, at which van der Waals forces are in equilibrium.

H	C	N	O
1.2 Å (0.12 nm)	2.0 Å (0.2 nm)	1.5 Å (0.15 nm)	1.4 Å (0.14 nm)

Two atoms will be attracted to each other by van der Waals forces until the distance between them equals the sum of their van der Waals radii. Although they are individually very weak, these van der Waals attractions can become important when two macromolecular surfaces fit very close together.

ENERGY — attraction ← → repulsion

van der Waals force equilibrium at this point

WEAK CHEMICAL BONDS

Organic molecules can interact with other molecules through short-range noncovalent forces.

weak bond

Weak chemical bonds have less than 1/20 the strength of a strong covalent bond. They are strong enough to provide tight binding only when many of them are formed simultaneously.

HYDROGEN BONDS

A hydrogen atom is shared between two other atoms (both electronegative, such as O and N) to give a hydrogen bond.

N — H ||||||||||| O

covalent bond   hydrogen bond
~0.1 nm long   ~0.2 nm long

Hydrogen bonds are strongest when the three atoms are in a straight line:

O—H|||||||||O   N—H|||||||||O

Examples in macromolecules:

HYDROGEN BONDS IN WATER

Any molecules that can form hydrogen bonds to each other can alternatively form hydrogen bonds to water molecules. Because of this competition with water molecules, the

three atoms are in a straight line:

O—H IIIIIIIIO   N—H IIIIIIIIO

Examples in macromolecules:

Amino acids in polypeptide chains hydrogen-bonded together.

R—C—H   R—C—H   H—C—R

C=O IIIIIIIII H—N

C=O IIIIIIII H—N
Two bases, G and C, hydrogen-bonded in DNA or RNA.
HYDROGEN BONDS IN WATER

Any molecules that can form hydrogen bonds to each other can alternatively form hydrogen bonds to water molecules. Because of this competition with water molecules, the hydrogen bonds formed between two molecules dissolved in water are relatively weak.

peptide bond

$2H_2O$

$2H_2O$
HYDROPHOBIC FORCES
Water forces hydrophobic groups together in order to minimize their disruptive effects on the hydrogen-bonded water network. Hydrophobic groups held together in this way are sometimes said to be held together by "hydrophobic bonds," even though the attraction is actually caused by a repulsion from the water.

IONIC BONDS IN AQUEOUS SOLUTIONS

Charged groups are shielded by their interactions with water molecules. Ionic bonds are therefore quite weak in aqueous solution.
Ionic bonds are further weakened by the presence of salts, whose atoms form the counterions that cluster around ions of opposite charge.
Measurement of the extent of destabilization of an interaction by salt provides a quantitative estimate of the total number of ionic bonds involved.

Despite being weakened by water and salt, ionic bonds are very important in biological systems; an enzyme that binds a positively charged substrate will often have a negatively charged amino acid side chain at the appropriate place.

substrate

enzyme

IONIC BONDS

Ionic interactions occur either between fully charged groups (ionic bond) or between partially charged groups.

δ^+ δ^-

The force of attraction between the two charges δ^+ and δ^- is

$$force = \frac{\delta^+ \delta^-}{r^2 D} \quad \text{(Coulomb's law)}$$

where D = dielectric constant
(1 for vacuum; 80 for water)

r = distance of separation

In the absence of water, ionic forces are very strong. They are responsible for the strength of such minerals as marble and agate.

NaCl crystal
Table 3-2. Covalent and Noncovalent Chemical Bonds

		Strength (kcal/mole)*	
		---	---
Bond Type	Length (nm)	In Vacuum	In Water
Covalent	0.15	90	90
Ionic	0.25	80	3
Hydrogen	0.30	4	1
van der Waals attraction (per atom)	0.35	0.1	0.1

*. The strength of a bond can be measured by the energy required to break it, here given in kilocalories per mole (kcal/mole). (*One kilocalorie* is the quantity of energy needed to raise the temperature of 1000 g of water by 1°C. An alternative unit in wide use is the kilojoule, kJ, equal to 0.24 kcal.) Individual bonds vary a great deal in strength, depending on the atoms involved and their precise environment, so that the above values are only a rough guide. Note that the aqueous environment in a cell will greatly weaken both the ionic and the hydrogen bonds between nonwater molecules (Panel 3-1, pp. 92-93). The bond length is the center-to-center distance between the two interacting atoms; the length given here for a hydrogen bond is that between its two nonhydrogen atoms.

amino acid

peptide bonds

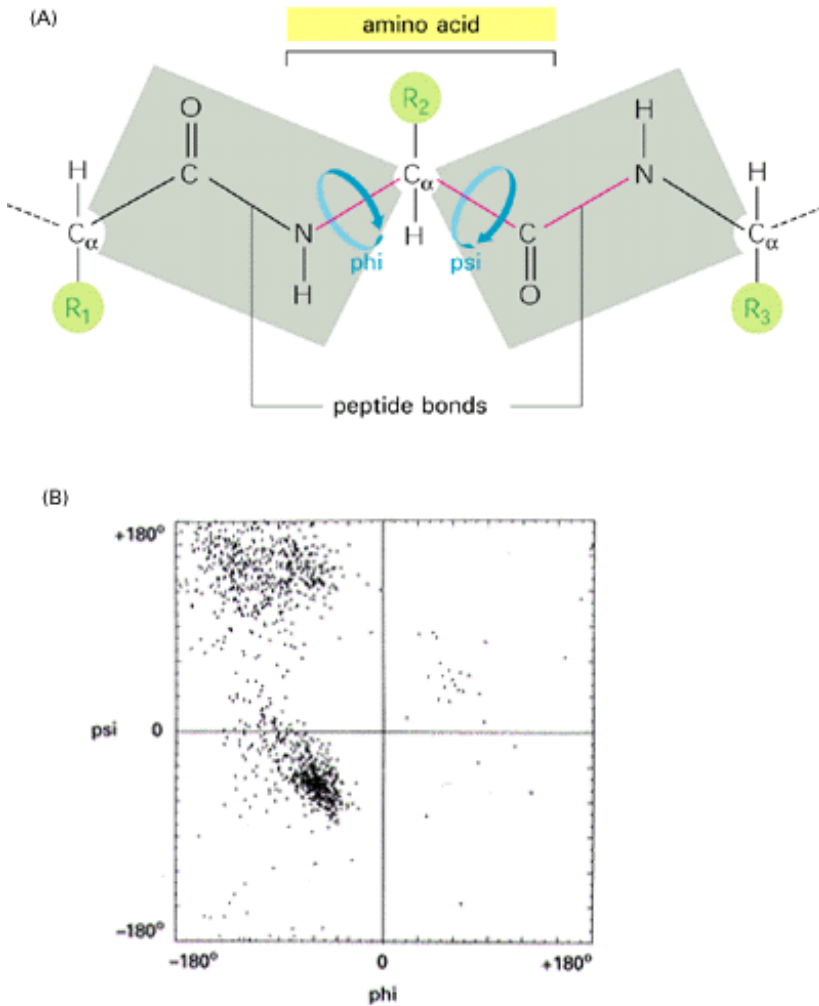
(B)


Figure 3-4. Steric limitations on the bond angles in a polypeptide chain. (A) Each amino acid contributes three bonds (colored *red*) to its polypeptide chain. The peptide bond is planar (*gray* shading) and does not permit rotation. By contrast, rotation can occur about the C_a-C bond, whose angle of rotation is called psi (y), and about the N-C_a bond, whose angle of rotation is called phi (f). The R group denotes an amino acid side chain. (B) The conformation of the main-chain atoms in a protein is determined by one pair of phi and psi angles for each amino acid; because of steric collisions within each amino acid, most pairs of phi and psi angles do not occur. In this so-called Ramachandran plot, each dot represents an observed pair of angles in a protein. (B, from J. Richardson, *Adv. Prot. Chem.* 34:174-175, 1981.)
Figure 3-5. A helix will form when a series of subunits bind to each other in a regular way. In the foreground the interaction between two subunits is shown; behind it are the helices that result. These helices have two (A), three (B), and six (C and D) subunits per turn. At the top, the arrangement of subunits has been photographed from directly above the helix. Note that the helix in (D) has a wider path than that in (C).

left-handed
helix
right-handed
helix

Figure 3-6. Comparison of a left-handed and a right-handed helix. As a reference, it is useful to remember that standard screws, which insert when turned clockwise, are right-handed. Note that a helix preserves the same handedness when it is turned upside down.

Figure 3-7. A random walk. Molecules in solution move in a random fashion due to the continual buffeting they receive in collisions with other molecules. This movement allows small molecules to diffuse from one part of the cell to another in a surprisingly short time: such molecules will generally diffuse across a typical animal cell in less than a second.

100 nm
Figure 3-8. Macromolecules in the cell cytoplasm. The drawing is approximately to scale and emphasizes the crowding in the cytoplasm. Only the macromolecules are shown: RNAs are shown in *blue,* ribosomes in *green,* and proteins in *red.* Macromolecules diffuse relatively slowly in the cytoplasm because they interact with many other macromolecules; small molecules, by contrast, diffuse nearly as rapidly as they do in water. (Adapted from D.S. Goodsell, *Trends in Biochem. Sci.*16:203-206, 1991.)

1

dissociation

A B $\xrightarrow{\text{dissociation}}$ A + B

dissociation rate = $\frac{\text{dissociation}}{\text{rate constant}}$ × $\frac{\text{concentration}}{\text{of AB}}$

dissociation rate = k_{off} [AB]

2

A + B $\xrightarrow{\text{association}}$ A B

association rate = $\frac{\text{association}}{\text{rate constant}}$ × $\frac{\text{concentration}}{\text{of A}}$ × $\frac{\text{concentration}}{\text{of B}}$

association rate = k_{on} [A] [B]

3

AT EQUILIBRIUM:

association rate = dissociation rate

k_{on} [A] [B] = k_{off} [AB]

$\frac{[AB]}{[A][B]} = \frac{k_{on}}{k_{off}}$ = K = equilibrium constant

EXAMPLE:

The concentration of a molecule present in only one copy in a typical mammalian cell (volume of 2000 μm³) is about 10^{-12}M.
If such a cell contains 10^4 copies of protein molecule A and 10^6 copies of protein molecule B,

[A] = 10^{-8} M and [B] = 10^{-6} M

Suppose that protein A binds to protein B with K = 10^7M⁻¹. The ratio of bound to unbound A will be [AB]/[A] and since

$\frac{[AB]}{[A]}$ = K[B] = $(10^7 \text{ M}^{-1})(10^{-6} \text{ M})$ = 10

we expect one molecule of A to be free for every 10 molecules of A that are bound to B inside the cell.

Repeating the calculation for K = 10^4M⁻¹ shows that only about one molecule of A in a hundred would be bound to B.

Figure 3-9. The principle of equilibrium. The equilibrium between molecules A and B and the complex AB is maintained by a balance between the two opposing reactions shown in (1) and (2). As shown in (3), the ratio of the rate constants for the association and the dissociation reactions is equal to the *equilibrium constant (K)* for the reaction. Molecules A and B must collide in order to react, and the rate in reaction (2) is therefore proportional to the product of their individual concentrations. As

a result, the product [A] x [B] appears in the final expression for *K*, where [ ] indicates concentration.As traditionally defined, the concentrations of products appear in the numerator and the concentrations of reactants appear in the denominator of the equation for an equilibrium constant. Thus the equilibrium constant in (3) is that for the *association* reaction A + B $\rightarrow$ AB. For simple binding interactions this constant is called the *affinity constant* or *association constant* (in units of liters per mole); the larger the value of the association constant (K_a), the stronger is the binding between A and B. The reciprocal of K_a is the *dissociation constant* (in units of moles per liter); the smaller the value of the dissociation constant (K_d), the stronger is the binding between A and B.

Table 3-3. The Relationship Between Free-Energy Differences and Equilibrium Constants

Equilibrium Constant $\dfrac{[AB]}{[A][B]} = K$ (liters/mole)	Free Energy of AB minus Free Energy of A + B (kcal/mole)
10^5	−7.1
10^4	−5.7
10^3	−4.3
10^2	−2.8
10	−1.4
1	0
10^{-1}	1.4
10^{-2}	2.8
10^{-3}	4.3
10^{-4}	5.7
10^{-5}	7.1

If the reaction A + B $\rightleftharpoons$ AB is allowed to come to equilibrium, the relative amounts of A, B, and AB will depend on the free-energy difference, ΔG°, between them. The above values are given for 37°C (310°K) and are calculated from the equation

$$\Delta G^\circ = - RT \ln \frac{[AB]}{[A][B]}$$

or

$$\frac{[AB]}{[A][B]} = e^{-\Delta G^\circ / RT} = e^{-\Delta G^\circ / 0.6138}$$

Here ΔG° is in kilocalories per mole and represents the free-energy difference under standard conditions (where all components are present at a concentration of 1.0 mole/liter); *T* is the temperature in kelvins (°K).

Similar principles apply to the even simpler case of a reaction A $\rightleftharpoons$ A′, where a molecule is interconvertible between two states A and A′ differing in free energy by an amount ΔG°. The quantities of molecules in the two states at equilibrium will be in the ratio

$$\frac{[A^*]}{[A]} = e^{-\Delta G^\circ / RT}$$

Thus, we see from this table that, if there is a favorable free-energy change of 4.3 kcal/mole for the transition A → A′, there will be 1000 times more molecules in state A′ than state A.

is a favorable free-energy change of 4.3 kcal/mole for the transition A → A', there will be 1000 times more molecules in state A' than state A.

Nucleic Acids 8

Genes Are Made of DNA 9

It has been obvious for as long as humans have sown crops or raised animals that each seed or fertilized egg must contain a hidden plan, or design, for the development of the organism. In modern times the science of genetics grew up around the premise of invisible information-containing elements, called genes, that are distributed to each daughter cell when a cell divides. Therefore, before dividing, a cell has to make a copy of its genes in order to give a complete set to each daughter cell. The genes in the sperm and egg cells carry the hereditary information from one generation to the next.

The inheritance of biological characteristics must involve patterns of atoms that follow the laws of physics and chemistry: in other words, genes must be formed from molecules. At first the nature of these molecules was hard to imagine. What kind of molecule could be stored in a cell and direct the activities of a developing organism and also be capable of accurate and almost unlimited replication?

By the end of the nineteenth century biologists had recognized that the carriers of inherited information were the *chromosomes* that become visible in the nucleus as a cell begins to divide. But the evidence that the deoxyribonucleic acid (DNA) in these chromosomes is the substance of which genes are made came only much later, from studies on bacteria. In 1944 it was shown that adding purified DNA from one strain of bacteria to a second, slightly different bacterial strain conferred heritable properties characteristic of the first strain upon the second. Because it had been commonly believed that only proteins have enough conformational complexity to carry genetic information, this discovery came as a surprise, and it was not generally accepted until the early 1950s. Today the idea that DNA carries genetic information in its long chain of nucleotides is so fundamental to biological thought that it is sometimes difficult to realize the enormous intellectual gap that it filled.

DNA Molecules Consist of Two Long Chains Held Together by Complementary Base Pairs 10

The difficulty that geneticists had in accepting DNA as the substance of genes is understandable, considering the simplicity of its chemistry. A DNA chain is a long, unbranched polymer composed of only four types of subunits. These are the deoxyribonucleotides containing the bases adenine (A), cytosine (C), guanine (G), and thymine (T). The nucleotides are linked together by covalent phospho-diester bonds that join the 5' carbon of one deoxyribose group to the 3' carbon of the next (see Panel 2-6, pp. 58-59). The four kinds of bases are attached to this repetitive sugar-phosphate chain almost like four kinds of beads strung on a necklace.

How can a long chain of nucleotides encode the instructions for an organism or even a cell? And how can these messages be copied from one generation of cells to the next? The answers lie in the structure of the DNA molecule.

Early in the 1950s x-ray diffraction analyses of specimens of DNA pulled into fibers suggested that the DNA molecule is a helical polymer composed of two strands. The helical structure of DNA was not surprising since, as we have seen, a helix will often form if each of the neighboring subunits in a polymer is regularly oriented. But the finding that DNA is two-stranded was of crucial significance. It provided the clue that led, in 1953, to the construction of a model that fitted the observed x-ray diffraction pattern and thereby solved the puzzle of DNA structure and function.

An essential feature of the model was that all of the bases of the DNA molecule are on the *inside* of the double helix, with the sugar phosphates on the outside. This demands that the bases on one strand be extremely close to those on the other, and the fit proposed required specific *base-pairing* between a large purine base (A or G, each of which has a double ring) on one chain and a smaller pyrimidine base (T or C, each of which has a single ring) on the other chain (Figure 3-10).

Both evidence from earlier biochemical experiments and conclusions derived from model building suggested that complementary base pairs (also called *Watson-Crick base pairs*) form between A and T and between G and C. Biochemical analyses of DNA preparations from different species had shown that, although the nucleotide composition of DNA varies a great deal (for example, from 13% A residues to 36% A residues in the DNA of different types of bacteria), there is a general rule that quantitatively [G] = [C] and [A] = [T]. Model building revealed that the numbers of effective hydrogen bonds that

could be formed between G and C or between A and T were greater than for any other combinations (see Panel 3-2, pp. 100-101). The double-helical model for DNA thus neatly explained the quantitative biochemistry.

The Structure of DNA Provides an Explanation for Heredity [11]

A gene carries biological information in a form that must be precisely copied and transmitted from each cell to all of its progeny. The implications of the discovery of the DNA double helix were profound because the structure immediately suggested how information transfer could be accomplished. Since each strand contains a nucleotide sequence that is exactly complementary to the nucleotide sequence of its partner strand, both strands actually carry the same genetic information. If we designate the two strands A and A', strand A can serve as a mold or *template* for making a new strand A', while strand A' can serve in the same way to make a new strand A. Thus genetic information can be copied by a process in which strand A separates from strand A' and each separated strand then serves as a template for the production of a new complementary partner strand.

As a direct consequence of the base-pairing mechanism, it becomes evident that DNA carries information by means of the linear sequence of its nucleotides. Each nucleotide - A, C, T, or G - can be considered a letter in a four-letter alphabet that is used to write out biological messages in a linear "ticker-tape" form. Organisms differ because their respective DNA molecules carry different nucleotide sequences and therefore different biological messages.

Since the number of possible sequences in a DNA chain n nucleotides long is 4^n, the biological variety that could in principle be generated using even a modest length of DNA is enormous. A typical animal cell contains a meter of DNA (3×10^9 nucleotides). Written in a linear abet of four letters, an unusually small human gene would occupy a quarter of a page of text (Figure 3-11), while the genetic information carried in a human cell would fill a book of more than 500,000 pages.

Although the principle underlying gene replication is both elegant and simple, the actual machinery by which this copying is carried out in the cell is complicated and involves a complex of proteins that form a "replication machine." The fundamental reaction is that shown in Figure 3-12, in which the enzyme *DNA polymerase* catalyzes the addition of a deoxyribonucleotide to the 3' end of a DNA chain. Each nucleotide added to the chain is a *deoxyribonucleoside triphosphate;* the release of pyrophosphate from this activated nucleotide and its subsequent hydrolysis provide the energy for the DNA replication reaction and make it effectively irreversible.

Replication of the DNA helix begins with the local separation of its two complementary DNA strands. Each strand then acts as a template for the formation of a new DNA molecule by the sequential addition of deoxyribonucleoside triphosphates. The nucleotide to be added at each step is selected by a process that requires it to form a complementary base pair with the next nucleotide in the parental template strand, thereby generating a new DNA strand that is complementary in sequence to the template strand (see Figure 3-12). Eventually, the genetic information is duplicated in its entirety, so that two complete DNA double helices are formed, each identical in nucleotide sequence to the parental DNA helix that served as the template. Since each daughter DNA molecule ends up with one of the original strands plus one newly synthesized strand, the mechanism of DNA replication is said to be *semiconservative* (Figure 3-13).

Errors in DNA Replication Cause Mutations [12]

One of the most impressive features of DNA replication is its accuracy. Several proofreading mechanisms are used to eliminate incorrectly positioned nucleotides; as a result, the sequence of nucleotides in a DNA molecule is copied with fewer than one mistake in 10^9 nucleotides added. Very rarely, however, the replication machinery skips or adds a few nucleotides, or puts a T where it should have put a C, or an A instead of a G. Any change of this kind in the DNA sequence constitutes a genetic mistake, called a mutation, which will be copied in all future cell generations since "wrong" DNA sequences are copied as faithfully as "correct" ones. The consequence of such an error can be great, for even a single nucleotide change can have important effects on the cell, depending on where the mutation has occurred.

Geneticists demonstrated conclusively in the early 1940s that genes specify the structure of individual proteins. Thus a mutation in a gene, caused by an alteration in its DNA sequence, may lead to the inactivation of a crucial protein and result in cell death, in which case the mutation will be lost. On the other hand, a mutation may be *silent* and not affect the function of the protein. Very rarely, a mutation will create a gene with an improved or novel useful function. In this case organisms carrying the mutation will have an advantage, and the mutated gene may eventually replace the original gene in the population through natural selection.

The Nucleotide Sequence of a Gene Determines the Amino Acid Sequence of a Protein 13

DNA is relatively inert chemically. The information it contains is expressed indirectly via other molecules: DNA directs the synthesis of specific RNA and protein molecules, which in turn determine the cell's chemical and physical properties.

At about the time that biophysicists were analyzing the three-dimensional structure of DNA by x-ray diffraction, biochemists were intensively studying the chemical structure of proteins. It was already known that proteins are chains of amino acids joined together by sequential peptide linkages; but it was only in the early 1950s, when the small protein *insulin* was sequenced (Figure 3-14), that it was discovered that each type of protein consists of a unique sequence of amino acids. Just as solving the structure of DNA was seminal in understanding the molecular basis of genetics and heredity, so sequencing insulin provided a key to understanding the structure and function of proteins. If insulin had a definite, genetically determined sequence, then presumably so did every other protein. It seemed reasonable to suppose, moreover, that the properties of a protein would depend on the precise order in which its constituent amino acids are arranged.

Both DNA and protein are composed of a linear sequence of subunits; eventually, the analysis of the proteins made by mutant genes demonstrated that the two sequences are *co-linear* - that is, the nucleotides in DNA are arranged in an order corresponding to the order of the amino acids in the protein they specify. It became evident that the DNA sequence contains a coded specification of the protein sequence. The central question in molecular biology then became how a cell translates a nucleotide sequence in DNA into an amino acid sequence in a protein.

Portions of DNA Sequence Are Copied into RNA Molecules That Guide Protein Synthesis 14

The synthesis of proteins involves copying specific regions of DNA (the *genes*) into polynucleotides of a chemically and functionally different type known as ribonucleic acid, or RNA. RNA, like DNA, is composed of a linear sequence of nucleotides, but it has two small chemical differences: (1) the sugar-phosphate backbone of RNA contains ribose instead of a deoxyribose sugar and (2) the base thymine (T) is replaced by uracil (U), a very closely related base that likewise pairs with A (see Panel 3-2, pp. 100-101).

RNA retains all of the information of the DNA sequence from which it was copied, as well as the base-pairing properties of DNA. Molecules of RNA are synthesized by a process known as DNA transcription, which is similar to DNA replication in that one of the two strands of DNA acts as a template on which the base-pairing abilities of incoming nucleotides are tested. When a good match is achieved with the DNA template, a ribonucleotide is incorporated as a covalently bonded unit. In this way the growing RNA chain is elongated one nucleotide at a time.

DNA transcription differs from DNA replication in a number of ways. The RNA product, for example, does not remain as a strand annealed to DNA. Just behind the region where the ribonucleotides are being added, the original DNA helix re-forms and releases the RNA chain. Thus RNA molecules are single-stranded. Moreover, RNA molecules are relatively short compared to DNA molecules since they are copied from a limited region of the DNA - enough to make one or a few proteins (Figure 3-15). RNA transcripts that direct the synthesis of protein molecules are called messenger RNA (mRNA) molecules, while other RNA transcripts serve as *transfer RNAs (tRNAs)* or form the RNA components of ribosomes (rRNA) or smaller ribonucleoprotein particles.

The amount of RNA made from a particular region of DNA is controlled by *gene regulatory proteins* that bind to specific sites on DNA close to the coding sequences of a gene. In any cell at any given time, some genes are used to make RNA in very large quantities while other genes are not transcribed at all. For an active gene thousands of RNA transcripts can be made from the same DNA segment in each cell generation. Because each mRNA molecule can be translated into many thousands of copies of a polypeptide chain, the information contained in a small region of DNA can direct the synthesis of millions of copies of a specific protein. The protein *fibroin,* for example, is the major component of silk. In each silk gland cell a single fibroin gene makes 10^4 copies of mRNA, each of which directs the synthesis of 10^5 molecules of fibroin - producing a total of 10^9 molecules of fibroin in just 4 days.

Eucaryotic RNA Molecules Are Spliced to Remove Intron Sequences 15

In bacterial cells most proteins are encoded by a single uninterrupted stretch of DNA sequence that is copied without alteration to produce an mRNA molecule. In 1977 molecular biologists were astonished by the discovery that most eucaryotic genes have

their coding sequences (called *exons*) interrupted by noncoding sequences (called *introns*). To produce a protein, the entire length of the gene, including both its introns and its exons, is first transcribed into a very large RNA molecule - the *primary transcript.* Before this RNA molecule leaves the nucleus, a complex of RNA-processing enzymes removes all of the intron sequences, thereby producing a much shorter RNA molecule. After this RNA-processing step, called RNA splicing, has been completed, the RNA molecule moves to the cytoplasm as an mRNA molecule that directs the synthesis of a particular protein (see Figure 3-15).

This seemingly wasteful mode of information transfer in eucaryotes is presumed to have evolved because it makes protein synthesis much more versatile. The primary RNA transcripts of some genes, for example, can be spliced in various ways to produce different mRNAs, depending on the cell type or stage of development. This allows different proteins to be produced from the same gene. Moreover, because the presence of numerous introns facilitates genetic recombination events between exons, this type of gene arrangement is likely to have been profoundly important in the early evolutionary history of genes, speeding up the process whereby organisms evolve new proteins from parts of preexisting ones instead of evolving totally new amino acid sequences.

Sequences of Nucleotides in mRNA Are "Read" in Sets of Three and Translated into Amino Acids 16

The rules by which the nucleotide sequence of a gene is translated into the amino acid sequence of a protein, the so-called genetic code, were deciphered in the early 1960s. The sequence of nucleotides in the mRNA molecule that acts as an intermediate was found to be read in serial order in groups of three. Each triplet of nucleotides, called a codon, specifies one amino acid. Since RNA is a linear polymer of four different nucleotides, there are $4^3 = 64$ possible codon triplets (remember that it is the *sequence* of nucleotides in the triplet that is important). However, only 20 different amino acids are commonly found in proteins, so that most amino acids are specified by several codons; that is, the genetic code is *degenerate.* The code (shown in Figure 3-16) has been highly conserved during evolution: with a few minor exceptions, it is the same in organisms as diverse as bacteria, plants, and humans.

In principle, each RNA sequence can be translated in any one of three different *reading frames* depending on where the decoding process begins (Figure 3-17). In almost every case only one of these reading frames will produce a functional protein. Since there are no punctuation signals except at the beginning and end of the RNA message, the reading frame is set at the initiation of the translation process and is maintained thereafter.

tRNA Molecules Match Amino Acids to Groups of Nucleotides 17

The codons in an mRNA molecule do not directly recognize the amino acids they specify in the way that an enzyme recognizes a substrate. The translation of mRNA into protein depends on "adaptor" molecules that recognize both an amino acid and a group of three nucleotides. These adaptors consist of a set of small RNA molecules known as transfer RNAs (tRNAs), each about 80 nucleotides in length.

A tRNA molecule has a folded three-dimensional conformation that is held together in part by noncovalent base-pairing interactions like those that hold together the two strands of the DNA helix. In the single-stranded tRNA molecule, however, the complementary base pairs form between nucleotide residues in the *same* chain, which causes the tRNA molecule to fold up in a unique way that is important for its function as an adaptor. Four short segments of the molecule contain a double-helical structure, producing a molecule that looks like a "cloverleaf" in two dimensions. This cloverleaf is in turn further compacted into a highly folded, L-shaped conformation that is held together by more complex hydrogen-bonding interactions (Figure 3-18). Two sets of unpaired nucleotide residues at either end of the "L" are especially important for the function of the tRNA molecule in protein synthesis: one forms the *anticodon* that base-pairs to a complementary triplet in an mRNA molecule (the codon), while the *CCA sequence* at the 3' end of the molecule is attached covalently to a specific amino acid (see Figure 3-18A).

The RNA Message Is Read from One End to the Other by a Ribosome 18

The codon recognition process by which genetic information is transferred from mRNA via tRNA to protein depends on the same type of base-pair interactions that mediate the transfer of genetic information from DNA to DNA and from DNA to RNA (Figure 3-19). But the mechanics of ordering the tRNA molecules on the mRNA are complicated and require a ribosome, a complex of more than 50 different proteins associated with several structural RNA molecules (rRNAs). Each ribosome is a large protein-synthesizing machine on which tRNA molecules position themselves so as to read the genetic message encoded in an mRNA molecule. The ribosome first finds a specific start site on the mRNA that sets the reading frame and determines the

amino-terminal end of the protein. Then, as the ribosome moves along the mRNA molecule, it translates the nucleotide sequence into an amino acid sequence one codon at a time, using tRNA molecules to add amino acids to the growing end of the polypeptide chain (Figure 3-20). When a ribosome reaches the end of the message, both it and the freshly made carboxyl end of the protein are released from the 3' end of the mRNA molecule into the cytoplasm.

Ribosomes operate with remarkable efficiency: in one second a single bacterial ribosome adds about 20 amino acids to a growing polypeptide chain. Ribosome structure and the mechanism of protein synthesis are discussed in Chapter 6.

Some RNA Molecules Function as Catalysts 19

RNA molecules have commonly been viewed as strings of nucleotides with a relatively uninteresting chemistry. In 1981 this view was shattered by the discovery of a catalytic RNA molecule with the type of sophisticated chemical reactivity that biochemists had previously associated only with proteins. The ribosomal RNA molecules of the ciliated protozoan *Tetrahymena* are initially synthesized as a large precursor from which one of the rRNAs is produced by an RNA-splicing reaction. The surprise came with the discovery that this splicing can occur *in vitro* in the absence of protein. It was subsequently shown that the intron sequence itself has an enzymelike catalytic activity that carries out the two-step reaction illustrated in Figure 3-21. The 400-nucleotide-long intron sequence was then synthesized in a test tube and shown to fold up to form a complex surface that can function like an enzyme in reactions with other RNA molecules. For example, it can bind two specific substrates tightly - a guanine nucleotide and an RNA chain - and catalyze their covalent attachment so as to sever the RNA chain at a specific site (Figure 3-22).

In this model reaction, which mimics the first step in Figure 3-21, the same intron sequence acts repeatedly to cut many RNA chains. Although RNA splicing is most commonly achieved by means that are not autocatalytic (discussed in Chapter 8), self-splicing RNAs with intron sequences related to that in *Tetrahymena* have been discovered in other types of cells, including fungi and bacteria. This suggests that these RNA sequences may have arisen before the eucaryotic and procaryotic lineages diverged about 1.5 billion years ago.

Several other families of catalytic RNAs have recently been discovered. Most tRNAs, for example, are initially synthesized as a larger precursor RNA, and an RNA molecule has been shown to play the major catalytic role in an RNA-protein complex that recognizes these precursors and cleaves them at specific sites. A catalytic RNA sequence also plays an important part in the life cycle of many plant viroids. Most remarkably, ribosomes are now suspected to function largely by RNA-based catalysis, with the ribosomal proteins playing a supporting role to the ribosomal RNAs (rRNAs), which make up more than half the mass of the ribosome. The large rRNA by itself, for example, has peptidyl transferase activity and will catalyze the formation of new peptide bonds (Figure 3-23).

How is it possible for an RNA molecule to act like an enzyme? The example of tRNA indicates that RNA molecules can fold up in highly specific ways. A proposed three-dimensional structure for the core of the self-splicing *Tetrahymena* intron sequence is shown in Figure 3-24. Interactions between different parts of this RNA molecule (analogous to the unusual hydrogen bonds in tRNA molecules - see Figure 3-18) are responsible for folding it to create a complex three-dimensional surface with catalytic activity. An unusual juxtaposition of atoms presumably strains covalent bonds and thereby makes selected atoms in the folded RNA chain unusually reactive.

As explained in Chapter 1, the discovery of catalytic RNA molecules has profoundly changed our views of how the first living cells arose.

Summary

Genetic information is carried in the linear sequence of nucleotides in DNA. Each molecule of DNA is a double helix formed from two complementary strands of nucleotides held together by hydrogen bonds between G-C and A-T base pairs. Duplication of the genetic information occurs by the polymerization of a new complementary strand onto each of the old strands of the double helix during DNA replication.

The expression of the genetic information stored in DNA involves the translation of a linear sequence of nucleotides into a co-linear sequence of amino acids in proteins. A limited segment of DNA is first copied into a complementary strand of RNA. This primary RNA transcript is spliced to remove intron sequences, producing an mRNA molecule. Finally, the mRNA is translated

into protein in a complex set of reactions that occur on a ribosome. The amino acids used for protein synthesis are first attached to a family of tRNA molecules, each of which recognizes, by complementary base-pairing interactions, particular sets of three nucleotides in the mRNA (codons). The sequence of nucleotides in the mRNA is then read from one end to the other in sets of three, according to a universal genetic code.

Other RNA molecules in cells function as enzymelike catalysts. These RNA molecules fold up to create a surface containing nucleotides that have become unusually reactive. One of these catalysts is the large rRNA of the ribosome, which catalyzes the formation of peptide bonds during protein synthesis.
Figure 3-10. The DNA double helix. (A) A short section of the helix viewed from its side. Four complementary base pairs are shown. The bases are shown in *green,* while the deoxyribose sugars are *blue.* (B) The helix viewed from an end. Note that the two DNA strands run in opposite directions and that each base pair is held together by either two or three hydrogen bonds (see also Panel 3-2, pp. 100-101).

Panel 3-2: DNA and RNA structures

DNA AND RNA

The structure of RNA is shown in this half of the panel, while the structure of DNA is shown in the other half. Both DNA and RNA are linear polymers of nucleotides (see Panel 2–6, pp. 58–59). RNA differs from DNA in three ways:

1. the sugar phosphate backbone contains ribose rather than deoxyribose

2. it contains the base uracil (U) instead of thymine (T)

3. it exists as a single strand rather than a double-stranded helix

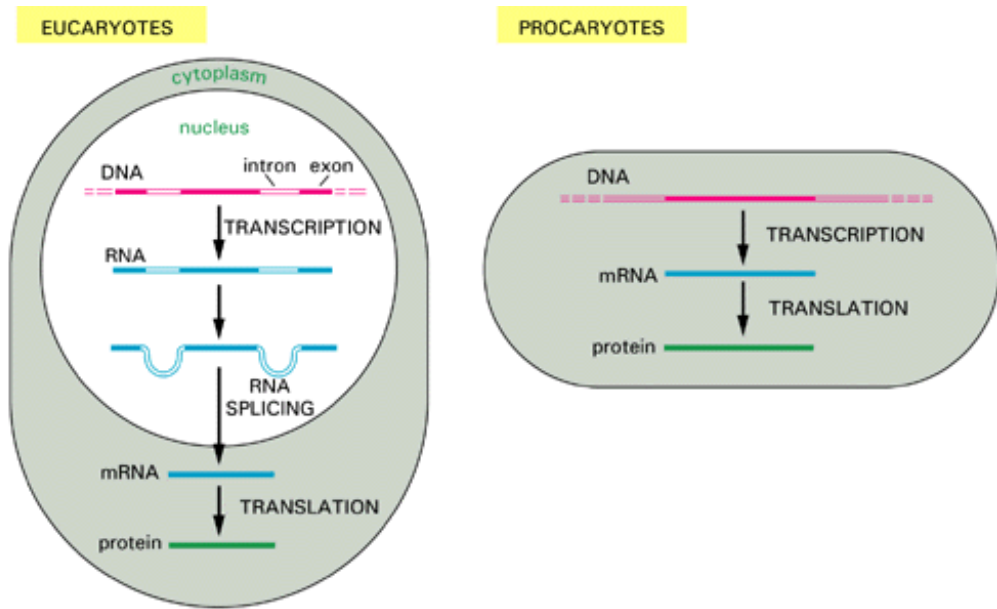
Figure 3-11. The DNA sequence of the human b-globin gene. The gene encodes one of the two subunits of the hemoglobin molecule, which carries oxygen in the blood. Only one of the two DNA strands is shown (the "coding strand"), since the other strand has a precisely complementary sequence. The sequence should be read from left to right in successive lines down the page, as if it were normal English text.
Figure 3-12. DNA synthesis. The addition of a deoxyribonucleotide to the 3' end of a polynucleotide chain is the fundamental reaction by which DNA is synthesized. As shown, base-pairing between this incoming deoxyribonucleotide and an existing strand of DNA (the *template* strand) guides the formation of a new strand of DNA with a complementary nucleotide sequence.
Figure 3-13. The semiconservative replication of DNA. In each round of replication each of the two strands of DNA is used as a template for the formation of a complementary DNA strand. The original strands therefore remain intact through many cell generations.
Figure 3-14. The amino acid sequence of bovine insulin. Insulin is a very small protein that consists of two polypeptide chains, one 21 and the other 30 amino acid residues long. Each chain has a unique, genetically determined sequence of amino acids. The one-letter symbols used to specify amino acids are those listed in Panel 2-5, pages 56-57; the SS bonds shown in *red* are disulfide bonds between cysteine residues. The protein is made initially as a single long polypeptide chain (encoded by a single gene) that is subsequently cleaved to give the two chains.


Figure 3-15. The transfer of information from DNA to protein. The transfer proceeds by means of an RNA intermediate called messenger RNA (mRNA). In procaryotic cells the process is simpler than in eucaryotic cells. In eucaryotes the coding regions of the DNA (in the *exons,* shown in color) are separated by noncoding regions (the *introns*). As indicated, these introns must be removed by an enzymatically catalyzed RNA-splicing reaction to form the mRNA.

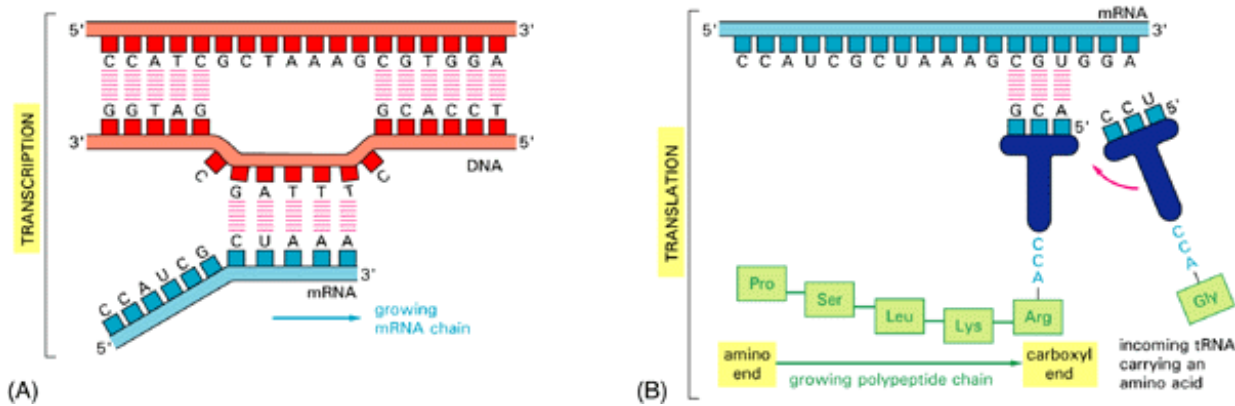
Figure 3-16. The genetic code. Sets of three nucleotides (*codons*) in an mRNA molecule are translated into amino acids in the course of protein synthesis according to the rules shown. The codons GUG and GAG, for example, are translated into valine and glutamic acid, respectively. Note that those codons with U or C as the second nucleotide tend to specify the more hydrophobic amino acids (compare with Panel 2-5, pp. 56-57).
Figure 3-17. The three possible reading frames in protein synthesis. In the process of translating a nucleotide sequence (*blue*) into an amino acid sequence (*green*), the sequence of nucleotides in an mRNA molecule is read from the 5' to the 3' end in sequential sets of three nucleotides. In principle, therefore, the same RNA sequence can specify three completely different amino acid sequences, depending on the "reading frame."
Figure 3-18. Phenylalanine tRNA of yeast. (A) The molecule is drawn with a cloverleaf shape to show the complementary base-pairing (*short gray bars*) that occurs in the helical regions of the molecule. (B) The actual shape of the molecule, based on x-ray diffraction analysis, is shown schematically. Complementary base pairs are indicated as *long gray bars.* In addition, the nucleotides involved in unusual base-pair interactions that hold different parts of the molecule together are colored *red* and are connected by a *red line* in both (A) and (B). The pairs are numbered in (B). (C) One of the unusual base-pair interactions. Here one base forms hydrogen-bond interactions with two others; several such "base triples" help fold up this tRNA molecule.


Figure 3-19. Information flow in protein synthesis. (A) The nucleo-tides in an mRNA molecule are joined together to form a complementary copy of a segment of one strand of DNA. (B) They are then matched three at a time to complementary sets of three nucleotides in the anticodon regions of tRNA molecules. At the other end of each type of tRNA molecule, a specific amino acid is held in a high-energy linkage, and when matching occurs, this amino acid is added to the end of the growing polypeptide chain. Thus translation of the mRNA nucleotide sequence into an amino acid sequence depends on complementary base-pairing between codons in the mRNA and corresponding tRNA anticodons. The molecular basis of information transfer in translation is therefore very similar to that in DNA replication and transcription. Note that the mRNA is both synthesized and translated starting from its 5' end.
Figure 3-20. Synthesis of a protein by ribosomes attached to an mRNA molecule. Ribosomes become attached to a start signal near the 5' end of the mRNA molecule and then move toward the 3' end, synthesizing protein as they go. A single mRNA will usually have a number of ribosomes traveling along it at the same time, each making a separate but identical polypeptide chain; the entire structure is known as a *polyribosome*.
Figure 3-21. A self-splicing RNA molecule. The diagram shows the self-splicing reaction in which an intron sequence catalyzes its own excision from a *Tetrahymena* ribosomal RNA molecule. As shown, the reaction is initiated when a G nucleotide is added to the intron sequence, cleaving the RNA chain in the process; the newly created 3' end of the RNA chain then attacks the other side of the intron to complete the reaction.
Figure 3-22. An enzymelike reaction catalyzed by the purified *Tetrahymena* intron sequence. In this reaction, which corresponds to the first step in Figure 3-21, both a specific substrate RNA molecule and a G nucleotide become tightly bound to the surface of the catalytic RNA molecule. The nucleotide is then covalently attached to the substrate RNA molecule, cleaving it at a specific site. The release of the resulting two RNA chains frees the intron sequence for further cycles of reaction.
Figure 3-23. A peptidyl transferase reaction catalyzed by a deproteinized ribosomal RNA molecule. The puromycin molecule mimics a tRNA charged with the amino acid tyrosine, and it acts as a powerful inhibitor of protein synthesis in cells by adding to the growing end of a polypeptide chain on a ribosome. In this model reaction the growing polypeptide chain end is mimicked by a hexanucleotide (*red*, representing a tRNA) that is covalently linked to N-formyl methionine (representing the polypeptide). A highly purified large rRNA molecule catalyzes the addition of the puromycin to the N-formyl methionine, forming a new peptide bond and releasing the hexanucleotide.
Figure 3-24. A three-dimensional view of the catalytic core of the type of intron RNA sequence illustrated in Figures 3-21 and 3-22. (A) The folded molecule, with hydrogen-bond interactions shown in *red*. This molecule, which is about 240 nucleotides long, is shown immediately after the initial cut at the 5' side of the intron (*yellow*). (B) Schematic of the molecule in (A) in its unfolded form. (Adapted from L. Jaeger, E. Westhof, and F. Michel, *J. Mol. Biol.* 221:1153-1164, 1991.)

Protein Structure <u>20</u>

Introduction

To a large extent, cells are made of protein, which constitutes more than half of their dry weight (see <u>Table 3-1</u>). Proteins determine the shape and structure of the cell and also serve as the main instruments of molecular recognition and catalysis. Although DNA stores the information required to make a cell, it has little direct influence on cellular processes. The gene for hemoglobin, for example, cannot carry oxygen; that is a property of the protein specified by the gene.

DNA and RNA are chains of nucleotides that are chemically very similar to one another. In contrast, proteins are made from an assortment of 20 very different amino acids, each with a distinct chemical personality (see <u>Panel 2-5</u>, pp. 56-57). This variety allows for enormous versatility in the chemical properties of different proteins, and it presumably explains why evolution eventually selected proteins rather than RNA molecules to catalyze most cellular reactions.

The Shape of a Protein Molecule Is Determined by Its Amino Acid Sequence <u>21</u>

Many of the bonds in a long polypeptide chain allow free rotation of the atoms they join, giving the protein backbone great flexibility. In principle, then, any protein molecule could adopt an almost unlimited number of shapes (*conformations*). Most polypeptide chains, however, fold into only one particular conformation determined by their amino acid sequence. This is because the backbones and side chains of the amino acids associate with one another and with water to form various weak noncovalent bonds (see <u>Panel 3-1</u>, pp. 92-93). Provided that the appropriate side chains are present at crucial positions in the chain, large forces are developed that make one particular conformation especially stable.

Most proteins can fold spontaneously into their correct shape. By treatment with certain solvents, a protein can be unfolded, or *denatured,* to give a flexible polypeptide chain that has lost its native conformation. When the denaturing solvent is removed, the protein will usually refold spontaneously into its original conformation, indicating that all the information necessary to specify the shape of a protein is contained in the amino acid sequence itself.

One of the most important factors governing the folding of a protein is the distribution of its polar and nonpolar side chains. The many hydrophobic side chains in a protein tend to be pushed together in the interior of the molecule, which enables them to avoid contact with the aqueous environment (just as oil droplets coalesce after being mechanically dispersed in water). By contrast, the polar side chains tend to arrange themselves near the outside of the protein molecule, where they can interact with water and with other polar molecules (<u>Figure 3-25</u>). Since the peptide bonds are themselves polar, they tend to interact both with one another and with polar side chains to form hydrogen bonds (<u>Figure 3-26</u>); nearly all polar residues buried within the protein are paired in this way (<u>Figure 3-27</u>). Hydrogen bonds thus play a major part in holding together different regions of polypeptide chain in a folded protein molecule. They are also crucially important for many of the binding interactions that occur on protein surfaces.

Secreted or cell-surface proteins often form additional *covalent* intrachain bonds. Most notably, the formation of disulfide bonds (also called S-S bonds) between the two -SH groups of neighboring cysteine residues in a folded polypeptide chain (<u>Figure 3-28</u>) often serves to stabilize the three-dimensional structure of extracellular proteins. These bonds are not required for the specific folding of proteins, since folding occurs normally in the presence of reducing agents that prevent S-S bond formation. In fact, S-S bonds are rarely, if ever, formed in protein molecules in the cytosol because the high cytosolic concentration of -SH reducing agents breaks such bonds.

The net result of all the individual amino acid interactions is that most protein molecules fold up spontaneously into precisely defined conformations. Those that are compact and globular have an inner core composed of clustered hydrophobic side chains - packed into a tight, nearly crystalline arrangement - while a very complex and irregular exterior surface is formed by the more polar side chains. The positioning and chemistry of the different atoms on this intricate surface make each protein unique and enable it to bind specifically to other macromolecular surfaces and to certain small molecules (discussed below). > From both a chemical and a structural standpoint, proteins are the most sophisticated molecules known.

Common Folding Patterns Recur in Different Protein Chains <u>22</u>

Although all the information required for the folding of a protein chain is contained in its amino acid sequence, we have not yet learned how to "read" this information so as to predict the detailed three-dimensional structure of a protein whose sequence is known. Consequently, the folded conformation can be determined only by an elaborate *x-ray diffraction analysis* performed on crystals of the protein or, if the protein is very small, by nuclear magnetic resonance techniques (see Chapter 4). So far, more than 100 types of protein folds have been discovered by this technique. Each protein has a specific conformation so intricate and irregular that it would require a chapter to describe it in full three-dimensional detail.

When the three-dimensional structures of different protein molecules are compared, it becomes clear that, although the overall conformation of each protein is unique, several structural patterns recur repeatedly in parts of these macromolecules. Two patterns are particularly common because they result from regular hydrogen-bonding interactions between the peptide bonds themselves rather than between the side chains of particular amino acids. Both patterns were correctly predicted in 1951 from model-building studies based on the different x-ray diffraction patterns of silk and hair. The two regular patterns discovered are now known as the *b sheet,* which occurs in the protein fibroin, found in silk, and the *a helix,* which occurs in the protein a-keratin, found in skin and its appendages, such as hair, nails, and feathers.

The core of most (but not all) globular proteins contains extensive regions of b sheet. In the example illustrated in Figure 3-29, which shows part of an antibody molecule, an *antiparallel b sheet* is formed when an extended polypeptide chain folds back and forth upon itself, with each section of the chain running in the direction opposite to that of its immediate neighbors. This gives a very rigid structure held together by hydrogen bonds that connect the peptide bonds in neighboring chains. The antiparallel b sheet and the closely related *parallel b sheet* (which is formed by regions of polypeptide chain that run in the same direction) frequently serve as the framework around which globular proteins are constructed.

An a helix is generated when a single polypeptide chain turns regularly about itself to make a rigid cylinder in which each peptide bond is regularly hydrogen-bonded to other peptide bonds nearby in the chain. Many globular proteins contain short regions of such a helices (Figure 3-30), and those portions of a transmembrane protein that cross the lipid bilayer are usually a helices because of the constraints imposed by the hydrophobic lipid environment (discussed in Chapter 10).

In aqueous environments an isolated a helix is usually not stable on its own. Two identical a helices that have a repeating arrangement of nonpolar side chains, however, will twist around each other gradually to form a particularly stable structure known as a *coiled-coil* (see p. 125). Long rodlike coiled-coils are found in many fibrous proteins, such as the intracellular a-keratin fibers that reinforce skin and its appendages.

Space-filling representations of an a helix and a b sheet from actual proteins are shown with and without their side chains in Figure 3-31.

Proteins Are Amazingly Versatile Molecules 23

Because of the variety of their amino acid side chains, proteins are remarkably versatile with respect to the types of structures they can form. Contrast, for example, two abundant proteins secreted by cells in connective tissue - collagen and elastin - both present in the extracellular matrix. In collagen molecules three separate polypeptide chains, each rich in the amino acid proline and containing the amino acid glycine at every third residue, are wound around one another to generate a regular triple helix. These collagen molecules are packed together into fibrils in which adjacent molecules are tied together by covalent cross-links between neighboring lysine residues, giving the fibril enormous tensile strength (Figure 3-32).

Elastin is at the opposite extreme. Its relatively loose and unstructured polypeptide chains are cross-linked covalently to generate a rubberlike elastic meshwork that enables tissues such as arteries and lungs to deform and stretch without damage. As illustrated in Figure 3-32, the elasticity is due to the ability of individual protein molecules to uncoil reversibly whenever a stretching force is applied.

It is remarkable that the same basic chemical structure - a chain of amino acids - can form so many different structures: a rubberlike elastic meshwork (elastin), an inextensible cable with the tensile strength of steel (collagen), or any of the wide variety of catalytic surfaces on the globular proteins that function as enzymes. Figure 3-33 illustrates and compares the range of shapes that could, in theory, be adopted by a polypeptide chain 300 amino acids long. As we have already emphasized, the conformation actually adopted depends on the amino acid sequence.

Proteins Have Different Levels of Structural Organization 24

In describing the structure of a protein, it is helpful to distinguish various levels of organization. The amino acid sequence is called the primary structure of the protein. Regular hydrogen-bond interactions within contiguous stretches of polypeptide chain give rise to a helices and b sheets, which constitute the protein's secondary structure. Certain combinations of a helices and b sheets pack together to form compactly folded globular units, each of which is called a protein domain. Domains are usually constructed from a section of polypeptide chain that contains between 50 and 350 amino acids, and they seem to be the modular units from which proteins are constructed (see below). While small proteins may contain only a single domain, larger proteins contain a number of domains, which are often connected by relatively open lengths of polypeptide chain. Finally, individual polypeptides often serve as subunits for the formation of larger molecules, sometimes called *protein assemblies* or *protein complexes,* in which the subunits are bound to one another by a large number of weak, noncovalent interactions; in extracellular proteins these interactions are often stabilized by disulfide bonds.

The three-dimensional structure of a protein can be illustrated in various ways. Consider the unusually small protein basic pancreatic trypsin inhibitor (BPTI), which contains 58 amino acid residues folded into one domain. BPTI can be shown as a stereo pair displaying all of its nonhydrogen atoms (Figure 3-34A) or as an accurate space-filling model, where most of the details are obscured (Figure 3-34B). Alternatively, it can be shown more schematically, with all of the side chains and actual atoms omitted so that it is easier to follow the course of the main polypeptide chain (Figures 3-34C, D, and E). An average-size protein contains about six times more amino acid residues than BPTI, and many proteins are more than 20 times its size. Schematic drawings are essential for displaying the structure of these larger proteins, and we use them throughout this text.

Figure 3-35 shows how the structure of a large protein can be resolved into several levels of organization, each level constructed from the one below it in a hierarchical fashion. These levels of increased organizational complexity may correspond to the steps by which a newly synthesized protein folds into its final native structure inside the cell.

Domains Are Formed from a Polypeptide Chain That Winds Back and Forth, Making Sharp Turns at the Protein Surface 24

A protein domain can be viewed as the basic structural unit of a protein structure. The core of each domain is largely composed of a set of interconnected b sheets or a helices or both. These regular secondary structures are favored because they permit an extensive hydrogen bonding between the backbone atoms, which is essential for stabilizing the interior of the domain, where water is not available to form hydrogen bonds with the polar carbonyl oxygen or amide hydrogen of the peptide bond.

Because there are only a limited number of ways of combining a helices and b sheets to make a globular structure, certain combinations of these elements, called motifs, occur repeatedly in the core of many unrelated proteins. One example is the *hairpin beta motif* found in BPTI (colored *green* in Figure 3-34D), which consists of two antiparallel b strands joined by a sharp turn formed by a loop of polypeptide chain. Another example is the *beta-alpha-beta motif,* in which two adjacent parallel b strands are connected by a length of a helix (Figure 3-36). Several other common motifs are discussed in Chapter 9, where we consider the various DNA-binding motifs found in several families of gene regulatory proteins.

Various combinations of motifs form the protein domain itself, in which the polypeptide chain tends to wind its way back and forth across the entire structure, either as a b sheet or an a helix, reversing direction suddenly by making a tight turn when it reaches the surface of the domain. As a result, a typical domain is a compact structure whose surface is covered by protruding loops of polypeptide chain (Figure 3-37). The *loop regions,* which vary in length and have an irregular shape, often form the binding sites for other molecules. Because the loop regions are exposed to water, they are rich in hydrophilic amino acids, and on this basis their positions can frequently be predicted from a careful examination of the amino acid sequence of a protein.

Relatively Few of the Many Possible Polypeptide Chains Would Be Useful

Since each of the 20 amino acids is chemically distinct and each can, in principle, occur at any position in a protein chain, there are 20 x 20 x 20 x 20 = 160,000 different possible polypeptide chains 4 amino acids long, or 20^n different possible polypeptide chains n amino acids long. For a typical protein length of about 300 amino acids, more than 10^{390} different proteins can be made.

We know, however, that only a very small fraction of these possible proteins would adopt a stable three-dimensional conformation. The vast majority would have many different conformations of roughly equal energy, each with different

chemical properties. Proteins with such variable properties would not be useful and would therefore be eliminated by natural selection in the course of evolution. Present-day proteins have an amazingly sophisticated structure and chemistry because of their unique folding properties. Not only is the amino acid sequence such that a single conformation is extremely stable, but this conformation has the precise chemical properties that enable the protein to perform a specific catalytic or structural function in the cell. Proteins are so precisely built that the change of even a few atoms in one amino acid can sometimes disrupt the structure and cause a catastrophic change in function.

New Proteins Usually Evolve by Alterations of Old Ones [25]

Cells have genetic mechanisms that allow genes to be duplicated, modified, and recombined in the course of evolution. Consequently, once a protein with useful surface properties has evolved, its basic structure can be incorporated in many other proteins. Proteins of different but related function in present-day organisms often have similar amino acid sequences. Such families of proteins are believed to have evolved from a single ancestral gene that duplicated in the course of evolution to give rise to other genes in which mutations gradually accumulated to produce related proteins with new functions.

Consider the serine proteases, a family of protein-cleaving (proteolytic) enzymes that includes the digestive enzymes chymotrypsin, trypsin, and elastase and some of the proteases in the blood-clotting and complement enzymatic cascades. When two of these enzymes are compared, about 40% of the positions in their amino acid sequences are found to be occupied by the same amino acid (Figure 3-38). The similarity of their three-dimensional conformations as determined by x-ray crystallography is even more striking: most of the detailed twists and turns in their polypeptide chains, which are several hundred amino acids long, are identical (Figure 3-39).

The story that we have told for the serine proteases could be repeated for hundreds of other protein families. In many cases the amino acid sequences have diverged much further than for the serine proteases, so that one cannot be sure of a family relationship between two proteins without determining their three-dimensional structures. The yeast *a2* protein and the *Drosophila*engrailed protein, for example, are both gene regulatory proteins in the homeodomain family. Because they are identical in only 17 of their 60 amino acid residues, their relationship became certain only when their three-dimensional structures were compared (Figure 3-40).

The various members of a large protein family will often have distinct functions. Some of the amino acid changes that make these proteins different were no doubt selected in the course of evolution because they resulted in changes in biological activity, giving the individual family members the different functional properties that they have today. Other amino acid changes are likely to be "neutral," having neither a beneficial nor a damaging effect on the basic structure and function of the protein. Since mutation is a random process, there must also have been many deleterious changes that altered the three-dimensional structure of these proteins sufficiently to inactivate them. Such inactive proteins would have been lost whenever the individual organisms making them were at enough of a disadvantage to be eliminated by natural selection. It is not surprising, then, that cells contain whole sets of structurally related polypeptide chains that have a common ancestry but different functions.

New Proteins Can Evolve by Recombining Preexisting Polypeptide Domains [26]

Once a number of stable protein surfaces have been made in a cell, new surfaces with different binding properties can be generated by joining two or more proteins together by noncovalent interactions between them, producing a *protein complex*. This combining of proteins to make larger, functional protein assemblies is common. Many protein complexes have molecular weights of a million or more, even though an average polypeptide chain has a molecular weight of 40,000 (about 300 to 400 amino acids), and relatively few polypeptide chains are more than three times this size.

An alternative way of making a new protein from existing chains is to join the corresponding DNA sequences to make a gene that encodes a single large polypeptide chain. Proteins in which different parts of the polypeptide chain fold independently into separate globular domains are believed to have evolved in this way, perhaps after existing for a prolonged period as a protein complex formed from separate polypeptides. Many proteins have such "multidomain" structures, and, as might be expected from the evolutionary considerations discussed above, the binding sites for substrate molecules frequently lie where the separate domains are juxtaposed (Figure 3-41). Thus, for the multidomain protein whose three-dimensional structure is shown in Figure 3-42, a protein surface on one domain that binds NAD $^+$ was apparently combined with a surface on a second domain that binds a sugar, as part of the process of evolving an active site that uses the NAD $^+$ to catalyze sugar oxidation.

Another way of reutilizing an amino acid sequence is especially widespread among long fibrous proteins such as collagen (see Figure 3-32). In these cases a structure is formed from multiple internal repeats of an ancestral amino acid sequence. Putting together amino acid sequences by joining preexisting coding DNA sequences is clearly a much more efficient strategy for a cell than the alternative of deriving new protein sequences from scratch by random DNA mutation.

Structural Homologies Can Help Assign Functions to Newly Discovered Proteins 27

The development of techniques for rapidly sequencing DNA molecules has made it possible to determine the amino acid sequences of many thousands of proteins from the nucleotide sequences of their genes. A rapidly enlarging *protein data base* is therefore available that biologists routinely scan by computer to search for possible sequence homologies between a newly sequenced protein and previously studied ones. Although sequences have so far been determined for only a few percent of the proteins in eucaryotic organisms, it is common to find that a newly sequenced protein is homologous to some other, known protein over part of its length, indicating that most proteins may have descended from relatively few ancestral types. As expected, the sequences of many large proteins often show signs of having evolved by the joining of preexisting domains in new combinations - a process called *domain shuffling* (Figure 3-43).

These protein comparisons are important because related structures often imply related functions. Many years of experimentation can be saved by discovering an amino acid sequence homology with a protein of known function. Such sequence homologies, for example, first indicated that certain cell-cycle regulatory genes in yeast cells and certain genes that cause mammalian cells to become cancerous are protein kinases. In the same way many of the proteins that control pattern formation in the fruit fly *Drosophila* were recognized to be gene regulatory proteins, while another protein involved in pattern formation was identified as a serine protease.

The discovery of domain homologies can also be useful in another way. It is much more difficult to determine the three-dimensional structure of a protein than to determine its amino acid sequence. But the conformation of a newly sequenced protein domain can be guessed if it is homologous to a domain of a protein whose conformation has already been determined by x-ray diffraction analysis. By assuming that the twists and turns of the polypeptide chain will be conserved in the two proteins despite the presence of discrepancies in amino acid sequence, one can often sketch the structure of the new protein with reasonable accuracy (see Figure 3-40).

Many new protein sequences are being added to the data base each year, each one increasing the chance of finding useful homologies. Protein-sequence comparisons have therefore become a very important tool in cell biology.

Protein Subunits Can Assemble into Large Structures 28

The same principles that enable several protein domains to associate to form binding sites for small molecules operate to generate much larger structures in the cell. Supramolecular structures such as enzyme complexes, ribosomes, protein filaments, viruses, and membranes are not made as single, giant, covalently linked molecules; instead they are formed by the noncovalent assembly of many preformed molecules, which are called *subunits* of the final structure.

There are several advantages to the use of smaller subunits to build larger structures: (1) building a large structure from one or a few repeating smaller subunits reduces the amount of genetic information required; (2) both assembly and disassembly can be readily controlled, since the subunits associate through multiple bonds of relatively low energy; and (3) errors in the synthesis of the structure can be more easily avoided, since correction mechanisms can operate during the course of assembly to exclude malformed subunits.

A Single Type of Protein Subunit Can Interact with Itself to Form Geometrically Regular Assemblies 29

If a protein has a binding site that is complementary to a region of its own surface, it will assemble spontaneously to form a larger structure. In the simplest case, a binding site recognizes itself and forms a symmetrical *dimer*. Many enzymes and other proteins form dimers of this kind, which frequently act as subunits in the formation of larger assemblies (Figures 3-44 and 3-45).

If the binding site of a protein is complementary to a region of its surface that does not include the binding site itself, a chain of subunits will be formed. For certain special orientations of the two binding sites, the chain will soon run into itself and terminate, forming a closed ring of subunits (Figure 3-46). More commonly, an extended polymer of subunits will result, and

provided that each subunit is bound to its neighbor in an identical way, the subunits in the polymer will be arranged in a helix that can be extended indefinitely (see Figure 3-5). An *actin filament,* for example, is a helical structure formed from a single globular protein subunit called *actin;*actin filaments are major components in the cytosol of most eucaryotic cells (Figure 3-47). As we discuss below, globular proteins may also associate with like neighbors to form extended sheets or tubes (see Figure 3-49).

Coiled-Coil Proteins Help Build Many Elongated Structures in Cells 30

Where mechanical strength is of major importance, supramolecular assemblies are usually made from fibrous rather than globular subunits. Such assemblies can be stabilized by extensive regions of protein-protein contact when the subunits are wound around one another as a multistranded helix. A particularly stable structural unit that is used repeatedly for this purpose is known as the coiled-coil. It forms by the pairing of two a-helical subunits that have a repeating arrangement of nonpolar side chains. The two a-helical subunits are usually identical and run in parallel (that is, in the same direction from amino to carboxyl terminal). They coil gradually around each other to produce a stiff filament with a diameter of about 2 nm (Figure 3-48). Whereas short coiled-coils serve as dimerization domains in several families of gene regulatory proteins, more commonly a coiled-coil will extend for more than 100 nm and serve as a building block for a large fibrous structure, such as the thick filaments in a muscle cell.

Proteins Can Assemble into Sheets, Tubes, or Spheres 31

Some protein subunits assemble into flat sheets in which the subunits are arranged in hexagonal arrays. Specialized membrane proteins are sometimes arranged in this way in lipid bilayers. With a slight change in the geometry of the individual subunits, a hexagonal sheet can be converted into a tube (Figure 3-49) or, with more changes, into a hollow sphere. Protein tubes and spheres that bind specific RNA and DNA molecules form the coats of viruses.

The formation of closed structures, such as rings, tubes, or spheres, provides additional stability because it increases the number of bonds that can form between the protein subunits. Moreover, because such a structure is formed by mutually dependent, cooperative interactions between subunits, it can be driven to assemble or disassemble by a relatively small change that affects the subunits individually. These principles are dramatically illustrated in the protein *capsid* of many simple viruses, which takes the form of a hollow sphere. These coats are often made of hundreds of identical protein subunits that enclose and protect the viral nucleic acid (Figure 3-50). The protein in such a capsid must have a particularly adaptable structure, since it must make several different kinds of contacts and also change its arrangement to let the nucleic acid out to initiate viral replication once the virus has entered a cell.

Many Structures in Cells Are Capable of Self-assembly 32

The information for forming many of the complex assemblies of macromolecules in cells must be contained in the subunits themselves, since under appropriate conditions the isolated subunits can spontaneously assemble in a test tube into the final structure. The first large macromolecular aggregate shown to be capable of self-assembly from its component parts was *tobacco mosaic virus (TMV).* This virus is a long rod in which a cylinder of protein is arranged around a helical RNA core (Figure 3-51). If the dissociated RNA and protein subunits are mixed together in solution, they recombine to form fully active virus particles. The assembly process is unexpectedly complex and includes the formation of double rings of protein, which serve as intermediates that add to the growing virus coat.

Another complex macromolecular aggregate that can reassemble from its component parts is the bacterial ribosome. These ribosomes are composed of about 55 different protein molecules and 3 different rRNA molecules. If the individual components are incubated under appropriate conditions in a test tube, they spontaneously re-form the original structure. Most important, such reconstituted ribosomes are able to carry out protein synthesis. As might be expected, the reassembly of ribosomes follows a specific pathway: certain proteins first bind to the RNA, and this complex is then recognized by other proteins, and so on until the structure is complete.

It is still not clear how some of the more elaborate self-assembly processes are regulated. Many structures in the cell, for example, appear to have a precisely defined length that is many times greater than that of their component macromolecules. How such length determination is achieved is in most cases a mystery. Three possible mechanisms are illustrated in Figure 3-52. In the simplest case a long core protein or other macromolecule provides a scaffold that determines the extent of the final assembly. This is the mechanism that determines the length of the TMV particle, where the RNA chain provides the core.

Similarly, a core protein is thought to determine the length of the thin filaments in muscle, as well as the long tails of some bacterial viruses (Figure 3-53).

Not All Biological Structures Form by Self-assembly [33]

Some cellular structures held together by noncovalent bonds are not capable of self-assembly. A mitochondrion, a cilium, or a myofibril, for example, cannot form spontaneously from a solution of their component macromolecules because part of the information for their assembly is provided by special enzymes and other cellular proteins that perform the function of jigs or templates but do not appear in the final assembled structure. Even small structures may lack some of the ingredients necessary for their own assembly. In the formation of some bacterial viruses, for example, the head structure, which is composed of a single protein subunit, is assembled on a temporary scaffold composed of a second protein. The second protein is absent from the final virus particle, and so the head structure cannot spontaneously reassemble once it is taken apart. Other examples are known in which proteolytic cleavage is an essential and irreversible step in the assembly process. This is the case for the coats of some bacterial viruses and even for some simple protein assemblies, including the structural protein collagen and the hormone insulin (Figure 3-54). From these relatively simple examples, it seems very likely that the assembly of a structure as complex as a mitochondrion or a cilium will involve both temporal and spatial ordering imparted by other cellular components, as well as irreversible processing steps catalyzed by degradative enzymes.

Summary

The three-dimensional conformation of a protein molecule is determined by its amino acid sequence. The folded structure is stabilized by noncovalent interactions between different parts of the polypeptide chain. The amino acids with hydrophobic side chains tend to cluster in the interior of the molecule, and local hydrogen-bond interactions between neighboring peptide bonds give rise to a helices and b sheets. Globular regions known as domains are the modular units from which many proteins are constructed; small proteins typically contain only a single domain, while large proteins contain several domains linked together by short lengths of polypeptide chain. As proteins evolved, domains were modified and combined with other domains to construct new proteins.

Proteins are brought together into larger structures by the same noncovalent forces that determine protein folding. Proteins with binding sites for their own surface can assemble into dimers, closed rings, spherical shells, or helical polymers. Although mixtures of proteins and nucleic acids can assemble spontaneously into complex structures in the test tube, many assembly processes involve irreversible steps. Consequently, not all structures in the cell are capable of spontaneous reassembly after they are dissociated into their component parts.
Figure 3-25. **How a protein folds into a globular conformation.** The polar amino acid side chains tend to gather on the outside of the protein, where they can interact with water. The nonpolar amino acid side chains are buried on the inside to form a hydrophobic core that is "hidden" from water.
Figure 3-26. Hydrogen bonding. Some of the hydrogen bonds (shown in color) that can form between the amino acids in a protein. The peptide bonds are shaded in *gray*.
Figure 3-27. Details of intra-molecular hydrogen bonds in a protein. In this region of the enzyme lysozyme, hydrogen bonds form between two side chains (*blue*), between a side chain and an atom in a peptide bond (*yellow*), or between atoms in two peptide bonds (*red*). For reference, see Figure 3-26. (After C.K. Mathews and K.E. van Holde, Biochemistry. Redwood City, CA: Benjamin/Cummings, 1990.)
Figure 3-28. Disulfide-bond formation. The drawing illustrates the formation of a covalent disulfide bond between the side chains of neighboring cysteine residues in a protein.
Figure 3-29. A b sheet is a common structure formed by parts of the polypeptide chain in globular proteins. At the top, a domain of 115 amino acids from an immunoglobulin molecule is shown; it consists of a sandwich-like structure of two b sheets, one of which is drawn in color. At the bottom, a perfect antiparallel b sheet is shown in detail, with the amino acid side chains denoted R. Note that every peptide bond is hydrogen-bonded to a neighboring peptide bond. The actual sheet structures in globular proteins are usually less regular than the b sheet shown here, and most sheets are slightly twisted (see Figure 3-31).
Figure 3-30. An a helix is another common structure formed by parts of the polypeptide chain in proteins. (A) The oxygen-carrying molecule myoglobin (153 amino acids long) is shown, with one region of a helix outlined in color. (B) A perfect a helix is shown in outline. (C) As in the b sheet, every peptide bond in an a helix is hydrogen-bonded to a neighboring peptide bond. Note that for clarity in (B) both the side chains [which protrude radially along the outside of the helix and are denoted by R in (C)] and the hydrogen atom are omitted on the a-carbon atom of each amino acid (see also Figure 3-31).
Figure 3-31. Space-filling models of an a helix and a b sheet with (*right*) and without (*left*) their amino acid side chains. (A) An a helix (part of the structure of myoglobin). (B) A region of b sheet (part of the structure of an immunoglobulin domain). In the photographs on the left, each side chain is represented by a single darkly shaded atom (the R groups in Figures 3-29 and 3-30), while the entire side chain is shown on the right. (Courtesy of Richard J. Feldmann.)
Figure 3-32. Contrast between collagen and elastin. (A) *Collagen* is a triple helix formed by three extended protein chains that wrap around each other. Many rodlike collagen molecules are cross-linked together in the extracellular space to form inextensible collagen fibrils (*top*) that have the tensile strength of steel. (B) *Elastin* polypeptide chains are cross-linked together to form elastic fibers. Each elastin molecule uncoils into a more extended conformation when the fiber is stretched. The striking contrast between the physical properties of elastin and collagen is due entirely to their very different amino acid sequences.
Figure 3-33. Some possible sizes and shapes of a protein molecule 300 amino acid residues long. The structure formed is determined by the amino acid sequence. (Adapted from D.E. Metzler, Biochemistry. New York: Academic Press, 1977.)
Figure 3-34. Basic pancreatic trypsin inhibitor (BPTI). The three-dimensional conformation of this small protein is shown in five commonly used representations. (A) A stereo pair illustrating the positions of all nonhydrogen atoms. The main chain is shown with heavy lines and the side chains with thin lines. (B) Space-filling model showing the van der Waals radii of all atoms (see Panel 3-1). (C) Backbone wire model composed of lines that connect each a carbon along the polypeptide backbone. (D) "Ribbon model," which represents all regions of regular hydrogen-bonded interactions as either helices (a helices) or sets of arrows (b sheets) pointing toward the carboxyl-terminal end of the chain. (E) "Sausage model," which shows the course of the polypeptide chain but omits all detail. In the bottom three panels the *hairpin b motif* is colored *green*; this motif is also found in many other proteins (see text). Note that the core of all globular proteins is densely packed with atoms. Thus the impression of an open structure produced by models (C), (D), and (E) is misleading. (B and C, courtesy of Richard J. Feldmann; A and D, courtesy of Jane Richardson.)
Figure 3-35. Three levels of organization of a protein. The three-dimensional structure of a protein can be described in terms of different levels of folding, each of which is constructed from the preceding one in hierarchical fashion. These levels are illustrated here using the catabolite activator protein (CAP), a bacterial gene regulatory protein with two domains. When the large domain binds cyclic AMP, it causes a conformational change in the protein that enables the small domain to bind to a specific DNA sequence. The amino acid sequence is termed the *primary structure* and the first folding level the *secondary structure.* As indicated under the brackets at the bottom of this figure, the combination of the second and third folding levels shown here is commonly termed the *tertiary structure,* and the fourth level (the assembly of subunits) the *quaternary structure* of a protein. (Modified from a drawing by Jane Richardson.)
Figure 3-36. Example of a common protein motif. In the beta-alpha-beta motif two adjacent parallel strands that form a b sheet structure are connected by an a helix. Like the hairpin b motif highlighted in Figure 3-34, this motif is found in many different proteins.

(A)   (B)   (C)
Figure 3-37. Ribbon models of the three-dimensional structure of several differently organized protein domains. (A) Cytochrome b $_{562}$, a single-domain protein composed almost entirely of a helices. (B) The NAD-binding domain of lactic dehydrogenase, composed of a mixture of a helices and b sheets. (C) The variable domain of an immunoglobin light chain, composed of a sandwich of two b sheets. In these examples the a helices are shown in *green,* while strands organized as b sheets are denoted by *red arrows.* Note that the polypeptide chain generally traverses back and forth across the entire domain, making sharp turns only at the protein surface. The protruding *loop regions* (*yellow*) often form the binding sites for other molecules. (Drawings courtesy of Jane Richardson.)

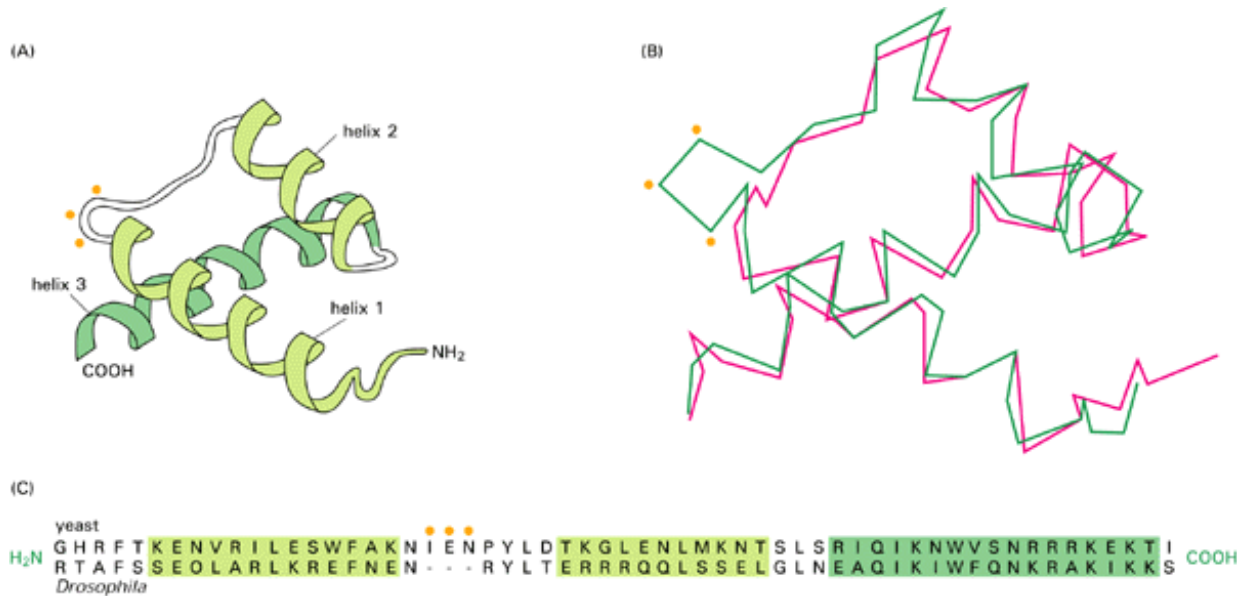
Figure 3-38. (A) Comparison of the amino acid sequences of two members of the serine protease family of enzymes. The carboxyl-terminal portions of the two proteins are shown (amino acids 149 to 245). Identical amino acids are connected by colored bars, and the serine residue in the active site at position 195 is highlighted. In the *yellow* boxed sections of the polypeptide chains, each amino acid occupies a closely equivalent position in the three-dimensional structures of the two enzymes (see Figure 3-39). (B) The standard one-letter and three-letter codes for amino acids. (Modified from J. Greer, *Proc. Natl. Acad. Sci. USA* 77:3393-3397, 1980.)
Figure 3-39. Comparison of the conformations of the two serine proteases shown in Figure 3-38. Elastase is shown in (A) and chymotrypsin in (B). Although only those amino acid residues in the polypeptide chain shaded in *green* are the same in the two proteins, their conformations are very similar everywhere. The active site, which is circled in *red,* contains an activated serine residue (see Figure 3-57). Chymotrypsin contains more than two chain termini because it is formed by the proteolytic cleavage of chymotrypsinogen, an inactive precursor.


Figure 3-40. Comparison of DNA-binding homeodomains from two organisms separated by more than a billion years of evolution. (A) Schematic of structure. (B) Trace of the a-carbon positions. The three-dimensional structures shown were determined by x-ray crystallography for the yeast a2 protein (*green*) and the *Drosophila* engrailed protein (*red*). (C) Comparison of amino acid sequences for the region of the proteins shown in (A) and (B). *Orange dots*demark the position of a three amino acid insert in the a2 protein. (Adapted from C. Wolberger, et al., *Cell*67:517-528, 1991.)
Figure 3-41. The evolution of new ligand-binding sites. The general principle by which the juxtaposition of separate protein surfaces in the course of evolution has given rise to proteins that contain new binding sites for other molecules (*ligands*see p. 129). As indicated here, the ligand-binding sites often lie at the interface between two protein domains and are formed from loop regions on the protein surface (see also Figure 3-42).
Figure 3-42. The structure of the glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase. The protein is composed of two domains, each shown in a different color, with regions of a helix represented by cylinders and regions of b sheet represented by arrows. The details of the reaction catalyzed by the enzyme are shown in Figure 2-22. Note that the three bound substrates lie at an interface between the two domains. (Courtesy of Alan J. Wonacott.)
Figure 3-43. Domain shuffling. An extensive shuffling of blocks of protein sequence (protein *modules*) has occurred during the evolution of proteins. Those portions of a protein denoted by the same shape and color are evolutionarily related but not identical. (A) The bacterial catabolite gene activator protein (CAP) contains one domain (*blue triangle*) that binds a specific DNA sequence and a second domain (*red rectangle*) that binds cyclic AMP (see Figure 3-35). The DNA-binding domain here is related to the DNA-binding domains of many other gene regulatory proteins, including the lac repressor and cro repressor proteins. In addition, two copies of the cyclic-AMP-binding domain are found in eucaryotic protein kinases regulated by the binding of cyclic nucleotides. (B) Serine proteases like chymotrypsin are formed from two domains (*brown*). In some related proteases that are highly regulated and more specialized, the two protease domains are connected to one or more domains homologous to domains found in epidermal growth factor (*green hexagon*), to a calcium-binding protein (*yellow triangle*), or to a "kringle" domain (*blue square*) that contains three internal disufide bridges.
Figure 3-44. The formation of a dimer from a single type of protein subunit. A protein with a binding site that recognizes itself will often form symmetrical dimers. These may then pair with other subunits to form tetramers and larger assemblies (not shown).

Figure 3-45. Ribbon model of a dimer formed from two identical protein subunits (monomers). The protein shown is the bacterial catabolite gene activator protein (CAP) illustrated previously in Figure 3-35. (Courtesy of Jane Richardson.)
Figure 3-46. Rings or helices can form if a single type of protein subunit interacts with itself repeatedly. The formation of a helix was illustrated in Figure 3-5; a ring forms instead of a helix if the subunits run into one another, stopping further growth of the chain.
Figure 3-47. An actin filament. There are about two globular protein subunits per turn in this important filament, which is discussed in detail in Chapter 16.
Hexagonally packed globular protein subunits can form either a flat sheet or a tube.

stripe of hydrophobic "a" and "d" amino acids

(A)   (B)   (C)
Figure 3-48. The structure of a coiled-coil. In (A) a single a helix is shown, with successive amino acid side chains labeled in a sevenfold sequence "abcdefg" (from bottom to top). Amino acids "a" and "d" in such a sequence lie close together on the cylinder surface, forming a "stripe" (shaded in *red*) that winds slowly around the a helix. Proteins that form coiled-coils typically have hydrophobic amino acids at positions "a" and "d." Consequently, as shown in (B), the two a helices can wrap around each other with the hydrophobic side chains of one a helix interacting with the hydrophobic side chains of the other, while the more hydrophilic amino acid side chains are left exposed to the aqueous environment. (C) The atomic structure of a coiled-coil determined by x-ray crystallography. The *red* side chains are hydrophobic. (C, from T. Alber, *Curr. Opin. Genet. Devel.*2:205-210, 1992. © Current Science.)
Figure 3-50. The structure of a spherical virus. In many viruses, identical protein subunits pack together to create a spherical shell (a capsid) that encloses the viral genome, composed of either RNA or DNA (see Figure 6-72). For geometric reasons, no more than 60 identical subunits can pack together in a precisely symmetrical way. If slight irregularities are allowed, however, more subunits can be used to produce a larger capsid. The tomato bushy stunt virus (TBSV) shown here, for example, is a spherical virus about 33 nm in diameter that is formed from 180 identical copies of a 386 amino acid capsid protein plus an RNA genome of 4500 nucleotides. To form such a large capsid, the protein must be able to fit into three somewhat different environments, each of which is differently colored in the particle shown here. The postulated pathway of assembly is shown; the precise three-dimensional structure has been determined by x-ray diffraction. (Courtesy of Steve Harrison.)

Figure 3-54. The polypeptide hormone insulin cannot spontaneously re-form if its disulfide bonds are disrupted. It is synthesized as a larger protein (*proinsulin*) that is cleaved by a proteolytic enzyme after the protein chain has folded into a specific shape. Excision of part of the proinsulin polypeptide chain causes an irretrievable loss of the information needed for the protein to fold spontaneously into its normal conformation.

Proteins as Catalysts <u>34</u>

Introduction

The chemical properties of a protein molecule depend almost entirely on its exposed surface residues, which are able to form weak, noncovalent bonds with other molecules. When a protein molecule binds to another molecule, the second molecule is commonly referred to as a ligand. Because an effective interaction between a protein molecule and a ligand requires that many weak bonds be formed simultaneously between them, the only ligands that can bind tightly to a protein are those that fit precisely onto its surface.

The region of a protein that associates with a ligand, known as its binding site, usually consists of a cavity formed by a specific arrangement of amino acids on the protein surface. These amino acids often belong to widely separated regions of the polypeptide chain (Figure 3-55), and they represent only a minor fraction of the total amino acids present. The rest of the

protein molecule is presumably necessary to maintain the polypeptide chain in the correct position and to provide additional binding sites for regulatory purposes; the interior of the protein is often important only insofar as it gives the surface of the molecule the appropriate shape and rigidity.

A Protein's Conformation Determines Its Chemistry [20]

Neighboring surface residues on a protein often interact in a way that alters the chemical reactivity of selected amino acid side chains. These interactions are of several types.

First, neighboring parts of the polypeptide chain may interact in a way that restricts the access of water molecules to other parts of the protein surface. Because water molecules tend to form hydrogen bonds, they compete with ligands for selected side chains on the protein surface (Figure 3-56). The tightness of hydrogen bonds (and ionic interactions) between proteins and their ligands is therefore greatly increased if water molecules are excluded. At first sight it is hard to imagine a mechanism that would exclude a molecule as small as water from a protein surface without affecting the access of the ligand itself. Because of their strong tendency for hydrogen bonding, however, water molecules exist in a large hydrogen-bonded network (see Panel 2-1, pp. 48-49), and it is often energetically unfavorable for individual molecules to break away from this network to reach into a crevice on the protein surface.

Second, the clustering of neighboring polar amino acid side chains can alter their reactivity. If a number of negatively charged side chains are forced together against their mutual repulsion by the way the protein folds, for example, the affinity of the site for a positively charged ion is greatly increased. Selected amino acid side chains can also interact with one another through hydrogen bonds, which can activate normally unreactive side groups (such as the CH_2OH on the serine shown in Figure 3-57) so that they are able to enter into reactions that make or break selected covalent bonds.

The surface of each protein molecule therefore has a unique chemical reactivity that depends not only on which amino acid side chains are exposed, but also on their exact orientation relative to one another. For this reason even two slightly different conformations of the same protein molecule may differ greatly in their chemistry.

Where side-chain reactivities are insufficient, proteins often enlist the help of selected nonpolypeptide molecules that the proteins bind to their surface. These ligands serve as coenzymes in enzyme-catalyzed reactions, and they may be so tightly bound to the protein that they are effectively part of the protein itself. Examples are the iron-containing *hemes* in hemoglobin and cytochromes, *thiamine pyrophosphate* in enzymes involved in aldehyde-group transfers, and *biotin* in enzymes involved in carboxyl-group transfers. Most coenzymes are very complex organic molecules that have been selected for the unique chemical reactivity they acquire when bound to a protein surface. Besides its reactive center such a coenzyme has other residues designed to bind it to its host protein (Figure 3-58). A space-filling model of an enzyme bound to a coenzyme is shown in Figure 3-59A.

Substrate Binding Is the First Step in Enzyme Catalysis [35]

One of the most important functions of proteins is to act as enzymes that catalyze specific chemical reactions. The ligand in this case is called a substrate molecule, and the binding of the substrate to the enzyme is an essential prelude to the chemical reaction (see Figure 3-59B). If we denote the enzyme by E, the substrate by S, and the product by P, the basic reaction path is E + S ⇌ ES ⇌ EP ⇌ E + P. From this simple outline of an enzyme-catalyzed reaction, we see that there is a limit to the amount of substrate that a single enzyme molecule can process in a given time. If the concentration of substrate is increased, the rate at which product is formed also increases, up to a maximum value (Figure 3-60). At that point the enzyme molecule is saturated with substrate and the rate of reaction (denoted V_{max}) depends only on how rapidly the substrate molecule can be processed. This rate divided by the enzyme concentration is called the turnover number. The turnover number is often about 1000 substrate molecules processed per second per enzyme molecule, but it can be much greater in extreme cases.

The other kinetic parameter frequently used to characterize an enzyme is its K_M, which is the substrate concentration that allows the reaction to proceed at one-half its maximum rate (see Figure 3-60). A *low* K_M value means that the enzyme reaches its maximum catalytic rate at a *low concentration* of substrate and generally indicates that the enzyme binds its substrate very tightly.

Enzymes Speed Reactions by Selectively Stabilizing Transition States [36]

Extremely high rates of chemical reaction are achieved by enzymes - far higher than for any synthetic catalysts. This efficiency is attributable to several factors. The enzyme serves, first, to increase the local concentration of substrate molecules at the catalytic site and to hold all of the appropriate atoms in the correct orientation for the reaction that is to follow. More important, however, some of the binding energy contributes directly to the catalysis. Substrate molecules pass through a series of intermediate forms of altered geometry and electron distribution before they form the ultimate products of the reaction, and the free energies of these intermediate forms - especially of those in the most unstable transition states - are the major determinants of the rate of reaction. Enzymes have a much greater affinity for these transition states of the substrate than they have for the stable forms. Because this binding interaction lowers the energies of crucial transition states, the enzyme greatly accelerates one particular reaction (Figure 3-61).

A dramatic demonstration of how stabilizing a transition state can greatly increase reaction rates is provided by the intentional production of antibodies that act like enzymes. Consider, for example, the hydrolysis of an amide bond, which is similar to the peptide bond that joins adjacent amino acids in a protein. In an aqueous solution an amide bond hydrolyzes very slowly by the mechanism illustrated in Figure 3-62A. In the central intermediate, or transition state, the carbonyl carbon is bonded to four atoms that are arranged at the corners of a tetrahedron. By generating monoclonal antibodies that bind tightly to a stable analogue of this very unstable *tetrahedral intermediate,*as illustrated in Figure 3-62B, an antibody that functions like an enzyme can be obtained. This *catalytic antibody* binds to and stabilizes the tetrahedral intermediate and thereby increases the spontaneous rate of amide-bond hydrolysis more than 10,000-fold.

Enzymes Can Promote the Making and Breaking of Covalent Bonds Through Simultaneous Acid and Base Catalysis [37]

Enzymes are better catalysts than catalytic antibodies. In addition to binding tightly to the transition state, the active site of an enzyme contains precisely positioned atoms that speed up the reaction by altering the distribution of electrons in those atoms involved in the making and breaking of covalent bonds. Peptide bonds, for example, can be hydrolyzed in the absence of an enzyme by exposing a polypeptide to either a strong acid or a strong base, as explained in Figure 3-63B and C. Enzymes are unique, however, in being able to use acid and base catalysis simultaneously, since the acidic and basic residues required are prevented from combining with each other (as they would do in solution) by being tied to the rigid framework of the protein itself (Figure 3-63D).

The fit between an enzyme and its substrate needs to be precise. A small change introduced by genetic engineering in the active site of an enzyme can have a profound effect. Replacing a glutamic acid with an aspartic acid in one enzyme, for example, shifts the position of the catalytic carboxylate ion by only 1 Å (about the radius of a hydrogen atom), and yet this is enough to reduce the activity of the enzyme a thousandfold.

Enzymes Can Further Increase Reaction Rates by Forming Covalent Intermediates with Their Substrates [38]

In addition to the above roles, many enzymes further speed the reaction they catalyze by interacting covalently with one of their substrates, thereby temporarily attaching the substrate to an amino acid or to a coenzyme molecule. Generally, one substrate enters the binding site, becomes covalently bound, and then reacts with a second molecule on the enzyme surface that breaks the covalent attachment just made. At the end of each reaction cycle, the free enzyme is regenerated.

Consider, for example, the mechanism of action of the serine proteases. The reaction they catalyze, the hydrolysis of a peptide bond, is greatly accelerated by the enzymes' affinity for the tetrahedral intermediate of the reaction. But a serine protease does more than a typical catalytic antibody: instead of waiting for an oxygen from a water molecule to attack the carbonyl carbon, it makes the reaction go much more quickly by first using a precisely positioned amino acid side chain for this purpose (the activated serine in Figure 3-57). This step breaks the peptide bond, but it leaves the enzyme covalently linked to the carboxyl group. Then, in a rapid second step, this covalent intermediate is destroyed by the enzyme-catalyzed addition of water, completing the reaction and regenerating the free enzyme (Figure 3-64). Even though this two-step reaction is less direct than a one-step reaction (in which water is added to the peptide bond), it is faster because each step has a relatively low activation energy.

Enzymes Accelerate Chemical Reactions but Cannot Make Them Energetically More Favorable

No matter how sophisticated an enzyme is, it cannot make the chemical reaction it catalyzes either more or less energetically favorable. It cannot alter the free-energy difference between the initial substrates and the final products of the reaction. Like the simple binding interactions already discussed, any given chemical reaction has an *equilibrium point,* at which the backward and

forward reaction fluxes are equal, so that no net change occurs (see Figure 3-9). If an enzyme speeds up the rate of the forward reaction, A + B $\rightarrow$ AB, by a factor of 10^8, it must speed up the rate of the backward reaction, AB $\rightarrow$ A + B, by a factor of 10^8 as well. The *ratio* of the forward to the backward rates of reaction depends only on the concentrations of A, B, and AB. The equilibrium point remains precisely the same whether or not the reaction is catalyzed by an enzyme.

Enzymes Determine Reaction Paths by Coupling Selected Reactions to ATP Hydrolysis [39]

The living cell is a chemical system that is far from equilibrium. The product of each enzyme usually serves as a substrate for another enzyme in the metabolic pathway and is rapidly consumed. More important, by means of a reaction pathway that is determined by enzymes, many reactions are driven in one direction by being *coupled* to the energetically favorable hydrolysis of ATP to ADP and inorganic phosphate, as previously described in Chapter 2. To make this strategy effective, the ATP pool is itself maintained at a level far from its equilibrium point, with a high ratio of ATP to its hydrolysis products (discussed in Chapter 14). This ATP pool thereby serves as a "storage battery" that keeps energy and atoms continually passing through the cell directed along pathways determined by the enzymes present. For a living system, approaching chemical equilibrium means decay and death.

Multienzyme Complexes Help to Increase the Rate of Cell Metabolism [40]

The efficiency of enzymes in accelerating chemical reactions is crucial to the maintenance of life. Cells, in effect, must race against the unavoidable processes of decay, which run downhill toward chemical equilibrium. If the rates of desirable reactions were not greater than the rates of competing side reactions, a cell would soon die. Some idea of the rate at which cellular metabolism proceeds can be obtained by measuring the rate of ATP utilization. A typical mammalian cell turns over (that is, completely degrades and replaces) its entire ATP pool once every 1 or 2 minutes. For each cell this turnover represents the utilization of roughly 10^7 molecules of ATP per second (or, for the human body, about a gram of ATP every minute).

The rates of cellular reactions are rapid because of the effectiveness of enzyme catalysis. Many important enzymes have become so efficient that there is no possibility of further useful improvement: the factor limiting the reaction rate is no longer the intrinsic speed of action of the enzyme, rather it is the frequency with which the enzyme collides with its substrate. Such a reaction is said to be *diffusion-limited*.

If a reaction is diffusion-limited, its rate will depend on the concentration of both the enzyme and its substrate. For a sequence of reactions to occur very rapidly, each metabolic intermediate and enzyme involved must therefore be present in high concentration. Given the enormous number of different reactions carried out by a cell, there are limits to the concentrations of substrates that can be achieved. In fact, most metabolites are present in micromolar (10^{-6} M) concentrations, and most enzyme concentrations are much lower. How is it possible, therefore, to maintain very fast metabolic rates?

The answer lies in the spatial organization of cell components. Reaction rates can be increased without raising substrate concentrations by bringing the various enzymes involved in a reaction sequence together to form a large protein assembly known as a multienzyme complex. In this way the product of enzyme A is passed directly to enzyme B and so on to the final product, and diffusion rates need not be limiting even when the concentration of substrate in the cell as a whole is very low. Such enzyme complexes are very common (the structure of one, pyruvate dehydrogenase, was shown in Figure 2-41), and they are involved in nearly all aspects of metabolism, including the central genetic processes of DNA, RNA, and protein synthesis. In fact, it may be that few enzymes in eucaryotic cells diffuse freely in solution; instead, most may have evolved binding sites that concentrate them with other proteins of related function in particular regions of the cell, thereby increasing the rate and efficiency of the reactions that they catalyze.

Cells have another way of increasing the rate of metabolic reactions. It depends on the extensive intracellular membrane systems of eucaryotic cells. These membranes can segregate certain substrates and the enzymes that act on them into the same membrane-bounded compartment, such as the endoplasmic reticulum or the cell nucleus. If, for example, the compartment occupies a total of 10% of the volume of the cell, the concentration of reactants in the compartment can be 10 times greater than in a similar cell with no compartmentalization (Figure 3-65). Reactions that would otherwise be limited by the speed of diffusion can thereby be speeded up by the same factor.

Further details of protein structure and function will be presented in Chapter 5, where we discuss how cells construct tiny machines out of proteins.

Summary

The biological function of a protein depends on the detailed chemical properties of its surface. Binding sites for ligands are formed as surface cavities in which precisely positioned amino acid side chains are brought together by protein folding. In this way, normally unreactive amino acid side chains can be activated. Enzymes greatly speed up reaction rates by binding the high-energy transition states in a reaction especially tightly; they also carry out acid catalysis and base catalysis simultaneously. The rates of enzyme reactions are often so fast that they are limited only by diffusion; rates can be further increased if enzymes that act sequentially on a substrate are joined into a single multienzyme complex or if the enzymes and their substrates are confined to the same compartment of the cell.
Figure 3-55. The ligand-binding site of the catabolite gene activator protein (CAP). Hydrogen bonding between CAP and its ligand, cyclic AMP (*green*), was determined by x-ray crystallographic analysis of the complex. As indicated, the two identical subunits of the dimer cooperate to form this binding site (see also Figure 3-45). (Courtesy of Tom Steitz.)
Figure 3-56. Competition for hydrogen bonding. The ability of water molecules to make favorable hydrogen bonds with groups on the protein surface greatly reduces the tendency of these groups to pair with each other.
Figure 3-57. An unusually reactive amino acid at the active site of an enzyme. The example shown is the "catalytic triad" found in chymotrypsin, elastase, and other serine proteases (see Figure 3-39). The aspartic acid side chain induces the histidine to remove the proton from serine 195; this activates the serine to form a covalent bond with the enzyme substrate, hydrolyzing a peptide bond as illustrated later in Figure 3-64.
Figure 3-58. Coenzymes. Coenzymes, such as thiamine pyrophosphate (TPP), shown here in *gray,* are small molecules that bind to an enzyme's surface and enable it to catalyze specific reactions. The reactivity of TPP depends on its "acidic" carbon atom, which readily exchanges its hydrogen atom for a carbon atom of a substrate molecule. Other regions of the TPP molecule act as "handles" by which the enzyme holds the coenzyme in the correct position. Coenzymes presumably evolved first in an "RNA world," where they were bound to RNA molecules to help with catalysis (discussed in Chapter 1).

(A)   (B)
Figure 3-59. Computer-generated space-filling models of two enzymes. In (A) cytochrome c is shown with its bound heme coenzyme. In (B) egg-white lysozyme is shown with a bound oligosaccharide substrate. In both cases the bound ligand is *red.* (Courtesy of Richard J. Feldmann.)
Figure 3-60. Enzyme kinetics. The rate of an enzyme reaction (V) increases as the substrate concentration increases until a maximum value (V_{max}) is reached. At this point all substrate-binding sites on the enzyme molecules are fully occupied, and the rate of reaction is limited by the rate of the catalytic process on the enzyme surface. For most enzymes the concentration of substrate at which the reaction rate is half-maximal (K_M) is a measure of how tightly the substrate is bound, with a large value of K_M corresponding to weak binding.
Figure 3-61. Enzymes accelerate chemical reactions by decreasing the activation energy. Often both the uncatalyzed reaction (A) and the enzyme-catalyzed reaction (B) go through several transition states. It is the transition state with the highest energy (S ^{T} and ES ^{T}) that determines the activation energy and limits the rate of the reaction. (S = substrate; P = product of the reaction.)

(A) HYDROLYSIS OF AN AMIDE BOND

water   tetrahedral intermediate
(B) TRANSITION-STATE ANALOGUE FOR AMIDE HYDROLYSIS

analogue   amide
Figure 3-62. Catalytic antibodies. The stabilization of a transition state by an antibody creates an enzyme. (A) The reaction path for hydrolysis of an amide bond goes through a *tetrahedral intermediate,* which is the high-energy transition state for the reaction. (B) The molecule shown on the left was covalently linked to a protein and used as an antigen to generate an antibody

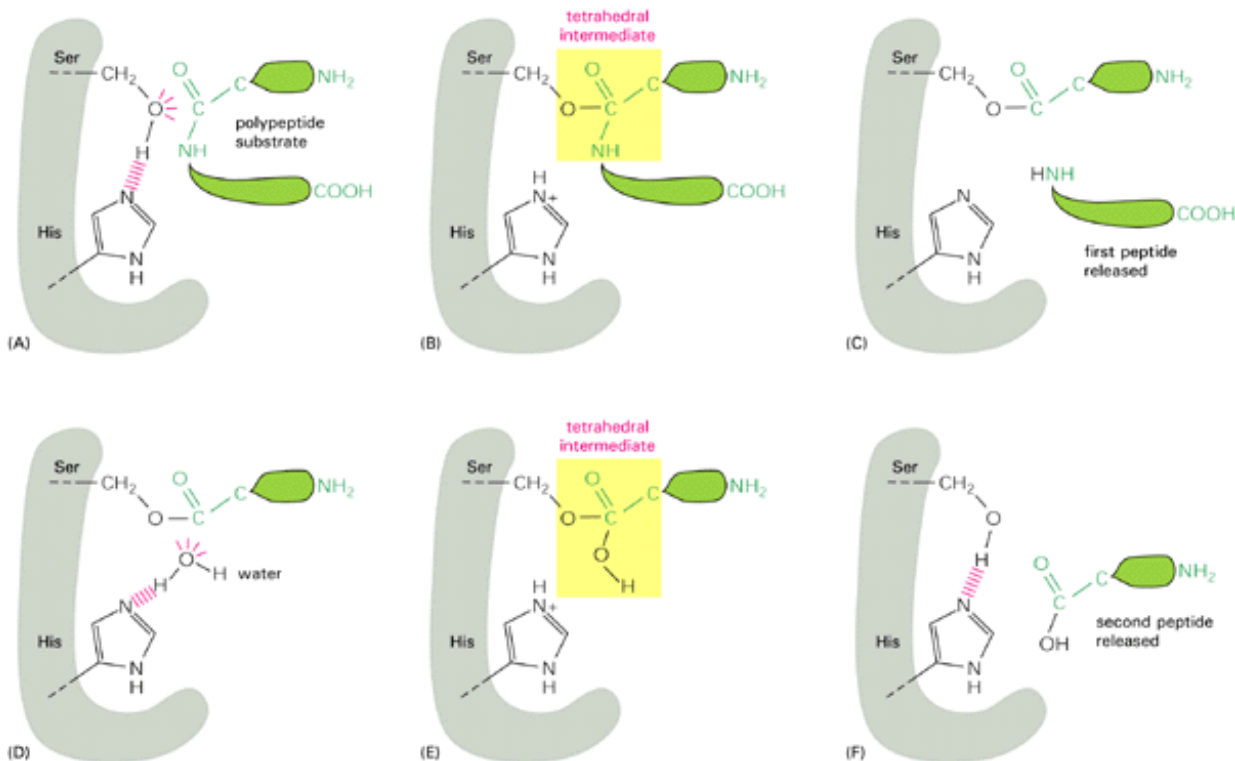
that binds tightly to the region of the molecule shown in *yellow*. Because this antibody also bound tightly to the transition state in (A), it was found to function as an enzyme that efficiently catalyzed the hydrolysis of the amide bond in the molecule shown on the right.
Figure 3-63. Acid catalysis and base catalysis. (A) The start of the uncatalyzed reaction shown in Figure 3-62A is diagrammed, with *blue*shading as a schematic indicator of electron distribution in the water and carbonyl bonds. (B) An acid likes to donate a proton (H $^+$) to other atoms. By pairing with the carbonyl oxygen, an acid causes electrons to move away from the carbonyl carbon, making this atom much more attractive to the electronegative oxygen of an attacking water molecule. (C) A base likes to take up H $^+$; by pairing with a hydrogen of the attacking water molecule, a base causes electrons to move toward the water oxygen, making it a better attacking group for the carbonyl carbon. (D) By having appropriately positioned atoms on its surface, an enzyme can carry out both acid catalysis and base catalysis at the same time.


Figure 3-64. Some enzymes form covalent bonds with their substrates. In the example shown here, a carbonyl group in a polypeptide chain (shown in *green*) forms a covalent bond with a specially activated serine residue (see Figure 3-57) of a serine protease (shown in *gray*), which cleaves the polypeptide chain. When the unbound portion of the polypeptide chain has diffused away, a second step occurs in which a water molecule hydrolyzes the newly formed covalent bond, thereby releasing the portion of the polypeptide bound to the enzyme surface and freeing the serine for another cycle of reaction. Note that two unstable tetrahedral intermediates (shaded in *yellow*) serve as transition states in this reaction and both are stabilized by the enzyme.
Figure 3-65. Compartmentalization. A large increase in the concentration of interacting molecules can be achieved by confining them to the same membrane-bounded compartment in a eucaryotic cell.

4. How Cells Are Studied

Introduction

Cells are small and complex. It is hard to see their structure, hard to discover their molecular composition, and harder still to find out how their various components function. What we can learn about cells depends on the tools at our disposal, and major advances in cell biology have frequently sprung from the introduction of new techniques. To understand contemporary cell biology, therefore, it is necessary to know something of its methods.

In this chapter we briefly review some of the principal methods used to study cells. We start with techniques for examining the cell as a whole and then proceed to techniques for analyzing its constituent macromolecules. Microscopy will be our starting point, for cell biology began with the light microscope, and this is still an essential tool in the field, along with more recent imaging devices based on beams of electrons and other forms of radiation. From passive observation we move to active intervention: we consider how cells of different types can be separated from tissues and grown outside the body and how cells

can be disrupted and their organelles and constituent macromolecules isolated in pure form. Finally, we describe how we can detect, follow, and quantify individual types of molecules and ions within the cell. A revolution in our understanding of cellular function has come from recombinant DNA technology, but because it is a complex subject in itself and depends on an understanding of basic genetic mechanisms, this powerful array of methods will be considered in detail in Chapter 7.

Although methods are of basic importance, it is what we discover with them that makes them interesting. The present chapter, therefore, is meant to be used for reference and to be read in conjunction with the later chapters of the book, rather than as an introduction to them.

Looking at the Structure of Cells in the Microscope 1

Introduction

A typical animal cell is 10 to 20 μm in diameter, which is about five times smaller than the smallest particle visible to the naked eye. It was not until good light microscopes became available in the early part of the nineteenth century that all plant and animal tissues were discovered to be aggregates of individual cells. This discovery, proposed as the cell doctrine by Schleiden and Schwann in 1838, marks the formal birth of cell biology.

Animal cells are not only tiny, they are also colorless and translucent. Consequently, the discovery of their main internal features depended on the development, in the latter part of the nineteenth century, of a variety of stains that provided sufficient contrast to make those features visible. Likewise, introduction of the far more powerful electron microscope in the early 1940s required the development of new techniques for preserving and staining cells before the full complexities of their internal fine structure could begin to emerge. To this day, microscopy depends as much on techniques for preparing the specimen as on the performance of the microscope itself. In the discussions that follow, we therefore consider both instruments and specimen preparation, beginning with the light microscope.

Figure 4-1 shows the fineness of detail that can be resolved with modern light microscopes, in comparison with electron microscopes. Some of the landmarks in the development of light microscopy are outlined in Table 4-1.

The Light Microscope Can Resolve Details 0.2 μm Apart 2

In general, a beam of a given type of radiation cannot be used to probe structural details much smaller than its own wavelength. This is a fundamental limitation of microscopes. The limit to the resolution of a light microscope, therefore, is set by the wavelength of visible light, which ranges from about 0.4 μm (for violet) to 0.7 μm (for deep red). In practical terms, bacteria and mitochondria, which are about 500 nm (0.5 μm) wide, are generally the smallest objects whose shape can be clearly discerned in the light microscope; details smaller than this are obscured by effects resulting from the wave nature of light. To understand why this occurs, we must follow what happens to a beam of light waves as it passes through the lenses of a microscope.

Because of its wave nature, light does not follow exactly the idealized straight ray paths predicted by geometrical optics. Instead, light waves travel through an optical system by a variety of slightly different routes, so that they interfere with one another and cause *optical diffraction* effects. If two trains of waves reaching the same point by different paths are precisely in phase, with crest matching crest and trough matching trough, they will reinforce each other so as to increase brightness. On the other hand, if the trains of waves are out of phase, they will interfere with each other in such a way as to cancel each other partially or entirely (Figure 4-2). The interaction of light with an object will change the phase relationships of the light waves in a way that produces complex interference effects. At high magnification, for example, the shadow of a straight edge that is evenly illuminated with light of uniform wavelength appears as a set of parallel lines, whereas that of a circular spot appears as a set of concentric rings (Figure 4-3). For the same reason, a single point seen through a microscope appears as a blurred disc, and two point objects close together give overlapping images and may merge into one. No amount of refinement of the lenses can overcome this limitation imposed by the wavelike nature of light.

The limiting separation at which two objects can still be seen as distinct - the so-called limit of resolution - depends on both the wavelength of the light and the numerical aperture of the lens system used (Figure 4-4). Under the best conditions, with violet light (wavelength, l = 0.4 μm) and a numerical aperture of 1.4, a limit of resolution of just under 0.2 μm can theoretically be obtained in the light microscope. This resolution was achieved by microscope makers at the end of the nineteenth century and is

only rarely matched in contemporary, factory-produced microscopes. Although it is possible to *enlarge*an image as much as one wants - for example, by projecting it onto a screen - it is never possible to resolve two objects in the light microscope that are separated by less than about 0.2 μm: such objects will appear as one.

We shall see later how interference and diffraction can be exploited to study unstained cells in the living state. First we discuss how permanent preparations of cells are made for viewing in the light microscope and how chemical stains are used to enhance the visibility of the cell structures in such preparations.

Tissues Are Usually Fixed and Sectioned for Microscopy

To make a permanent preparation that can be stained and viewed at leisure in the microscope, one first must treat cells with a fixative so as to immobilize, kill, and preserve them. In chemical terms, fixation makes cells permeable to staining reagents and cross-links their macromolecules so that they are stabilized and locked in position. Some of the earliest fixation procedures involved immersion in acids or in organic solvents, such as alcohol. Current procedures usually include treatment with reactive aldehydes, particularly formaldehyde and glutaraldehyde, which form covalent bonds with the free amino groups of proteins and thereby cross-link adjacent proteins.

Most tissue samples are too thick for their individual cells to be examined directly at high resolution. After fixation, therefore, the tissues are usually cut into very thin slices (sections) with a *microtome,* a machine with a sharp metal blade that operates like a meat slicer (Figure 4-5). The sections (typically 1 to 10 μm thick) are then laid flat on the surface of a glass microscope slide.

Tissues are generally soft and fragile, even after fixation, and need to be embedded in a supporting medium before sectioning. The usual embedding media are waxes or resins. In liquid form these media will both permeate and surround the fixed tissue; they then can be hardened (by cooling or by polymerization) to a solid block, which is readily sectioned by the microtome.

There is a serious danger that any treatment used for fixation and embedding may alter the structure of the cell or its constituent molecules in undesirable ways. Rapid freezing provides an alternative method of preparation that to some extent avoids this problem by eliminating the need for fixation and embedding. The frozen tissue can be cut directly with a cryostat - a special microtome that is maintained in a cold chamber. Although frozen sections produced in this way avoid some artifacts, they suffer from others: the native structures of individual molecules such as proteins are well preserved, but the fine structure of the cell is often disrupted by ice crystals.

Once sections have been cut, by whatever method, the next step is usually to stain them.

Different Components of the Cell Can Be Selectively Stained 3

There is little in the contents of most cells (which are 70% water by weight) to impede the passage of light rays. Thus most cells in their natural state, even if fixed and sectioned, are almost invisible in an ordinary light microscope. One way to make them visible is to stain them with dyes.

In the early nineteenth century the demand for dyes to stain textiles led to a fertile period for organic chemistry. Some of the dyes were found to stain biological tissues and, unexpectedly, often showed a preference for particular parts of the cell - the nucleus or mitochondria, for example - making these internal structures clearly visible. Today a rich variety of organic dyes is available, with such colorful names as *Malachite green, Sudan black,* and *Coomassie blue,* each of which has some specific affinity for particular subcellular components. The dye *hematoxylin,* for example, has an affinity for negatively charged molecules and therefore reveals the distribution of DNA, RNA, and acidic proteins in a cell (Figure 4-6). The chemical basis for the specificity of many dyes, however, is not known.

The relative lack of specificity of these dyes at the molecular level has stimulated the design of more rational and selective staining procedures and, in particular, of methods that reveal specific proteins or other macromolecules in cells. It is a problem, however, to achieve adequate sensitivity for this purpose. Since relatively few copies of most macromolecules are present in any given cell, one or two molecules of stain bound to each macromolecule will often be invisible. One way to solve this problem is to increase the number of stain molecules associated with a single macromolecule. Thus some enzymes can be located in cells through their catalytic activity: when supplied with appropriate substrate molecules, each enzyme molecule generates many molecules of a localized, visible reaction product. An alternative and much more generally applicable approach to the problem

of sensitivity depends on using dyes that are fluorescent, as we explain next.

Specific Molecules Can Be Located in Cells by Fluorescence Microscopy [4]

Fluorescent molecules absorb light at one wavelength and emit it at another, longer wavelength. If such a compound is illuminated at its absorbing wavelength and then viewed through a filter that allows only light of the emitted wavelength to pass, it is seen to glow against a dark background. Because the background is dark, even a minute amount of the glowing fluorescent dye can be detected. The same number of molecules of an ordinary stain viewed conventionally would be practically invisible because they would give only the faintest tinge of color to the light transmitted through this stained part of the specimen.

The fluorescent dyes used for staining cells are detected with the help of a fluorescence microscope. This microscope is similar to an ordinary light microscope except that the illuminating light, from a very powerful source, is passed through two sets of filters - one to filter the light before it reaches the specimen and one to filter the light obtained from the specimen. The first filter is selected so that it passes only the wavelengths that excite the particular fluorescent dye, while the second filter blocks out this light and passes only those wavelengths emitted when the dye fluoresces (Figure 4-7).

Fluorescence microscopy is most often used to detect specific proteins or other molecules in cells and tissues. A very powerful and widely used technique is to couple fluorescent dyes to antibody molecules, which then serve as highly specific and versatile staining reagents that bind selectively to the particular macromolecules that they recognize in cells or in the extracellular matrix. Two fluorescent dyes that are commonly used for this purpose are *fluorescein,* which emits an intense green fluorescence when excited with blue light, and *rhodamine,* which emits a deep red fluorescence when excited with green-yellow light (Figure 4-8). By coupling one antibody to fluorescein and another to rhodamine, the distributions of different molecules can be compared in the same cell; the two molecules are visualized separately in the microscope by switching back and forth between two sets of filters, each specific for one dye. As shown in Figure4-9, three fluorescent dyes can be used in the same way to distinguish three types of molecules in the same cell.

Important new methods, to be discussed later, enable fluorescence microscopy to be used to monitor changes in the concentration and location of specific molecules inside *living*cells (see p. 183).

Living Cells Are Seen Clearly in a Phase-Contrast or a Differential-Interference-Contrast Microscope [2], [5]

The possibility that some components of the cell may be lost or distorted during specimen preparation has always worried microscopists. The only certain way to avoid the problem is to examine cells while they are alive, without fixing or freezing. For this purpose light microscopes with special optical systems are especially useful.

When light passes through a living cell, the phase of the light wave is changed according to the cell's refractive index: light passing through a relatively thick or dense part of the cell, such as the nucleus, is retarded; its phase, consequently, is shifted relative to light that has passed through an adjacent thinner region of the cytoplasm. Both the phase-contrast microscope and the differential-interference-contrast microscope exploit the interference effects produced when these two sets of waves recombine, thereby creating an image of the cell's structure (Figure 4-10). Both types of light microscopy are widely used to visualize living cells.

A simpler way to see some of the features of a living cell is to observe the light that is scattered by its various components. In the dark-field microscope the illuminating rays of light are directed from the side so that only scattered light enters the microscope lenses. Consequently, the cell appears as an illuminated object against a black background. Images of the same cell obtained by four kinds of light microscopy are shown in Figure 4-11.

One of the great advantages of phase-contrast, differential-interference-contrast, and dark-field microscopy is that each makes it possible to watch the movements involved in such processes as mitosis and cell migration. Since many cellular motions are too slow to be seen in real time, it is often helpful to take time-lapse motion pictures (*microcinematography*) or video recordings. Here, successive frames separated by a short time delay are recorded, so that when the resulting film or videotape is projected or played at normal speed, events appear greatly speeded up.

Images Can Be Enhanced and Analyzed by Electronic Techniques [6]

In recent years electronic imaging systems and the associated technology of image processing have had a major impact on light microscopy. They have enabled certain practical limitations of microscopes (due to imperfections in the optical system) to be largely overcome. They have also circumvented two fundamental limitations of the human eye: the eye cannot see well in extremely dim light, and it cannot perceive small differences in light intensity against a bright background. The first limitation can be overcome by attaching highly light-sensitive video cameras (of the kind used in night surveillance) to a microscope. It is then possible to observe cells for long periods at very low light levels, thereby avoiding the damaging effects of prolonged bright light (and heat). Such *image-intensification systems* are especially important for viewing fluorescent molecules in living cells.

Because images produced by video cameras are in electronic form, they can be readily digitized, fed to a computer, and processed in various ways to extract latent information. Such image processing makes it possible to compensate for various optical faults in microscopes in order to attain the theoretical limit of resolution. Moreover, by using video systems linked to image processors, contrast can be greatly enhanced so that the eye's limitations in detecting small differences in light intensity are overcome. Although this processing also enhances the effects of random background irregularities in the optical system, this "noise" can be removed by electronically subtracting an image of a blank area of the field. Small transparent objects then become visible that were previously impossible to distinguish from the background.

The high contrast attainable by computer-assisted, differential-interference-contrast microscopy makes it possible to see even very small objects such as single microtubules (Figure 4-12), which have a diameter of 0.025 μm, less than one-tenth the wavelength of light. Individual microtubules can also be seen in a fluorescence microscope if they are fluorescently labeled (see Figure4-62). In both cases, however, the unavoidable diffraction effects badly blur the image so that the microtubules appear at least 0.2 μm wide, making it impossible to distinguish a single microtubule from a bundle of several microtubules.

Imaging of Complex Three-dimensional Objects Is Possible with the Confocal Scanning Microscope [7]

For ordinary light microscopy, as we have seen, a tissue has to be sliced into thin sections in order to be examined; the thinner the section, the crisper the image. In the process of sectioning, information about the third dimension is lost. How then can one get a picture of the three-dimensional architecture of a cell or tissue, and how can one view the microscopic structure of a specimen that, for one reason or another, cannot first be sliced into sections? If a thick specimen is viewed with a conventional light microscope, the image obtained by focusing at any one level is degraded by blurred, out-of-focus information from the parts of the specimen that lie above and below the plane of focus. Although this problem can be overcome by complex computer-based image processing applied to a series of images in different focal planes, the method is slow and costly in computing power. The confocal scanning microscope provides another, more direct way of achieving the same end result: electronic-imaging methods make it possible to focus on a chosen plane in a thick specimen while rejecting the light that comes from out-of-focus regions above and below that plane. Thus one sees a crisp, thin *optical section*. From a series of such optical sections taken at different depths and stored in a computer, it is easy to reconstruct a three-dimensional image. The confocal scanning microscope does for the microscopist what the CAT scanner does (by different means) for the radiologist investigating a human body: both machines give detailed sectional views of the interior of an intact structure.

The optical details of the confocal scanning microscope are complex, but the basic idea is simple, as illustrated in Figure 4-13. The microscope is generally used with fluorescence optics (see Figure 4-7), but instead of illuminating the whole specimen at once, in the usual way, the optical system at any instant focuses a spotlight onto a single point at a specific depth in the specimen. A very bright source of pinpoint illumination is required; this is usually supplied by a laser whose light has been passed through a pinhole. The fluorescence emitted from the illuminated material is collected and brought to an image at the entry port of a suitable light detector. A pinhole aperture is placed at the detector, at the site that is *confocal*with the illuminating pinhole - that is, precisely where the rays emitted from the illuminated point in the specimen come to a focus. Thus the light from this point in the specimen converges on this aperture and enters the detector. By contrast, the light from regions out of the plane of focus of the spotlight is also out of focus at the pinhole aperture and is therefore largely excluded from the detector (Figure 4-14). To build up a two-dimensional image, data from each point in the plane of focus are collected sequentially by scanning across the field in a raster pattern (as on a television screen) and are displayed on a video screen. Although not shown in Figure 4-13, the scanning is done by deflecting the beam with an oscillating mirror placed between the dichroic mirror and the objective lens in such a way that the illuminating spotlight and the confocal pinhole at the detector remain strictly in register.

The confocal scanning microscope has been used to resolve the structure of numerous complex three-dimensional objects (Figure 4-15), including the networks of cytoskeletal fibers in the cytoplasm and the arrangements of chromosomes and genes in the nucleus.

The Electron Microscope Resolves the Fine Structure of the Cell 8

The relationship between the limit of resolution and the wavelength of the illuminating radiation (see Figure 4-4) holds true for any form of radiation, whether it is a beam of light or a beam of electrons. With electrons, however, the limit of resolution can be made very small. The wavelength of an electron decreases as its velocity increases. In an electron microscope with an accelerating voltage of 100,000 V, the wavelength of an electron is 0.004 nm. In theory the resolution of such a microscope should be about 0.002 nm, which is 10,000 times greater than that of the light microscope. Because the aberrations of an electron lens are considerably harder to correct than those of a glass lens, however, the practical resolving power of most modern electron microscopes is, at best, 0.1 nm (1 Å) (Figure 4-16). Furthermore, problems of specimen preparation, contrast, and radiation damage effectively limit the normal resolution for biological objects to 2 nm (20 Å). This is nonetheless about 100 times better than the resolution of the light microscope. Some of the landmarks in the development of electron microscopy are outlined in Table 4-2.

In overall design the transmission electron microscope (TEM) is similar to a light microscope, although it is much larger and upside down (Figure 4-17). The source of illumination is a filament or cathode that emits electrons at the top of a cylindrical column about 2 meters high. Since electrons are scattered by collisions with air molecules, air must first be pumped out of the column to create a vacuum. The electrons are then accelerated from the filament by a nearby anode and allowed to pass through a tiny hole to form an electron beam that travels down the column. Magnetic coils placed at intervals along the column focus the electron beam, just as glass lenses focus the light in a light microscope. The specimen is put into the vacuum, through an airlock, into the path of the electron beam. As in the case of light microscopy, the specimen is usually stained, in this case with *electron-dense* material, as we see in the next section. Some of the electrons passing through the specimen are scattered by structures stained with the electron-dense material; the remainder are focused to form an image - in a manner analogous to the way an image is formed in a light microscope - either on a photographic plate or on a phosphorescent screen. Because the scattered electrons are lost from the beam, the dense regions of the specimen show up in the image as areas of reduced electron flux, which look dark.

Biological Specimens Require Special Preparation for the Electron Microscope 9

In the early days of its application to biological materials, the electron microscope revealed many previously unimagined structures in cells. But before these discoveries could be made, electron microscopists had to develop new procedures for embedding, cutting, and staining tissues.

Since the specimen is exposed to a very high vacuum in the electron microscope, there is no possibility of viewing it in the living, wet state. Tissues are usually preserved by fixation - first with *glutaraldehyde,* which covalently cross-links protein molecules to their neighbors, and then with *osmium tetroxide,* which binds to and stabilizes lipid bilayers as well as proteins (Figure 4-18). Since electrons have very limited penetrating power, the fixed tissues normally have to be cut into extremely thin sections (50 to 100 nm thick - about 1/200 of the thickness of a single cell) before they are viewed. This is achieved by dehydrating the specimen and permeating it with a monomeric resin that polymerizes to form a solid block of plastic; the block is then cut with a fine glass or diamond knife on a special microtome. These *thin sections,* free of water and other volatile solvents, are placed on a small circular metal grid for viewing in the microscope (Figure 4-19).

Contrast in the electron microscope depends on the atomic number of the atoms in the specimen: the higher the atomic number, the more electrons are scattered and the greater is the contrast. Biological molecules are composed of atoms of very low atomic number (mainly carbon, oxygen, nitrogen, and hydrogen). To make them visible, they are usually impregnated (before or after sectioning) with the salts of heavy metals such as uranium and lead. Different cellular constituents are revealed with various degrees of contrast according to their degree of impregnation, or "staining," with these salts. Lipids, for example, tend to stain darkly following osmium fixation, revealing the location of cell membranes (Figure 4-20).

In some cases specific macromolecules can be located in thin sections by techniques adapted from light microscopy. Certain enzymes in cells can be detected by incubating the specimen with a substrate whose reaction leads to the local deposition of an electron-dense precipitate (Figure 4-21). Alternatively, as discussed on page 186, antibodies can be coupled to an indicator enzyme (usually peroxidase) or to an electron-dense marker (usually tiny spheres of metallic gold, which are referred to as *colloidal gold* particles) and then used to locate the macromolecules that the antibodies recognize (see Figure 4-63).

Three-dimensional Images of Surfaces Can Be Obtained by Scanning Electron Microscopy 10

Thin sections are effectively two-dimensional slices of tissue and fail to convey the three-dimensional arrangement of cellular components. Although the third dimension can be reconstructed from serial sections (Figure4-22), this is a lengthy and tedious process.

Fortunately, there are more direct means to obtain a three-dimensional image. One is to examine a specimen in a scanning electron microscope (SEM), which is usually a smaller, simpler, and cheaper device than a transmission electron microscope. Whereas the transmission electron microscope uses the electrons that have passed through the specimen to form an image, the scanning electron microscope uses electrons that are scattered or emitted from the specimen's surface. The specimen to be examined is fixed, dried, and coated with a thin layer of heavy metal. The specimen is then scanned with a very narrow beam of electrons. The quantity of electrons scattered or emitted as this primary beam bombards each successive point of the metallic surface is measured and used to control the intensity of a second beam, which moves in synchrony with the primary beam and forms an image on a television screen. In this way a highly enlarged image of the surface as a whole is built up.

The SEM technique provides great depth of focus; moreover, since the amount of electron scattering depends on the angle of the surface relative to the beam, the image has highlights and shadows that give it a three-dimensional appearance (Figure 4-23). Only surface features can be examined, however, and in most forms of SEM the resolution attainable is not very high (about 10 nm, with an effective magnification of up to 20,000 times). As a result, the technique is usually used to study whole cells and tissues rather than subcellular organelles (see also Figure 4-32).

Metal Shadowing Allows Surface Features to Be Examined at High Resolution by Transmission Electron Microscopy [11]

The transmission electron microscope can also be used to study the surface of a specimen - and at a generally higher resolution than in a scanning electron microscope - such that individual macromolecules can be seen. As for scanning electron microscopy, a thin film of a heavy metal such as platinum is evaporated onto the dried specimen. The metal is sprayed from an oblique angle in order to deposit a coating that is thicker in some places than others - a process known as shadowing because a shadow effect is created that gives the image a three-dimensional appearance.

Some specimens coated in this way are thin enough or small enough for the electron beam to penetrate them directly; this is the case for individual molecules, viruses, and cell walls (Figure 4-24). For thicker specimens the organic material of the cell must be dissolved away after shadowing so that only the thin metal *replica* of the surface of the specimen is left. The replica is reinforced with a film of carbon so that it can be placed on a grid and examined in the transmission electron microscope in the ordinary way (Figure 4-25).

Freeze-Fracture and Freeze-Etch Electron Microscopy Provide Unique Views of the Cell Interior [12]

Two methods that use metal replicas have been particularly useful in cell biology. One of these, freeze-fracture electron microscopy, provides a way of visualizing the interior of cell membranes. Cells are frozen at the temperature of liquid nitrogen (-196°C) in the presence of a *cryoprotectant* (antifreeze) to prevent distortion from ice crystal formation, and then the frozen block is cracked with a knife blade. The fracture plane often passes through the hydrophobic middle of lipid bilayers, thereby exposing the interior of cell membranes. The resulting fracture faces are shadowed with platinum, the organic material is dissolved away, and the replicas are floated off and viewed in the electron microscope (as in Figure 4-25). Such replicas are studded with small bumps, called *intramembrane particles,* which represent large transmembrane proteins. The technique provides a convenient and dramatic way to visualize the distribution of such proteins in the plane of a membrane (Figure 4-26).

Another important and related replica method is freeze-etch electron microscopy, which can be used to examine either the exterior or interior of cells. In this technique the cells are frozen extremely rapidly - using a special device to slam the sample against a copper block cooled with liquid helium, for example - and the frozen block is cracked with a knife blade as just described. But now the ice level is lowered around the cells (and to a lesser extent within the cells) by the sublimation of ice in a vacuum as the temperature is raised (a process called *freeze-drying*) (Figure 4-27). The parts of the cell exposed by this *etching* process are then shadowed as before to make a platinum replica. This technique exposes structures in the interior of the cell and can reveal their three-dimensional organization with exceptional clarity (Figure4-28).

Because a metal-shadowed replica rather than the sample itself is viewed under vacuum in the microscope, both freeze-fracture and freeze-etch microscopy can be used to study frozen unfixed cells, thereby avoiding the risk of artifacts caused by fixation.

Negative Staining and Cryoelectron Microscopy Allow Macromolecules to Be Viewed at High Resolution 13

Although isolated macromolecules, such as DNA or large proteins, can be visualized readily in the electron microscope if they are shadowed with a heavy metal to provide contrast (see Figure 4-24), finer detail can be seen by using negative staining. Here, the molecules, supported on a thin film of carbon (which is nearly transparent to electrons), are washed with a concentrated solution of a heavy-metal salt such as uranyl acetate. After the sample has dried, a very thin film of metal salt covers the carbon film everywhere except where it has been excluded by the presence of an adsorbed macromolecule. Because the macromolecule allows electrons to pass much more readily than does the surrounding heavy-metal stain, a reversed or negative image of the molecule is created. Negative staining is especially useful for viewing large macromolecular aggregates such as viruses or ribosomes and for seeing the subunit structure of protein filaments (Figure 4-29).

Shadowing and negative staining are capable of providing high-contrast surface views of small macromolecular assemblies, but both are limited in resolution by the size of the smallest metal particles in the shadow or stain employed. Recent methods provide an alternative that has allowed even the interior features of three-dimensional structures such as viruses to be visualized directly at high resolution. In this technique, called cryoelectron microscopy, a very thin (~100 nm) layer of rapidly frozen hydrated sample is prepared on a microscope grid. A special sample holder is required to keep this hydrated specimen at -160°C in the vacuum of the microscope, where it can be viewed directly without fixation, staining, or drying. Surprisingly for unstained material, these specimens can be imaged with a considerable degree of contrast (Figure 4-30).

Regardless of the method used, a single protein molecule gives only a weak and ill-defined image in the electron microscope. Efforts to get better information by prolonging the time of inspection or by increasing the intensity of the illuminating beam are self-defeating because they damage and disrupt the object under examination. Therefore, to discover the details of molecular structure, it is necessary to combine the information obtained from many molecules in such a way as to average out the random errors in the individual images. This is possible for viruses or protein filaments, in which the individual subunits are present in regular repeating arrays; it is also possible for any substance that can be made to form a crystalline array in two dimensions in which large numbers of molecules are held in identical orientation and in regularly spaced positions. Given an electron micrograph of either type of array, one can use image-processing techniques to compute the average image of an individual molecule, revealing details obscured by the random "noise" in the original picture.

Image reconstructions of this type have allowed the interior structure of an enveloped virus to be obtained to a resolution of 3.5 nm and have revealed the shape of an individual protein molecule to the remarkable resolution of 0.35 nm (see Figure 10-31). But even in its most sophisticated forms, electron microscopy falls short of providing a full description of molecular structure because the atoms in a molecule are separated by distances of only 0.1 or 0.2 nm. Resolving molecular structure in atomic detail takes us beyond microscopy to techniques such as x-ray diffraction, which are described in a later section.

Summary

Many light-microscope techniques are available for observing cells. Cells that have been fixed and stained can be studied in a conventional light microscope, while antibodies coupled to fluorescent dyes can be used to locate specific molecules in cells in a fluorescence microscope. The confocal scanning microscope provides thin optical sections and can be used to reconstruct a three-dimensional image. Living cells can be seen with phase-contrast, differential-interference-contrast, or dark-field optics. All forms of light microscopy are facilitated by electronic image-processing techniques, which enhance sensitivity and refine the image.

Determining the detailed structure of the membranes and organelles in cells requires the higher resolution attainable in a conventional transmission electron microscope. Three-dimensional views of the surfaces of cells and tissues can be obtained by scanning electron microscopy, while the interior of membranes and cells can be visualized by freeze-fracture and freeze-etch electron microscopy, respectively. The shapes of isolated macromolecules that have been shadowed with a heavy metal or outlined by negative staining can also be readily visualized by electron microscopy.

Table 4-1. Some Important Discoveries in the History of Light Microscopy

1611 **Kepler** suggested a way of making a compound microscope.

1655 **Hooke** used a compound microscope to describe small pores in sections of cork that he called "cells".

1674 **Leeuwenhoek** reported his discovery of protozoa. He saw bacteria for the first time nine years later.

1833 **Brown** published his microscopic observations of orchids, clearly describing the cell nucleus.

1838 **Schleiden** and **Schwann** proposed the cell theory, stating that the nucleated cell is the unit of structure and function in plants and animals.

1857 **Kolliker** described mitochondria in muscle cells.

1876 **Abbé** analyzed the effects of diffraction on image formation in the microscope and showed how to optimize microscope design.

1879 **Flemming** described with great clarity chromosome behavior during mitosis in animal cells.

1881 **Retzius** described many animal tissues with a detail that has not been surpassed by any other light microscopist. In the next two decades he, **Cajal**, and other histologists developed staining methods and laid the foundations of microscopic anatomy.

1882 **Koch** used aniline dyes to stain microorganisms and identified the bacteria that cause tuberculosis and cholera. In the following two decades other bacteriologists, such as **Klebs** and **Pasteur**, identified the causative agents of many other diseases by examining stained preparations under the microscope.

1886 **Zeiss** made a series of lenses, to the design of **Abbé**, that enabled microscopists to resolve structures at the theoretical limits of visible light.

1898 **Golgi** first saw and described the Golgi apparatus by staining cells with silver nitrate.

1924 **Lacassagne** and collaborators developed the first autoradiographic method to localize radioactive polonium in biological specimens.

1930 **Lebedeff** designed and built the first interference microscope. In 1932 **Zernicke** invented the phase-contrast microscope. These two developments allowed unstained living cells to be seen in detail for the first time.

1941 **Coons** used antibodies coupled to fluorescent dyes to detect cellular antigens.

1952 **Nomarski** devised and patented the system of differential interference contrast for the light microscope that still bears his name.

1981 **Allen** and **Inoué** perfected video-enhanced-contrast light microscopy.

1988 Commercial confocal scanning microscopes came into widespread use.
Figure 4-1. Resolving power. Sizes of cells and their components drawn on a logarithmic scale, indicating the range of objects that can be readily resolved by the naked eye and in the light and electron microscopes. The following units of length are commonly employed in microscopy: μm (micrometer) = 10^{-6} m nm (nanometer) = 10^{-9} m Å (Ångström unit) = 10^{-10} m
Figure 4-2. Interference between light waves. When two light waves combine *in phase,* the amplitude of the resultant wave is larger and the brightness is increased. Two light waves that are *out of phase* partially cancel each other and produce a wave whose amplitude, and therefore brightness, is decreased.
Figure 4-3. Edge effects. The interference effects observed at high magnification when light passes the edges of a solid object placed between the light source and the observer.

LENSES

IMAGE

the **objective** lens collects a cone of light rays to create an image

specimen

2θ

the **condenser** lens focuses a cone of light rays onto each point of the specimen

LIGHT

RESOLUTION: the resolving power of the microscope depends on the width of the cone of illumination and therefore on both the condenser and the objective lens. It is calculated using the formula

$$\text{resolution} = \frac{0.61\,\lambda}{n\,\sin\theta}$$

where:

- θ = half the angular width of the cone of rays collected by the objective lens from a typical point in the specimen (since the maximum width is 180°, $\sin\theta$ has a maximum value of 1)
- n = the refractive index of the medium (usually air or oil) separating the specimen from the objective and condenser lenses
- λ = the wavelength of light used (for white light, a figure of 0.53 μm is commonly assumed)

NUMERICAL APERTURE: $n\sin\theta$ in the equation above is called the numerical aperture of the lens (NA) and is a function of its light-collecting ability. For dry lenses this cannot be more than 1, but for oil-immersion lenses it can be as high as 1.4. The higher the numerical aperture, the greater the resolution and the brighter the image (brightness is important in fluorescence microscopy). However, this advantage is obtained at the expense of very short working distances and a very small depth of field.

EXAMINATION WITH LIGHT MICROSCOPE
Figure 4-5. Making tissue sections. How an embedded tissue is sectioned with a microtome in preparation for examination in the light microscope.
Figure 4-6. A stained tissue section. A section of thick human skin, stained with a combination of dyes, hematoxylin and eosin, that is commonly used in histology.
Figure 4-7. The optical system of a modern fluorescence microscope. A filter set consists of two barrier filters (1 and 3) and a dichroic (beam-splitting) mirror (2). In this example the filter set for detection of the fluorescent molecule fluorescein is shown. High-numerical-aperture objective lenses are especially important in this type of microscopy since, for a given magnification, the brightness of the fluorescent image is proportional to the fourth power of the numerical aperture (see also Figure 4-4).

In the figure above:

1 first barrier filter: lets through only blue light with a wavelength between 450 and 490 nm

2 beam-splitting mirror: reflects light below 510 nm but transmits light above 510 nm

3 second barrier filter: cuts out unwanted fluorescent signals, passing the specific green fluorescein emission between 520 and 560 nm

fluorescein (green)

tetramethylrhodamine (red)

Figure 4-8. Fluorescent dyes. The structures of fluorescein and tetramethylrhodamine, two dyes that are commonly used for fluorescence microscopy. Fluorescein emits green light when activated by light of the appropriate wavelength, whereas the rhodamine dye emits red light. The portion of each molecule shown in *orange* denotes the position of a chemically reactive group; at this position a covalent bond is commonly formed between the dye and a protein (or other molecule). Commercially available versions of these dyes with different types of reactive groups allow the dye to be coupled either to an -SH group or to an -NH$_2$ group on a protein.

tubulin   actin   DNA

50 µm
Figure 4-9. Fluorescence microscopy. Micrographs of a portion of the surface of an early *Drosophila* embryo in which the microtubules have been labeled with an antibody coupled to fluorescein (*left panel*) and the actin filaments have been labeled with an antibody coupled to rhodamine (*middle panel*). In addition, the chromosomes have been labeled with a third dye that fluoresces only when it binds to DNA (*right panel*). At this stage, all the nuclei of the embryo share a common cytoplasm, and they are in the metaphase stage of mitosis. The three micrographs were taken of the same region of a fixed embryo using three different filter sets in the fluorescence microscope (see also Figure4-7). (Courtesy of Tim Karr.)

(A) incident light   (B) incident light

waves in phase

stained cell

unstained cell

waves out of phase
Figure 4-10. Two ways to obtain contrast in light microscopy. The stained portions of the cell in (A) reduce the amplitude of light waves of particular wavelengths passing through them. A colored image of the cell is thereby obtained that is visible in the ordinary way. Light passing through the unstained, living cell (B) undergoes very little change in amplitude, and the structural details cannot be seen even if the image is highly magnified. The *phase* of the light, however, is altered by its passage through the cell, and small phase differences can be made visible by exploiting interference effects using a phase-contrast or a differential-interference-contrast microscope.
Figure 4-11. Four types of light microscopy. (A) The image of a fibroblast in culture obtained by the simple transmission of light through the cell, a technique known as *bright-field microscopy.* The other images were obtained by techniques discussed in the text: (B) phase-contrast microscopy, (C) Nomarski differential-interference-contrast microscopy, and (D) dark-field microscopy. All four types of image can be obtained with most modern microscopes simply by interchanging optical components.
Figure 4-12. Extending the limits of detection. Light-microscope images of unstained microtubules that have been visualized by differential-interference-contrast microscopy followed by electronic image processing. (A) The original unprocessed image. (B) The final result of an electronic process that greatly enhances contrast and reduces "noise." Microtubules are only 0.025 μm in diameter and therefore in this image should appear only 0.1 mm wide. Instead, they appear much wider because of diffraction effects. (Courtesy of Bruce Schnapp.)
Figure 4-62. Immunofluorescence. (A) An electron micrograph of the periphery of a cultured epithelial cell showing the distribution of microtubules and other filaments. (B) The same area stained with fluorescent antibodies to tubulin, the protein subunit of microtubules, using the technique of indirect immunocytochemistry (see Figure 4-64). Arrows indicate individual microtubules that are readily recognizable in the two figures. (From M. Osborn, R. Webster, and K. Weber, *J. Cell Biol.* 77:R27-R34, 1978, by copyright permission of the Rockefeller University Press.)
Figure 4-13. The confocal scanning fluorescence microscope. This simplified diagram shows that the basic arrangement of optical components is similar to that of the standard fluorescence microscope shown in Figure 4-7 except that a laser is used to illuminate a small pinhole whose image is focused at a single point in the specimen (A). Emitted fluorescence from this focal point in the specimen is focused at a second (confocal) pinhole (B). Emitted light from elsewhere in the specimen is not focused here and therefore does not contribute to the final image (C). By scanning the beam of light across the specimen, a very sharp two-dimensional image of the exact plane of focus is built up that is not significantly degraded by light from other regions of the

specimen.
Figure 4-14. Comparison of conventional and confocal fluorescence microscopy. These two micrographs are of the same intact gastrula-stage *Drosophila* embryo that has been stained with a fluorescent probe for actin filaments. The conventional, unprocessed image (A) is blurred by the presence of fluorescent structures above and below the plane of focus. In the confocal image (B), this out-of-focus information is removed, which results in a crisp optical section of the cell in the embryo. (Courtesy of Richard Warn and Peter Shaw.)

Figure 4-15. Three-dimensional reconstruction from confocal scanning microscope images. Pollen grains, in this case from a passion flower, have a complex sculptured cell wall that contains fluorescent compounds. Images obtained at different depths through the grain, using a confocal scanning microscope, can be recombined to give a three-dimensional view of the whole grain, shown on the right. Three selected individual optical sections from the full set of 30, each of which shows little contribution from its neighbors, are shown on the left. (Courtesy of John White.)

Table 4-2. Major Events in the Development of the Electron Microscope and Its Applications to Cell Biology

1897 **J.J. Thomson** announced the existence of negatively charged particles, later termed *electrons*.

1924 **de Broglie** proposed that a moving electron has wavelike properties.

1926 **Busch** proved that it was possible to focus a beam of electrons with a cylindrical magnetic lens, laying the foundations of electron optics.

1931 **Ruska** and colleagues built the first transmission electron microscope.

1935 **Knoll** demonstrated the feasibility of the scanning electron microscope; three years later a prototype instrument was built by **Von Ardenne**.

1939 **Siemens** produced the first commercial transmission electron microscope.

1944 **Williams** and **Wyckoff** introduced the metal shadowing technique.

1945 **Porter, Claude**, and **Fullam** used the electron microscope to examine cells in tissue culture after fixing and staining them with OsO_4.

1948 **Pease** and **Baker** reliably prepared thin sections (0.1 to 0.2 m m thick) of biological material.

1952 **Palade, Porter**, and **Sjöstrand** developed methods of fixation and thin sectioning that enabled many intracellular structures to be seen for the first time. In one of the first applications of these techniques, **H.E. Huxley** showed that skeletal muscle contains overlapping arrays or protein filaments, supporting the "sliding filament" hypothesis of muscle contraction.

1953 **Porter and Blum** developed the first widely accepted ultramicrotome, incorporating many features introduced by **Claude** and **Sjöstrand** previously.

1956 **Glauert** and associates showed that the epoxy resin Araldite was a highly effective embedding agent for electron microscopy. **Luft** introduced another embedding resin, Epon, five years later.

1957 **Robertson** described the trilaminar structure of the cell membrane, seen for the first time in the electron microscope.

1957 Freeze-fracture techniques, initially developed by **Steere**, were perfected by **Moor and Mühlethaler**. Later (1966), **Branton** demonstrated that freeze-fracture allows the interior of the membrane to be visualized.

1959 **Singer** used antibodies coupled to ferritin to detect cellular molecules in the electron microscope.

1959 **Brenner and Horne** developed the negative staining technique, invented four years previously by **Hall**, into a generally useful technique for visualizing viruses, bacteria, and protein filaments.

1963 **Sabatini, Bensch, and Barrnett** introduced glutaraldehyde (usually followed by OsO_4) as a fixative for electron microscopy.

1965 **Cambridge Instruments** produced the first commercial scanning electron microscope.

1968 **de Rosier and Klug** described techniques for the reconstruction of three-dimensional structures from electron micrographs.

1975 **Henderson and Unwin** determined the first structure of a membrane protein by computer-based reconstruction from electron micrographs of unstained samples.

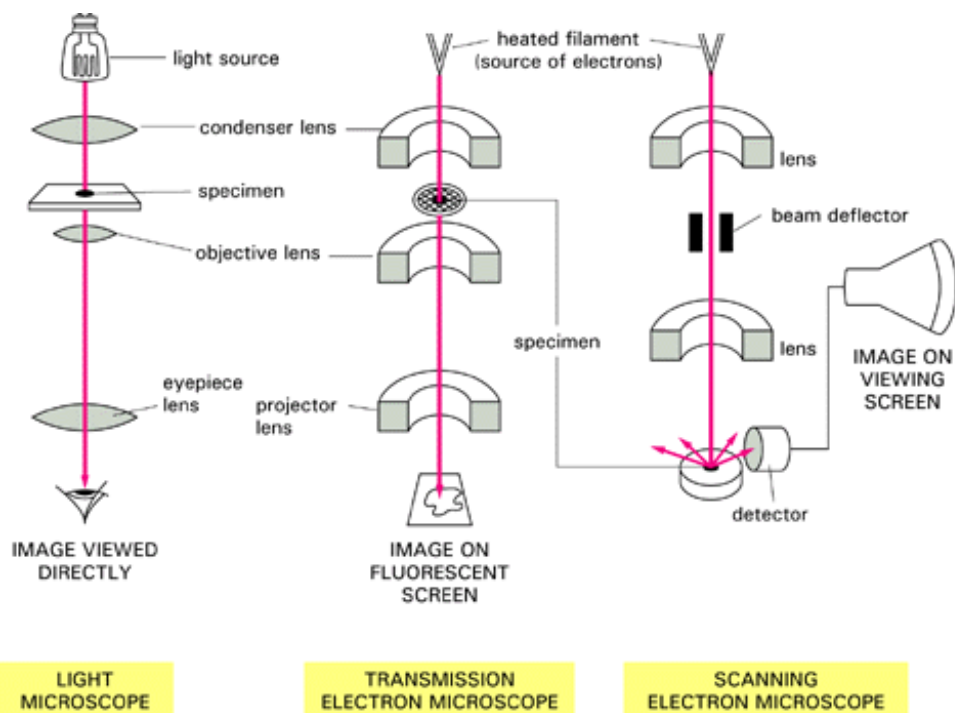
1979 **Heuser**, **Reese**, and colleagues developed a high-resolution, deep-etching technique using very rapidly frozen specimens.
Figure 4-16. Limit of resolution of the electron microscope. Electron micrograph of a thin layer of gold showing the individual files of atoms in the crystal as bright spots. The distance between adjacent files of gold atoms is about 0.2 nm (2 Å). (Courtesy of Graham Hills.)


Figure 4-17. Principal features of a light microscope, a transmission electron microscope, and a scanning electron microscope. These drawings emphasize the similarities of overall design. Whereas the lenses in the light microscope are made of glass, those in the electron microscope are magnetic coils. The two types of electron microscopes require that the specimen be placed in a vacuum.

glutaraldehyde   osmium tetroxide
Figure 4-18. Two common chemical fixatives used for electron microscopy. The two reactive aldehyde groups of glutaraldehyde enable it to cross-link various types of molecules, forming covalent bonds between them. Osmium tetroxide is reduced by many organic compounds with which it forms cross-linked complexes. It is especially useful for fixing cell membranes, since it reacts with the C=C double bonds present in many fatty acids.
Figure 4-19. Diagram of the copper grid used to support the thin sections of a specimen in the transmission electron microscope.
Figure 4-20. Electron micrograph of a root-tip cell stained with osmium and other heavy metal ions. The cell wall, nucleus, vacuoles, mitochondria, endoplasmic reticulum, Golgi apparatus, and ribosomes are easily seen. (Courtesy of Brian Gunning.)
Figure 4-21. Electron micrograph of a cell showing the location of a particular enzyme (nucleotide diphosphatase) in the Golgi apparatus. A thin section of the cell was incubated with a substrate that formed an electron-dense precipitate upon reaction with the enzyme. (Courtesy of Daniel S. Friend.)
Figure 4-63. Immunogold electron microscopy. Electron micrographs of an insulin-secreting cell in which the insulin molecules have been labeled with anti-insulin antibodies bound to tiny colloidal gold spheres (each seen as a black dot). Most of the insulin is stored in the dense cores of secretory vesicles; in addition, some cores are being degraded in lysosomes. (From L. Orci, *Diabetologia* 28:528-546, 1985.)
Figure 4-22. Three-dimensional reconstruction from serial sections. Single thin sections sometimes give misleading impressions. In this example most sections through a cell containing a branched mitochondrion will appear to contain two or three separate mitochondria. Sections 4 and 7, moreover, might be interpreted as showing a mito-chondrion in the process of dividing. The true three-dimensional shape, however, can be reconstructed from serial sections.

As in light microscopy, phase contrast can be used to get an image of the unstained specimen. A large number of these images can then be combined by image-processing methods to produce a three-dimensional image of the virus at high resolution (B). (Courtesy of Stephen Fuller.)

Introduction

Although the structure of organelles and large molecules in a cell can be seen with microscopes, a molecular understanding of a cell requires detailed biochemical analysis. Unfortunately, most biochemical procedures require large numbers of cells and begin by disrupting them. If the sample is a piece of tissue, fragments of all of its cells will be mixed together, creating confusion if the cells are of several types, which is almost always the case. In order to preserve as much information as possible about each individual type of cell, cell biologists have developed ways of dissociating cells from tissues and separating the various types. The resulting, relatively homogenous population of cells then can be analyzed - either directly or after their number has been greatly increased by allowing them to proliferate in culture.

Cells Can Be Isolated from a Tissue and Separated into Different Types <u>15</u>

The first step in isolating cells of a uniform type from a tissue that contains a mixture of cell types is to disrupt the extracellular matrix and intercellular junctions that hold the cells together. The best yields of viable dissociated cells are usually obtained from fetal or neonatal tissues, typically by treating them with proteolytic enzymes (such as trypsin and collagenase) and with agents (such as ethylenediaminetetraacetic acid, or EDTA) that bind, or *chelate,* the Ca^{2+} on which cell-cell adhesion depends. The tissue can then be dissociated into single viable cells by gentle agitation.

Several approaches are used to separate the different cell types from a mixed cell suspension. One involves exploiting differences in physical properties. Large cells can be separated from small cells and dense cells from light cells by centrifugation, for example. These techniques will be described in connection with the separation of organelles and macromolecules, for which they were originally developed. Another approach is based on the tendency of some cell types to adhere strongly to glass or plastic, which allows them to be separated from cells that adhere less strongly.

An important refinement of this last technique depends on the specific binding properties of antibodies. Antibodies that bind specifically to the surface of only one cell type in a tissue can be coupled to various matrices - such as collagen, polysaccharide beads, or plastic-to form an *affinity surface* to which only cells recognized by the antibodies will adhere. The bound cells are then recovered by gentle shaking, by treatment with trypsin to digest the proteins that mediate the adhesion, or, in the case of a digestible matrix (such as collagen), by degrading the matrix itself with enzymes (such as collagenase).

The most sophisticated cell-separation technique involves labeling specific cells with antibodies coupled to a fluorescent dye and then separating the labeled cells from the unlabeled ones in an electronic fluorescence-activated cell sorter. Here, individual cells traveling in single file in a fine stream are passed through a laser beam and the fluorescence of each cell is measured. Slightly farther downstream, tiny droplets, most containing either one cell or no cells, are formed by a vibrating nozzle. The droplets containing a single cell are automatically given a positive or a negative charge at the moment of formation, depending on whether the cell they contain is fluorescent; they are then deflected by a strong electric field into an appropriate container. Occasional clumps of cells, detected by their increased light scattering, are left uncharged and are discarded into a waste container. Such machines can select 1 cell in 1000 and sort about 5000 cells each second (<u>Figure 4-31</u>).

When a uniform population of cells has been obtained by any of these methods, it can be used directly for biochemical analysis. Alternatively, it provides a suitable starting material for cell culture, allowing the complex behavior of cells to be studied under the strictly defined conditions of a culture dish.

Cells Can Be Grown in a Culture Dish <u>16</u>

Given appropriate conditions, most kinds of plant and animal cells will live, multiply, and even express differentiated properties in a tissue-culture dish. The cells can be watched under the microscope or analyzed biochemically, and the effects of adding or removing specific molecules, such as hormones or growth factors, can be explored. In addition, in a mixed culture the interactions between one cell type and another can be studied. Experiments on cultured cells are sometimes said to be carried out *in vitro* (literally, "in glass") to contrast them with experiments on intact organisms, which are said to be carried out *in vivo* (literally, "in the living organism"). The terms can be confusing because they are often used in a different sense by biochemists, for whom *in vitro* refers to biochemical reactions occurring outside living cells, while *in vivo* refers to any reaction taking place

inside a living cell.

Tissue culture began in 1907 with an experiment designed to settle a controversy in neurobiology. The hypothesis under examination was known as the *neuronal doctrine,* which states that each nerve fiber is the outgrowth of a single nerve cell and not the product of the fusion of many cells. To test this contention, small pieces of spinal cord were placed on clotted tissue fluid in a warm, moist chamber and observed at regular intervals under the microscope. After a day or so, individual nerve cells could be seen extending long, thin processes into the clot. Thus the neuronal doctrine was validated, and the foundations for the cell-culture revolution were laid.

The original experiments in 1907 involved the culture of small tissue fragments, or explants. Today, cultures are more commonly made from suspensions of cells dissociated from tissues as described above. Unlike bacteria, most tissue cells are not adapted to living in suspension and require a solid surface on which to grow and divide, which is now usually the surface of a plastic tissue-culture dish (Figure 4-32). Cells vary in their requirements, however, and some will not grow or differentiate unless the culture dish is coated with specific extracellular matrix components, such as collagen or laminin.

Cultures prepared directly from the tissues of an organism, either with or without an initial cell-fractionation step, are called primary cultures. In most cases cells in primary cultures can be removed from the culture dish and used to form a large number of secondary cultures; they may be repeatedly subcultured in this way for weeks or months. Such cells often display many of the differentiated properties appropriate to their origin: fibroblasts continue to secrete collagen; cells derived from embryonic skeletal muscle fuse to form giant muscle fibers that spontaneously contract in the culture dish; nerve cells extend axons that are electrically excitable and make synapses with other nerve cells; and epithelial cells form extensive sheets with many of the properties of an intact epithelium. Since these phenomena occur in culture, they are accessible to study in ways that are not possible in intact tissues.

Serum-free, Chemically Defined Media Permit Identification of Specific Growth Factors 17

Until the early 1970s tissue culture was something of a blend of science and witchcraft. Although tissue fluid clots were replaced by dishes of liquid media containing specified quantities of small molecules such as salts, glucose, amino acids, and vitamins, most media also included a poorly defined mixture of macromolecules in the form of horse serum or fetal calf serum or a crude extract made from chick embryos. Such media are still used today for most routine cell culture (Table 4-3), but they make it difficult for the investigator to know which specific macromolecules a particular type of cell needs to have in the medium in order to thrive and function normally.

This difficulty led to the development of various *serum-free, chemically defined media.* In addition to the usual small molecules, such defined media contain one or more specific proteins that most cells require in order to survive and proliferate in culture. These include growth factors, which stimulate cell proliferation, and *transferrin,* which carries iron into cells. Many of the extracellular protein signaling molecules essential for the survival, development, and proliferation of specific cell types have been discovered by studies in cell culture, and the search for new ones has been made very much easier by the availability of serum-free, chemically defined media.

Eucaryotic Cell Lines Are a Widely Used Source of Homogeneous Cells 18

Most vertebrate cells die after a finite number of divisions in culture. Human skin cells, for example, typically last for several months in culture, dividing only 50 to 100 times before they die out. It has been suggested that this limited life-span is related to the limited life-span of the animal from which the cells are derived. Occasionally, however, some cells in a culture will undergo a genetic change that makes them effectively immortal. Such cells will proliferate indefinitely and can be propagated as a cell line (Table 4-4).

Cells lines can also be prepared from cancer cells, but they differ from those prepared from normal cells in several ways. Cancer cell lines often grow without attaching to a surface, for example, and they proliferate to a very much higher density in a culture dish. Similar properties can be experimentally induced in normal cells by *transforming* them with a tumor-inducing virus or chemical. The resulting transformed cell lines, in reciprocal fashion, can often cause tumors if injected into a susceptible animal. Both transformed and untransformed cell lines are extremely useful in cell research as sources of very large numbers of cells of a uniform type, especially since they can be stored in liquid nitrogen at -196°C for an indefinite period and are still viable when thawed. It is important to recognize, however, that the cells in both types of cell lines nearly always differ in important ways from their normal progenitors in the tissues from which they were derived.

Although all the cells in a cell line are very similar, they are often not identical. The genetic uniformity of a cell line can be improved by cell cloning, in which a single cell is isolated and allowed to proliferate to form a large colony. A *clone* is any such collection of cells that are all descendants of a single ancestor cell. One of the most important uses of cell cloning has been the isolation of mutant cell lines with defects in specific genes. Studying cells that are defective in a specific protein often reveals a good deal about the function of that protein in normal cells.

Cells Can Be Fused Together to Form Hybrid Cells [19]

It is possible to fuse one cell with another to form a combined cell with two separate nuclei, called a heterocaryon. Typically, a suspension of cells is treated with certain inactivated viruses or with polyethylene glycol, either of which alters the plasma membranes of cells in a way that induces them to fuse with each other. Heterocaryons provide a way of mixing the components of two separate cells in order to study their interactions. The inert nucleus of a chicken red blood cell, for example, is reactivated to make RNA and eventually to replicate its DNA when it is exposed to the cytoplasm of a growing tissue-culture cell by fusion. The first direct evidence that membrane proteins are able to move in the plane of the plasma membrane came from an experiment in which mouse cells and human cells were fused: although the mouse and human cell-surface proteins were initially confined to their own halves of the heterocaryon plasma membrane, they quickly diffused and mixed over the entire surface of the cell.

Eventually, a heterocaryon will proceed to mitosis and produce a hybrid cell in which the two separate nuclear envelopes have been disassembled, allowing all the chromosomes to be brought together in a single large nucleus (Figure4-33). Although such hybrid cells can be cloned to produce hybrid cell lines, the cells tend to be unstable and lose chromosomes. For unknown reasons, mouse-human hybrid cells predominantly lose human chromosomes. These chromosomes are lost at random, giving rise to a variety of mouse-human hybrid cell lines, each of which contains only one or a few human chromosomes. This phenomenon has been put to good use in mapping the locations of genes in the human genome: only hybrid cells containing human chromosome 11, for example, synthesize human insulin, indicating that the gene encoding insulin is located on chromosome 11. The same hybrid cells are also used as a source of human DNA for preparing chromosome-specific human DNA libraries. Later in this chapter we shall learn how hybrid cells have been useful in the production of monoclonal antibodies.

Some important steps in the development of cell culture are outlined in Table 4-5.

Summary

Tissues, usually from very young organisms, can be dissociated into their component cells, from which individual cell types can be purified and used for biochemical analysis or for the establishment of cell cultures. Many animal and plant cells survive and proliferate in a culture dish if they are provided with a suitable medium containing nutrients and specific protein growth factors. Although most animal cells die after a finite number of divisions, rare immortal variant cells arise spontaneously in culture and can be maintained indefinitely as cell lines. Clones derived from a single ancestor cell make it possible to isolate uniform populations of mutant cells with defects in a single protein. Two types of cell can be fused to produce heterocaryons with two nuclei, which can be used to study interactions between the components of the original two cells. Heterocaryons eventually form hybrid cells with one fused nucleus; such cells provide a convenient method for assigning genes to specific chromosomes.
Figure 4-31. A fluorescence-activated cell sorter. When a cell passes through the laser beam, it is monitored for fluorescence. Droplets containing single cells are given a negative or positive charge, depending on whether the cell is fluorescent or not. The droplets are then deflected by an electric field into collection tubes according to their charge. Note that the cell concentration must be adjusted so that most droplets contain no cells and flow to a waste container together with any cell clumps. The same apparatus can also be used to separate fluorescently labeled chromosomes from one another, providing valuable starting material for the isolation and mapping of genes.

Table 4-3. Composition of a Typical Medium Suitable for the Cultivation of Mammalian Cells

Amino Acids	Vitamins	Salts	Miscellaneous	Proteins (required in serum-free, chemically defined media)
Arginine	Biotin	NaCl	Glucose	Insulin
Cystine	Choline	KCl	Penicillin	Transferrin
Glutamine	Folate	NaH_2PO_4	Streptomycin	Specific growth factors
Histidine	Nicotinamide	$NaHCO_3$	Phenol red	
Isoleucine	Pantothenate	$CaCl_2$	Whole serum	
Leucine	Pyridoxal	$MgCl_2$		
Lysine	Thiamine			
Methionine	Riboflavin			
Phenylalanine				
Threonine				

Tryptophan

Tyrosine

Valine

Glucose is used at a concentration of 5 to 10 mM. The amino acids are all in the L form and, with one or two exceptions, are used at concentrations of 0.1 or 0.2 mM; vitamins are used at a 100-fold lower concentration, that is, about 1 μM. Serum, which is usually from horse or calf, is added to make up 10% of the total volume. Penicillin and streptomycin are antibiotics added to suppress the growth of bacteria. Phenol red is a pH indicator dye whose color is monitored to assure a pH of about 7.4.Cultures are usually grown in a plastic or glass container with a suitably prepared surface that allows the attachment of cells. The containers are kept in an incubator at 37°C in an atmosphere of 5% CO_2, 95% air.

Table 4-4. Some Commonly Used Cell Lines

Cell Line*	Cell Type and Origin
3T 3	fibroblast (mouse)
BHK 21	fibroblast (Syrian hamster)
MDCK	epithelial cell (dog)
HeLa	epithelial cell (human)
PtK 1	epithelial cell (rat kangaroo)
L 6	myoblast (rat)
PC 12	chromaffin cell (rat)
SP 2	plasma cell (mouse)

*. Many of these cell lines were derived from tumors. All of them are capable of indefinite replication in culture and express at least some of the differentiated properties of their cell of origin. BHK 21 cells, HeLa cells, and SP 2 cells are capable of growth in suspension; the other cell lines require a solid culture substratum in order to multiply.
Figure 4-33. The production of hybrid cells. Human cells and mouse cells are fused to produce heterocaryons (each with two or more nuclei), which eventually form hybrid cells (each with one fused nucleus). These particular hybrid cells are useful for mapping human genes on specific human chromosomes because most of the human chromosomes are quickly lost in a random

manner, leaving clones that retain only one or a few. The hybrid cells produced by fusing other types of cells often retain most of their chromosomes.

Table 4-5. Some Landmarks in the Development of Tissue and Cell Culture

1885 **Roux** showed that embryonic chick cells could be maintained alive in a saline solution outside the animal body.

1907 **Harrison** cultivated amphibian spinal cord in a lymph clot, thereby demonstrating that axons are produced as extensions of single nerve cells.

1910 **Rous** induced a tumor by using a filtered extract of chicken tumor cells, later shown to contain an RNA virus (Rous sarcoma virus).

1913 **Carrel** showed that cells could grow for long periods in culture provided they were fed regularly under aseptic conditions.

1948 **Earle** and colleagues isolated single cells of the L cell line and showed that they formed clones of cells in tissue culture.

1952 **Gey** and colleagues established a continuous line of cells derived from human cervical carcinoma, which later became the well-known HeLa cell line.

1954 **Levi-Montalcini** and associates showed that nerve growth factor (NGF) stimulated the growth of axons in tissue culture.

1955 **Eagle** made the first systematic investigation of the essential nutritional requirements of cells in culture and found that animal cells could propagate in a defined mixture of small molecules supplemented with a small proportion of serum proteins.

1956 **Puck** and associates selected mutants with altered growth requirements from cultures of HeLa cells.

1958 **Temin and Rubin** developed a quantitative assay for the infection of chick cells in culture by purified Rous sarcoma virus. In the following decade the characteristics of this and other types of viral transformation were established by **Stoker, Dulbecco, Green,** and other virologists.

1961 **Hayflick and Moorhead** showed that human fibroblasts die after a finite number of divisions in culture.

1964 **Littlefield** introduced HAT medium for the selective growth of somatic cell hybrids. Together with the technique of cell fusion, this made somatic-cell genetics accessible. **Kato and Takeuchi** obtained a complete carrot plant from a single carrot root cell in tissue culture.

1965 **Ham** introduced a defined, serum-free medium able to support the clonal growth of certain mammalian cells. **Harris and Watkins** produced the first heterocaryons of mammalian cells by the virus-induced fusion of human and mouse cells.

1968 **Augusti-Tocco and Sato** adapted a mouse nerve cell tumor (neuroblastoma) to tissue culture and isolated clones that were electrically excitable and that extended nerve processes. A number of other differentiated cell lines were isolated at about this time, including skeletal muscle and liver cell lines.

1975 **Köhler and Milstein** produced the first monoclonal antibody-secreting hybridoma cell lines.

1976 **Sato** and associates published the first of a series of papers showing that different cell lines require different mixtures of hormones and growth factors to grow in serum-free medium.

1977 **Wigler and Axel** and their associates developed an efficient method for introducing single-copy mammalian genes into cultured cells, adapting an earlier method developed by **Graham and van der Eb.**

Fractionation of Cells and Analysis of Their Molecules [20]

Introduction

Although biochemical analysis requires disruption of the anatomy of the cell, gentle separation techniques have been devised that preserve the functions of the various cell components. Just as a tissue can be separated into its living constituent cell types, so the cell can be separated into its functioning organelles and macromolecules. In this section we consider the methods that allow organelles and proteins to be purified and analyzed biochemically. The powerful recombinant DNA techniques used to analyze genes and proteins are discussed in Chapter 7.

Organelles and Macromolecules Can Be Separated by Ultracentrifugation [21]

Cells can be disrupted in various ways: they can be subjected to osmotic shock or ultrasonic vibration, or forced through a small orifice, or ground up. These procedures break many of the membranes of the cell (including the plasma membrane and membranes of the endoplasmic reticulum) into fragments that immediately reseal to form small closed vesicles. If carefully applied, however, the disruption procedures leave organelles such as nuclei, mitochondria, the Golgi apparatus, lysosomes, and peroxisomes largely intact. The suspension of cells is thereby reduced to a thick soup (called a *homogenate* or *extract*) containing a variety of membrane-bounded particles, each with a distinctive size, charge, and density. Provided that the homogenization medium has been carefully chosen (by trial and error for each organelle), the various particles - including the vesicles derived from the endoplasmic reticulum, called *microsomes* - retain most of their original biochemical properties.

The various components of the homogenate must then be separated. This became possible only after the commercial development in the early 1940s of an instrument known as the preparative ultracentrifuge, in which preparations of broken cells are rotated at high speeds (Figure 4-34). This treatment separates cell components on the basis of size and density: in general, the largest units experience the largest centrifugal force and move the most rapidly. At relatively low speed, large components such as nuclei and unbroken cells sediment to form a pellet at the bottom of the centrifuge tube; at slightly higher speed, a pellet of mitochondria is deposited; and at even higher speeds and with longer periods of centrifugation, first the small closed vesicles and then the ribosomes can be collected (Figure 4-35). All of these fractions are impure, but many of the contaminants can be removed by resuspending the pellet and repeating the centrifugation procedure several times.

Centrifugation is the first step in most fractionations, but it separates only components that differ greatly in size. A finer degree of separation can be achieved by layering the homogenate as a narrow band on top of a dilute salt solution that fills a centrifuge tube. When centrifuged, the various components in the mixture move as a series of distinct bands through the salt solution, each at a different rate, in a process called velocity sedimentation (Figure 4-36). For the procedure to work effectively, the bands must be protected from convective mixing, which would normally occur whenever a denser solution (for example, one containing organelles) finds itself on top of a lighter one (the salt solution). This is achieved by filling the centrifuge tube with a shallow gradient of sucrose prepared by a special mixing device; the resulting *density gradient,* with the dense end at the bottom of the tube, keeps each region of the salt solution denser than any solution above it and thereby prevents convective mixing from distorting the separation.

When sedimented through such dilute sucrose gradients, different cell components separate into distinct bands that can be collected individually. The rate at which each component sediments depends primarily on its size and shape and is normally described in terms of its *sedimentation coefficient,* or *s value*. Present-day ultracentrifuges rotate at speeds of up to 80,000 rpm and produce forces as high as 500,000 times gravity. With these enormous forces, even small macromolecules, such as tRNA molecules and simple enzymes, can be driven to sediment at an appreciable rate and so can be separated from one another on the basis of their size. Measurements of sedimentation coefficients are routinely used to help determine the size and subunit composition of the organized assemblies of macromolecules found in cells.

The ultracentrifuge is also used to separate cellular components on the basis of their *buoyant density,* independently of their size and shape. In this case the sample is usually sedimented through a steep density gradient that contains a very high concentration of sucrose or cesium chloride. Each cellular component begins to move down the gradient as in Figure 4-36, but it eventually reaches a position where the density of the solution is equal to its own density. At this point the component floats and can move no farther. A series of distinct bands is thereby produced in the centrifuge tube, with the bands closest to the bottom of the tube containing the components of highest buoyant density. This method, called equilibrium sedimentation, is so sensitive that it is capable of separating macromolecules that have incorporated heavy isotopes, such as ^{13}C or ^{15}N, from the same macromolecules that have not. In fact, the cesium-chloride method was developed in 1957 to separate the labeled from the unlabeled DNA produced after exposure of a growing population of bacteria to nucleotide precursors containing ^{15}N; this classic experiment provided direct evidence for the semiconservative replication of DNA.

The Molecular Details of Complex Cellular Processes Can Be Deciphered in Cell-free Systems [22]

Studies of organelles and other large subcellular components isolated in the ultracentrifuge have played an important part in determining the *functions* of different components of the cell. Experiments on mitochondria and chloroplasts purified by centrifugation, for example, demonstrated the central function of these organelles in energy interconversions. Similarly, resealed vesicles formed from fragments of rough and smooth endoplasmic reticulum (microsomes) have been separated from each other and analyzed as functional models of these compartments of the intact cell. An extension of this approach makes it possible to study other biological processes free from all of the complex side reactions that occur in a cell and without being constrained by the need to keep the cell as a whole alive. Fractionated cell homogenates that maintain a biological function (called cell-free

systems) are widely used in this way.

An early triumph was the elucidation of the mechanisms of protein synthesis. The starting point was a crude cell homogenate that could translate RNA molecules into protein. Fractionation of this homogenate, step by step, produced in turn the ribosomes, tRNA, and various enzymes that together constitute the protein-synthetic machinery. Once individual pure components were available, they could be added separately or withheld and their exact role in the process defined. The same *in vitro translation system*was later used to decipher the genetic code by using synthetic polyribonucleotides of known sequence as the "messenger RNA" (mRNA) to be translated. Today, *in vitro* translation systems are used to determine how newly made proteins are sorted into various intracellular compartments, as well as to identify the proteins encoded by purified preparations of mRNA - an important step in gene-cloning procedures. Some landmarks in the development of methods for the preparation of fractionated cell homogenates are outlined in Table 4-6.

Much of what we know about the molecular biology of the cell has been discovered by studying cell-free systems. As a few of many examples, they have been used to analyze the molecular details of DNA replication and transcription, RNA splicing, muscle contraction, and particle transport along microtubules. Cell-free systems have even been used to study such complex and highly organized processes as the cell-division cycle, the separation of chromosomes on the mitotic spindle, and the vesicular-transport steps involved in the movement of proteins from the endoplasmic reticulum through the Golgi apparatus to the plasma membrane. Cell-free extracts of this kind then provide the starting material for the complete separation of all of the individual macromolecular components of the extract, especially all of its proteins. We now consider how this is achieved.

Proteins Can Be Separated by Chromatography 23

One of the most generally useful methods for protein fractionation is chromatography, a technique originally developed to separate small molecules such as sugars and amino acids. A common type of chromatography, still widely used to separate small molecules, is *partition chromatography.* Typically, a drop of the sample is applied as a spot to a sheet of absorbent material, which may be paper (*paper chromatography*) or a sheet of plastic or glass covered with a thin layer of inert absorbent material, such as cellulose or silica gel (*thin-layer chromatography*). A mixture of solvents, such as water and an alcohol, is allowed to permeate the sheet from one edge; as the liquid moves across the sheet, the molecules in the sample become separated according to their relative solubilities in the two solvents. To achieve this, the solvents are selected so that one of them is held more strongly than the other by the absorbent material and forms a stationary solvent layer adsorbed on its surface. In each region of the sheet molecules equilibrate between the stationary and moving solvents: those that are most soluble in the strongly adsorbed solvent are relatively retarded because they spend more time in the stationary layer, while those that are most soluble in the other solvent move more quickly. After a number of hours the sheet is dried and stained to determine the location of the various molecules (Figure 4-37).

Proteins are most often fractionated by *column chromatography,* in which a mixture of proteins in solution is passed through a column containing a porous solid matrix. The different proteins are retarded to different extents by their interaction with the matrix, and they can be collected separately as they flow out of the bottom of the column (Figure 4-38). According to the choice of matrix, proteins can be separated according to their charge (ion-exchange chromatography), their hydrophobicity (hydrophobic chromatography), their size (gel-filtration chromatography), or their ability to bind to particular chemical groups (affinity chromatography).

Many types of matrices are commercially available for these purposes (Figure 4-39). *Ion-exchange columns* are packed with small beads that carry either a positive or negative charge, so that proteins are fractionated according to the arrangement of charges on their surface. *Hydrophobic columns* are packed with beads from which hydrophobic side chains protrude, so that proteins with exposed hydrophobic regions are retarded. *Gel-filtration columns,* which separate proteins according to their size, are packed with tiny porous beads: molecules that are small enough to enter the pores linger inside successive beads as they pass down the column, while larger molecules remain in the solution flowing between the beads and therefore move more rapidly, emerging from the column first. Besides providing a means of separating molecules, gel-filtration chromatography is a convenient way to determine their size.

These types of column chromatography do not produce very highly purified fractions if one starts with a complex mixture of proteins: a single passage through the column generally increases the proportion of a given protein in the mixture by no more than twentyfold. Since most individual proteins represent less than 1/1000 of the total cellular protein, it is usually necessary to use several different types of column in succession to attain sufficient purity (Figure4-40). A more efficient procedure, known as affinity chromatography, takes advantage of the biologically important binding interactions that occur on protein surfaces. If an

enzyme substrate is covalently coupled to an inert matrix such as a polysaccharide bead, for example, the enzyme that operates on that substrate will often be specifically retained by the matrix and can then be eluted (washed out) in nearly pure form. Likewise, short DNA oligonucleotides of a specifically designed sequence can be immobilized in this way and used to purify DNA-binding proteins that normally recognize this sequence of nucleotides in chromosomes (see Figure 9-23). Alternatively, specific antibodies can be coupled to a matrix in order to purify protein molecules recognized by the antibodies. Because of the great specificity of all such *affinity columns,* 1000- to 10,000-fold purifications can sometimes be achieved in a single pass.

The resolution of conventional column chromatography is limited by inhomogeneities in the matrices (such as cellulose), which cause an uneven flow of solvent through the column. Newer chromatography resins (usually silica-based) have been developed in the form of tiny spheres (3 to 10 μm in diameter) that can be packed with a special apparatus to form a uniform column bed. A high degree of resolution is attainable on such high-performance liquid chromatography (HPLC) columns. Because they contain such tightly packed particles, HPLC columns have negligible flow rates unless high pressures are applied. For this reason these columns are typically packed in steel cylinders and require an elaborate system of pumps and valves to force the solvent through them at sufficient pressure to produce the desired rapid flow rates of about one column volume per minute. In conventional column chromatography, flow rates must be kept slow (often about one column volume per hour) to give the solutes being fractionated time to equilibrate with the interior of the large matrix particles. In HPLC the solutes equilibrate very rapidly with the interior of the tiny spheres, so solutes with different affinities for the matrix are efficiently separated from one another even at fast flow rates. This allows most fractionations to be carried out in minutes, whereas hours are required to obtain a poorer separation by conventional chromatography. HPLC has therefore become the method of choice for separating many proteins and small molecules.

The Size and Subunit Composition of a Protein Can Be Determined by SDS Polyacrylamide-Gel Electrophoresis [24]

Proteins usually have a net positive or negative charge that reflects the mixture of charged amino acids they contain. If an electric field is applied to a solution containing a protein molecule, the protein will migrate at a rate that depends on its net charge and on its size and shape. This technique, known as electrophoresis, was originally used to separate mixtures of proteins either in free aqueous solution or in solutions held in a solid porous matrix such as starch.

In the mid-1960s a modified version of this method - which is known as SDS polyacrylamide-gel electrophoresis (SDS-PAGE) - was developed that has revolutionized the way proteins are routinely analyzed. It uses a highly cross-linked gel of polyacrylamide as the inert matrix through which the proteins migrate. The gel is usually prepared immediately before use by polymerization from monomers; the pore size of the gel can be adjusted so that it is small enough to retard the migration of the protein molecules of interest. The proteins themselves are not in a simple aqueous solution but in one that includes a powerful negatively charged detergent, sodium dodecyl sulfate, or SDS (Figure 4-41). Because this detergent binds to hydrophobic regions of the protein molecules, causing them to unfold into extended polypeptide chains, the individual protein molecules are released from their associations with other proteins or lipid molecules and rendered freely soluble in the detergent solution. In addition, a reducing agent such as *mercaptoethanol*(Figure 4-41) is usually added to break any S - S linkages in the proteins so that all of the constituent polypeptides in multisubunit molecules can be analyzed separately.

What happens when a mixture of SDS-solubilized proteins is electrophoresed through a slab of polyacrylamide gel? Each protein molecule binds large numbers of the negatively charged detergent molecules, which overwhelm the protein's intrinsic charge and cause it to migrate toward the positive electrode when a voltage is applied. Proteins of the same size tend to behave identically because (1) their native structure is completely unfolded by the SDS, so that their shapes are the same, and (2) they bind the same amount of SDS and therefore have the same amount of negative charge. Larger proteins, with more charge, will be subjected to larger electrical forces and also to a larger drag. In free solution the two effects would cancel out, but in the meshes of the polyacrylamide gel, which acts as a molecular sieve, large proteins are retarded much more severely than small ones. As a result, a complex mixture of proteins is fractionated into a series of discrete protein bands arranged in order of molecular weight (Figure 4-42). The major proteins are readily detected by staining the gel with a dye such as Coomassie blue, and even minor proteins are seen in gels treated with a silver stain (where as little as 10 ng of protein can be detected in a band).

SDS polyacrylamide-gel electrophoresis is a more powerful procedure than any previous method of protein analysis principally because it can be used to separate all types of proteins, including those that are insoluble in water. Membrane proteins, protein components of the cytoskeleton, and proteins that are part of large macromolecular aggregates can all be resolved. Since the method separates polypeptides according to size, it also provides information about the molecular weight and the subunit composition of any protein complex. A photograph of a gel that has been used to analyze each of the successive stages in the purification of a protein is shown in Figure 4-43.

More Than 1000 Proteins Can Be Resolved on a Single Gel by Two-dimensional Polyacrylamide-Gel Electrophoresis [25]

Since closely spaced protein bands or peaks tend to overlap, one-dimensional separation methods, such as SDS polyacrylamide-gel electrophoresis or chromatography, can resolve only a relatively small number of proteins (generally fewer than 50). In contrast, two-dimensional gel electrophoresis, which combines two different separation procedures, can be used to resolve more than 1000 proteins in the form of a two-dimensional protein map.

In the first step the proteins are separated on the basis of their intrinsic charge. The sample is dissolved in a small volume of a solution containing a nonionic (uncharged) detergent, together with mercaptoethanol and the denaturing reagent urea. This solution solubilizes, denatures, and dissociates all the polypeptide chains but leaves their intrinsic charge unchanged. The polypeptide chains are then separated by a procedure called isoelectric focusing, which depends on the fact that the net charge on a protein molecule varies with the pH of the surrounding solution. For any protein there is a characteristic pH, called its *isoelectric point,* at which the protein has no net charge and therefore will not migrate in an electric field. In isoelectric focusing, proteins are electrophoresed in a narrow tube of polyacrylamide gel in which a gradient of pH is established by a mixture of special buffers. Each protein moves to a position in the gradient that corresponds to its isoelectric point and stays there (Figure4-44). This is the first dimension of two-dimensional gel electrophoresis.

In the second step the narrow gel containing the separated proteins is again subjected to electrophoresis but in a direction at right angles to that used in the first step. This time SDS is added, and the proteins are separated according to their size, as in one-dimensional SDS-PAGE: the original narrow gel is soaked in SDS and then placed on one edge of an SDS polyacrylamide-gel slab, through which each polypeptide chain migrates to form a discrete spot. This is the second dimension of two-dimensional polyacrylamide-gel electrophoresis. The only proteins left unresolved will be those that have both an identical size and an identical isoelectric point, a relatively rare situation. Even trace amounts of each polypeptide chain can be detected on the gel by various staining procedures - or by autoradiography if the protein sample was initially labeled with a radioisotope. Up to 2000 individual polypeptide chains - almost the number of different proteins in a bacterium - have been resolved on a single two-dimensional gel (Figure 4-45). The resolving power is so great that two proteins that differ in only a single charged amino acid can be readily distinguished.

A specific protein can be identified after its fractionation on either one-dimensional or two-dimensional gels by exposing all the proteins present to a specific antibody that has been coupled to a radioactive isotope, to an easily detectable enzyme, or to a fluorescent dye. For convenience, this is normally done after all the separated proteins present in the gel have been transferred (by "blotting") onto a sheet of nitrocellulose paper, as will be described later for nucleic acids (see Figure 7-13). This protein-detection method is called *Western blotting*(Figure 4-46).

Some landmarks in the development of chromatography and electrophoresis are outlined in Table 4-7.

Selective Cleavage of a Protein Generates a Distinctive Set of Peptide Fragments [26]

Although the molecular weight and isoelectric point are distinctive features of a protein, unambiguous identification ultimately depends on determining the amino acid sequence. The first stage of this process, which involves cleaving the protein into smaller fragments, can itself provide information that helps to characterize the molecule. Proteolytic enzymes and chemical reagents are available that will cleave proteins between specific amino acid residues (Table 4-8). The enzyme *trypsin,*for instance, cuts on the carboxyl side of lysine or arginine residues, whereas the chemical *cyanogen bromide* cuts peptide bonds next to methionine residues. Since these enzymes and chemicals cleave at relatively few sites in a protein, they tend to produce relatively large and relatively few peptides. If such a mixture of peptides is separated by chromatographic or electrophoretic procedures, the resulting pattern, or peptide map, is diagnostic of the protein from which the peptides were generated and is sometimes referred to as the protein's "fingerprint" (Figure 4-47)

Protein fingerprinting was developed in 1956 as a way of comparing normal hemoglobin with the mutant form of the protein found in patients suffering from *sickle-cell anemia.* A single peptide difference was found and eventually traced to a single amino acid change, providing the first demonstration that a mutation can change a single amino acid in a protein.

Short Amino Acid Sequences Can Be Analyzed by Automated Machines [27]

Once a protein has been cleaved into smaller peptides, the next logical step in the analysis is to determine the amino acid

sequence of each isolated peptide fragment. This is accomplished by a repeated series of chemical reactions originally devised in 1967. First the peptide is exposed to a chemical that forms a covalent bond only with the free amino group at the amino terminus of the peptide. This chemical is then further activated by exposure to a weak acid so that it specifically cleaves the peptide bond that attaches the amino-terminal amino acid to the peptide chain; the released amino acid is then identified by chromatographic methods. The remaining peptide, which is shorter by one amino acid, is then submitted to the same sequence of reactions, and so on, until every amino acid in the peptide has been determined.

The reiterative nature of these reactions lends itself to automation, and machines called amino acid sequenators are commercially available for automatic determination of the amino acid sequence of peptide fragments. The final step is to arrange the sequences of the various peptide fragments in the order in which they occur in the intact polypeptide chain. This was traditionally achieved by comparing the sequences of different sets of overlapping peptide fragments obtained by cleaving the same protein with different proteolytic enzymes.

Improvements in protein-sequencing technology have greatly increased its speed and sensitivity, allowing analysis of minute samples; the sequence of several dozen amino acids at the amino-terminal end of a peptide can be obtained overnight from a few micrograms of protein - the amount available from a single band on an SDS polyacrylamide gel. This has been important for characterizing many minor cell proteins, such as the receptors for steroid and polypeptide hormones. Knowing the sequence of as few as 20 amino acids of a protein is frequently enough to allow a DNA probe to be designed so that the gene encoding the protein can be cloned (Figure 7-27). Once the gene has been isolated, the rest of the protein's amino acid sequence can be deduced from the DNA sequence by reference to the genetic code. This is a major advantage because, even with automation, the direct determination of the entire amino acid sequence of a protein is a major undertaking. A protein of 100 residues can often be sequenced in a month of hard work. But the difficulty increases steeply with the length of the polypeptide chain, and the chemical peculiarities of individual peptide fragments prevent the process from being routine. Since DNA sequencing can be done so quickly and simply (see Chapter 7), the sequences of most proteins are now determined largely from the nucleotide sequences of their genes.

The Diffraction of X-rays by Protein Crystals Can Reveal a Protein's Exact Structure 28

From the amino acid sequence of a protein, one can often predict secondary structural elements in the protein, such as membrane-spanning alpha helices, as well as the protein's resemblance to other known proteins. It is presently not possible, however, to deduce reliably the three-dimensional folded structure of a protein from its amino acid sequence, and without knowing its detailed folded structure, it is not possible to understand the molecular basis of a protein's function. The main technique that has been used to discover the three-dimensional structure of molecules, including proteins, at atomic resolution is x-ray crystallography.

X-rays, like light, are a form of electromagnetic radiation, but they have a much smaller wavelength, typically around 0.1 nm (the diameter of a hydrogen atom). If a narrow parallel beam of x-rays is directed at a sample of a pure protein, most of the x-rays will pass straight through it. A small fraction, however, will be scattered by the atoms in the sample. If the sample is a well-ordered crystal, the scattered waves will reinforce one another at certain points (see Figure 4-2) and will appear as diffraction spots when the x-rays are recorded by a suitable detector (Figure 4-48).

The position and intensity of each spot in the x-ray diffraction pattern contain information about the positions of the atoms in the crystal that gave rise to it. Deducing the three-dimensional structure of a large molecule from the diffraction pattern of its crystal is a complex task and was not achieved for a protein molecule until 1960. In recent years x-ray diffraction analysis has become increasingly automated, and now the slowest step is likely to be the production of suitable protein crystals. This requires large amounts of very pure protein and often involves years of trial-and-error searching for the proper crystallization conditions. There are still many proteins, especially membrane proteins, that have so far resisted all attempts to crystallize them.

The immediate product of a diffraction-pattern analysis is a complex three-dimensional electron-density map. It is then a complicated matter to interpret this map, and to do so requires the amino acid sequence of the protein. Largely by trial and error, the sequence and the electron-density map are correlated by computer to give the best possible fit. The reliability of the final atomic model will depend on the resolution of the original crystallographic data: 0.5 nm resolution might produce a low-resolution map of the polypeptide backbone, whereas a resolution of 0.15 nm allows all of the non-hydrogen atoms in the molecule to be reliably positioned. A complete atomic model is often too complex to appreciate directly, but simplified versions that show the essential structural features of the structure can be readily derived from it (see Figure3-34). The structures of several hundred proteins have been determined by x-ray crystallography - enough to begin to see families of common structures

emerging. These structures have often been more conserved in evolution than the amino acid sequences that form them.

Molecular Structure Can Also Be Determined Using Nuclear Magnetic Resonance (NMR) Spectroscopy [29]

Nuclear magnetic resonance (NMR) spectroscopy has been used in the past to analyze the structure of small molecules and now is increasingly used to study the structure of small proteins or protein domains. Unlike x-ray crystallography, NMR does not depend on having a crystalline sample; it simply requires a small volume of concentrated protein solution that is placed in a strong magnetic field.

Certain atomic nuclei, and in particular those of hydrogen, have a magnetic moment or *spin:*that is, they have an intrinsic magnetization, like a bar magnet.

The spin aligns along the strong magnetic field, but it can be changed to a misaligned excited state in response to applied radiofrequency (RF) pulses of electromagnetic radiation. When the excited hydrogen nuclei relax to their aligned state, they emit RF radiation, which can be measured and displayed as a spectrum. The nature of the emitted radiation depends on the environment of each hydrogen nucleus, and if one nucleus is excited, it will influence the absorption and emission of radiation by other nuclei that lie close to it. It is consequently possible, by an ingenious elaboration of the basic NMR technique known as *two-dimensional NMR,*to distinguish the signals from hydrogen nuclei in different amino acid residues and to identify and measure the small shifts in these signals that occur when these hydrogen nuclei lie close enough together to interact: the size of such a shift reveals the distance between the interacting pair of hydrogen atoms. In this way NMR can give information about the distances between the parts of the protein molecule. By combining this information with a knowledge of the amino acid sequence, it is possible in principle to compute the three-dimensional structure of the protein (Figure 4-49).

For technical reasons only the structure of small proteins of about 15,000-20,000 daltons or less can currently be determined by NMR spectroscopy, and it is very unlikely that the method will ever be able to tackle molecules larger than about 30,000-40,000 daltons. Many functional domains of proteins are much smaller than this, however, and can often be obtained on their own as stable structures amenable to analysis by NMR. This is especially useful when the protein has resisted attempts at crystallization. The structures of the DNA-binding domains of various gene regulatory proteins, for example, were first determined in this way. NMR is also used widely to investigate molecules other than proteins and is valuable, for example, as a method to discover the structures of the complex carbohydrate side chains of glycoproteins.

Some landmarks in the development of x-ray crystallography and NMR are outlined in Table 4-9.

Summary

Populations of cells can be analyzed biochemically by disrupting them and fractionating their contents by ultracentrifugation. Further fractionations allow functional cell-free systems to be developed; such systems are required to determine the molecular details of complex cellular processes. Protein synthesis, DNA replication, RNA splicing, the cell cycle, mitosis, and various types of intracellular transport are all currently being studied in this way. The molecular weight and subunit composition of even very small amounts of a protein can be determined by SDS polyacrylamide-gel electrophoresis. In two-dimensional gel electrophoresis proteins are resolved as separate spots by isoelectric focusing in one dimension, followed by SDS polyacrylamide-gel electrophoresis in a second dimension. These electrophoretic separations can be applied even to proteins that are normally insoluble in water.

The major proteins in soluble cell extracts can be purified by column chromatography; depending on the type of column matrix, biologically active proteins can be separated according to their molecular weight, hydrophobicity, charge characteristics, or affinity for other molecules. In a typical purification the sample is passed through several different columns in turn - the enriched fractions obtained from one column being applied to the next. Once a protein has been purified to homogeneity, its biological activities can be examined in detail. In addition, a small part of the protein's amino acid sequence can be determined, which then allows the DNA sequence that encodes the entire protein to be cloned; the remaining amino acid sequence is then deduced from the nucleotide sequence of the cloned DNA. While the amino acid sequence is required to determine the three-dimensional structure of a protein, it is not sufficient on its own. To determine this structure at atomic resolution, large proteins have to be crystallized and studied by x-ray diffraction. The structure of small proteins in solution can be determined using a nuclear magnetic resonance analysis.
Figure 4-34. The preparative ultracentrifuge. The sample is contained in tubes that are inserted into a ring of cylindrical holes in a metal *rotor*. Rapid rotation of the rotor generates enormous centrifugal forces, which cause particles in the sample to sediment. The vacuum reduces friction, preventing heating of the rotor and allowing the refrigeration system to maintain the sample at 4°C.

Figure 4-36. Comparison of methods of velocity sedimentation and equilibrium sedimentation. In velocity sedimentation (A) subcellular components sediment at different speeds according to their size when layered over a dilute sucrose-containing solution. In order to stabilize the sedimenting bands against convective mixing caused by small differences in temperature or solute concentration, the tube contains a continuous shallow gradient of sucrose that increases in concentration toward the

bottom of the tube (typically from 5% to 20% sucrose). Following centrifugation, the different components can be collected individually, most simply by puncturing the plastic centrifuge tube and collecting drops from the bottom, as illustrated here. In equilibrium sedimentation (B) subcellular components may move up or down when centrifuged in a gradient until they reach a position where their density matches their surroundings. Although a sucrose gradient is shown here, denser gradients, which are especially useful for protein and nucleic acid separation, can be formed from cesium chloride. The final bands, at equilibrium, can be collected as in (A).

Table 4-6. Some Major Events in the Development of the Ultracentrifuge and the Preparation of Cell-free Extracts

1897 **Buchner** showed that cell-free extracts of yeast can ferment sugars to form carbon dioxide and ethanol, laying the foundations of enzymology.

1926 **Svedberg** developed the first analytical ultracentrifuge and used it to estimate the molecular weight of hemoglobin as 68,000.

1935 **Pickels and Beams** introduced several new features of centrifuge design that led to its use as a preparative instrument.

1938 **Behrens** employed differential centrifugation to separate nuclei and cytoplasm from liver cells, a technique further developed for the fractionation of cell organelles by **Claude, Brachet, Hogeboom**, and others in the 1940s and early 1950s.

1939 **Hill** showed that isolated chloroplasts, when illuminated, could perform the reactions of photosynthesis.

1949 **Szent-Györgyi** showed that isolated myofibrils from skeletal muscle cells contract upon the addition of ATP. In 1955 a similar cell-free system was developed for ciliary beating by **Hofmann-Berling**.

1951 **Brakke** used density-gradient centrifugation in sucrose solutions to purify a plant virus.

1954 **de Duve** isolated lysosomes and, later, peroxisomes by centrifugation.

1954 **Zamecnik** and colleagues developed the first cell-free system to carry out protein synthesis. This was followed by a decade of intense research activity, during which the genetic code was elucidated.

1957 **Meselson, Stahl, and Vinograd** developed equilibrium density-gradient centrifugation in cesium chloride solutions for separating nucleic acids.

1975 **Dobberstein and Blobel** demonstrated protein translocation across membranes in a cell-free system.

1976 **Neher and Sakmann** developed patch-clamp recording to measure the activity of single ion channels.

1983 **Lohka and Masui** made concentrated extracts from frog eggs that perform the entire cell cycle *in vitro*.

1984 **Rothman** and colleagues reconstituted Golgi vesicle trafficking *in vitro* using a cell-free system.
Figure 4-37. The separation of small molecules by paper chromatography. After the sample has been applied to one end of the paper (the "origin") and dried, a solution containing a mixture of two or more solvents is allowed to flow slowly through the paper by capillary action. Different components in the sample move at different rates in the paper according to their relative solubility in the solvent that is preferentially adsorbed onto the fibers of the paper. The development of this technique revolutionized biochemical analyses in the 1940s.
Figure 4-38. The separation of molecules by column chromatography. The sample is applied to the top of a cylindrical glass or plastic column filled with a permeable solid matrix, such as cellulose, immersed in solvent. Then a large amount of solvent is pumped slowly through the column and is collected in separate tubes as it emerges from the bottom. Various components of the sample travel at different rates through the column and are thereby fractionated into different tubes.
Figure 4-39. Three types of matrices used for chromatography. In ion-exchange chromatography (A) the insoluble matrix carries ionic charges that retard molecules of opposite charge. Matrices commonly used for separating proteins are diethylaminoethylcellulose (DEAE-cellulose), which is positively charged, and carboxymethylcellulose (CM-cellulose) and phosphocellulose, which are negatively charged. The strength of the association between the dissolved molecules and the ion-exchange matrix depends on both the ionic strength and the pH of the solution that is passing down the column, which may therefore be varied in a systematic fashion (as in Figure 4-40) to achieve an effective separation. In gel-filtration chromatography (B) the matrix is inert but porous. Molecules that are small enough to penetrate into the matrix are thereby delayed and travel more slowly through the column. Beads of cross-linked polysaccharide (dextran or agarose) are available commercially in a wide range of pore sizes, making them suitable for the fractionation of molecules of various molecular weights, from less than 500 to more than 5×10^6. Affinity chromatography (C) utilizes an insoluble matrix that is covalently linked to a specific ligand, such as an antibody molecule or an enzyme substrate, that will bind a specific protein. Enzyme molecules that bind to immobilized substrates on such columns can be eluted with a concentrated solution of the free form of the substrate molecule, while molecules that bind to immobilized antibodies can be eluted by dissociating the antibody-antigen

complex with concentrated salt solutions or solutions of high or low pH. High degrees of purification are often achieved in a single pass through an affinity column.

(B) GEL-FILTRATION CHROMATOGRAPHY

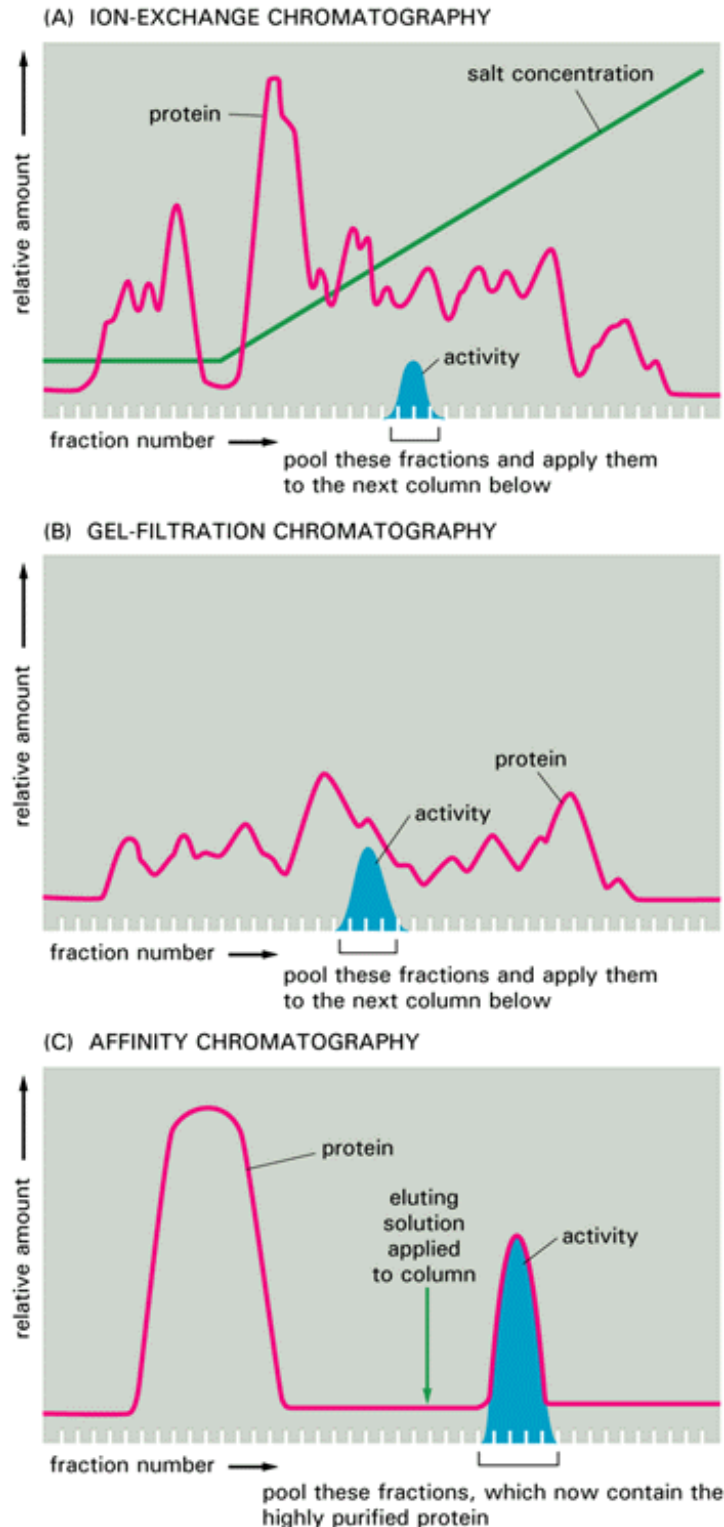
(C) AFFINITY CHROMATOGRAPHY


Figure 4-40. Protein purification by chromatography. Typical results obtained when three different chromatographic steps are used in succession to purify a protein. In this example a homogenate of cells was first fractionated by allowing it to percolate through an ion-exchange resin packed into a column (A). The column was washed, and the bound proteins were then eluted by passing a solution containing a gradually increasing concentration of salt onto the top of the column. Proteins with the lowest affinity for the ion-exchange resin passed directly through the column and were collected in the earliest fractions eluted from the bottom of the column. The remaining proteins were eluted in sequence according to their affinity for the resin—those proteins binding most tightly to the resin requiring the highest concentration of salt to remove them. The protein of interest eluted in a

narrow peak and was detected by its enzymatic activity. The fractions with activity were pooled and then applied to a second, gel-filtration column (B). The elution position of the still-impure protein was again determined by its enzymatic activity and the active fractions pooled and purified to homogeneity on an affinity column (C) that contained an immobilized substrate of the enzyme.

SDS   β-mercaptoethanol
Figure 4-41. The detergent sodium dodecyl sulfate (SDS) and the reducing agent beta-mercaptoethanol. These two chemicals are used to solubilize proteins for SDS polyacrylamide-gel electrophoresis. The SDS is shown here in its ionized form.
Figure 4-42. SDS polyacrylamide-gel electrophoresis (SDS-PAGE). (A) Apparatus. (B) Individual polypeptide chains form a complex with negatively charged molecules of sodium dodecyl sulfate (SDS) and therefore migrate as a negatively charged SDS-protein complex through a porous gel of polyacrylamide. Since the speed of migration under these conditions is greater the smaller the polypeptide, this technique can be used to determine the approximate molecular weight of a polypeptide chain as well as the subunit composition of a complex protein. If the protein contains a large amount of carbohydrate, however, it will move anomalously on the gel and its apparent molecular weight estimated by SDS-PAGE will be misleading.
Figure 4-43. Analysis of protein samples by SDS polyacrylamide-gel electrophoresis. The photograph shows a gel that has been used to detect the proteins present at successive stages in the purification of an enzyme. The leftmost lane (lane 1) contains the complex mixture of proteins in the starting cell extract, and each succeeding lane analyzes the proteins obtained after a chromatographic fractionation of the protein sample analyzed in the previous lane (see Figure 4-40). The same total amount of protein (10 mg) was loaded onto the gel at the top of each lane. Individual proteins normally appear as sharp, dye-stained bands; a band broadens, however, when it contains too much protein. (Courtesy of Tim Formosa.)
Figure 4-44. Separation of protein molecules by isoelectric focusing. At low pH (high H^+ concentration) the carboxylic acid groups of proteins tend to be uncharged (-COOH) and their nitrogen-containing basic groups fully charged (for example, $-NH_3^+$), giving most proteins a net positive charge. At high pH the carboxylic acid groups are negatively charged ($-COO^-$) and the basic groups tend to be uncharged (for example, $-NH_2$), giving most proteins a net negative charge. At its *isoelectric pH*a

protein has no net charge since the positive and negative charges balance. Thus, when a tube containing a fixed pH gradient is subjected to a strong electric field in the appropriate direction, each protein species present will migrate until it forms a sharp band at its isoelectric pH, as shown.
Figure 4-45. Two-dimensional polyacrylamide-gel electrophoresis. All the proteins in an *E. coli* bacterial cell are separated in this gel, in which each spot corresponds to a different polypeptide chain. The proteins were first separated according to their isoelectric points by isoelectric focusing from left to right. They were then further fractionated according to their molecular weights by electrophoresis from top to bottom in the presence of SDS. Note that different proteins are present in very different amounts. The bacteria were fed with a mixture of radioisotope-labeled amino acids so that all of their proteins were radioactive and could be readily detected by auto-radiography (see p. 180). (Courtesy of Patrick O'Farrell.)
Figure 4-46. Western blotting or immunoblotting. The total proteins from dividing tobacco cells in culture are first separated by two-dimensional polyacrylamide-gel electrophoresis as shown in Figure 4-45 and their positions revealed by a sensitive protein stain (A). The separated proteins on an identical gel were then transferred to a sheet of nitrocellulose and incubated with an antibody that recognizes those proteins that, during mitosis, are phosphorylated on threonine residues. The positions of the dozen or so proteins that are recognized by this antibody are revealed by an enzyme-linked second antibody (B). (From J.A. Traas, A.F. Bevan, J.H. Doonan, J. Cordewener, and P.J. Shaw. *Plant Journal* 2:723-732, 1992, by permission of Blackwell Scientific Publications.)

Table 4-7. Landmarks in the Development of Chromatography and Electrophoresis and Their Application to Protein Molecules

1833 **Faraday** described the fundamental laws concerning the passage of electricity through ionic solutions.

1850 **Runge** separated inorganic chemicals by their differential adsorption to paper, a forerunner of later chromatographic separations.

1906 **Tswett** invented column chromatography, passing petroleum extracts of plant leaves through columns of powdered chalk.

1933 **Tiselius** introduced electrophoresis for separating proteins in solution.

1942 **Martin and Synge** developed partition chromatography, leading to paper chromatography two years later.

1946 **Stein and Moore** determined for the first time the amino acid composition of a protein, initially using column chromatography on starch and later developing chromatography on ion-exchange resins.

1955 **Smithies** used gels made of starch to separate serum proteins by electrophoresis. **Sanger** completed the analysis of the amino acid sequence of bovine insulin, the first protein to be sequenced.

1956 **Ingram** produced the first protein fingerprints, showing that the difference between sickle-cell hemoglobin and normal hemoglobin is due to a change in a single amino acid.

1959 **Raymond** introduced polyacrylamide gels, which are superior to starch gels for separating proteins by electrophoresis; improved buffer systems allowing high-resolution separations were developed in the next few years by **Ornstein and Davis**.

1966 **Maizel** introduced the use of sodium dodecyl sulfate (SDS) for improving polyacrylamide-gel electrophoresis of proteins.

1975 **O'Farrell** devised a two-dimensional gel system for analyzing protein mixtures in which SDS polyacrylamide-gel electrophoresis is combined with separation according to isoelectric point.

Table 4-8. Some Reagents Commonly Used to Cleave Peptide Bonds in Proteins

	Amino Acid 1	Amino Acid 2
Enzyme		
Trypsin	Lys or Arg	any
Chymorypsin	Phe, Trp, or Tyr	any
V8 protease	Glu	any
Chemical		
Cyanogen bromide	Met	any
2-Nitro-5-thiocyanobenzoate	any	Cys

The specificity for the amino acids on either side of the cleaved bond is indicated. The carboxyl group of amino acid 1 is released by the cleavage; this amino acid is to the left of the peptide bond as normally written (see panel 2-5, pp. 56-57).
Figure 4-47. Production of a peptide map, or fingerprint, of a protein. Here, the protein was digested with trypsin to generate a mixture of polypeptide fragments, which was then fractionated in two dimensions by electrophoresis and partition chromatography. The pattern of spots obtained is diagnostic of the protein analyzed.

Hajdu and I. Andersson; C, adapted from original provided by B. Furugren.)
Figure 4-49. NMR spectroscopy. (A) An example of the data from an NMR machine. This is a two-dimensional NMR spectrum derived from the carboxyl-terminal domain of the enzyme cellulase. The spots represent interactions between hydrogen atoms that are near neighbors in the protein and hence their distance apart. Complex computing methods, in

conjunction with the known amino acid sequence, enable possible compatible structures to be derived. In (B) 10 structures, which all satisfy the distance constraints equally well, are shown superimposed on one another, giving a good indication of the probable three-dimensional structure. (Courtesy of P. Kraulis.)

Table 4-9. Landmarks in the Development of X-ray Crystallography and NMR and Their Application to Biological Molecules

1864	**Hoppe-Seyler** crystallized, and named, the protein hemoglobin.
1895	**Röntgen** observed that a new form of penetrating radiation, which he named x-rays, was produced when cathode rays (electrons) hit a metal target.
1912	**Von Laue** obtained the first x-ray diffraction patterns by passing x-rays through a crystal of zinc sulfide.
W.L. Bragg proposed a simple relationship between an x-ray diffraction pattern and the arrangement of atoms in a crystal that produced the pattern.	
1926	**Summer** obtained crystals of the enzyme urease from extracts of jack beans and demonstrated that proteins possess catalytic activity.
1931	**Pauling** published his first essays on "The Nature of the Chemical Bond," detailing the rules of covalent bonding.
1934	**Bernal and Crowfoot** presented the first detailed x-ray diffraction patterns of a protein obtained from crystals of the enzyme pepsin.
1935	**Patterson** developed an analytical method for determining interatomic spacings from x-ray data.
1941	**Astbury** obtained the first x-ray diffraction pattern of DNA.
1951	**Pauling and Corey** proposed the structure of a helical conformation of a chain of L-amino acids - the a helix - and the structure of the b sheet, both of which were later found in many proteins.
1953	**Watson and Crick** proposed the double-helix model of DNA, based on x-ray diffraction patterns obtained by **Franklin and Wilkins**.
1954	**Perutz** and colleagues developed heavy-atom methods to solve the phase problem in protein crystallography.
1960	**Kendrew** described the first detailed structure of a protein (sperm whale myoglobin) to a resolution of 0.2 nm, and **Perutz** proposed a lower-resolution structure of the larger protein hemoglobin.
1966	**Phillips** described the structure of lysozyme, the first enzyme to be analyzed in detail.
1971	**Jeener** proposed the use of two-dimensional NMR, and **Wuthrich** and colleagues first used the method to solve a protein structure in the early 1980s.
1976	**Kim and Rich** and **Klug** and colleagues described the detailed three-dimensional structure of tRNA determined by x-ray diffraction.
1977-1978	**Holmes and Klug** determined the structure of tobacco mosaic virus (TMV), and **Harrison and Rossman** determined the structure of two small spherical viruses.
1985	**Michel** and colleagues determined the first structure of a transmembrane protein (a bacterial photosynthetic reaction center) by x-ray crystallography. **Henderson** and colleagues obtained the structure of bacteriorhodopsin, a transmembrane protein, by electron-microscopy methods between 1975 and 1990.

Tracing and Assaying Molecules Inside Cells

Introduction

The classical methods of microscopy give good views of cell architecture, but they provide little information about cell chemistry. In cell biology it is often important to determine the quantities of specific molecules and to know where they are in the cell and how their level or location changes in response to extracellular signals. The molecules of interest range from small inorganic ions, such as Ca^{2+} or H^+, to large macromolecules, such as specific proteins, RNAs, or DNA sequences.

Sensitive methods have been developed for assaying each of these types of molecules, as well as for following the dynamic behavior of many of them in living cells. In this section we describe how specific probes can be introduced into living cells in order to monitor the chemical conditions in the cytosol. In addition, two other detection methods that are widely used in cell biology are discussed: those involving *radioisotopes* and those utilizing *antibodies.* Both of these methods are capable of detecting a specific molecule in a complex mixture with great sensitivity: under optimal conditions, they can detect fewer than 1000 copies of a molecule in a sample.

Radioactive Atoms Can Be Detected with Great Sensitivity [30]

Most naturally occurring elements are a mixture of slightly different *isotopes.* These differ from one another in the mass of their atomic nuclei, but because they have the same number of electrons, they have the same chemical properties. In radioactive isotopes, or radioisotopes, the nucleus is unstable and undergoes random disintegration to produce a different atom. In the course of these disintegrations, either energetic subatomic particles, such as electrons, or radiations, such as g-rays, are given off. By using chemical synthesis to incorporate one or more radioactive atoms into a small molecule of interest, such as a sugar or an amino acid, the fate of that molecule can be traced during any biological reaction.

Although naturally occurring radioisotopes are rare (because of their instability), they can be produced in large amounts in nuclear reactors, where stable atoms are bombarded with high-energy particles. As a result, radioisotopes of many biologically important elements are readily available (Table 4-10). The radiation they emit is detected in various ways. Electrons (b particles) can be detected in a *Geiger counter* by the ionization they produce in a gas, or they can be measured in a *scintillation counter* by the small flashes of light they induce in a scintillation fluid. These methods make it possible to measure accurately the quantity of a particular radioisotope present in a biological specimen. It is also possible to determine the location of a radioisotope in a specimen by *autoradiography,* as we describe below. All of these methods of detection are extremely sensitive: in favorable circumstances, nearly every disintegration - and therefore every radioactive atom that decays - can be detected.

Radioisotopes Are Used to Trace Molecules in Cells and Organisms [31]

One of the earliest uses of radioactivity in biology was to trace the chemical pathway of carbon during photosynthesis. Unicellular green algae were maintained in an atmosphere containing radioactively labeled CO_2 ($^{14}CO_2$), and at various times after they had been exposed to sunlight, their soluble contents were separated by paper chromatography. Small molecules containing ^{14}C atoms derived from CO_2 were detected by a sheet of photographic film placed over the dried paper chromatogram. In this way most of the principal components in the photosynthetic pathway from CO_2 to sugar were identified.

Radioactive molecules can be used to follow the course of almost any process in cells. In a typical experiment the cells are supplied with a precursor molecule in radioactive form. The radioactive molecules mix with the preexisting unlabeled ones; both are treated identically by the cell as they differ only in the weight of their atomic nuclei. Changes in the location or chemical form of the radioactive molecules can be followed as a function of time. The resolution of such experiments is often sharpened by using a pulse-chase labeling protocol, in which the radioactive material (the *pulse*) is added for only a very brief period and then washed away and replaced by nonradioactive molecules (the *chase*). Samples are taken at regular intervals, and the chemical form or location of the radioactivity is identified for each sample (Figure 4-50). Pulse-chase experiments, combined with autoradiography (see below), have been important, for example, in elucidating the pathway taken by secreted proteins from the ER to the cell exterior (Figure 4-51).

Radioisotopic labeling is a uniquely valuable way of distinguishing between molecules that are chemically identical but have different histories - for example, those that differ in their time of synthesis. In this way, for example, it was shown that almost all of the molecules in a living cell are continually being degraded and replaced, even when the cell is not growing and is apparently in a steady state. This "turnover," which sometimes takes place very slowly, would be almost impossible to detect without radioisotopes.

Today, nearly all common small molecules are available in radioactive form from commercial sources, and virtually any biological molecule, no matter how complicated, can be radioactively labeled. Compounds can be made with radioactive atoms incorporated at particular positions in their structure, enabling the separate fates of different parts of the same molecule to be followed during biological reactions (Figure 4-52).

One of the important uses of radioactivity in cell biology is to localize a radioactive compound in sections of whole cells or tissues by autoradiography. In this procedure living cells are briefly exposed to a pulse of a specific radioactive compound and then incubated for a variable period - to allow them time to incorporate the compound - before being fixed and processed for light or electron microscopy. Each preparation is then overlaid with a thin film of photographic emulsion and left in the dark for a number of days, during which the radioisotope decays. The emulsion is then developed, and the position of the radioactivity in each cell is indicated by the position of the developed silver grains (see Figure 4-51). If cells are exposed to ^3H-thymidine, a radioactive precursor of DNA, for example, it can be shown that DNA is made in the nucleus and remains there. By contrast, if cells are exposed to ^3H-uridine, a radioactive precursor of RNA, it is found that RNA is initially made in the nucleus and then moves rapidly into the cytoplasm. Radiolabeled molecules can also be detected by autoradiography after they are separated from other molecules by gel electrophoresis: the positions of both proteins (see Figure 4-45) and nucleic acids (see Figure 7-5) are commonly detected on gels in this way. In addition, when radioactive nucleic acid molecules are used as probes to find complementary nucleic acid mole-cules, autoradiography serves to detect both the positions and amounts of those molecules hybridizing to the probe, either on a gel or in a tissue section (see Figure 7-20).

Ion Concentrations Can Be Measured with Intracellular Electrodes [32]

One way to study the chemistry of a single living cell is to insert the tip of a fine glass pipette directly into the cell interior, a technique developed by electrophysiologists to study voltages and current flows across the plasma membrane. For this purpose intracellular *microelectrodes* are made from pieces of fine glass tubing that are pulled to a tip diameter of a fraction of a micrometer and filled with a conducting solution (usually a simple salt, such as KCl, in water). The tip of the microelectrode can be poked into the cytoplasm through the plasma membrane, which seals around the shaft, adhering tightly to the glass so that the cell is left relatively undisturbed.

Microelectrodes are useful for studying the cell interior in two ways: they can be converted into probes for measuring intracellular concentrations of common inorganic ions, such as H^+, Na^+, K^+, Cl^-, Ca^{2+}, and Mg^{2+}, and they can be used as micropipettes to inject molecules into cells. The principle that allows the measurement of ion concentrations with a microelectrode is the same as that of the familiar pH meter. The tendency of ions to diffuse down their concentration gradient can be balanced by an opposing electric field: the greater the concentration gradient, the greater is the electric field required. The magnitude of the electric field required to maintain the concentration gradient at a stable equilibrium therefore gives a measure of the ion concentration gradient. To find the concentration of a specific ion, it is necessary to use a material that is permeable only to that ion, formed into a sheet or barrier, which is placed between the test solution and a solution that contains a known concentration of the ion. The electrical potential difference across the selectively permeable barrier when no current flows will then be a direct measure of the ratio of concentrations of the specific ion on the two sides. (The theory is discussed in Panel 11-2, in connection with ion transport across a cell membrane.) In practice, the tip of a microelectrode is filled with an appropriate organic compound to make a barrier that is selectively permeable to the chosen ion. The microelectrode is then inserted, together with a reference microelectrode, into the interior of a cell, as shown in Figure 4-53.

More recently, the microelectrode technique has been adapted to study the movement of ions through specialized channel proteins (called ion channels) contained in a small patch of plasma membrane. Here, a glass microelectrode with a somewhat larger tip is pressed gently against the plasma membrane instead of being poked through it (Figure 4-54). It is then possible to study the electrical behavior of the small patch of membrane covering the tip of the electrode the patch either can be left attached to the cell or can be pulled free of it (Figure 4-55). This technique, known as patch-clamp recording, has revolutionized the study of ion channels. It is one of the few techniques in cell biology that allows one to study the function of a single protein molecule in real time, as we discuss in Chapter 11.

Rapidly Changing Intracellular Ion Concentrations Can Be Measured with Light-emitting Indicators [33]

Ion-sensitive electrodes reveal the ion concentration only at one point in a cell, and for an ion, such as Ca^{2+}, that is present at very low concentration, their responses are slow and somewhat erratic. Thus these electrodes are not ideally suited to record the rapid and transient changes in the concentration of cytosolic Ca^{2+} that play an important part in allowing cells to respond to extracellular signals. Such changes can be analyzed with the use of ion-sensitive indicators, whose light emission reflects the local concentration of the ion. Some of these indicators are luminescent (emitting light spontaneously), while others are fluorescent (emitting light on exposure to light). *Aequorin* is a luminescent protein isolated from certain marine jellyfish; it emits light in the presence of Ca^{2+} and responds to changes in Ca^{2+} concentration in the range 0.5 to 10 mM. If microinjected into an egg, for example, aequorin emits a flash of light in response to the sudden localized release of free Ca^{2+} into the cytoplasm that occurs when the egg is fertilized (Figure 4-56).

Fluorescent Ca^{2+} indicators have recently been synthesized that bind Ca^{2+} tightly and are excited at slightly longer wavelengths when they are free of Ca^{2+} than when in their Ca^{2+}-bound form. By measuring the ratio of fluorescence intensity at two excitation wavelengths, the concentration ratio of the Ca^{2+}-bound indicator to the Ca^{2+}-free indicator can be determined; this provides an accurate measurement of the free Ca^{2+} concentration. Two indicators of this type, called *quin-2* and *fura-2,* are widely used for second-by-second monitoring of changes in intracellular Ca^{2+} concentrations in the different parts of a cell viewed in a fluorescence microscope (Figure 4-57). Similar fluorescent indicators are available for measuring other ions; some are used for measuring H^+, for example, and hence intracellular pH. Some of these indicators can enter cells by diffusion and so need not be microinjected; this makes it possible to monitor large numbers of individual cells simultaneously in a fluorescence microscope. By constructing new types of indicators and using them in conjunction with modern image-processing methods, it should be possible to develop similarly rapid and precise methods for analyzing changes in the concentrations of many types of small molecules in cells.

There Are Several Ways of Introducing Membrane-impermeant Molecules into Cells [34]

It is often useful to be able to introduce membrane-impermeant molecules into a living cell, whether they are antibodies that recognize intracellular proteins, normal cell proteins tagged with a fluorescent label, or molecules that influence cell behavior. One approach is to microinject the molecules into the cell through a glass micropipette. An especially useful technique is called fluorescent analogue cytochemistry, in which a purified protein is coupled to a fluorescent dye and microinjected into a cell; in this way the fate of the injected protein can be followed in a fluorescence microscope as the cell grows and divides. If tubulin (the subunit of microtubules) is labeled with a dye that fluoresces red, for example, microtubule dynamics can be followed second by second in a living cell (Figure 4-58).

Antibodies can be microinjected into a cell in order to block the function of the molecule the antibodies recognize. Anti-myosin-II antibodies injected into a fertilized sea urchin egg, for example, prevent the egg cell from dividing in two, even though nuclear division occurs normally. This observation demonstrates that this myosin plays an essential part in the contractile process that divides the cytoplasm during cell division but that it is not required for nuclear division (see Figure 18-34).

Microinjection, although widely used, demands that each cell be injected individually; therefore it is possible to study at most a few hundred cells at a time. Other approaches allow large populations of cells to be permeabilized simultaneously. One can partially disrupt the structure of the cell plasma membrane, for example, so as to make it more permeable; this is usually accomplished by using a powerful electric shock or a chemical such as a low concentration of detergent. The electrical technique has the advantage of creating large pores in the plasma membrane without damaging intracellular membranes. The pores remain open for minutes or hours, depending on the cell type and size of the electric shock, and allow even macromolecules to enter (and leave) the cytosol rapidly. With a limited treatment a large fraction of the cells repair their plasma membrane and survive. A third method for introducing large molecules into cells is to cause membranous vesicles that contain these molecules to fuse with the cell's plasma membrane. These three methods are used widely in cell biology and are illustrated in Figure 4-59.

The Light-induced Activation of "Caged" Precursor Molecules Facilitates Studies of Intracellular Dynamics [35]

The complexity and rapidity of many intracellular processes, such as the action of signaling molecules or the movements of cytoskeletal proteins, make them difficult to study at a single-cell level. Ideally, one would like to be able to introduce any molecule of interest into a living cell at a precise time and location and follow its subsequent behavior, as well as the response of

the cell. Microinjection is limited by the difficulty of controlling the place and time of delivery. A more powerful approach involves synthesizing an inactive form of the molecule of interest, introducing it into the cell and then activating it suddenly at a chosen site in the cell by focusing a spot of light on it. Inactive photosensitive precursors of this type, called caged molecules, have been made for a variety of small molecules, including Ca^{2+}, cyclic AMP, GTP, and inositol trisphosphate. The caged molecules can be introduced into living cells by any of the methods described in Figure 4-59 and then activated by a strong pulse of light from a laser (Figure 4-60). A microscope can be used to focus the light pulse on any tiny region of the cell, so that the experimenter can control exactly where and when a molecule is delivered. In this way, for example, one can study the instantaneous effects of releasing an intracellular signaling molecule into the cytosol.

Caged fluorescent molecules are also tools with great promise. They are made by attaching a photoactivatable fluorescent dye to a purified protein. It is important that the modified protein remain biologically active: unlike labeling with radioisotopes (which changes only the number of neutrons in the nuclei of the labeled atoms), labeling with a caged fluorescent dye adds a large bulky group to the surface of a protein, which can easily change the protein's properties. A satisfactory labeling protocol is usually found by trial and error. Once a biologically active labeled protein has been produced, its behavior can be followed inside living cells. Tubulin labeled with caged fluorescein, for example, has been incorporated into microtubules of the mitotic spindle: when a small region of the spindle was illuminated with a laser, the labeled tubulin became fluorescent, so that its movement along the spindle microtubules could be readily followed (Figure 4-61). In principle, the same technique can be applied to any protein.

Antibodies Can Be Used to Detect and Isolate Specific Molecules 36

Antibodies are proteins produced by the vertebrate immune system as a defense against infection (see Chapter 23). They are unique among proteins because they are made in billions of different forms, each with a different binding site that recognizes a specific target molecule (or *antigen*). The precise antigen specificity of antibodies makes them powerful tools for the cell biologist. Labeled with fluorescent dyes, they are invaluable for locating specific molecules in cells by fluorescence microscopy (Figure 4-62); labeled with electron-dense particles such as colloidal gold spheres, they are used for similar purposes in the electron microscope (Figure 4-63). As biochemical tools, they are used to detect and quantify molecules in cell extracts and to identify specific proteins after they have been fractionated by electrophoresis in polyacrylamide gels (see Figure4-46). When coupled to an inert matrix to produce an affinity column, antibodies can be used either to purify a specific molecule from a crude cell extract or, if the molecule is on the cell surface, to pick out specific types of living cells from a heterogeneous population.

The sensitivity of antibodies as probes for detecting and assaying specific molecules in cells and tissues is frequently enhanced by a signal-amplification method. For example, although a marker molecule such as a fluorescent dye can be linked directly to an antibody used for specific recognition (the *primary antibody*, a stronger signal is achieved by using an unlabeled primary antibody and then detecting it with a group of labeled *secondary antibodies*that bind to it (Figure 4-64).

The most sensitive and versatile amplification methods use an enzyme as a marker molecule attached to the secondary antibody. The enzyme alkaline phosphatase, for example, in the presence of appropriate chemicals, produces inorganic phosphate and leads to the local formation of a colored precipitate. This reveals the location of the secondary antibody that is coupled to the enzyme and hence the location of the antibody-antigen complex to which the secondary antibody is bound. Since each enzyme molecule acts catalytically to generate many thousands of molecules of product, even tiny amounts of antigen can be detected. Enzyme-linked immunosorbent assays (ELISA) based on this principle are frequently used in medicine as a sensitive test - for pregnancy or for various types of infections, for example.

Antibodies are made most simply by injecting a sample of the antigen several times into an animal such as a rabbit or a goat and then collecting the antibody-rich serum. This *antiserum*contains a heterogeneous mixture of antibodies, each produced by a different antibody-secreting cell (a B lymphocyte). The different antibodies recognize various parts of the antigen molecule as well as impurities in the antigen preparation. The specificity of an antiserum for a particular antigen sometimes can be sharpened by removing the unwanted antibody molecules that bind to other molecules; an antiserum produced against protein X, for example, can be passed through an affinity column of antigens Y and Z to remove any contaminating anti-Y and anti-Z antibodies. Even so, the heterogeneity of such antisera sometimes limits their usefulness.

Hybridoma Cell Lines Provide a Permanent Source of Monoclonal Antibodies 37

In 1976 the problem of antiserum heterogeneity was overcome by the development of a technique that revolutionized the use of

antibodies as tools in cell biology. The principle is to propagate a clone of cells from a single antibody-secreting B lymphocyte so that a homogeneous preparation of antibodies can be obtained in large quantities. The practical problem, however, is that B lymphocytes normally have a limited life-span in culture. To overcome this limitation, individual antibody-producing B lymphocytes from an immunized mouse or rat are fused with cells derived from an "immortal" B lymphocyte tumor. From the resulting heterogeneous mixture of hybrid cells, those hybrids that have both the ability to make a particular antibody and the ability to multiply indefinitely in culture are selected. These hybridomas are propagated as individual clones, each of which provides a permanent and stable source of a single type of monoclonal antibody (Figure 4-65). This antibody will recognize a single type of antigenic site - for example, a particular cluster of five or six amino acid side chains on the surface of a protein. Their uniform specificity makes monoclonal antibodies much more useful for most purposes than conventional antisera, which usually contain a mixture of antibodies that recognize a variety of different antigenic sites on even a small macromolecule.

But the most important advantage of the hybridoma technique is that monoclonal antibodies can be made against molecules that constitute only a minor component of a complex mixture. In an ordinary antiserum made against such a mixture, the proportion of antibody molecules that recognize the minor component would be too small to be useful. But if the B lymphocytes that produce the various components of this antiserum are made into hybridomas, it becomes possible to screen individual hybridoma clones from the large mixture to select one that produces the desired type of monoclonal antibody and to propagate the selected hybridoma indefinitely so as to produce that antibody in unlimited quantities. In principle, therefore, a monoclonal antibody can be made against any protein in a biological sample. Once the antibody is made, it can be used as a specific probe - both to track down and localize the protein that induced its formation and to purify the protein in order to study its structure and function. Since fewer than 5% of the estimated 10,000 proteins in a typical mammalian cell have thus far been isolated, many monoclonal antibodies made against impure protein mixtures in fractionated cell extracts identify new proteins. Using monoclonal antibodies and gene-cloning technology, it is no longer difficult to identify and characterize novel proteins and genes. The problem is to determine their function, and the most powerful way of doing this is often by the use of recombinant DNA technology, as we discuss in Chapter 7.

Summary

A large number of techniques are now available for detecting, measuring, and following almost any chosen molecule in a cell. Any type of molecule can, for example, be "labeled" by the incorporation of one or more radioactive atoms. The unstable nuclei of these atoms disintegrate, emitting radiation that allows the molecule to be detected and its movements and metabolism to be traced in the cell. Applications of radioisotopes in cell biology include the analysis of metabolic pathways by pulse-chase methods and the determination of the location of individual molecules in a cell or on a gel by autoradiography.

Fluorescent indicator dyes can be used to measure the concentration of specific ions in individual cells and even in different parts of a cell. Glass microelectrodes, besides being indispensable for studying the electrical potentials and ionic currents across the plasma membrane, provide an alternative way of measuring the concentrations of specific intracellular ions. They can also be used as micropipettes to inject membrane-impermeant molecules, such as fluorescently labeled proteins and antibodies, into living cells. The dynamic behavior and movements of many types of molecules can be followed in a living cell by constructing an inactive "caged" pre-cursor, which can be introduced into a cell and then activated in a selected region of the cell by a light-stimulated reaction.

Antibodies are also versatile and sensitive tools for detecting and localizing specific biological molecules. Vertebrates make billions of different antibody molecules, each with a binding site that recognizes a specific region of a macromolecule. The hybridoma technique allows monoclonal antibodies of a single specificity to be obtained in virtually unlimited amounts. In principle, monoclonal antibodies can be made against any cell macromolecule and so can be used to locate and purify the molecule and, in some cases, to analyze its function.

Table 4-10. Some Radioisotopes in Common Use in Biological Research

Isotope	Half-life
^{32}P	14 days
^{131}I	8.1 days
^{35}S	87 days
^{14}C	5570 years
^{45}Ca	164 days
^{3}H	12.3 years

The isotopes are arranged in decreasing order of the energy of the b radiation (electrons) they emit.^{131}I also emits g radiation. The *half-life* is the time required for 50% of the atoms of an isotope to disintegrate.
Figure 4-50. The logic of a typical pulse-chase experiment using radioisotopes. The chambers labeled A, B, C, and D represent either different compartments in the cell (detected by autoradiography or by cell-fractionation experiments) or different chemical compounds (detected by chromatography or other chemical methods). The results of a real pulse-chase experiment can be seen in Figure 4-51.
Figure 4-51. Electron-microscopic autoradiography. The results of a pulse-chase experiment in which pancreatic beta cells were fed ^{3}H-leucine for 5 minutes (the pulse) followed by excess unlabeled leucine (the chase). The amino acid is largely incorporated into insulin, which is destined for secretion. After a 10-minute chase the labeled protein has moved from the rough ER to the Golgi stacks (A), where its position is revealed by the black silver grains in the photographic emulsion. After a further 45-minute chase the labeled protein is found in electron-dense secretory granules (B). The small round silver grains seen here

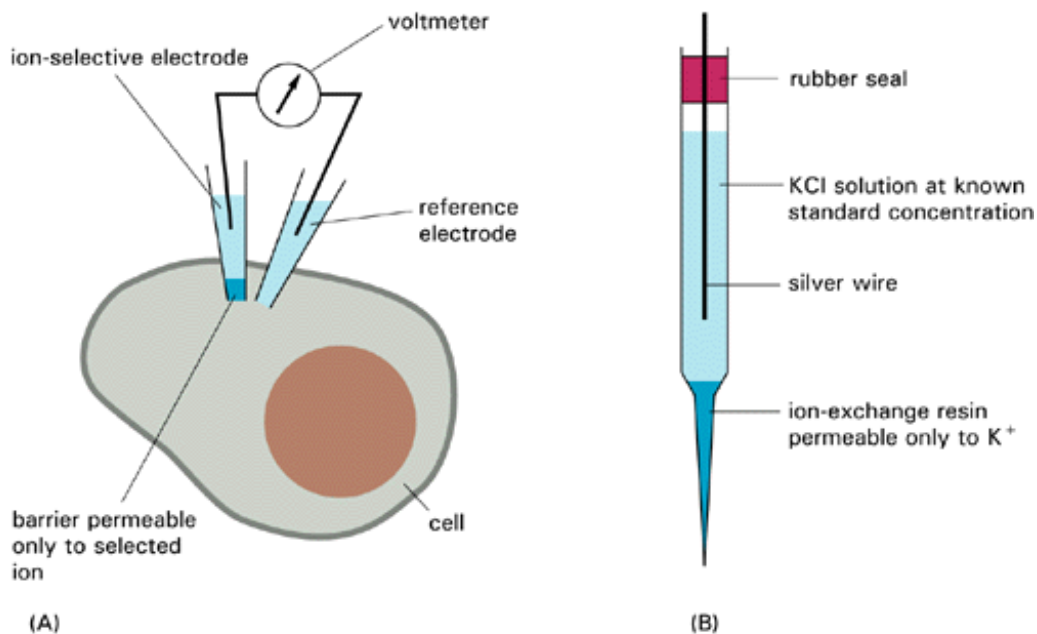
are produced by using a special photographic developer and should not be confused with the similar-looking black dots seen with immunogold labeling methods (e.g., Figure 4-63). Experiments similar to this one were important in establishing the intracellular pathway taken by newly synthesized secretory proteins. (Courtesy of L. Orci, from *Diabetes* 31:538-565, 1982. © 1982 American Diabetes Association, Inc.)
Figure 4-52. Radioisotopically labeled molecules. Three commercially available radioactive forms of ATP, with the radioactive atoms shown in *red*. The nomenclature used to identify the position and type of the radioactive atoms is also shown.


Figure 4-53. An ion-selective microelectrode used to measure the intracellular concentration of a specific ion. The experimental arrangement is shown in (A). The construction of a microelectrode selectively permeable to K^+ is shown in (B). In general, the tip of the ion-sensitive intracellular microelectrode is either constructed from special glass or filled with a special organic compound to make it permeable only to a chosen ion. The rest of the tube is filled with an aqueous solution of the ion at a known concentration, with a metal conductor connected to one terminal of a voltmeter dipping into it. The other terminal of the voltmeter is connected in a similar way to a glass reference microelectrode that has an open tip and contains a simple conducting solution. The two microelectrodes are both poked through the plasma membrane of the cell to be studied. The voltage measured by the voltmeter, which equals the potential difference across the selectively permeable barrier, reveals the concentration of the ion in the cell.

Figure 4-54. Micropipettes used for patch-clamp recording. A rod cell from the eye of a salamander is shown held by a suction pipette while a fine-tipped glass pipette, pressed against the cell so that the glass is sealed tightly to the plasma membrane, serves as a microelectrode. The term "clamp" is used because an electronic device is generally utilized to "clamp" the voltage across the patch so that the voltage is maintained at a fixed value. (From T.D. Lamb, H.R. Matthews, and V. Torre, *J. Physiol.* 37:315-349, 1986.)
Figure 4-55. The four standard configurations used for patch-clamp recording. The mouth of the glass recording pipette is first pressed against the cell membrane so that a tight seal forms (*top*). Recordings of the current entering the pipette through the patch of membrane can then be made with the patch still attached to the cell (A) or pulled free from it, exposing the cytoplasmic surface of the plasma membrane (B). Alternatively, the patch can be ruptured by gentle suction so that the interior of the electrode communicates directly with the interior of the cell (C); in this latter, "whole-cell" configuration, one can record the electrical behavior of the cell in the same way as with an intracellular electrode, with the added option that the internal chemistry of the cell can be altered by allowing substances to diffuse out of the relatively wide recording pipette into the cytoplasm. Configuration (D) is reached via configuration (C) by pulling the pipette away from the cell, thereby causing a fragment of the adjacent plasma membrane to fold back over the tip to form a seal. In (D) the exterior surface rather than the cytoplasmic surface of the membrane is exposed [compare with (B)].
Figure 4-56. The luminescent protein aequorin emits light in the presence of free Ca^{2+}. Here an egg of the medaka fish has been injected with aequorin, which has diffused throughout the cytosol, and the egg has then been fertilized with a sperm and examined with the help of an image intensifier. The four photographs shown were taken looking down on the site of sperm entry at intervals of 10 seconds and reveal a wave of release of free Ca^{2+} into the cytosol from internal stores just beneath the plasma membrane. This wave sweeps across the egg starting from the site of sperm entry, as indicated in the diagrams on the left. (Photographs reproduced from J.C. Gilkey, L.F. Jaffe, E.B. Ridgway, and G.T. Reynolds, *J. Cell Biol.* 76:448-466, 1978, by copyright permission of the Rockefeller University Press.)
Figure 4-57. Visualizing intracellular Ca^{2+} concentrations using a fluorescent indicator. The branching tree of dendrites of the Purkinje cell in the cerebellum receives more than 100,000 synapses from other neurons. The output from the cell is conveyed along the single axon seen leaving the cell body at the bottom of the picture. This image of the intracellular calcium concentration in a single Purkinje cell (from the brain of a guinea pig) was taken using a low-light camera and the Ca^{2+}-sensitive fluorescent indictor fura-2. The concentration of free Ca^{2+} is represented by different colors, *red* being the highest and *blue* the lowest. The highest Ca^{2+} levels are present in the thousands of dendritic branches. (Courtesy of D.W. Tank, J.A. Connor, M. Sugimori, and R.R. Llinas.)
Figure 4-58. Fluorescent analogue cytochemistry. Fluorescence micrograph of the leading edge of a living fibroblast that has been injected with rhodamine-labeled tubulin. The microtubules throughout the cell have incorporated the labeled tubulin molecules. Thus individual microtubules can be detected and their dynamic behavior followed using computer-enhanced imaging, as shown here. Although the microtubules appear to be about 0.25 μm thick, this is an optical effect; they are, in reality, only one-tenth this diameter. (Courtesy of P. Sammeh and G. Borisy.)
Figure 4-59. Methods to introduce a membrane-impermeant substance into a cell. In (A) the substance is injected through a micropipette, either by applying pressure or, if the substance is electrically charged, by applying a voltage that drives the substance into the cell as an ionic current (a technique called *iontophoresis*). In (B) the cell membrane is made transiently permeable to the substance by disrupting the membrane structure with a brief but intense electric shock (2000 volts per centimeter for 200 microseconds, for example). In (C) membrane-bounded vesicles are loaded with the desired substance and then induced to fuse with the target cells.
Figure 4-60. Caged molecules. Generalized scheme to show how a light-sensitive caged derivative of a molecule (here designated as X) can be converted by a flash of UV light to its free, active form. Small molecules such as ATP can be caged in this way. Even ions like Ca^{2+} can be indirectly caged; in this case a Ca^{2+}-binding chelator is used, which is inactivated by photolysis, thus releasing its Ca^{2+}.
Figure 4-61. Determining microtubule flux in the mitotic spindle using caged fluorescein linked to tubulin. (A) A metaphase spindle formed *in vitro* from an extract of *Xenopus* eggs has incorporated three fluorescent markers: rhodamine-labeled tubulin (*red*) to mark all of the microtubules, a *blue* DNA-binding dye that labels the chromosomes, and caged-fluorescein-labeled tubulin, which is also incorporated into all of the microtubules but is invisible because it is nonfluorescent until activated by utlraviolet light. In (B) a beam of ultraviolet light is used to uncage the caged-fluorescein-labeled tubulin locally, mainly just to the left side of the metaphase plate. Over the next few minutes (after 1 1/2; minutes in C, after 2 1/2; minutes in D) the uncaged fluorescein-tubulin signal is seen to move toward the left spindle pole, indicating that tubulin is continuously moving poleward even though the spindle (visualized by the *red* rhodamine-labeled tubulin fluorescence) remains largely unchanged. (From K.E. Sawin and T.J. Mitchison, *J. Cell Biol.* 112:941-954, 1991, by copyright permission of the Rockefeller University Press.)
Figure 4-64. Indirect immunocytochemistry. The method is very sensitive because the primary antibody is itself recognized by many molecules of the secondary antibody. The secondary antibody is covalently coupled to a marker molecule that makes it readily detectable. Commonly used marker molecules include fluorescein or rhodamine dyes (for fluorescence microscopy), the

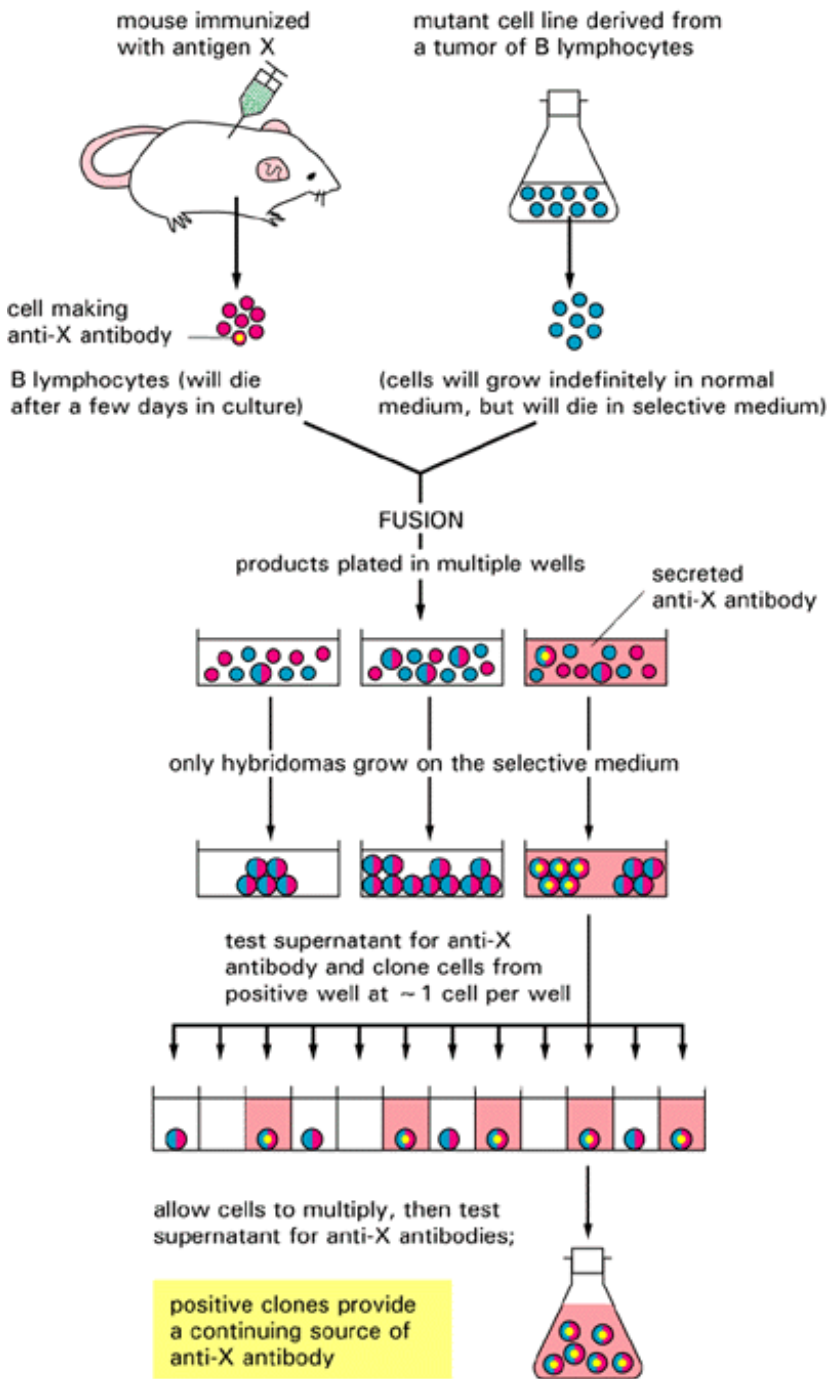
enzyme horseradish peroxidase (for either conventional light microscopy or electron microscopy), the iron-containing protein ferritin or colloidal gold spheres (for electron microscopy), and the enzymes alkaline phosphatase or peroxidase (for biochemical detection).


Figure 4-65. Preparation of hybridomas that secrete monoclonal antibodies against a particular antigen (X). The selective growth medium used contains an inhibitor (aminopterin) that blocks the normal biosynthetic pathways by which nucleotides are made. The cells must therefore use a bypass pathway to synthesize their nucleic acids, and this pathway is defective in the mutant cell line to which the normal B lymphocytes are fused. Because neither cell type used for the initial fusion can grow on its own, only the hybrid cells survive.

II. Molecular Genetics

5. Protein Function

Introduction

Proteins make up most of the dry mass of a cell, and they play the predominant part in most biological processes. One must understand proteins, therefore, before one can hope to understand the cell. An elementary introduction to the structure of proteins was provided in Chapter 3, where we presented a general overview of biological macromolecules and discussed their shapes and chem-istry. But proteins are not just rigid lumps of material with chemically reactive surfaces. They have precisely engineered moving parts whose mechanical actions are coupled to chemical events. It is this coupling of chemistry and movement that gives proteins the extraordinary capabilities that underlie all the dynamic processes in living cells. Without a grasp of how proteins operate as molecules with moving parts, it is hard to appreciate the rest of cell biology.

In this chapter, which begins the more advanced sections of the book, we use selected examples to show how proteins function not only as catalysts but also as sophisticated transducers of motion, signal integrators, and components of multisubunit protein machines. The discussion relies on advances that have revealed the detailed three-dimensional structures of many proteins; it will emphasize general principles and is intended to set the stage for the descriptions of specific cell structures and processes in subsequent chapters.

In the last part of the chapter we describe the life and death of proteins - from their folding, guided by molecular chaperones, to their destruction by targeted proteolysis - emphasizing the modular construction of most proteins and protein complexes.

Making Machines Out of Proteins

Introduction

We begin by considering how the shape of a protein can be altered by the binding of another molecule, called a *ligand.* We then demonstrate the profound implications of this apparently simple phenomenon by describing a few of the many ways in which ligand-driven alterations in protein shape are exploited by cells.

The Binding of a Ligand Can Change the Shape of a Protein[1]

The first example involves the enzyme *hexokinase,* which is present in nearly all cells. This enzyme catalyzes an early step in sugar metabolism - the transfer of the terminal phosphate of an ATP molecule to glucose, forming glucose 6-phosphate (discussed in Chapter 2). Hexokinase binds glucose tightly, and this greatly increases the affinity of the enzyme for ATP, which binds to a neighboring site on the protein. Specific amino acid side chains on the protein then catalyze the phosphate transfer, and the two products - glucose 6-phosphate and ADP - are released to finish the reaction cycle (Figure 5-1).

The hexokinase from yeast is composed of two domains. The binding sites for glucose and ATP lie in a cleft between these domains, and the domains move toward each other to narrow the cleft when glucose binds (Figure 5-2).

This type of domain movement in response to ligand binding is common and is easily explained. In the case of hexokinase there are binding sites for different parts of the glucose molecule on the inside face of each domain. The unfavorable change in the free energy of the protein that occurs when the domains move relative to each other to close the cleft is more than compensated for by the free energy released when the cleft clamps down on the glucose; in other words, the noncovalent bonds that glucose forms with the protein serve to "glue" the two domains together, causing the protein to shift from an *open* to a *closed* conformation.

Two Ligands That Bind to the Same Protein Often Affect Each Other's Binding[2]

The binding of glucose to hexokinase causes a fiftyfold increase in the affinity of the enzyme for ATP. The reason is easy to see. Like glucose, ATP can form noncovalent bonds with amino acids on the inside faces of the two domains if the cleft closes. When ATP alone binds to hexokinase, some of the binding energy must be used to close up the cleft; this energy is not required, however, if glucose binding has already induced this shape change (Figure 5-3). By the same reasoning, one would predict that glucose would bind more tightly to hexokinase when ATP is present than when it is absent, and this is what one observes

(<u>Figure 5-4</u>).

ATP and glucose bind to neighboring sites in hexokinase. But the binding of one ligand to a protein's surface can sometimes affect the binding of a second ligand even if the two binding sites are far apart. Suppose, for example, that a protein that binds glucose in the same way as hexokinase also binds another molecule, X, at a distant site on the protein's surface. If the binding site for X changes shape as part of the large conformational change induced by glucose binding, one would say that the binding sites for X and for glucose are *coupled.* If the shift to the closed conformation, for example, causes the binding site for Xto fitXbetter, then glucose binding will increase the affinity of the protein for X, just as glucose binding increases the affinity of hexokinase for ATP (<u>Figure 5-5</u>).

As we discuss next, proteins in which conformational changes couple two widely separated binding sites have been selected in evolution because they enable a cell to link the fate of one molecule to the presence or absence of any other. This type of conformational coupling is known as *allostery.* A protein whose activity is regulated in this way is said to undergo an allosteric transition, and the protein is called an *allosteric protein.*

Two Ligands Whose Binding Sites Are Coupled Must Reciprocally Affect Each Other's Binding<u>2</u>

Whenever two ligands prefer to bind to the *same* conformation of an allosteric protein, it follows from basic thermodynamic considerations that each ligand must increase the affinity of the protein for the other. This concept is called linkage. It is well illustrated by the example already considered in <u>Figure 5-5</u>, where the binding of glucose to hexokinase increases the enzyme's affinity for molecule X and vice versa. The linkage relationship is quantitatively reciprocal, so that, for example, if glucose has a very large effect on the binding of X, X will have a very large effect on the binding of glucose.

Linkage will operate in a negative way if two ligands bind to *different* conformations of an allosteric protein. As a general rule, a ligand will act to stabilize the particular conformation of the protein to which it binds; if this is different from the conformation favored by a second ligand, the binding of the first will discourage the binding of the second. Thus, if a shape change caused by glucose binding reduces the affinity of a protein for molecule X, the binding of X must decrease the protein's affinity for glucose (<u>Figure 5-6</u>).

The relationships shown schematically in <u>Figures 5-5</u> and <u>5-6</u> underlie all of cell biology. They seem so obvious in retrospect that we now take them for granted. But their discovery in the 1950s, followed by a general description of allostery in the early 1960s, was revolutionary at the time. Since the X in these examples binds at a site that is distinct from the site where catalysis occurs, it need have no chemical relationship to glucose or to any other ligand that binds at the active site. For enzymes that are regulated in this way, molecule X could either turn the enzyme on (see <u>Figure 5-5</u>) or turn it off (see <u>Figure 5-6</u>). By such a mechanism, allosteric proteins serve as general switches that allow one molecule in a cell to affect the fate of another.

Allosteric Transitions Help Regulate Metabolism<u>3</u>

As described in <u>Chapter 2</u>, the end product of a metabolic pathway often inhibits the enzyme that starts the pathway. Because of this *negative feedback* on the flux through a pathway, the intracellular concentration of the end product is kept approximately constant, despite large changes in the chemical conditions in the cell. Allosteric transitions are essential to this type of *feedback regulation.* Enzymes that act early in a pathway, for example, generally exist in two conformations. One is an active conformation that binds substrate at its active site and catalyzes its conversion to the next substance in the pathway. The other is an inactive conformation that binds the final product of the pathway at a different, regulatory site. As the final product accumulates, it binds to the enzymeand converts it to its inactive conformation (see <u>Figure 2-38</u>).

An enzyme involved in a metabolic pathway can also be *activated* by an allosteric transition induced by ligand binding. In this case the ligand is a molecule that accumulates when the cell is deficient in a product of the pathway; because the ligand binds preferentially to the active form of the protein, it drives the enzyme from an inactive to an active conformation. Examples of this type of *positive feedback* are provided by many of the enzymes involved in the catabolic pathways that produce ATP: they are stimulated by the rise in ADP concentration that occurs when ATP levels drop. For these enzymes the ADP has a purely regulatory role, in contrast to the substrate role played by ATP in the function of hexokinase.

Proteins Often Form Symmetrical Assemblies That Undergo Cooperative Allosteric Transitions<u>4</u>

An enzyme that is regulated by negative feedback and that consists of only one subunit with one regulatory site can at most decrease from 90% to about 10% activity in response to a 100-fold increase in the concentration of the inhibitory ligand (Figure 5-7, *red line*). Responses of this type are apparently not sharp enough for optimal cell regulation, and most enzymes that are turned on or off by ligand binding consist of symmetrical assemblies of identical subunits. With this arrangement the binding of a molecule of ligand to a single site on one subunit can trigger an allosteric change in the subunit that can be transmitted to the neighboring subunits, helping them to bind the same ligand. As a result of this *cooperative* allosteric transition, a relatively small change in ligand concentration in the cell can switch the whole assembly from an almost fully active to an almost fully inactive conformation or vice versa (Figure 5-7, *blue line*).

The principles involved in a cooperative "all-or-none" transition are easiest to visualize for an enzyme that forms a symmetrical dimer. In the example shown in Figure 5-8, the first molecule of an inhibitory ligand binds with great difficulty since its binding destroys an energetically favorable interaction between the two identical monomers in the dimer. A second ligand molecule now binds more easily, however, because its binding restores the monomer-monomer contacts of a symmetrical dimer (and also completely inactivates the enzyme). An even sharper response to a ligand can be obtained with larger assemblies, such as the enzyme formed from 12 polypeptide chains discussed next.

The Allosteric Transition in Aspartate Transcarbamoylase Is Understood in Atomic Detail[5]

One enzyme used in the early studies of negative feedback, allosteric regulation was aspartate transcarbamoylase from *E. coli*. It catalyzes the important reaction carbamoylphosphate + aspartate $\rightarrow$ N-carbamoylaspartate, which begins the synthesis of the pyrimidine ring of C, U, and T nucleotides. One of the final products of this pathway, cytosine triphosphate (CTP), binds to the enzyme to turn it off whenever CTP is plentiful.

Aspartate transcarbamoylase is a large complex of six regulatory and six catalytic subunits. The catalytic subunits are present as two trimers, each arranged like an equilateral triangle; the two trimers face each other and are held together by three regulatory dimers that form a bridge between them. The entire molecule is poised to undergo a concerted, all-or-none allosteric transition between two conformations, designated T ("tense") and R ("relaxed") states (Figure 5-9).

The binding of substrates (carbamoylphosphate and aspartate) to the catalytic trimers drives aspartate transcarbamoylase into its catalytically active R state, from which the regulatory CTP molecules dissociate. By contrast, the binding of CTP to the regulatory dimers converts the enzyme to the inactive T state, from which the substrates dissociate. This tug-of-war between CTP and substrates is identical in principle to that described previously in Figure 5-6 for a simpler allosteric protein. But because here the tug-of-war occurs in a symmetrical molecule with multiple binding sites, the effect is a cooperative allosteric transition that can either turn the enzyme on suddenly as substrates accumulate (forming the R state) or shut it off rapidly when CTP accumulates (forming the T state).

A combination of biochemistry and x-ray crystallography has revealed many fascinating details of this allosteric transition. Each regulatory subunit has two domains, and the binding of CTP causes the two domains to move relative to each other, so that they function like a lever that rotates the two catalytic trimers and pulls them closer together into the T state (see Figure 5-9). When this occurs, hydrogen bonds form between opposing catalytic subunits that help to widen the cleft that forms the active site within each catalytic subunit, thereby destroying the binding sites for the substrates (Figure 5-10). Adding large amounts of substrate has the opposite effect, favoring the R state by binding in the cleft of each catalytic subunit and opposing the above conformational change. Conformations that are intermediate between R and T are unstable, so that the enzyme mostly clicks back and forth between its R and T forms, producing a mixture of these two species, whose composition varies depending on the relative concentrations of CTP and substrates.

Protein Phosphorylation Is a Common Way of Driving Allosteric Transitions in Eucaryotic Cells[6]

The activity of proteins in a bacterium such as *E. coli* is regulated mainly by the myriad small molecules in the cell that bind to specific proteins to cause allo-steric transitions that control the protein's activity. Many of the proteins regulated in this way are enzymes that catalyze metabolic reactions; others transduce signals or turn genes on and off (see, for example, Figure 9-27). Some bacterial proteins are controlled in a different way, however - by the covalent attachment of a phosphate group to an amino acid side chain. Because each phosphate group carries two negative charges, its addition to a protein can cause a structural change, for example, by attracting a cluster of positively charged side chains (Figure 5-11). Such a change occurring at one site in a protein can in turn alter the protein's conformation elsewhere - to control allosterically the activity of a distant ligand-binding site, for instance.

Reversible protein phosphorylation is the predominant strategy used to control the activity of proteins in eucaryotic cells. More than 10% of the 10,000 proteins in a typical mammalian cell are thought to be phosphorylated. The phosphates are transferred from ATP molecules by *protein kinases* and are taken off by *protein phosphatases.* Eucaryotic cells contain a large variety of these enzymes, many of which play a central role in intracellular signaling (discussed in Chapter 15).

A Eucaryotic Cell Contains Many Protein Kinases and Phosphatases[7]

The protein kinases that phosphorylate proteins in eucaryotic cells belong to a large family of enzymes, which contain a similar 250 amino acid catalytic (kinase) domain (Figure 5-12). The various family members contain different amino acid sequences on either side of the kinase domain, and often have short amino acid sequences inserted into loops within it (see *red arrowheads* in Figure 5-12). Some of these additional amino acid sequences enable each kinase to recognize the specific set of proteins that it phosphorylates. Other unique sequences allow the activity of each enzyme to be tightly regulated, so that it can be turned on and off in response to different specific signals, as described below.

By comparing the numbers of amino acid sequence differences between the members of a protein family, one can construct an "evolutionary tree" that is thought to reflect the pattern of gene duplication and divergence that gave rise to the family (see Figure 8-76). An evolutionary tree of protein kinases is shown in Figure 5-13. Not surprisingly, kinases with related functions are often located on nearby branches of the tree: the protein kinases involved in cell signaling that phosphorylate tyrosine side chains, for example, are all clustered at the upper left corner of the tree. The other kinases shown phosphorylate either a serine or a threonine side chain, and many are organized into clusters that seem to reflect their function - in transmembrane signaling, intracellular amplification of signals, cell-cycle control, and so on.

The basic reaction catalyzed by a protein kinase is illustrated in Figure 5-14. A phosphate group is transferred from an ATP molecule to a hydroxyl group on a serine, threonine, or tyrosine side chain of a protein. This reaction is essentially unidirectional because of the large amount of free energy released when the phosphate-phosphate bond in ATP is broken to produce ADP (see Figure 2-28). The phosphorylations catalyzed by protein kinases can nevertheless be reversed by a second group of enzymes, called protein phosphatases, which remove the phosphate (see Figure 5-14). There are several families of protein phosphatases: some are highly specific and remove phosphate groups from only one or a few proteins, while others are relatively nonspecific and act on a broad range of proteins. The extent of phosphorylation of a particular protein in a cell at a particular time depends on the relative activities of the protein kinases and phosphatases that act on it.

The Structure of Cdk Protein Kinase Shows How a Protein Can Function as a Microchip[8]

The hundreds of different protein kinases in a eucaryotic cell are organized into complex networks of signaling pathways that help coordinate the cell's activities, drive the cell cycle, and relay signals into the cell from the cell's environment. Many of the signals involved need to be both integrated and amplified. Individual protein kinases (and other signaling proteins) serve as processing devices, or "microchips," in the integration process. An important part of the input to these proteins comes from the control that is exerted by phosphates added to them by other protein kinases in the network: specific sets of phosphate groups serve to activate the protein, while other sets inactivate it.

A cyclin-dependent protein kinase (Cdk) represents a good example of such a processing device. Kinases in this class are central components of the cell-division-cycle control system in eucaryotic cells (discussed in Chapter 17). In a vertebrate cell, individual Cdk enzymes turn on and off in succession as a cell proceeds through the different phases of its division cycle, and when they are on, they influence various aspects of cell behavior through their effects on the proteins they phosphorylate. The three-dimensional structure of this important class of protein kinases is now known, and we shall use it to demonstrate how a protein can function as a microchip.

A Cdk protein is active as a protein kinase only when it is bound to a second protein called a *cyclin.* But, as illustrated in Figure 5-15, the binding of cyclin is only one of three distinct "inputs" required to activate the Cdk: in addition, a phosphate must be added to a specific threonine side chain and a phosphate elsewhere in the protein (covalently bound to a specific tyrosine side chain) must be removed. Cdk thus monitors a specific set of cell components - a cyclin, a protein kinase, and a protein phosphataseand turns on if, and only if, each of these components has attained its appropriate activity state. Some cyclins, for example, rise and fall in concentration in step with the cell cycle, increasing gradually in amount until they are suddenly destroyed at a particular point in the cycle. The sudden destruction of a cyclin (by targeted proteolysis) will immediately shut off its partner Cdk enzyme, and this is an important way of controlling intracellular events such as mitosis.

The three-dimensional structure of Cdk (Figure 5-16A) suggests a likely molecular explanation for the regulation of this enzyme. The Cdk protein on its own is inactive for two reasons: its ATP-binding site is distorted, and a flexible loop of about 20 amino acids blocks access of the protein substrate to the active site. Cyclin binding both removes the distortion and permits the addition of the activating phosphate group to the tip of the flexible loop; this phosphate is then thought to be attracted to a pocket formed by positively charged amino acids, pulling down the loop so as to permit access to the active site (Figure 5-16B). Cyclin binding also allows the rapid addition of the inhibitory phosphate, however, which interferes with the ATP site, and this keeps the Cdk protein in an inactive state. The kinase is finally activated when a specific phosphatase removes the inhibiting phosphate (Figure 5-17).

Proteins That Bind and Hydrolyze GTP Are Ubiquitous Cellular Regulators[9]

We have described how the addition or removal of phosphate groups on a protein can be used by a cell to control the protein's activity. In the examples discussed so far, the phosphate is transferred from an ATP molecule to an amino acid side chain of the protein in a reaction that is catalyzed by a specific protein kinase. Eucaryotic cells also use another way to control protein activity by phosphate addition and removal. In this case the phosphate is not attached directly to the protein; instead, it is a part of the guanine nucleotide GTP, which binds tightly to the protein. With GTP bound the protein is active. The loss of a phosphate group occurs when the bound GTP is hydrolyzed to GDP in a reaction that is catalyzed by the protein itself; with GDP bound the protein is inactive.

GTP-binding proteins (also called *GTPases* because of the GTP hydrolysis that they catalyze) constitute a large family of proteins that all have a similar GTP-binding globular domain. When its bound GTP is hydrolyzed to GDP, this domain undergoes a conformational change that inactivates the protein. The three-dimensional structure of a small GTP-binding protein called *Ras* is illustrated in Figure 5-18.

The Ras protein plays a crucial role in cell signaling (as discussed in Chapter 15). In its GTP-bound form it is active and stimulates a cascade of protein phosphorylations in the cell. Most of the time, however, the protein is in its inactive, GDP-bound form. It is activated when it exchanges its GDP for a GTP molecule in response to extracellular signals, such as growth factors, that bind to receptors in the plasma membrane (see Figure 15-53). Thus the Ras protein acts as an on-off switch whose activity is determined by the presence or absence of an additional phosphate on a bound GDP molecule, just as the activity of a Cdk protein is controlled by the presence of one or more phosphate groups on amino acid side chains (see Figure 5-17).

Other Proteins Control the Activity of GTP-binding Proteins by Determining Whether GTP or GDP Is Bound[10]

The activity of Ras and other GTP-binding proteins is controlled by regulatory proteins that determine whether GTP or GDP is bound, just as the activity of a Cdk protein is controlled by cyclins, protein kinases, and protein phosphatases. Ras is inactivated by a GTPase-activating protein (or GAP), which binds to the Ras protein and induces it to hydrolyze its bound GTP molecule to GDP - which remains tightly bound - and inorganic phosphate (P_i), which is rapidly released. The Ras protein will stay in its inactive, GDP-bound conformation until it encounters a guanine nucleotide releasing protein (GNRP), which binds to GDP-Ras and causes it to release its GDP. Because the empty nucleotide-binding site is immediately filled by a GTP molecule (GTP is present in large excess over GDP in cells), the GNRP activates Ras by *indirectly* adding back the phosphate removed by GTP hydrolysis. Thus, in a sense, the roles of GAP and GNRP are analogous to those of a protein phosphatase and a protein kinase, respectively (Figure 5-19).

The Allosteric Transition in EF-Tu Protein Shows How Large Movements Can Be Generated from Small Ones[11]

The Ras protein is a member of a family of *monomeric regulatory GTPases,* each of which consists of a single GTP-binding domain of about 200 amino acids. During the course of evolution this domain has also become joined to other protein domains to create a large family of GTP-binding proteins, whose members include the receptor-associated trimeric G proteins (discussed in Chapter 15), proteins regulating the traffic of vesicles between intracellular compartments (discussed in Chapter 13), and proteins that bind to transfer RNA and are required for protein synthesis on the ribosome (discussed in Chapter 6). In each case, an important biological activity is controlled by a change in the protein's conformation caused by GTP hydrolysis in a Ras-like domain.

The *EF-Tu protein* provides a good example of how this family of proteins works. EF-Tu is an abundant molecule in bacterial

cells, where it serves as an elongation factor in protein synthesis, loading each amino-acyl tRNA molecule onto the ribosome. The tRNA molecule forms a tight complex with the GTP-bound form of EF-Tu. In this complex, the amino acid attached to the tRNA is masked; its unmasking, which is required for protein synthesis, occurs on the ribosome when the tRNA is released following hydrolysis of the GTP bound to EF-Tu (see Figure 6-31 for an illustration of the clock-like function of EF-Tu).

The three-dimensional structure of EF-Tu, in both its GTP- and GDP-bound forms, has been determined by x-ray crystallography. These studies reveal how the unmasking of the tRNA occurs. The dissociation of the inorganic phosphate group (P_i), which follows the reaction GTP $\rightarrow$ GDP + P_i, causes a shift of a few tenths of a nanometer at the GTP-binding site, just as it does in the Ras protein. This tiny movement, equivalent to a few times the diameter of a hydrogen atom, causes a conformational change to propagate along a crucial piece of alpha helix, called the *switch helix,* in the Ras-like domain of the protein. The switch helix seems to serve as a latch that adheres to a specific site in another domain of the molecule, holding the protein in a "shut" conformation. The conformational change triggered by GTP hydrolysis causes the switch helix to detach, allowing separate domains of the protein to swing apart, through a distance of about 4 nanometers, thereby releasing the bound tRNA (Figure 5-20).

One can see from this example how cells can exploit simple chemical changes that occur on the surface of a small protein domain to evolve larger proteins with sophisticated functions. In the transition from Ras to EF-Tu we have entered a world that begins to feel like biology.

Proteins That Hydrolyze ATP Do Mechanical Work in Cells[12]

Allosteric shape changes can be used to generate orderly movements in cells as well as to regulate chemical reactions. Suppose, for example, that a protein is required that can "walk" along a narrow thread, such as a DNA molecule. Figure 5-21 shows schematically how an allosteric protein might do this by undergoing a series of conformational changes. With nothing to drive these changes in an orderly sequence, however, they will be perfectly reversible, and the protein will wander randomly back and forth along the thread.

We can look at this situation another way. Since the directional movement of a protein does work, the laws of thermodynamics demand that such movement depletes free energy from some other source (otherwise the protein could be used to make a perpetual motion machine). Therefore, no matter what modifications we make to the model shown in Figure 5-21, such as adding ligands that favor particular conformations, without an input of energy the protein molecule shown could only wander aimlessly.

How can one make the series of conformational changes unidirectional? To make the entire cycle proceed in one direction, it is enough to make any one of the steps irreversible. One way to do this is to use the mechanism just discussed for driving allosteric changes in a protein molecule by GTP hydrolysis. For example, because a great deal of free energy is released when GTP is hydrolyzed, it is very unlikely that the EF-Tu protein will directly add a phosphate molecule to GDP to reverse the hydrolysis of its GTP. Precisely the same principle applies to ATP hydrolysis, and most proteins that are able to walk in one direction for long distances (the so-called *motor proteins*) do so by hydrolyzing ATP.

In the highly schematic model shown in Figure 5-22, ATP binding shifts a motor protein from conformation 1 to conformation 2. The bound ATP is then hydrolyzed to produce ADP and inorganic phosphate (P_i), causing a change from conformation 2 to conformation 3. Finally, the release of the bound ADP and P_i drives the protein back to conformation 1. Because the transitions $1 \rightarrow 2 \rightarrow 3 \rightarrow 1$ are driven by the energy provided by ATP hydrolysis, this series of conformational changes will be effectively irreversible under physiological conditions (that is, the probability that ADP will recombine with P_i to form ATP by the route $1 \rightarrow 3 \rightarrow 2 \rightarrow 1$ is extremely low). Thus the entire cycle will go in only one direction, causing the protein molecule to move continuously to the right in this example. Many proteins generate directional movement in this way, including *DNA helicase* enzymes that propel themselves along DNA at rates as high as 1000 nucleotides per second.

The Structure of Myosin Reveals How Muscles Exert Force[13]

In Chapter 16 we discuss how various cell movements are produced by motor proteins that move rapidly along protein filaments, driven by energy derived from repeated cycles of ATP hydrolysis (see Figure 5-22). The best understood of these motor proteins is myosin, whose directed movement along actin filaments causes both intracellular movements and muscle contraction. The three-dimensional structures of myosin (and actin) have been determined by x-ray diffraction analyses,

providing a glimpse of the inner workings of a biological motor. The structure of the myosin head domain (Figure 5-23) suggests how ATP hydrolysis may be coupled to force generation. ATP binding and hydrolysis are thought to cause an ordered series of conformational changes that move the tip of the head by about 5 nanometers, as illustrated schematically in Figure 5-24. This movement, coupled to the making and breaking of interactions with actin and repeated with each round of ATP hydrolysis, propels the myosin molecule unidirectionally along an actin filament (see Figure 16-91). Thus in myosin, as in the EF-Tu protein discussed earlier, a small perturbation in the nucleotide-binding site is translated, via allosteric transitions that magnify the effect, to create the much more extensive, orderly protein motions that underlie much of cell biology.

ATP-driven Membrane-bound Allosteric Proteins Can Either Act as Ion Pumps or Work in Reverse to Synthesize ATP14

Besides generating mechanical force, allosteric proteins can use the energy of ATP hydrolysis to do other forms of work, such as pumping specific ions into or out of the cell. An important example is the Na^+-K^+ ATPase found in the plasma membrane of all animal cells, which pumps 3 Na^+ out of the cell and 2 K^+ in during each cycle of conformational changes driven by ATP hydrolysis (see Figure 11-11). This ATP-driven pump consumes more than 30% of the total energy requirement of most cells. By continuously pumping Na^+ out and K^+ in, it keeps the Na^+ concentration much lower inside the cell than outside and the K^+ concentration much higher inside than outside, thereby generating two ion gradients (in opposite directions) across the plasma membrane. These and other ion gradients across various cell membranes can store energy, just as the differences of water pressure on either side of a dam can. The energy is used to drive conformational changes in a variety of membrane-bound allosteric proteins that do useful work. The large Na^+ gradient across the plasma membrane, for example, drives many other plasma-membrane-bound protein pumps that transport glucose or specific amino acids into the cell; the glucose and amino acids are dragged in by the simultaneous influx of Na^+ that occurs as Na^+ moves down its concentration gradient.

The membrane-bound allosteric pumps that are driven by ATP hydrolysis can also work in reverse and employ the energy in the ion gradient to synthesize ATP. In fact, the energy available in the H^+ gradient across the inner mitochondrial membrane is used in this way by the membrane-bound allosteric protein complex, ATP synthase, which synthesizes most of the ATP required by animal cells, as we discuss in Chapter 14.

Energy-coupled Allosteric Transitions in Proteins Allow the Proteins to Function as Motors, Clocks, Assembly Factors, or Transducers of Information15

Many proteins undergo ordered conformational changes that are coupled to the energy released when a nucleoside triphosphate (either ATP or GTP) is hydrolyzed to a nucleoside diphosphate (ADP or GDP, respectively). Some of these changes involve the covalent attachment of a phosphate group to the protein (protein phosphorylation), but many others, as for myosin, do not. Each change is generally triggered by a specific event (the binding of myosin to an actin filament, for example, triggers ATP hydrolysis by myosin), imparting directionality and order to the interactions of macromolecules in the cell.

The ability to harness the energy in nucleoside triphosphates to drive allosteric changes in proteins has been crucial for the evolution of cells in much the same way that the ability to harness electrical energy has been crucial for the development of modern technology. In both cases rich opportunities have opened up for the development of useful devices. Proteins like Cdk, for example, act as sophisticated integrating switches (see Figure 5-15), receiving information about a cell's environment and the stage of the cell cycle and using it to coordinate the behavior of the cell. Motor proteins like myosin move unidirectionally along filaments to generate various movements and create order inside the cell. Proteins such as EF-Tu serve as timing devices that improve the fidelity of important biological reactions (see Figure 6-31). Other proteins use the energy released by nucleoside triphosphate hydrolysis to catalyze the assembly of specific protein complexes. A summary is presented in Figure 5-25.

Proteins Often Form Large Complexes That Function as Protein Machines16

As one progresses from small proteins to large proteins formed from many domains, the functions that a protein can perform become more elaborate. The most impressive tasks, however, are carried out by large protein assemblies formed from multiple individual subunits. Now that it is possible to reconstruct most biological processes in cell-free systems in a test tube, one can see that each central process in a cell - such as DNA replication, RNA or protein synthesis, vesicle budding, or transmembrane signaling - is catalyzed by a complex of 10 or more proteins. In such protein machines the hydrolysis of bound nucleoside triphosphate molecules (ATP or GTP) drives ordered conformational changes in the individual proteins, enabling the ensemble of proteins to move coordinately. In this way, for example, the appropriate enzymes are moved directly into the positions where

they are needed to carry out each reaction in a series instead of waiting for the random collision of each separate component that would otherwise be required. A simple mechanical analogy is illustrated in Figure 5-26.

Cells have evolved protein machines for the same reason that humans have invented mechanical and electronic machines: manipulations that are spatially and temporally coordinated through linked processes are much more efficient for accomplishing almost any task than is the sequential use of individual tools.

Summary

Allosteric proteins reversibly change their shape when ligands bind to their surface. The changes produced by one ligand often affect the binding of a second ligand, and this type of linkage between two ligand-binding sites provides a crucial mechanism for regulating cell processes. Metabolic pathways, for example, are controlled by feedback regulation: some small molecules will inhibit and other small molecules activate enzymes early in a pathway. Enzymes regulated in this way generally form symmetrical assemblies, allowing cooperative conformational changes to create a steep response to ligands.

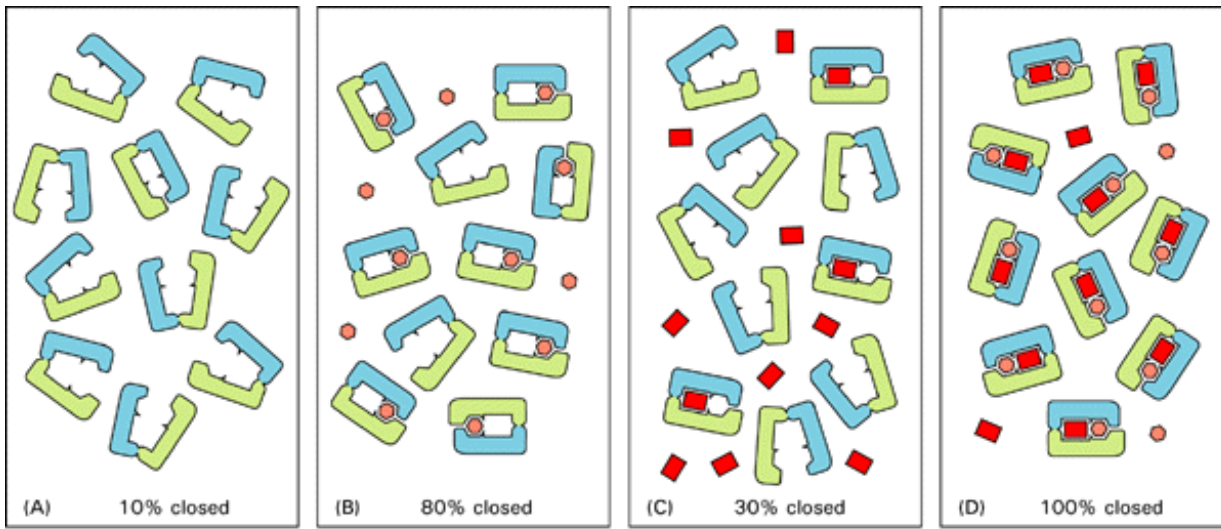
Changes in protein shape can be driven in a unidirectional manner by the expenditure of chemical energy. By coupling allosteric shape changes to ATP hydrolysis, for example, proteins can do useful work, such as generating a mechanical force or pumping ions across a membrane. The three-dimensional structures of several proteins, determined by x-ray crystallography, have revealed how a small local change caused by nucleoside triphosphate hydrolysis is amplified to create major changes elsewhere in the protein; by such means these proteins are able to serve as transducers of information, motors, clocks, or assembly factors. Highly efficient "protein machines" are formed by incorporating many different protein subunits into larger assemblies in which allosteric movements of the individual components are coordinated to carry out many, if not most, biological reactions.
Figure 5-1. The reaction catalyzed by hexokinase. As the first step in the breakdown of glucose, a phosphate group is transferred from ATP to glucose to form glucose 6-phosphate. The glucose 6-phosphate is then processed by a series of other enzymes, which catalyze the chain of reactions known as glycolysis. Glycolysis converts glucose to pyruvate and produces a net gain of ATP molecules for the cell (see Figure 2-21).
Figure 5-2. The conformational change in hexokinase caused by glucose binding. The lines trace the course of the polypeptide backbone of hexokinase. These structures were determined by x-ray diffraction analysis of crystals of the protein with and without glucose bound. Glucose binding shifts the protein from an *open* to a *closed* conformation.
Figure 5-3. Glucose helps ATP bind to hexokinase. Like glucose, ATP binds best to the *closed* conformation of the enzyme and therefore binds best if glucose has already bound. For simplicity, the actual structure of the protein shown in Figure 5-2 has been replaced (both here and in Figure 5-4) by a schematic diagram.


Figure 5-4. The conformational equilibrium in hexokinase. Because ATP and glucose both individually drive hexokinase toward its *closed* conformation, each ligand helps the other to bind. To help make this clear, each panel has been drawn to represent a test tube containing 10 molecules of hexokinase in an aqueous solution. Panel A shows how the protein behaves with no ligand present; although a small fraction of the molecules spontaneously adopt the closed form, most are in the open configuration. The other panels show how the 10 molecules of protein behave with 12 molecules of glucose (panel B), with 12 molecules of ATP (panel C), and with 12 molecules of glucose and 12 molecules of ATP (panel D). The symbols for glucose and ATP are the same as in Figure 5-3. A comparison of the amount of free (unbound) glucose in panels B and D shows that the addition of ATP helps glucose to bind, whereas a comparison of the amount of free ATP in panels C and D shows that the addition of glucose helps ATP to bind.
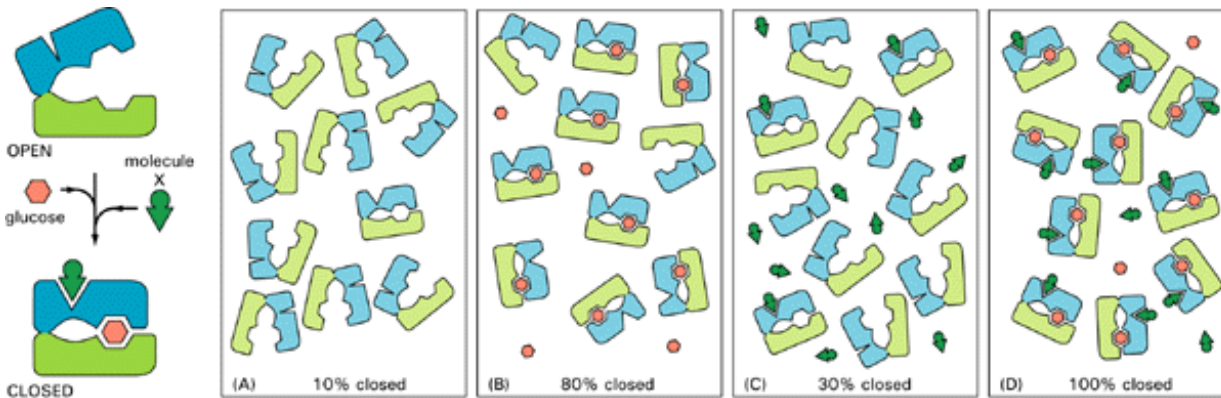

Figure 5-5. Cooperative binding caused by conformational coupling between two distant binding sites. In this example both glucose and molecule X bind best to the *closed* conformation of a protein with two domains. Because both glucose and molecule X drive the protein toward its closed conformation, each ligand helps the other to bind. Glucose and molecule X are therefore said to bind cooperatively to the protein.This figure is very similar to Figures 5-3 and 5-4; the only difference is that whereas the binding site for ATP lies in the cleft of hexokinase, the binding site for molecule X lies outside the cleft.
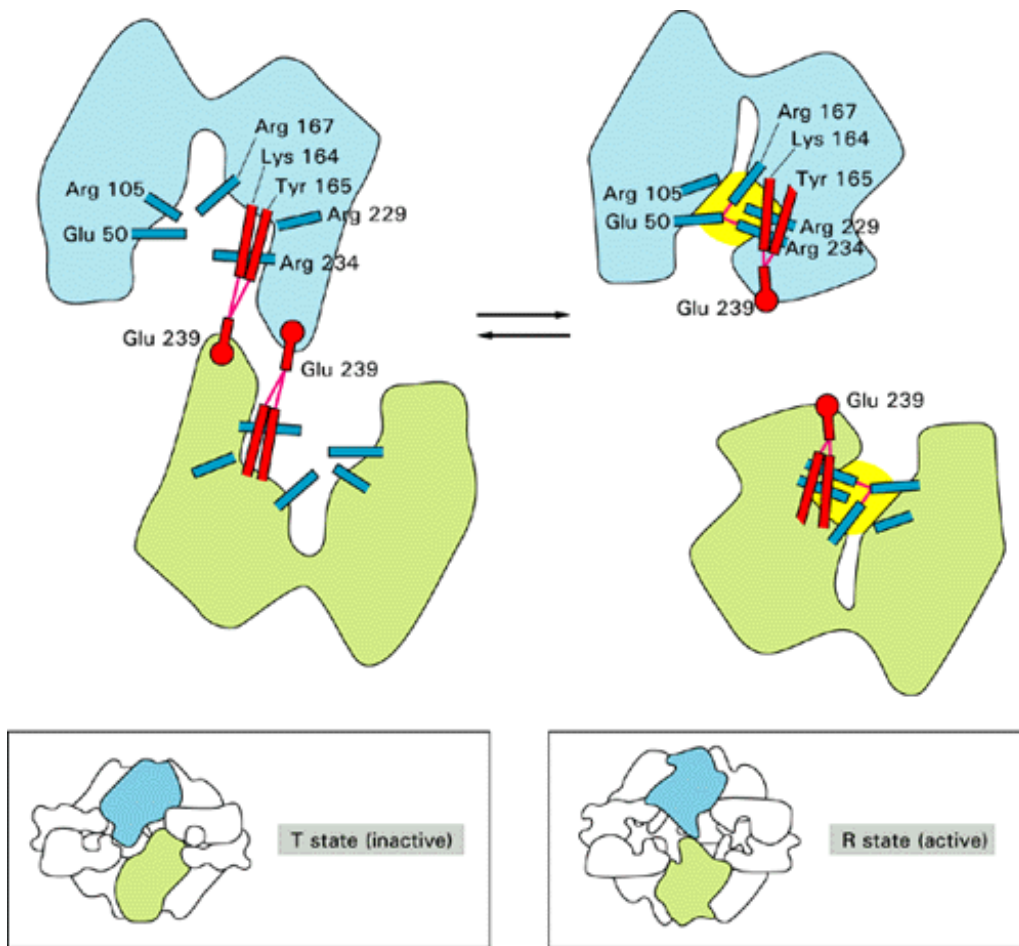
Figure 5-6. Competitive binding caused by conformational coupling between two distant binding sites. The design of this figure is the same as that described previously for Figure 5-5, but here molecule X prefers the *open* conformation, while glucose prefers the *closed* conformation. Because glucose and molecule X drive the protein toward opposite conformations (*closed* and *open,* respectively), the presence of either ligand interferes with the binding of the other.
Figure 5-7. A plot of enzyme activity versus the concentration of inhibitory ligand for monomeric and multisubunit allosteric enzymes. For an enzyme with a single subunit (*red line*) a drop from 90% enzyme activity to 10% activity (indicated by *dots* on the curve) requires a 100-fold increase in the concentration of inhibitor. The enzyme activity is calculated from the simple equilibrium relationship K = [I][P]/[IP], where P is active protein, I is inhibitor, and IP is the inactive protein bound to inhibitor. An identical curve applies to any simple binding interaction between two molecules, A and B (see Figure 3-9). In contrast, a multisubunit allosteric enzyme can respond in a switchlike manner to a change in ligand concentration: the steep response is caused by a cooperative binding of the ligand molecules, as explained in Figure 5-8. The *green line* represents the idealized result expected for the cooperative binding of 2 inhibitory ligand molecules to an allosteric enzyme with 2 subunits, and the *blue line* shows the idealized response of an enzyme with 4 subunits. As indicated by the dots on the curves, the more complex enzymes drop from 90% to 10% activity over a much narrower range of inhibitor concentration than does the enzyme composed of a single subunit.
Figure 5-8. A cooperative allosteric transition. Schematic diagram illustrating how the conformation of one subunit can influence that of its neighbor in a symmetrical protein composed of two identical allosteric subunits. The binding of a single molecule of an inhibitory ligand (*yellow*) to one subunit of the enzyme occurs with difficulty because it changes the conformation of this subunit and thereby destroys the symmetry of the enzyme; once this conformational change has been accomplished, however, the energy gained by restoring the symmetrical pairing makes it especially easy for the second subunit to bind a molecule of the inhibitory ligand and undergo the same conformational change. Because the binding of the first molecule of ligand increases the affinity with which the other subunit binds the same ligand, the response of the enzyme to changes in the concentration of the ligand will be much steeper than that of a monomeric enzyme (see Figure 5-7).
Figure 5-9. The transition between the R and T states in the enzyme aspartate transcarbamoylase. The enzyme consists of a complex of six catalytic subunits and six regulatory subunits, and the structures of its inactive (*T state*) and active (*R state*) forms have been determined by x-ray crystallography. The enzyme is turned off when CTP concentrations rise. Each of the regulatory subunits can bind one molecule of CTP, which is one of the final products in the pathway. By means of this negative feedback regulation, the pathway is prevented from producing more CTP than the cell needs. (Based on K.L. Krause, K.W. Volz, and W.N. Lipscomb, *Proc. Natl. Acad. Sci. USA* 82:1643-1647, 1985.)


Figure 5-10. Part of the on-off switch in the catalytic subunits of aspartate transcarbamoylase. Changes in the indicated hydrogen-bonding interactions are partly responsible for switching this enzyme's active site between active (*yellow*) and inactive conformations. Hydrogen bonds are indicated by *thin red lines.* The amino acids involved in the subunit-subunit interaction are shown in *red,* while those that form the active site of the enzyme are shown in *blue.* The upper pair of pictures show the catalytic site in the interior of the enzyme; the lower pictures show the external surface of the enzyme. (Adapted from E.R. Kantrowitz and W.N. Lipscomb, *Trends Biochem. Sci.* 15:53-59, 1990.)
Figure 5-11. The influence of a phosphate group on a protein. The negatively charged phosphate group shown here is covalently attached to a threonine side chain of the protein cyclic AMP-dependent protein kinase, which is discussed in Chapter 15. As determined by x-ray crystallography, the phosphate is surrounded by several positively charged amino acid side chains of the same protein. (Adapted from S.S. Taylor et al.,*Annu. Rev. Cell Biol.* 8:429-462, 1992. ©1992 Annual Reviews Inc.)

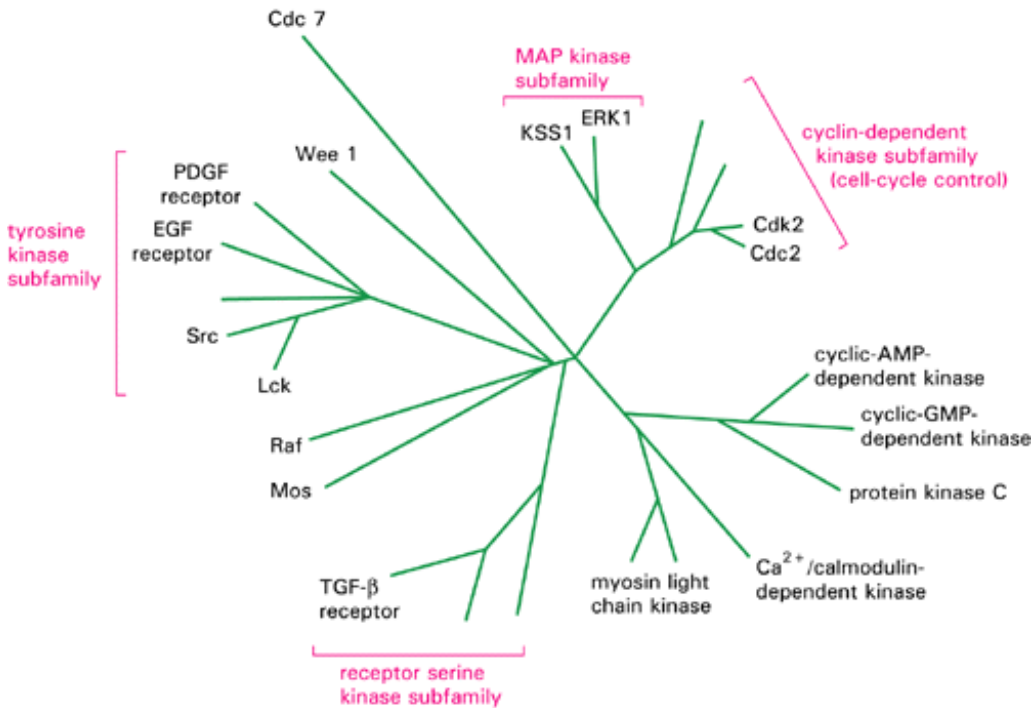
Figure 5-12. The three-dimensional structure of a protein kinase domain. Superimposed on this structure of the kinase domain of cyclic AMP-dependent kinase are *red arrowheads* to indicate sites where insertions of 5 to 100 amino acids are found in some other members of the protein kinase family. These insertions are located in loops on the surface of the enzyme where other ligands interact with the protein. Thus they distinguish different kinases and confer on them distinctive interactions with other proteins. The ATP (which will donate a phosphate group) and the peptide to be phosphorylated are held in the active site, which extends between the phosphate-binding loop (*yellow*) and the catalytic loop (*red*). (Adapted from D.R. Knighton et al., *Science* 253:407-414, 1991. © 1991 the AAAS.)


Figure 5-13. An evolutionary tree of selected protein kinases. Although a higher eucaryotic cell contains hundreds of such enzymes, only some of those discussed in this book are shown.
Figure 5-14. The enzymes that control the phosphorylation of proteins in cells. The reaction catalyzed by a protein kinase puts a phosphate onto an amino acid side chain, whereas the reaction catalyzed by a protein phosphatase removes this phosphate.
Figure 5-15. How a Cdk acts as an integrating device. The function of these central regulators of the cell cycle is discussed in Chapter 17.

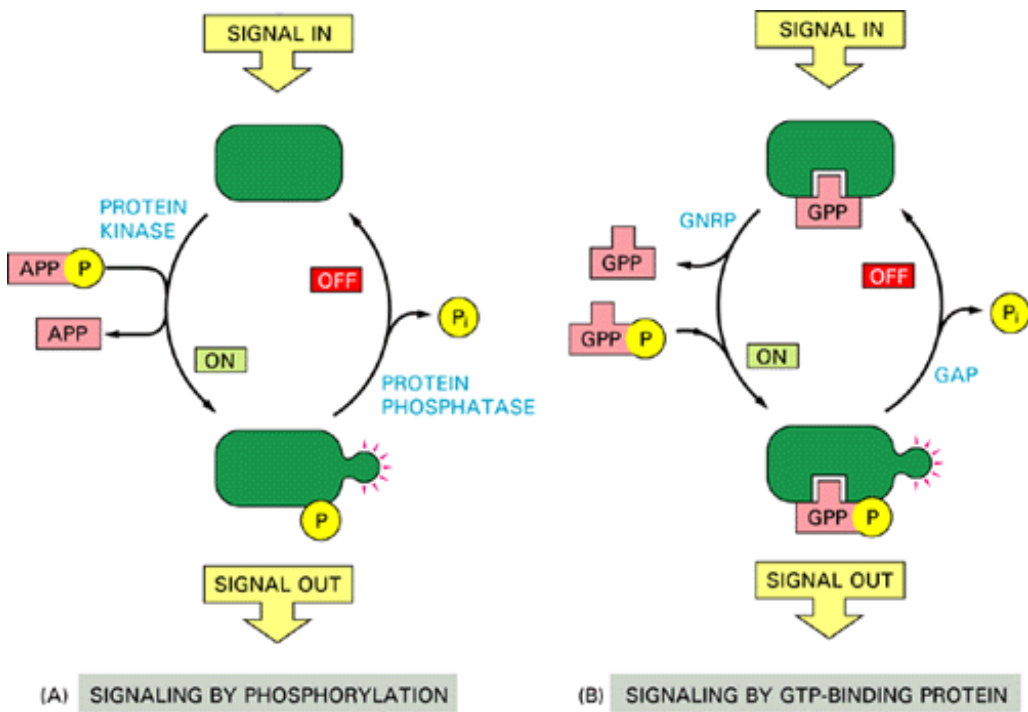
Figure 5-16. The three-dimensional structure of a Cdk. (A) A diagram of the detailed structure, as determined by x-ray diffraction analysis. Bound ATP is shown in *light red,* with its three phosphate groups in *yellow.* (B) The suggested pathway for enzyme activation includes the phosphorylation of a specific threonine located at the tip of a flexible loop (*red*) that otherwise blocks access of the protein substrate to the active site in the kinase domain. This activation also requires the binding of cyclin, as illustrated in Figure 5-17. (A, adapted from H.L. DeBondt et al., *Nature* 363:595-602, 1993. © 1993 Macmillan Magazines Ltd.)
Figure 5-17. A detailed model for Cdk activation. This model, based on the three-dimensional structure of Cdk, explains why Cdk is turned on only if the three separate conditions specified in Figure 5-15 are satisfied. In step A cyclin binds, leading to the addition of the inhibitory phosphate in step B. The activating phos-phorylation occurs in step C, but the enzyme turns on only after the inhibitory phosphate is removed in step D. The sudden degradation of cyclin after step D causes enzyme inactivation, including the loss of the activating phosphate, which resets the system to its initial inactive state.
Figure 5-18. The structure of the Ras protein in its GTP-bound form. This relatively small protein illustrates the structure of a GTP-binding domain, which is present in other GTP-binding proteins (see Figure 5-20, for example). The regions shown in *blue* change their conformation when the GTP molecule is hydrolyzed to GDP and inorganic phosphate by the protein; the GDP remains bound to the protein, while the inorganic phosphate is released. The special role of the "switch helix" in proteins related to Ras is explained below (see Figure 5-20).


Figure 5-19. A comparison of the two major intracellular signaling mechanisms in eucaryotic cells. In both cases a signaling protein is activated by the addition of a phosphate group and inactivated by removal of this phosphate. To emphasize the similarities in the two pathways, ATP and GTP are drawn as APPP and GPPP, and ADP and GDP are drawn as APP and GPP, respectively. As shown in Figure 5-17, addition of a phosphate to a protein can also be inhibitory.
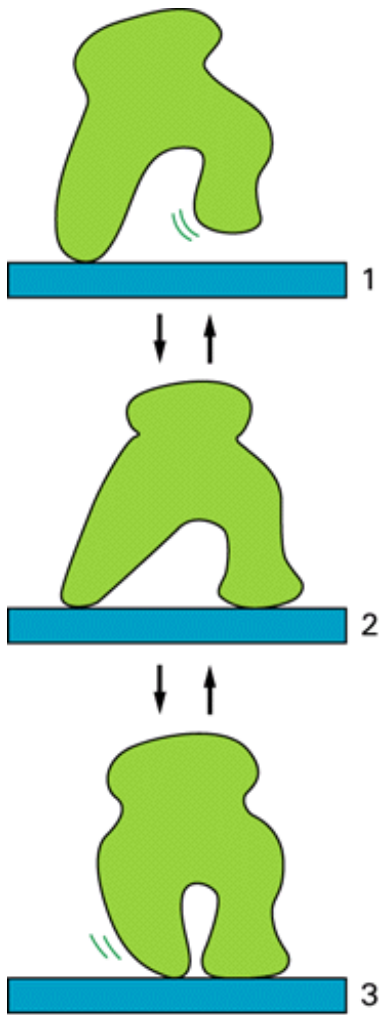
Figure 5-20. The large conformational change in EF-Tu caused by GTP hydrolysis. (A) The three-dimensional structure of EF-Tu with GTP bound. The domain at the top is homologous to the Ras protein, and its *red* alpha helix is the "switch helix," which moves after GTP hydrolysis, as shown in Figure 5-18. (B) The change in the conformation of the switch helix in domain 1 causes domains 2 and 3 to rotate as a single unit by about 90° toward the viewer, which releases the tRNA. (A, adapted from Berchtold et al., *Nature* 365:126-132, 1993. © 1993 Macmillan Magazines, Ltd.; B, courtesy of Mathias Sprinzl and Rolf Hilgenfeld.)


Figure 5-21. An allosteric "walking" protein. Although its three different conformations allow it to wander randomly back and forth while bound to the thread, the protein cannot move uniformly in a single direction.
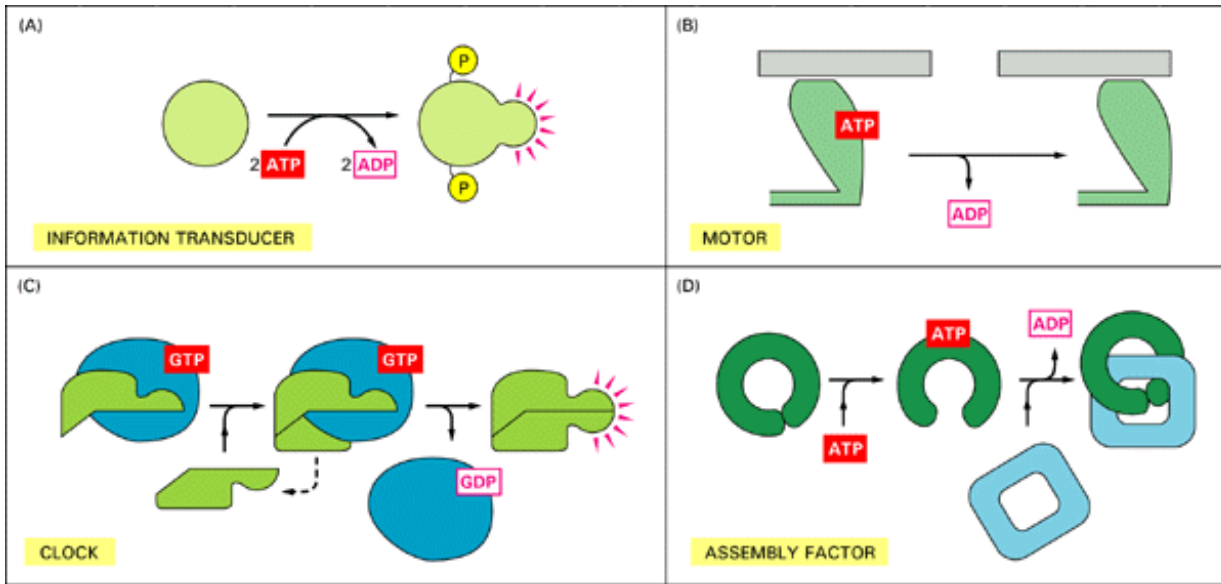
Figure 5-22. An allosteric motor protein. An orderly transition among three conformations is driven by the hydrolysis of a bound ATP molecule. Because one of these transitions is coupled to the hydrolysis of ATP, the cycle is essentially irreversible. By repeated cycles the protein moves continuously to the right along the thread.
Figure 5-23. The structure of the myosin head. In this stereo diagram of the myosin head domain, ATP hydrolysis occurs at the *active site*. ELC denotes the essential light chain and the RLC the regulatory light chain, both of which contribute, along with the myosin heavy chain, to the head domain. (From I. Rayment et al., *Science* 261:50-58, 1993. © 1993 the AAAS.)
Figure 5-24. A conceptual view of a major conformational change in myosin that is postulated to be caused by ATP binding and hydrolysis. This model is based on the structure shown in Figure 5-23. At the next step in the hydrolysis process, the inorganic phosphate molecule produced (*top*) will be released into solution. (After I. Rayment et al., *Science* 261:58-65, 1993. © 1993 the AAAS.)


Figure 5-25. Some devices made from proteins. In these examples the energy of nucleoside triphosphate hydrolysis is used to drive conformational changes in allosteric proteins. (A) A transducer of information, such as a protein kinase. (B) A motor, such as myosin. (C) A clock, such as EF-Tu, that delays assembly of an active complex to insure that incorrect complexes dissociate (*dotted line*). (D) An assembly factor that builds larger structures.
Figure 5-26. A "protein machine". Protein assemblies often contain one or more subunits that can move in an orderly way, driven by an energetically favorable change that occurs in a bound substrate molecule (see Figure 5-22). Protein movements of this type are especially useful to the cell if they occur in a large protein assembly in which, as illustrated here, the activities of several subunits can be coordinated.

The Birth, Assembly, and Death of Proteins

Introduction

Having described some of the remarkable devices that cells make out of proteins, we now consider how these devices are produced and how they are destroyed. The mechanism of protein synthesis is discussed elsewhere. We begin by considering how a protein folds and assembles once it leaves the ribosome as a finished polypeptide chain.

Proteins Are Thought to Fold Through a Molten Globule Intermediate[17]

Because many purified proteins will refold properly on their own after being unfolded *in vitro,* for many years it was thought that a protein will try out every conceivable conformation as it folds until it attains the one conformation with the lowest free energy, which was assumed to be its correctly folded state. We now know that this view is incorrect: despite the high speed of molecular motions in a protein (see p. 97), there are vastly more possible conformations for any large protein than can be explored in the few seconds that are typically required for folding. Moreover, the existence of mutant proteins that have specific defects in folding indicates that a protein's amino acid sequence has been selected during evolution, not only for the properties of its final structure, but also for the ability to fold rapidly into its native conformation.

The ability of pure, denatured proteins to reform their native structures on their own has made it possible to dissect the process of protein folding experimentally. Proteins appear to fold rapidly into a structure in which most (but not all) of the final secondary structure (a helices and b sheets) has formed and in which these elements of structure are aligned in roughly the right way (Figure 5-27). This unusually open and flexible conformation, which is called a *molten globule* (Figure 5-28), is the starting point for a relatively slow process in which many side-chain adjustments occur in order to form the correct tertiary structure. In the latter process a variety of pathways can be taken toward the final conformation. Some of these may be nonproductive dead ends without the help of a *molecular chaperone*, special proteins in cells whose function is to help other proteins fold and assemble into stable, active structures (see Figure 5-27).

Molecular Chaperones Facilitate Protein Folding[18]

Molecular chaperones were first identified in bacteria when *E. coli* mutants that failed to allow bacteriophage lambda to replicate in them were studied. These mutants produce slightly altered versions of two components of the chaperone machinery, related to heat-shock proteins 60 and 70 (hsp60 and hsp70), and as a result are defective in specific steps in the assembly of the viral proteins.

Eucaryotic cells have families of hsp60 and hsp70 proteins, and different family members function in different organelles. Thus, as discussed in Chapter 12, mitochondria contain their own hsp60 and hsp70 molecules that are distinct from those that function in the cytosol, and a special hsp70 (called *BIP*) helps to fold proteins in the endoplasmic reticulum.

Both hsp60-like and hsp70 proteins work with a small set of associated proteins when they help other proteins to fold. They share an affinity for the exposed hydrophobic patches on incompletely folded proteins, and they hydrolyze ATP, possibly binding and releasing their protein with each cycle of ATP hydrolysis. Originally, molecular chaperones were thought to act only by preventing the promiscuous aggregation of still unfolded proteins (hence their name). It is now thought, however, that they also interact more intimately with their clients, producing effects that can be likened to a "protein massage." By binding to exposed hydrophobic regions, the chaperone massages those regions of a protein that are likely to have misfolded from the molten globule state, changing their structure in a way that gives the protein another chance to fold (see Figure 5-27).

In some other respects the two types of hsp proteins function differently. The hsp70 machinery is thought to act early in the life of a protein, binding to a string of about seven hydrophobic amino acids before the protein leaves the ribosome (Figure 5-29). In contrast, hsp60-like proteins form a large barrel-shaped structure (Figure 5-30) that acts later in a protein's life; this chaperone is thought to form an "isolation chamber" into which misfolded proteins are fed, providing them with a favorable environment in which to attempt to refold (see Figure 5-29).

These molecular chaperones are called *heat-shock proteins* because they are synthesized in dramatically increased amounts following a brief exposure of cells to an elevated temperature (for example, 42°C). This seems to reflect the operation of a

feedback system that responds to any increase in misfolded proteins (such as those produced by elevated temperatures) by boosting the synthesis of the chaperones that help the protein refold.

Many Proteins Contain a Series of Independently Folded Modules[19]

The folding of a newly synthesized protein often begins with the formation of a number of distinct structurally stable domains that correspond to functional units, which seem to have ancient evolutionary origins. Elsewhere we discuss the pathways by which proteins are thought to have evolved, emphasizing how new proteins have been created by the shuffling of exons that code for conserved domains with useful properties (see pp. 386-394). Evolution has preserved some of these domains as folding units that retain their structure even when cut out of the protein - either by selected proteolysis or, more efficiently, by genetic engineering techniques. Protein domains of this type that are very frequently involved in evolutionary exon shuffling are called modules; their importance has become clear now that DNA sequences are available for thousands of genes.

Protein modules are typically 40 to 100 amino acids in length. Their small size and ability to fold independently has made it possible to determine many of their three-dimensional structures in solution by high-resolution NMR techniques, which is a convenient alternative to x-ray crystallography. Some typical modules are illustrated in Figure 5-31. Each of these modules has a stable core structure formed from strands of b sheet, from which less-ordered loops of polypeptide chain protrude (shown in *green*). The loops are ideally situated to form binding sites for other molecules, as well demonstrated for the immunoglobulin fold, which was first recognized in antibody molecules (see Figure 23-35). The evolutionary success of b-sheet-based modules is likely to have been due to their forming a convenient framework for the generation of new binding sites for ligands through changes to these protruding loops.

Modules Confer Versatility and Often Mediate Protein-Protein Interactions[19, 20]

A second feature of protein modules that explains their utility is the ease with which they can be integrated into other proteins. Five of the six modules illustrated in Figure 5-31 have their N- and C-terminal ends (marked with *red balls*) at opposite ends of the module. This "in-line" arrangement means that when the DNA encoding such a module undergoes tandem duplication, which is not unusual in the evolution of genomes (discussed in Chapter 8), the duplicated modules can be readily accommodated in the protein. In this way such modules can become linked in series to form extended structures, either with themselves (Figure 5-32) or with other in-line modules. Stiff extended structures composed of a series of modules are commonly found both in extracellular matrix molecules and in the extracellular portions of cell surface receptor proteins.

Other modules, like the kringle module in Figure 5-31, are of a "plug-in" type. After genomic rearrangements, they can be easily accommodated as an insertion into a loop region of a second protein. Some of these modules act as specific binding sites for other proteins or structures in the cell. An important example is the SH2 domain, which can bind tightly to a region of polypeptide chain that contains a phosphorylated tyrosine side chain. Because each SH2 domain also recognizes other features of the polypeptide, it binds only to a subset of proteins that contains phosphorylated tyrosines. The presence of an SH2 domain in a protein allows it to form complexes with proteins that become phosphorylated on tyrosines in response to cell-signaling events (Figure 5-33). Such protein complexes that form and break up as a result of changes in protein phosphorylation play a central part in transducing extracellular signals into intracellular ones, as described in Chapter 15.

Proteins Can Bind to Each Other Through Several Types of Interfaces

Proteins can bind to other proteins in at least three ways. In many cases a portion of the surface of one protein contacts an extended loop of polypeptide chain (a "string") on a second protein (Figure 5-34A). Such a surface-string interaction, for example, allows the SH2 domain to recognize a phosphorylated loop of another protein, and it also enables a protein kinase to recognize the proteins that it will phosphorylate (see Figure 5-16B).

A second type of protein-protein interface is formed when two alpha helices, one from each protein, pair together to form a coiled-coil (Figure 5-34B). This type of protein interface is found in several families of gene regulatory proteins, as discussed in Chapter 9.

The most common way for proteins to interact, however, is by the precise matching of one rigid surface with that of another (Figure 5-34C). Such interactions can be very tight, since a large number of weak bonds can form between two surfaces that match well. For the same reason such surface-surface interactions can be extremely specific, allowing one protein to select a specific partner from the many thousands of different proteins found in a higher eucaryotic cell.

Linkage and Selective Proteolysis Ensure All-or-None Assembly

Many proteins are present in large complexes with other proteins. This requires that the protein bind to several other proteins at the same time. It is crucial for the cell that each protein complex form efficiently and that the formation of partial complexes, which can interfere with the function of complete complexes, be kept to a minimum. There must be mechanisms, therefore, for ensuring that assembly is an all-or-none process.

One important mechanism relies on the phenomenon of *linkage,* which we described earlier. Because of linkage, if a ligand changes the shape of an allo-steric protein so that the protein binds a second ligand more tightly, the second ligand must similarly increase the affinity of the protein for the first ligand (see Figure 5-5). The same principle applies to protein-protein interactions. When two proteins bind to each other, they often increase the affinity of one of the partners for a third protein. Because of linkage, the complex of all three proteins will be much more stable than a complex containing only two. A mechanism of this type can produce all-or-none assembly (Figure 5-35).

Even if an all-or-none assembly mechanism drives the formation of complete protein complexes, unless the cell contains exactly the right proportions of each protein in the complex, unassembled proteins will be left over. In fact, cells do not always produce their components in precise amounts and are instead able to degrade selectively any protein component that is left unassembled (Figure 5-36). Cells therefore require a sophisticated system to identify abnormally assembled proteins and destroy them. Indeed, the eucaryotic cell contains an elaborate set of proteins that enables such incomplete assemblies to be selectively directed to its protein-degradation machinery, as we now discuss.

Ubiquitin-dependent Proteolytic Pathways Are Largely Responsible for Selective Protein Turnover in Eucaryotes[21]

One function of intracellular proteolytic mechanisms is to recognize and eliminate unassembled proteins, as just described. Another is to dispose of damaged or misfolded proteins (see Figure 5-27). Yet another is to confer short half-lives on certain normal proteins whose concentrations must change promptly withalterations in the state of a cell; many of these short-lived proteins are degraded rapidly at all times, while others, most notably the cyclins, are stable until they are suddenly degraded at one particular point in the cell cycle. Although here we mainly discuss how proteins are degraded in the cytosol, important degradation pathways also operate in the endoplasmic reticulum (ER) and, as discussed in Chapter 13, in lysosomes.

Most of the proteins that are degraded in the cytosol are delivered to large protein complexes called proteasomes, which are present in many copies and are dispersed throughout the cell. Each proteasome consists of a central cylinder formed from multiple distinct proteases, whose active sites are thought to face an inner chamber. Each end of the cylinder is "stoppered" by a large protein complex formed from at least 10 types of polypeptides, some of which hydrolyze ATP (Figure 5-37). These protein stoppers are thought to select the proteins for destruction by binding to them and feeding them into the inner chamber of the cylinder, where multiple proteases degrade the proteins to short peptides that are then released.

Proteasomes act on proteins that have been specifically marked for destruction by the covalent attachment of a small protein called ubiquitin (Figure 5-38). Ubiquitin exists in cells either free or covalently linked to proteins. Most ubiquinated proteins have been tagged for degradation. (Some long-lived proteins such as histones are also ubiquinated, but in these cases the function of ubiquitin is not understood.) Different *ubiquitin-dependent* proteolytic pathways employ structurally similar but distinct ubiquitin-conjugating enzymes that are associated with recognition subunits that direct them to proteins carrying a particular degradation signal. The conjugating enzyme adds ubiquitin to a lysine residue of a target protein and thereafter adds a series of additional ubiquitin moieties, forming a multiubiquitin chain (Figure 5-39) that is thought to be recognized by a specific receptor protein in the proteasome.

Denatured or misfolded proteins, as well as proteins containing oxidized or otherwise abnormal amino acids, are recognized and degraded by ubiquitin-dependent proteolytic systems. The ubiquitin-conjugating enzymes presumably recognize signals that are exposed on these proteins as a result of their misfolding or chemical damage; such signals are likely to include amino acid sequences or conformational motifs that are buried and therefore inaccessible in the normal counterparts of these proteins.

A proteolytic pathway that recognizes and destroys abnormal proteins must be able to distinguish between *completed* proteins that have "wrong" conformations and the many growing polypeptides on ribosomes (as well as polypeptides just released from ribosomes) that have not yet achieved their normal folded conformation. That this is not a trivial problem can be demonstrated

experimentally: if puromycin - an inhibitor of protein synthesis - is added to cells, the prematurely terminated proteins that are formed are rapidly degraded by a ubiquitin-dependent pathway. One possibility is that the normally forming proteins are temporarily protected by the translation machinery or by chaperone molecules. Another is that nascent and newly completed proteins are actually vulnerable to proteolysis but manage to fold up into their native conformations fast enough to escape being targeted for destruction by proteolysis.

The Lifetime of a Protein Can Be Determined by Enzymes That Alter Its N-Terminus[22]

One feature that has an important influence on the stability of a protein is the nature of the first (N-terminal) amino acid in the polypeptide chain. There is a strong relation, called the *N-end rule,* between the *in vivo* half-life of a protein and the identity of its N-terminal amino acid. Distinct versions of the N-end rule operate in all organisms examined, from bacteria to mammals. The amino acids Met, Ser, Thr, Ala, Val, Cys, Gly, or Pro, for example, protect proteins in the yeast *S. cerevisiae* when present at the N-terminus; these amino acids are not recognized by targeting components of the N-end rule pathway, while the remaining 12 amino acids attract a proteolytic attack. Most of the proteins that are rapidly degraded by the N-end rule pathway (which operates in both the cytosol and the nucleus) remain to be identified. Since destabilizing amino acids, however, are rare at the N-termini of cytosolic proteins but are frequently present at the N-terminus of proteins that have been transported to other compartments, one hypothetical function of the N-end rule pathway is to degrade proteins that normally function in the ER, the Golgi apparatus, or another membrane-bounded compartment but for some reason have leaked back into the cytosol.

It is not known how destabilizing amino acids become exposed at the N-terminus of a newly formed protein. As discussed in Chapter 6, all proteins are initially synthesized with methionine (or formyl-methionine in bacteria) as their N-terminal amino acid. This methionine, which is a stabilizing amino acid in the N-end rule, is often removed by a specific aminopeptidase. The presently known methionine aminopeptidases, however, will remove the N-terminal methionine if and only if the second amino acid is *also* stabilizing in the N-end rule. The proteases that produce physiological substrates of the N-end rule pathway, and the sequences they recognize as signals for cleavage, remain to be discovered.

Certain destabilizing N-terminal amino acids, such as aspartate and glutamate, are not recognized directly by the targeting component of the N-end rule pathway. Instead, they are modified by the enzyme arginyl-tRNA-protein transferase, which links arginine, one of the directly recognized destabilizing amino acids, to the N-terminus of proteins bearing N-terminal aspartate or glutamate. Arginine is thus one of the *primary* destabilizing amino acids in the N-end rule, while aspartate and glutamate are *secondary* destabilizing amino acids. In eucaryotes there are also *tertiary* destabilizing N-terminal amino acids - asparagine and glutamine - which are destabilizing through their conversion, by a specific amidase, into the secondary destabilizing amino acids aspartate and glutamate.

The N-terminal amino acid of a protein is often found to be resistant to hydrolysis by the reagents used in protein sequenators. Such proteins have a chemically modified ("blocked") N-terminus, the most frequent modification being acetylation. This modification was believed to play a role in protecting long-lived proteins from degradation. However, recent experiments with yeast mutants that lack the major species of N-terminal acetylase, so that the bulk of the normally acetylated proteins are unacetylated, show that most of these unacetylated proteins remain long-lived. The function of N-terminal acetylation in these proteins remains to be deciphered.

Summary

From the moment of its birth on a ribosome to its death by targeted proteolysis, a protein is accompanied by molecular chaperones and other surveying devices whose purpose is to massage it into shape, repair it, or eliminate it. Misfolded proteins are first induced to refold correctly by hsp70 or hsp60 chaperone molecules; if this fails, they are coupled to ubiquitin and thereby targeted for digestion in proteasomes.

Proteins are often composed of discrete modular domains that have been juxtaposed during evolution by duplication and shuffling of the DNA sequences that encode the modules. The modules often contain specific binding sites for other molecules, including other proteins, and they often enable proteins to assemble into large complexes. The principle of linkage explains how cells manage to use allosteric transitions to assemble such protein complexes in an all-or-none fashion.
Figure 5-27. A current view of protein folding. A newly synthesized protein rapidly attains a "molten globule" state (see Figure 5-28). Subsequent folding occurs more slowly and by multiple pathways, some of which reach dead ends without the help of a molecular chaperone. Some molecules may still fail to fold correctly; these are recognized and degraded by proteolytic enzymes (see Figure 5-39).
Figure 5-28. The structure of a molten globule. (A) A molten globule form of cytochrome b562 is more open and less highly ordered than the native protein, shown in (B). Note that the molten globule contains most of the secondary structure of the native form, although the ends of the alpha helices are frayed and one of these helices is only partly formed. (Courtesy of Joshua Wand.)
Figure 5-29. Two families of molecular chaperones. The hsp70 proteins act early, recognizing small patches on a protein's surface. The hsp60-like proteins appear to act later and form a container into which proteins that have still failed to fold are transferred. In both cases repeated cycles of ATP hydrolysis by the hsp proteins contribute to a cycle of binding and release of the client protein that helps this protein to fold.

Figure 5-30. The structure of an hsp60-like chaperone, as determined by electron microscopy. A large number of negatively stained particles is shown in (A) and a 3-D model of a single particle, derived by computer-based image processing methods, is shown in (B). A similar large barrel-shaped structure is found in both eucaryotes and procaryotes. This type of protein is called hsp60 in mitochondria, groEL in bacteria, and TCP-1 in the cytosol of vertebrate cells. (A, from B.M. Phipps et al., *EMBO J.* 10:1711-1722, 1991; B, from B.M. Phipps et al., *Nature* 361:475-477, 1993. © 1993 Macmillan Magazines Ltd.)
Figure 5-31. The three-dimensional structures of some protein modules. In these ribbon diagrams, beta-sheet strands are shown as *arrows,* and the N- and C-termini are marked with *red balls.* (Adapted from M. Baron, D.G. Norman, and I.D. Campbell, *Trends Biochem. Sci.* 16:13-17, 1991, and D.J. Leahy et al., *Science* 258:987-991, 1992. © by AAAS.)

Figure 5-32. An extended structure formed from a series of in-line protein modules. Here, five fibronectin type 3 modules are shown forming a repeating array. Similar structures are found in several extracellular matrix molecules. Side-chain interactions between the ends of modules are thought to impart rigidity to such structures.
Figure 5-33. SH2 domains mediate protein assembly reactions that depend on protein phosphorylations. The structure of an SH2 domain, which has the form of a plug-in module, is illustrated in Figure 15-49.

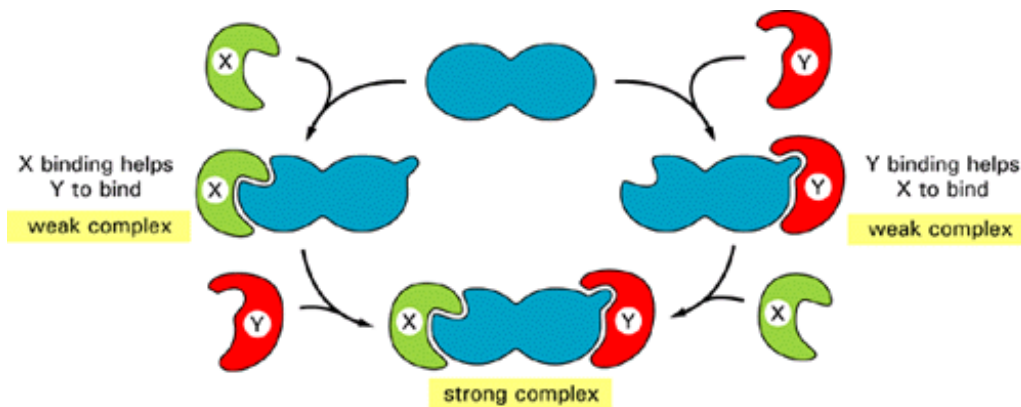
(A)   SURFACE-STRING   (B)   HELIX-HELIX   (C)   SURFACE-SURFACE
Figure 5-34. Three ways that two proteins can bind to each other. Only the interacting parts of the two proteins are shown. (A) A rigid surface on one protein can bind to an extended loop of polypeptide chain (a "string") on a second protein. (B) Two alpha helices can bind together to form a coiled-coil. (C) Two complementary rigid surfaces often link two proteins together.


Figure 5-35. Linkage facilitates an efficient all-or-none assembly of protein complexes. As indicated, proteins X and Y each induce an allosteric shape change in a third protein (shown in *blue*) that helps the other protein to bind. As a result, the complex of all three proteins may be the only one that is strong enough to exist in the cell, resulting effectively in all-or-none assembly.
Figure 5-36. Proteolysis of the extra components of a protein complex prevents them from accumulating in a cell. The degradation shown here requires that an unassembled protein be recognized by enzymes that covalently add ubiquitin to it, as discussed in the text.
Figure 5-37. A proteasome. A large number of negatively stained particles is shown in (A). A 3-D model of a single complete proteasome complex, derived by computer-based image processing of such images, is shown in (B). Many copies of this structure are present throughout the cell, where they serve as trash cans for the cell's unwanted proteins. (Electron micrographs courtesy of Wolfgang Baumeister, from J.M. Peters et al. *J. Mol Biol.* 234: 932–937, 1993.)

Permission to reproduce this figure in this web version of *Molecular Biology of the Cell* is either pending or has not been granted.

Figure 5-38. The three-dimensional structure of ubiquitin. This protein contains 76 amino acid residues. The addition of a chain of ubiquitin molecules to a protein results in the degradation of this protein by the proteasome (see Figure 5-39). (Based on S. Vijay-Kumar, C.E. Bugg, K.D. Wilkinson, and W.J. Cook, *Proc. Natl. Acad. Sci. USA* 82:3582-3585, 1985.)
Figure 5-39. Ubiquitin-dependent protein degradation. In step 1 a target protein (containing a degradation signal) is recognized by the ubiquitinating enzyme complex. Then, in step 2 a repeated series of biochemical reactions joins ubiquitin molecules together to produce a multiubiquitin chain attached to the epsilon-amino group of a lysine side chain in the target protein. Finally, in step 3 the proteasome cuts the target protein into a series of small fragments.

6. Basic Genetic Mechanisms

Introduction

The ability of cells to maintain a high degree of order in a chaotic universe depends on the genetic information that is expressed, maintained, replicated, and occasionally improved by the basic genetic processes *RNA and protein synthesis, DNA repair, DNA replication,* and *genetic recombination.* In these processes, which produce and maintain the proteins and nucleic acids of a cell (Figure 6-1), the information in a linear sequence of nucleotides is used to specify either another linear chain of nucleotides (a DNA or an RNA molecule) or a linear chain of amino acids (a protein molecule). The framework underlying genetic events is therefore one-dimensional and conceptually simple. In contrast, most other processes in cells result solely from information expressed in the complex three-dimensional surfaces of protein molecules. Perhaps that is why we understand more about genetic mechanisms than about most other biological processes.

In this chapter we examine the molecular machinery that repairs, replicates, and alters on occasion the DNA of the cell. We shall see that the machinery depends on enzymes that cut, copy, and recombine nucleotide sequences. We shall also see that these and other enzymes can be parasitized by viruses, plasmids, and transposable genetic elements, which not only direct their own replication, but also can alter the cell genome by genetic recombination events.

First, however, we reconsider a central topic mentioned briefly in Chapter 3 - the mechanisms of RNA and protein synthesis.
Figure 6-1. The basic genetic processes. The processes shown here are thought to occur in all present-day cells. Very early in the evolution of life, however, much simpler cells probably existed that lacked both DNA and proteins (see Figure 1-11). Note that a sequence of three nucleotides (a codon) in an RNA molecule codes for a specific amino acid in a protein.

RNA and Protein Synthesis

Introduction

Proteins constitute more than half the total dry mass of a cell, and their synthesis is central to cell maintenance, growth, and development. Protein synthesis occurs on *ribosomes*. It depends on the collaboration of several classes of RNA molecules and begins with a series of preparatory steps. First, a molecule of *messenger RNA (mRNA)* must be copied from the DNA that encodes the protein. Meanwhile, in the cytoplasm, each of the 20 amino acids from which the protein is to be built must be attached to its specific *transfer RNA (tRNA)* molecule, and the subunits of the ribosome on which the new protein is to be made must be preloaded with auxiliary protein factors. Protein synthesis begins when all of these components come together in the cytoplasm to form a functioning ribosome. As a single molecule of mRNA moves stepwise through a ribosome, the sequence of nucleotides in the mRNA molecule is translated into a corresponding sequence of amino acids to produce a distinctive protein chain, as specified by the DNA sequence of its gene. We begin by considering how the many different RNA molecules in a cell are made.

RNA Polymerase Copies DNA into RNA: The Process of DNA Transcription 1

RNA is synthesized on a DNA template by a process known as DNA transcription. Transcription generates the mRNAs that carry the information for protein synthesis, as well as the transfer, ribosomal, and other RNA molecules that have structural or catalytic functions. All of these RNA molecules are synthesized by RNA polymerase enzymes, which make an RNA copy of a DNA sequence. In eucaryotes three kinds of RNA polymerase molecules synthesize different types of RNA, as described in Chapter 8. These RNA polymerases are thought to have derived during evolution from the single enzyme present in bacteria that mediates all bacterial RNA synthesis.

The bacterial RNA polymerase is a large multisubunit enzyme associated with several additional protein subunits that enter and leave the polymerase-DNA complex at different stages of transcription. Free RNA polymerase molecules collide randomly with the bacterial chromosome, sliding along it but sticking only weakly to most DNA. The polymerase binds very tightly, however, when it contacts a specific DNA sequence, called the promoter, that contains the *start site* for RNA synthesis and signals where RNA synthesis should begin. The reactions that ensue are outlined in Figure 6-2. After binding to the promoter, the RNA polymerase opens up a local region of the double helix to expose the nucleotides on a short stretch of DNA on each strand. One of the two exposed DNA strands acts as a template for complementary base-pairing with incoming ribonucleoside triphosphate monomers, two of which are joined together by the polymerase to begin an RNA chain. The RNA polymerase molecule then

moves stepwise along the DNA, unwinding the DNA helix just ahead to expose a new region of the template strand for complementary base-pairing. In this way the growing RNA chain is extended by one nucleotide at a time in the 5'-to-3' direction (Figure 6-3). The chain elongation process continues until the enzyme encounters a second special sequence in the DNA, the stop (termination) signal, where the polymerase halts and releases both the DNA template and the newly made RNA chain.

By convention, when a DNA sequence associated with a gene is specified, it is the sequence of the nontemplate strand that is given, and it is written in the 5'-to-3' direction. This convention is adopted because the sequence of the nontemplate strand corresponds to the sequence of the RNA that is made.

Nucleotide sequences that act as start sites and stop signals for the bacterial RNA polymerase are illustrated in Figure 6-4. Nucleotide sequences that are found in many examples of a particular type of region in DNA (such as a promoter) are called consensus sequences. In bacteria strong promoters (those associated with genes that produce large amounts of mRNA) have sequences that match the promoter consensus sequences closely (as in Figure 6-4A), whereas weak promoters (those associated with genes that produce relatively small amounts of mRNA) match these sequences less well.

Only Selected Portions of a Chromosome Are Used to Produce RNA Molecules 2

As an RNA polymerase molecule moves along the DNA, an RNA/DNA double helix is formed at the enzyme's active site. This helix is very short because the RNA just made is displaced, allowing the DNA/DNA helix immediately at the rear of the polymerase to rewind (Figure 6-5). As a result, each completed RNA chain is released from the DNA template as a free, single-stranded RNA molecule, typically between 70 and 10,000 nucleotides long.

In principle, any region of the DNA double helix could be copied into two different RNA molecules - one from each of the two DNA strands. In reality, only one DNA strand is used as a template in each region. The RNA made is equivalent in nucleotide sequence to the opposite, nontemplate DNA strand. Which of the two strands is copied varies along the length of a single DNA molecule and is determined by the promoter of each gene. As illustrated in Figure 6-4, a promoter is an oriented DNA sequence that points the RNA polymerase in one direction or the other, and this orientation determines which DNA strand is copied (Figure 6-6). The DNA strand that is copied into RNA can be either different or the same for neighboring genes (Figure 6-7).

Both bacterial and eucaryotic RNA polymerases are large, complicated molecules, with multiple subunits and a total mass of more than 500,000 daltons. Some bacterial viruses, in contrast, encode single-chain RNA polymerases of one-fifth this mass that catalyze RNA synthesis at least as well as the host-cell enzyme. Presumably, the multiple subunit composition of the cellular RNA polymerases is important for various regulatory aspects of cellular RNA synthesis that have not yet been well defined.

This brief outline of DNA transcription omits many details. Other complex steps usually must occur before an mRNA molecule is produced. *Gene regulatory proteins,* for example, help to determine which regions of DNA are transcribed by the RNA polymerase and thereby play a major part in determining which proteins are made by a cell. Moreover, although mRNA molecules are produced directly by DNA transcription in procaryotes, in higher eucaryotic cells most RNA transcripts are altered extensively - by a process called *RNA splicing* - before they leave the cell nucleus and enter the cytoplasm as mRNA molecules. All of these aspects of mRNA production are discussed in Chapters 8 and 9, where we consider the cell nucleus and the control of gene expression, respectively. For now, let us assume that functional mRNA molecules have been produced and proceed to examine how they direct protein synthesis.

Transfer RNA Molecules Act as Adaptors That Translate Nucleotide Sequences into Protein Sequences 3

All cells contain a set of transfer RNAs (tRNAs), each of which is a small RNA molecule (most have a length between 70 and 90 nucleotides). The tRNAs, by binding at one end to a specific codon in the mRNA and at their other end to the amino acid specified by that codon, enable amino acids to line up according to the sequence of nucleotides in the mRNA. Each tRNA is designed to carry only one of the 20 amino acids used for protein synthesis: a tRNA that carries glycine is designated tRNA^{Gly} and so on. Each of the 20 amino acids has at least one type of tRNA assigned to it, and most have several tRNAs. Before an amino acid is incorporated into a protein chain, it is attached by its carboxyl end to the 3' end of an appropriate tRNA molecule. This attachment serves two purposes. First, and most important, it covalently links the amino acid to a tRNA containing the correct anticodon - the sequence of three nucleotides that is complementary to the three-nucleotide *codon* that specifies that amino acid on an mRNA molecule. Codon-anticodon pairings enable each amino acid to be inserted into a growing protein chain according to the dictates of the sequence of nucleotides in the mRNA, thereby allowing the genetic code to be used to translate nucleotide sequences into protein sequences. This is the essential "adaptor" function of the tRNA molecule: with one

end attached to an amino acid and the other paired to a codon, the tRNA converts sequences of nucleotides into sequences of amino acids.

The second function of the amino acid attachment is to activate the amino acid by generating a high-energy linkage at its carboxyl end so that it can react with the amino group of the next amino acid in the protein sequence to form a *peptide bond*. The activation process is necessary for protein synthesis because nonactivated amino acids cannot be added directly to a growing polypeptide chain. (In contrast, the reverse process, in which a peptide bond is hydrolyzed by the addition of water, is energetically favorable and can occur spontaneously.)

The function of a tRNA molecule depends on its precisely folded three-dimensional structure. A few tRNAs have been crystallized and their complete structures determined by x-ray diffraction analyses. Both intramolecular complementary base-pairings and unusual base interactions are required to fold a tRNA molecule (see Figure 3-18). The nucleotide sequences of tRNA molecules from many types of organisms reveal that tRNAs can form the loops and base-paired stems of a "cloverleaf" structure (Figure 6-8), and all are thought to fold further to adopt the L-shaped conformation detected in crystallographic analyses. In the native structure the amino acid is attached to one end of the "L," while the anticodon is located at the other (Figure 6-9).

The nucleotides in a completed nucleic acid chain (like the amino acids in proteins) can be covalently modified to modulate the biological activity of the nucleic acid molecule. Such posttranscriptional modifications are especially common in tRNA molecules, which contain a variety of modified nucleotides (Figure 6-10). Some of the modified nucleotides affect the conformation and base-pairing of the anticodon and thereby facilitate the recognition of the appropriate mRNA codon by the tRNA molecule.

Specific Enzymes Couple Each Amino Acid to Its Appropriate tRNA Molecule 4

Only the tRNA molecule, and not its attached amino acid, determines where the amino acid is added during protein synthesis. This was established by an ingenious experiment in which an amino acid (cysteine) was chemically converted into a different amino acid (alanine) after it was already attached to its specific tRNA. When such "hybrid" tRNA molecules were used for protein synthesis in a cell-free system, the wrong amino acid was inserted at every point in the protein chain where that tRNA was used. Thus the accuracy of protein synthesis is crucially dependent on the accuracy of the mechanism that normally links each activated amino acid specifically to its corresponding tRNA molecules.

How does a tRNA molecule become covalently linked to the one amino acid in 20 that is its appropriate partner? The mechanism depends on enzymes called aminoacyl-tRNA synthetases, which couple each amino acid to its appropriate set of tRNA molecules. There is a different synthetase enzyme for every amino acid (20 synthetases in all): one attaches glycine to all tRNA[Gly] molecules, another attaches alanine to all tRNA[Ala] molecules, and so on. The coupling reaction that creates an aminoacyl-tRNA molecule is catalyzed in two steps, as illustrated in Figure 6-11. The structure of the amino acid-RNA linkage is shown in Figure 6-12.

Although the tRNA molecules serve as the final adaptors in converting nucleotide sequences into amino acid sequences, the aminoacyl-tRNA synthetase enzymes are adaptors of equal importance to the decoding process (Figure 6-13). Thus the genetic code is translated by two sets of adaptors that act sequentially, each matching one molecular surface to another with great specificity; it is their combined action that associates each sequence of three nucleotides in the mRNA molecule - that is, each codon - with its particular amino acid (Figure 6-14).

Amino Acids Are Added to the Carboxyl-Terminal End of a Growing Polypeptide Chain

The fundamental reaction of protein synthesis is the formation of a peptide bond between the carboxyl group at the end of a growing polypeptide chain and a free amino group on an amino acid. Consequently, a protein is synthesized stepwise from its amino-terminal end to its carboxyl-terminal end. Throughout the entire process the growing carboxyl end of the polypeptide chain remains activated by its covalent attachment to a tRNA molecule (a *peptidyl-tRNA* molecule). This high-energy covalent linkage is disrupted in each cycle but is immediately replaced by the identical linkage on the most recently added amino acid (Figure 6-15). In this way each amino acid added carries with it the activation energy for the addition of the *next* amino acid rather than the energy for its own addition - an example of the "head growth" type of polymerization described in Chapter 2 (see Figure 2-36).

The Genetic Code Is Degenerate 5

In the course of protein synthesis, the translation machinery moves in the 5'-to-3' direction along an mRNA molecule and the mRNA sequence is read three nucleotides at a time. As we have seen, each amino acid is specified by the triplet of nucleotides (codon) in the mRNA molecule that pairs with a sequence of three complementary nucleotides at the anticodon tip of a particular tRNA. Because only one of the many types of tRNA molecules in a cell can base-pair with each codon, the codon determines the specific amino acid residue to be added to the growing polypeptide chain end (Figure 6-16).

Since RNA is constructed from four types of nucleotides, there are 64 possible sequences composed of three nucleotides ($4 \times 4 \times 4$). Three of these 64 sequences do not code for amino acids but instead specify the termination of a polypeptide chain; they are known as *stop codons*. That leaves 61 codons to specify only 20 different amino acids. For this reason, most of the amino acids are represented by more than one codon (Figure 6-17) and the genetic code is said to be *degenerate*. Two amino acids, methionine and tryptophan, have only one codon each, and they are the least abundant amino acids in proteins.

The degeneracy of the genetic code implies either that there is more than one tRNA for each amino acid or that a single tRNA molecule can base-pair with more than one codon. In fact, both situations occur. For some amino acids there is more than one tRNA molecule, and some tRNA molecules are constructed so that they require accurate base-pairing only at the first two positions of the codon and can tolerate a mismatch (or wobble) at the third. This *wobble base-pairing* explains why so many of the alternative codons for an amino acid differ only in their third nucleotide (see Figure 6-17). The standard wobble pairings make it possible to fit the 20 amino acids to 61 codons with as few as 31 kinds of tRNA molecules; in animal mitochondria a more extreme wobble allows protein synthesis with only 22 tRNAs (discussed in Chapter 14).

The Events in Protein Synthesis Are Catalyzed on the Ribosome 6

The protein synthesis reactions just described require a complex catalytic machinery to guide them. The growing end of the polypeptide chain, for example, must be kept in register with the mRNA molecule to ensure that each successive codon in the mRNA engages precisely with the anticodon of a tRNA molecule and does not slip by one nucleotide, thereby changing the reading frame (see Figure 3-17). This precise movement and the other events in protein synthesis are catalyzed by ribosomes, which are large complexes of RNA and protein molecules. Eucaryotic and procaryotic ribosomes are very similar in design and function. Both are composed of one large and one small subunit that fit together to form a complex with a mass of several million daltons (Figure 6-18). The small subunit binds the mRNA and tRNAs, while the large subunit catalyzes peptide bond formation.

More than half of the weight of a ribosome is RNA, and there is increasing evidence that the ribosomal RNA (rRNA) molecules play a central part in its catalytic activities. Although the rRNA molecule in the small ribosomal subunit varies in size depending on the organism, its complicated folded structure is highly conserved (Figure 6-19); there are also close homologies between the rRNAs of the large ribosomal subunits in different organisms. Ribosomes contain a large number of proteins (Figure 6-20), but many of these have been relatively poorly conserved in sequence during evolution, and a surprising number seem not to be essential for ribosome function. Therefore, it has been suggested that the ribosomal proteins mainly enhance the function of the rRNAs and that the RNA molecules rather than the protein molecules catalyze many of the reactions on the ribosome.

A Ribosome Moves Stepwise Along the mRNA Chain 7

A ribosome contains three binding sites for RNA molecules: one for mRNA and two for tRNAs. One site, called the peptidyl-tRNA-binding site, or P-site, holds the tRNA molecule that is linked to the growing end of the polypeptide chain. Another site, called the aminoacyl-tRNA-binding site, or A-site, holds the incoming tRNA molecule charged with an amino acid. A tRNA molecule is held tightly at either site only if its anticodon forms base pairs with a complementary codon on the mRNA molecule that is bound to the ribosome. The A- and P-sites are so close together that the two tRNA molecules are forced to form base pairs with adjacent codons in the mRNA molecule (Figure 6-21).

The process of polypeptide chain elongation on a ribosome can be thought of as a cycle with three discrete steps (Figure 6-22):

1. In step 1, an aminoacyl-tRNA molecule becomes bound to a vacant ribosomal A-site (adjacent to an occupied P-site) by forming base pairs with the three mRNA nucleotides (*codon*) exposed at the A-site.

2. In step 2, the carboxyl end of the polypeptide chain is uncoupled from the tRNA molecule in the P-site and joined by a peptide bond to the amino acid linked to the tRNA molecule in the A-site. This central reaction of protein synthesis (see Figure 6-15) is catalyzed by a peptidyl transferase enzyme. Recent experiments with ribosomes that have been experimentally stripped of proteins show that this catalysis is mediated not by a protein but by a specific region of the major rRNA molecule in the large subunit (see Figure 3-23).

3. In step 3, the new peptidyl-tRNA in the A-site is translocated to the P-site as the ribosome moves exactly three nucleotides along the mRNA molecule. This step requires energy and is driven by a series of conformational changes induced in one of the ribosomal components by the hydrolysis of a GTP molecule.

As part of the translocation process of step 3, the free tRNA molecule that was generated in the P-site during step 2 is released from the ribosome to reenter the cytoplasmic tRNA pool. Upon completion of step 3, the unoccupied A-site is free to accept a new tRNA molecule linked to the next amino acid, which starts the cycle again. In a bacterium each cycle requires about 1/20th of a second under optimal conditions, so that the complete synthesis of an average-sized protein of 400 amino acids is accomplished in about 20 seconds. Ribosomes move along an mRNA molecule in the 5'-to-3' direction, which is also the direction of RNA synthesis (see Figure 6-3).

In most cells protein synthesis consumes more energy than any other biosynthetic process. At least four high-energy phosphate bonds are split to make each new peptide bond: two of these are required to charge each tRNA molecule with an amino acid (see Figure 6-11), and two more drive steps in the cycle of reactions occurring on the ribosome during synthesis itselfone for the aminoacyl-tRNA binding in step 1 (see Figure 6-31) and one for the ribosome translocation in step 3.

A Protein Chain Is Released from the Ribosome When Any One of Three Stop Codons Is Reached 8

Of the 64 possible codons in an mRNA molecule, 3 (UAA, UAG, and UGA) are stop codons, which terminate the translation process. Cytoplasmic proteins called *release factors* bind directly to any stop codon that reaches the A-site on the ribosome. This binding alters the activity of the peptidyl transferase, causing it to catalyze the addition of a water molecule instead of an amino acid to the peptidyl-tRNA. This reaction frees the carboxyl end of the growing polypeptide chain from its attachment to a tRNA molecule, and since only this attachment normally holds the growing polypeptide to the ribosome, the completed protein chain is immediately released into the cytoplasm. The ribosome releases the mRNA and dissociates into its two separate subunits (Figure 6-23), which can assemble on another mRNA molecule to begin a new round of protein synthesis by the process to be described next.

The Initiation Process Sets the Reading Frame for Protein Synthesis 9

In principle, an RNA sequence can be translated in any one of three reading frames, each of which will specify a completely different polypeptide chain (see Figure 3-17). Which of the three frames is actually read is determined by the RNA sequence, which determines how the ribosome assembles. During the *initiation* phase of protein synthesis, the two subunits of the ribosome are brought together at the exact spot on the mRNA where the polypeptide chain is to begin.

The initiation process is complicated, involving a number of steps catalyzed by proteins called initiation factors (IFs), many of which are themselves composed of several polypeptide chains. Because the process is so complex, many of the details of initiation are still uncertain. It is clear, however, that each ribosome is assembled onto an mRNA chain in two steps: only after the small ribosomal subunit loaded with initiation factors finds the start codon (AUG, see below) does the large subunit bind.

Before a ribosome can begin a new protein chain, it must bind an aminoacyl tRNA molecule in its P-site, where normally only peptidyl tRNA molecules are bound. (As explained previously, the peptidyl tRNA is translocated to the P-site during step 3 of the elongation reaction.) A special tRNA molecule is required for this purpose. This initiator tRNA provides the amino acid that starts a protein chain, and it always carries methionine (aminoformyl methionine in bacteria). In eucaryotes the initiator tRNA molecule must be loaded onto the small ribosomal subunit before this subunit can bind to an mRNA molecule. An initiation factor called *eucaryotic initiation factor 2 (eIF-2)* is required to position the initiator tRNA on the small subunit. One molecule of eIF-2 becomes tightly bound to each initiator tRNA molecule as soon as this tRNA acquires its methionine, and in some cells the overall rate of protein synthesis is controlled by this factor (see Figure 9-82).

As described in more detail in the next section, the small ribosomal subunit helps its bound initiator tRNA molecule find a special AUG codon (the *start codon*) on an mRNA molecule. Once this has occurred, the several initiation factors that were

previously associated with the small ribosomal subunit are discharged to make way for the binding of a large ribosomal subunit to the small one. Because the initiator tRNA molecule is bound to the P-site of the ribosome, the synthesis of a protein chain can begin directly with the binding of a second aminoacyl-tRNA molecule to the A-site of the ribosome (Figure 6-24). Thus a complete functional ribosome is assembled, with the mRNA molecule threaded through it (Figure 6-25). Further steps in the elongation phase of protein synthesis then proceed as described previously (see Figure 6-22). Because an initiator tRNA molecule has begun each polypeptide chain, all newly made proteins have a methionine (or the aminoformyl derivative of methionine in bacteria) as their amino-terminal residue. The methionine is often removed shortly after its incorporation by a specific aminopeptidase; this trimming process is important because the amino acid left at the amino terminus can determine the protein's lifetime in the cell by its effects on a ubiquitin-dependent protein-degradation pathway (see Figure 5-39).

Evidently the correct initiation site on the mRNA molecule must be selected by the small subunit acting in concert with initiation factors but in the absence of the large subunit. This requirement helps to explain why all ribosomes are formed from two separate subunits. We shall now consider how the correct start codon is selected.

Only One Species of Polypeptide Chain Is Usually Synthesized from Each mRNA Molecule in Eucaryotes 10

A messenger RNA molecule will typically contain many AUG sequences, each of which can code for methionine. In eucaryotes, however, only one of these AUG sequences will normally be recognized by the initiator tRNA and thereby serve as a start codon. How does the ribosome distinguish this start codon?

Eucaryotic RNAs (except those that are synthesized in mitochondria and chloroplasts) are extensively modified in the nucleus immediately after their transcription (discussed in Chapter 8). Two general modifications are the addition of a unique "cap" structure, composed of a 7-methylguanosine residue linked to a triphosphate at the 5' end (Figure 6-26) and the addition of a run of about 200 adenylic residues ("poly A") at the 3' end. What part the poly A plays in the translation process is uncertain (see Figure 9-87), but the 5' cap structure is essential for efficient protein synthesis. Experiments carried out with extracts of eucaryotic cells have shown that the small ribosomal subunit first binds at the 5' end of an mRNA chain, aided by recognition of the 5' cap (see Figure 6-24). This subunit then propels itself along the mRNA chain in a scanning mode, carrying its bound initiator tRNA in a search of an AUG start codon. The requirements for a start codon apparently are not very stringent, since the small subunit usually selects the first AUG it encounters; however, a few nucleotides in addition to the AUG are also important for the selection process. For most eucaryotic RNAs, once a start codon near the 5' end has been selected, none of the many other AUG codons farther down the chain will serve as initiation sites. As a result, only a single species of polypeptide chain is usually synthesized from an mRNA molecule (for exceptions see p. 467).

The mechanism for selecting a start codon in bacteria is different. Bacterial mRNAs have no 5' cap structure. Instead, they contain a specific ribosome-binding site sequence, up to six nucleotides long, which can occur at several places in the same mRNA molecule. These sequences are located four to seven nucleo-tides upstream from an AUG, and they form base pairs with a specific region of the rRNA in a ribosome to signal the initiation of protein synthesis at this nearby start codon. Bacterial ribosomes, unlike eucaryotic ribosomes, bind directly to start codons in the interior of an mRNA molecule to initiate protein synthesis. As a result, bacterial messenger RNAs are commonly *polycistronic*that is, they encode multiple proteins that are separately translated from the same mRNA molecule. Eucaryotic mRNAs, in contrast, are typically *monocistronic,* with only one species of polypeptide chain being translated per messenger molecule (Figure 6-27).

The Binding of Many Ribosomes to an Individual mRNA Molecule Generates Polyribosomes 11

The complete synthesis of a protein takes 20 to 60 seconds on average. But even during this very short period, multiple initiations usually take place on each mRNA molecule being translated. A new ribosome hops onto the 5' end of the mRNA molecule almost as soon as the preceding ribosome has translated enough of the amino acid sequence to be out of the way. Such mRNA molecules are thus found in the cell as polyribosomes, or polysomes, formed by several ribosomes spaced as close as 80 nucleotides apart along a single messenger molecule (Figures 6-28 and 6-29). Polyribosomes are a common feature of cells. They can be isolated and separated from single ribosomes in the cytosol by ultracentrifugation after cell lysis (Figure 6-30). The mRNA purified from these polyribosomes can be used to determine if the protein encoded by a particular DNA sequence is being actively synthesized in the cells used to prepare the polyribosomes. These mRNA molecules can also serve as the starting material for the preparation of specialized cDNA libraries (discussed in Chapter 7).

In eucaryotes the nuclear envelope keeps transcription and protein synthesis separate. But in procaryotes, RNA is accessible to ribosomes as soon as it is made. Thus, ribosomes will begin synthesizing a polypeptide chain at the 5' end of a nascent mRNA

molecule and then follow behind the RNA polymerase as it completes an mRNA chain.

The Overall Rate of Protein Synthesis in Eucaryotes Is Controlled by Initiation Factors 12

As we discuss in Chapter 17, the cells in a multicellular organism proliferate only when they are stimulated to do so by specific growth factors. Although the mechanisms by which growth factors act are incompletely understood, one of their major effects must be to increase the overall rate of protein synthesis, for cells must double their contents before they divide. What determines the rate of protein synthesis? When eucaryotic cells in culture are starved of nutrients, there is a marked reduction in the rate of polypeptide chain *initiation*. This is the result of inactivation of the protein synthesis initiation factor eIF-2 (see Figure 9-82). The initiation factors required for protein synthesis are much more numerous and complex in eucaryotes than in procaryotes, even though they perform the same basic functions. Many of the extra components may be regulatory proteins that respond to growth factors and help coordinate cell growth and proliferation in multicellular organisms. Less complex controls are needed in bacteria, which generally grow as fast as the nutrients in their environment allow.

The Fidelity of Protein Synthesis Is Improved by Two Proofreading Mechanisms 13

The error rate in protein synthesis can be estimated by monitoring the frequency of incorporation of an amino acid into a protein that normally lacks that amino acid. Error rates of about 1 amino acid misincorporated for every 10^4 amino acids polymerized are observed, which means that only about 1 in every 25 protein molecules of average size (400 amino acids) should contain an error. The fidelity of protein synthesis depends on the accuracy of the two adaptor mechanisms previously discussed: the linking of each amino acid to its corresponding tRNA molecule and the base-pairing of the codons in mRNA to the anticodons in tRNA (see Figure 6-14). Not surprisingly, cells have evolved "proofreading" mechanisms to reduce the number of errors in both these crucial steps of protein synthesis.

Two fundamentally different proofreading mechanisms are used, each representative of strategies used in other processes in the cell. Both involve expenditure of free energy, since, as discussed in Chapter 2, a price must be paid for any increase in order in the cell. A relatively simple mechanism is used to improve the accuracy of amino acid attachment to tRNA. Many aminoacyl tRNA synthetases have two active sites, one that carries out the loading reaction shown earlier (Figure 6-11) and one that recognizes an incorrect amino acid attached to its tRNA molecule and removes it by hydrolysis. The correction process is energetically costly because to be effective it must remove an appreciable fraction of correctly attached amino acids as well. The same type of costly two-step proofreading process is used in DNA replication (see Figure 6-42).

A more subtle "kinetic proofreading" mechanism is used to improve the fidelity of codon-anticodon pairing. Thus far we have given a simplified account of this pairing. In fact, once tRNA molecules have acquired an amino acid, they form a complex with an abundant protein called an *elongation factor (EF)*, which binds tightly to both the amino acid end of a tRNA and to a molecule of GTP. It is this complex, and not free tRNA, that pairs with the appropriate codon in an mRNA molecule. The bound elongation factor allows correct codon-anticodon pairing to occur but prevents the amino acid from being incorporated into the growing polypeptide chain. The initial codon recognition, however, triggers the elongation factor to hydrolyze its bound GTP (to GDP and inorganic phosphate), whereupon the factor dissociates from the ribosome without its tRNA, allowing protein synthesis to proceed. The elongation factor thereby introduces a short delay between codon-anticodon base-pairing and polypeptide chain elongation, which provides an opportunity for the bound tRNA molecule to exit from the ribosome. An incorrect tRNA molecule forms a smaller number of codon-anticodon hydrogen bonds than a correct one; it therefore binds more weakly to the ribosome and is more likely to dissociate during this period. Because the delay introduced by the elongation factor causes most incorrectly bound tRNA molecules to leave the ribosome without being used for protein synthesis, this factor increases the ratio of correct to incorrect amino acids incorporated into protein (Figure 6-31).

Many Inhibitors of Procaryotic Protein Synthesis Are Useful as Antibiotics 14

Many of the most effective antibiotics used in modern medicine are compounds made by fungi that act by inhibiting bacterial protein synthesis. A number of these drugs exploit the structural and functional differences between procaryotic and eucaryotic ribosomes so as to interfere with the function of procaryotic ribosomes preferentially. Thus some of these compounds can be taken in high doses without undue toxicity to humans. Because different antibiotics bind to different regions of bacterial ribosomes, they often inhibit different steps in the synthetic process. Some of the more common antibiotics of this kind are listed in Table 6-1 along with several other commonly used inhibitors of protein synthesis, some of which act on eucaryotic cells and therefore cannot be used as antibiotics.

Because they block specific steps in the processes that lead from DNA to protein, many of the compounds listed in Table 6-1 are useful for cell biological studies. Among the most commonly used drugs in such experimental studies are *chloramphenicol, cycloheximide,* and *puromycin,* all of which specifically inhibit protein synthesis. In a eucaryotic cell, for example, chloramphenicol inhibits protein synthesis on ribosomes only in mitochondria (and in chloroplasts in plants), presumably reflecting the procaryotic origins of these organelles (discussed in Chapter 14). Cycloheximide, on the other hand, affects only ribosomes in the cytosol. The difference in the sensitivity of protein synthesis to these two drugs provides a powerful way to determine in which cell compartment a particular protein is translated. Puromycin is especially interesting because it is a structural analogue of a tRNA molecule linked to an amino acid; the ribosome mistakes it for an authentic amino acid and covalently incorporates it at the carboxyl terminus of the growing polypeptide chain, thereby causing the premature termination and release of the polypeptide (see Figure 3-23). As might be expected, puromycin inhibits protein synthesis in both procaryotes and eucaryotes.

How Did Protein Synthesis Evolve? 15

The molecular processes underlying protein synthesis seem inexplicably complex. Although we can describe many of them, they do not make conceptual sense in the way that DNA transcription, DNA repair, and DNA replication do. As we have seen, protein synthesis in present-day organisms centers on the ribosome, which consists of proteins arranged around a core of rRNA molecules. Why should rRNA molecules exist at all, and how did they come to play such a dominant part in the structure and function of the ribosome?

Before the discovery of mRNA in the early 1960s, it was suspected that the large amount of RNA in ribosomes served a "messenger" function, carrying genetic information from DNA to proteins. Now we know, however, that all of the ribosomes in a cell contain an identical set of rRNA molecules that have no such informational role. In bacterial ribosomes, rRNA molecules have been shown to have catalytic functions in protein synthesis. As mentioned earlier, the major rRNA of the large ribosomal subunit appears to be the peptidyl transferase; in addition, the rRNA of the small ribosomal subunit forms a short base-paired helix with the initiation site sequence on bacterial mRNA molecules, positioning the neighboring AUG start codon at the P-site. A variety of specific base-pair interactions likewise form between tRNA molecules and bacterial rRNAs, although these interactions involve individual bases on the rRNA that are far apart in the nucleotide sequence, suggesting complex sets of interactions that depend on the tertiary structure of the rRNA.

Protein synthesis also relies heavily on a large number of proteins that are bound to the rRNAs in a ribosome (see Figure 6-20). The complexity of a process with so many interacting components has made many biologists despair of ever understanding the pathway by which protein synthesis evolved. The discovery that RNA molecules can act as enzymes, however, has provided a new way of viewing the pathway. As discussed in Chapter 1, early biological reactions probably used RNA molecules rather than protein molecules as catalysts. In the earliest cells tRNA molecules on their own may have formed catalytic surfaces that allowed them to bind and activate specific amino acids without requiring aminoacyl-tRNA synthetase enzymes. Likewise, rRNA molecules may have served by themselves as the entire "ribosome," folding up in complex ways to generate an intricate set of surfaces that both guided tRNA pairings with mRNA codons and catalyzed the polymerization of the tRNA-linked amino acids (see Figure 1-7). Over the course of evolution individual proteins have been added to this machinery, each one making the process a little more accurate and efficient, or adding regulatory controls. In this view the large amount of RNA in present-day ribosomes is a remnant of a very early stage in evolution, before proteins dominated biological catalysis.

Summary

Before the synthesis of a particular protein can begin, the corresponding mRNA molecule must be produced by DNA transcription. Then a small ribosomal subunit binds to the mRNA molecule at a start codon (AUG) that is recognized by a unique initiator tRNA molecule. A large ribosomal subunit binds to complete the ribosome and initiate the elongation phase of protein synthesis. During this phase aminoacyl tRNAs, each bearing a specific amino acid, sequentially bind to the appropriate codon in mRNA by forming complementary base pairs with the tRNA anticodon. Each amino acid is added to the carboxyl-terminal end of the growing polypeptide by means of a cycle of three sequential steps: aminoacyl-tRNA binding, followed by peptide bond formation, followed by ribosome translocation. The ribosome progresses from codon to codon in the 5'-to-3' direction along the mRNA molecule until one of three stop codons is reached. A release factor then binds to the stop codon, terminating translation and releasing the completed polypeptide from the ribosome.

Eucaryotic and procaryotic ribosomes are highly homologous, despite substantial differences in the number and size of their rRNA and protein components. The predominant role of rRNA in ribosome structure and function is likely to reflect the ancient

origin of protein synthesis, which is thought to have evolved in an environment dominated by RNA-mediated catalysis.
Figure 6-2. The synthesis of an RNA molecule by RNA polymerase. The enzyme binds to the promoter sequence on the DNA and begins its synthesis at a start site within the promoter. It completes its synthesis at a stop (termination) signal, whereupon both the polymerase and its completed RNA chain are released. During RNA chain elongation, polymerization rates average about 30 nucleotides per second at 37°C. Therefore, an RNA chain of 5000 nucleotides takes about 3 minutes to complete.
Figure 6-3. The chain elongation reaction catalyzed by an RNA polymerase enzyme. In each step an incoming ribonucleoside triphosphate is selected for its ability to base-pair with the exposed DNA template strand; a ribonucleoside monophosphate is then added to the growing, 3'-OH end of the RNA chain (*red arrow*), and pyrophosphate is released (*red atoms*). The new RNA chain therefore grows by one nucleotide at a time in the 5'-to-3' direction, and it is complementary in sequence to the DNA template strand. The reaction is driven both by the favorable free-energy change that accompanies the release of pyrophosphate and by the subsequent hydrolysis of the pyrophosphate to inorganic phosphate (see Figure 2-30).

Figure 6-4. Start and stop signals for RNA synthesis by a bacterial RNA polymerase. Here, the lower strand of DNA is the template strand, whereas the upper strand corresponds in sequence to the RNA that is made (note the substitution of U in RNA for T in DNA). (A) The polymerase begins transcribing at the start site. Two short sequences (*shaded red*), about -35 and -10 nucleotides from the start, determine where the polymerase binds; close relatives of these two hexanucleotide sequences, properly spaced from each other, specify the promoter for most *E. coli* genes. (B) A stop (termination) signal. The *E. coli*RNA polymerase stops when it synthesizes a run of U residues (*shaded blue*) from a complementary run of A residues on the template strand, provided that it has just synthesized a self-complementary RNA nucleotide sequence (*shaded green*), which rapidly forms a hairpin helix that is crucial for stopping transcription. The sequence of nucleotides in the self-complementary region can vary widely.
Figure 6-5. DNA unwinding and rewinding by RNA polymerase. A moving RNA polymerase molecule is continuously unwinding the DNA helix ahead of the polymerization site while rewinding the two DNA strands behind this site to displace the newly formed RNA chain. A short region of DNA/RNA helix is therefore formed only transiently, and the final RNA product is released as a single-stranded copy of one of the two DNA strands.

Figure 6-6. RNA polymerase orientation determines which DNA strand serves as template. The DNA strand serving as template must be traversed from its 3' end to its 5' end, as illustrated in Figure 6-3. Thus the direction of RNA polymerase movement determines which of the two DNA strands will serve as a template for the synthesis of RNA, as shown here. Polymerase direction is, in turn, determined by the orientation of the promoter sequence, where the RNA polymerase initially binds.

Figure 6-7. Directions of transcription along a short portion of a bacterial chromosome. Note that some genes are transcribed from one DNA strand, while others are transcribed from the other DNA strand. Approximately 0.2% of the *E. coli* chromosome is depicted here. (Adapted from D.L. Daniels et al., *Science* 257:771-777, 1992.)
Figure 6-8. The "cloverleaf" structure of tRNA. This is a view of the molecule shown in <u>Figure 6-9</u> after it has been partially unfolded. There are many different tRNA molecules, including at least one for each kind of amino acid. Although they differ in nucleotide sequence, they all have the three stem loops shown plus an amino acid-accepting arm. The particular tRNA molecule shown binds phenylalanine and is therefore denoted tRNA^{Phe}. In all tRNA molecules the amino acid is attached to the A residue of a CCA sequence at the 3' end of the molecule. Complementary base-pairings are shown by *red bars.*
Figure 6-9. The folded structure of a typical tRNA molecule. Two views of the three-dimensional conformation determined by x-ray diffraction are shown. Note that the molecule is L-shaped; one end is designed to accept the amino acid, while the other end contains the three nucleotides of the anticodon. Each loop is colored to match <u>Figure 6-8</u>.

Figure 6-10. A few of the unusual nucleotides found in tRNA molecules. These nucleotides are produced by covalent modification of a normal nucleotide after it has been incorporated into an RNA chain. In most tRNA molecules about 10% of the nucleotides are modified (see Figure 6-8).
Figure 6-11. Amino acid activation. The two-step process in which an amino acid (with its side chain denoted by R) is activated for protein synthesis by an aminoacyl-tRNA synthetase enzyme is shown. As indicated, the energy of ATP hydrolysis is used to attach each amino acid to its tRNA molecule in a high-energy linkage. The amino acid is first activated through the linkage of its carboxyl group directly to an AMP moiety, forming an *adenylated amino acid;* the linkage of the AMP, normally an unfavorable reaction, is driven by the hydrolysis of the ATP molecule that donates the AMP. Without leaving the synthetase enzyme, the AMP-linked carboxyl group on the amino acid is then transferred to a hydroxyl group on the sugar at the 3' end of the tRNA molecule. This transfer joins the amino acid by an activated ester linkage to the tRNA and forms the final aminoacyl-tRNA molecule. The synthetase enzyme is not shown in these diagrams.
Figure 6-12. The structure of the aminoacyl-tRNA linkage. The carboxyl end of the amino acid forms an ester bond to ribose. Because the hydrolysis of this ester bond is associated with a large favorable change in free energy, an amino acid held in this way is said to be *activated.* (A) Schematic drawing of the structure. (B) Actual structure corresponding to boxed region in (A). As in Figure 6-11, the "R-group" indicates the side chain of the amino acid (see Panel 2-5, pp. 56-57).
Figure 6-13. The recognition of a tRNA molecule by its aminoacyl-tRNA synthetase. For this tRNA (tRNA^{Gln}), specific nucleotides in both the anticodon (*bottom*) and the amino acid-accepting arm allow the correct tRNA to be recognized by the synthetase enzyme (*blue*). (Courtesy of Tom Steitz.)
Figure 6-14. The genetic code is translated by means of two sequential "adaptors". The first adaptor is the aminoacyl-tRNA synth-etase enzyme, which couples a par-ticular amino acid to its correspond-ing tRNA; the second adaptor is the tRNA molecule, whose *anticodon* forms base pairs with the appropriate nucleotide sequence (*codon*) on the mRNA. An error in either step will cause the wrong amino acid to be incorporated into a protein chain.
Figure 6-15. The incorporation of an amino acid into a protein. A poly-peptide chain grows by the stepwise addition of amino acids to its carboxyl-terminal end. The formation of each peptide bond is energetically favorable because the growing carboxyl terminus has been activated by the covalent attachment of a tRNA molecule. The peptidyl-tRNA linkage that activates the growing end is regenerated in each cycle. The amino acid side chains have been abbreviated as R_1, R_2, R_3, and R_4; as a reference point, all of the atoms in the second amino acid in the polypeptide chain are shaded *gray*.
Figure 6-16. Decoding an mRNA molecule. Each amino acid added to the growing end of a polypeptide chain is selected by complementary base-pairing between the anticodon on its attached tRNA molecule and the next codon on the mRNA chain.

Figure 6-17. The genetic code. The standard one-letter abbreviation for each amino acid is presented below its three-letter abbreviation. Codons are written with the 5'-terminal nucleotide on the left. Note that most amino acids are represented by more than one codon and that variation is common at the third nucleotide (see also Figure 3-16).

small subunit large subunit ribosome

Figure 6-18. The ribosome. A three-dimensional model of the bacterial ribosome as viewed from two angles. The positions of many ribosomal proteins in this structure have been determined by using an electron microscope to visualize the positions where specific antibodies bind, as well as by measuring the neutron scattering from ribosomes containing one or more deuterated proteins. (After J.A. Lake, *Annu. Rev. Biochem.* 54:507-530, 1985. © 1985 by Annual Reviews Inc.)

Figure 6-19. The structure of the rRNA in the small subunit. This model of *E. coli* 16S rRNA is indicative of the complex

folding that underlies the catalytic activities of the RNAs in the ribosome. The 16S rRNA molecule contains 1540 nucleotides, and it is folded into three domains: 5' (*blue*), central (*red*), and 3' (*green*). (Adapted from S. Stern, B. Weiser, and H.F. Noller, *J. Mol. Biol.* 204:447-481, 1988.)
Figure 6-20. A comparison of the structures of procaryotic and eucaryotic ribosomes. Ribosomal components are commonly designated by their "S values," which indicate their rate of sedimentation in an ultracentrifuge. Despite the differences in the number and size of their rRNA and protein components, both types of ribosomes have nearly the same structure and they function in very similar ways. Although the 18S and 28S rRNAs of the eucaryotic ribosome contain many extra nucleotides not present in their bacterial counterparts, these nucleotides are present as multiple insertions that are thought to protrude as loops and leave the basic structure of each rRNA largely unchanged.
Figure 6-21. The three major RNA-binding sites on a ribosome. An empty ribosome is shown on the left and a loaded ribosome on the right. The representation of a ribosome used here and in the next three figures is highly schematic; for a more accurate view, see Figures 6-18 and 6-25.
Figure 6-22. The elongation phase of protein synthesis on a ribosome. The three-step cycle shown is repeated over and over during the synthesis of a protein chain. An aminoacyl-tRNA molecule binds to the A-site on the ribosome in step 1, a new peptide bond is formed in step 2, and the ribo-some moves a distance of three nucleotides along the mRNA chain in step 3, ejecting an old tRNA molecule and "resetting" the ribosome so that the next aminoacyl-tRNA molecule can bind. As indicated in Figure 6-21, the P-site is drawn on the left side of the ribosome, with the A-site on the right.
Figure 6-31. Kinetic proofreading selects for the correct tRNA molecule on the ribosome. This more detailed view of step 1 of the elongation phase of protein synthesis shows how, in the initial binding event, an aminoacyl-tRNA molecule that is tightly bound to an elongation factor pairs transiently with the codon at the A-site. This pairing triggers GTP hydrolysis by the elongation factor, enabling the factor to dissociate from the aminoacyl-tRNA molecule, which can now participate in chain elongation (see Figure 6-22). A delay between aminoacyl tRNA binding and its availability for protein synthesis is thereby inserted into the protein synthesis mechanism. As a result, only those tRNAs with the correct anticodon are likely to remain paired to the mRNA long enough to be added to the growing polypeptide chain.The elongation factor, which is an abundant protein, is called EF-Tu in procaryotes and EF-1 in eucaryotes. The dramatic change in the three-dimensional structure of EF-Tu that is caused by GTP hydrolysis is illustrated in Figure 5-20.
Figure 6-23. The final phase of protein synthesis. The binding of release factor to a stop codon terminates translation. The completed polypeptide is released, and the ribosome dissociates into its two separate subunits.

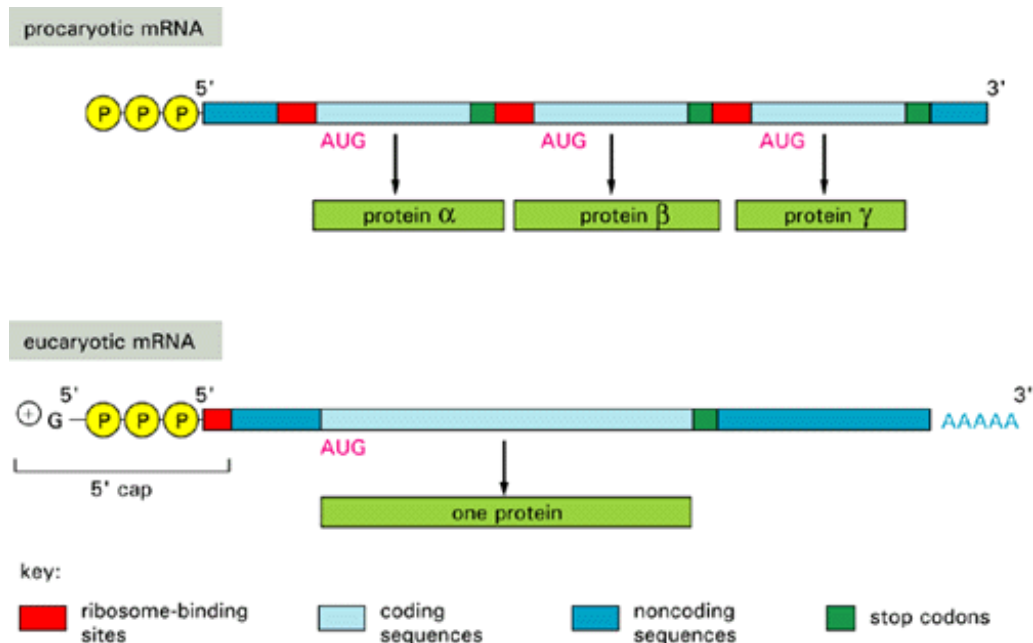
Figure 6-25. A three-dimensional model of a functioning bacterial ribosome. The small (*dark green*) subunit and the large (*light green*) subunit form a complex through which the messenger RNA is threaded. Although the exact paths of the mRNA and the nascent polypeptide chain are unknown, the addition of amino acids occurs in the general region shown, with the tRNAs held in the pocket formed between the large and small subunit. (Modified from J.A. Lake, *Annu. Rev. Biochem.* 54:507-530, 1985. © 1985 by Annual Reviews Inc.)
Figure 6-26. The structure of the cap at the 5 ' end of eucaryotic mRNA molecules. Note the unusual 5'-to-5' linkage to the positively charged 7-methylguanosine and the methylation of the 2' hydroxyl group on the first ribose sugar in the RNA. (The second sugar may or may not be methylated.)


Figure 6-27. A comparison of the structures of procaryotic and eucaryotic messenger RNA molecules. Although both mRNAs are synthesized with a triphosphate group at the 5' end, the eucaryotic RNA molecule immediately acquires a 5' cap, which is part of the structure recognized by the small ribosomal subunit. Protein synthesis therefore begins at a start codon near the 5' end of the mRNA (see Figure 6-24). In procaryotes, by contrast, the 5' end has no special significance, and there can be multiple ribosome-binding sites (called *Shine-Dalgarno sequences*) in the interior of an mRNA chain, each resulting in the

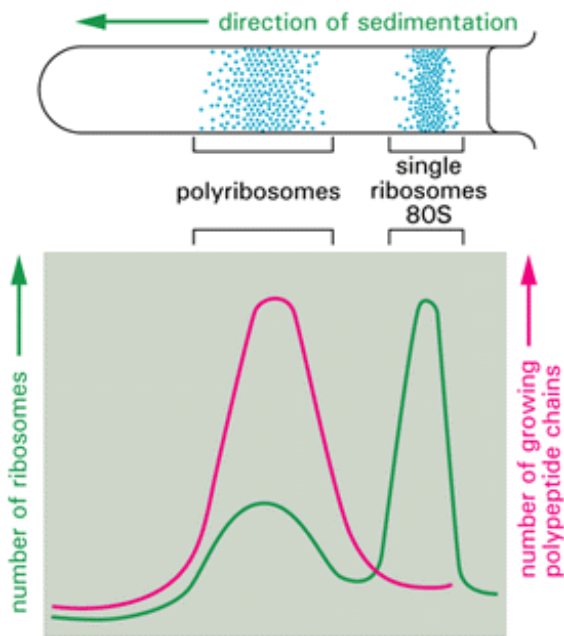
synthesis of a different protein.
Figure 6-28. A polyribosome. Schematic drawing showing how a series of ribosomes can simul-taneously translate the same mRNA molecule.
Figure 6-29. Freeze-etch (A) and transmission (B) electron micrographs of typical polyribosomes in a eucaryotic cell. The cell cytoplasm is generally crowded with such polyribosomes, some free in the cytosol and some membrane-bound. (A, courtesy of John Heuser; B, courtesy of George Palade.)


Figure 6-30. The isolation of polyribosomes. Polyribosomes are separated from single ribosomes (and their subunits) by sedimentation in a centrifuge. This method is based on the fact that large molecular aggregates move faster than small ones in a strong gravitational field. Generally, the sedimentation is done through a gradient of sucrose to stabilize the solution against convective mixing. Note that most of the growing polypeptide chains (*red line*) are associated with the polyribosomes.
Proofreading during DNA replication.

Inhibitor	Specific Effect
*Acting Only on Procaryotes**	
Tetracycline	blocks binding of aminoacyl-tRNA to A-site of ribosome
Streptomycin	prevents the transition from initiation complex to chain-elongating ribosome and also causes miscoding
Chloramphenicol	blocks the peptidyl transferase reaction on ribosomes (step 2 in Figure 6-22)
Erythromycin	blocks the translocation reaction on ribosomes (step 3 in Figure 6-22)
Rifamycin	blocks initiation of RNA chains by binding to RNA polymerase (prevents RNA synthesis)
Acting on Procaryotes and Eucaryotes	
Puromycin	causes the premature release of nascent polypeptide chains by its addition to growing chain end
Actinomycin D	binds to DNA and blocks the movement of RNA polymerase (prevents RNA synthesis)
Acting Only on Eucaryotes	
Cycloheximide	blocks the translocation reaction on ribosomes (step 3 in Figure 6-22)
Anisomycin	blocks the peptidyl transferase reaction on ribosomes (step 2 in Figure 6-22)
a-Amanitin	blocks mRNA synthesis by binding preferentially to RNA polymerase II

*. The ribosomes of eucaryotic mitochondria (and chloroplasts) often resemble those of procaryotes in their sensitivity to inhibitors. Therefore, some of these antibiotics can have a deleterious effect on human mitochondria.

DNA Repair 16

Introduction

The long-term survival of a species may be enhanced by genetic changes, but the survival of the individual demands genetic stability. Maintaining genetic stability requires not only an extremely accurate mechanism for replicating the DNA before a cell divides, but also mechanisms for repairing the many accidental lesions that occur continually in DNA. Most such spontaneous changes in DNA are temporary because they are immediately corrected by processes collectively called *DNA repair*. Only rarely do the cell's DNA maintenance processes fail and allow a permanent change in the DNA. Such a change is called a mutation, and it can destroy an organism if the change occurs in a vital position in the DNA sequence.

Before examining the mechanisms of DNA repair, we briefly discuss the maintenance of DNA sequences from one generation to the next.

DNA Sequences Are Maintained with Very High Fidelity 17

The rate at which stable changes occur in DNA sequences (the *mutation rate*) can be estimated only indirectly. One way is to compare the amino acid sequence of the same protein in several species. The fraction of the amino acids that are different can then be compared with the estimated number of years since each pair of species diverged from a common ancestor, as determined from the fossil record. In this way one can calculate the number of years that elapse, on average, before an inherited change in the amino acid sequence of a protein becomes fixed in the species. Because each such change will commonly reflect the alteration of a single nucleotide in the DNA sequence of the gene encoding that protein, this value can be used to estimate the average number of years required to produce a single, stable mutation in the gene.

Such calculations always will substantially underestimate the actual mutation rate because most mutations will spoil the function of the protein and vanish from the population through natural selection. But there is one family of proteins whose sequence does not seem to matter, and so the genes that encode them can accumulate mutations without being selected against. These proteins are the fibrinopeptides - 20-residue-long fragments that are discarded from the protein *fibrinogen* when it is activated to form *fibrin* during blood clotting. Since the function of fibrinopeptides apparently does not depend on their amino acid sequence, they can tolerate almost any amino acid change. Sequence analysis of the fibrinopeptides indicates that an average-sized protein 400 amino acids long would be randomly altered by an amino acid change roughly once every 200,000 years. More recently, DNA sequencing technology has made it possible to compare corresponding nucleotide sequences in regions of the genome that do not code for protein. Comparisons of such sequences in several mammalian species produce estimates of the mutation rate during evolution that are in excellent agreement with those obtained from the fibrinopeptide studies.

The Observed Mutation Rates in Proliferating Cells Are Consistent with Evolutionary Estimates 18

The mutation rate can be estimated more directly by observing the rate at which spontaneous genetic changes arise in a large population of cells followed over a relatively short period of time. This can be done either by estimating the frequency with which new mutants arise in very large animal populations (in a colony of fruit flies or mice, for example) or by screening for changes in specific proteins in cells growing in culture. Although they are only approximate, the numbers obtained in both cases are consistent with an error frequency of 1 base-pair change in roughly 10^9 base pairs for each cell generation. Consequently, a single gene that encodes an average-sized protein (containing about 10^3 coding base pairs) would suffer a mutation once in about 10^6 cell generations. This number is at least roughly consistent with the evolutionary estimate described above, in which one mutation appears in an average gene in the germ line every 200,000 years.

Most Mutations in Proteins Are Deleterious and Are Eliminated by Natural Selection 19

When the number of amino acid differences in a particular protein is plotted for several pairs of species against the time since the species diverged, the result is a reasonably straight line. That is, the longer the period since divergence, the larger the number of differences. For convenience, the slope of this line can be expressed in terms of the "unit evolutionary time" for that protein, which is the average time required for 1 amino acid change to appear in a sequence of 100 amino acid residues. When various proteins are compared, each shows a different but characteristic rate of evolution (Figure 6-32). Since all DNA base pairs are thought to be subject to roughly the same rate of random mutation, these different rates must reflect differences in the probability that an organism with a random mutation over the given protein will survive and propagate. Changes in amino acid sequence are evidently much more harmful for some proteins than for others. From Table 6-2 we can estimate that about 6 of every 7 random amino acid changes are harmful over the long term in hemoglobin, about 29 of every 30 amino acid changes are harmful in cytochrome c, and virtually all amino acid changes are harmful in histone H4. We assume that individuals who carried such harmful mutations have been eliminated from the population by natural selection.

Low Mutation Rates Are Necessary for Life as We Know It 19

Since most mutations are deleterious, no species can afford to allow them to accumulate at a high rate in its germ cells. We discuss later why the observed mutation frequency, low though it is, nevertheless, is thought to limit the number of essential proteins that any organism can encode in its germ line to about 60,000. By an extension of the same arguments, a mutation frequency tenfold higher would limit an organism to about 6000 essential proteins. In this case evolution would probably have stopped at an organism no more complex than a fruit fly.

While *germ* cells must be protected against high rates of mutation in order to maintain the species, the other cells of a multicellular organism (its *somatic* cells) must be protected from genetic change to safeguard the individual. Nucleotide changes

in somatic cells can give rise to variant cells, some of which, through a process of natural selection, grow rapidly at the expense of the rest of the organism. In the extreme case the uncontrolled cell proliferation known as cancer results, which is responsible for about 30% of the deaths that occur in Europe and North America. These deaths are due largely to the accumulation of changes in the DNA sequences of somatic cells (discussed in Chapter 24). A tenfold increase in the mutation frequency would presumably cause a disastrous increase in the incidence of cancer by accelerating the rate at which somatic cell variants arise. Thus, both for the perpetuation of a species with 60,000 proteins (germ cell stability) and for the prevention of cancer resulting from mutations in somatic cells (somatic cell stability), eucaryotes depend on the remarkably high fidelity with which DNA sequences are maintained.

Low Mutation Rates Mean That Related Organisms Must Be Made from Essentially the Same Proteins [20]

Humans, as a genus distinct from the great apes, have existed for only a few million years. Each human gene has therefore had the chance to accumulate relatively few nucleotide changes since our inception, and most of these have been eliminated by natural selection. A comparison of humans and monkeys, for example, shows that their cytochrome c molecules differ in about 1% and their hemoglobins in about 4% of their amino acid positions. Clearly, a great deal of our genetic heritage must have been formed long before *Homo sapiens* appeared, during the evolution of mammals (which started about 300 million years ago) and even earlier. Because the proteins of mammals as different as whales and humans are very similar, the evolutionary changes that have produced such striking morphological differences must involve relatively few changes in the molecules from which we are made. Instead, it is thought that the morphological differences arise from differences in the temporal and spatial pattern of gene expression during embryonic development, which then determine the size, shape, and other characteristics of the adult. At the end of Chapter 8 we discuss the mechanisms that are thought to underlie such evolutionary changes in gene expression.

If Left Uncorrected, Spontaneous DNA Damage Would Rapidly Change DNA Sequences [21]

The physicist Erwin Schroedinger pointed out in 1945 that, whatever its chemical nature (at that time unknown), a gene must be extremely small and composed of few atoms. Otherwise the very large number of genes thought to be necessary to generate an organism would not fit in the cell nucleus. On the other hand, because it was so small, a gene would be expected to undergo significant changes as a result of spontaneous reactions induced by random thermal collisions with solvent molecules. This poses a serious dilemma, since genetic data imply that genes are composed of a remarkably stable substance in which spontaneous changes (mutations) occur rarely.

This dilemma is real. DNA does undergo major changes as a result of thermal fluctuations. We now know, for example, that about 5000 purine bases (adenine and guanine) are lost per day from the DNA of each human cell because of the thermal disruption of their *N*-glycosyl linkages to deoxyribose (*depurination*). Similarly, spontaneous *deamination* of cytosine to uracil in DNA is estimated to occur at a rate of 100 bases per genome per day (Figure 6-33). DNA bases are also subject to change by reactive metabolites (including reactive forms of oxygen) that can alter their base-pairing abilities and by ultraviolet light from the sun, which promotes a covalent linkage of two adjacent pyrimidine bases in DNA (forming, for example, the *thymine dimers* shown in Figure 6-34B). These are only a few of many changes that can occur in our DNA (Figure 6-34A). Most of them would be expected to lead either to deletion of one or more base pairs in the daughter DNA chain after DNA replication or to a base-pair substitution (each C $\longrightarrow$ U deamination, for example, would eventually change a C-G base pair to a T-A base pair, since U closely resembles T and forms a complementary base pair with A). As we have seen, a high rate of such random changes would have disastrous consequences for an organism.

The Stability of Genes Depends on DNA Repair [22]

Despite the thousands of random changes created every day in the DNA of a human cell by heat energy and metabolic accidents, only a few stable changes (mutations) accumulate in the DNA sequence of an average cell in a year. We now know that fewer than one in a thousand accidental base changes in DNA causes a mutation; the rest are eliminated with remarkable efficiency by DNA repair. There are a variety of repair mechanisms, each catalyzed by a different set of enzymes. Nearly all of these mechanisms depend on the existence of two copies of the genetic information, one in each strand of the DNA double helix: if the sequence in one strand is accidentally changed, information is not lost irretrievably because a complementary copy of the altered strand remains in the sequence of nucleotides in the other strand. The basic pathway for DNA repair is illustrated schematically in Figure 6-35. As indicated, it involves three steps:

1. The altered portion of a damaged DNA strand is recognized and removed by enzymes called *DNA repair nucleases,* which hydrolyze the phospho-diester bonds that join the damaged nucleotides to the rest of the DNA molecule, leaving a small gap in

the DNA helix in this region.

2. Another enzyme, DNA polymerase, binds to the 3'-OH end of the cut DNA strand and fills in the gap by making a complementary copy of the information stored in the "good" (*template*) strand.

3. The break or "nick" in the damaged strand left when the DNA polymerase has filled in the gap is sealed by a third type of enzyme, DNA ligase, which completes the restoration process.

Both DNA polymerase and DNA ligase have important general roles in DNA metabolism; both function in DNA replication as well as in DNA repair, for example. The reactions that these two enzymes catalyze are illustrated in Figures 6-36 and 6-37, respectively.

DNA Damage Can Be Removed by More Than One Pathway 23

The details of the excision step in DNA repair depend on the type of damage. Depurination, for example, which is by far the most frequent lesion that occurs in DNA, leaves a deoxyribose sugar with a missing base (see Figure 6-33). This exposed sugar is rapidly recognized by the enzyme *AP endonuclease,* which cuts the DNA phosphodiester backbone at the 5' side of the altered site. After excision of the sugar phosphate residue by a phosphodiesterase enzyme, an undamaged DNA sequence is restored by DNA polymerase and DNA ligase (see Figure 6-35).

A related repair pathway, called base excision repair, involves a battery of enzymes called *DNA glycosylases.* Each DNA glycosylase recognizes an altered base in DNA and catalyzes its hydrolytic removal. There are at least six types of these enzymes, including those that remove deaminated Cs, deaminated As, different types of alkylated or oxidized bases, bases with opened rings, and bases in which a carbon-carbon double bond has been accidentally converted to a carbon-carbon single bond. As an example of the general mechanism that operates in all cases, the removal of a deaminated C by uracil DNA glycosylase is shown in Figure 6-38A. The DNA glycosylase reaction produces a deoxyribose sugar with a missing base. Because this sugar phosphate is the same substrate recognized by the AP endonuclease, the subsequent steps in the repair process proceed in the same way as for depurinated sites. The importance of removing accidentally deaminated DNA bases has been directly demonstrated. In mutant bacteria that lack the enzyme uracil DNA glycosylase, the normally low spontaneous rate of change of a C-G to a T-A base pair is increased about twentyfold.

Cells have a separate nucleotide excision repair pathway capable of removing almost any type of DNA damage that creates a large change in the DNA double helix. Such "bulky lesions" include those created by the covalent reaction of DNA bases with large hydrocarbons (such as the carcinogen benzopyrene), as well as the various pyrimidine dimers (T-T, T-C, and C-C) caused by sunlight. In these cases a large multienzyme complex scans the DNA for a distortion in the double helix rather than for a specific base change. Once a bulky lesion is found, the phosphodiester backbone of the abnormal strand is cleaved on both sides of the distortion, and the portion of the strand containing the lesion (an oligonucleotide) is peeled away from the DNA double helix by a *DNA helicase* enzyme (discussed later). The gap produced in the DNA helix is then repaired in the usual manner by DNA polymerase and DNA ligase (Figure 6-38B).

The importance of these repair processes is indicated by the large investment that cells make in DNA repair enzymes. A comprehensive genetic analysis of a yeast suggests that these cells contain more than 50 different genes that code for DNA repair functions. DNA repair pathways are likely to be at least as complex in humans. Individuals with the genetic disease *xeroderma pigmentosum,* for example, are defective in a nucleotide excision repair process that can be shown by genetic analysis to require at least seven different gene products. Such individuals develop severe skin lesions, including skin cancer, because of the accumulation of pyrimidine dimers in cells that are exposed to sunlight.

Cells Can Produce DNA Repair Enzymes in Response to DNA Damage 24

Cells have evolved a number of mechanisms to help them survive in a hazardous world. Often an extreme environmental insult activates a battery of genes whose products protect the cell from its effects. One such mechanism shared by all cells is the *heat-shock response,* which is evoked by the exposure of cells to unusually high temperatures. The induced "heat-shock proteins" include some that are thought to help stabilize and repair partially denatured cell proteins (see Figure 5-29).

Many cells also have mechanisms that enable them to synthesize DNA repair enzymes as an emergency response to severe DNA

damage. The best-studied example is the SOS response in *E. coli.* In this bacterium any block to DNA replication caused by DNA damage produces a signal (thought to be an excess of single-stranded DNA) that induces an increase in the transcription of more than 15 genes, many of which code for proteins that function in DNA repair. The signal first activates the *E. coli* RecA protein (discussed later), which then destroys a negatively acting gene regulatory protein (a *repressor*) that normally suppresses the transcription of the entire set of SOS response genes. Studies of mutant bacteria deficient in different parts of the response indicate that the newly synthesized proteins have two effects. First, as would be expected, the induction of new DNA repair enzymes increases cell survival. When the mutants deficient in this part of the SOS response are treated with a DNA-damaging agent such as ultraviolet radiation, an unusually high proportion of them die. Second, several of the induced proteins transiently increase the mutation rate by greatly increasing the number of errors made in copying DNA sequences. While this has little effect on short-term survival, it is presumably advantageous in the long term because it produces a burst of genetic variability in the bacterial population and hence increases the chance that a mutant cell with increased fitness will arise.

The DNA repair system activated in the SOS response is not the only inducible DNA repair system known. Bacteria have another system that is activated specifically by the presence of methylated nucleotides in DNA, and there is at least one inducible DNA repair system in yeast cells. Some higher eucaryotic cells have been reported to adapt to DNA damage in similar ways.

The Structure and Chemistry of the DNA Double Helix Make It Easy to Repair 25

The DNA double helix seems to be optimally constructed for repair. As discussed in Chapter 1, RNA is thought to have evolved before DNA, and it seems likely that the genetic code was initially carried in the four nucleotides A, C, G, and U. This raises the question of why the U in RNA has been replaced in DNA by T (which is 5-methyl U). We have seen that spontaneous C deamination converts C to U but that this event is rendered harmless by uracil DNA glycosylase (see Figure 6-38A). One can imagine how any repair enzyme designed to recognize and excise such accidents would be confused by the normal U nucleotides in a U-containing DNA molecule. Thus it is not surprising that U is not used in DNA.

This line of argument is strengthened by the observation that every possible deamination event in DNA yields an unnatural base, which can therefore be directly recognized and removed by a specific DNA glycosylase. Hypoxanthine, for example, is the simplest purine base capable of pairing specifically with C, but hypoxanthine is the direct deamination product of A. The addition of a second amino group to hypoxanthine produces G, which cannot be formed from A by spontaneous deamination and whose deamination product is likewise unique (Figure 6-39A).

A special situation occurs in vertebrate DNA, where selected C nucleotides are methylated at specific CG sequences associated with inactive genes (discussed in Chapter 9). As illustrated in Figure 6-39B, the accidental deamination of these methylated C nucleotides produces the natural nucleotide T, which forms a mismatched base pair with a G on the opposite DNA strand. To help protect methylated C nucleotides against such mutations, a special DNA glycosylase recognizes a mismatched base pair involving T in the sequence TG and removes the T. This DNA repair mechanism must be relatively ineffective, however, as methylated C nucleotides are common sites for mutations in vertebrate DNA. Even though only about 3% of the C nucleotides in human DNA are methylated, mutations in these methylated nucleotides account for about one-third of the single-base mutations that have been observed in inherited human diseases (see also Figure 9-71).

Whereas the chemistry of the bases ensures that deamination will be detected, accurate repair - and the fundamental answer to Schroedinger's dilemma - depends on the existence of separate copies of the genetic information in the two strands of the double helix. Only in the very unlikely event that both strands are damaged simultaneously at the same base pair is the cell left without one good copy to serve as a template for DNA repair. Even in this case mechanisms have evolved that are sometimes able to repair the damage. These repair mechanisms require that a second DNA helix of the same sequence be present in the cell, and they use genetic recombination mechanisms to transfer the missing information from one DNA helix to another - a process called *gene conversion,* which we discuss later.

Genetic information is stored in single-stranded DNA or RNA molecules only in some very small viruses with genomes of a few thousand nucleotides. The types of repair processes that we have described cannot operate on such nucleic acids, and the chance of a nucleotide change occurring in these viruses is very high. It seems that only organisms with tiny genomes can afford to encode their genetic information in a structure other than a DNA double helix.

Summary

The fidelity with which DNA sequences are maintained in higher eucaryotes can be estimated from the rates at which changes have occurred in nonessential protein and DNA sequences over evolutionary time. This fidelity is so high that a mammalian germ-line cell with a genome of 3×10^9 base pairs is subjected on average to only about 10 to 20 base-pair changes per year. But unavoidable chemical processes damage thousands of DNA nucleotides in a typical mammalian cell every day. Genetic information can be stored stably in DNA sequences only because a large variety of DNA repair enzymes continuously scan the DNA and replace the damaged nucleotides.

The process of DNA repair depends on the presence of a separate copy of the genetic information in each strand of the DNA double helix. An accidental lesion on one strand can therefore be cut out by a repair enzyme and a good strand resynthesized from the information in the undamaged strand. Most of the damage to DNA bases is excised by one of two major pathways. In base excision repair an altered base is removed by a DNA glycosylase enzyme, followed by excision of the resulting sugar phosphate. In nucleotide excision repair a small region of the strand surrounding the damage is removed from the DNA helix as an oligonucleotide. In both cases the small gap left in the DNA helix is filled in by the sequential action of DNA polymerase and DNA ligase.

Table 6-2. Observed Rates of Change of the Amino Acid Sequences in Four Proteins over Evolutionary Time

Protein	Unit Evolutionary Time*(in millions of years)
Fibrinopeptide	0.7
Hemoglobin	5
Cytochrome c	21
Histone H4	500

*. The "unit evolutionary time" is defined as the average time required for one *acceptable* amino acid change to appear in the indicated protein for every 100 amino acids that it contains.
Figure 6-32. Different proteins evolve at very different rates. A comparison of the rates of amino acid change found in hemoglobin, cytochrome c, and the fibrinopeptides. Hemoglobin and cytochrome c have changed much more slowly during evolution than the fibrinopeptides. In determining rates of change per year (as in Table 6-2), it is important to realize that two species that diverged from a common ancestor 100 million years ago are separated by 200 million years of evolutionary time.
Figure 6-33. Deamination and depurination. These hydrolytic reactions are the two most frequent spontaneous chemical reactions known to create serious DNA damage in cells. Only a single example is shown for each type of reaction. (See also Figure 6-39.)
Figure 6-34. A summary of spontaneous alterations likely to require DNA repair. (A) The sites on each nucleotide that are known to be modified by spontaneous oxidative damage (*red arrows*), hydrolytic attack (*blue arrows*), and uncontrolled methylation by the methyl group donor S-adenosyl-methionine (*green arrows*) are indicated, with the size of each arrow indicating the relative frequency of each event. The two most frequent types of hydrolytic events are illustrated in more detail in Figure 6-33. (B) The thymine dimer, a type of damage introduced into DNA in cells that are exposed to ultraviolet irradiation (as in sunlight). A similar dimer will form between any two neighboring pyrimidine bases (C or T residues) in DNA. (A, after T. Lindahl, *Nature* 362:709-715, 1993. © 1993 Macmillan Magazines Ltd.)

Figure 6-35. DNA repair. The three steps common to most types of repair are excision (step 1), resynthesis (step 2), and ligation (step 3). In step 1 the damage is excised; in steps 2 and 3 the original DNA sequence is restored. *DNA polymerase* fills in the gap created by the excision events, and *DNA ligase* seals the nick left in the repaired strand. Nick sealing consists of the re-formation of a broken phosphodiester bond (see Figure 6-37).

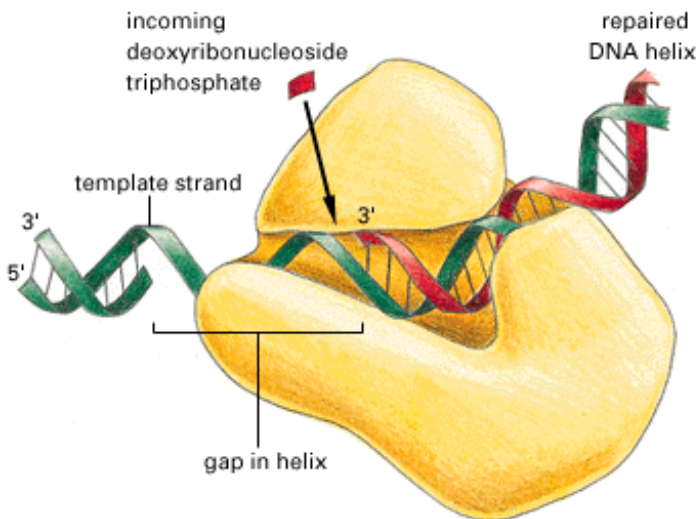
(A)
(B)


Figure 6-36. The DNA polymerase enzyme. (A) The reaction catalyzed by DNA polymerase. This enzyme catalyzes the stepwise addition of a deoxyribonucleotide to the 3'-OH end of a polynucleotide chain (the *primer strand*) that is paired to a second, *template strand*. The new DNA strand therefore grows in the 5'-to-3' direction. Because each incoming deoxyribonucleoside triphosphate must pair with the template strand in order to be recognized by the polymerase, this strand determines which of the four possible deoxyribonucleotides (A, C, G, or T) will be added. As in the case of RNA polymerase, the reaction is driven by a large favorable free-energy change (see Figure 6-3). (B) The structure of an *E. coli* DNA polymerase molecule has been determined by x-ray crystallography. This drawing illustrates how the polymerase is thought to function during the DNA synthesis involved in DNA repair. (B, adapted from L.S. Beese, V. Derbyshire, and T.A. Steitz, *Science* 260:352-355, 1993. © 1993 the AAAS.)
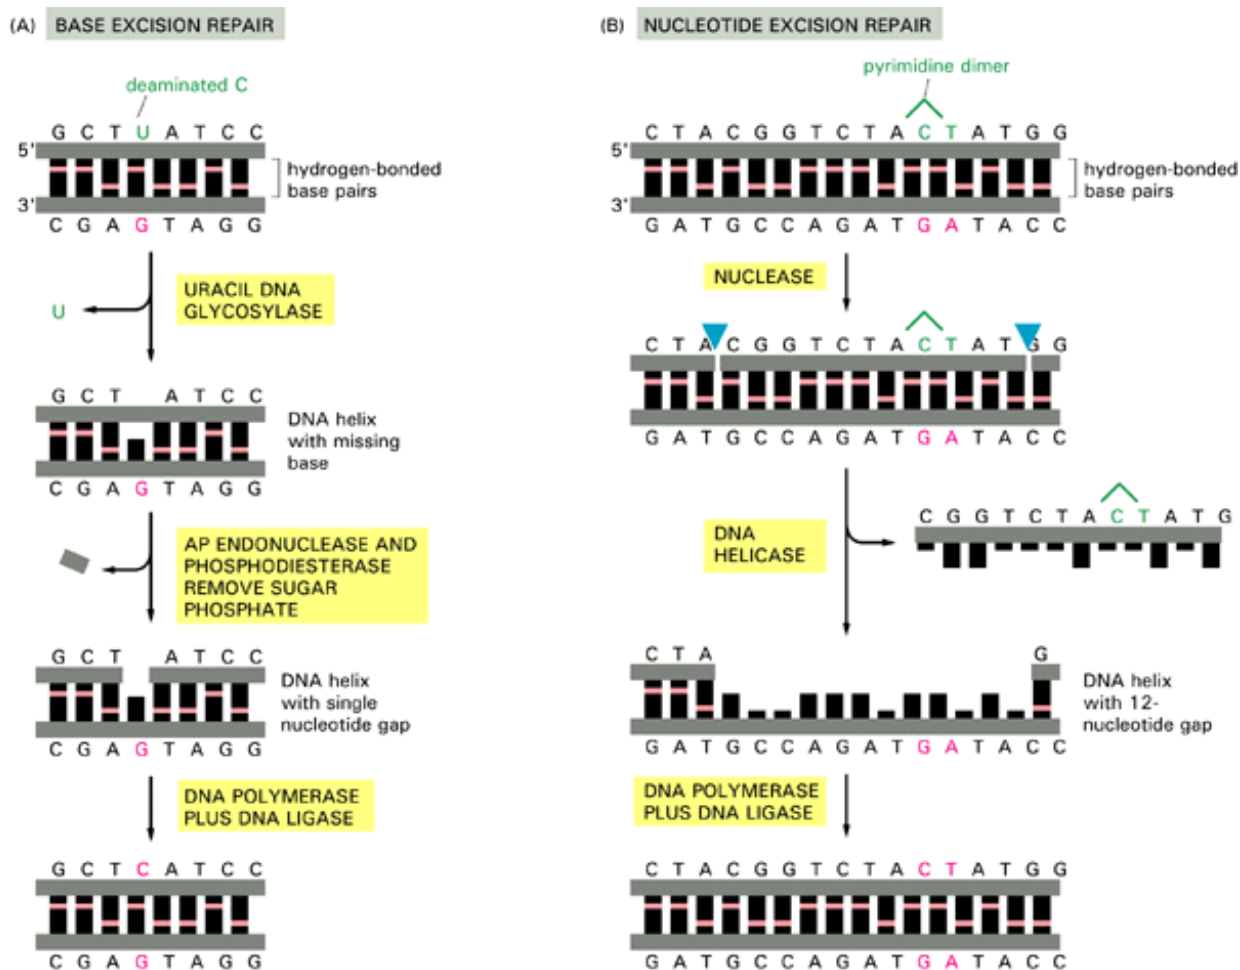
Figure 6-37. The reaction catalyzed by DNA ligase. This enzyme seals a broken phosphodiester bond. As shown, DNA ligase uses a molecule of ATP to activate the 5' end at the nick (step 1) before forming the new bond (step 2). In this way the energetically unfavorable nick-sealing reaction is driven by being coupled to the energetically favorable process of ATP hydrolysis. In *Bloom's syndrome,* an inherited human disease, individuals are partially defective in DNA ligation and consequently are deficient in DNA repair; as a consequence, they have a dramatically increased incidence of cancer.


Figure 6-38. Comparison of two major DNA repair pathways. (A) *Base excision repair.* This pathway starts with a DNA glycosylase. Here the enzyme uracil DNA glycosylase removes an accidentally deaminated cytosine in DNA. After the action of this glycosylase (or another DNA glycosylase that recognizes a different kind of damage) the sugar phosphate with the missing base is cut out by the sequential action of AP endonuclease and a phosphodiesterase, the same enzymes that initiate the repair of depurinated sites. The gap of a single nucleotide is then filled by DNA polymerase and DNA ligase. The net result is that the U that was created by accidental deamination is restored to a C. The AP endonuclease derives its name from the fact that it recognizes any site in the DNA helix that contains a deoxyribose sugar with a missing base; such sites can arise either by the loss of a purine (*ap*urinic sites) or by the loss of a pyrimidine (*ap*yriminic sites). (B) *Nucleotide excision repair.* After a

multienzyme complex recognizes a bulky lesion such as a pyrimidine dimer (see Figure 6-34B), one cut is made on each side of the lesion, and an associated DNA helicase then removes the entire portion of the damaged strand. The multienzyme complex in bacteria leaves the gap of 12 nucleotides shown; the gap produced in human DNA is more than twice this size.
Figure 6-39. The deamination of DNA nucleotides. In each case the oxygen atom added from the reaction with water is colored *red*. (A) The spontaneous deamination products of A and G are recognizable as unnatural when they occur in DNA and thus are readily recognized and repaired. The deamination of C to U was illustrated in Figure 6-33, and T has no amino group to deaminate. (B) A few percent of the C nucleotides in vertebrate DNAs are methylated to help control gene expression. When these 5-methyl C nucleotides are accidentally deaminated, they form T. This T will be paired with a G on the opposite strand, forming a mismatched base pair.

DNA Replication 26

Introduction

Besides maintaining the integrity of DNA sequences by DNA repair, all organisms must duplicate their DNA accurately before every cell division. *DNA replication* occurs at polymerization rates of about 500 nucleotides per second in bacteria and about 50 nucleotides per second in mammals. Clearly, the proteins that catalyze this process must be both accurate and fast. Speed and accuracy are achieved by means of a multienzyme complex that guides the process and constitutes an elaborate "replication machine."

Base-pairing Underlies DNA Replication as well as DNA Repair 27

DNA templating is the process in which the nucleotide sequence of a DNA strand (or selected portions of a DNA strand) is copied by complementary base-pairing (A with T or U, and G with C) into a complementary nucleic acid sequence (either DNA or RNA). The process entails the recognition of each nucleotide in the DNA strand by an unpolymerized complementary nucleotide and requires that the two strands of the DNA helix be separated, at least transiently, so that the hydrogen bond donor and acceptor groups on each base become exposed for base-pairing. The appropriate incoming single nucleotides are thereby aligned for their enzyme-catalyzed polymerization into a new nucleic acid chain. In 1957 the first such nucleotide polymerizing enzyme, *DNA polymerase,* was discovered. The substrates for this enzyme were found to be deoxyribonucleoside triphosphates, which are polymerized on a single-stranded DNA template. The stepwise mechanism of this reaction is the one previously illustrated in Figure 6-36 in connection with DNA repair. The discovery of DNA polymerase led to the isolation of *RNA polymerase,* which was correctly inferred to use ribonucleoside tri-phosphates as its substrates.

During DNA replication each of the two old DNA strands serves as a template for the formation of an entire new strand. Because each of the two daughters of a dividing cell inherits a new DNA double helix containing one old and one new strand (see Figure 3-13), DNA is said to be replicated "semiconservatively" by DNA polymerase.

The DNA Replication Fork Is Asymmetrical 28

Autoradiographic analyses carried out in the early 1960s on whole replicating chromosomes labeled with a short pulse of the radioactive DNA precursor 3H-thymidine revealed a localized region of replication that moves along the parental DNA double helix. Because of its Y-shaped structure, this active region is called a DNA replication fork. At a replication fork the DNA of both new daughter strands is synthesized by a multienzyme complex that contains the DNA polymerase.

Initially, the simplest mechanism of DNA replication appeared to be continuous growth of both new strands, nucleotide by nucleotide, at the replication fork as it moves from one end of a DNA molecule to the other. But because of the antiparallel orientation of the two DNA strands in the DNA double helix (see Figure 3-10 and Panel 3-2, pp. 100-101), this mechanism would require one daughter strand to grow in the 5'-to-3' direction and the other in the 3'-to-5' direction. Such a replication fork would require two different DNA polymerase enzymes. One would polymerize in the 5'-to-3' direction (see Figure 6-36), where each incoming deoxyribonucleoside triphosphate carries the triphosphate activation needed for its own addition. The other would move in the 3'-to-5' direction and work by so-called "head growth," in which the end of the growing DNA chain carries the triphosphate activation required for the addition of each subsequent nucleotide. Although head-growth polymerization occurs elsewhere in biochemistry (see Figure 2-36), it does not occur in DNA synthesis; no 3'-to-5' DNA polymerase has ever been found (Figure 6-40).

How, then, is 3'-to-5' DNA synthesis achieved? The answer was first suggested in the late 1960s by experiments in which highly radioactive 3H-thymidine was added to dividing bacteria for a few seconds so that only the most recently replicated DNA, just behind the replication fork, became radiolabeled. This selective labeling method revealed the transient existence of pieces of DNA that were 1000 to 2000 nucleotides long, now commonly known as *Okazaki fragments,* at the bacterial growing fork. (Such replication intermediates were later found in eucaryotes, where they are only 100 to 200 nucleotides long.) The Okazaki fragments were shown to be synthesized only in the 5'-to-3' chain direction and to be joined together after their synthesis to create long DNA chains by the same *DNA ligase* enzyme that seals nicks during DNA repair (see Figure 6-37).

A replication fork has an asymmetric structure. The DNA daughter strand that is synthesized continuously is known as the leading strand, and its synthesis slightly precedes the synthesis of the daughter strand that is synthesized discontinuously, which is known as the lagging strand. The synthesis of the lagging strand is delayed because it must wait for the leading strand to expose the template strand on which each Okazaki fragment is synthesized (Figure 6-41). The synthesis of the lagging strand by a discontinuous, "backstitching" mechanism means that only the 5'-to-3' type of DNA polymerase is needed for DNA replication.

The High Fidelity of DNA Replication Requires a Proofreading Mechanism 29

The fidelity of copying that is observed after DNA replication has occurred is such that only about 1 error is made in every 10^9 base-pair replications, as required to maintain the mammalian genome of 3×10^9 DNA base pairs. This fidelity is much higher than expected, given that the standard complementary base pairs are not the only ones possible. With small changes in helix geometry, for example, two hydrogen bonds will form between G and T in DNA. In addition, rare tautomeric forms of the four DNA bases occur transiently in ratios of 1 part to 10^4 or 10^5. These forms will mispair without a change in helix geometry: the rare tautomeric form of C pairs with A instead of G, for example. If the DNA polymerase accepts a mispairing that occurs between an incoming deoxyribonucleoside triphosphate and the DNA template, the wrong nucleotide can be incorporated into the new DNA chain, producing a mutation. The high fidelity of DNA replication depends on several "proofreading" mechanisms that act sequentially to remove errors brought about in these ways.

One important proofreading process depends on special properties of the DNA polymerase enzyme. Unlike RNA polymerases, DNA polymerases do not begin a new polynucleotide chain by linking two nucleoside triphosphates together. They absolutely require the 3'-OH end of a base-paired *primer strand* on which to add further nucleotides (see Figure 6-36). Moreover, DNA molecules with a mismatched (not base-paired) nucleotide at the 3'-OH end of the primer strand are not effective as templates. DNA polymerase molecules are able to deal with such mismatched DNAs by means of either a separate catalytic subunit or a covalently linked, separate catalytic site that clips off any unpaired residues at the primer terminus. Clipping by this *3'-to-5' proofreading exonuclease* activity continues until enough nucleotides have been removed from the 3' end to regenerate a base-paired terminus that can prime DNA synthesis. In this way DNA polymerase functions as a "self-correcting" enzyme that removes its own polymerization errors as it moves along the DNA. Figure 6-42 illustrates how this proofreading process can correct a base-pairing error.

The requirement for a perfectly base-paired terminus is essential to the self-correcting properties of the DNA polymerase. For such an enzyme to start synthesis in the complete absence of a primer without losing any of its discrimination between base-paired and unpaired growing 3'-OH termini is apparently not possible. By contrast, the RNA polymerase enzymes involved in gene transcription need not be self-correcting: errors in making RNA are not passed on to the next generation, and an occasional defective molecule has no significance. RNA polymerases are able to start new polynucleotide chains without a primer, and an error frequency of about 1 in 10^4 is found both in RNA synthesis and in the separate process of translating mRNA sequences

into protein sequences.

Only DNA Replication in the 5'-to-3' Direction Allows Efficient Error Correction

The need for accuracy probably explains why DNA replication occurs only in the 5'-to-3' direction. If there were a DNA polymerase that added deoxyribonucleoside triphosphates in such a way as to cause chains to grow in the 3'-to-5' chain direction, the growing 5'-chain end rather than the incoming mononucleotide would carry the activating triphosphate. In this case the mistakes in polymerization could not be simply hydrolyzed away, since the bare 5'-chain end thus created would immediately terminate DNA synthesis. It is much easier, therefore, to correct a mismatched base that has just been added to the 3' end than one that has just been added to the 5' end of a DNA chain. Although the type of mechanism for DNA replication shown in Figure 6-41 seems at first sight much more complex than the incorrect mechanism depicted in Figure 6-40, it is much more accurate because it involves DNA synthesis only in the 5'-to-3' direction.

A Special Nucleotide Polymerizing Enzyme Synthesizes Short RNA Primer Molecules on the Lagging Strand 30

For the leading strand a special primer is needed only at the start of replication; once a replication fork is established, the DNA polymerase is continuously presented with a base-paired chain end on which to add new nucleotides. But the DNA polymerase on the lagging side of the fork requires only about 4 seconds to complete each short DNA fragment, after which it must start synthesizing a completely new fragment at a site farther along the template strand (see Figure 6-41). A special mechanism is needed to produce the base-paired primer strand required by this DNA polymerase molecule. The mechanism involves an enzyme called *DNA primase,* which uses ribonucleoside triphosphates to synthesize short RNA primers (Figure 6-43). These primers are about 10 nucleotides long in eucaryotes, and they are made at intervals on the lagging strand, where they are elongated by the DNA polymerase to begin each Okazaki fragment. The synthesis of each Okazaki fragment ends when this DNA polymerase runs into the RNA primer attached to the 5' end of the previous fragment. To produce a continuous DNA chain from the many DNA fragments made on the lagging strand, a special DNA repair system acts quickly to erase the old RNA primer and replace it with DNA. DNA ligase then joins the 3' end of the new DNA fragment to the 5' end of the previous one to complete the process (Figure 6-44).

Why might an erasable RNA primer be preferred to a DNA primer that need not be erased? The argument that a self-correcting polymerase cannot start chains *de novo* also implies its converse: an enzyme that starts chains *de novo* cannot be efficient at self-correction. Thus any enzyme that primes the synthesis of Okazaki fragments will of necessity make a relatively inaccurate copy (at least 1 error in 10^5). Even if the copies retained in the final product constituted as little as 5% of the total genome (for example, 10 nucleotides per 200-nucleotide DNA fragment), the resulting increase in overall mutation rate would be enormous. It therefore seems likely that the evolution of RNA rather than DNA for priming entailed a powerful advantage, since the ribonucleotides in the primer automatically mark these sequences as "bad copy" to be removed.

Special Proteins Help Open Up the DNA Double Helix in Front of the Replication Fork 31

The DNA double helix must be opened up ahead of the replication fork so that the incoming deoxyribonucleoside triphosphates can form base pairs with the template strand. The DNA double helix is very stable under normal conditions: the base pairs are locked in place so strongly that temperatures approaching that of boiling water are required to separate the two strands in a test tube. For this reason most DNA polymerases can copy DNA only when the template strand has already been separated from its complementary strand. Additional proteins are needed to help open the double helix and thus provide the appropriate exposed DNA template for the DNA polymerase to copy. Two types of replication proteins contribute to this processDNA helicases and single-strand DNA-binding proteins.

DNA helicases were first isolated as proteins that hydrolyze ATP when they are bound to single strands of DNA. As described in Chapter 5, the hydrolysis of ATP can change the shape of a protein molecule in a cyclical manner that allows the protein to perform mechanical work. DNA helicases utilize this principle to move rapidly along a DNA single strand; where they encounter a region of double helix, they continue to move along their strand, thereby prying apart the helix (Figure 6-45). We have previously described how a special DNA repair helicase functions in nucleotide excision repair (see Figure 6-38B).

The unwinding of the template DNA helix at a replication fork could in principle be catalyzed by two DNA helicases acting in concert - one running along the leading strand and one along the lagging strand. These two helicases would need to move in opposite directions along a DNA single strand and therefore would have to be different enzymes. Both types of DNA helicase, in fact, do exist, although in bacteria the DNA helicase on the lagging strand plays the predominant role, for reasons that will

become clear shortly.

Single-strand DNA-binding (SSB) proteins - also called *helix-destabilizing proteins* - bind to exposed DNA strands without covering the bases, which therefore remain available for templating. These proteins are unable to open a long DNA helix directly, but they aid helicases by stabilizing the unwound, single-stranded conformation. In addition, their cooperative binding completely coats the regions of single-stranded DNA on the lagging strand, thereby preventing formation of the short hairpin helices that would otherwise impede synthesis by the DNA polymerase (Figure 6-46).

A Moving DNA Polymerase Molecule Is Kept Tethered to the DNA by a Sliding Ring 32

On their own, most DNA polymerase molecules will synthesize only a short string of nucleotides before falling off a DNA template. This tendency to leave a DNA molecule quickly allows the DNA polymerase molecule that has just finished synthesizing one Okazaki fragment on the lagging strand to be recycled quickly to begin the synthesis of the next Okazaki fragment on the same strand. This rapid dissociation, however, would make it difficult for the polymerase to synthesize long DNA strands at a replication fork were it not for an accessory protein that functions as a regulated clamp. This clamp keeps the polymerase firmly on the DNA when it is moving, but releases it as soon as the polymerase stops.

How can a clamp prevent the polymerase from dissociating without at the same time impeding the polymerase's rapid movement along the DNA molecule? The three-dimensional structure of a clamp protein, determined by x-ray diffraction, indicates that it forms a large ring around the DNA helix. One side of the ring binds to the back of the DNA polymerase, and the whole ring slides freely as the polymerase moves along a DNA strand (Figure 6-47). The assembly of the clamp around DNA requires ATP hydrolysis by special accessory proteins that bind both to the clamp protein and to DNA; it is not known how the clamp is disassembled to remove it from the DNA.

The Proteins at a Replication Fork Cooperate to Form a Replication Machine 33

Although we have discussed DNA replication as though it were carried out by a mixture of replication proteins that act independently, in reality most of the proteins are held together in a large multienzyme complex that moves rapidly along the DNA. This complex can be likened to a tiny sewing machine composed of protein parts and powered by nucleoside triphosphate hydrolyses. Although the replication complex has been best characterized in *E. coli* and several of its viruses, a very similar complex operates in eucaryotes (see p. 358).

The functions of the subunits of the replication machine are summarized in the two-dimensional diagram of the complete replication fork shown in Figure 6-48. Two identical DNA polymerase molecules work at the fork, one on the leading strand and one on the lagging strand. The DNA helix is opened by a DNA polymerase molecule clamped on the leading strand, acting in concert with a DNA helicase molecule running along the lagging strand; helix opening is aided by cooperatively bound molecules of single-strand DNA-binding protein. While the DNA polymerase molecule on the leading strand can operate in a continuous fashion, the DNA polymerase molecule on the lagging strand must restart at short intervals, using a short RNA primer made by a DNA primase molecule.

The efficiency of replication is greatly increased by the close association of all these protein components. The primase molecule is linked directly to the DNA helicase to form a unit on the lagging strand called a primosome. Powered by the DNA helicase, the primosome moves with the fork, synthesizing RNA primers as it goes. Similarly, the DNA polymerase molecule that synthesizes DNA on the lagging strand moves in concert with the rest of the proteins, synthesizing a succession of new Okazaki fragments. To accommodate this arrangement, its DNA template strand is thought to be folded back in the manner shown in Figure 6-49. The replication proteins are thus linked together into a single large unit (total mass > 10^6 daltons) that moves rapidly along the DNA, enabling DNA to be synthesized on both sides of the fork in a coordinated and efficient manner.

This DNA replication machine leaves behind on the lagging strand a series of unsealed Okazaki fragments, which still contain the RNA that primed their synthesis at their 5' ends. This RNA must be removed and the fragments joined up by DNA repair enzymes that operate behind the replication fork (see Figure 6-44).

A Mismatch Proofreading System Removes Replication Errors That Escape from the Replication Machine 34

Bacteria such as *E. coli* are capable of dividing once every 30 minutes, so it is relatively easy to screen large populations to find

rare mutants that are altered in a specific process. One interesting class of mutants contains alterations in so-called *mutator genes,* which greatly increase the rate of spontaneous mutation. Not surprisingly, one such mutant encodes a defective form of the 3'-to-5' proofreading exonuclease (discussed earlier) that is a subunit of the DNA polymerase enzyme (see Figure 6-42). When this protein is defective, the DNA polymerase no longer proofreads effectively, and many replication errors that would otherwise have been removed accumulate in the DNA.

The study of other *E. coli* mutants that exhibit abnormally high mutation rates has uncovered another proofreading system that removes replication errors missed by the proofreading exonuclease. This mismatch proofreading system (also called a *mismatch repair* system) differs from most DNA repair systems in that it does not depend on the presence in the DNA of abnormal nucleotides that can be recognized and excised. Instead, it detects the distortion on the outside of the helix that results from the misfit between noncomplementary base pairs. But if the proofreading system simply recognized a mismatch in newly replicated DNA and randomly excised one of the two mismatched nucleotides, it would make the mistake of "correcting" the original template strand to match the error exactly half the time and would not therefore lower the overall error rate. To be effective, the proofreading system must be able to distinguish and remove the mismatched nucleotide only on the new strand, where the replication error occurred.

The recognition system used by the mismatch proofreading system in *E. coli* depends on the methylation of selected A residues in the DNA. Methyl groups are added to all A residues in the sequence GATC, but not until some time after the A has been incorporated into a newly synthesized DNA chain. Because only the new strands just behind a replication fork will contain GATC sequences that have not yet been methylated, these new DNA strands can be distinguished from old ones.

More recently, eucaryotic proteins have been discovered that are homologous in their amino acid sequence to several of the bacterial proteins that catalyze mismatch proofreading. As expected, when the genes that encode these proteins are deleted in a yeast cell, mutation rates can increase by 100-fold or more. There must, however, be some important differences between the bacterial and eucaryotic proofreading mechanisms, as the mechanism for distinguishing the newly synthesized strand from the parental template strand at the site of a mismatch cannot depend on DNA methylation as in bacteria, since some eucaryotes, such as yeasts and *Drosophila,* do not methylate any of their DNA. Newly synthesized DNA strands are known to be preferentially *nicked,* and it has been suggested that such nicks (single-strand breaks) provide the signal that directs mismatch proofreading to the appropriate strand in a eucaryotic cell (Figure 6-50).

Replication Forks Initiate at Replication Origins 35

In both bacteria and mammals replication forks originate at a structure called a *replication bubble,* a local region where the two strands of the parental DNA helix have been separated from each other to serve as templates for DNA synthesis (Figure 6-51). For bacteria, yeasts, and several viruses that grow in mammalian cells, replication bubbles have been shown to form at special DNA sequences called replication origins, which can be as long as 300 nucleotides. For reasons that are not clear, the replication origins in mammalian chromosomes have thus far been very difficult to characterize at the molecular level.

For several well-defined replication origins, it has been possible to reproduce the fork initiation reaction *in vitro.* The *in vitro* studies reveal that fork initiation in bacteria and bacterial viruses starts in the manner indicated in Figure 6-52. *Initiator proteins* bind in multiple copies to specific sites at the replication origin, wrapping the DNA around them to form a large protein-DNA complex. This complex then binds the DNA helicase and loads it onto an exposed DNA single strand in an adjacent region of helix. The DNA primase also binds, forming the primosome, which moves away from the origin and makes an RNA primer that starts the first DNA chain. This quickly leads to assembly of the remaining proteins to create two replication protein complexes moving away from the origin in opposite directions (see Figure 6-51); these continue to synthesize DNA until all of the DNA template downstream of each fork has been replicated.

Replication fork initiation in eucaryotic chromosomes is discussed in detail in Chapter 8.

DNA Topoisomerases Prevent DNA Tangling During Replication 36

When we draw the DNA helix (incorrectly) as a flat, ladderlike structure, we are ignoring the "winding problem" that arises during DNA replication. Every 10 base pairs replicated at the fork correspond to one complete turn about the axis of the parental double helix. Therefore, for a replication fork to move, the entire chromosome ahead of the fork would normally have to rotate rapidly (Figure 6-53), which would require large amounts of energy for long chromosomes. An alternative strategy is used during DNA replication: a swivel is formed in the DNA helix by proteins known as DNA topoisomerases.

A DNA topoisomerase can be viewed as a reversible nuclease that adds itself covalently to a DNA phosphate, thereby breaking a phosphodiester bond in a DNA strand. Because the covalent linkage that joins a topoisomerase to a DNA phosphate retains the energy of the cleaved phosphodiester bond, the cleavage reaction is reversible; resealing is rapid and does not require additional energy input. The rejoining mechanism is different in this respect from that of the enzyme DNA ligase, discussed previously (see Figure 6-37).

One type of topoisomerase (*topoisomerase I*) causes a *single-strand break* (or *nick*), which can allow the two sections of DNA helix on either side of the nick to rotate freely relative to each other, using the phosphodiester bond in the strand opposite the nick as a swivel point (Figure 6-54). Any tension in the DNA helix will drive this rotation in the direction that relieves the tension. As a result, DNA replication can occur with the rotation of only a short length of helix - the part just ahead of the fork. The analogous problem that arises during DNA transcription is solved in a similar way.

A second type of DNA topoisomerase (*topoisomerase II*) forms a covalent linkage to both strands of the DNA helix at the same time, making a transient *double-strand break* in the helix. These enzymes are activated by sites on chromosomes where two double helices cross over each other. When the topo-isomerase binds to such a crossing site, it (1) breaks one double helix reversibly to create a DNA "gate," (2) causes the second, nearby double helix to pass through this break, and (3) reseals the break and dissociates from the DNA. In this way type II DNA topoisomerases can efficiently separate two interlocked DNA circles (Figure 6-55). The same reaction prevents the severe DNA tangling problems that would otherwise arise during DNA replication. For example, mutant yeast cells have been isolated that produce, in place of the normal topoisomerase II, a version that is inactive at 37°C. When the mutant yeast cells are warmed to this temperature, their chromosomes remain intertwined at mitosis and are unable to separate. The usefulness of topoisomerase II for untangling chromosomes can readily be appreciated by anyone who has struggled to remove a tangle from a fishing line without the aid of scissors.

DNA Replication Is Basically Similar in Eucaryotes and Procaryotes [37]

Much of what we know about DNA replication comes from studies of purified bacterial and bacteriophage multienzyme systems capable of DNA replication *in vitro*. The development of these systems in the 1970s was greatly facilitated by the prior isolation of mutants in a variety of replication genes; these mutants were exploited to identify and purify the corresponding replication proteins.

Less is known about the detailed enzymology of DNA replication in eucaryotes, largely because it is difficult to obtain replication-deficient mutants. Nevertheless, the basic mechanisms of DNA replication, including both the geometry of the replication fork and the protein components of the multiprotein replication machine, are similar for procaryotes and eucaryotes (see Figure 8-35). The major difference is that eucaryotic DNA is replicated not as bare DNA but as *chromatin,* in which the DNA is complexed with tightly bound proteins called *histones.* As described in Chapter 8, histones form disclike structures around which the eucaryotic DNA is wound, creating a repeating structural unit called a *nucleosome.* Nucleosomes are spaced at intervals of about 200 base pairs along the DNA, which may be why new Okazaki fragments are synthesized on the lagging strand at intervals of 100 to 200 nucleotides in eucaryotes instead of at intervals of 1000 to 2000 nucleotides as in bacteria. Nucleosomes may also act as barriers that slow down the movement of DNA polymerase molecules, which could explain why eucaryotic replication forks move only one-tenth as fast as bacterial replication forks.

Summary

A self-correcting DNA polymerase catalyzes nucleotide polymerization in a 5'-to-3' direction, copying a DNA template with remarkable fidelity. Since the two strands of a DNA double helix are antiparallel, this 5'-to-3' DNA synthesis can take place continuously on only one of the strands at a replication fork (the leading strand). On the lagging strand short DNA fragments are made by a "backstitching" process. Because the self-correcting DNA polymerase cannot start a new chain, these lagging-strand DNA fragments are primed by short RNA primer molecules that are subsequently erased and replaced with DNA.

DNA replication requires the cooperation of many proteins, including (1) DNA polymerase and DNA primase to catalyze nucleoside triphosphate polymerization, (2) DNA helicases and single-strand binding proteins to help open up the DNA helix so that it can be copied, (3) DNA ligase and an enzyme that degrades RNA primers to seal together the discontinuously synthesized lagging-strand DNA fragments, (4) DNA topoisomerases to help relieve helical winding and tangling problems, and (5) initiator proteins that bind to specific DNA sequences at a replication origin and catalyze the formation of a replication fork at that site. At a replication origin a specialized protein-DNA structure is formed that subsequently loads a DNA helicase onto the DNA

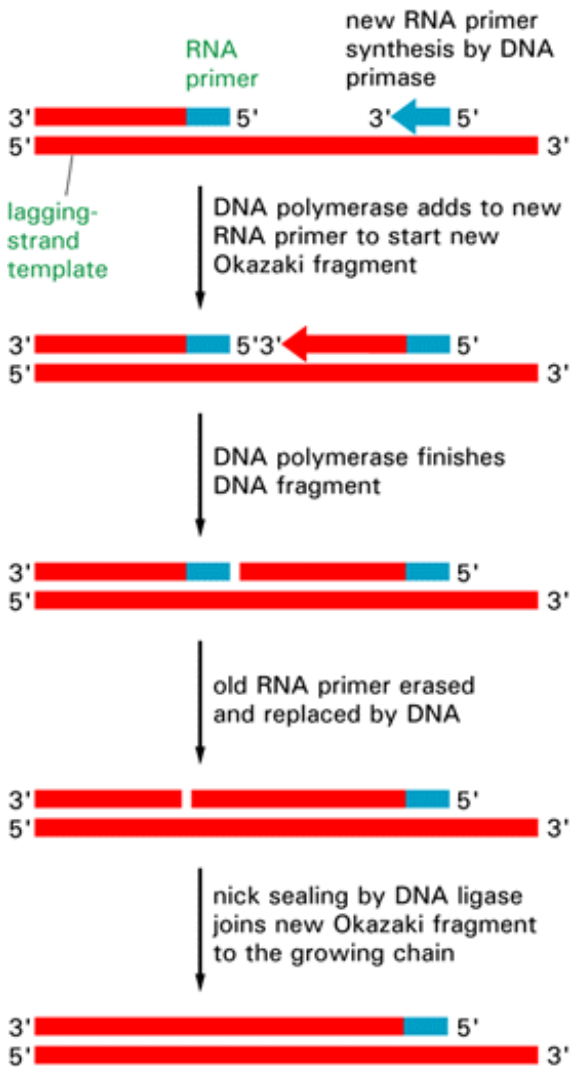
template; other proteins are then added to form the multienzyme "replication machine" that catalyzes DNA synthesis.
Figure 6-40. An incorrect model for DNA replication. Although it might appear to be the simplest mechanism for DNA replication, the mechanism illustrated here is not the one that cells use. Note that in this scheme both daughter DNA strands would grow continuously, using the energy of hydrolysis of the *yellow* phosphates to add the next nucleotide on each strand. This would require chain growth in both the 5'-to-3' direction (*bottom*) and the 3'-to-5' direction (*top*). No enzyme that catalyzes 3'-to-5' nucleotide polymerization has ever been found.
Figure 6-41. The structure of a DNA replication fork. Because both daughter DNA strands (*colored*) are synthesized in the 5'-to-3' direction, the DNA synthesized on the lagging strand must be made initially as a series of short DNA molecules, called *Okazaki fragments.*
Figure 6-43. RNA primer synthesis. A schematic view of the reaction catalyzed by DNA primase, the enzyme that synthesizes the short RNA primers made on the lagging strand. Unlike DNA polymerase, this enzyme can start a new polynucleotide chain by joining two nucleoside triphosphates together. The primase stops after a short polynucleotide has been synthesized and makes the 3' end of this primer available for the DNA polymerase.


Figure 6-44. The synthesis of one of the many DNA fragments on the lagging strand. In eucaryotes the RNA primers are made at intervals spaced by about 200 nucleotides on the lagging strand, and each RNA primer is 10 nucleotides long. This primer is erased by a special DNA repair enzyme that recognizes an RNA strand in an RNA/DNA helix and excises it; this

leaves a gap that is filled in by DNA polymerase and DNA ligase, as we saw for the DNA repair process (see <u>Figure 6-35</u>).
Figure 6-45. The assay used to test for DNA helicase enzymes. A short DNA fragment is annealed to a long DNA single strand to form a region of DNA double helix. The double helix is melted as the helicase runs along the DNA single strand, releasing the short DNA fragment in a reaction that requires the presence of both the helicase protein and ATP. The movement of the helicase is powered by its ATP hydrolysis (see <u>Figure 5-22</u>).
Figure 6-46. The effect of single-strand binding proteins on the structure of single-stranded DNA. Because each protein molecule prefers to bind next to a previously bound molecule (*cooperative binding*) long rows of this protein will form on a DNA single strand. This cooperative binding straightens out the DNA template and facilitates the DNA polymerization process. The "hairpin helices" shown in the bare single-stranded DNA result from a chance matching of short regions of complementary nucleotide sequence; they are similar to the short helices that typically form in RNA molecules.
Figure 6-47. The regulated sliding clamp that holds DNA polymerase on the DNA. (A) The structure of the sliding clamp from *E. coli*, with a DNA helix added to indicate how the protein fits around DNA. A similar protein is present in eucaryotic cells. (B) Schematic illustration of how the clamp is thought to hold a moving DNA polymerase molecule on the DNA. (A, from X.-P. Kong et al. , *Cell* 69:425-437, 1992. © Cell Press.)
Figure 6-48. The proteins at a DNA replication fork. The major types of proteins that act at a DNA replication fork are illustrated, showing their positions on the DNA.
Figure 6-49. A replication fork in three dimensions. This diagram shows a current view of how the replication proteins are arranged at a replication fork when the fork is moving. The two-dimensional structure of Figure 6-48 has been altered by folding the DNA on the lagging strand to bring the lagging-strand DNA polymerase molecule into a complex with the leading-strand DNA polymerase molecule. This folding process also brings the 3' end of each completed Okazaki fragment close to the start site for the next Okazaki fragment (compare with Figure 6-48). Because the lagging-strand DNA polymerase molecule is held to the rest of the replication proteins, it can be reused to synthesize successive Okazaki fragments; thus it is about to let go of its completed DNA fragment and move to the RNA primer that will be synthesized nearby, as required to start the next DNA fragment. Note that one daughter DNA helix extends toward the bottom right and the other toward the top left in this diagram.
Figure 6-50. A model for mismatch proofreading in eucaryotes. The two proteins shown are present in both bacteria and eucaryotic cells: MutS binds specifically to a mismatched base pair, while MutL scans the nearby DNA for a nick. Once a nick is found, MutL triggers the degradation of the nicked strand all the way back through the mismatch. Because nicks are largely confined to newly replicated strands in eucaryotes, replication errors are selectively removed. In bacteria the mechanism is the same except that an additional protein in the complex (MutH) nicks unmethylated (and therefore newly replicated) GATC sequences and thereby begins the process that is illustrated here. We know the mechanism because these reactions have been reconstituted in a cell-free system containing purified bacterial proteins and DNA.

Figure 6-52. The proteins that initiate DNA replication. The major types of proteins involved in the formation of replication forks at the *E. coli* and bacteriophage lambda replication origins are indicated. The mechanism shown was established by *in vitro* studies utilizing a mixture of highly purified proteins. Subsequent steps result in the initiation of three more DNA chains (see Figure 6-51) by a pathway that is not yet clear. For *E. coli* DNA replication, the major initiator protein is the dnaA protein; for both lambda and *E. coli*, the primosome is composed of the dnaB (DNA helicase) and dnaG (DNA primase) proteins.
Figure 6-53. The "winding problem" that arises during DNA replication. For a bacterial replication fork moving at 500 nucleotides per second, the parental DNA helix ahead of the fork must rotate at 50 revolutions per second.

Figure 6-55. DNA topoisomerase II. An example of a DNA-helix-passing reaction catalyzed by a type II DNA topoisomerase. Unlike type I topoisomerases, these enzymes require ATP hydrolysis for their function, and some of the bacterial versions can introduce superhelical tension into DNA (see p. 438). Type II topoisomerases are largely confined to proliferating cells in eucaryotes; partly for that reason, they have been popular targets for anticancer drugs.

Genetic Recombination <u>38</u>

Introduction

In the two preceding sections we discussed the mechanisms by which DNA sequences in cells are maintained from generation to generation with very little change. Although such genetic stability is crucial for the survival of individuals, in the longer term the survival of organisms may depend on genetic variation, through which they can adapt to a changing environment. Thus an important property of the DNA in cells is its ability to undergo rearrangements that can vary the particular combination of genes present in any individual genome, as well as the timing and the level of expression of these genes. These DNA rearrangements are caused by genetic recombination. Two broad classes of genetic recombination are commonly recognized - general recombination and site-specific recombination.

In *general recombination,* genetic exchange takes place between any pair of homologous DNA sequences, usually located on two copies of the same chromosome. One of the most important examples is the exchange of sections of homologous chromosomes (homologues) in the course of *meiosis.* This "crossing-over" occurs between tightly apposed chromosomes early in the development of eggs and sperm (discussed in <u>Chapter 20</u>), and it allows different versions (*alleles*) of the same gene to be tested in new combinations with other genes, increasing the chance that at least some members of a mating population will survive in a changing environment. Although meiosis occurs only in eucaryotes, the advantage of this type of gene mixing is so great that mating and the reassortment of genes by general recombination is also widespread in bacteria.

DNA homology is not required in *site-specific recombination.* Instead, exchange occurs at short, specific nucleotide sequences (on either one or both of the two participating DNA molecules) that are recognized by a variety of site-specific recombination enzymes. Site-specific recombination therefore alters the relative positions of nucleotide sequences in genomes. In some cases these changes are scheduled and organized, as when an integrated bacterial virus is induced to leave a chromosome of a bacterium under stress (see <u>Figure 6-80</u>); in others they are haphazard, as when the DNA sequence of a transposable element is inserted at a randomly selected site in a chromosome.

As for DNA replication, most of what we know about the biochemistry of genetic recombination has come from studies of procaryotic organisms, especially of *E. coli* and its viruses.

General Recombination Is Guided by Base-pairing Interactions Between Complementary Strands of Two Homologous DNA Molecules <u>39</u>

General recombination involves DNA strand-exchange intermediates that require some effort to understand. Although the exact pathway followed is likely to be different in different organisms, detailed genetic analyses of viruses, bacteria, and fungi suggest that the major outcome of general recombination is always the same. (1) Two homologous DNA molecules "cross over"; that is, their double helices break and the two broken ends join to their opposite partners to re-form two intact double helices, each composed of parts of the two initial DNA molecules (<u>Figure 6-56</u>). (2) The site of exchange (that is, where a *red* double helix is joined to a *green* double helix in <u>Figure 6-56</u>) can occur anywhere in the homologous nucleotide sequences of the two participating DNA molecules. (3) At the site of exchange, a strand of one DNA molecule becomes base-paired to a strand of the second DNA molecule to create a *staggered joint* (usually called a *heteroduplex joint*) between the two double helices (<u>Figure 6-57</u>). The heteroduplex region can be thousands of base pairs long; we shall explain later how it forms. (4) No nucleotide sequences are altered at the site of exchange; the cleavage and rejoining events occur so precisely that not a single nucleotide is lost or gained. Despite this precision, general recombination creates DNA molecules of novel sequence: the heteroduplex joint can contain a small number of mismatched base pairs, and, more important, the two DNAs that cross over are usually not exactly the same on either side of the joint.

The mechanism of general recombination ensures that two regions of DNA double helix undergo an exchange reaction only if they have extensive sequence homology. The formation of a heteroduplex joint requires that such homology be present because it involves a long region of complementary base-pairing between a strand from one of the two original double helices and a complementary strand from the other. But how does this heteroduplex joint arise, and how do the two homologous regions of DNA at the site of crossing-over recognize each other? As we shall see, recognition takes place by means of a direct base-pairing interaction. The formation of base pairs between complementary strands from the two DNA molecules then guides the general recombination process, allowing it to occur only between long regions of matching DNA sequence.

General Recombination Can Be Initiated at a Nick in One Strand of a DNA Double Helix 40

Each of the two strands in a DNA molecule is helically wound around the other. As a result, extensive base-pair interactions can occur between two homologous DNA double helices only if a nick is first made in a strand of one of them, freeing that strand for the unwinding and rewinding events required to form a heteroduplex with another DNA molecule. For the same reason, any *exchange* of strands between two DNA double helices requires at least two nicks, one in a strand of each interacting double helix. Finally, to produce the heteroduplex joint illustrated in Figure 6-57, each of the four strands present must be cut to allow each to be joined to a different partner. In general recombination, these nicking and resealing events are coordinated so that they occur only when two DNA helices share an extensive region of matching DNA sequence.

There is evidence from a number of sources that a single nick in only one strand of a DNA molecule is sufficient to initiate general recombination. Chemical agents or types of irradiation that introduce single strand nicks, for example, will trigger a genetic recombination event. Moreover, one of the special proteins required for general recombination in *E. coli*the *RecBCD protein*has been shown to make single strand nicks in DNA molecules. The RecBCD protein is also a DNA helicase, hydrolyzing ATP and traveling along a DNA helix transiently exposing its strands. By combining its nuclease and helicase activities, the RecBCD protein will create a single-stranded "whisker" on the DNA double helix (Figure 6-58). Figure 6-59 shows how such a whisker could initiate a base-pairing interaction between two complementary stretches of DNA double helix.

DNA Hybridization Reactions Provide a Simple Model for the Base-pairing Step in General Recombination 41

In its simplest form, the type of base-pairing interaction central to general recombination can be mimicked in a test tube by allowing a DNA double helix to re-form from its separated single strands. This process, called DNA renaturation or hybridization, occurs when a rare random collision juxtaposes complementary nucleotide sequences on two matching DNA single strands, allowing the formation of a short stretch of double helix between them. This relatively slow *helix nucleation* step is followed by a very rapid "zippering" step as the region of double helix is extended to maximize the number of base-pairing interactions (Figure 6-60).

Formation of a new double helix in this way requires that the annealing strands be in an open, unfolded conformation. For this reason *in vitro* hybridization reactions are carried out at high temperature or in the presence of an organic solvent such as formamide; these conditions "melt out" the short hairpin helices formed where base-pairing interactions occur within a single strand that folds back on itself. Bacterial cells could not survive such harsh conditions and instead use a single-strand binding protein, the *SSB protein,* to open their helices. This protein is essential for DNA replication as well as for general recombination in *E. coli;*it binds tightly and cooperatively to the sugar-phosphate backbone of all single-stranded regions of DNA, holding them in an extended conformation with their bases exposed (see Figure 6-46). In this extended conformation a DNA single strand can base-pair efficiently with either a nucleoside triphosphate molecule (in DNA replication) or a complementary section of another DNA single strand (in genetic recombination). When hybridization reactions are carried out *in vitro* under conditions that mimic those inside a cell, the SSB protein speeds up the rate of DNA helix nucleation and thereby the overall rate of strand annealing by a factor of more than 1000.

The RecA Protein Enables a DNA Single Strand to Pair with a Homologous Region of DNA Double Helix in *E. coli* 42

General recombination is more complex than the simple hybridization reactions just described. In the course of general recombination, a single DNA strand from one DNA double helix must invade another double helix (see Figure 6-59). In *E. coli* this requires the RecA protein, produced by the *recA* gene, which was identified in 1965 as being essential for recombination between chromosomes. Long sought by biochemists, this elusive gene product was finally purified to homogeneity in 1976, a feat that allowed its detailed characterization (Figure 6-61). Like a single-strand binding (SSB) protein, the RecA protein binds tightly and in large cooperative clusters to single-stranded DNA to form a nucleoprotein filament. This filament has several distinctive properties. The RecA protein has more than one DNA-binding site, for example, and it can therefore hold a single strand and a double helix together. These sites allow the RecA protein to catalyze a multistep reaction (called synapsis) between a DNA double helix and a homologous region of single-stranded DNA. The crucial step in synapsis occurs when a region of homology is identified by an initial base-pairing between complementary nucleotide sequences. The nucleation step in this case appears to involve a three-stranded structure, in which the DNA single strand forms nonconventional base pairs in the major groove of the DNA double helix (Figure 6-62). This begins the pairing shown previously in Figure 6-59 and so initiates the exchange of strands between two recombining DNA double helices. Studies *in vitro* suggest that the *E. coli* SSB protein cooperates with the RecA protein to facilitate these reactions.

Once synapsis has occurred, a short heteroduplex region where the strands from two different DNA molecules have begun to pair is enlarged through *protein-directed branch migration,* which can also be catalyzed by the RecA protein. Branch migration can take place at any point where two single DNA strands with the same sequence are attempting to pair with the same complementary strand; an unpaired region of one of the single strands will displace a paired region of the other single strand, moving the branch point without changing the total number of DNA base pairs. Spontaneous branch migration proceeds equally in both directions, and so it makes little progress and is unlikely to complete recombination efficiently (Figure 6-63A). Because the RecA protein catalyzes unidirectional branch migration, it readily produces a region of heteroduplex that is thousands of base pairs long (Figure 6-63B).

The catalysis of branch migration depends on a further property of the RecA protein. In addition to having two DNA-binding sites, the RecA protein is a DNA-dependent ATPase, with an additional site for binding and hydrolyzing ATP. The protein associates much more tightly with DNA when it has ATP bound than when it has ADP bound. Moreover, new RecA molecules with ATP bound are preferentially added at one end of the RecA protein filament, and the ATP is then hydrolyzed to ADP. The RecA protein filaments that form on DNA may therefore share many of the dynamic assembly properties displayed by the cytoskeletal filaments formed from actin or tubulin (discussed in Chapter 16); an ability of the protein to "treadmill" unidirectionally along a DNA strand, for example, could drive the branch migration reaction shown in Figure 6-63B.

General Genetic Recombination Usually Involves a Cross-Strand Exchange 43

Exchanging a single strand between two double helices is presumed to be the slow and difficult step in a general recombination event (see Figure 6-59). After this initial exchange, extending the region of pairing and establishing further strand exchanges between the two closely apposed helices is thought to proceed rapidly. During these events a limited amount of nucleotide excision and local DNA resynthesis often occurs, resembling some of the events in DNA repair. Because of the large number of possibilities, different organisms are likely to follow different pathways at this stage. In most cases, however, an important intermediate structure, the cross-strand exchange, will be formed by the two participating DNA helices. One of the simplest ways in which this structure can form is shown in Figure 6-64.

In the cross-strand exchange (also called a *Holliday junction*) the two homologous DNA helices that initially paired are held together by mutual exchange of two of the four strands present, one originating from each of the helices. No disruption of base-pairing is necessary to maintain this structure, which has two important properties(1) the point of exchange between the two homologous DNA double helices (where the two strands cross in Figure 6-64) can migrate rapidly back and forth along the helices by a double branch migration; (2) the cross-strand exchange contains two pairs of strands: one pair of crossing strands and one pair of noncrossing strands. The structure can *isomerize,* however, by undergoing a series of rotational movements, so that the two original noncrossing strands become crossing strands and vice versa (Figure 6-65).

In order to regenerate two separate DNA helices and thus terminate the pairing process, the two crossing strands must be cut. If the crossing strands are cut *before* isomerization, the two original DNA helices separate from each other nearly unaltered, with only a very short piece of single-stranded DNA exchanged. If the crossing strands are cut *after* isomerization, however, one section of each original DNA helix is joined to a section of the other DNA helix; in other words, the two DNA helices have crossed over (see Figure 6-65).

The isomerization of the cross-strand exchange should occur spontaneously at some rate, but it may also be enzymatically driven or otherwise regulated by cells. Some kind of control probably operates during meiosis, when the two DNA double helices that pair are constrained in an elaborate structure called the *synaptonemal complex* (discussed in Chapter 20).

Gene Conversion Results from Combining General Recombination and Limited DNA Synthesis 44

It is a fundamental law of genetics that each parent makes an equal genetic contribution to the offspring, one complete set of genes being inherited from the father and one from the mother. Thus, when a diploid cell undergoes meiosis to produce four haploid cells (discussed in Chapter 20), exactly half of the genes in these cells should be maternal (genes that the diploid cell inherited from its mother) and the other half paternal (genes that the diploid cell inherited from its father). In a complex animal, such as a human, it is not possible to check this prediction directly. But in other organisms, such as fungi, where it is possible to recover and analyze all four of the daughter cells produced from a single cell by meiosis, one finds cases in which the standard genetic rules have apparently been violated. Occasionally, for example, meiosis yields three copies of the maternal version of a gene (allele) and only one copy of the paternal allele, indicating that one of the two copies of the paternal allele has been

changed to a copy of the maternal allele. This phenomenon is known as gene conversion. It often occurs in association with general genetic recombination events, and it is thought to be important in the evolution of certain genes (see Figure 8-74). Gene conversion is believed to be a straightforward consequence of the mechanisms of general recombination and DNA repair.

During meiosis heteroduplex joints are formed at the sites of crossing-over between homologous maternal and paternal chromosomes. If the maternal and paternal DNA sequences are slightly different, the heteroduplex joint may include some mismatched base pairs. The resulting mismatch in the double helix may then be corrected by the DNA repair machinery, which either can erase nucleotides on the paternal strand and replace them with nucleotides that match the maternal strand or vice versa. The consequence of this mismatch repair will be a gene conversion. Gene conversion can also take place by a number of other mechanisms, but they all require some type of general recombination event that brings two copies of a closely related DNA sequence together. Because an extra copy of one of the two DNA sequences is generated, a limited amount of DNA synthesis must also be involved. Genetic studies show that usually only small sections of DNA undergo gene conversion, and in many cases only part of a gene is changed.

Gene conversion can also occur in mitotic cells, but it does so more rarely. As in meiotic cells, some gene conversions in mitotic cells probably result from a mismatch repair process operating on heteroduplex DNA. Another likely mechanism in both meiotic and mitotic cells is illustrated in Figure 6-66.

Mismatch Proofreading Can Prevent Promiscuous Genetic Recombination Between Two Poorly Matched DNA Sequences 45

As previously discussed, general recombination is triggered whenever two DNA strands of complementary sequence pair to form a heteroduplex joint between two double helices (see Figure 6-64). Experiments carried out *in vitro* with purified RecA protein show that pairing can occur efficiently even when the sequences of the two DNA strands do not match well - when, for example, only four out of every five nucleotides on average can form base pairs. How, then, do vertebrate cells avoid promiscuous general recombination between the many thousands of copies of closely related DNA sequences that are repeated in their genomes (see p. 395)?

Although the answer is not known, studies with bacteria and yeasts demonstrate that the same mismatch proofreading system that removes replication errors (see Figure 6-50) has the additional role of interrupting genetic recombination events between imperfectly matched DNA sequences. It has long been known, for example, that homologous genes in two closely related bacteria, *Escherichia coli* and *Salmonella typhimurium,* generally will not recombine, even though their nucleotide sequences are 80% identical; when the mismatch proofreading system is inactivated by mutation, however, there is a 1000-fold increase in the frequency of such interspecies recombination events. It is thought, then, that the mismatch proofreading system normally recognizes the mispaired bases in an initial strand exchange and prevents the subsequent steps required to break and rejoin the two paired DNA helices. This mechanism protects the bacterial genome from the sequence changes that would otherwise be caused by recombination with foreign DNA molecules that occasionally enter the cell. In vertebrate cells, which contain many closely related DNA sequences, the same type of proofreading is thought to help prevent promiscuous recombination events that would otherwise scramble the genome (Figure 6-67).

Site-specific Recombination Enzymes Move Special DNA Sequences into and out of Genomes 46

Site-specific genetic recombination, unlike general recombination, is guided by a recombination enzyme that recognizes specific nucleotide sequences present on one or both of the recombining DNA molecules. Base-pairing between the recombining DNA molecules need not be involved, and even when it is, the heteroduplex joint that is formed is only a few base pairs long. By separating and joining double-stranded DNA molecules at specific sites, this type of recombination enables various types of mobile DNA sequences to move about within and between chromosomes.

Site-specific recombination was first discovered as the means by which a bacterial virus, bacteriophage *lambda,* moves its genome into and out of the *E. coli* chromosome. In its integrated state the virus is hidden in the bacterial chromosome and replicated as part of the host's DNA. When the virus enters a cell, a virus-encoded enzyme called *lambda integrase* is synthesized. This enzyme catalyzes a recombination process that begins when several molecules of the integrase protein bind tightly to a specific DNA sequence on the circular bacteriophage chromosome. The resulting DNA-protein complex can now bind to a related but different specific DNA sequence on the bacterial chromosome, bringing the bacterial and bacteriophage chromosomes close together. The integrase then catalyzes the required DNA cutting and resealing reactions, using a short region of sequence homology to form a tiny heteroduplex joint at the point of union (Figure 6-68). The integrase resembles a DNA

topoisomerase in that it forms a reversible covalent linkage to DNA wherever it breaks a DNA chain.

The same type of site-specific recombination mechanism can also be carried out in *reverse* by the lambda bacteriophage, enabling it to exit from its integration site in the *E. coli* chromosome in order to multiply rapidly within the bacterial cell. This excision reaction is catalyzed by a complex of the integrase enzyme with a second bacteriophage protein, which is produced by the virus only when its host cell is stressed. If the sites recognized by such a recombination enzyme are flipped, the DNA between them will be inverted rather than excised (see Figure 9-57).

Many other enzymes that catalyze site-specific recombination resemble lambda integrase in requiring a short region of identical DNA sequence on the two regions of DNA helix to be joined. Because of this requirement, each enzyme in this class is fastidious with respect to the DNA sequences that it recombines, and it can be expected to catalyze one particular DNA joining event that is useful to the virus, plasmid, transposable element, or cell that contains it. These enzymes can be exploited as tools in transgenic animals to study the influence of specific genes on cell behavior, as illustrated in Figure 6-69.

Site-specific recombination enzymes that break and rejoin two DNA double helices at specific sequences on each DNA molecule often do so in a reversible way: as for lambda bacteriophage, the same enzyme system that joins two DNA molecules can take them apart again, precisely restoring the sequences of the two original DNA molecules. This type of recombination is therefore called *conservative site-specific recombination* to distinguish it from the mechanistically distinct *transpositional site-specific recombination* that we discuss next.

Transpositional Recombination Can Insert a Mobile Genetic Element into Any DNA Sequence [47]

Many mobile DNA sequences, including many viruses and transposable elements, encode integrases that insert their DNA into a chromosome by a mechanism that is different from that used by bacteriophage lambda. Like the lambda integrase, each of these enzymes recognizes a specific DNA sequence in the particular mobile genetic element whose recombination it catalyzes. Unlike the lambda enzyme, however, these integrases do not require a specific DNA sequence in the "target" chromosome and they do not form a heteroduplex joint. Instead, they introduce cuts into both ends of the linear DNA sequence of the mobile genetic element and then catalyze a direct attack by these DNA ends on the target DNA molecule, breaking two closely spaced phosphodiester bonds in the target molecule. Because of the way that these breaks are made, two short single-stranded gaps are left in the recombinant DNA molecule, one at each end of the mobile element; these are filled in by DNA polymerase to complete the recombination process. As illustrated in Figure 6-70, this mechanism creates a short duplication of the adjacent target DNA sequence; such flanking duplications are the hallmark of a transpositional site-specific recombination event.

An integrase enzyme of this type was first purified in active form from bacteriophage Mu. Like the bacteriophage lambda integrase, it carries out all of its cutting and rejoining reactions without requiring an energy source (such as ATP). Very similar enzymes are present in organisms as diverse as bacteria, fruit flies, and humans - all of which contain mobile genetic elements, as we discuss next.

Summary

Genetic recombination mechanisms allow large sections of DNA double helix to move from one chromosome to another. There are two broad classes of recombination events. In general recombination the initial reactions rely on extensive base-pairing interactions between strands of the two DNA double helices that will recombine. As a result, general recombination occurs only between two homologous DNA molecules, and although it moves sections of DNA back and forth between chromosomes, it does not normally change the arrangement of the genes in a chromosome. Site-specific recombination, on the other hand, alters the relative positions of nucleotide sequences in chromosomes because the pairing reactions depend on a protein-mediated recognition of the two DNA sequences that will recombine, and extensive sequence homology is not required. Two site-specific recombination mechanisms are common: (1) conservative site-specific recombination, which produces a very short heteroduplex and therefore requires some DNA sequence that is the same on the two DNA molecules, and (2) transpositional site-specific recombination, which produces no heteroduplex and usually does not require a specific sequence on the target DNA.
Figure 6-80. The life cycle of bacteriophage lambda. The lambda genome contains about 50,000 nucleotide pairs and encodes about 50 proteins. Its double-stranded DNA can exist in either linear or circular forms. As shown, the bacteriophage can multiply by either a lytic or a lysogenic pathway in the *E. coli* bacterium. When the bacteriophage is growing in the lysogenic state, damage to the cell causes the integrated viral DNA (provirus) to exit from the host chromosome and shift to lytic growth. The entrance and exit of the DNA from the chromosome are site-specific genetic recombination events catalyzed by the lambda *integrase* protein (see Figure 6-68).

have base-paired

Figure 6-57. A heteroduplex joint. This structure unites two DNA molecules where they have crossed over. Such a joint is often thousands of nucleotides long.
Figure 6-58. One way to start a recombination event. The RecBCD protein is an enzyme required for general genetic recombination in *E. coli*. The protein enters the DNA from one end of the double helix and then uses energy derived from the hydrolysis of bound ATP molecules to propel itself in one direction along the DNA at a rate of about 300 nucleotides per second. A special recognition site (a DNA sequence of eight nucleotides scattered throughout the *E. coli* chromosome) is cut in the traveling loop of DNA created by the RecBCD protein, and thereafter a single-stranded whisker is displaced from the helix, as shown. This whisker is thought to initiate genetic recombination by pairing with a homologous helix, as in Figure 6-59.
Figure 6-59. The initial strand exchange in general recombination. A nick in a single DNA strand frees the strand, which then invades a homologous DNA double helix to form a short pairing region with one of the strands in the second helix. Only two DNA molecules that are complementary in nucleotide sequence can base-pair in this way and thereby initiate a general

recombination event. All of the steps shown here can be catalyzed by known enzymes (see Figures 6-58 and 6-62).
Figure 6-60. DNA hybridization. DNA double helices re-form from their separated strands in a reaction that depends on the random collision of two complementary strands (see p. 300). Most such collisions are not productive, as shown at the left, but a few result in a short region where complementary base pairs have formed (helix nucleation). A rapid zippering then leads to the formation of a complete double helix. A DNA strand can use this trial-and-error process to find its complementary partner in the midst of millions of nonmatching DNA strands. Trial-and-error recognition of a complementary partner DNA sequence appears to initiate all general recombination events.
Figure 6-61. The structure of the RecA protein. A string of three RecA monomers is shown, with the position of each ATP in *red.* The *white spheres* show the putative position of the single-strand DNA in the filament, with three nucleotides (each shown as a sphere) bound per monomer. (From R.M. Story, I.T. Weber, and T.A. Steitz, *Nature* 256:318-325, 1992. © 1992 Macmillan Magazines Ltd.)
Figure 6-62. DNA synapsis catalyzed by the RecA protein. *In vitro* experiments show that several types of complexes are formed between a DNA single strand covered with RecA protein (*red*) and a DNA double helix (*green*). First a non-base-paired complex is formed, which is converted to a three-stranded structure as soon as a region of homologous sequence is found. This complex is presumably unstable because it involves an unusual form of DNA, and it spins out a DNA heteroduplex (one strand *green* and the other strand *red*) plus a displaced single strand from the original helix (*green*); thus the structure shown in this diagram migrates to the left, reeling in the "input DNAs" while producing the "output DNAs." The net result is a DNA strand exchange identical to that diagrammed earlier in Figure 6-59. (Adapted from S.C. West, *Annu. Rev. Biochem.* 61:603-640, 1992. © Annual Reviews Inc.)

(A) SPONTANEOUS BRANCH MIGRATION

(B) PROTEIN-DIRECTED BRANCH MIGRATION
Figure 6-63. Two types of DNA branch migration observed in experiments *in vitro*. (A) Spontaneous branch migration is a back-and-forth, random-walk type of process, and it therefore makes little progress over long distances. (B) RecA-protein-directed branch migration proceeds at a uniform rate in one direction, and it may be driven by the polarized assembly of the RecA protein filament on a DNA single strand, which occurs in the direction indicated. In addition, special DNA helicases that catalyze protein-directed branch migration even more efficiently are involved in recombination.
Figure 6-64. The formation of a cross-strand exchange. There are many possible pathways that can lead from a single-strand exchange (see Figure 6-59) to a cross-strand exchange, but only one is shown.

Figure 6-65. The isomerization of a cross-strand exchange. Without isomerization, cutting the two crossing strands would terminate the exchange and crossing over would not occur. With isomerization (steps B and C), cutting the two crossing strands creates two DNA molecules that have crossed over (*bottom*). Isomerization is therefore thought to be required for the breaking and rejoining of two homologous DNA double helices that result from general genetic recombination. Step A was illustrated previously (see Figure 6-64).

NET RESULT: ONE GREEN ALLELE OF GENE X HAS BEEN
CONVERTED TO A RED ALLELE

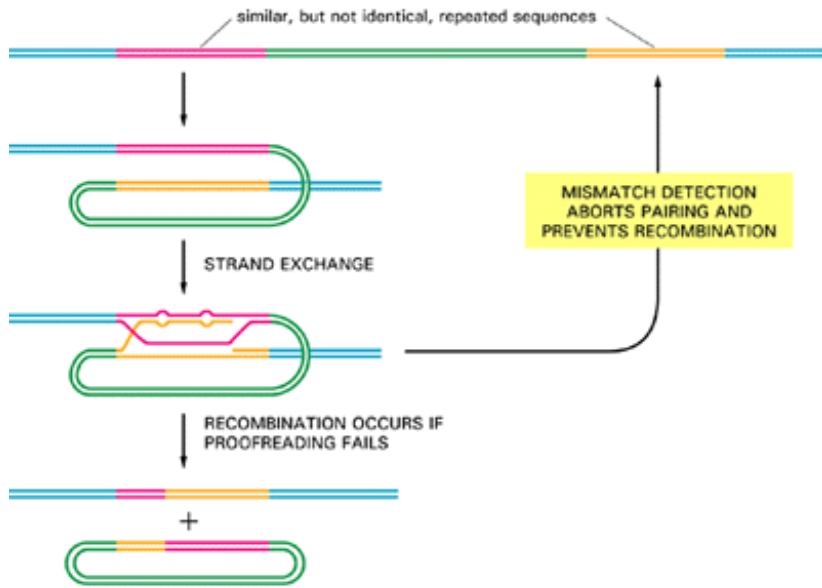
Figure 6-66. One general recombination pathway that can cause gene conversion. The process begins when a nick is formed in one of the strands in the *red* DNA helix. In step 1 DNA polymerase begins the synthesis of an extra copy of a strand in the *red* helix, displacing the original copy as a single strand. This single strand then pairs with the homologous region of the *green* helix in the manner shown in Figure 6-59. In step 2 the short region of unpaired *green* strand produced in step 1 is degraded, completing the transfer of nucleotide sequences. The result is normally seen in the next cell cycle, after DNA replication has separated the two nonmatching strands (step 3). As described in the text, the repair of mismatched base pairs in a heteroduplex joint also causes gene conversion.


Figure 6-67. Proofreading prevents general recombination from destabilizing genomes that contain repeated sequences. Studies with bacterial and yeast cells suggest that the mismatch proofreading system diagrammed previously in Figure 6-50 has the additional function shown here.
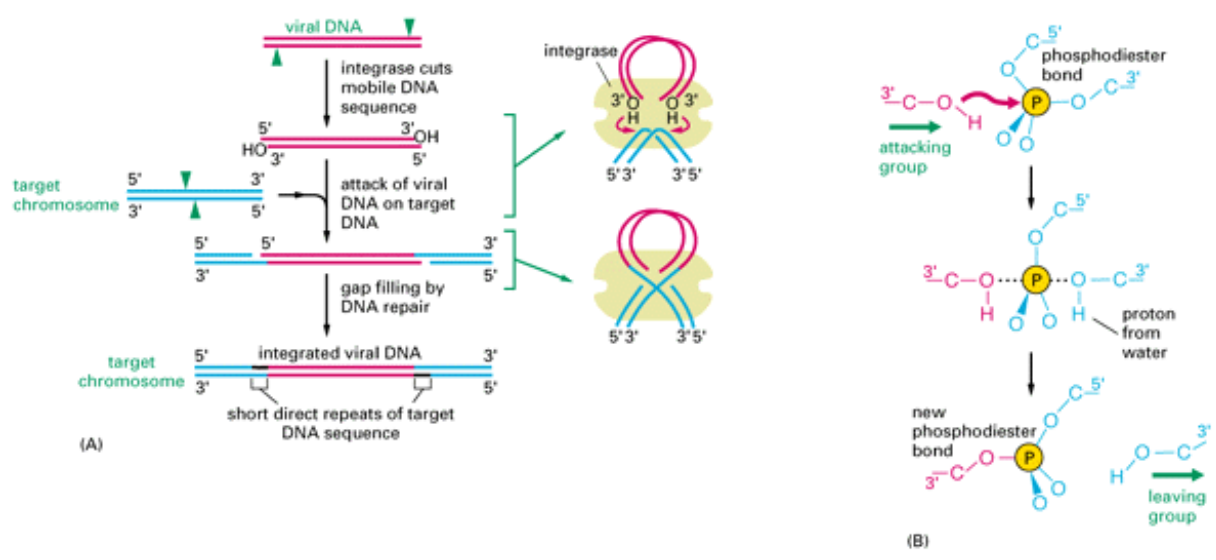
Figure 6-68. The insertion of bacteriophage lambda DNA into the bacterial chromosome. In this example of site-specific recombination, the lambda integrase enzyme binds to a specific "attachment site" DNA sequence on each chromosome, where it makes cuts that bracket a short homologous DNA sequence; the integrase thereby switches the partner strands and reseals them so as to form a heteroduplex joint 7 base pairs long. Each of the four strand-breaking and strand-joining reactions required resembles that made by a DNA topoisomerase, inasmuch as the energy of a cleaved phosphodiester bond is stored in a transient covalent linkage between the DNA and the enzyme (see Figure 6-64).
Figure 6-69. Using a site-specific recombination enzyme to turn on a gene in a group of cells in a transgenic animal. (A) The DNA molecule shown has been engineered so that the gene of interest is transcribed only when a site-specific recombination enzyme is activated, which both removes the marker gene and brings the promoter next to the gene of interest. The recombination enzyme is encoded by a second DNA molecule (not shown) that is engineered so that the enzyme is made only when the temperature is increased. Both DNA molecules are introduced into the chromosomes of the same transgenic animal. When the temperature of this animal is transiently increased, there is a brief burst of synthesis of the recombination enzyme, which causes a DNA rearrangement in an occasional cell such that the marker gene is removed and the gene of interest is simultaneously activated. (B) The strategy can be used to turn on a gene of interest permanently in small clones of cells in a developing animal. The clones can be identified by their loss of the marker gene product, which, for example, could cause a change in the pigmentation of the cells. This technique therefore allows one to study the effect of expressing any gene of interest in a group of cells in an intact animal.


Figure 6-70. Transpositional site-specific recombination. (A) Outline of the strand-breaking and -rejoining events that lead to integration of the linear double-stranded DNA of a retrovirus (*red*) into an animal cell chromosome (*blue*). In an initial endonuclease step the integrase enzyme makes a cut in one strand at each end of the viral DNA sequence, exposing a protruding 3'-OH group. Each of these 3'-OH ends then directly attacks a phosphodiester bond on opposite strands of a randomly selected site on a target chromosome. This inserts the viral DNA sequence into the target chromosome, leaving short gaps on each side that are filled in by DNA repair processes. Because of the gap filling, this type of mechanism leaves short repeats of target DNA sequence [3 to 12 nucleotides in length (*black*), depending on the integrase enzyme] on either side of the integrated DNA

segment. (B) An atomic-level view of the attack by one DNA chain end in (A) on a phosphodiester bond of the target DNA (*blue*). This mechanism resembles that used in RNA splicing, and is distinctly different from the topoisomerase-like activity of lambda integrase. (Adapted from K. Mizuuchi, *J. Biol. Chem.* 267:21273-21276, 1992.)

Viruses, Plasmids, and Transposable Genetic Elements [48]

Introduction

In our description of the basic genetic mechanisms, we have so far focused on their selective advantage for the cell. We saw that the short-term survival of the cell depends on the maintenance of genetic information by DNA repair, while the multiplication of the cell requires rapid and accurate DNA replication. On a longer time scale the appearance of genetic variants, on which evolution of the species depends, is greatly facilitated by the reassortment of genes and the occasional rearrangement of DNA sequences caused by genetic recombination. We shall now examine a group of genetic elements that seem to act as parasites, subverting the genetic mechanisms of the cell for their own benefit. These genetic elements are interesting in their own right. In addition, because they must heavily exploit the metabolism of the host cell in order to multiply, they serve as powerful tools for investigating the normal cell machinery.

Many DNA sequences can replicate independently of the rest of the genome. Such sequences have widely different degrees of independence from their host cells. Of these, virus chromosomes are the most independent because they have a protein coat that allows them to move freely from cell to cell. To varying degrees, the *viruses* are closely related to *plasmids* and *transposable elements*, which are DNA sequences that lack a coat and are therefore more host-cell-dependent and confined to replicate within a single cell and its progeny. More primitive still are some DNA sequences that are suspected of being mobile because they are repeated many times in a cell's chromosome. They move or multiply so rarely, however, that it is not clear if they should be considered as separate genetic elements at all.

We begin our discussion with viruses, which are the best understood of the mobile genetic elements. Then we describe the properties of plasmids and transposable elements, some of which bear a remarkable resemblance to viruses and may in fact have been their ancestors. The many repetitive DNA sequences in vertebrate chromosomes are discussed in Chapter 8.

Viruses Are Mobile Genetic Elements [49]

Viruses were first described as disease-causing agents that can multiply only in cells and that by virtue of their tiny size pass through ultrafine filters that hold back even the smallest bacteria. Before the advent of the electron microscope, their nature was obscure, although it was suspected that they might be naked genes that had somehow acquired the ability to move from one cell to another. The use of ultracentrifuges in the 1930s made it possible to separate viruses from host cell components, and by the early 1940s the generalization emerged that all viruses contain nucleic acids. The idea that viruses and genes carry out similar functions was confirmed by studies on bacteriophages, which are bacterial viruses. In 1952 it was shown for the bacteriophage T4 that only the phage DNA, and not the phage protein, enters the bacterial host cell and initiates the replication events that lead to the production of several hundred progeny viruses in every infected cell.

These observations led to the notion of viruses as genetic elements enclosed by a protective coat that enables them to move from one cell to another. Virus multiplication per se is often lethal to the cells in which it occurs; in many cases the infected cell breaks open (*lyses*) and thereby allows the progeny viruses access to nearby cells. Many of the clinical manifestations of viral infection reflect this cytolytic effect of the virus. Both the cold sores formed by herpes simplex virus and the lesions caused by smallpox, for example, reflect the killing of the epithelial cells in a local area of the skin.

As we shall see, the type of nucleic acid in a virus, the structure of its coat, its mode of entry into the host cell, and its mechanism of replication once inside all vary from one type of virus to another.

The Outer Coat of a Virus May Be a Protein Capsid or a Membrane Envelope [50]

Initially, it was thought that the outer coat of a virus might be constructed from a single type of protein molecule. Viral infections were believed to start with the dissociation of the viral chromosome (its nucleic acid) from its protein coat, followed by replication of the chromosome inside the host cell, to form many identical copies. After the synthesis of new copies of the virus-specific coat protein from virally encoded messenger RNA molecules, formation of the progeny virus particles would

occur by the spontaneous assembly of these coat protein molecules around the progeny viral chromosomes (Figure 6-71).

It is now known that these ideas vastly oversimplify the diversity of virus life cycles. The protein shell that surrounds the nucleic acid of most viruses (the capsid), for example, contains more than one type of polypeptide chain, often arranged in several layers (Figure 6-72). In many viruses, moreover, the protein capsid is further enclosed by a lipid bilayer membrane that contains proteins. Many of these *enveloped viruses* acquire their envelope in the process of budding from the plasma membrane (Figure 6-73). This budding process allows the virus particles to leave the cell without disrupting the plasma membrane and, therefore, without killing the cell. Electron micrographs that emphasize the differences among viral coats are presented in Figure 6-74.

Viral Genomes Come in a Variety of Forms and Can Be Either RNA or DNA 51

As discussed earlier, the DNA double helix has the advantages of stability and easy repair. If one polynucleotide chain is accidentally damaged, its complementary chain permits the damage to be readily corrected. This concern with repair, however, need not bother small viral chromosomes that contain only several thousand nucleotides. The chance of accidental damage is very small compared with the risk to a cell genome containing millions of nucleotides.

The genetic information of a virus can, therefore, be carried in a variety of unusual forms, including RNA instead of DNA. A viral chromosome may be a single-stranded RNA chain, a double-stranded RNA helix, a circular single-stranded DNA chain, or a linear single-stranded DNA chain. Moreover, although some viral chromosomes are simple linear DNA double helices, circular DNA double helices and more complex linear DNA double helices are also common. Several viruses have protein molecules covalently attached to the 5' ends of their DNA strands, for example, and the DNA double helices from the very large poxviruses have their opposite strands at each end covalently joined through phosphodiester linkages (Figure 6-75).

A Viral Chromosome Codes for Enzymes Involved in the Replication of Its Nucleic Acid 52

Each type of viral genome requires unique enzymatic tricks for its replication and thus must encode not only the viral coat protein but also one or more of the enzymes needed to replicate the viral nucleic acid. The amount of information that a virus brings into a cell to ensure its own selective replication varies greatly. The DNA of the relatively large bacteriophage T4, for example, contains about 300 genes, including at least 30 genes that ensure the rapid replication of the T4 chromosome in its *E. coli* host cell (Figure 6-76). T4 DNA replication has the unusual feature that 5-hydroxymethyl-C is incorporated in place of C in its DNA. The unusual base composition of the T4 DNA makes it readily distinguishable from host DNA and selectively protects it from nucleases encoded in the T4 genome that thus degrade only the *E. coli* chromosome. Still other proteins alter host cell RNA polymerase molecules so that they are unable to transcribe *E. coli* DNA and instead transcribe different sets of bacteriophage genes at different stages of infection, according to the needs of the phage.

Smaller DNA viruses, such as the monkey virus SV40 and the tiny bacterio-phage M13, carry much less genetic information. They rely heavily on host-cell enzymes to carry out their DNA synthesis, parasitizing most of the host-cell DNA replication proteins. Most DNA viruses, however, code for proteins that selectively initiate the synthesis of their own DNA, recognizing a particular nucleotide sequence in the virus that serves as a *replication origin*. This is important because a virus must override the cellular control signals that would otherwise cause the viral DNA to replicate in pace with the host cell DNA, doubling only once in each cell cycle. We do not yet understand very much about how eucaryotic cells regulate their own DNA synthesis, and the mechanisms used by viruses to escape from this regulation - which are much more accessible to study - provide insights into the host mechanisms.

RNA viruses have particularly specialized requirements for replication, since to reproduce their genomes they must copy RNA molecules, which means polymerizing nucleoside triphosphates on an RNA template. Cells normally do not have enzymes to carry out this reaction, so even the smallest RNA viruses must encode their own RNA-dependent polymerase enzymes in order to replicate. We now look in more detail at the replication mechanisms of the various types of viruses.

Both RNA Viruses and DNA Viruses Replicate Through the Formation of Complementary Strands 53

Like DNA replication, the replication of the genomes of RNA viruses occurs through the formation of complementary strands. For most RNA viruses this process is catalyzed by specific RNA-dependent RNA polymerase enzymes (*replicases*). These enzymes are encoded by the viral RNA chromosome and are often incorporated into the progeny virus particles, so that upon entry of the virus into a cell, they can immediately begin replicating the viral RNA. Replicases are always packaged into the capsid of the so-called *negative-strand RNA viruses,* such as influenza or vesicular stomatitis virus. Negative-strand viruses are

so called because the infecting single strand does not code for protein; instead its complementary strand carries the coding sequences. Thus the infecting strand remains impotent without a preformed replicase. In contrast, the viral RNA of *positive-strand RNA viruses,* such as poliovirus, can serve as mRNA and produce a replicase once it enters the cell; therefore the naked genome itself is infectious.

The synthesis of viral RNA always begins at the 3' end of the RNA template, starting with the synthesis of the 5' end of the new viral RNA molecule and progressing in the 5'-to-3' direction until the 5' end of the template is reached. There are no error-correcting mechanisms for viral RNA synthesis, and error rates are similar to those in DNA transcription (about 1 error in 10^4 nucleotides synthesized). This is not a serious deficiency as long as the RNA chromosome is relatively short; for this reason the genomes of all RNA viruses are small relative to those of the large DNA viruses.

All DNA viruses begin their replication at a replication origin, where special initiator proteins bind and then attract the replication enzymes of the host cell (see Figure 8-34). There are many different replication pathways, however. The complexity of these diverse replication schemes reflects, in part, the problem of replicating the ends of a simple linear DNA molecule, given a DNA polymerase enzyme that cannot begin synthesis without a primer (see pp. 253-254). DNA viruses have solved this problem in a variety of ways: some have circular DNA genomes and thus no ends; others have linear DNA genomes that repeat their terminal sequences or end in loops; while still others have special terminal proteins that serve to prime the DNA polymerase directly (see Figure 6-75).

Viruses Exploit the Intracellular Traffic Machinery of their Host Cells [54]

All viruses have only a limited amount of nucleic acid in their genome, and so they must parasitize host-cell pathways for most of the steps in their reproduction. In fact, because viral products are usually synthesized in large amounts during infection, and because during its life cycle the virus follows a sequential route through the compartments of the host cell, virus-infected cells have served as important models for tracing the pathways of intracellular transport and for studying how essential biosynthetic reactions are compartmentalized in eucaryotic cells.

Enveloped animal viruses, in which the genome is enclosed in a lipid-bilayer membrane, have exploited the compartmentalization of the cell to an especially fine degree. To follow the life cycle of an enveloped virus is to take a tour through the cell. A well-studied example is *Semliki forest virus,* which consists of a single-stranded RNA genome surrounded by a *capsid* formed by a regularly arranged icosahedral (20-faced) shell composed of many copies of one protein (called C protein). The *nucleocapsid* (genome + capsid) is surrounded by a closely apposed lipid bilayer that contains only three types of polypeptide chains, each encoded by the viral RNA. These envelope proteins form heterotrimers that span the lipid bilayer and interact with the C protein of the nucleocapsid, linking the membrane and nucleocapsid together (Figure 6-77). The glycosylated portions of the envelope proteins are always on the outside of the lipid bilayer, and each trimer forms a "spike" that can be seen in electron micrographs projecting outward from the surface of the virus (Figure 6-77C).

Infection is initiated when an envelope protein on the virus binds to a normal cell protein that serves as its receptor on the host-cell plasma membrane. The virus then uses the cell's normal endocytic pathway to enter the cell by receptor-mediated endocytosis and is delivered to early endosomes (discussed in Chapter 13). But instead of being transferred from endosomes to lysosomes, the virus escapes from the endosome by virtue of the special properties of one of its envelope proteins. At the acidic pH of the endosome, this protein causes the viral envelope to fuse with the endosome membrane, releasing the bare nucleocapsid into the cytosol. The nucleocapsid is "uncoated" in the cytosol, releasing the viral RNA, which is then translated by host-cell ribosomes to produce a virus-encoded RNA polymerase. This in turn makes many copies of viral RNA, some of which serve as mRNA molecules to direct the synthesis of the structural proteins of the virus - the capsid C protein and the three envelope proteins.

The newly synthesized capsid and envelope proteins follow separate pathways through the cytoplasm. The envelope proteins, like the plasma membrane proteins of the host cell, are synthesized by ribosomes that are bound to the rough ER; in contrast, the capsid protein, like the cytosolic proteins of the cell, is synthesized by ribosomes that are not membrane bound. The newly synthesized capsid protein binds to the recently replicated viral RNA to form new nucleocapsids. The envelope proteins, in contrast, are inserted into the membrane of the ER, where they are glycosylated, transported to the Golgi apparatus, and then delivered to the plasma membrane (Figure 6-78).

The viral nucleocapsids and envelope proteins finally meet at the plasma membrane. As a result of a specific interaction with a cluster of envelope proteins, the nucleocapsid forms a bud whose envelope contains the envelope proteins embedded in host-cell

lipids. Finally, the bud pinches off and a free virus is released on the outside of the cell. The clustering of envelope proteins as they assemble around the nucleocapsid during viral budding excludes the host plasma membrane proteins from the final virus particle.

Different Enveloped Viruses Bud from Different Cellular Membranes 55

Viral envelope proteins are all transmembrane proteins that are synthesized in the ER. Like other ER proteins, they carry sorting signals that direct them to a particular cell membrane (discussed in Chapter 13). Their final location determines the site of viral budding. Epithelial cell lines, for example, can form polarized cell sheets when they are cultured on an appropriate surface, such as a collagen-coated porous filter. When viruses infect such polarized cells, which maintain distinct domains of apical and basolateral plasma membrane, some of them (such as influenza virus) bud exclusively from the apical plasma membrane, whereas others (such as Semliki forest virus and vesicular stomatitis virus) bud only from the basolateral plasma membrane (Figure 6-79). This polarity of budding reflects the presence on the envelope proteins of distinct apical or basolateral sorting signals, which direct the proteins to only one cell-surface domain; the proteins in turn cause the virus to assemble in that domain.

Other viruses have envelope proteins with different kinds of sorting signals. *Herpes virus,* for example, is a DNA virus that replicates in the nucleus, where its nucleocapsid assembles, and then acquires an envelope by budding through the inner nuclear membrane into the ER lumen; the envelope proteins therefore must be specifically transported from the ER membrane to the inner nuclear membrane, probably via the lipid bilayer that surrounds the nuclear pores. *Flavivirus,* in contrast, buds directly into the ER lumen, and *bunyavirus* buds into the Golgi apparatus, indicating that their envelope proteins carry signals for retention in the ER and Golgi membranes, respectively. After budding, the enveloped herpes virus, flavivirus, and bunyavirus particles become soluble in the ER and Golgi lumen, and they move outward toward the cell surface exactly as if they were secreted proteins; in the *trans* Golgi network they are incorporated into transport vesicles and secreted from the cell by the constitutive secretory pathway (discussed in Chapter 13).

Viral Chromosomes Can Integrate into Host Chromosomes 56

The end result of the entry of a viral chromosome into a cell is not always its immediate multiplication to produce large numbers of progeny. Many viruses enter a *latent* state, in which their genomes are present but inactive in the cell and no progeny are produced. Viral latency was discovered when it was found that exposure to ultraviolet light induced many apparently uninfected bacteria to produce progeny bacteriophages. Subsequent experiments showed that these *lysogenic bacteria* carry in their chromosomes a dormant but complete viral chromosome. Such integrated viral chromosomes are called proviruses.

Bacteriophages that can integrate their DNA into bacterial chromosomes are known as *temperate bacteriophages.* The prototypic example is the bacteriophage lambda, discussed earlier. When lambda infects a suitable *E. coli* host cell, it normally multiplies to produce several hundred progeny particles, which are released when the bacterial cell lyses; this is called a *lytic infection.* More rarely, the free ends of the linear infecting DNA molecules join to form a DNA circle that becomes integrated into the circular host *E. coli* chromosome by a site-specific recombination event. The resulting lysogenic bacterium, carrying the proviral lambda chromosome, multiples normally until it is subjected to an environmental insult, such as exposure to ultraviolet light or ionizing radiation. The resulting cell debilitation induces the integrated provirus to leave the host chromosome and begin a normal cycle of viral replication. In this way the integrated provirus need not perish with its damaged host cell but has a chance to escape to other *E. coli* cells (Figure 6-80).

The Continuous Synthesis of Some Viral Proteins Can Make Cells Cancerous 57

Animal cells, like bacteria, can offer viruses an alternative to lytic growth. *Permissive* cells permit DNA viruses to multiply lytically and kill the cell. *Nonpermissive* cells may allow the DNA virus to enter but not to replicate lytically; in a small percentage of such cells the viral chromosome either becomes integrated into the host cell genome, where it is replicated along with the host chromosomes, or forms a plasmida circular DNA moleculethat replicates in a controlled fashion without killing the cell. Such nonpermissive infections sometimes result in a genetic change in the host cell, causing it to proliferate in an ill-controlled way and thus transforming it into its cancerous equivalent. In this case the DNA virus is called a *DNA tumor virus* and the process is called virus-mediated *neoplastic transformation.* The most extensively studied DNA tumor viruses are two papovaviruses, SV40 and polyoma. Their transforming ability has been traced to several viral proteins that cooperate to stimulate quiescent cells to proliferate - that is, they drive the cells from G_0 into S phase. In permissive cells the shift to S phase (the phase of the cell cycle where DNA is synthesized) provides the virus with all of the host-cell replication enzymes required

for viral DNA synthesis. When a provirus happens to make these viral proteins in a nonpermissive cell, they can override some of the normal growth control mechanisms in the cell and its progeny. By this means some DNA tumor viruses that infect humans are known to contribute to the development of some types of human cancers (although the great majority of human cancers are thought not to involve tumor viruses).

RNA Tumor Viruses Are Retroviruses <u>58</u>

For one group of RNA viruses, the so-called *RNA tumor viruses,* the infection of a permissive cell often leads simultaneously to a nonlethal release of progeny virus from the cell surface by budding and a permanent genetic change in the infected cell that makes it cancerous. How RNA virus infection could lead to a permanent genetic alteration was unclear until the discovery of the enzyme *reverse transcriptase,* which transcribes the infecting RNA chains of these viruses into complementary DNA molecules that integrate into the host cell genome. RNA tumor viruses - which include the first well-known tumor virus, the Rous sarcoma virus - are members of a large class of viruses known as retroviruses. These viruses are so named because as part of their normal life cycle they reverse the normal process in which DNA is transcribed into RNA.

The enzyme reverse transcriptase is an unusual DNA polymerase that uses either RNA or DNA as a template (<u>Figure 6-81</u>); it is encoded by the retrovirus RNA and is packaged inside each viral capsid during the production of new virus particles. When the single-stranded RNA of the retrovirus enters a cell, the reverse transcriptase brought in with the capsid first makes a DNA copy of the RNA strand to form a DNA-RNA hybrid helix, which is then used by the same enzyme to make a double helix with two DNA strands. The two ends of the linear viral DNA molecule are recognized by a virus-encoded integrase that catalyzes the insertion of the viral DNA into virtually any site on a host-cell chromosome (see <u>Figure 6-70</u>). The next step in the infectious process is transcription of the integrated viral DNA by host-cell RNA polymerase, producing large numbers of viral RNA molecules identical to the original infecting genome. Finally, these RNA molecules are translated to produce the capsid, envelope, and reverse transcriptase proteins that are assembled with the RNA into new enveloped virus particles, which bud from the plasma membrane (<u>Figure 6-82</u>).

Both RNA and DNA tumor viruses transform cells because the permanent presence of the viral DNA in the cell causes the synthesis of new proteins that alter the control of host-cell proliferation. The genes that code for such proteins are called *oncogenes.* Unlike DNA tumor viruses, whose oncogenes typically encode normal viral proteins essential for viral multiplication, the oncogenes carried by RNA tumor viruses are modified versions of normal host-cell genes that are not required for viral replication. Since only a limited amount of RNA can be packed into the capsid of a retrovirus, the acquired oncogene sequences often replace an essential part of the retroviral genome. In Chapters 15 and 24 we discuss how viral oncogenes have provided important clues to the causes and nature of cancer, as well as to the normal mechanisms that control cell growth and division in multicellular animals. We also discuss how the random integration of viral DNA into genomes can alter normal genes and thereby affect cell behavior (see <u>Figure 24-24</u>).

The Virus That Causes AIDS Is a Retrovirus <u>59</u>

In 1982 physicians first became aware of a new sexually transmitted disease that was associated with an unusual form of cancer (Kaposi's sarcoma) and a variety of unusual infections. Because both of these problems reflect a severe deficiency in the immune system - specifically in helper T lymphocytes - the disease was named *acquired immune deficiency syndrome (AIDS).* By culturing lymphocytes from patients with an early stage of the disease, a retrovirus was isolated that is now known to be the causative agent of AIDS, which has become a rapidly spreading epidemic that threatens to kill millions of people worldwide.

The retrovirus, called *human immunodeficiency virus (HIV),* enters helper T lymphocytes by first binding to a functionally important plasma membrane protein called CD4 (discussed in <u>Chapter 23</u>). There are two features of HIV that make it especially deadly. First, it eventually kills the helper T cells that it infects rather than living in symbiosis with them, as do most other retroviruses, and helper T cells are vitally important in defending us against infection. Second, the provirus tends to persist in a latent state in the chromosomes of an infected cell without producing virus until it is activated by an unknown rare event; this ability to hide greatly complicates any attempt to treat the infection with antiviral drugs.

Much current research on AIDS is aimed at understanding the life cycle of HIV. The complete nucleotide sequence of the viral RNA has been determined. This has made it possible to identify and study each of the proteins that it encodes. The three-dimensional structure of its reverse transcriptase (see <u>Figure 6-81</u>) is being used to help design new drugs that inhibit the enzyme. The nine genes of this retrovirus are displayed on the HIV genetic map in <u>Figure 6-83</u>.

Some Transposable Elements Are Close Relatives of Retroviruses <u>60</u>

Because many viruses can move into and out of their host chromosomes, any large genome is likely to contain a number of different proviruses. Most genomes are also likely to house a variety of mobile DNA sequences that do not form viral particles and cannot leave the cell. Such transposable elements range in length from a few hundred to tens of thousands of base pairs, and they are usually present in multiple copies per cell. One can consider these elements as tiny parasites hidden in chromosomes. Each transposable element is occasionally activated to move to another DNA site in the same cell by a process called *transposition,* catalyzed by its own site-specific recombination enzyme. These integrases, also referred to as *transposases,* are often encoded in the DNA of the element itself. Since most transposable elements move only very rarely (once in 10^5 cell generations for many elements in bacteria), it is often difficult to distinguish them from nonmobile parts of the chromosome. It is not known what suddenly triggers their movement.

Transposition can occur by a variety of mechanisms. One large family of transposable elements uses a mechanism that is indistinguishable from part of a retrovirus life cycle. These elements, called *retrotransposons,* are present in organisms as diverse as yeasts, flies, and mammals. One of the best-understood retrotransposons is the so-called Ty1 element of yeasts. The first step in its transposition is the transcription of the entire transposable element, producing an RNA copy of the element that is more than 5000 nucleotides long. This transcript encodes a reverse transcriptase enzyme that makes a double-stranded DNA copy of the RNA molecule via a RNA/DNA hybrid intermediate, precisely mimicking the early stages of infection by a retrovirus (see <u>Figure 6-82</u>). The analogy continues as the linear DNA molecule uses an integrase to integrate into a randomly selected site on the chromosome. Although the resemblance to a retrovirus is striking, unlike a retrovirus, the Ty1 element does not have a functional protein coat and therefore can only move within a single cell and its progeny.

Other Transposable Elements Transfer Themselves Directly from One Site in the Genome to Another <u>61</u>

Unlike retrotransposons, many transposable elements rarely exist free of the host chromosome; the transposases that catalyze their movement can act on the DNA of the element while it is still integrated in the host genome. The transposase binds to a short sequence that is repeated in reverse orientation at each end of the element, thereby holding these two ends close together while catalyzing the subsequent recombination event. The mechanism is closely related to that used by the retrovirus integrase (see <u>Figure 6-70</u>). For some transposable elements the transposition mechanism differs only in that the linear DNA molecule to be integrated must be cut out of a much longer DNA molecule, leaving a break in the vacated chromosome (<u>Figure 6-84</u>). This break is subsequently resealed, but in the process the DNA sequence is often altered, resulting in a mutation at the old chromosomal site.

Other transposable elements replicate when they move. In the best-studied example, a covalent connection is first made between the transposable element and a randomly selected target site; this connection then triggers a localized synthesis of DNA that results in one copy of the replicated transposable element being inserted at a new chromosomal site, while the other copy remains at the old one (<u>Figure 6-85</u>). The mechanism is closely related to the nonreplicative mechanism just described, and it starts in nearly the same way; indeed, some transposable elements can move by either pathway.

In addition to moving themselves, all types of transposable elements occasionally move or rearrange neighboring DNA sequences of the host genome. They frequently cause deletions of adjacent nucleotide sequences, for example, or carry them to another site. The presence of transposable elements makes the arrangement of the DNA sequences in chromosomes much less stable than previously thought, and it is likely that they have been responsible for many important evolutionary changes in genomes (discussed in <u>Chapter 8</u>).

Are the transposable elements also of evolutionary importance as the most ancient ancestors of viruses? Although the precursors of retroviruses were almost certainly retrotransposons, all present-day transposable elements rely heavily on DNA-based reaction mechanisms. But very early cells are thought to have had RNA rather than DNA genomes, so we must look to RNA-based mechanisms for the ultimate origin of viruses.

Most Viruses Probably Evolved from Plasmids <u>62</u>

Even the largest viruses depend heavily on their host cells for biosynthesis; no known virus makes its own ribosomes or generates the ATP it requires, for example. Clearly, therefore, cells must have evolved before viruses. The precursors of the first viruses were probably small nucleic acid fragments that developed the ability to multiply independently of the chromosomes of their host cells. Such independently replicating elements, called plasmids, can replicate indefinitely outside the host

chromosome. Plasmids occur in both DNA and RNA forms, and, like viruses, they contain a special nucleotide sequence that serves as an origin of replication. Unlike viruses, however, they cannot make a protein coat and therefore cannot move from cell to cell in this way.

The first RNA plasmids may have resembled the *viroids* found in some plant cells. These small RNA circles, only 300 to 400 nucleotides long, are replicated despite the fact that they do not code for any protein. Having no protein coat, viroids exist as naked RNA molecules and pass from plant to plant only when the surfaces of both donor and recipient cells are damaged so that there is no membrane barrier for the viroid to pass. Under the pressure of natural selection, such independently replicating elements could be expected to acquire nucleotide sequences from the host cell that would facilitate their own multiplication, including sequences that code for proteins. Some present-day plasmids are indeed quite complex, encoding proteins and RNA molecules that regulate their replication, as well as proteins that control their partitioning into daughter cells. The largest known plasmids are double-stranded DNA circles more than 100,000 base pairs long.

The first virus probably appeared when an RNA plasmid acquired a gene coding for a capsid protein. But a capsid can enclose only a limited amount of nucleic acid; therefore a virus is limited in the number of genes it can contain. Forced to make optimal use of their limited genomes, some small viruses evolved *overlapping genes,* in which part of the nucleotide sequence encoding one protein is used (in the same or a different reading frame) to encode a second protein. Other viruses evolved larger capsids and consequently could accommodate more genes.

With their unique ability to transfer nucleic acid sequences across species barriers, viruses have almost certainly played an important part in the evolution of the organisms they infect. Many recombine frequently with their host-cell genome and with one another. In this way they can pick up small pieces of host chromosome at random and carry them to different cells or organisms. Moreover, integrated copies of viral DNA (proviruses) have become a normal part of the genome of most organisms. Examples of such proviruses include the lambda family of bacteriophages and the so-called endogenous retroviruses found in numerous copies in vertebrate genomes. The integrated viral DNA can become altered so that it cannot produce a complete virus but can still encode proteins, some of which may be useful to the host cell. Therefore, viruses, like sexual reproduction, can speed up evolution by promoting the mixing of gene pools.

The process in which DNA sequences are transferred between different host-cell genomes by means of a virus is called *DNA transduction,* and several viruses that transduce DNA with particularly high frequencies are commonly used by researchers to move genes from one cell to another. Viruses and their close relatives - plasmids and transposable elements - have also been important to cell biology in many other ways. Because of their relative simplicity, for example, studies of their reproduction have progressed unusually rapidly and have illuminated many of the basic genetic mechanisms in cells. In addition, both viruses and plasmids have been crucial elements in the development of the recombinant DNA technologies that will be described in Chapter 7.

Summary

Viruses are infectious particles that consist of a DNA or an RNA molecule (the viral genome) packaged in a protein capsid, which in the enveloped viruses is surrounded by a lipid-bilayer-based membrane. Both the structure of the viral genome and its mode of replication vary widely among viruses. A virus can multiply only inside a host cell, whose genetic mechanisms it subverts for its own reproduction. A common outcome of a viral infection is the lysis of the infected cell and release of infectious viral particles. In some cases, however, the viral chromosome instead integrates into a host-cell chromosome, where it is replicated as a provirus along with the host genome. Many viruses are thought to have evolved from plasmids, which are self-replicating DNA or RNA molecules that lack the ability to wrap themselves in a protein coat.

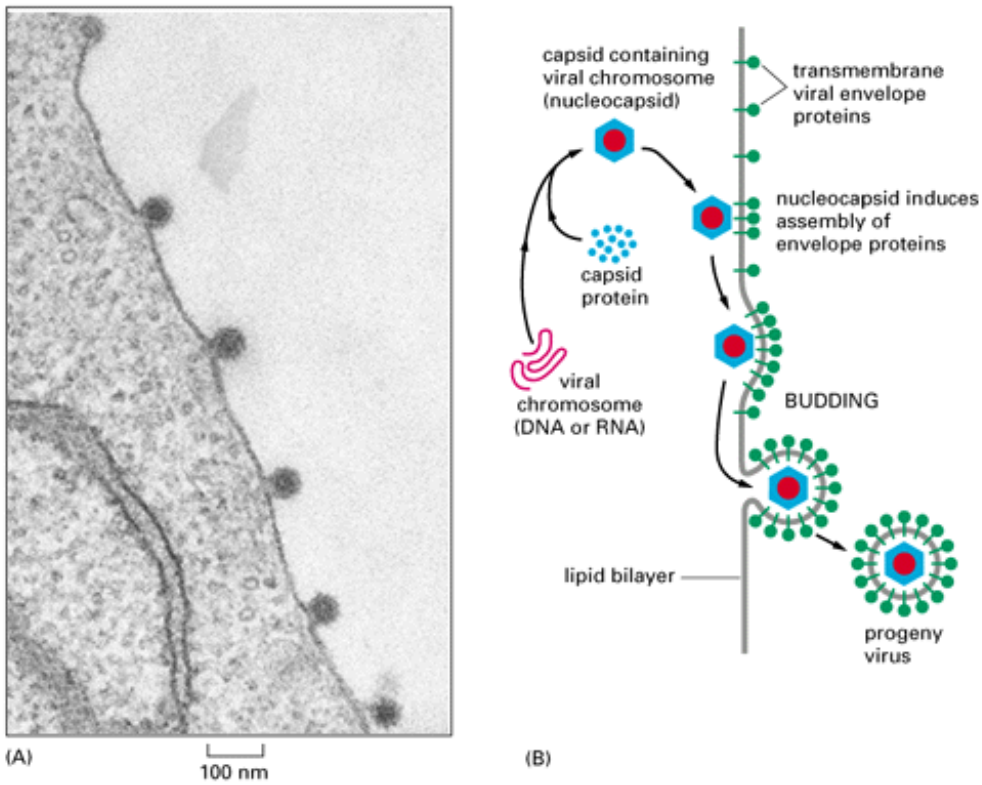
Transposable elements are DNA sequences that differ from viruses in being able to multiply only in their host cell and its progeny; like plasmids, they cannot exist stably outside of cells. Unlike plasmids, they normally replicate only as an integral part of a chromosome. Some transposable elements, however, are closely related to retroviruses and can move from place to place in the genome by the reverse transcription of an RNA intermediate. Although both viruses and transposable elements can be viewed as parasites, many of the DNA sequence rearrangements they cause are important for the evolution of cells and organisms.
Figure 6-71. The simplest of all viral life cycles. The hypothetical virus shown consists of a small double-stranded DNA molecule that codes for only a single viral capsid protein. No known virus is this simple.
Figure 6-72. The capsids of some viruses, all shown at the same scale. (A) Tomato bushy stunt virus; (B) poliovirus; (C) simian virus 40 (SV40); (D) satellite tobacco necrosis virus. The structures of all of these capsids have been determined by x-ray crystallography and are known in atomic detail. (Courtesy of Robert Grant, Stephan Crainic, and James M. Hogle.)


Figure 6-73. Acquisition of a viral envelope. (A) Electron micrograph of a thin section of an animal cell from which several copies of an enveloped virus (Semliki forest virus) are budding. (B) Schematic view of the envelope assembly and budding process. Whereas the lipid bilayer that surrounds the capsid is parasitized directly from the plasma membrane of the host cell, the only proteins in this lipid bilayer are those encoded by the viral genome. (A, courtesy of M. Olsen and G. Griffiths.)
Figure 6-74. The coats of viruses. These electron micrographs of negatively stained virus particles are all at the same scale. (A) *Bacteriophage T4,* a large DNA-containing virus that infects *E. coli.* The DNA is stored in the bacteriophage head and injected into the bacterium through the cylindrical tail. (B) *Potato virus X,* a filamentous plant virus that contains an RNA genome. (C) *Adenovirus,* a DNA-containing virus that can infect human cells. The protein capsid forms the outer surface of this virus. (D) *Influenza virus,* a large RNA-containing animal virus whose protein capsid is further enclosed in a lipid-bilayer-based envelope containing protruding spikes of viral glycoprotein. (A, courtesy of James Paulson; B, courtesy of Graham Hills; C, courtesy of Mei Lie Wong; D, courtesy of R.C. Williams and H.W. Fisher.)
Figure 6-75. Schematic drawings of several types of viral genomes. The smallest viruses contain only a few genes and can have an RNA or a DNA genome; the largest viruses contain hundreds of genes and have a double-stranded DNA genome. Some examples of these types of viruses are as follows: *single-stranded RNA*tobacco mosaic virus, bacteriophage R17, poliovirus; *double-stranded RNA*reovirus; *single-stranded DNA*parvovirus; *single-stranded circular DNA*M13 and fX174 bacteriophages; *double-stranded circular DNA*SV40 and polyomaviruses; *double-stranded DNA*T4 bacteriophage, herpes virus; *double-stranded DNA with covalently linked terminal protein*adenovirus; *double-stranded DNA with covalently sealed ends*poxvirus. The peculiar ends (as well as the circular forms) overcome the difficulty of replicating the last few nucleotides at the end of a DNA chain (see pp. 388 and 364).
Figure 6-76. The T4 bacteriophage chromosome, showing the positions of the more than 30 genes involved in T4 DNA

replication. The genome of bacteriophage T4 consists of 169,000 nucleotide pairs and encodes about 300 different proteins.

Figure 6-81. Reverse transcriptase. (A) The three-dimensional structure of the enzyme from HIV-1 (the AIDS virus), determined by x-ray crystallography; (B) a schematic view of a model for its activity on an RNA template. Note that the polymerase domain (*yellow*) has a covalently attached RNAse domain (*red*) that degrades an RNA strand in an RNA/DNA helix. This activity helps the polymerase convert the initial hybrid helix into a DNA double helix. (A, courtesy of Tom Steitz; B, adapted from L.A. Kohlstaedt et al. , *Science* 256:1783-1790, 1992. © 1992 the AAAS.)
Figure 6-82. The life cycle of a retrovirus. The retrovirus genome consists of an RNA molecule of about 8500 nucleotides; two such molecules are packaged into each viral particle. The enzyme *reverse transcriptase* first makes a DNA copy of the viral RNA molecule and then a second DNA strand, generating a double-stranded DNA copy of the RNA genome. The integration of this DNA double helix into the host chromosome, catalyzed by the viral integrase, is required for the synthesis of new viral RNA molecules by the host-cell RNA polymerase.
Figure 6-83. A map of the HIV genome. The genome consists of about 9000 nucleotides and contains nine genes, whose locations are shown in *green* and *red*. Three of the genes (*green*) are common to all retroviruses: *gag* encodes capsid proteins, *env* encodes envelope proteins, and *pol* encodes both the reverse transcriptase (see Figure 6-81) and the integrase (see Figure 6-70) proteins. The HIV genome is unusually complex, since it contains six small genes (in *red*) in addition to the three (in *green*) that are normally required for the retrovirus life cycle. At least some of these small genes encode proteins that regulate viral gene expression, and it is tempting to speculate that it is this extra complexity that makes HIV so deadly. As indicated by the *red lines,* RNA splicing (see Figure 8-7) is required to produce the Rev and Tat proteins.
Figure 6-84. The direct movement of a transposable element from one chromosomal site to another. Transposable elements of this type can be recognized by the "inverted repeat DNA sequences" (*orange*) at their ends. Experiments show that these sequences, which can be as short as 20 nucleotides, are all that is necessary for the DNA between them to be transposed by the particular transposase enzyme associated with the element. The mechanism shown here is closely related to that used by a retrovirus to integrate its double-stranded DNA into a chromosome (compare with Figure 6-70). Although the gap left in donor chromosome is resealed, the process often alters the DNA sequence, causing a mutation at the donor site (not shown).

new copy inserted
Figure 6-85. The replicative movement of a transposable element within a chromosome. The element shown replicates during transposition, its movement occurring without it being excised from its original site. The two inverted repeat DNA sequences that commonly flank the two ends of transposable elements are shown in *orange*. At the start of transposition the transposase cuts one of the two DNA strands at each end of the element, and the element then serves as a template for DNA synthesis, which begins by the addition of nucleotides to the 3' ends of chromosomal DNA sequences. Many details are known, but the process is too complex to be illustrated here.

7. Recombinant DNA Technology

Introduction

Until the early 1970s DNA was the most difficult cellular molecule for the biochemist to analyze. Enormously long and chemically monotonous, the nucleotide sequence of DNA could be approached only by indirect means, such as by protein or RNA sequencing or by genetic analysis. Today the situation has changed entirely. From being the most difficult macromolecule of the cell to analyze, DNA has become the easiest. It is now possible to excise a specific region of DNA, to produce a virtually unlimited number of copies of it, and to determine the sequence of its nucleotides at a rate of hundreds of nucleotides a day. By variations of the same techniques, an isolated gene can be altered (engineered) at will and transferred back into cells in culture. With more difficulty, the redesigned gene can be inserted into the germ line of an animal or plant, so as to become a functional and heritable part of the organism's genome.

These technical breakthroughs have had a dramatic impact on all aspects of cell biology by allowing the study of cells and their macromolecules in previously unimagined ways. They have led to the discovery of whole new classes of genes and proteins and have revealed that many proteins have been much more highly conserved in evolution than had been suspected. They have provided new means to determine the functions of proteins and of individual domains within proteins, revealing a host of unexpected relationships between them. By making available large amounts of any protein, they have shown the way to efficient mass production of protein hormones and vaccines. Finally, by allowing the regulatory regions of genes to be dissected, they have provided biologists with an important tool for unraveling the complex mechanisms by which eucaryotic gene expression is regulated.

Recombinant DNA technology comprises a mixture of techniques, some new and some borrowed from other fields such as microbial genetics (Table7-1). The most important of these techniques are the following:

1. Cleavage of DNA at specific sites by *restriction nucleases,* which greatly facilitates the isolation and manipulation of individual genes.

2. Rapid *sequencing* of all the nucleotides in a purified DNA fragment, which makes it possible to determine the boundaries of a gene and the amino acid sequence it encodes.

3. *Nucleic acid hybridization,* which makes it possible to find a specific sequence of DNA or RNA with great accuracy and sensitivity on the basis of its ability to bind a complementary nucleic acid sequence.

4. *DNA cloning,* whereby a single DNA molecule can be copied to generate many billions of identical molecules.

5. *DNA engineering,* by which DNA sequences are altered to make modified versions of genes, which are reinserted back into cells or organisms.

In this chapter we explain how recombinant DNA technology has generated the new experimental approaches that have revolutionized cell biology.

Table 7-1. Some Major Steps in the Development of Recombinant DNA Technology

---

1869	**Miescher** isolated DNA for the first time.
1944	**Avery** provided evidence that DNA, rather than protein, carries the genetic information during bacterial transformation.
1953	**Watson and Crick** proposed the double-helix model for DNA structure based on x-ray results of **Franklin and Wilkins.**
1957	**Kornberg** discovered DNA polymerase, the enzyme now used to produce labeled DNA probes.
1961	**Marmur and Doty** discovered DNA renaturation, establishing the specificity and feasibility of nucleic acid hybridization reactions.
1962	**Arber** provided the first evidence for the existence of DNA restriction nucleases, leading to their later purification and use in DNA sequence characterization by **Nathans and H. Smith**.
1966	**Nirenberg**, **Ochoa**, and **Khorana** elucidated the genetic code.
1967	**Gellert** discovered DNA ligase, the enzyme used to join DNA fragments together.
1972-1973	DNA cloning techniques were developed by the laboratories of **Boyer**, **Cohen**, **Berg**, and their colleagues at Stanford University and the University of California at San Francisco.
1975	**Southern** developed gel-transfer hybridization for the detection of specific DNA sequences.
1975-1977	**Sanger and Barrell** and **Maxam and Gilbert** developed rapid DNA-sequencing methods.
1981-1982	**Palmiter and Brinster** produced transgenic mice; **Spradling and Rubin** produced transgenic fruit flies.
1985	**Mullis** and co-workers invented the polymerase chain reaction (PCR).

The Fragmentation, Separation, and Sequencing of DNA Molecules [1]

Introduction

Before the 1970s the goal of isolating a single gene from a large chromosome seemed unattainable. Unlike a protein, a gene does not exist as a discrete entity in cells, but rather as a small region of a much larger DNA molecule. Although the DNA molecules in a cell can be randomly broken into small pieces by mechanical force, a fragment containing a single gene in a mammalian genome would still be only one among a hundred thousand or more DNA fragments, indistinguishable in their average size. How could such a gene be purified? Since all DNA molecules consist of an approximately equal mixture of the same four nucleotides, they cannot be readily separated, as proteins can, on the basis of their different charges and binding properties. Moreover, even if a purification scheme could be devised, vast amounts of DNA would be needed to yield enough of any particular gene to be useful for further experiments.

The solution to all of these problems began to emerge with the discovery of *restriction nucleases*. These enzymes, which can be purified from bacteria, cut the DNA double helix at specific sites defined by the local nucleotide sequence, producing double-stranded DNA fragments of strictly defined sizes. Different species of bacteria make restriction nucleases with different sequence specificities, and it is relatively simple to find a restriction nuclease that will create a DNA fragment that includes a particular gene. The size of the DNA fragment can then be used as a basis for partially purifying the gene from a mixture. Most important, the DNA fragment usually serves as the starting material for the production of the highly purified gene in unlimited amounts by *DNA cloning*.

We begin this section by discussing how restriction nucleases are used to produce specific DNA fragments and how these (and other) DNA molecules are separated according to their size. We then explain how, after the purification and amplification of a DNA fragment by DNA cloning, this DNA can be *sequenced* to determine the order of its nucleotides.

Restriction Nucleases Hydrolyze DNA Molecules at Specific Nucleotide Sequences [2]

Many bacteria make restriction nucleases, which protect the bacterial cell from viruses by degrading the viral DNA. Each such nuclease recognizes a specific sequence of four to eight nucleotides in DNA. These sequences, where they occur in the genome of the bacterium itself, are protected from cleavage by methylation at an A or a C residue; where the sequences occur in foreign DNA, they are generally not methylated and so are cleaved by the restriction nucleases. Large numbers of restriction nucleases have been purified from various species of bacteria; more than 100, most of which recognize different nucleotide sequences, are now available commercially.

Some restriction nucleases produce staggered cuts, which leave short single-stranded tails at the two ends of each fragment (Figure7-1). Ends of this type are known as *cohesive ends,* as each tail can form complementary base pairs with the tail at any other end produced by the same enzyme (Figure7-2). The cohesive ends generated by restriction enzymes allow any two DNA fragments to be easily joined together, as long as the fragments were generated with the same restriction nuclease (or with another nuclease that produces the same cohesive ends). DNA molecules produced by splicing together two or more DNA fragments in this way are called *recombinant DNA molecules;* they have made possible many new types of cell biological studies.

Restriction Maps Show the Distribution of Short Marker Nucleotide Sequences Along a Chromosome 3

A particular restriction nuclease will cut any double-helical DNA molecule extracted from a cell into a series of specific DNA fragments (known as *restriction fragments*). By comparing the sizes of the DNA fragments produced from a particular genetic region after treatment with a combination of different restriction nucleases, a restriction map of that region can be constructed showing the location of each cutting (restriction) site in relation to neighboring restriction sites (Figure 7-3). The different short DNA sequences recognized by different restriction nucleases serve as convenient markers, and the restriction map reflects their arrangement in the region. This allows one to compare the same region of DNA in different individuals (by comparing their restriction maps) without having to determine the nucleotide sequences in detail. By comparing the restriction maps illustrated in Figure 7-4, for example, we know that the chromosomal regions that code for hemoglobin chains in humans and various other primates have remained largely unchanged during the 5 to 10 million years since these species first diverged. Restriction maps are also used in DNA cloning and DNA engineering, where they make it possible to locate a gene of interest on a particular restriction fragment and thus facilitate its isolation.

Gel Electrophoresis Separates DNA Molecules of Different Sizes 4

In the early 1970s it was found that the length and purity of DNA molecules could be accurately determined by the same types of gel electrophoresis methods that had proved so useful in the analysis of proteins. The procedure is actually simpler than for proteins: because each nucleotide in a nucleic acid molecule already carries a single negative charge, there is no need to add the negatively charged detergent SDS that is required to make protein molecules move uniformly toward the positive electrode. For DNA fragments less than 500 nucleotides long, specially designed polyacrylamide gels allow molecules that differ in length by as little as a single nucleotide to be separated from each other (Figure7-5 A). The pores in polyacrylamide gels, however, are too small to permit very large DNA molecules to pass; to separate these by size, the much more porous gels formed by dilute solutions of agarose (a polysaccharide isolated from seaweed) are used (Figure 7-5B). These DNA separation methods are widely used for both analytical and preparative purposes.

A variation of agarose gel electrophoresis, called *pulsed-field gel electrophoresis,* makes it possible to separate even extremely long DNA molecules. Ordinary gel electrophoresis fails to separate such molecules because the steady electric field stretches them out so that they travel end-first through the gel in snakelike configurations at a rate that is independent of their length. In pulsed-field gel electrophoresis, by contrast, the direction of the electric field is changed periodically, which forces the molecules to reorient before continuing to move snakelike through the gel. This reorientation takes much more time for larger molecules, so that progressively longer molecules move more and more slowly. As a consequence, even entire bacterial or yeast chromosomes separate into discrete bands in pulsed-field gels and so can be sorted and identified on the basis of their size (Figure 7-5C). Although a typical mammalian chromosome of 10^8 base pairs is too large to be sorted even in this way, large subregions of these chromosomes are readily separated and identified if the chromosomal DNA is first cut with a restriction nuclease selected to recognize sequences that occur only extremely rarely (once every 10^6 to 10^7 nucleotide pairs, for example).

The DNA bands on agarose or polyacrylamide gels are invisible unless the DNA is labeled or stained in some way. One sensitive method of staining DNA is to expose it to the dye *ethidium bromide,* which fluoresces under ultraviolet light when it is bound to DNA (see Figure 7-5B and C). An even more sensitive detection method involves incorporating a radioisotope into the DNA molecules before electrophoresis; 32P is often used as it can be incorporated into DNA phosphates and emits an energetic

b-particle that is easily detected by autoradiography (Figure 7-5A).

Purified DNA Molecules Can Be Specifically Labeled with Radioisotopes or Chemical Markers *in Vitro* 5

Two procedures are widely used to add distinct labels to isolated DNA molecules. In the first the DNA is copied by an *E. coli* enzyme, *DNA polymerase I,* in the presence of nucleotides that are either radioactive (usually labeled with 32P) or chemically tagged (Figure 7-6A). In this way "DNA probes" containing many labeled nucleotides can be produced for nucleic acid hybridization reactions (see below). The second procedure uses the bacteriophage enzyme *polynucleotide kinase* to transfer a single 32P-labeled phosphate from ATP to the 5' end of each DNA chain (Figure 7-6B). Because only one 32P atom is incorporated by the kinase into each DNA strand, the DNA molecules labeled in this way are often not radioactive enough to be used as DNA probes; because they are labeled at only one end, however, they are invaluable for DNA sequencing and DNA footprinting, as we see next.

Isolated DNA Fragments Can Be Rapidly Sequenced 6

In the late 1970s methods were developed that allow the nucleotide sequence of any purified DNA fragment to be determined simply and quickly. They have made it possible to determine the complete DNA sequences of thousands of genes, including those coding for such well-known proteins as insulin, hemoglobin, interferon, and cytochrome c. The volume of DNA sequence information is already so large (many tens of millions of nucleotides) that computers must be used to store and analyze it. Several continuous stretches of DNA sequence have been determined that each contain more than 10^5 nucleotide pairs; these include the entire genomes of the Epstein-Barr virus (which infects humans and causes infectious mononucleosis) and of a plant chloroplast, as well as an entire chromosome of yeast. Two powerful DNA sequencing methods were originally developed: the principle underlying the *chemical method* is illustrated in Figure 7-7, and the *enzymatic method* is explained in Figure7-8. The latter method, which is based on *in vitro* DNA synthesis carried out in the presence of chain-terminating nucleoside triphosphates, has now become the standard procedure for sequencing DNA.

DNA sequencing methods are so rapid and reliable that the easiest and most accurate way to determine the amino acid sequence of a protein is to determine the nucleotide sequence of its gene: a cDNA clone is made from the appropriate mRNA (see below), its nucleotide sequence is determined, and the genetic code is then used as a dictionary to convert this sequence back to an amino acid sequence. Although in principle there are six different reading frames in which a DNA sequence can be translated into protein (three on each strand), the correct one is generally recognizable as the only one lacking frequent *stop codons* (Figure 7-9). A limited amount of amino acid sequence can be determined from the purified protein to confirm the sequence determined from the DNA.

As techniques for DNA sequencing have improved, scientists have begun to envisage the possibility of determining the entire DNA sequence of a human genome of 3 x 10^9 nucleotides. Because this sequence specifies all of the possible RNA and protein molecules that are used to construct the body, knowledge of it will provide us with a "dictionary of the human being," which will greatly expedite future studies of human cells and tissues. DNA sequencing on such a scale will require the development of highly automated methods that will lower the current cost of DNA sequencing by at least fivefold.

DNA Footprinting Reveals the Sites Where Proteins Bind on a DNA Molecule 7

A modification of the chemical method for DNA sequencing can be used to determine the nucleotide sequences recognized by DNA-binding proteins. Some of these proteins play a central part in determining which genes are active in a particular cell by binding to regulatory DNA sequences, which are usually located outside the coding regions of a gene. In analyzing how such a protein functions, it is important to identify the specific sequences to which it binds. A method used for this purpose is called DNA footprinting. First, a pure DNA fragment that is labeled at one end with 32P is isolated (see Figure7-6B); this molecule is then cleaved with a nuclease or a chemical that makes random single-stranded cuts in the DNA. After the DNA molecule is denatured to separate its two strands, the resultant subfragments from the labeled strand are separated on a gel and detected by autoradiography. The pattern of bands from DNA cut in the presence of a DNA-binding protein is compared with that from DNA cut in its absence. When the protein is present, it covers the nucleotides at its binding site and protects their phosphodiester bonds from cleavage. As a result, the labeled fragments that terminate in the binding site will be missing, leaving a gap in the gel pattern called a "footprint" (Figure7-10A). The footprint of a DNA-binding protein that activates the transcription of a eucaryotic gene is shown in Figure7-10B.

Summary

Recombinant DNA technology has revolutionized the study of the cell. The development of this technology was neither planned nor anticipated. Instead, steady advances in the ability of researchers to manipulate DNA molecules were made on many different fronts until the combination of techniques became powerful enough to allow researchers to pick out any gene at will and, after an amplification step, to determine the exact molecular structure of both the gene and its products. Crucial elements in this technology are the ability to fragment chromosomes into DNA molecules with specific ends and the means to separate and sequence the resulting DNA fragments. The fragmentation step is carried out by proteins that are normally produced by bacteria in order to destroy invading DNA molecules. These proteins, called restriction nucleases, are purified and used to cut the DNA double helix at a specific short nucleotide sequence. The resulting DNA fragments can be separated from one another according to their size by using electrophoresis to move the mixture of fragments through the pores of a gel. Under certain conditions, even DNA molecules that differ in length by only a single nucleotide can be detected as separate bands. DNA sequencing takes advantage of this powerful separation method: after electrophoresis, the sequence of nucleotides in a DNA molecule is determined from the pattern of labeled DNA bands observed when a fixed end of one of its DNA strands has been labeled and the other end terminates at a randomly selected nucleotide of a single type (A, G, C, or T).
Figure 7-1. The DNA nucleotide sequences recognized by four widely used restriction nucleases. As in the examples shown, such sequences are often six base pairs long and "palindromic" (that is, the nucleotide sequence is the same if the helix is turned by 180 degrees around the center of the short region of helix that is recognized). The enzymes cut the two strands of DNA at or near the recognition sequence. For some enzymes, such as Hpa I, the cleavage leaves blunt ends; for others, such as Eco RI, Hind III, and Pst I, the cleavage is staggered and creates cohesive ends. Restriction nucleases are obtained from various species of bacteria: Hpa I is from *Hemophilus parainfluenzae*, Eco RI is from *Escherichia coli,* Hind III is from *Hemophilus influenzae*, and Pst I is from *Providencia stuartii.*
Figure 7-2. Many kinds of restriction nucleases produce DNA fragments with cohesive ends. DNA fragments with the same cohesive ends can readily join by complementary base-pairing between their cohesive ends as illustrated. The two DNA fragments that join in this example were both produced by the Eco RI restriction nuclease, whereas the three other fragments were produced by different restriction nucleases that generate different cohesive ends (see Figure 7-1).
Figure 7-3. Restriction mapping. A simple example illustrating how the positions of cutting sites for different restriction nucleases (known as *restriction sites*) are determined relative to one another on double-helical DNA molecules to create a *restriction map*. (kb = kilobases, an abbreviation designating either 1000 nucleotides or 1000 nucleotide pairs.)
Figure 7-4. Restriction maps of human and various primate DNAs in a cluster of genes coding for hemoglobin. The two *red squares* in each map indicate the positions of the DNA corresponding to the two a-globin genes. Each letter stands for a site cut by a different restriction nuclease. As in Figure 7-3, the location of each cut was determined by comparing the sizes of the DNA fragments generated by treating the DNAs with the various restriction nucleases, individually and in combinations. Note that the chimpanzee, which is most closely related to humans, has the most similar restriction map, whereas the gibbon is more distantly related and has the most diverged map including three DNA insertions. (Courtesy of Elizabeth Zimmer and Allan Wilson.)
Figure 7-5. Gel electrophoresis techniques for separating DNA molecules by size. In the three examples shown, electrophoresis is from top to bottom, so that the largest - and so slowest-moving - DNA molecules are near the top of the gel. In (A) a polyacrylamide gel with small pores is used to fractionate single-stranded DNA. In the size range 10 to 500 nucleotides, DNA molecules that differ in size by only a single nucleotide can be separated from each other. In the example the four lanes represent sets of DNA molecules synthesized in the course of a DNA-sequencing procedure. The DNA to be sequenced has been artificially replicated from a fixed start site up to a variable stopping point, producing a set of partial replicas of differing lengths. (Figure 7-8 explains how such sets of partial replicas are synthesized.) Lane 1 shows all the partial replicas that terminate in a G; lane 2, all those that terminate in an A; lane 3, all those that terminate in a T; and lane 4, all those that terminate in a C. Since the DNA molecules used in these reactions are radiolabeled, their positions can be determined by autoradiography, as shown. In (B) an agarose gel with medium-sized pores is used to separate double-stranded DNA molecules. This method is most useful in the size range 300 to 10,000 nucleotide pairs. These DNA mole-cules are restriction fragments produced from the genome of a bacterial virus, and they have been detected by their fluorescence when stained with the dye ethidium bromide. In (C) the technique of pulsed-field agarose gel electrophoresis has been used to separate 16 different yeast (*Saccharomyces cerevisiae*) chromosomes that range in size from 220,000 to 2.5 million nucleotide pairs. The DNA was stained as in (B). DNA molecules as large as 10^7 nucleotide pairs can be separated in this way. (A, courtesy of Leander Lauffer and Peter Walter; B, courtesy of Ken Kreuzer; C, from D. Vollrath and R.W. Davis, *Nucleic Acids Res.* 15:7876, 1987, by permission of Oxford University Press.)
Figure 7-6. Two procedures are used routinely for making DNA molecules radioactive. (A) A purified DNA polymerase enzyme labels all the nucleotides in a DNA molecule and can thereby produce highly radioactive DNA probes. (B) Polynucleotide kinase labels only the 5' ends of DNA strands; therefore, when labeling is followed by restriction nuclease cleavage, as shown, DNA molecules containing a single 5'-end-labeled strand can be readily obtained. The method in (A) is also

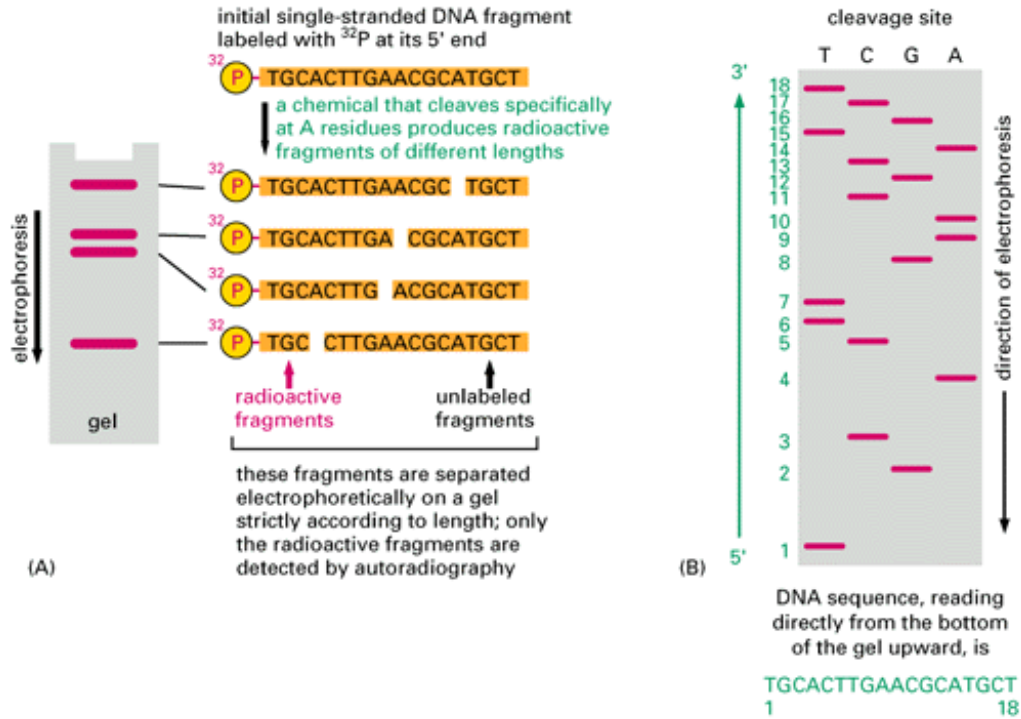
used to produce nonradioactive DNA molecules that carry a specific chemical marker that can be detected with an appropriate antibody (see Figure 7-18).


Figure 7-7. The chemical method for sequencing DNA. (A) The procedure starts with a set of identical end-labeled double-stranded DNA molecules produced by the method outlined in Figure 7-6B. In the first step the strands of the double helix are dissociated and exposed to mild treatment with a chemical that destroys one of the four bases (in this case, A residues) in the DNA. Because the treatment is mild, usually only one of the A residues in each molecule is destroyed at random. This generates a family of DNA fragments of different lengths, reflecting the different sites at which A residues occur in the original DNA. These fragments are separated on a gel and detected by autoradiography: only the fragments possessing a 5'-terminal 32P-phosphate group show up on the gel, and their sizes reveal the distances from the labeled end at which A residues occur. (B) To determine the full sequence, similar procedures are carried out simultaneously on four separate samples of the same 5'-end-labeled DNA molecule using chemicals that cleave DNA preferentially at T for the first sample, C for the second, G for the third, and A for the fourth. The resulting fragments are separated in parallel lanes of a gel like that shown in Figure7-5A, giving a pattern of radioactive DNA bands from which the DNA sequence is read. The nucleotide closest to the 5' end of the sequence is determined by looking across the gel at level 1 (at the bottom of the gel) and seeing in which lane a band appears (T). The same procedure is repeated for level 2, then level 3, and so on, to obtain the sequence. The method has been idealized here; the actual chemical treatments are less specific than shown.
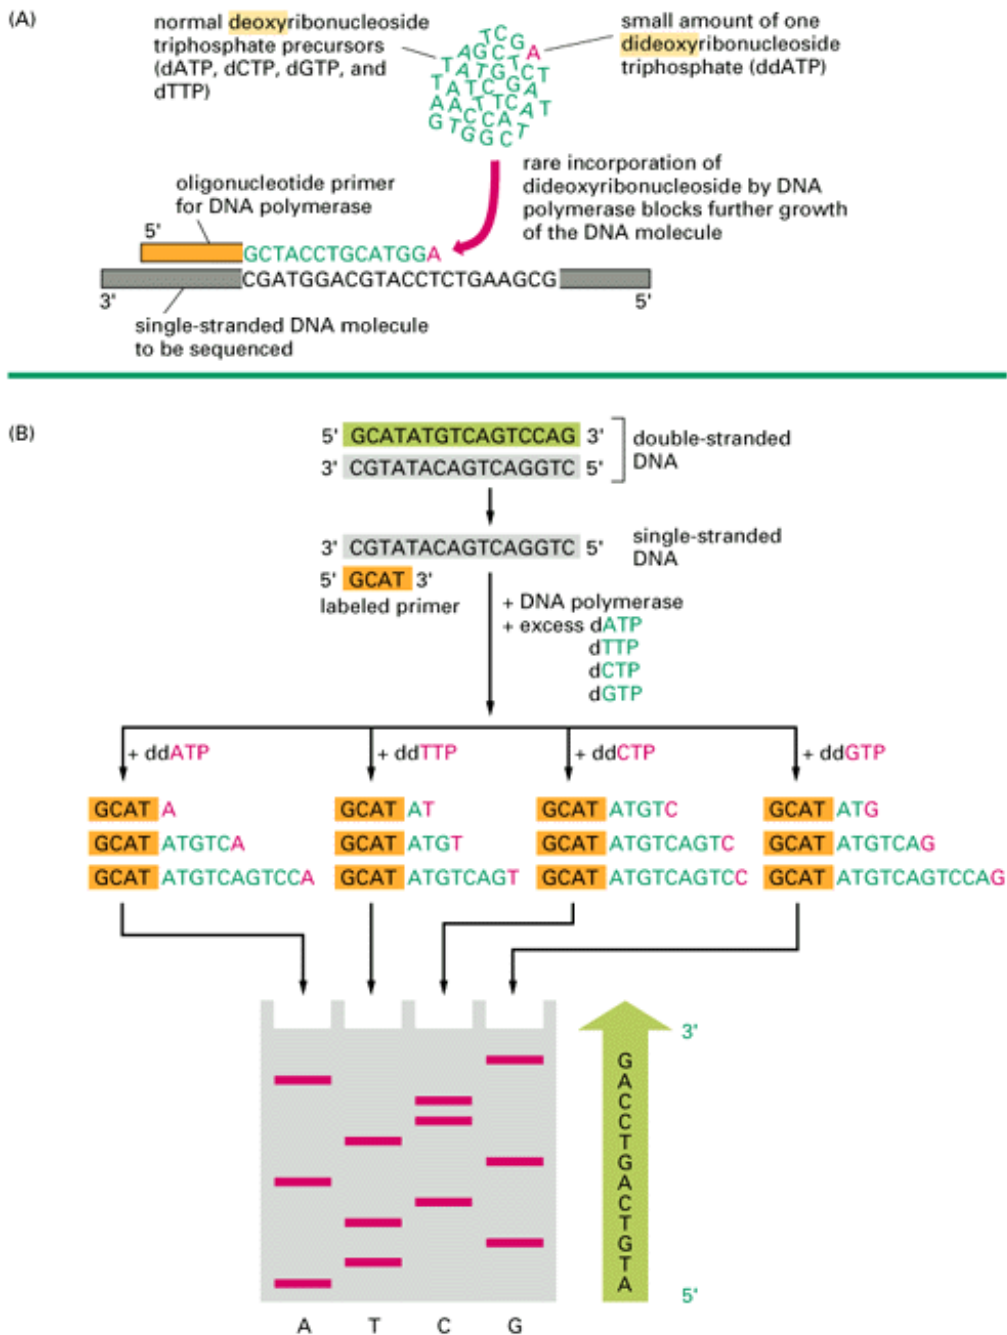

Figure 7-8. The enzymatic method for sequencing DNA. (A) The DNA to be sequenced is used as template for the *in vitro* synthesis, by DNA polymerase, of a set of partial replicas, all beginning at the same place, but terminating at different points along the DNA chain. The key to this method is the use of dideoxyribonucleoside triphosphates in which the deoxyribose 3'-OH group present in normal nucleotides is missing; when such a modified nucleotide is incorporated into a DNA chain, it blocks the addition of the next nucleotide. In the example illustrated, dideoxy ATP (ddATP) competes with an excess of deoxy ATP (dATP), so that each newly synthesized DNA strand made in a test tube by DNA polymerase will stop at a randomly selected A in the sequence. This reaction therefore generates a ladder of DNA fragments similar to that shown previously for the chemical method (Figure 7-7); these fragments are detected by a label (chemical or radioactive) that is either incorporated into the oligonucleotide primer (*orange*), or into one of the deoxyribonucleoside triphosphates (*green*) used to extend the DNA chain. (B) To determine the full sequence, four different chain-terminating nucleoside triphosphates (*red*) are used in separate DNA synthesis reactions on the same primed single-stranded DNA template. When the products of these four reactions are analyzed by electrophoresis in four parallel lanes of a polyacrylamide gel, the DNA sequence can be derived in the manner illustrated for the chemical method in Figure7-7B.
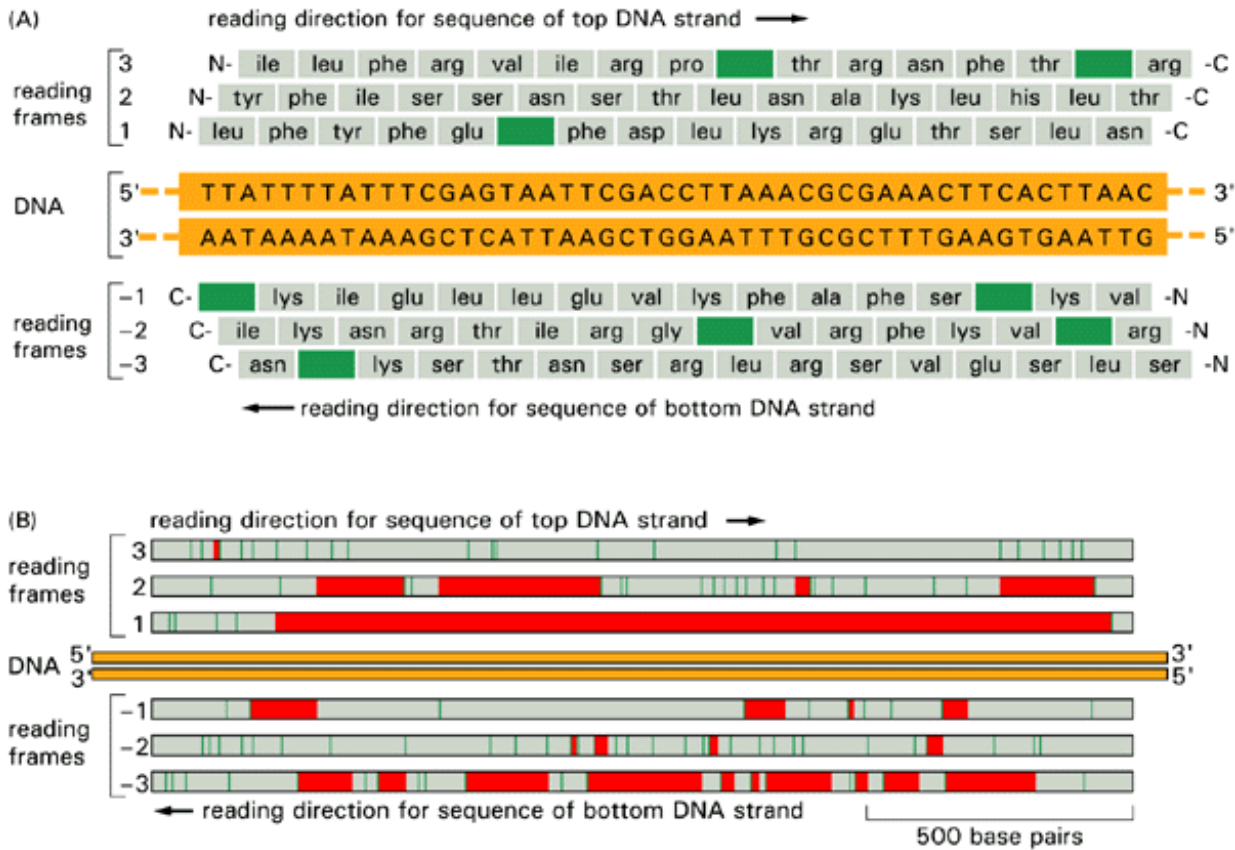

Figure 7-9. Finding the regions in a DNA sequence that encode a protein. (A) Any region of the DNA sequence can, in principle, code for six different amino acid sequences, because any one of three different reading frames can be used to interpret the nucleotide sequence on each strand. Note that a nucleotide sequence is always read in the 5'-to-3' chain direction and encodes a polypeptide from the amino (N) to the carboxyl (C) terminus. For a random nucleo-tide sequence, a stop signal for protein synthesis will be encountered, on average, about once every 21 amino acids (once every 63 nucleo-tides). In this sample sequence of 48 base pairs, each such signal (*stop codon*) is colored *green*, and only reading frame 2 lacks a stop signal. (B) Search of a 1700 base-pair DNA sequence for a possible protein-encoding sequence. The information is displayed as in (A), with each stop signal for protein synthesis denoted by a *green line.* In addition, all of the regions between possible start and stop signals for protein synthesis (see p. 234) are displayed as *red bars.* Only reading frame 1 actually encodes a protein, which is 475 amino acid residues long.
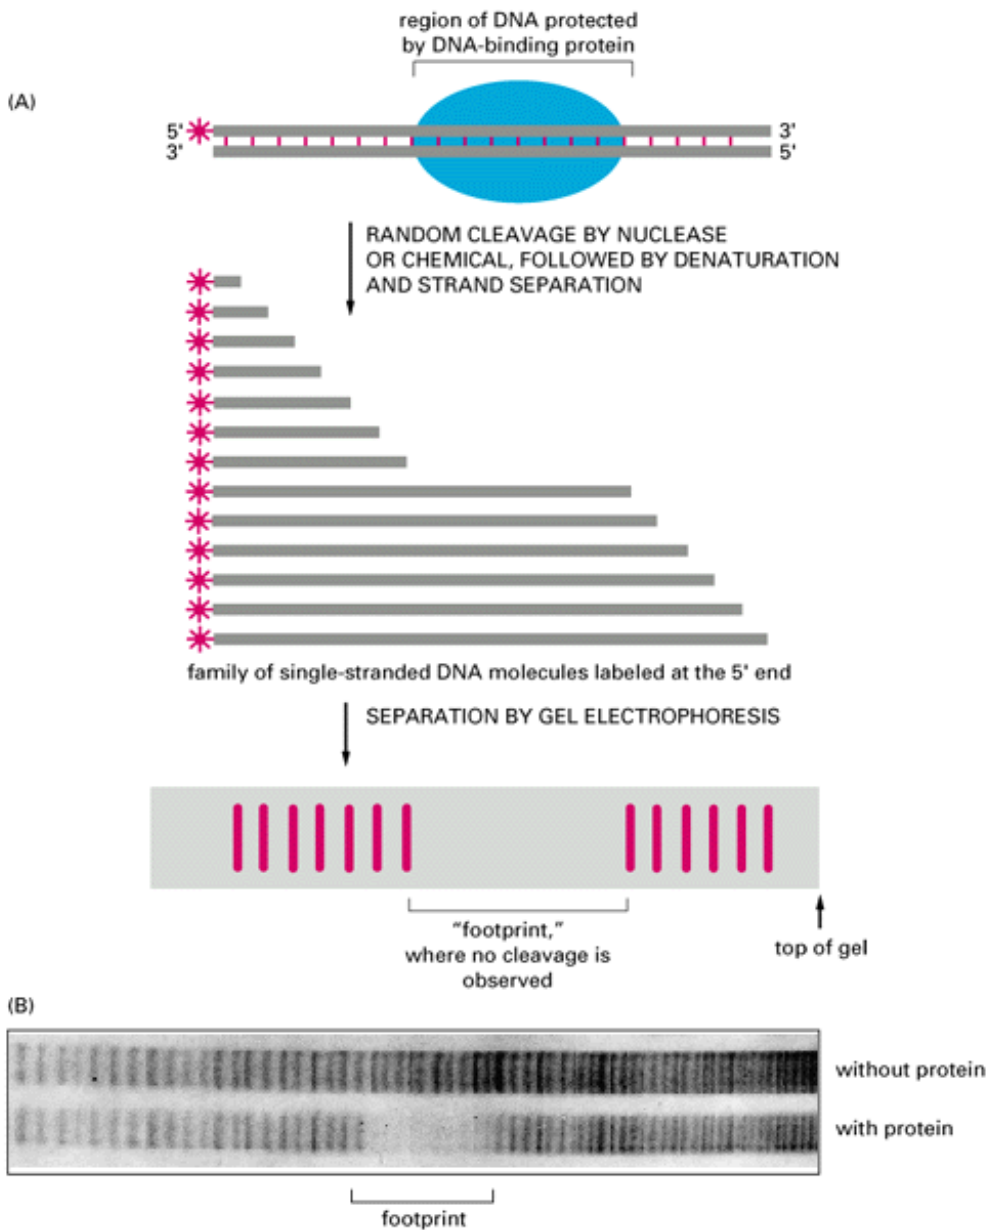

Figure 7-10. The DNA footprinting technique. (A) This technique requires a DNA molecule that has been radioactively labeled at one end (see Figure7-6B). The protein shown binds tightly to a specific DNA sequence that is seven nucleotides long, thereby protecting these seven nucleotides from the cleaving agent. If the same reaction were carried out without the DNA-binding protein, a complete ladder of bands would be seen on the gel (not shown). (B) An actual footprint used to determine the binding site for a human protein that stimulates the transcription of specific eucaryotic genes. These results locate the binding site about 60 nucleotides upstream from the start site for RNA synthesis. The cleaving agent was a small, iron-containing organic molecule that normally cuts at every phosphodiester bond with nearly equal frequency. (B, courtesy of Michele Sawadogo and Robert Roeder.)

Nucleic Acid Hybridization <u>8</u>

Introduction

When an aqueous solution of DNA is heated at 100°C or exposed to a very high pH (pH $\geqq$ 13), the complementary base pairs that normally hold the two strands of the double helix together are disrupted and the double helix rapidly dissociates into two single strands. This process, called *DNA denaturation,* was for many years thought to be irreversible. In 1961, however, it was discovered that complementary single strands of DNA will readily re-form double helices (a process called DNA renaturation or hybridization) if they are kept for a prolonged period at 65°C. Similar hybridization reactions will occur between any two single-stranded nucleic acid chains (DNA/DNA, RNA/RNA, or RNA/DNA), provided that they have a complementary nucleotide

sequence. In this section we explain how these specific hybridization reactions can be used to detect and characterize specific nucleotide sequences in both RNA and DNA molecules.

Nucleic Acid Hybridization Reactions Provide a Sensitive Way of Detecting Specific Nucleotide Sequences 9

The rate of double-helix formation during hybridization reactions is limited by the rate at which two complementary nucleic acid chains happen to collide. Since this collision rate is proportional to the concentration of complementary chains in the solution, hybridization rates can be used to determine the concentration of any desired DNA or RNA sequence in a mixture of other sequences. The assay requires a pure single-stranded DNA fragment that is complementary in sequence to the desired nucleic acid (DNA or RNA). This DNA fragment can be obtained by cloning, or, if the sequence is short, it can be synthesized by chemical means. In either case the DNA fragment must carry a unique marker (either a radioisotope or a chemical label), so that its incorporation into double-stranded molecules can be followed during the course of a hybridization reaction. A single-stranded DNA molecule used as an indicator in this way is known as a *DNA probe;* it can be anywhere from fifteen to thousands of nucleotides long.

Hybridization reactions using DNA probes are so sensitive and selective that complementary sequences present at a concentration as low as one molecule per cell can be detected (Figure 7-11). It is thus possible to determine how many copies of a particular DNA sequence are present in a cell's genome. The same technique can be used to search for related but nonidentical genes; once an interesting gene has been cloned from a mouse or a chicken, for example, part of its sequence can be used as a probe to find the corresponding gene in a human.

Alternatively, DNA probes can be used in hybridization reactions with RNA rather than DNA to find out whether a cell is *expressing* a given gene. In this case a DNA probe that contains part of the gene's sequence is hybridized with RNA purified from the cell in question to see whether the RNA includes molecules matching the probe DNA and, if so, in what quantities. In somewhat more elaborate procedures the DNA probe is treated with specific nucleases after the hybridization is complete to determine the exact regions of the DNA probe that have paired with cellular RNA molecules. One can thereby determine the start and stop sites for RNA transcription, as well as the precise boundaries of the regions that are cut out of the RNA transcripts by *RNA splicing* (the intron sequences) (Figure 7-12).

Large numbers of genes are switched on and off in elaborate patterns as an embryo develops. The hybridization of DNA probes to cellular RNAs allows one to determine whether a particular gene is off or on; moreover, when the expression of a gene changes, one can determine whether the change is due to controls that act on the transcription of DNA, the splicing of the gene's RNA, or the translation of its mature mRNA molecules into protein. Hybridization methods are in such wide use in cell biology today that it is difficult to imagine what it would be like to study gene structure and expression without them.

Northern and Southern Blotting Facilitate Hybridization with Electrophoretically Separated Nucleic Acid Molecules 10

DNA probes are often used following gel electrophoresis to detect the nucleic acid molecules with sequences that are complementary to all or part of the probe. The electrophoresis fractionates the many different RNA or DNA molecules in a crude mixture according to their size before the hybridization reaction is carried out; if molecules of only one or a few sizes become labeled with the probe, one can be certain that the hybridization was indeed specific. Moreover, the size information obtained can be invaluable in itself. An example will illustrate this point.

Suppose that one wishes to determine the nature of the defect in a mutant mouse that produces abnormally low amounts of *albumin,* a protein that liver cells normally secrete into the blood in large amounts. First, one collects identical samples of liver tissue from mutant and normal mice (the latter serving as controls) and disrupts the cells in a strong detergent to inactivate cellular nucleases that might otherwise degrade the nucleic acids. Next, one separates the RNA and DNA from all of the other cell components: the proteins present are completely denatured and removed by repeated extractions with phenol - a potent organic solvent that is partly miscible with water; the nucleic acids, which remain in the aqueous phase, are then precipitated with alcohol to separate them from the small molecules of the cell. Then one separates the DNA from the RNA by their different solubilities in alcohols and degrades any contaminating nucleic acid of the unwanted type by treatment with a highly specific enzyme - either an RNase or a DNase.

To analyze the albumin-encoding RNAs with a DNA probe, a technique called Northern blotting is used. First, the intact RNA molecules purified from mutant and control liver cells are fractionated according to their size into a series of bands by gel electrophoresis. Then, to make the RNA molecules accessible to DNA probes, a replica of the pattern of RNA bands on the gel

is made by transferring ("blotting") the fractionated RNA molecules onto a sheet of nitrocellulose paper (nylon). The RNA molecules that hybridize to the labeled DNA probe (because they are complementary to part of the normal albumin gene sequence) are then located by incubating the paper with a solution containing the probe and detecting the hybridized probe by autoradiography or by chemical means (Figure 7-13). The size of the RNA molecules in each band that binds the probe can be determined by reference to bands of RNA molecules of known size (*RNA standards*) that are electrophoresed side by side with the experimental sample. In this way one might discover that liver cells from the mutant mice make albumin RNA in normal amounts and of normal size; alternatively, albumin RNA of normal size might be detected in greatly reduced amounts. Another possibility is that the mutant albumin RNA molecules might be abnormally short and therefore move unusually quickly through the gel; in this case the gel blot could be retested with a series of shorter DNA probes, each corresponding to small portions of the gene, to reveal which part of the normal RNA is missing.

An analogous gel-transfer hybridization method, called Southern blotting, analyzes DNA rather than RNA. Isolated DNA is first cut into readily separable fragments with restriction nucleases. The double-stranded fragments are then separated according to their size by gel electrophoresis, and those complementary to a DNA probe are identified by blotting and hybridization, as just described for RNA (see Figure 7-13). To characterize the structure of the albumin gene in the mutant mice, an albumin-specific DNA probe would be used (after cutting the DNA with different restriction nucleases) to construct a detailed *restriction map* of the genome in the region of the albumin gene. > From this map one could determine if the albumin gene has been rearranged in the defective animals - for example, by the deletion or the insertion of a short DNA sequence; most single base changes, however, could not be detected in this way.

RFLP Markers Greatly Facilitate Genetic Approaches to the Mapping and Analysis of Large Genomes 11

Very large genomes can be mapped either physically or genetically. Physical maps are based on direct analysis of the DNA molecules that constitute each chromosome. They include restriction maps and ordered libraries of genomic DNA clones (see Figure 7-29), both of which can be viewed as incomplete representations of the ultimate physical map, which is the complete nucleotide sequence of the genome. Genetic linkage maps, by contrast, are based on the frequency of coinheritance of two or more features of the organism that serve as *genetic markers* when individuals interbreed. A genetic marker can be any site in the genome where there is variation in the DNA sequence that is detectable as differences between individuals in a population. If the difference is a rare one, it is called a *mutation;* if it is a common one, it is called a *polymorphism.* Genetic linkage maps are constructed by following the pattern of inheritance of such genetic variants.

Traditionally, linkage mapping has depended on the identification of mutations by their effects on characteristics such as eye color or blood groups. More recently, recombinant DNA methods have made it possible to use as genetic markers short DNA sequences that differ between normal individuals without having a detectable effect on the organism. A widely used genetic marker of this type depends on the way small differences in DNA sequence can alter restriction-enzyme cutting patterns. A single base-pair difference in a particular chromosomal position, for example, may eliminate a restriction-enzyme cutting site, giving rise to a large difference in the lengths of certain restriction fragments produced from the DNA at that position. Similarly, short deletions or insertions will change the size of any DNA restriction fragment in which they occur. Such small differences between individuals are known as restriction fragment length polymorphisms (RFLPs). An RFLP is most useful when it is very common in the population, so that there is a high probability that the parents of an individual will carry distinguishable markers. For this reason, short, tandemly repeated sequences whose exact length is highly variable in the population are the basis for the most useful RFLP markers (Figure 7-14).

RFLPs can be used for genetic mapping because the fragment size differences that an individual inherits are readily detected by Southern blotting with a DNA probe complementary to a specific DNA sequence in the region (Figure7-15). RFLPs provide an immediate way to relate a genetic linkage map to a physical map: on the one hand, they serve as heritable genetic markers, like eye color; on the other hand, the DNA probes that detect them represent DNA sequences whose positions on the physical map are easily found by DNA hybridization.

If two genetic markers are on different chromosomes, the inheritance of a variation in either of them will be *unlinked* - that is, they will have only a 50-50 chance of being inherited together. The same is true for the variants of markers at opposite ends of a single chromosome because of the high probability that they will be separated during the frequent crossing-over that occurs during meiosis in the development of eggs and sperm. The closer together two markers are on the same chromosome, the greater the chance that the form of each marker in the parent will not be separated by crossover events and will therefore be coinherited by each progeny (*linked*). By screening large family groups for the coinheritance of a gene of interest (such as one associated with a disease) and a large number of individual RFLPs, a few RFLP markers can be identified that are unambiguously

coinherited with the gene (this requires the analysis of many individuals, as explained in Figure 7-16). DNA sequences that surround the gene can thereby be located. Eventually the DNA corresponding to the gene itself can be found by techniques to be described later (see Figure7-30). Many genes that cause human diseases are being isolated in this way, allowing the proteins they encode to be analyzed in detail.

It is clear from Figure7-16 that the closer an RFLP marker is to the mutant gene of interest, the easier it is to locate the gene unambiguously. To facilitate these and other studies, an intensive effort is underway to prepare a *high-resolution RFLP map* of the human genome, with thousands of RFLP markers spaced an average of 10^6 nucleotide pairs apart. On average, two markers separated by this distance will be coinherited by 99 of every 100 progeny. Such a map will make it relatively easy to use genetic linkage studies to locate a gene that has been identified only by the effect of a mutation in humans, allowing it to be mapped to one or a few large DNA clones in an ordered genomic DNA library. Isolation of the gene might then be accomplished relatively quickly.

Synthetic DNA Molecules Facilitate the Prenatal Diagnosis of Genetic Diseases 12

At the same time that microbiologists were developing DNA cloning techniques, organic chemists were improving the methods for synthesizing short DNA chains. Today, such synthetic *DNA oligonucleotides* are routinely produced by machines that can automatically synthesize any DNA sequence up to 120 nucleotides long overnight. This ability to produce DNA molecules of a desired sequence makes it possible to redesign genes at will, an important aspect of genetic engineering, as explained later. Such synthetic oligonucleotides can also be used as labeled probes to detect corresponding genomic sequences by DNA hybridization. By varying the temperature at which the hybridization reaction is run, it is possible to vary the *stringency* of the hybridization: above a certain temperature, only perfectly matched sequences will hybridize, and this can make it possible, for example, to detect a mutant gene in the prenatal diagnosis of genetic disease.

More than 3000 human genetic diseases are attributable to single-gene defects. In most of these the mutation is recessive: that is, it shows its effect only when an individual inherits two defective copies of the gene, one from each parent. One goal of modern medicine is to identify those fetuses that carry two copies of the defective gene long before birth so that the mother, if she wishes, can have the pregnancy terminated. In sickle-cell anemia, for example, the exact nucleotide change in the mutant gene is known (the sequence GAG is changed to GTG at a specific point in the DNA strand that codes for the b chain of hemoglobin). For prenatal diagnosis, two DNA oligonucleotides are synthesized - one corresponding to the normal gene sequence in the region of the mutation and the other corresponding to the mutant sequence. If the oligonucleotides are kept short (about 20 nucleotides), they can be hybridized with DNA at a temperature selected so that only the perfectly matched helix will be stable. Such oligonucleotides can thus be used as labeled probes to distinguish between the two forms of the gene by Southern blotting on DNA isolated from fetal cells collected by amniocentesis. A fetus carrying two copies of the mutant b-chain gene can be readily recognized because its DNA will hybridize *only* with the oligonucleotide that is complementary to the mutant DNA sequence.

For many genetic abnormalities the exact nucleotide sequence change is not known. For an increasing number of these, prenatal diagnosis is still possible by using Southern blotting to assay for specific variations in the human genome (the *RFLPs* in Figure 7-16) that are known to be closely linked to the defective gene.

The same techniques can also be used to detect an individual's susceptibility to future disease. Individuals who have inherited abnormal copies of certain genes, for example, have a greatly increased risk of cancer. They need to take protective measures to improve their prospects for a healthy life.

Hybridization at Reduced Stringency Allows Even Distantly Related Genes to Be Identified 13

New genes arise during evolution by the duplication and divergence of old genes and by the reutilization of portions of old genes in new combinations. For this reason, most genes have a family of close relatives elsewhere in the genome, many of which are likely to have a related function. Laborious methods are usually required to isolate a DNA clone corresponding to the first member of such a *gene family*. Other members of the family, however, can then often be isolated relatively easily by using sequences from the first gene as DNA probes. Because the new genes are unlikely to have *identical* sequences, hybridizations with the DNA probe are usually carried out under conditions of "reduced stringency" - that is, conditions that allow even an imperfect match with the probe sequence to form a stable double helix (Figure7-17). Although using reduced stringency for hybridization carries the risk of obtaining a false signal from a chance region of short sequence homology in an unrelated DNA sequence, such false positives can be eliminated by further investigation.

This technique is one of the most powerful uses of recombinant DNA technology. It has led, for example, to the isolation of a whole family of DNA-binding proteins that function as master regulators of gene expression during embryonic development in *Drosophila* and also made it possible to isolate members of this same gene family from a variety of other organisms, including mice and humans.

In Situ Hybridization Techniques Locate Specific Nucleic Acid Sequences in Cells or on Chromosomes 14

Nucleic acids, no less than other macromolecules, occupy precise positions in cells and tissues, and a great deal of potential information is lost when these molecules are extracted by homogenization. For this reason, techniques have been developed in which nucleic acid probes are used in much the same way as labeled antibodies to locate specific nucleic acid sequences *in situ,* a procedure called *in situ* hybridization. This can now be done both for DNA in chromosomes and for RNA in cells. Labeled nucleic acid probes can be hybridized to chromosomes that have been exposed briefly to a very high pH to disrupt their DNA base pairs. The chromosomal regions that bind the probe during the hybridization step are then visualized. Originally, this technique was developed using highly radioactive DNA probes, which were detected by autoradiography. The spatial resolution of the technique, however, can be greatly improved by labeling the DNA probes chemically instead of radioactively. For this purpose the probes are synthesized with special nucleotides that contain a modified side chain (Figure 7-18), and the hybridized probes are detected with an antibody (or other ligand) that specifically recognizes this side chain (Figure7-19).

In situ hybridization methods have also been developed that reveal the distribution of specific RNA molecules in cells in tissues. In this case the tissues are not exposed to a high pH, so the chromosomal DNA remains double-stranded and cannot bind the probe. Instead the tissue is gently fixed so that its RNA is retained in an exposed form that will hybridize when the tissue is incubated with a complementary DNA or RNA probe. In this way the patterns of differential gene expression can be observed in tissues. In the *Drosophila* embryo, for example, such patterns have provided new insights into the mechanisms that create distinctions between cells in different positions during development (Figure 7-20).

Summary

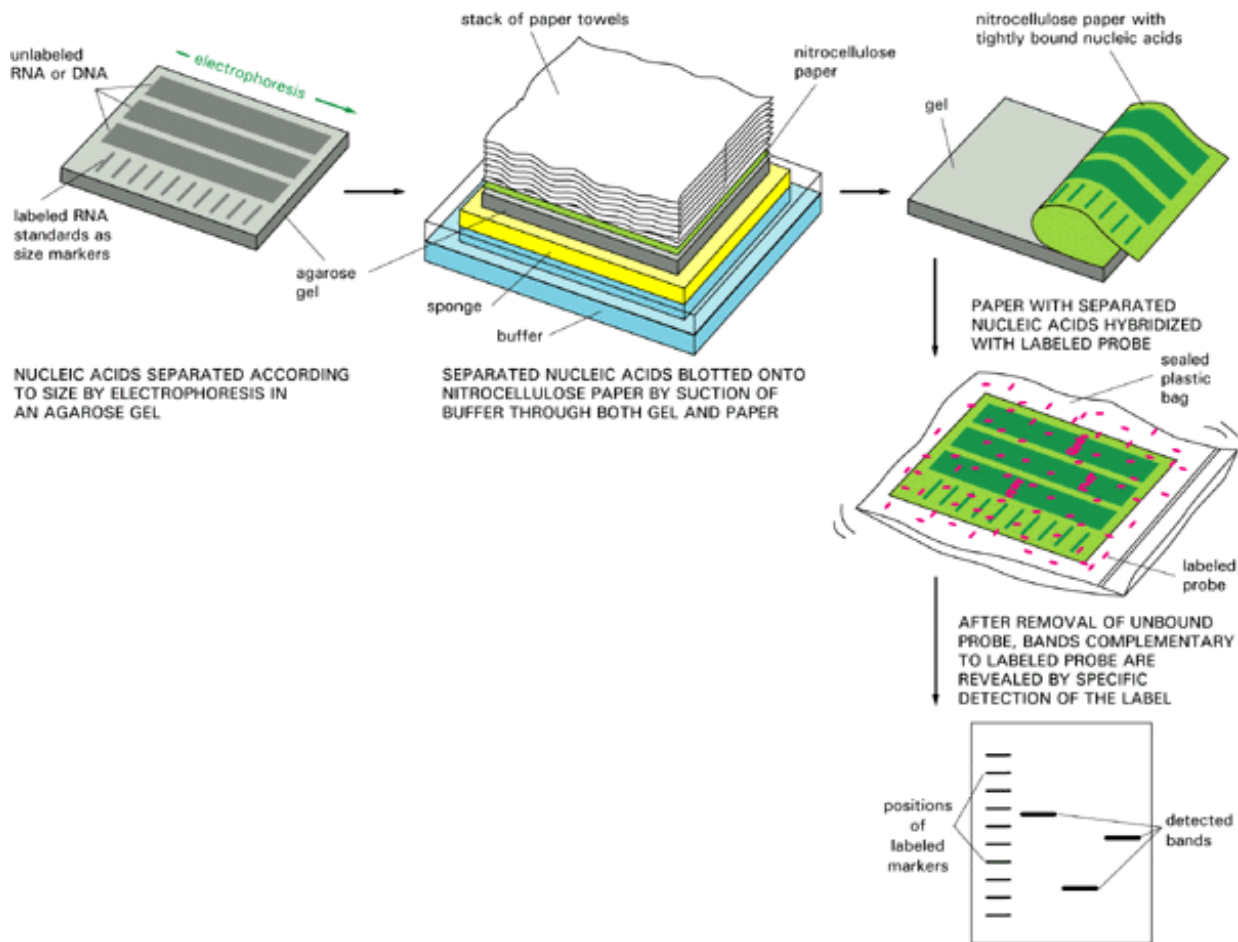
In nucleic acid hybridization reactions, single strands of DNA or RNA randomly collide with one another, rapidly testing out billions of possible alignments. Under stringent hybridization conditions (a combination of solvent and temperature where a perfect double helix is barely stable), two strands will pair to form a "hybrid" helix only if their nucleotide sequences are almost perfectly complementary. The enormous specificity of this hybridization reaction allows any single-stranded sequence of nucleotides to be labeled with a radioisotope or chemical and used as a probe to find a complementary partner strand, even in a cell or cell extract that contains millions of different DNA and RNA sequences. Probes of this type are widely used to detect the nucleic acids corresponding to specific genes, both to facilitate the purification and characterization of the genes after cell lysis and to localize them in cells, tissues, and organisms. Moreover, by carrying out hybridization reactions under conditions of "reduced stringency," a probe prepared from one gene can be used to find its evolutionary relatives - both in the same organism, where the relatives form part of a gene family, and in other organisms, where the evolutionary history of the nucleotide sequence can be traced.
Figure 7-11. Measurement of the number of copies of a specific gene in a sample of DNA by means of DNA hybridization. The single-stranded DNA fragment used in such experiments is commonly referred to as a *DNA probe.* The probe must be specially marked to distinguish it from the vast excess of the chromosomal DNA. In this example the label is a radioactive isotope; alternatively, chemically labeled nucleotides can be used as the label (see Figure7-18).
Figure 7-12. The use of nucleic acid hybridization to determine the region of a cloned DNA fragment that is present in an mRNA molecule. The method shown requires a nuclease that cuts the DNA chain only where it is not base-paired to a complementary RNA chain. The positions of the introns (intervening sequences) in eucaryotic genes are mapped by the method shown; the beginning and the end of an RNA molecule can be determined in the same way.


Figure 7-13. Detection of specific RNA or DNA molecules by gel-transfer hybridization. A mixture of either single-stranded RNA molecules (*Northern blotting*) or the double-stranded DNA molecules created by restriction nuclease treatment (*Southern blotting*) is fractionated by electrophoresis. The many different RNA or DNA molecules present are then transferred to nitrocellulose, or nylon, paper by blotting. The paper sheet is exposed to a labeled DNA probe for a prolonged period under conditions favoring hybridization. The sheet is washed thoroughly afterward, so that only those immobilized RNA or DNA molecules that hybridize to the probe become labeled and show up as bands on the paper sheet. For Southern blotting, the strands of the double-stranded DNA molecules on the paper must be separated prior to the hybridization process; this is done by exposing the DNA to alkaline denaturing conditions after the gel has been run (not shown).
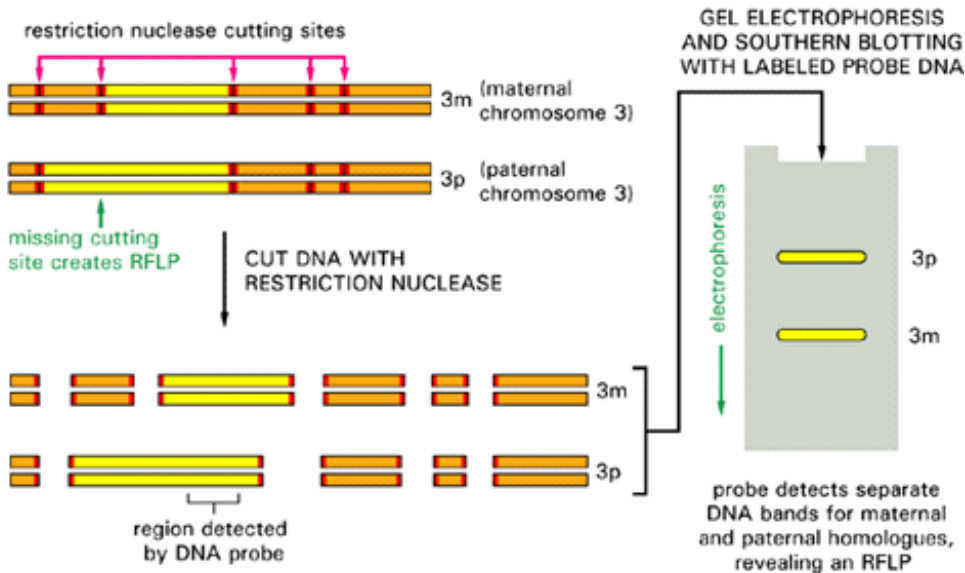
Figure 7-29. Overlapping genomic DNA clones. The collection of clones shown covers a small region of a chromosome of the nematode worm *Caenorhabditis elegans* and represents 0.3% of the total genome. (Adapted from J. Sulston et al., *Nature* 356:37-41, 1992. © 1992 Macmillan Magazines Ltd.)
Figure 7-14. Some DNA sequence changes that produce a restriction fragment length polymorphism (RFLP). (A) In many individuals in the population, a restriction nuclease cuts the chromosomal DNA shown at three sites, producing two DNA fragments; one of these DNA fragments is detected with a labeled DNA probe after gel electrophoresis and Southern blotting. (B) In other examples of the same chromosome, a single base-pair change in the short sequence recognized by the restriction nuclease prevents cutting at the central restriction site. The labeled probe now detects a much longer DNA fragment as an RFLP. (C) In yet other examples of the same chromosome, a sequence duplication increases the length of the DNA fragment that is detected by the labeled probe. This type of RFLP is commonly found in regions containing runs of short repeated sequences, such as GTGTGT...; the number of such tandem repeats is found to be highly variable in the population, with each individual typically containing a different number of copies (generally 4 to 40) of the repeat at each particular locus. A repeat of this type is commonly referred to as either a *microsatellite* or a *VNTR (variable number of tandem repeat)* sequence.


Figure 7-15. Detection of an RFLP by Southern blotting. In this example, the technique is being used to distinguish the maternally and paternally inherited copies of a region of chromosome 3 that are present in a single individual. A variant of this method uses the PCR technique (see Figure7-32) to amplify the appropriate DNA region selectively before the restriction nuclease treatment. The relevant restriction fragments are then vastly more abundant than other DNA fragments in the preparation and can be seen simply by staining the gel, avoiding the need for blotting and labeled probes.

TESTS PERFORMED ON 7 CHILDREN
CONCLUSION: gene causing disease is coinherited with RFLP marker from diseased mother in 75% of the diseased progeny. If this same correlation is observed in other families that have been examined, the gene causing disease is mapped to this chromosome close to the RFLP marker

Figure 7-16. Genetic linkage analysis using an RFLP marker. In this procedure one studies the coinheritance of a specific human phenotype (here a genetic disease) with an RFLP marker. If individuals who inherit the disease nearly always inherit the RFLP marker, then the gene causing the disease and the RFLP marker are likely to be close together on the chromosome, as shown here. To prove that an observed linkage is statistically significant, hundreds of individuals may need to be examined. Note that the linkage will not be absolute unless the RFLP marker is located in the gene itself. Thus, occasionally the RFLP marker will be separated from the disease gene by meiotic crossing-over during the formation of the egg or sperm: this has happened in the case of the chromosome pair on the far right.
Figure 7-30. Positional cloning. The procedure requires a mutant human gene whose inheritance can be traced in many family groups by virtue of the phenotype that the mutation causes. Step 1, *genetic mapping:* RFLP markers that are coinherited with the phenotype are identified and used to position the gene within about 10^6 base pairs (one megabase, or about 1% the length of a typical human chromosome). Step 2, *assembly of an ordered clone library:* genomic DNA clones are obtained that cover the entire region between two RFLP markers that bracket the gene. Step 3, *search for conserved DNA sequences:* the portions of each DNA clone that hybridize with mouse DNA are identified; only those regions of the human chromosome whose nucleotide sequence is important will have been sufficiently conserved during evolution to form such a hybrid DNA helix (one strand human and the other mouse). Step 4, *search for appropriate mRNAs:* the subset of conserved DNA sequences that encode an mRNA in tissues where the mutant phenotype is expressed are the most likely to represent the mutant gene. Step 5, *finding a difference in the DNA sequence of mutated genes.* When the deleterious mutations in a typical human gene are analyzed, about 1 in 10 turns out to be a deletion that is easily detected as a change in the size of a restriction fragment detected by Southern blotting. For this reason one generally begins by screening the DNA of many human patients with the same disease using probes identified in step 4, looking for such a change. If the mutation is not detectable as a deletion, other, more laborious methods that are capable of detecting single base changes must be used to identify the gene of interest.
Figure 7-17. Comparison of stringent and reduced-stringency hybridization conditions. In the reaction on the left (stringent conditions), the solution is kept only a few degrees below the temperature at which a perfect DNA helix denatures (its *melting temperature*), so that the imperfect helices that can form under the conditions of reduced stringency are unstable. Only the hybridization conditions on the right can be used to find genes that are nonidentical but related to gene A.
Figure 7-18. A chemical label for DNA probes. The modified nucleotide shown can be incorporated into DNA by DNA polymerase so as to allow the DNA molecule to serve as a probe that can be readily detected. The base on the nucleoside triphosphate shown is an analogue of thymine, in which the methyl group on T has been replaced by a spacer arm linked to the plant steroid digoxygenin. To visualize the probe, the digoxygenin is detected by a specific antibody coupled to a visible marker such as a fluorescent dye. Other chemical labels such as biotin can be attached to nucleotides and used in essentially the same way.
Figure 7-19. *In situ* hybridization to locate specific genes on chromosomes. Here, six different DNA probes have been used to mark the location of their respective nucleotide sequences on human chromosome 5 at metaphase. The probes have been chemically labeled and detected with fluorescent antibodies. Both copies of chromosome 5 are shown, aligned side by side. Each probe produces two dots on each chromosome, since a metaphase chromosome has replicated its DNA and therefore contains two identical DNA helices (see Figure8-4). (Courtesy of David C. Ward.)

Figure 7-20. *In situ* hybridization for RNA localization in tissues. Autoradiograph of a section of a very young *Drosophila* embryo that has been subjected to *in situ* hybridization using a radioactive DNA probe complementary to a gene involved in segment development. The probe has hybridized to RNA in the embryo, and the pattern of autoradiographic silver grains reveals that the RNA made by the gene (called *ftz*) is localized in alternating stripes across the embryo that are three or four cells wide. At this stage of development (cellular blastoderm), the embryo contains about 6000 cells. (From E. Hafen, A. Kuriowa, and W. J. Gehring, *Cell* 37:833-841, 1984. © Cell Press.)

DNA Cloning [15]

Introduction

In DNA cloning, a DNA fragment that contains a gene of interest is inserted into the purified DNA genome of a self-replicating genetic element - generally a virus or a plasmid. A DNA fragment containing a human gene, for example, can be joined in a test tube to the chromosome of a bacterial virus, and the new *recombinant DNA molecule* can then be introduced into a bacterial cell. Starting with only one such recombinant DNA molecule that infects a single cell, the normal replication mechanisms of the virus can produce more than 10^{12} identical virus DNA molecules in less than a day, thereby amplifying the amount of the inserted human DNA fragment by the same factor. A virus or plasmid used in this way is known as a *cloning vector,* and the DNA propagated by insertion into it is said to have been *cloned.*

A DNA Library Can Be Made Using Either Viral or Plasmid Vectors [16]

In order to clone a specific gene, one begins by constructing a *DNA library*a comprehensive collection of cloned DNA fragments, including (one hopes) at least one fragment that contains the gene of interest. The library can be constructed using either a virus or a plasmid vector and is generally housed in a population of bacterial cells. The principles underlying the methods used for cloning genes are the same for either type of cloning vector, although the details may be different. For simplicity, in this chapter we ignore these differences and illustrate the methods with reference to plasmid vectors.

The plasmid vectors used for gene cloning are small circular molecules of double-stranded DNA derived from larger plasmids that occur naturally in bacterial cells. They generally account for only a minor fraction of the total host bacterial cell DNA, but they can easily be separated on the basis of their small size from chromosomal DNA molecules, which are large and precipitate as a pellet upon centrifugation. For use as cloning vectors, the purified plasmid DNA circles are first cut with a restriction nuclease to create linear DNA molecules. The cellular DNA to be used in constructing the library is cut with the same restriction nuclease, and the resulting restriction fragments (including those containing the gene to be cloned) are then added to the cut plasmids and annealed via their cohesive ends to form recombinant DNA circles. These recombinant molecules containing foreign DNA inserts are then covalently sealed with the enzyme DNA ligase (Figure 7-21).

In the next step in preparing the library, the recombinant DNA circles are introduced into bacterial cells that have been made transiently permeable to DNA; such cells are said to be *transfected* with the plasmids. As these cells grow and divide, doubling in number every 30 minutes, the recombinant plasmids also replicate to produce an enormous number of copies of DNA circles containing the foreign DNA (Figure 7-22). Many bacterial plasmids carry genes for antibiotic resistance, a property that can be exploited to select those cells that have been successfully transfected; if the bacteria are grown in the presence of the antibiotic, only cells containing plasmids will survive. Each original bacterial cell that was initially transfected will, in general, contain a

different foreign DNA insert; this insert will be inherited by all of the progeny cells of that bacterium, which together form a small colony in a culture dish.

The mixture of many different surviving bacteria contains the DNA library, composed of a large number of different DNA inserts. The problem is that only a few of the bacteria will harbor the particular recombinant plasmids that contain the desired gene. One needs to be able to identify these rare cells in order to recover the DNA of interest in pure form and in useful quantities. Before discussing how this is achieved, we need to describe a second strategy for generating a DNA library that is commonly used in gene cloning.

Two Types of DNA Libraries Serve Different Purposes 17

Cleaving the entire genome of a cell with a specific restriction nuclease as just described is sometimes called the "shotgun" approach to gene cloning. It produces a very large number of DNA fragments - on the order of a million for a mammalian genome - which will generate millions of different colonies of transfected bacterial cells. Each of these colonies will be composed of a *clone* derived from a single ancestor cell and therefore will harbor a recombinant plasmid with the same inserted genomic DNA sequence. Such a plasmid is said to contain a genomic DNA clone, and the entire collection of plasmids is said to constitute a genomic DNA library. But because the genomic DNA is cut into fragments at random, only some fragments will contain genes; many will contain only a portion of a gene, while most of the genomic DNA clones obtained from the DNA of a higher eucaryotic cell will contain only noncoding DNA, which, as we shall discuss in Chapter 8, makes up most of the DNA in such genomes.

An alternative strategy is to begin the cloning process by selecting only those DNA sequences that are transcribed into RNA and thus are presumed to correspond to genes. This is done by extracting the mRNA (or a purified subfraction of the mRNA) from cells and then making a complementary DNA (cDNA) copy of each mRNA molecule present; this reaction is catalyzed by the *reverse transcriptase* enzyme of retroviruses, which synthesizes a DNA chain on an RNA template. The single-stranded DNA molecules synthesized by the reverse transcriptase are converted into double-stranded DNA molecules by DNA polymerase, and these molecules are inserted into a plasmid or virus vector and cloned (Figure 7-23). Each clone obtained in this way is called a cDNA clone, and the entire collection of clones derived from one mRNA preparation constitutes a cDNA library.

There are important differences between genomic DNA clones and cDNA clones, as illustrated in Figure 7-24. Genomic clones represent a random sample of all of the DNA sequences in an organism and, with very rare exceptions, will be the same regardless of the cell type used to prepare them. By contrast, cDNA clones contain only those regions of the genome that have been transcribed into mRNA; as the cells of different tissues produce distinct sets of mRNA molecules, a different cDNA library will be obtained for each type of cell used to prepare the library.

cDNA Clones Contain Uninterrupted Coding Sequences 18

The use of a cDNA library for gene cloning has several advantages. First, some proteins are produced in very large quantities by specialized cells. In this case, the mRNA encoding the protein is likely to be produced in such large quantities that a cDNA library prepared from the cells will be highly enriched for the cDNA molecules encoding the protein, greatly reducing the problem of identifying the desired clone in the library (see Figure7-24). Hemoglobin, for example, is made in large amounts by developing erythrocytes (red blood cells); for this reason the globin genes were among the first to be cloned.

By far the most important advantage of cDNA clones is that they contain the uninterrupted coding sequence of a gene. Eucaryotic genes usually consist of short coding sequences of DNA (exons) separated by longer noncoding sequences (introns); the production of mRNA entails the removal of the noncoding sequences from the initial RNA transcript and the splicing together of the coding sequences. Neither bacterial nor yeast cells will make these modifications to the RNA produced from a gene of a higher eucaryotic cell. Thus, if the aim of the cloning is either to deduce the amino acid sequence of the protein from the DNA or to produce the protein in bulk by expressing the cloned gene in a bacterial or yeast cell, it is much preferable to start with cDNA.

Genomic and cDNA libraries are inexhaustible resources that are widely shared among investigators. Today, many such libraries are also available from commercial sources.

cDNA Libraries Can Be Prepared from Selected Populations of mRNA Molecules 19

When cDNAs are prepared from cells that express the gene of interest at extremely high levels, the majority of cDNA clones may contain the gene sequence, which can therefore be selected with minimal effort. For less abundantly transcribed genes, various methods can be used to enrich for particular mRNAs before making the cDNA library. If an antibody against the protein is available, for example, it can be used to precipitate selectively those polyribosomes (see pp. 237-238) that have the appropriate growing polypeptide chains attached to them. Since these polyribosomes will also have attached to them the mRNA coding for the protein, the precipitate may be enriched in the desired mRNA by as much as 1000-fold.

Subtractive hybridization provides a powerful alternative way of enriching for particular nucleotide sequences prior to cDNA cloning. This selection procedure can be used, for example, if two closely related cell types are available from the same organism, only one of which produces the protein or proteins of interest. It was first used to identify cell-surface receptor proteins present on T lymphocytes but not on B lymphocytes. It can also be used wherever a cell that expresses the protein has a mutant counterpart that does not. The first step is to synthesize cDNA molecules using the mRNA from the cell type that makes the protein of interest. These cDNAs are then hybridized with a large excess of mRNA molecules from the second cell type. Those rare cDNA sequences that fail to find a complementary mRNA partner are likely to represent mRNA sequences present only in the first cell type. Because these cDNAs remain unpaired after the hybridization, they can be purified by a simple biochemical procedure (a hydroxyapatite column) that separates single-stranded from double-stranded nucleic acids (Figure 7-25). Besides providing a powerful way to clone genes whose products are known to be restricted to a specific differentiated cell type, cDNA libraries prepared after subtractive hybridization are useful for defining the differences in gene expression between any two related types of cells.

Either a DNA Probe or a Test for Expressed Protein Can Be Used to Identify the Clones of Interest in a DNA Library [20]

The most difficult part of gene cloning is often the identification of the rare colonies in the library that contain the DNA fragment of interest. This is especially true in the case of a genomic library, where one has to identify one bacterial cell in a million to select a specific mammalian gene. The technique most frequently used is a form of *in situ* hybridization that takes advantage of the exquisite specificity of the base-pairing interactions between two complementary nucleic acid molecules. Culture dishes containing the growing bacterial colonies are blotted with a piece of filter paper, to which some members of each bacterial colony adhere. The adhering colonies, known as *replicas,* are treated with alkali to disrupt the cells and to separate the strands of their DNA molecules; the paper is then incubated with either a radioactive or a chemically labeled DNA probe containing part of the sequence of the gene being sought (Figure 7-26). If necessary, millions of bacterial clones can be screened in this way to find the one clone that hybridizes with the probe.

In order to find the clone of interest, a specific probe must be made. How this is done will depend on the information that is available about the gene to be cloned. In many cases the protein of interest has been identified by biochemical studies and purified in small amounts. Only a few micrograms of pure protein are often enough to determine the sequence of 30 or so amino acid residues. From this amino acid sequence the corresponding nucleotide sequence can be deduced using the genetic code (with some ambiguities corresponding to amino acids that can be represented by several alternative codons). Two sets of DNA oligonucleotides, chosen to match different parts of the predicted nucleotide sequence of the gene, are then synthesized by chemical methods (Figure 7-27). Colonies of cells that hybridize with both sets of DNA probes are strong candidates for containing the desired gene and are saved for further characterization (see below).

Probes can also be obtained in other ways. If an antibody is available that recognizes the protein produced by the gene, it can be labeled and used as a probe to find a clone that is producing the protein, which therefore contains the desired gene. Any other ligand that is known to bind to the protein encoded by the gene can also be used as a probe: if the gene encodes a receptor protein, for example, the ligand that normally binds to the receptor can, in principle, be used as a probe.

Whenever the protein product of a gene is to be detected rather than the gene itself, a special type of cDNA library is required. It is prepared in a special plasmid or virus called an *expression vector*, which directs the transfected bacterium to synthesize large amounts of the protein encoded by the foreign DNA insert contained within the vector's DNA, as we shall discuss later.

In Vitro Translation Facilitates Identification of the Correct DNA Clone [21]

Any method that is used to find a specific clone from a cDNA or genomic DNA library will usually pick out many false positive clones. Further ingenuity is required to discriminate between these and the authentic clones desired. The task is easiest when the desired clone encodes a protein that has already been characterized by other means. In this case each candidate DNA can be

tested by one of several methods for its ability to encode the appropriate protein. The cloned DNA can be inserted into an expression vector, for example, so that the protein that it encodes is produced in large amounts in a bacterium. Alternatively, the cloned DNA can be used to obtain a corresponding RNA molecule, either through *in vitro* synthesis with a purified RNA polymerase (see Figure 7-36) or by a technique called *hybrid selection.* In the latter method a mixture of cellular RNAs is added to an excess of single strands of the candidate DNA, and DNA/RNA hybridization is used to purify complementary mRNA molecules from the mixture. In either case the mRNA obtained is allowed to direct protein synthesis in a cell-free system using radioactive amino acids, and the radioactive protein produced is then characterized and compared with the expected protein product of the desired clone. A match in any of these tests allows one to conclude that a cloned DNA fragment encodes the correct protein.

The Selection of Overlapping DNA Clones Allows One to "Walk" Along the Chromosome to a Nearby Gene of Interest [22]

Many of the most interesting genes - for example, those that control development - are known only from genetic analysis of mutants in such organisms as the fruit fly *Drosophila* and the nematode *Caenorhabditis elegans.* The protein products of these genes are unknown and may be present in very small quantities in a few cells or produced only at one stage of development. A study of the genetic linkage between different mutations, however, can be used to generate *chromosome maps,* which give the relative locations of the genes (see Figure 7-16). Once one mapped gene has been cloned, the clones in a genomic DNA library that correspond to neighboring genes can be identified using a technique called chromosome walking. The methods described in this chapter can then be used to deduce the exact structure and function of the gene of interest and the protein that it encodes.

In chromosome walking one starts with a DNA clone corresponding to a gene or an RFLP marker that is known to be as close as possible to the gene of interest. One end of this clone is used to prepare a DNA probe, which is then used in DNA hybridization experiments to find an overlapping clone in a genomic DNA clone library. The DNA from this second DNA clone is purified, and its far end is used to prepare a second DNA probe, which is used to find a clone that is overlapping, and so on. In this way one can walk along a chromosome one clone at a time, in steps of 30,000 base pairs or more in either direction (Figure 7-28).

How does one know when the gene of interest (identified originally by a deleterious mutation) has been reached, given that the walk is generally too long for complete DNA sequencing to be practicable? For experimental organisms such as fruit flies, nematodes, *Arabidopsis*, yeast, and mice, the ultimate proof of the correct gene is to transfer the normal form of the gene (as a cloned DNA molecule) into a chromosome of the mutant organism, producing a transgenic organism (see Figures 7-45 and 7-49). If the original mutation was a recessive one, the correct DNA should reverse the original mutant phenotype. Other, less stringent criteria, however, are often used and are necessary in the case of human genes, as described later (see Figure 7-30).

Ordered Genomic Clone Libraries Are Being Produced for Selected Organisms [23]

The whole task of identifying mutant genes should become vastly easier as knowledge of the sequence of the normal genome becomes more complete and systematic. By using methods related to those described for chromosome walking, it has been possible to order (map) a complete, or nearly complete, set of large genomic clones along the chromosomes of the *E. coli* bacterium, the yeast *Saccharomyces cerevisiae*, the fruit fly *Drosophila*, the plant *Arabidopsis*, and the nematode *C. elegans.* Such large clones, each about 30,000 base pairs in length, are usually prepared in bacteriophage lambda vectors called *cosmids,* which are specially designed to accept only large DNA inserts. It takes a few thousand such clones to cover the entire genome of an organism such as *C. elegans* or *Drosophila.* To map the entire human genome in this way would require ordering more than 100,000 clones in cosmids, which is very time consuming but technically feasible. DNA fragments that are more than 10 times larger than these clones (300,000 to 1.5 million base pairs) can be cloned in yeast cells as *YACs (yeast artificial chromosomes)* (Figure7-29); in principle, the human genome could be represented as about 10,000 clones of this type (see Figure8-5).

In the near future, ordered sets of genomic clones will no doubt be available from centralized DNA libraries for use by all research workers. Eventually, a complete library will be available for each commonly studied organism, with each DNA fragment catalogued according to its chromosome of origin and numbered sequentially with respect to the positions of all other DNA fragments derived from the same chromosome. One will then begin a "chromosome walk" simply by obtaining from the library all the clones covering the region of the genome that contains the mutant gene of interest.

Positional DNA Cloning Reveals Human Genes with Unanticipated Functions [24]

Thousands of human diseases are caused by alterations in single genes. Our understanding of these genetic diseases is being

revolutionized by recombinant DNA methods, which allow the altered DNA to be cloned and sequenced, revealing the precise defect in each patient. In this way, for example, Duchenne's muscular dystrophy was shown to be due to an abnormal cytoskeletal protein in muscle cells, and cystic fibrosis to be an abnormal chloride channel in epi-thelial cells. This knowledge not only improves the accuracy of diagnosis but also makes it possible, in principle at least, to design treatments.

Although the techniques used to find human disease genes have differed depending on the disease, a standard approach has recently been developed that makes it possible to isolate any human gene that is responsible by itself for a specific trait or disease. It is called positional cloning because it starts with genetic linkage mapping to locate the gene in the genome (Figure 7-30). While the approach is straightforward, it presently requires 10 to 100 person-years to isolate a gene in this way. It will become much easier once DNA sequencing is highly automated and the full DNA sequence of the human genome is known: genetic linkage mapping will reveal immediately which genes are prime suspects, and the sequences of these genes can then be analyzed directly in individual patients. The functions of thousands of human genes are likely to be identified in this way.

Selected DNA Segments Can Be Cloned in a Test Tube by a Polymerase Chain Reaction 25

The availability of purified DNA polymerases and chemically synthesized DNA oligonucleotides has made it possible to clone specific DNA sequences rapidly without the need for a living cell. The technique, called the polymerase chain reaction (PCR), allows the DNA from a selected region of a genome to be amplified a billionfold, provided that at least part of its nucleotide sequence is already known. First, the known part of the sequence is used to design two synthetic DNA oligonucleotides, one complementary to each strand of the DNA double helix and lying on opposite sides of the region to be amplified. These oligonucleotides serve as primers for *in vitro* DNA synthesis, which is catalyzed by a DNA polymerase, and they determine the ends of the final DNA fragment that is obtained (Figure 7-31).

The principle of the PCR technique is illustrated in Figure 7-32. Each cycle of the reaction requires a brief heat treatment to separate the two strands of the genomic DNA double helix (step 1). The success of the technique depends on the use of a special DNA polymerase isolated from a thermophilic bacterium that is stable at much higher temperatures than normal, so that it is not denatured by the repeated heat treatments. A subsequent cooling of the DNA in the presence of a large excess of the two primer DNA oligonucleotides allows these oligonucleotides to hybridize to complementary sequences in the genomic DNA (step 2). The annealed mixture is then incubated with DNA polymerase and the four deoxyribonucleoside triphosphates so that the regions of DNA downstream from each of the two primers are selectively synthesized (step 3). When the procedure is repeated, the newly synthesized fragments serve as templates in their turn, and within a few cycles the predominant product is a single species of DNA fragment whose length corresponds to the distance between the two original primers. In practice, 20 to 30 cycles of reaction are required for effective DNA amplification. Each cycle doubles the amount of DNA synthesized in the previous cycle. A single cycle requires only about 5 minutes, and an automated procedure permits "cell-free molecular cloning" of a DNA fragment in a few hours, compared with the several days required for standard cloning procedures.

The PCR method is extremely sensitive; it can detect a single DNA molecule in a sample. Trace amounts of RNA can be analyzed in the same way by first transcribing them into DNA with reverse transcriptase. The PCR cloning technique is rapidly replacing Southern blotting for the diagnosis of genetic diseases and for the detection of low levels of viral infection. It also has great promise in forensic medicine as a means of analyzing minute traces of blood or other tissue - seven as little as a single cell - and identifying the person from whom they came by his or her genetic "fingerprint" (Figure7-33).

Summary

DNA cloning allows a copy of any specific part of a DNA or RNA sequence to be selected from the millions of other sequences in a cell and produced in unlimited amounts in pure form. DNA sequences are amplified after cutting chromosomal DNA with a restriction nuclease and inserting the resulting DNA fragments into the chromosome of a self-replicating genetic element (a plasmid or a virus). When a plasmid vector is used, the resulting "genomic DNA library" is housed in millions of bacterial cells, each carrying a different cloned DNA fragment. The bacterial colony containing a DNA fragment of interest is identified by hybridization using a DNA probe or, following expression of a cloned gene or gene fragment in the bacterial host cell, by using a test that detects the desired protein product. The cells in the identified bacterial colony are then allowed to proliferate, producing large amounts of the desired DNA fragment.

The procedure used to obtain DNA clones that correspond in sequence to mRNA molecules are the same except that the starting material is a DNA copy of the mRNA sequence, called cDNA, rather than fragments of chromosomal DNA. Unlike genomic DNA clones, cDNA clones lack intron sequences, making them the clones of choice for expressing and characterizing the

protein product of a gene.

PCR is a new form of DNA cloning that is carried out outside cells using a purified, thermostable DNA polymerase enzyme. This type of DNA amplification requires a prior knowledge of gene sequence, since two synthetic oligonucleotide primers must be synthesized that bracket the DNA sequence to be amplified. PCR cloning, however, has the advantage of being much faster and easier than standard cloning methods.
Figure 7-21. The formation of a recombinant DNA molecule. The cohesive ends produced by many kinds of restriction nucleases allow two DNA fragments to join by complementary base-pairing (see Figure 7-2). DNA fragments joined in this way can be covalently linked in a highly efficient reaction catalyzed by the enzyme DNA ligase. In this example a recombinant plasmid DNA molecule containing a chromosomal DNA insert is formed.
Figure 7-22. Purification and amplification of a specific DNA sequence by DNA cloning in a bacterium. Each bacterial cell carrying a recombinant plasmid develops into a colony of identical cells, visible as a spot on the nutrient agar. By inoculating a

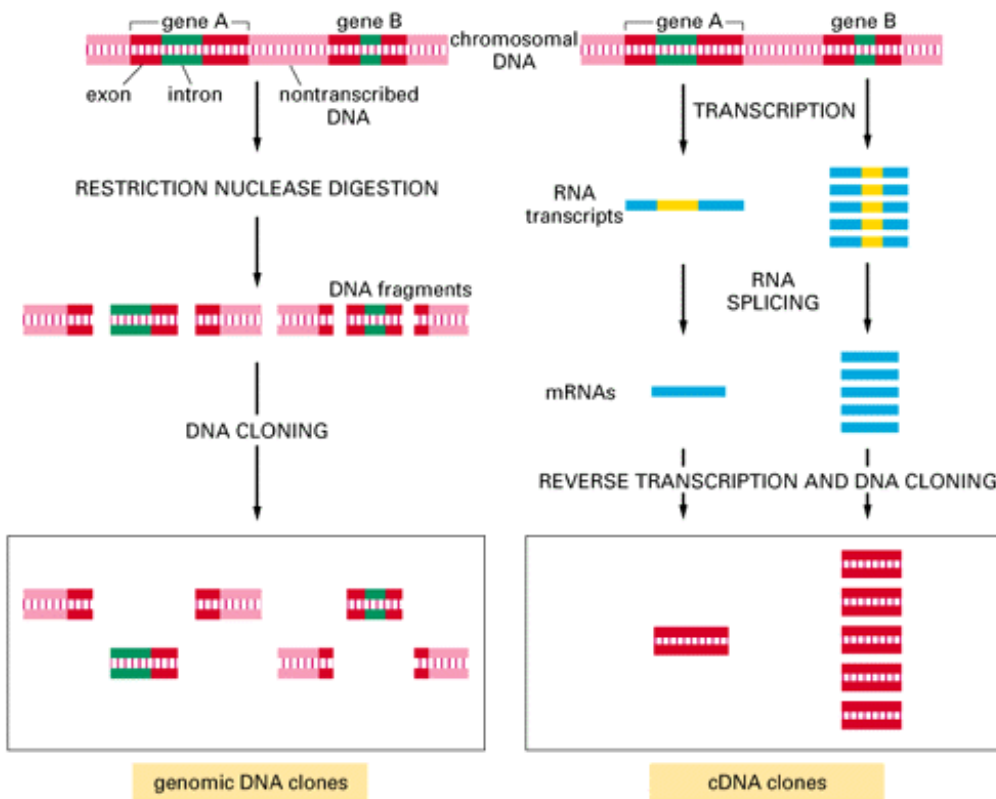
single colony of interest into a liquid culture, one can obtain a large number of identical plasmid DNA molecules, each containing the same DNA insert.
Figure 7-23. The synthesis of cDNA. A DNA copy (cDNA) of an mRNA molecule is produced by the enzyme reverse transcriptase (see p. 282), thereby forming a DNA/RNA hybrid helix. Treating the DNA/RNA hybrid with alkali selectively degrades the RNA strand into nucleotides. The remaining single-stranded cDNA is then copied into double-stranded cDNA by the enzyme DNA polymerase. As indicated, both reverse transcriptase and DNA polymerase require a primer to begin their synthesis. For reverse transcriptase a small oligonucleotide is used; in this example oligo(dT) has been annealed with the long poly-A tract at the 3' end of most mRNAs. Note that the double-stranded cDNA molecule produced here lacks cohesive ends; such blunt-ended DNA molecules can be cloned by one of several procedures that are analogous to (but less efficient than) that shown in Figure7-21.


Figure 7-24. The differences between cDNA clones and genomic DNA clones. In this example gene A is infrequently transcribed while gene B is frequently transcribed, and both genes contain introns (*green*). In the genomic DNA clones both the introns and the nontranscribed DNA are included, and most clones will contain only part of the coding sequence of a gene. In the cDNA clones the intron sequences have been removed by RNA splicing during the formation of the mRNA, and a continuous coding sequence is therefore present.
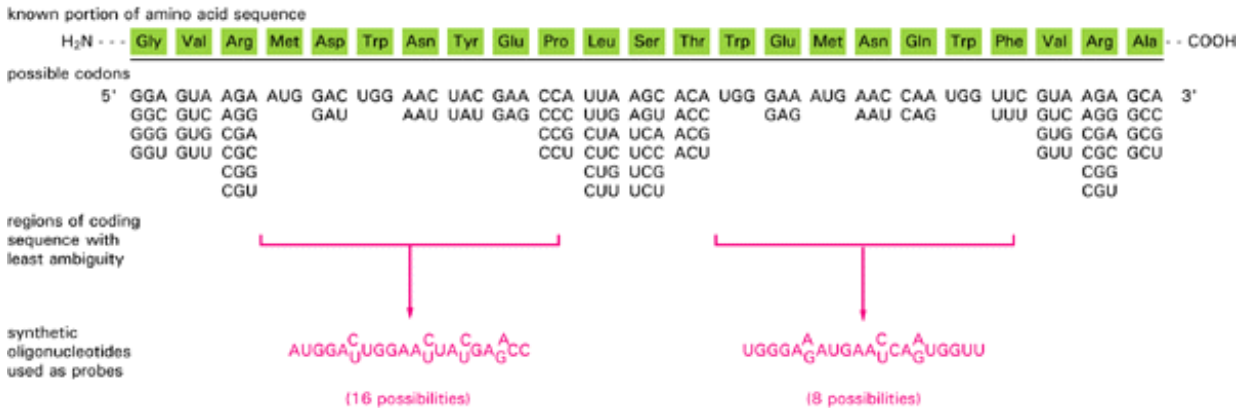
Figure 7-25. Subtractive hybridization. In this example the technique is used to purify rare cDNA clones corresponding to mRNA molecules present in T lymphocytes but not in B lymphocytes. Because the two cell types are very closely related, most of the mRNAs will be common to both cell types; subtractive hybridization is thus a powerful way to enrich for those specialized molecules that distinguish the two cells.
Figure 7-26. An efficient technique commonly used to detect a bacterial colony carrying a particular DNA clone. A replica of the culture is made by pressing a piece of absorbent paper against the surface. This replica is treated with alkali (to disrupt the cells and denature the plasmid DNA) and then hybridized to a highly radioactive DNA probe. Those bacterial colonies that have bound the probe are identified by autoradiography. (See also Figure 7-22.)


Figure 7-27. Selecting regions of a known amino acid sequence to make synthetic oligonucleotide probes. Although only one nucleotide sequence will actually code for the protein, the degeneracy of the genetic code means that several different nucleotide sequences will give the same amino acid sequence, and it is impossible to tell in advance which is the correct one. Because it is desirable to have as large a fraction of the correct nucleotide sequence as possible in the mixture of oligonucleotides to be used as a probe, those regions with the fewest possibilities are chosen, as illustrated. In this example the mixture of 8 closely related oligonucleotides shown might be synthesized and used to probe a clone library, and the indicated mixture of 16 oligonucleotides would be used to reprobe all positive clones to find those that actually code for the desired protein. After the oligonucleotide mixture is synthesized by chemical means, the 5' end of each oligonucleotide is radioactively labeled (see Figure7-6B); alternatively, the probe can be marked with a chemical label by incorporating a modified nucleotide during its synthesis (see Figure7-18).
Figure 7-36. Large amounts of any RNA molecule can be prepared *in vitro* **using a viral RNA polymerase.** The use of this unusually efficient enzyme requires that the DNA template be engineered so that the short DNA sequence that specifies the viral promoter is adjacent to the DNA sequence that encodes the RNA molecule to be synthesized. As indicated, the 3' end of the RNA is determined by cutting the DNA template at a unique site with a restriction nuclease.
Figure 7-28. The use of overlapping DNA clones to find a new gene by "chromosome walking". To speed up the walk, genomic libraries containing very large cloned DNA molecules are optimal. To probe for the next clone in the walk by DNA hybridization, a short DNA fragment (labeled with a chemical or a radioisotope) from one end of the previously identified clone is purified: If a "right-handed" end is used, for example, the walk will go in the "rightward" direction, as shown in this example. Use of a small end fragment as a probe also reduces the probability that the probe will contain a repeated DNA sequence that would hybridize with many clones from different parts of the genome and thereby interrupt the walk.
Figure 7-45. Comparison of the standard procedures used to make transgenic mice and transgenic *Drosophila*. In these examples the gene injected into the mouse egg causes a change in coat color, whereas the gene injected into the fly embryo

causes a change in eye color. In both organisms some of the transgenic animals are found to have DNA insertions at more than one chromosomal site.
Figure 7-49. A procedure used to make a transgenic plant. (A) Outline of the process. A disc is cut out of a leaf and incubated in culture with *Agrobacteria* that carry a recombinant plasmid with both a selectable marker and a desired transgene. The wounded cells at the edge of the disc release substances that attract the *Agrobacteria* and cause them to inject DNA into these cells. Only those plant cells that take up the appropriate DNA and express the selectable marker gene survive to proliferate and form a callus. The manipulation of growth factors supplied to the callus induces it to form shoots that subsequently root and grow into adult plants carrying the transgene. (B) The preparation of the recombinant plasmid and its transfer to plant cells. An *Agrobacterium* plasmid that normally carries the T-DNA sequence is modified by substituting a selectable marker (such as the

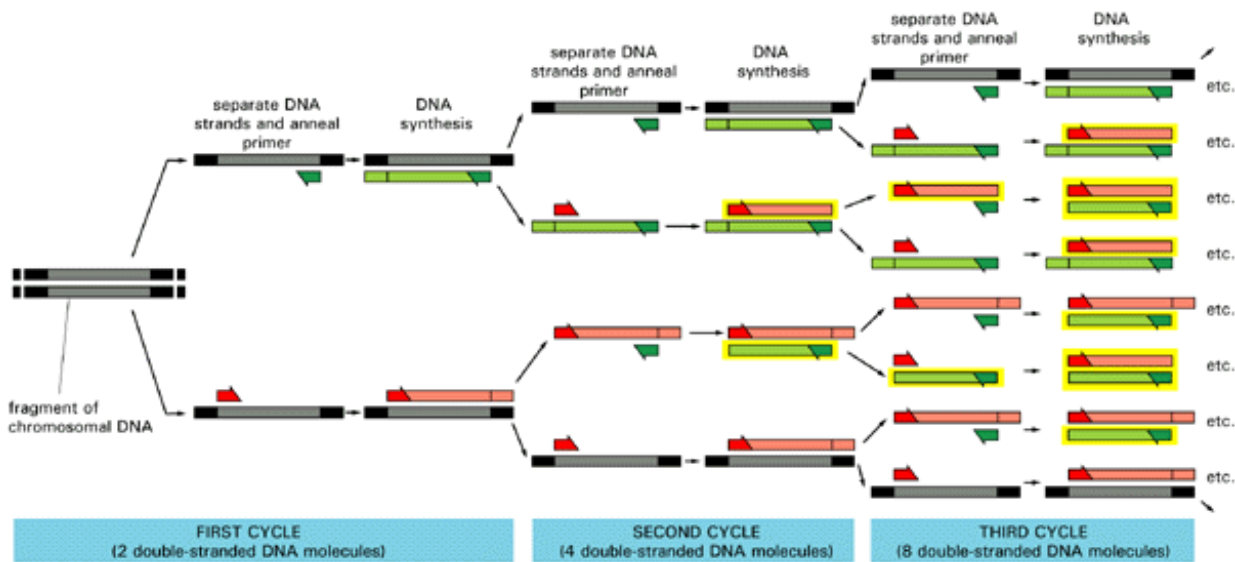
kanamycin-resistance gene) and a desired transgene between the 25-nucleotide-pair T-DNA repeats. When the *Agrobacterium* recognizes a plant cell, it efficiently passes a DNA strand that carries these sequences into the plant cell, using the special machinery that normally transfers the plasmid's T-DNA sequence.
Figure 7-31. The start of the polymerase chain reaction (PCR) for amplifying specific nucleotide sequences *in vitro*. DNA isolated from cells is heated to separate its complementary strands. These strands are then annealed with an excess of two DNA oligonucleotides (each 15 to 20 nucleotides long) that have been chemically synthesized to match sequences separated by X nucleotides (where X is generally between 50 and 2000). The two oligonucleotides serve as specific primers for *in vitro* DNA synthesis catalyzed by DNA polymerase, which copies the DNA between the sequences corresponding to the two oligonucleotides.


Figure 7-32. PCR amplification. PCR produces an amount of DNA that doubles in each cycle of DNA synthesis and includes a uniquely sized DNA species. Three steps constitute each cycle, as described in the text. After many cycles of reaction, the population of DNA molecules becomes dominated by a single DNA fragment, X nucleotides long, provided that the original DNA sample contains the DNA sequence that was anticipated when the two oligonucleotides were designed. In the example illustrated, three cycles of reaction produce 16 DNA chains, 8 of which have this unique length (*yellow*); but after three more cycles, 240 of the 256 DNA chains would be X nucleotides long.
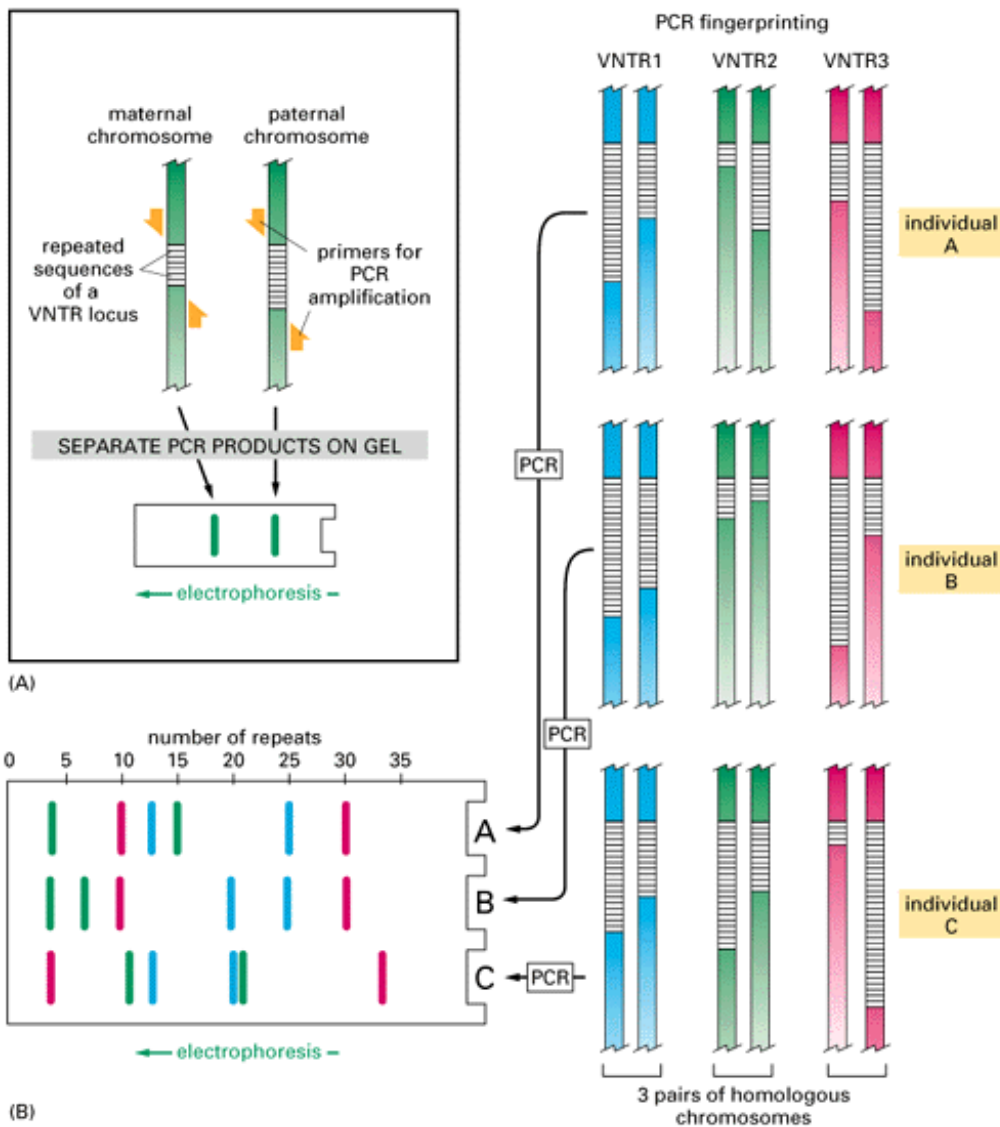

Figure 7-33. The use of PCR in forensic science. (A) A PCR reaction using two primers that bracket a particular microsatellite, or VNTR, sequence (see Figure7-14C) pro-duces a different pair of DNA bands from each individual. One of these bands contains the repeated VNTR sequence that was inherited from the individual's mother and the other contains the repeated VNTR sequence that was inherited from the individual's father. (B) The large set of DNA bands obtained from a set of different PCR reactions, each of which amplifies the DNA from a different VNTR sequence, can serve as a "fingerprint" to identify each individual nearly uniquely. The starting material for the PCR reaction can be a single hair that was left at the scene of a crime.

DNA Engineering [26]

Introduction

The methods described thus far in this chapter make it possible, in principle, to determine the exact organization and nucleotide sequence of any chromosome, including all of the chromosomes that constitute the human genome. In this section we describe how extensions of these methods have revolutionized all other aspects of cell biology by providing new ways to study the functions of genes, RNA molecules, and proteins.

New DNA Molecules of Any Sequence Can Be Formed by Joining Together DNA Fragments [27]

As we have seen, recombinant DNA molecules are generally constructed by using the enzyme DNA ligase to join together two

DNA molecules with matching cohesive ends. For production of a DNA library, one of the two DNA molecules to be joined is the *vector*, derived from a bacterial plasmid or virus, while the other is either a fragment of a chromosome or a cDNA molecule (see Figure7-21). A recombinant DNA molecule can in turn serve as a vector for cloning additional DNA molecules, and by the stepwise repetition of the cloning procedure, a series of DNA fragments can be joined together end to end. In this way new DNA molecules can be generated that are different from any molecule that occurs naturally (Figure 7-34).

Automated oligonucleotide synthesizers rapidly produce any DNA molecule containing up to about 100 nucleotides. The sequence of such synthetic DNA molecules is entirely determined by the experimenter, and they can be joined together by repeated DNA cloning steps in various combinations to produce long custom-designed DNAs of any sequence. But the DNA sequences of interest to cell biologists are mostly those that code for protein domains that already exist in nature. The polymerase chain reaction (PCR) can be used both to amplify any natural nucleotide sequence and to redesign its two ends, so that any two naturally occurring DNA sequences can be amplified and spliced together very rapidly and efficiently (Figure 7-35). Thus, rather than generating novel DNA molecules from chemically synthesized fragments, it is almost always easier to produce them using PCR and repeated cloning steps to link selected naturally occurring DNA segments.

Homogeneous RNA Molecules Can Be Produced in Large Quantities by DNA Transcription *in Vitro* 28

Pure RNA molecules are useful for many types of cell biological studies. If the RNA encodes a protein, large amounts of the pure species will facilitate *invitro* studies of RNA splicing or protein synthesis; if the RNA has a catalytic function, its catalytic mechanism can be tested in cell-free systems. But most species of RNA molecules are present in only tiny quantities in cells, and they are very difficult to purify away from the many thousands of other species present in a typical cell extract. By making available pure DNA templates that can be used to produce large amounts of any RNA molecule, genetic engineering provides the best path to a pure RNA species.

The technique uses the unusually efficient RNA polymerase molecules produced by certain bacterial viruses. To prepare a suitable DNA template, the DNA sequence encoding the RNA is cloned in a way that joins it to a second DNA segment that contains the start signal (promoter) for the viral RNA polymerase enzyme. The pure recombinant DNA molecule is then mixed with a pure preparation of the RNA polymerase plus the four ribonucleoside triphosphates used in RNA synthesis. During a prolonged incubation at 37°C, large amounts of the desired RNA are then generated by in vitro transcription (Figure 7-36).

Rare Cellular Proteins Can Be Made in Large Amounts Using Expression Vectors 29

Until recently, the only proteins in a cell that could be studied easily were the relatively abundant ones. Starting with several hundred grams of cells, a major protein - one that constitutes 1% or more of the total cellular protein - can be purified by sequential chromatography steps to yield perhaps 0.1 g (100 mg) of pure protein. This amount is sufficient for conventional amino acid sequencing, for detailed analysis of biological activity (if known), and for the production of antibodies, which can then be used to localize the protein in the cell. Moreover, if suitable crystals can be grown (usually a difficult task), the three-dimensional structure of the protein can be determined by x-ray diffraction techniques. In this way the structure and function of many abundant proteins - including hemoglobin, trypsin, immunoglobulin, and lysozyme - have been analyzed.

The vast majority of the thousands of different proteins in a eucaryotic cell, however, including many with crucially important functions, are present in very small amounts. For most of them it is extremely difficult, if not impossible, to obtain more than a few micrograms of pure material. One of the most important contributions of DNA cloning and genetic engineering to cell biology is that they have made it possible to produce any of the cell's proteins, including the minor ones, in large amounts.

Large amounts of a pure protein could, in principle, be produced by first synthesizing a large amount of the mRNA that encodes the protein and then translating it in a cell-free system that contains all of the many components required for protein synthesis, including ribosomes, transfer RNAs, translation enzymes, and so on. While this approach is occasionally used, a more efficient way is to produce both the mRNA and the protein in a living cell, using an *expression vector*(Figure 7-37). The vector is designed to produce a large amount of a stable mRNA that will be efficiently translated into protein in the transfected bacterial, yeast, insect, or mammalian cell. To prevent the high level of the foreign protein from interfering with the transfected cell's growth, the expression vector is often designed so that the synthesis of the foreign mRNA and protein can be delayed until shortly before the cells are harvested (Figure7-38).

Because the desired protein made from an expression vector is produced inside a cell, it must be purified away from the host cell proteins by chromatography following cell lysis; but because it is such a plentiful species in the cell lysate (often 1% to 10% of

the total cell protein), the purification is usually easy to accomplish in only a few steps. A variety of expression vectors are available, each engineered to function in the type of cell in which the protein is to be made. In this way cells can be induced to make vast quantities of medically useful proteins - such as human insulin and growth hormone, interferon, and viral antigens for vaccines. More generally, these methods make it possible to produce every protein in large enough amounts for the kinds of detailed structural and functional studies that were previously possible for only a rare few.

Reporter Genes Enable Regulatory DNA Sequences to Be Dissected <u>30</u>

The transcription of a gene is controlled by regulatory DNA sequences that are not transcribed. These sequences determine which cells will express the gene and under what conditions, as explained in <u>Chapter 9</u>. In higher eucaryotes these regulatory sequences can be located many thousands of base pairs upstream or downstream from the transcribed sequences, and they act in combinations to control gene transcription. The regulatory DNA sequences can be identified for any particular gene by a manipulation that involves replacing part of the gene's coding sequence with a different coding sequence (a so-called *reporter sequence*), selected because the protein it encodes is easily detected by either a simple cytological stain or an enzyme assay. The regulatory sequences for the gene of interest can then be identified by attaching the reporter sequence to various fragments of DNA sequence taken from upstream or downstream of the gene. When such recombinant DNA molecules are used to transfect cells, the level, timing, and cell specificity of reporter protein production will reflect the action of the regulatory sequences that each DNA construct contains (<u>Figure7-39</u>).

Mutant Organisms Best Reveal the Function of a Gene <u>31</u>

Suppose that one has cloned a gene that codes for a protein whose function is unknown. How can one discover what the protein does in the cell? This has become a common problem in cell biology and one that is surprisingly difficult to solve, since neither the three-dimensional structure of the protein nor the complete nucleotide sequence of its gene is usually sufficient to deduce the protein's function. Moreover, many proteins - such as those that have a structural role in the cell or normally form part of a large multienzyme complex - will have no obvious activity by themselves.

One approach, discussed in <u>Chapter 4</u>, is to inactivate the protein by injecting into a cell a specific antibody that recognizes the protein and then observing how the cell is affected. Although this provides a useful way to test protein function, the effect is transitory because the injected antibody is eventually diluted out during cell proliferation or destroyed by intracellular proteolytic enzymes. Moreover, many antibodies - even those that bind tightly to some part of the given protein - fail to block the protein's function.

Genetics provides a much more powerful solution to this problem. Mutants that lack a particular protein may quickly reveal the function of the normal molecule. Even more useful are mutants in which the abnormal protein is temperature sensitive, so that it is inactivated by a small increase or decrease in temperature, since in these mutants the abnormality can be switched on and off simply by changing the temperature. Before the advent of gene cloning technology, most genes were identified in this way, according to the processes disrupted when mutations occur. The genetic approach is most easily applicable to organisms that reproduce rapidly - such as bacteria, yeasts, nematode worms, and fruit flies. By treating these organisms with agents that alter their DNA (*mutagens*), very large numbers of mutants can be created quickly and then screened for a particular defect of interest. By screening populations of mutagen-treated bacteria for cells that stop making DNA when they are shifted from 30°C to 42°C, for example, many temperature-sensitive mutants were isolated in the genes that encode the bacterial proteins required for DNA replication. These mutants were later used to identify and characterize the corresponding DNA replication proteins. Similarly, the genetic approach has been used to demonstrate the function of enzymes involved in the principal metabolic pathways of bacteria, as well as to discover many of the gene products responsible for the orderly development of the *Drosophila* embryo.

Humans do not reproduce rapidly, and they are not, as a rule, intentionally treated with mutagens. Moreover, any human with a serious defect in an essential process, such as DNA replication, would die long before birth. Many mutations that are compatible with life, however - for example, tissue-specific defects in lysosomes or in cell-surface receptors - have arisen spontaneously in the human population. Analyses of the phenotypes of the affected individuals, together with studies of their cultured cells, have provided many unique insights into important cell functions. Although such mutants are rare, they are very efficiently discovered because of a unique human property: the mutant individuals call attention to themselves by seeking special medical care.

Cells Containing Mutated Genes Can Be Made to Order <u>32</u>

Although in rapidly reproducing organisms it is often not difficult to obtain mutants that are deficient in a particular process, such as DNA replication or eye development, it can take a long time to trace the defect to a particular altered protein. Recently, recombinant DNA technology has made possible a different type of genetic approach. Instead of starting with a randomly generated mutant and using it to identify a gene and its protein, one can start with a particular gene and proceed to make mutations in it, creating mutant cells or organisms so as to analyze the gene's function. Because the new approach reverses the traditional direction of genetic discovery - proceeding from genes and proteins to mutants, rather than vice versa - it is commonly referred to as *reverse genetics.*

Reverse genetics begins with a cloned gene or a protein with interesting features that has been isolated from a cell. If the starting point is a protein, the gene encoding it is first cloned and its nucleotide sequence is determined. The gene sequence is then altered by biochemical means to create a mutant gene that codes for an altered version of the protein. The mutant gene is transferred into a cell, where it can integrate into a chromosome by genetic recombination to become a permanent part of the cell's genome. If the gene is expressed, the cell and all of its descendants will now synthesize an altered protein.

If the original cell used for the gene transfer is a fertilized egg, whole multi-cellular organisms can be obtained that contain the mutant gene, and some of these *transgenic organisms* will pass the gene on to their progeny as a permanent part of their germ line. Such *genetic transformations* are now routinely performed with organisms as complex as fruit flies and mammals (see Figure 7-45). Technically, even humans could now be transformed in this way, although such procedures are not undertaken, even for therapeutic purposes, for fear of the unpredictable aberrations that might occur in such individuals.

Genes Can Be Redesigned to Produce Proteins of Any Desired Sequence 33

To facilitate reverse genetic studies of protein function, both the coding sequence of a gene and its regulatory regions can be altered to change the functional properties of the protein product, the amount of protein made, or the particular cell type in which the protein is produced.

Special techniques are required to alter a gene in such subtle ways: it is often desirable, for example, to change the protein the gene encodes by one or a few amino acids. The first step in redesigning a gene in this way is the chemical synthesis of a short DNA molecule containing the altered portion of the gene's nucleotide sequence. This synthetic DNA oligonucleotide is hybridized with single-stranded plasmid DNA that contains the DNA sequence to be altered, using conditions that allow imperfectly matched DNA strands to pair (Figure7-40). The synthetic oligonucleotide will now serve as a primer for DNA synthesis by DNA polymerase, thereby generating a DNA double helix that incorporates the altered sequence into one of its two strands. After transfection, plasmids that carry the fully modified gene sequence are obtained, and the appropriate DNA is inserted into an expression vector so that the redesigned protein can be produced in the appropriate type of cells for detailed studies of its function. By changing selected amino acids in a protein in this way, one can analyze which parts of the polypeptide chain are important in such fundamental processes as protein folding, protein-ligand interactions, and enzymatic catalysis.

Fusion Proteins Are Often Useful for Analyzing Protein Function 34

A protein will often contain short amino acid sequences that determine its location in a cell, or its stability after the protein has been synthesized. These special regions of the protein can be identified by fusing them to an easily detected reporter protein that lacks such regions and then following the behavior of the reporter protein in a cell (Figure 7-41). Such fusion proteins are produced by the recombinant DNA techniques discussed previously. Most nuclear proteins, for example, contain one or more specific short sequences of amino acids that serve as signals for their import into the nucleus after their synthesis in the cytosol. By artificially attaching different segments of such a nuclear protein to a cytoplasmic protein using gene-fusion techniques, the "signal peptides" responsible for nuclear import have been identified.

Not all of the important signals carried by proteins, however, can be transferred to a large reporter protein in the form of a short amino acid sequence. The information that moves newly synthesized lysosomal proteins to lysosomes from the Golgi apparatus, for example, resides in a "signal patch," whose formation requires that the lysosomal protein fold correctly so as to bring distant portions of the polypeptide chain into close proximity. In these cases a different strategy, called epitope tagging, can often be used. Again, a fusion protein is produced, but it contains the entire protein being analyzed plus a short peptide of 8 to 12 amino acids (the "epitope") that can be recognized by an antibody - hence its name. The fusion protein can therefore be specifically followed in cells with the anti-epitope antibody, even in the presence of a large excess of the normal protein, so that one can determine the effect of altering any of the amino acids in the fusion protein on its intracellular location (strategy B in Figure7-

Normal Genes Can Be Easily Replaced by Mutant Ones in Bacteria and Some Lower Eucaryotes 35

Unlike higher eucaryotes (which are multicellular and diploid), bacteria, yeasts, and the cellular slime mold *Dictyostelium* generally exist as haploid single cells. In these organisms an artificially introduced DNA molecule carrying a mutant gene will, with a relatively high frequency, replace the single copy of the normal gene by *homologous recombination* (see p. 263), so that it is easy to produce cells in which the mutant gene has replaced the normal gene (Figure7-42A). In this way cells can be made to order that produce an altered form of any specific protein or RNA molecule instead of the normal form of the molecule. If the mutant gene is completely inactive and the gene product normally performs an essential function, the cell will die; but in this case a less severely mutated version of the gene can be used to replace the normal gene, so that the mutant cell survives but is abnormal in the process for which the gene is required. Often the mutant of choice is one that produces a temperature-sensitive gene product, which functions normally at one temperature but is inactivated when cells are shifted to a higher or lower temperature.

The ability to perform direct *gene replacements* in lower eucaryotes, combined with the power of standard genetic analyses in these haploid organisms, in large part explains why studies in these types of cells have been so important for working out the details of those processes that are shared by all eucaryotes. Gene replacements occur more rarely in higher eucaryotes, for reasons that are not known.

Engineered Genes Can Be Used to Create Specific Dominant Mutations in Diploid Organisms 36

Higher eucaryotes, such as mammals or fruit flies, are diploid and therefore have two copies of each chromosome. Moreover, transfection with an altered gene generally leads to *gene addition* rather than gene replacement: the altered gene inserts at a random location in the genome, so that the cell (or the organism) ends up with the mutated gene in addition to its normal gene copies (Figure7-42B).

Because gene addition is much more easily accomplished than gene replacement in higher eucaryotic cells, it would be enormously useful to be able to create specific dominant negative mutations in which a mutant gene eliminates the activity of its normal counterparts in the cell. One ingenious and promising approach exploits the specificity of hybridization reactions between two complementary nucleic acid chains. Normally, only one of the two DNA strands in a given portion of double helix is transcribed into RNA, and it is always the same strand for a given gene. If a cloned gene is engineered so that the opposite DNA strand is transcribed instead, it will produce antisense RNA molecules that have a sequence complementary to the normal RNA transcripts. Antisense RNA, when synthesized in large enough amounts, will often hybridize with the "sense" RNA made by the normal genes and thereby inhibit the synthesis of the corresponding protein (Figure 7-43). A related method is to synthesize short antisense nucleic acid molecules by chemical or enzymatic means and then inject (or otherwise deliver) them into cells, again blocking (though only temporarily) production of the corresponding protein.

For unknown reasons the antisense RNA approach frequently fails to inactivate the desired gene. An alternative way of producing a dominant negative mutation takes advantage of the fact that most proteins function as part of a larger protein complex. Such complexes can be inactivated by the inclusion of just one nonfunctional component. Therefore, by designing a gene that produces large quantities of a mutant protein that is inactive but still able to assemble into the complex, it is often possible to produce a cell in which all the complexes are inactivated despite the presence of both normal and mutant copies of the protein (Figure 7-44).

If a protein is required for the survival of the cell (or the organism), a dominant negative mutant will die, making it impossible to test the function of the protein. To avoid this problem, one can couple the mutant gene to control sequences that have been engineered to produce the gene product only on command - for example, in response to an increase in temperature or to the presence of a specific signaling molecule. Cells or organisms containing such an *inducible* dominant mutant gene can be deprived of a specific protein at a particular time, and the effect can then be followed. In the future, techniques for producing dominant negative mutations to inactivate specific genes are likely to be widely used to determine the functions of proteins in higher organisms.

Engineered Genes Can Be Permanently Inserted into the Germ Line of Mice or Fruit Flies to Produce Transgenic Animals 37

The ultimate test of the function of an altered gene is to reinsert it into an organism and see what effect it has. Ideally one would like to be able to replace the normal gene with the altered one so that the function of the mutant protein can be analyzed in the absence of the normal protein. As discussed above, this can be readily accomplished in some haploid organisms, but in higher eucaryotic cells an integrative event leading to a gene replacement occurs only very rarely. Foreign DNA can, however, rather easily be randomly integrated into the genome. In mammals, for example, linear DNA fragments introduced into cells are rapidly ligated end to end by intracellular enzymes to form long tandem arrays, which usually become integrated into a chromosome at an apparently random site. Fertilized mammalian eggs behave like other mammalian cells in this respect. A mouse egg injected with 200 copies of a linear DNA molecule will often develop into a mouse containing, in many of its cells, a tandem array of copies of the injected gene integrated at a single random site in one of its chromosomes (Figure 7-45). If the modified chromosome is present in the germ line cells (eggs or sperm), the mouse will pass these foreign genes on to its progeny. Animals that have been permanently altered in this way are called transgenic organisms, and the foreign genes are called transgenes. Because the normal gene generally remains present, only dominant effects of the alteration will show up. Nevertheless, such transgenic animals have already provided important insights into how mammalian genes are regulated and how certain altered genes (called oncogenes) cause cancer.

It is also possible to produce transgenic fruit flies, in which single copies of a gene are inserted at random into the *Drosophila* genome. The trick in this case is first to insert the DNA fragment between the two terminal sequences of a particular *Drosophila* transposable element, called the *P element.* The terminal sequences enable the P element to integrate into *Drosophila* chromosomes if the P element transposase enzyme is also present (see p. 285). To make transgenic fruit flies, therefore, the appropriately modified DNA fragment is injected into a very young fruit fly embryo along with a separate plasmid containing the gene encoding the transposase. When this is done, the injected gene often enters the germ line in a single copy as the result of a transposition event (Figures 7-45 and 7-46).

Gene Targeting Makes It Possible to Produce Transgenic Mice That Are Missing Specific Genes [38]

If a DNA molecule carrying a mutated mouse gene is transferred into a mouse cell, it usually inserts into the chromosomes at random, but about once in a thousand times, it will replace one of the two copies of the normal gene by homologous recombination. By exploiting these rare "gene targeting" events, any specific gene can be inactivated in a mouse cell by a direct gene replacement. This technique can be extended to produce a mouse with a missing gene by means of the following two-step pathway.

In the first step, a DNA fragment containing a desired mutant gene (or part of a gene) is inserted into a vector and then introduced into a special line of embryo-derived mouse stem cells (called *embryonic stem cells,*or *ES cells*) that grow in cell culture and are capable of producing cells of any tissue. After a period of cell proliferation, the rare colonies of cells in which a homologous recombination event is likely to have caused a gene replacement to occur are isolated by a double drug selection (Figure 7-47). The correct colonies among these are identified by PCR or by Southern blotting: they will contain recombinant DNA sequences in which the inserted fragment has replaced all or part of one copy of the normal gene. In the second step, individual cells from the identified colony are taken up into a fine micropipette and injected into an early mouse embryo. The transfected embryo-derived stem cells collaborate with the cells of the host embryo to produce a normal-looking mouse (see Figure21-32); large parts of this chimeric animal, including in favorable cases cells of the germ line, will often derive from the artificially altered stem cells. Such mice are bred to produce both a male and a female animal, each heterozygous for the gene replacement (that is, they have one normal and one mutant copy of the gene). When these two mice are mated, one-fourth of their progeny will be homozygous for the altered gene. Studies of these homozygotes allow the function of the altered gene to be examined in the absence of the corresponding normal gene.

The ability to prepare transgenic mice lacking a known normal gene has been a major advance, and the technique is now being widely used to dissect the functions of specific mammalian genes (Figure 7-48).

Transgenic Plants Are Important for Both Cell Biology and Agriculture [39]

When a plant is damaged, it can often repair itself by a process in which mature differentiated cells "dedifferentiate," proliferate, and then redifferentiate into other cell types. In some circumstances the dedifferentiated cells can even form an apical meristem, which can then give rise to an entire new plant, including gametes. This remarkable plasticity of plant cells can be exploited to generate transgenic plants from cells growing in culture.

When a piece of plant tissue is cultured in a sterile medium containing nutrients and appropriate growth regulators, many of the

cells are stimulated to proliferate indefinitely in a disorganized manner, producing a mass of relatively undifferentiated cells called a *callus.* If the nutrients and growth regulators are carefully manipulated, one can induce the formation of a shoot and then root apical meristems within the callus, and, in many species, a whole new plant can be regenerated.

Callus cultures can also be mechanically dissociated into single cells, which will grow and divide as a suspension culture. In a number of plants - including tobacco, petunia, carrot, potato, and *Arabidopsis* - a single cell from such a suspension culture can be grown into a small clump (a clone) from which a whole plant can be regenerated. Just as mutant mice can be derived by genetic manipulation of embryonic stem cells in culture, so transgenic plants can be created from single plant cells transfected with DNA in culture (Figure7-49).

The ability to produce transgenic plants has greatly accelerated progress in many areas of plant cell biology. It has played an important part, for example, in isolating receptors for growth regulators and in analyzing the mechanisms of morphogenesis and of gene expression in plants. It has also opened up many new possibilities in agriculture that could benefit both the farmer and the consumer. It has made it possible, for example, to modify the lipid, starch, and protein storage reserved in seeds, to impart pest and virus resistance to plants, and to create modified plants that tolerate extreme habitats such as salt marshes or waterlogged soil.

Many of the major advances in understanding animal development have come from studies on the fruit fly *Drosophila* and the nematode worm *Caenorhabditis elegans,* which are amenable to extensive genetic analysis as well as to experimental manipulation . Progress in plant developmental biology has been relatively slow by comparison. Many of the organisms that have proved most amenable to genetic analysis, such as maize and tomato, have long life cycles and very large genomes, which have made both classical and molecular genetic analysis time-consuming. Increasing attention is consequently being paid to a fast-growing small weed, the common wall cress (*Arabidopsis thaliana*), which has several major advantages as a "model plant" (see Figure 21-93).

Summary

Genetic engineering has revolutionized the study of both cells and organisms. DNA engineering techniques can be used to create any mutant gene and insert it into a cell's chromosomes so that it becomes a permanent part of the genome. If the cell used for this gene transfer is a fertilized egg (for an animal) or a totipotent plant cell in culture, transgenic organisms can be produced that express the mutant gene and will pass it on to their progeny. Especially important for cell biology is the power that such technology gives the experimenter to alter cells and organisms in highly specific ways - allowing one to discern the effect on the cell or the organism of a designed change in a single protein that has been intentionally mutated by "reverse genetic" techniques.

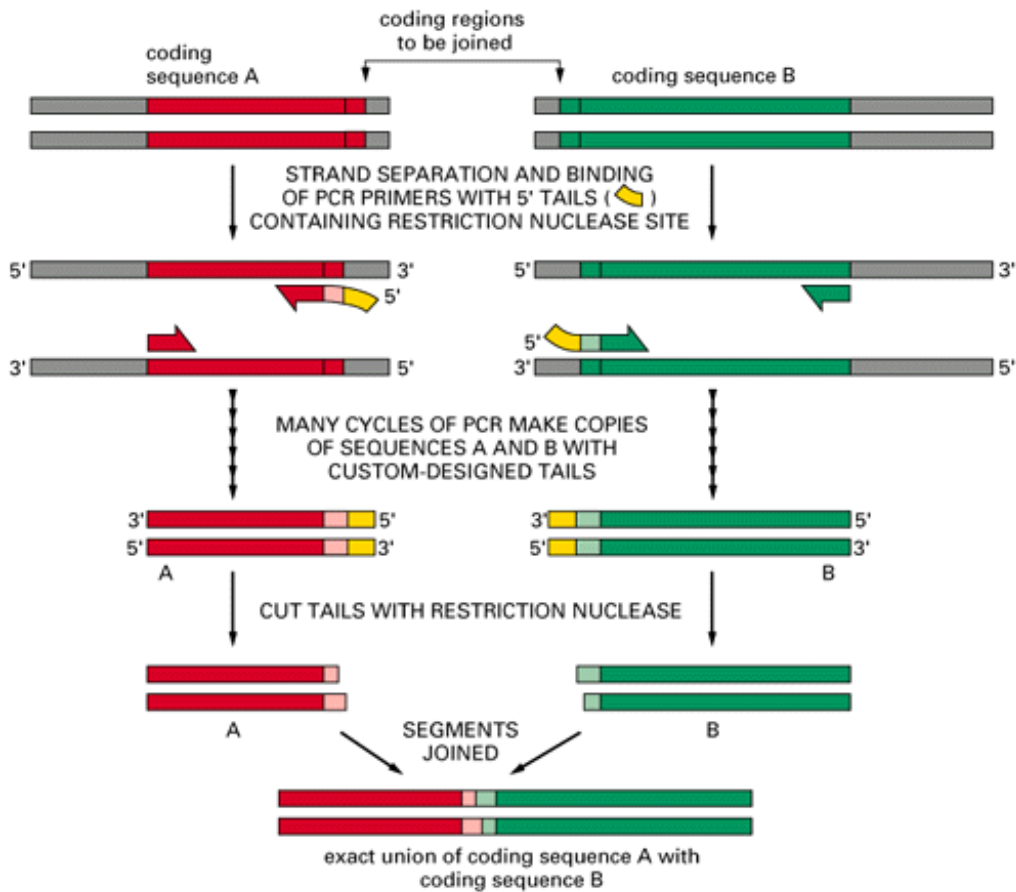
The consequences of genetic engineering are far-reaching in other ways as well. Plants can be altered in ways that increase their value as food crops. Bacteria, yeasts, or mammalian cells can be engineered to synthesize any desired protein in large quantities, making it possible to analyze the structure and function of the protein in detail or to use the protein as a drug or a vaccine for medical purposes.
Figure 7-34. Serial DNA cloning can be used to splice together a set of DNA fragments derived from different genes. All of the DNA molecules shown here are double-stranded. After each DNA insertion step, the plasmid is cloned to purify and amplify the new recombinant DNA molecule. The recombinant molecule is then cut once with a restriction nuclease, as indicated, and used as a cloning vector for the next DNA fragment.


Figure 7-35. Tailoring the ends of DNA fragments facilitates their precise joining. The PCR reaction allows any DNA segment to be amplified with modified ends in preparation for cloning. The synthetic oligonucleotide primers used here contain 5' tails whose sequence has been chosen to create a particular restriction nuclease cutting site.
Figure 7-37. Production of large amounts of a protein by cloning the protein-coding DNA sequence in a plasmid expression vector. The plasmid has been engineered to contain a highly active promoter, which causes unusually large amounts of mRNA encoding the protein to be synthesized in the transfected cells.
Figure 7-38. Production of large amounts of a protein using a plasmid expression vector. In this example bacterial cells have been transfected with the coding sequence for an enzyme, DNA helicase (*arrow*); transcription from this coding sequence is under the control of a viral promoter that becomes active only at temperatures of 37°C or higher. The total cell protein has been analyzed by SDS-polyacrylamide gel electrophoresis, either from bacteria grown at 25°C (no helicase protein made), or after a shift of the same bacteria to 42°C for up to two hours. —regulatory sequence 2 turns on gene X in cells D, E, and F
—regulatory sequence 1 turns off gene X in cell D

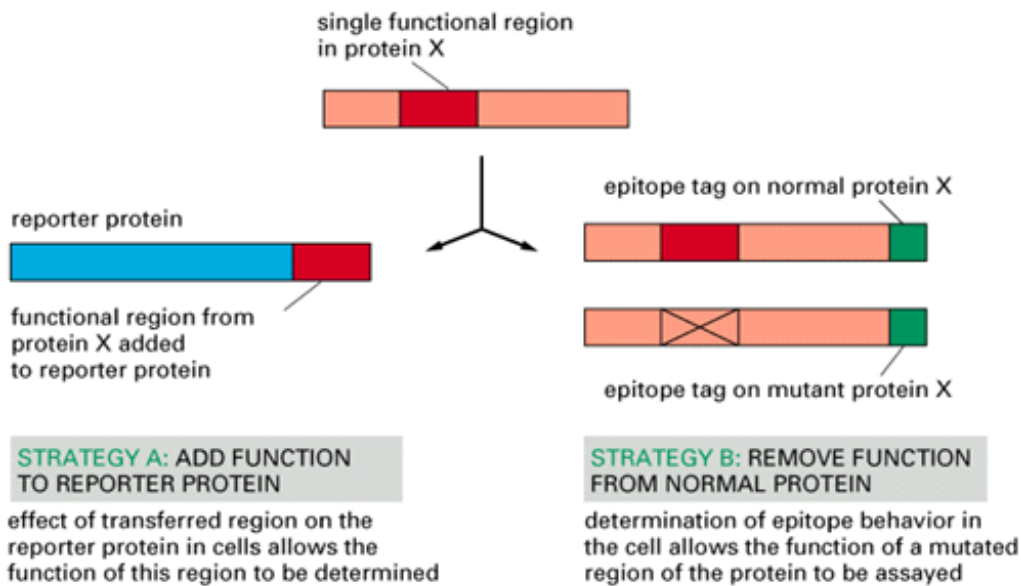
Figure 7-39. Using a reporter protein to locate the regulatory DNA sequences that determine the pattern of a gene's expression. In this example the coding sequence for protein X is replaced by the coding sequence for protein Y, and various fragments of DNA containing candidate regulatory sequences are added in combinations. The recombinant DNA molecules are then tested for expression after their transfection into a variety of different types of mammalian cells. For experiments in eucaryotic cells, two commonly used reporters are the enzymes b-galactosidase (*b-gal*) and chloramphenicol acetyltransferase (*CAT*). Because these are bacterial enzymes, their presence can be monitored by simple and sensitive assays of enzyme activity, without any interference from host cell enzymes.
Figure 7-40. The use of synthetic oligonucleotides to modify the protein-coding regions of genes. Only two of the many types of changes that can be engineered in this way are shown. With an appropriate oligonucleotide, for example, more than one amino acid substitution can be made at a time, or one or more amino acids can be deleted. As indicated, because only one of the two DNA strands in the original recombinant plasmid is altered by this procedure, only half of the transfected cells will end up with a plasmid that contains the desired mutant gene. Note that most of the plasmid DNA sequence is not illustrated here.


Figure 7-41. Two strategies for the analysis of protein function that exploit genetic engineering. In strategy A, a new function is imparted to a reporter protein by the addition of a small segment of normal protein X. In strategy B, minor alterations are made in the normal protein X and its behavior is followed by detection of a short epitope tag and compared to that of the normal protein. Both strategies have been used to analyze the structure and function of the nuclear localization signals found on nuclear proteins (see Chapter 12).
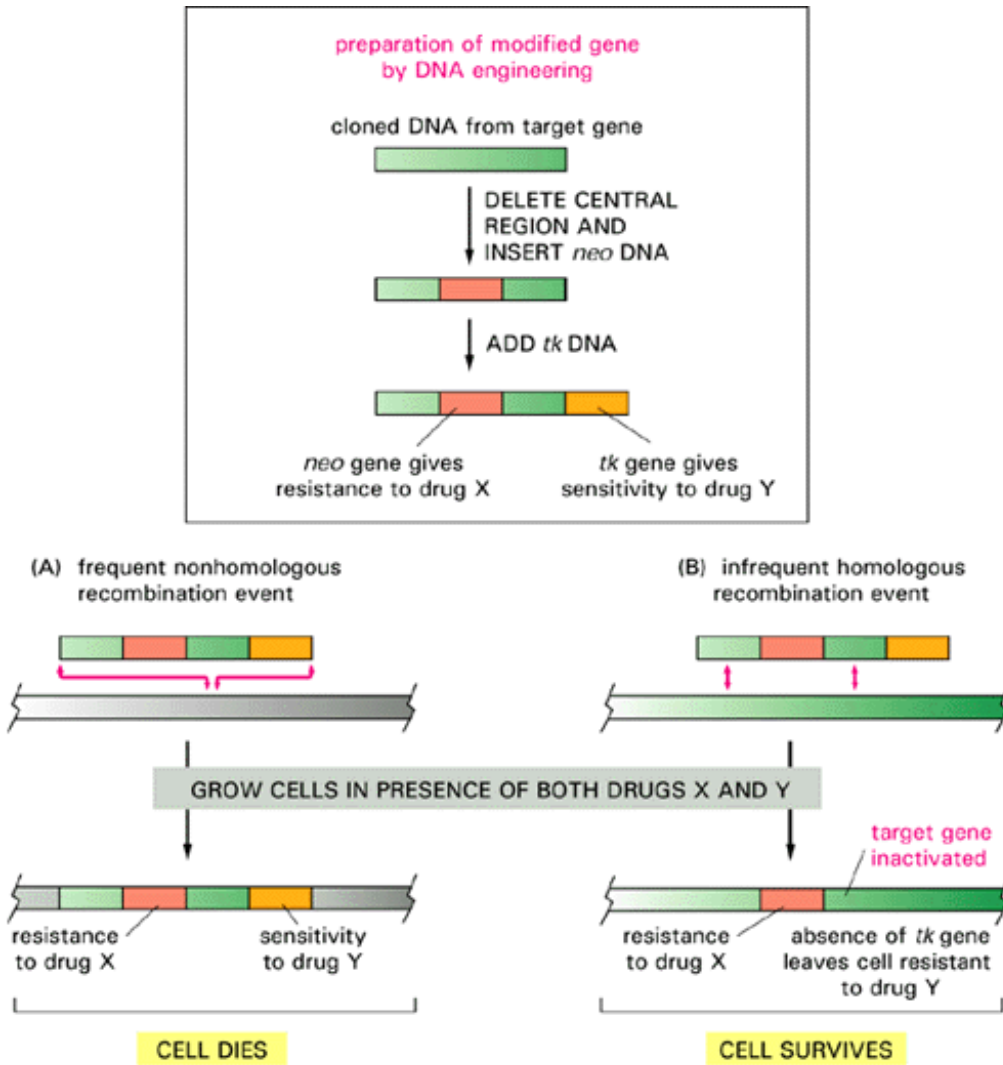
Figure 7-42. Gene replacement and gene addition. A gene whose nucleotide sequence has been altered can be inserted back into the chromosomes of an organism. In bacteria and some haploid eucaryotes such as yeast, the altered gene frequently replaces the normal gene, a process called *gene replacement* (A); in these cases, only the mutant gene remains in the cell. In higher eucaryotes, *gene addition* (B) generally occurs instead of gene replacement; the transformed cell or organism now contains the mutated gene in addition to the normal gene.
Figure 7-43. The antisense RNA strategy for generating dominant negative mutations. Mutant genes that have been engineered to produce antisense RNA, which is complementary in sequence to the RNA made by the normal gene X, can cause double-stranded RNA to form inside cells. If a large excess of the antisense RNA is produced, it can hybridize with - and thereby inactivate - most of the normal RNA produced by gene X. Although in the future it may become possible to inactivate any gene in this way, at present the technique seems to work for some genes but not others.
Figure 7-44. A dominant negative effect of a protein. Here a gene is engineered to produce a mutant protein that prevents the normal copies of the same protein from performing their function. In this simple example the normal protein must form a multi-subunit complex to be active, and the mutant protein blocks function by forming a mixed complex that is inactive. In this way a single copy of a mutant gene located anywhere in the genome can inactivate the normal products produced by other gene copies.
Figure 7-46. Genetic rescue. Comparison of a normal *Drosophila* larva and two mutant larvae that contain defective *ftz* genes. One of the defective (*ftz⁻*) larvae has been rescued by the injection of a DNA clone containing the normal *ftz* gene sequence into the egg of one of its ancestors. This added DNA sequence has become permanently integrated into one of the fly's chromosomes and is therefore faithfully inherited and expressed. The *ftz* gene is required for normal development, and the addition of this gene to the mutant genome restores the larval segments that are missing in the *ftz⁻* organism. For the technique used to make transgenic animals, see Figure 7-45. (Courtesy of Walter Gehring.)


Figure 7-47. Selective gene knockout by homologous recombination in the mouse. Cloned DNA from the mouse gene to be mutated is modified by genetic engineering so that it contains a bacterial gene within it, called *neo*, whose integration into a mouse chromosome makes the mouse cells *resistant* to a drug that otherwise kills them (drug X). A viral gene, called *tk*, is also added, attached to one end of the mouse DNA; the integration of *tk* into a mouse chromosome makes the cells *sensitive* to a different drug (drug Y). Most insertions occur into random sites in the mouse chromosome, and these nearly always include both ends of the engineered DNA fragment, as shown (A). By selecting for those rare mouse cells that grow in the presence of *both* drugs, colonies of cells are obtained in which homologous recombination has incorporated the center of the engineered DNA frag-ment *without* the ends; most of these cells will turn out to carry the targeted gene replacement shown in (B).
Figure 7-48. A transgenic mouse in which both copies of the *Wnt-1* growth factor gene have been eliminated by homologous recombination. (A) Section of the brain from a normal embryo. (B) Section of the brain from a mutant embryo, which lacks a cerebellum and most of the midbrain, and dies *in utero*. (Photographs courtesy of Mario Capecchi.)

8. The Cell Nucleus

Introduction

The DNA in a eucaryotic cell is sequestered in the nucleus, which occupies about 10% of the total cell volume. The nucleus is delimited by a *nuclear envelope* formed by two concentric membranes. These membranes are punctured at intervals by nuclear pores, which actively transport selected molecules to and from the cytosol. The envelope is directly connected to the extensive membranes of the endoplasmic reticulum, and it is supported by two networks of intermediate filaments: one called the *nuclear lamina* forms a thin shell just inside the nucleus underlying the inner nuclear membrane, while the other, less regularly organized, surrounds the outer nuclear membrane (Figure 8-1).

Like modern procaryotes, the ancestors of eucaryotic cells almost certainly lacked a nucleus, and one can only speculate on why a separate nuclear compartment evolved, segregating the DNA from the activities in the cytoplasm. Two special features of eucaryotic cells suggest possible reasons. One is the eucaryotic cytoskeleton, which is composed mainly of microtubules and actin filaments and mediates cell movements. Bacteria, whose DNA is in direct contact with the cytoplasm, lack a cytoskeleton and move by means of external structures such as flagella. One function of the nuclear envelope may therefore be to protect the long, fragile DNA molecules from the mechanical forces generated by the cytoplasmic filaments in eucaryotes.

A second special feature of eucaryotic cells is the extensive processing that RNA molecules undergo before they are translated into protein. In procaryotic cells RNA synthesis (*transcription*) and protein synthesis (*translation*) occur concurrently: ribosomes translate the 5' end of an RNA molecule into protein while the 3' end of the RNA molecule is still being synthesized. Consequently, there is relatively little opportunity to alter the RNA transcripts before they are translated into protein. In eucaryotes, by contrast, transcription (in the nucleus) is separated both temporally and spatially from translation (in the cytoplasm). The RNA transcripts in the nucleus are immediately packaged into ribonucleo-protein complexes and subjected to *RNA splicing*, in which certain portions of the nucleotide sequence are removed. Only when splicing is complete are the packaging proteins removed and the RNA molecules transported out of the nucleus to the cytosol, where ribosomes begin translating the RNA into protein (Figure 8-2). As we discuss later, RNA splicing is an important intermediate step in the transfer of genetic information in eucaryotes. It provides a number of advantages for the cell, including the potential for a single gene to make several different proteins. This may help explain why eucaryotic cells have a nucleus, where splicing can occur without interference from ribosomes (Figure 8-3).

In this chapter we describe how proteins package eucaryotic DNA into chromosomes, how chromosomes are folded and organized in the nucleus, and how they are replicated during each cell-division cycle. We then discuss RNA synthesis and RNA splicing, and, finally, we describe how genetic information is organized in the eucaryotic genome and how this organization may have arisen during evolution. The nuclear envelope is discussed in detail in Chapter 12 in connection with the selective transport of macromolecules into and out of the nucleus, and a hypothetical scheme of how the nuclear compartment might have evolved is presented there (see Figure 12-5).
Figure 8-1. Cross-section of a typical cell nucleus. The nuclear envelope consists of two membranes, the outer one being continuous with the endoplasmic reticulum membrane (see also Figure 12-9). The lipid bilayers of the inner and outer nuclear membranes are connected at each nuclear pore. Two networks of intermediate filaments (*green*) provide mechanical support for the nuclear envelope; the intermediate filaments inside the nucleus form a sheetlike *nuclear lamina*. The space inside the endoplasmic reticulum (the ER lumen) is colored *yellow*.
Figure 8-2. Protein synthesis (DNA → RNA → protein) in eucaryotes. Eucaryotic cells have evolved numerous membrane-bounded compartments that segregate their various chemical reactions so as to make them more efficient, and the nucleus is one such compartment. The nuclear envelope keeps functional ribosomes out of the nucleus, preventing RNA transcripts from being

translated into protein until they have been extensively processed (spliced) and transported out of the nucleus into the cytosol. Thus RNA splicing and transport steps are interposed between DNA transcription and RNA translation.
Figure 8-3. The nuclear envelope keeps the nuclear compartment free from cytoplasmic organelles. This electron micrograph shows a thin section of a sea urchin egg, which has a nucleus that stains unusually evenly and a cytoplasm densely packed with organelles. (Courtesy of David Begg and Tim Hunt.)

Chromosomal DNA and Its Packaging [1]

Introduction

For the first 40 years of this century, biologists tended to dismiss the possibility that DNA could carry the genetic information in chromosomes, partly because nucleic acids were erroneously believed to contain only a simple repeating tetranucleotide sequence (such as AGCTAGCTAGCT). We now know, however, that a DNA molecule is an enormously long, unbranched, linear polymer that can contain many millions of nucleotides arranged in an irregular but nonrandom sequence and that the genetic information of a cell is contained in the linear order of the nucleotides in its DNA. The genetic code, written in "words" of three nucleotides (*codons* that each specify an amino acid, discussed in Chapter 6), neatly solves the problem of storing a large amount of genetic information in a small amount of space: every million "letters" (nucleotides) take up a linear distance of only 3.4×10^5 nm (0.034 cm) and occupy a total volume of about 10^6 nm^3 (10^{-15}cm^3).

Each DNA molecule is packaged in a separate chromosome, and the total genetic information stored in the chromosomes of an organism is said to constitute its genome. The genome of the *E. coli* bacterium contains 4.7×10^6 nucleotide pairs of DNA, present in a single double-helical DNA molecule (one chromosome). The human genome, in contrast, contains about 3×10^9 nucleotide pairs, organized as 24 chromosomes (22 different autosomes and 2 different sex chromosomes), and thus consists of 24 different DNA molecules - each containing from 50×10^6 to 250×10^6 nucleotide pairs of DNA. DNA molecules of this size are 1.7 to 8.5 cm long when uncoiled, and even the slightest mechanical force will break them once the chromosomal proteins have been removed.

In diploid organisms such as ourselves, there are two copies of each different chromosome, one inherited from the mother and one from the father (except for the sex chromosomes in males, where a Y chromosome is inherited from the father and an X from the mother). A typical human cell thus contains a total of 46 chromosomes and about 6×10^9 nucleotide pairs of DNA. Other mammals have genomes of similar size. This amount of DNA could in theory be packed into a cube 1.9 microns on each side. By comparison, 6×10^9 letters in this book would occupy more than a million pages, thus requiring more than 10^{17} times as much space.

In this section we consider the relationship between DNA molecules, genes, and chromosomes, and we discuss how the DNA is folded into a compact and orderly structure - the chromosome - while still allowing access to its genetic information.

Throughout the discussion, it is important to bear in mind that the chromosomes in a cell change their structure and activities according to the stage of the cell-division cycle: in mitosis, or *M phase*, they are very highly condensed and transcriptionally inactive; in the other, much longer part of the division cycle, called *interphase*, they are less condensed and are continuously active in directing RNA synthesis.

Each DNA Molecule That Forms a Linear Chromosome Must Contain a Centromere, Two Telomeres, and Replication Origins 2

To form a functional chromosome, a DNA molecule must be able to do more than direct the synthesis of RNA: it must be able to propagate itself reliably from one cell generation to the next. This requires three types of specialized nucleotide sequences in the DNA, each of which serves to attach specific proteins that guide the machinery that replicates and segregates chromosomes. Experiments in yeasts, whose chromosomes are relatively small and easy to manipulate by recombinant DNA methods, have identified the minimal DNA sequence elements responsible for each of these functions. Two of the three elements were identified by studying small circular DNA molecules that can be propagated as *plasmids* in cells of the yeast *Saccharomyces cerevisiae*. In order to replicate, such a DNA molecule requires a specific nucleotide sequence to act as a DNA replication origin; as we discuss below, one can identify the many origins in each yeast chromosome by their ability to allow a test DNA molecule that contains one of them to replicate when free of the host chromosome. A second sequence element, called a centromere, attaches any DNA molecule that contains it to the mitotic spindle during cell division. Each yeast chromosome contains a single centromere; when this sequence is inserted into a plasmid, it guarantees that each daughter cell will receive one of the two copies of the newly replicated plasmid DNA molecule when the yeast cell divides.

The third required sequence element is a telomere, which is needed at each end of a linear chromosome. If a circular plasmid that contains a replication origin and a centromere is broken at a single site to create two free ends in the double helix, it will still replicate and attach to the mitotic spindle, but it will eventually be lost from the progeny cells. This is because replication on the lagging strand of a replication fork requires the presence of some DNA ahead of the sequence to be copied to serve as the template for an RNA primer (see Figure6-44). Since there can never be such a template for the last few nucleotides of a linear DNA molecule, special mechanisms are required to prevent each such DNA strand from becoming shorter with each replication cycle. Bacteria and many viruses solve this "end-replication problem" by having a circular DNA molecule as their chromosome. Eucaryotic cells have instead evolved a specialized telomeric DNA sequence at each chromosome end. This simple repeating sequence is periodically extended by an enzyme, *telomerase*, thus compensating for the loss of a few nucleotides of telomeric DNA in each cycle and permitting a linear chromosome to be completely replicated.

Figure 8-4summarizes the functions of the three DNA sequence elements that are required for a linear chromosome to propagate itself from generation to generation in a yeast cell. These sequence elements are relatively short (typically less than 1000 base pairs each) and therefore utilize only a tiny fraction of the information-carrying capacity of a chromosome. The same three types of sequence elements are thought to operate in human chromosomes, but to date only the human telomere sequences have been well defined. Although the yeast versions of these sequences do not function in higher eucaryotic cells, recombinant DNA methods allow the yeast sequence elements to be added to human DNA molecules, which can then replicate in yeast cells as artificial chromosomes. In this way yeast cells can be used to prepare human genomic DNA libraries (see p. 315) in which each DNA clone (propagated as an artificial chromosome) contains as many as a million nucleotide pairs of human DNA sequence (Figure 8-5).

Most Chromosomal DNA Does Not Code for Proteins or RNAs 3

The genomes of higher organisms seem to contain a large excess of DNA. Long before it was possible to examine the nucleotide sequences of chromosomal DNA directly, it was evident that the amount of DNA in the haploid genome of an organism has no systematic relationship to the complexity of the organism. Human cells, for example, contain about 700 times more DNA than the bacterium *E. coli*, but some amphibian and plant cells contain 30 times more DNA than human cells (Figure 8-6). Moreover, the genomes of different species of amphibians can vary 100-fold in their DNA content.

Population geneticists have tried to estimate how much of the DNA in higher organisms codes for essential proteins or RNA molecules on the basis of the following indirect argument. Each gene is inevitably subject to a small risk of accidental mutation, in which nucleotides in the DNA are altered at random. The greater the number of genes, the greater the probability that a mutation will occur in at least one of them. Since most mutations will impair the function of the gene in which they occur, the mutation rate sets an upper limit to the number of essential genes that an organism can depend on for its survival: if there are too many, disaster becomes almost a certainty, as with a complex machine dependent on too many components that are liable to fail.

Using this argument and the observed mutation rate, it has been estimated that no more than a small percentage of the mammalian genome can be involved in regulating or encoding essential proteins or RNA molecules. We shall see later that other evidence supports this conclusion.

The most important implication of this estimate is that although the mammalian genome contains enough DNA, in principle, to code for nearly 3 million average-sized proteins (3×10^9 nucleotides), the limited fidelity with which DNA sequences can be maintained means that no mammal (or any other organism) is likely to be constructed from more than perhaps 60,000 essential proteins. Thus, from a genetic point of view, humans are unlikely to be more than about 10 times more complex than the fruit fly *Drosophila*, which is estimated to have about 5000 essential genes.

Whatever the remaining nonessential DNA in higher eucaryotic chromosomes may do (we discuss this later), the data shown in Figure 8-6 make it clear that it is not a great handicap for a higher eucaryotic cell to carry a large amount of extra DNA. Indeed, even the essential coding regions are often interrupted by long stretches of noncoding DNA.

Each Gene Produces an RNA Molecule 4

The primary function of the genome is to specify RNA molecules. Selected portions of the DNA nucleotide sequence are copied into a corresponding RNA nucleotide sequence, which either encodes a protein (if it is an mRNA) or forms a "structural" RNA, such as a transfer RNA (tRNA) or ribosomal RNA (rRNA) molecule. Each region of the DNA helix that produces a functional RNA molecule constitutes a gene.

In higher eucaryotes genes that are more than 100,000 nucleotide pairs in length are common, and some contain more than 2 million nucleotide pairs (Table 8-1); yet only about 1000 nucleotide pairs are required to encode a protein of average size (one containing 300 to 400 amino acids). Most of the extra length consists of long stretches of noncoding DNA that interrupt the relatively short segments of coding DNA. The coding sequences are called exons; the intervening (noncoding) sequences are called introns. The RNA molecule (called a *primary RNA transcript*) synthesized from such a gene is altered to remove the intron sequences during its conversion to an mRNA molecule (see Figure 8-2) in the process of *RNA splicing*, as we discuss later.

Large genes consist of a long string of alternating exons and introns, with most of the gene consisting of introns. In addition, each gene is associated with *regulatory DNA sequences,* which are responsible for ensuring that the gene is transcribed at the proper time and in the appropriate cell type. We discuss in Chapter 9 how these regulatory sequences work. Many of them are located "upstream" (on the 5' side) of the site where RNA transcription begins, but they can also be located "downstream" (on the 3' side) of the site where RNA transcription ends, or even in introns or exons. A typical vertebrate chromosome is illustrated schematically in Figure 8-7, along with one of its many genes.

Comparisons Between the DNAs of Related Organisms Distinguish Conserved and Nonconserved Regions of DNA Sequence 5

Technical improvements in DNA sequencing are expected to allow the routine sequencing of stretches of chromosomal DNA that are millions of nucleotide pairs long, so that in the foreseeable future the sequence of all 3×10^9 nucleotides of the human genome will be determined. As more than 90% of this sequence is probably unimportant, it will be crucial to have some way of identifying the small proportion of sequence that is important. One approach to this problem is based on the observation that important sequences are conserved during evolution, while unimportant ones are free to mutate randomly. The strategy, therefore, is to compare the human sequence with that of the corresponding regions of a related genome, such as that of the mouse. Humans and mice are thought to have diverged from a common mammalian ancestor about 80×10^6 years ago, which is long enough for roughly two out of every three nucleotides to have been changed by random mutational events. Consequently, the only regions that will have remained closely similar in the two genomes are those where mutations would impair function and put animals carrying them at a disadvantage, resulting in their elimination from the population by natural selection. Such closely similar regions are known as *conserved regions.* In general, *nonconserved* regions represent noncoding DNA - both between genes and in introns - whose sequence is not critical for function, whereas conserved regions represent functionally important exons and regulatory sequences. By revealing in this way the results of a very long natural "experiment," comparative DNA sequencing studies highlight the most interesting regions in genomes. Such studies also provide strong support for the conclusion that only about 10% of the vertebrate genome sequence is vitally important to the organism.

Histones Are the Principal Structural Proteins of Eucaryotic Chromosomes 6

If chromosomes were composed simply of extended DNA, it is difficult to imagine how they could be replicated and segregated to daughter cells without becoming severely tangled or broken. In fact, the DNA of all chromosomes is packaged into a compact structure with the aid of specialized proteins. It is traditional to divide the DNA-binding proteins in eucaryotes into two general classes: the histones and the *nonhistone chromosomal proteins.* The complex of both classes of proteins with the nuclear DNA of eucaryotic cells is known as chromatin. Histones are unique to eucaryotes. They are present in such enormous quantities (about 60 million molecules of each type per cell, compared to 10,000 molecules per cell for a typical sequence-specific DNA-binding protein) that their total mass in chromatin is about equal to that of the DNA.

Histones are relatively small proteins with a very high proportion of positively charged amino acids (lysine and arginine); the positive charge helps the histones bind tightly to DNA (which is highly negatively charged), regardless of its nucleotide sequence. Histones probably only rarely dissociate from the DNA, and so they are likely to have an influence on any reaction that occurs on chromosomes.

The five types of histones fall into two main groups - the *nucleosomal histones* and the *H1 histones*. The nucleosomal histones are small proteins (102-135 amino acids) responsible for coiling the DNA into *nucleosomes*, as discussed later. These four histones are designated H2A, H2B, H3, and H4. H3 and H4 are among the most highly conserved of all known proteins (Figure 8-8). This evolutionary conservation suggests that their functions involve nearly all of their amino acids, so that a change in any position is deleterious to the cell. This suggestion has been tested in yeasts, where it is possible to mutate a given histone gene *in vitro* and introduce it into the yeast genome in place of the normal gene. As predicted, many mutations are found to be lethal; some that are not lethal cause changes in the normal pattern of gene expression (discussed in Chapter 9). The H1 histones are larger (containing about 220 amino acids) and have been less conserved during evolution than the nucleosomal histones.

Histones Associate with DNA to Form Nucleosomes, the Unit Particles of Chromatin 7

If it were stretched out, the DNA double helix in each human chromosome would span the cell nucleus thousands of times. Histones play a crucial part in packing this very long DNA molecule in an orderly way into a nucleus only a few micrometers in diameter. Their role in DNA folding is also important for a second reason. As we shall see, not all the DNA is folded in exactly the same way, and the manner in which a region of the genome is packaged into chromatin in a particular cell seems to influence the activity of the genes the region contains.

A major advance in our understanding of chromatin structure came in 1974 with the discovery of the fundamental packing unit known as the nucleosome, which gives chromatin a "beads-on-a-string" appearance in electron micrographs taken after treatments that unfold higher-order packing (Figure 8-9). The long DNA "string" can be broken into nucleosome "beads" by digestion with enzymes that degrade DNA, such as the bacterial enzyme micrococcal nuclease. (Enzymes that degrade both DNA and RNA are called *nucleases;* enzymes that degrade only DNA are *deoxyribonucleases*, or *DNases*.) After digestion for a short period with micrococcal nuclease, only the DNA between the nucleosome beads is degraded. The rest is protected from digestion and remains as double-helical DNA fragments 146 nucleotide pairs long bound to a specific complex of eight nucleosomal histones (the *histone octamer*). The nucleosome beads obtained in this way have been crystallized and analyzed by x-ray diffraction. Each is a disc-shaped particle with a diameter of about 11 nm containing two copies of each of the four nucleosomal histones H2A, H2B, H3, and H4. This histone octamer forms a protein core around which the double-stranded DNA helix is wound twice (Figure 8-10).

In undigested chromatin the DNA extends as a continuous double-helical thread from nucleosome to nucleosome. Each nucleosome is separated from the next by a region of *linker DNA*, which can vary in length from 0 to 80 nucleotide pairs. On average, nucleosomes repeat at intervals of about 200 nucleotide pairs (see Figure 8-10). Thus, a typical eucaryotic gene of 10,000 nucleotide pairs will be associated with 50 nucleosomes, and each human cell with 6 x 10^9 DNA nucleotide pairs contains 3 x 10^7 nucleosomes.

The Positioning of Nucleosomes on DNA Is Determined by the Propensity of the DNA to Form Tight Loops and by the Presence of Other DNA-bound Proteins 8

Experiments performed *in vitro* with isolated chromatin suggest that the histone octamers generally remain fixed in one position under physiological conditions, inasmuch as their tight binding to DNA prevents them from sliding back and forth along the

helix. There are two main influences that determine where nucleosomes form in the DNA. One is the difficulty of bending the DNA double helix into two tight turns around the outside of the histone octamer, a process that requires substantial compression of the minor groove of the helix. Because A-T-rich sequences in the minor groove are easier to compress than G-C-rich sequences, each histone octamer tends to position itself on the DNA so as to maximize A-T-rich minor grooves on the inside of the DNA coil (Figure 8-11). Thus a segment of DNA that contains short A-T-rich sequences spaced by integral numbers of DNA turns will be much easier to bend around the nucleosome than a segment of DNA lacking this feature. This probably explains some striking cases of very precise positioning of nucleosomes, such as those that bind to the tiny 5S rRNA genes, each of which has a single nucleosome bound to it in a unique location. If the DNA containing the 5S rRNA genes is added *in vitro* to a mixture of the four purified nucleosomal histones, nucleosomes will re-form at the exact position where they are located *in vivo*. For most of the DNA sequences found in chromosomes, however, there is no strongly preferred nucleosome binding site; instead, a nucleosome can occupy any one of a number of positions relative to the DNA sequence.

The second important influence on nucleosome positioning is the presence of other tightly bound proteins on the DNA that prevent nucleosomes from forming. For this reason some regions of DNA appear to lack a nucleosome even though they are hundreds of nucleotide pairs long. They can be detected by treating cell nuclei with trace amounts of a deoxyribonuclease (DNase I) that at low concentrations will digest long stretches of nucleosome-free DNA but not the short stretches of linker DNA between nucleosomes. Such nuclease-hypersensitive sites often lie in the regulatory regions of genes (Figure 8-12). The first evidence for this idea came from studies of the monkey virus SV40, whose circular DNA chromosome binds to histones produced by its host cells. The SV40 chromosome often contains a single nucleosome-free region about 300 nucleotide pairs long very near the sequences at which viral DNA synthesis and RNA synthesis begin. Although several sequence-specific DNA-binding proteins are bound to this region, they do not protect long stretches of DNA against nuclease attack as do the nucleosomes, which is why the site is DNase-I sensitive.

The default state of the DNA in eucaryotic cells is to be fully covered with nucleosomes, and most nucleosome-free regions are specifically created by gene regulatory proteins as part of the process of activating DNA transcription (discussed in Chapter 9). Wherever nucleosomes are specifically positioned by the DNA sequence itself, there may have been evolutionary pressure to keep the adjacent linker DNA free of a nucleosome so as to facilitate its recognition by sequence-specific DNA-binding proteins.

Nucleosomes Are Usually Packed Together by Histone H1 to Form Regular Higher-Order Structures 9

The linker DNA that connects adjacent nucleosomes can vary in length since nucleosomes position themselves according to the local flexibility of the DNA helix and the distribution of other proteins bound to specific DNA sequences. Although long strings of nucleosomes form on most chromosomal DNA, in the living cell chromatin probably rarely adopts the extended "beads-on-a-string" form. Instead, the nucleosomes are packed upon one another to generate regular arrays in which the DNA is even more highly condensed. Thus, when nuclei are very gently lysed onto an electron microscope grid, most of the chromatin is seen to be in the form of a fiber with a diameter of about 30 nm, which is considerably wider than chromatin in the "beads-on-a-string" form. One of several models proposed to explain how nucleosomes are packed in the 30-nm chromatin fiber is illustrated in Figure 8-13. Such models represent an idealized structure, since both the range of linker lengths that result from preferred nucleosome positioning and the presence of occasional nucleosome-free sequences will punctuate the 30-nm fiber with irregular features (Figure 8-14).

The histone H1 molecules, of which there are about six closely related subtypes in a mammalian cell, are thought to be responsible for pulling nucleosomes together to form the 30-nm fiber. The H1 molecule has an evolutionarily conserved globular central region linked to less conserved extended amino-terminal and carboxyl-terminal "arms." Each H1 molecule binds through its globular portion to a unique site on a nucleosome, and its arms extend to contact other sites on the histone cores of adjacent nucleosomes, so that the nucleosomes are pulled together into a regular repeating array (Figure 8-15).

Summary

A gene is defined as a nucleotide sequence in a DNA molecule that acts as a functional unit for the production of an RNA molecule. A chromosome is formed from a single, enormously long DNA molecule that contains a series of many genes. A chromosomal DNA molecule also contains three other types of functionally important nucleotide sequences: replication origins and telomeres allow the DNA molecule to be replicated, while a centromere is needed to attach the DNA molecule to the mitotic spindle, ensuring its accurate segregation to daughter cells. The human haploid genome contains 3×10^9 DNA nucleotide pairs, divided among 22 different autosomes and 2 sex chromosomes. Only a small percentage of this DNA is thought to code for proteins.

The DNA in eucaryotes is tightly bound to an equal mass of histones, which form a repeating array of DNA-protein particles called nucleosomes. The nucleosome is made up of an octameric core of histone proteins around which the DNA is wrapped twice. The ease with which a segment of DNA can undergo the severe bending required for this wrapping varies with its nucleotide sequence. Despite irregularities such as this, nucleosomes are usually packed together, with the aid of histone H1 molecules, into regular arrays to form a 30-nm fiber.
Figure 8-4. The functions of the three DNA sequence elements needed to produce a stable linear eucaryotic chromosome. Each chromosome has many origins of replication, one centromere, and two telomeres. The centromere serves to hold the two copies of the duplicated chromosome together and to attach them, via a protein complex called a kinetochore, to the mitotic spindle in such a way that one copy is distributed to each daughter cell at mitosis. The phases of the cell-division cycle corresponding to the events of chromosome replication and segregation are shown above the diagrams.
Figure 8-5. The making of a yeast artificial chromosome (YAC). A YAC vector allows the cloning of very large DNA molecules. TEL, CEN, and ORI are the telomere, centromere, and replication origin sequence elements, respectively, for the yeast *Saccharomyces cerevisiae*. BamH1 and EcoR1 are sites where the corresponding restriction nucleases cut the DNA double helix. The sequences denoted as A and B encode enzymes that serve as selectable markers to allow the easy isolation of yeast cells that have taken up the artificial chromosome. (Adapted from D.T. Burke, G.F. Carle, and M.V. Olson, *Science* 236:806-812, 1987. © 1987 AAAS.)
Figure 8-6. Lack of relationship between amount of DNA and organism complexity. The amount of DNA in a haploid genome varies over a 100,000-fold range from the smallest procaryotic cell - the mycoplasma - to the large cells of some plants and amphibia. Note that the genome size of humans (3×10^9 nucleotide pairs) is much smaller than that of many organisms that

appear to be simpler.

Table 8-1. The Size of Some Human Genes in Thousands of Nucleotides

	Gene Size	mRNA Size	Number of Introns
b-Globin	1.5	0.6	2
Insulin	1.7	0.4	2
Protein kinase C	11	1.4	7
Albumin	25	2.1	14
Catalase	34	1.6	12
LDL receptor	45	5.5	17
Factor VIII	186	9	25
Thyroglobulin	300	8.7	36
Dystrophin*	more than 2000	17	more than 50

*. An altered form of this gene causes Duchenne muscular dystrophy.The size specified here for a gene includes both its transcribed portion and nearby regulatory DNA sequences. (Compiled from data supplied by Victor McKusick.)
Figure 8-7. The organization of genes on a typical vertebrate chromosome. Proteins that bind to the DNA in regulatory regions determine whether a gene is transcribed; although often located on the 5' side of a gene, as shown here, regulatory regions can also be located in introns, in exons, or on the 3' side of a gene. Intron sequences are removed from primary RNA transcripts to produce messenger RNA (mRNA) molecules. The figure given here for the number of genes per chromosome is a minimal estimate.

Figure 8-8. The amino acid sequence of histone H4. The amino acids are designated by their single-letter abbreviations, with the positively charged amino acids colored for emphasis. As in the three other nucleosomal histones, an elongated amino-terminal "tail" is reversibly modified in the cell by the acetylation of selected lysines, which removes the lysine's positive charge. The sequence from a cow is shown; the sequence is the same in peas except that one valine is changed to an isoleucine and one lysine is changed to an arginine.

(A)

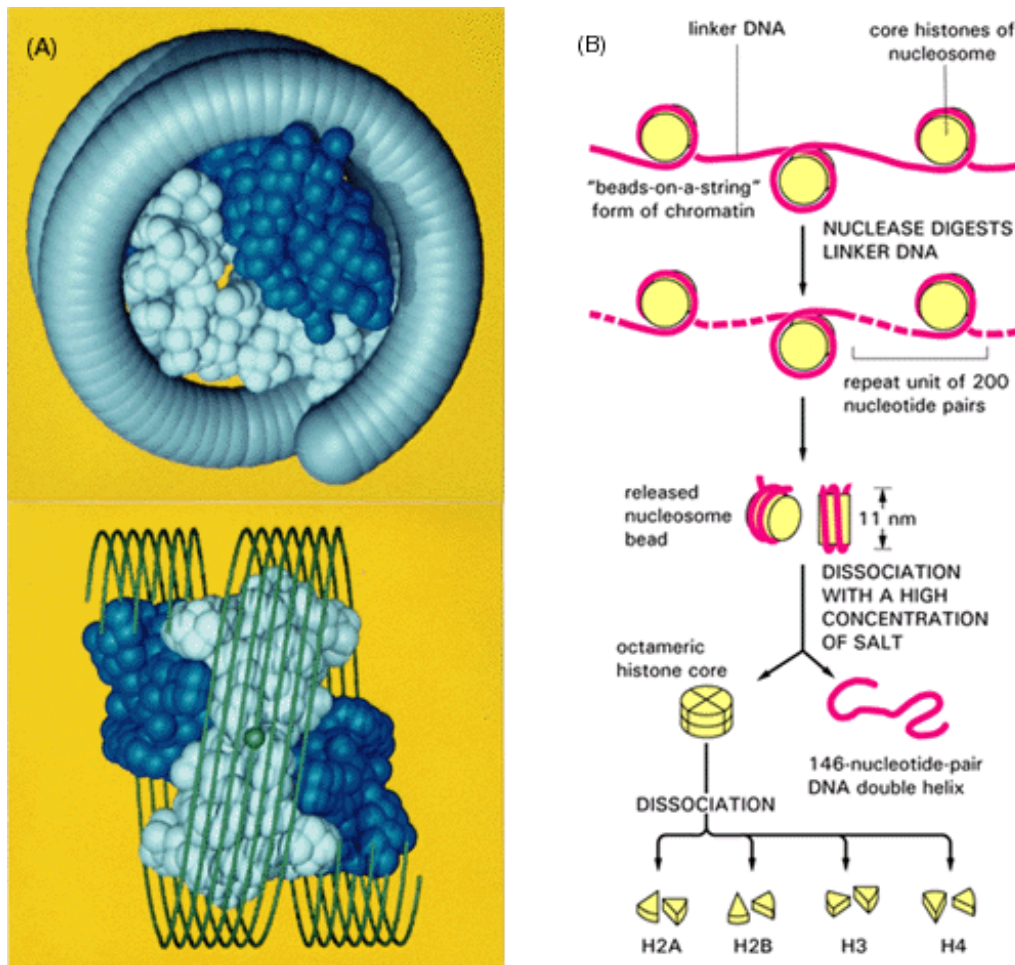
50 nm
Figure 8-9. Nucleosomes as seen in the electron microscope. These electron micrographs show chromatin strands before and after treatments that unpack, or "decondense," the native structure to produce the "beads-on-a-string" form. The native structure, known as the 30-nm fiber (discussed later), is shown in (A). The decondensed, "beads-on-a-string" form of chromatin is shown at the same magnification in (B). For a schematic drawing of the relation between these two chromatin forms, see Figure 8-30. These electron micrographs were taken by modifications of the procedure outlined in Figure 8-45. (A, courtesy of Barbara Hamkalo; B, courtesy of Victoria Foe.)


Figure 8-10. The nature of the nucleosome. (A) depicts two views of the three-dimensional structure of the histone octamer; the general path of the DNA wrapped around it is indicated by a coiled tube (*top*) and a series of parallel lines (*bottom*). Two H2A-H2B dimers (*blue*) flank an H3-H4 tetramer. The histone octamer is thus composed of two each of histones H2A, H2B, H3, and H4, with a total mass of about 100,000 daltons. (B) The nucleosome consists of two full turns of DNA (83 nucleotide pairs per turn) wound around an octameric histone core, plus the adjacent "linker DNA." The part of the nucleosome referred to here as the "nucleosome bead" is released from chromatin by digestion of the DNA with micrococcal nuclease. In each nucleosome bead 146 nucleotide pairs of DNA double helix (about 1.8 turns) remain wound around the octameric histone core. (A, courtesy of Evangelos Moudrianakis.)
Figure 8-11. The bending of DNA in a nucleosome. The DNA helix makes two tight turns around the histone octamer. This diagram is drawn approximately to scale to illustrate how the minor groove is compressed on the inside of the turn. Due to certain structural features of the DNA molecule, A-T base pairs are preferentially accommodated in a narrow minor groove.
Figure 8-12. The location of nuclease-hypersensitive sites in the regulatory regions of active genes. The genes shown encode histones (H1, H2A, H2B, H3, and H4) in *Drosophila*. The *horizontal arrows* denoting each gene point in the direction of DNA transcription, which always proceeds from the 5' to the 3' end of the transcript. Although the nuclease-hypersensitive sites (*vertical red arrows*) are often present on the 5' side of a gene, as illustrated here, they can also be located elsewhere (see Figure 9-34).
Figure 8-13. The 30-nm chromatin fiber. A model to explain how the "beads-on-a-string" form of nucleosomes is packed to form the 30-nm fiber seen in electron micrographs (see Figure 8-9A) in top (A) and side view (B). This type of packing requires one molecule of histone H1 per nucleosome (not shown). Although the position where the H1 attaches to the nucleosome has been defined (see Figure 8-15), the location of the H1 molecules in this fiber is unknown. (See also Figure 8-14.)
Figure 8-14. Nucleosome-free regions in 30-nm fibers. A schematic section of chromatin illustrating the interruption of its regular nucleosomal structure by short regions where the chromosomal DNA is unusually vulnerable to digestion by DNase I. At each of these nuclease-hypersensitive sites, a nucleosome appears to have been excluded from the DNA by one or more sequence-specific DNA-binding proteins. How these proteins bind DNA tightly is discussed in Chapter 9.
Figure 8-15. The way histone H1 is thought to help pack adjacent nucleosomes together. The globular core of H1 binds to each nucleosome near the site where the DNA helix enters and leaves the histone octamer. When H1 is present on the nucleosomes, 166 nucleotide pairs of DNA are protected from micrococcal nuclease digestion, compared with 146 nucleotide pairs for nucleosomes lacking H1 (see Figure 8-10).

The Global Structure of Chromosomes

Introduction

Having discussed the DNA and protein molecules from which chromosomes are made, we now turn to the organization of the chromosome on a more global scale. As a 30-nm fiber, the typical human chromosome would be 0.1 cm in length and could span the nucleus more than 100 times. Clearly, there must be a still higher level of folding. The DNA is not only packaged with histones into regularly repeating nucleosomes that are packed into 30-nm fibers; it is also elaborately folded and organized by other proteins into a series of subdomains of distinct character. This higher-order packaging is one of the most fascinating but also most poorly understood aspects of chromatin. Although its molecular basis is still a mystery, this packaging almost certainly plays a crucial part in the regulation of gene transcription. In this section we discuss what is known about higher-order chromatin structure and examine evidence that shows it is functionally important.

Lampbrush Chromosomes Contain Loops of Decondensed Chromatin [10]

Although packaged into chromatin, most chromosomes in interphase cells (cells not in mitosis) are too fine and too tangled to be visualized clearly. In a few exceptional cases, however, interphase chromosomes can be seen to have a precisely defined higher-order structure. The meiotically paired chromosomes in growing amphibian oocytes (immature eggs), for example, are highly active in RNA synthesis, and they form unusually stiff and extended chromatin loops that are covered with newly transcribed RNA packed into dense RNA-protein complexes. Because of this coating on the DNA, these so-called lampbrush chromosomes are clearly visible even in the light microscope, where they are seen to be organized into a series of large chromatin loops emanating from a linear chromosomal axis (Figure 8-16).

The organization of the lampbrush chromosome is illustrated schematically in Figure 8-17. Nucleic acid hybridization experiments show that a given loop always contains the same DNA sequence and that it remains extended in the same manner as the oocyte grows. Other experiments demonstrate that most of the looped DNA is being actively transcribed into RNA. The majority of the chromatin, however, is not in loops but remains highly condensed in the *chromomeres*, which are generally not transcribed. A general chromosome model based on these studies has been proposed in which loops of 30-nm fibers extend at an angle from the main axis of the chromosome (Figure 8-18).

Lampbrush chromosomes illustrate the recurrent themes of this section - when chromatin is actively transcribed, it has an extended structure; when the chromatin is condensed, it is inactive; and the structural units of regulation are large, precisely defined domains.

Orderly Domains of Interphase Chromatin Also Can Be Seen in Insect Polytene Chromosomes [11]

Because of a specialization (which is different from that of the lampbrush chromosome), chromatin structure is also unusually visible in certain insect cells. Many of the cells of the larvae of flies grow to an enormous size through multiple cycles of DNA synthesis without cell division. The resulting giant cells contain as much as several thousand times the normal DNA complement. Cells with more than the normal DNA complement are said to be *polyploid* when, as is usually the case, they contain increased numbers of standard chromosomes. In several types of secretory cells of fly larvae, however, all the homologous chromosome copies remain side by side, creating a single giant *polytene chromosome*. The fact that some large insect cells can undergo a direct polytene-to-polyploid conversion demonstrates that these two chromosomal states are closely related and that the basic structure of a polytene chromosome must be similar to that of a normal chromosome.

Polytene chromosomes are easy to see in the light microscope because they are so large and because the precisely aligned side-to-side adherence of individual chromatin strands greatly elongates the chromosome axis and prevents tangling. Like lampbrush chromosomes, these chromosomes are active in RNA synthesis. Polyteny has been most studied in the salivary gland cells of *Drosophila* larvae, in which the DNA in each of the four *Drosophila* chromosomes has been replicated through 10 cycles without separation of the daughter chromosomes, so that $1024 (= 2^{10})$ identical strands of chromatin are lined up side by side (Figure 8-19).

When polytene chromosomes are viewed in the light microscope, distinct alternating dark *bands* and light *interbands* are visible (Figure 8-20). Each band and interband represents a set of 1024 identical DNA sequences arranged in register. About 85% of

the DNA in polytene chromosomes is in bands, and 15% is in interbands. The chromatin in each band stains darkly because it is much more condensed than the chromatin in the interbands (Figure 8-21). Depending on their size, individual bands are estimated to contain 3000 to 300,000 nucleotide pairs per chromatin strand. Since the bands can be recognized by their different thicknesses and spacings, each one has been given a number to generate a polytene chromosome "map." There are approximately 5000 bands and 5000 interbands in the total *Drosophila* genome.

Individual Chromatin Domains Can Unfold and Refold as a Unit [12]

Long before anything was known at the molecular level about chromatin structure, studies of polytene chromosomes suggested that a major change in DNA packing accompanies gene transcription, since individual chromosome bands often expand when the genes they contain become active and recondense when these genes become quiescent.

The regions on a polytene chromosome being transcribed at any instant can be identified by labeling the cells briefly with the radioactive RNA precursor ^{3}H-uridine and locating the growing RNA transcripts by autoradiography (Figure 8-22). This analysis (see below) reveals that the most active chromosomal regions are decondensed, forming distinctive chromosome puffs.

One of the main factors controlling the activity of genes in polytene chromosomes of *Drosophila* is the insect steroid hormone *ecdysone,* the levels of which rise and fall periodically during larval development, inducing the transcription of various genes coding for proteins that the larva requires for each molt and for pupation. As the organism progresses from one developmental stage to another, new puffs arise and old puffs recede, as transcription units are activated and deactivated and different mRNAs and proteins are made (Figure 8-23). From inspection of each puff when it is relatively small and the banding pattern of the chromosome is still discernible, it seems that most puffs arise from the uncoiling of a single chromosome band (Figure 8-24). Electron microscopy of thin sections of such puffs shows that the DNA in the chromatin is much less condensed than it would be in the 30-nm chromatin fiber. These observations suggest that the chromatin in a band can decondense as a unit during transcription.

Both Bands and Interbands in Polytene Chromosomes Are Likely to Contain Genes [13]

The fixed pattern of bands and interbands in a *Drosophila* polytene chromosome suggested to early cytogeneticists that each band might correspond to a single gene. Mutational analyses that allowed geneticists to estimate that *Drosophila* contains only about 5000 essential genes, a number roughly equal to the number of chromosome bands, supported this view. Moreover, when an intensive effort was made to isolate as many mutants as possible in a small chromosomal region, about 50 essential genes were genetically identified in a region that contains about 50 visible bands. Although it is not possible with these techniques to determine whether a particular gene lies in a band or an interband region, these observations suggested that an average band might contain the DNA coding sequences for only one essential protein.

Genes that are not essential for survival in the laboratory (where predators are absent and both food and mates are provided), however, would have been missed in these genetic analyses, and more recent data have made the simple "one-band, one-gene" hypothesis seem unlikely. A continuous 315,000-nucleotide-pair region of the *Drosophila* genome has been cloned, for example, and fragments have been used as DNA probes to catalogue the mRNAs produced from the region: three times as many separate mRNAs as bands were identified, indicating that each band probably contains several genes. In addition, it has now been shown directly that mRNAs are produced from both interbands and bands in polytene chromosomes.

Although still controversial, it has been proposed that the DNA in polytene chromosome bands is arranged in loops in a manner analogous to that of the lampbrush chromosomes. According to this model, puff formation would correspond to the decondensation of one or more looped domains. Whether or not this model is correct, the above findings show that at least some interphase chromosomes are arranged in a complex, precisely ordered sequence of structural domains, each typically containing a small number of genes whose transcription is regulated in a coordinated way. It may be that all interphase chromosomes are packaged into ordered structures according to these same principles.

Transcriptionally Active Chromatin Is Less Condensed [14]

The studies of puffs on insect polytene chromosomes suggest that the chromatin structure of transcribed genes is selectively decondensed. Experiments of a completely different type support this suggestion. When nuclei isolated from vertebrate cells are exposed to the enzyme DNase I, about 10% of the genome is preferentially degraded. Although a small subset of these degraded sequences corresponds to the hypersensitive sites described earlier, most of them represent genes that are being transcribed:

different DNA sequences, for example, are digested by the nuclease in different cells of the same organism, depending on the genes that are being transcribed in the different cell types. Remarkably, even genes that are transcribed only a few times in every cell generation are sensitive to DNase I, indicating that a special state of the chromatin, rather than the process of DNA transcription itself, makes these regions unusually accessible to digestion (Figure 8-25). Chromatin in this accessible state is often termed active chromatin, and its structure appears to be altered in a way that makes the packing of the nucleosomes less condensed.

Active Chromatin Is Biochemically Distinct 15

What distinguishes active from inactive chromatin? The answer to this question will probably require purification and characterization of the chromosomal proteins that are unique to each chromatin conformation. Some progress has been made toward this goal by the development of biochemical methods designed to isolate active chromatin by taking advantage of its relatively decondensed state. The analysis of the chromosomal proteins in the active chromatin fraction has suggested the following: (1) Histone H1 seems to be less tightly bound to at least some active chromatin, and particular subtypes of this histone may be specific for active chromatin. (2) Although the four nucleosomal histones are present in normal amounts in active chromatin, they appear to be unusually highly acetylated when compared with the same histones in inactive chromatin. (3) The nucleosomal histone H2B in active chromatin appears to be less phosphorylated than it is in inactive chromatin. (4) Active chromatin is highly enriched in a minor variant form of histone H2A that is found in many species, including *Drosophila* and humans. (5) The nucleosomes in active chromatin selectively bind two closely related small chromosomal proteins, called HMG 14 and HMG 17. Consistent with their presence only in active chromatin, these "high-mobility-group" (HMG) proteins occur in roughly the quantities required to bind to 1 in every 10 nucleosomes in total chromatin; moreover, their amino acid sequences have been highly conserved during evolution, implying that they have important functions.

Any or all of these changes might play an important part in uncoiling the chromatin of active genes, helping to make the DNA available as a template for RNA synthesis, but more direct experiments are needed to test this idea. In Chapter 9 we discuss mechanisms by which the transition between inactive and active chromatin may be controlled.

Heterochromatin Is Highly Condensed and Transcriptionally Inactive 16

Light microscopic studies in the 1930s distinguished two types of chromatin in interphase nuclei of higher eucaryotic cells: a highly condensed form called heterochromatin and all the rest, which is less condensed, called euchromatin. Heterochromatin was originally identified because it remains unusually compact during interphase; it was later found to be transcriptionally inactive (Figure 8-26). In a typical cell in interphase, approximately 10% of the genome is packed into heterochromatin. It is now clear, as descri bed above, that the euchromatin exists in at least two forms: about 10% is in the form of active chromatin, which is the least condensed, while the rest is inactive euchromatin, which is more condensed than active chromatin but less condensed than heterochromatin. Heterochromatin is therefore thought to be a special variety of transcriptionally inactive chromatin with distinctive functions. In mammals, for example, and in many other higher eucaryotes, the DNA surrounding each centromere is composed of relatively simple repeating nucleotide sequences. These so-called *satellite DNAs* constitute a major portion of the heterochromatin in these organisms.

Mitotic Chromosomes Are Formed from Chromatin in Its Most Condensed State 17

With the exception of a few specialized cases, such as the lampbrush and polytene chromosomes discussed above, most *interphase* chromosomes are too extended, thin, and entangled to be readily detectable. In contrast, chromosomes from nearly all cells are visible during mitosis, when they coil up to form much more condensed structures. This coiling, which reduces a 5-cm length of DNA to about 5 mm, makes it possible for the mitotic spindle to segregate the chromosomes to separate daughter cells without breaking them. The condensation is accompanied by the phosphorylation of all of the histone H1 in the cell at five of its serine residues. Because histone H1 helps to pack nucleosomes together (see Figure 8-15), its phosphorylation during mitosis is suspected to play a role in chromosome condensation.

Figure 8-27depicts a typical mitotic chromosome at the metaphase stage of mitosis. The two daughter DNA molecules produced by DNA replication during the S phase of the cell-division cycle are separately folded to produce two sister chromosomes (called *sister chromatids*) held together at their *centromeres*. These chromosomes are normally covered with a variety of molecules, including large amounts of ribonucleoproteins. Once this covering is stripped away, each chromatid can be seen in electron micrographs to be organized into loops of chromatin emanating from a central axis (Figures8-28 and 8-29). Several types of experiments demonstrate that the order of visible features along a mitotic chromosome at least roughly reflects the

order of the genes along the DNA molecule. To illustrate how such an organized folding of the long DNA helix might be achieved, we have drawn each chromatid as a closely packed series of looped domains wound in a tight helix in Figure 8-30, which also presents a schematic view of all the different folding processes that would contribute to this structure.

The condensed form of chromatin found in mitotic chromosomes is thought to resemble heterochromatin in its high degree of packing. Not surprisingly, mitotic chromosomes are found to be transcriptionally inactive: all RNA synthesis ceases as the chromosomes condense. Presumably, the condensation prevents RNA polymerase from gaining access to the DNA, although other control factors may also be involved.

Each Mitotic Chromosome Contains a Characteristic Pattern of Very Large Domains 18

The display of the 46 human chromosomes at mitosis is called the human karyotype. Staining methods developed over the last 25 years permit unambiguous identification of each individual chromosome. Some of these methods involve staining mitotic chromosomes with dyes that fluoresce only when they bind to certain types of DNA sequences. Although these dyes have very low specificity and appear mainly to distinguish DNA that is rich in A-T nucleotide pairs (G bands) from DNA that is rich in G-C nucleotide pairs (R bands), they produce a striking and reproducible banding pattern along each mitotic chromosome (Figure 8-31). In this way each chromosome can be identified and numbered, as illustrated in Figure 8-32. Both the G bands and the R bands are known to contain genes. These bands are unrelated to those described earlier for the insect polytene chromosomes, which are thought to correspond to regions of condensed chromatin; in the human mitotic chromosomes, all of the chromatin is condensed and the bands are formed by the selective binding of specific dyes. Whereas a band in a polytene chromosome contains only a few genes, a typical band in a human karyotype contains several hundred.

By examining human chromosomes very early in mitosis, when they are less condensed than at metaphase, it has been possible to estimate that the total haploid genome contains about 2000 distinguishable A-T-rich bands. These progressively coalesce as condensation proceeds during mitosis to produce fewer and thicker bands.

Chromosome bands are detected in mitotic chromosomes from species as diverse as humans and flies. Moreover, the exact pattern of bands in a chromosome has remained unchanged over long periods of evolutionary time. Every human chromosome, for example, has a clearly recognizable counterpart with a nearly identical banding pattern in the chromosomes of the chimpanzee, gorilla, and orangutan (although there has been a single chromosome fusion that gives humans 46 chromosomes instead of the apes' 48). This conservation suggests that the long-range spatial organization of chromosomes may be important for chromosomal function. But why such bands exist at all is a mystery. Even the thinnest of the bands diagrammed in Figure 8-32 probably contain more than a million nucleotide pairs, which is nearly the size of a bacterial genome, and the average nucleotide-pair composition would be expected to be random over such long stretches of DNA sequence.

Summary

Chromosomes are generally decondensed during interphase, so that their structure is difficult to discern. Notable exceptions are the specialized lampbrush chromosomes of vertebrate oocytes and the polytene chromosomes of insect giant secretory cells. Studies of these two types of interphase chromosomes suggest that each long DNA molecule in a chromosome is divided into a large number of discrete domains that are folded differently. In both lampbrush and polytene chromosomes the regions that are actively synthesizing RNA are least condensed. Likewise, as judged by nuclease sensitivity, about 10% of the DNA in interphase vertebrate cells is in a relatively uncondensed conformation that correlates with DNA transcription in these regions. Such "active chromatin" is biochemically distinct from the more condensed inactive regions of chromatin.

All chromosomes adopt a highly condensed conformation during mitosis. When they are specially stained, these mitotic chromosomes have a banded structure that allows each individual chromosome to be recognized unambiguously; these bands contain millions of DNA nucleotide pairs, and they reflect a coarse heterogeneity of chromosome structure that is not understood.
Figure 8-16. Light micrograph of lampbrush chromosomes in an amphibian oocyte. Early in oocyte differentiation each chromosome replicates to begin meiosis, and the homologous replicated chromosomes pair to form this highly extended structure containing a total of four replicated DNA molecules, or chromatids. The lampbrush chromosome stage persists for months or years as the oocyte builds up a supply of mRNA and other materials required for its ultimate development into a new individual. (Courtesy of Joseph G. Gall.)
Figure 8-17. Lampbrush chromosome structure. The set of lampbrush chromosomes in many amphibians contains a total of about 10,000 chromatin loops, although most of the DNA in each chromosome remains highly condensed in the *chromomeres*. Each loop corresponds to a particular DNA sequence. Four copies of each loop are present in each cell, since each of the two chromosomes shown at the top consists of two closely apposed sister chromatids. This four-stranded structure is characteristic of this stage of development of the oocyte (the diplotene stage of meiosis, see Figure 20-9).

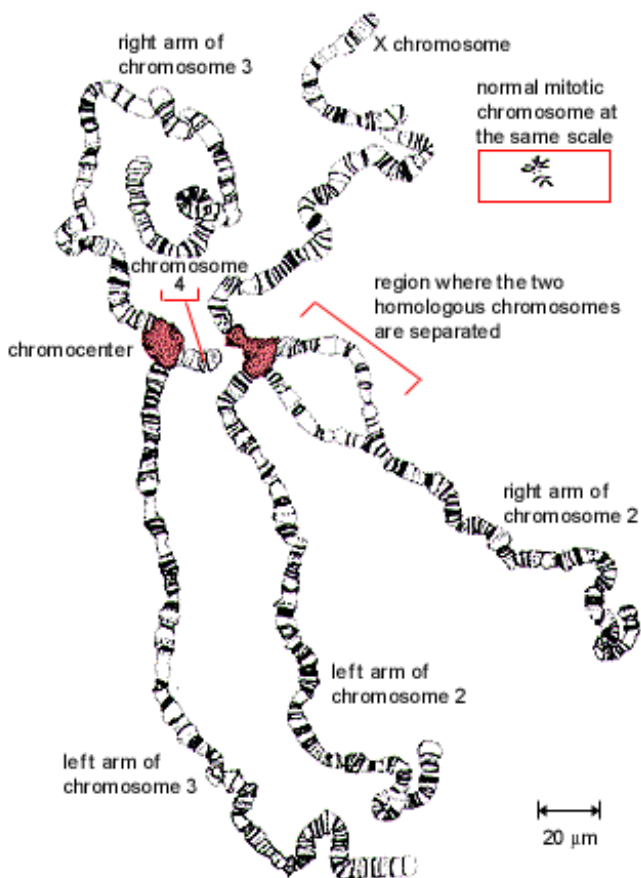

Figure 8-19. A detailed sketch of the entire set of polytene chromosomes in one *Drosophila* salivary cell. These chromosomes have been spread out for viewing by squashing them against a microscope slide. *Drosophila* has four chromosomes, and there are four different chromosome pairs present. But each chromosome is tightly paired with its homologue (so that each pair appears as a single structure), which is not the case in most nuclei (except in meiosis). The four polytene chromosomes are normally linked together by regions near their centromeres that aggregate to create a single large "chromocenter" (*colored region*); in this preparation, however, the chromocenter has been split into two halves by the squashing procedure used. (Modified from T.S. Painter, *J. Hered.* 25:465-476, 1934.)
Figure 8-20. Light micrograph of a portion of a polytene chromosome from *Drosophila* salivary glands. The distinct patterns recognizable in different chromosome bands are readily seen. The bands are regions of increased chromatin concentration. They occur in interphase chromosomes and are a special property of the giant polytene chromosomes. (Courtesy of Joseph G. Gall.)

Figure 8-21. Electron micrograph of a small section of a *Drosophila* polytene chromosome seen in thin section. Bands (B) of very different thickness can be readily distinguished, separated by interbands (I), which contain less condensed chromatin. (Courtesy of Viekko Sorsa.)

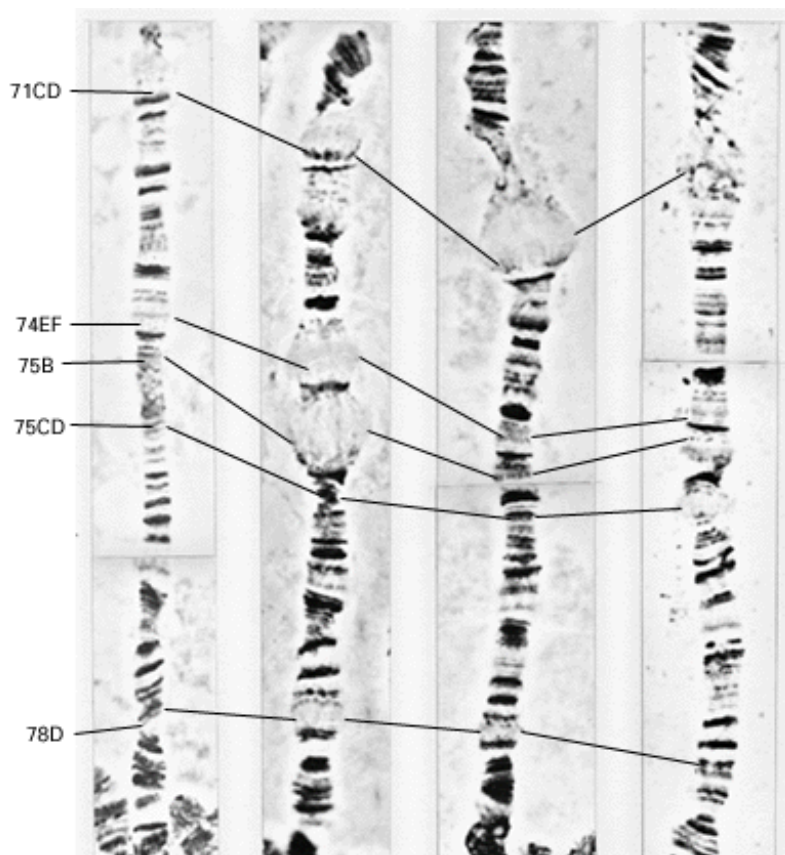
Figure 8-22. Synthesis of RNA along a giant polytene chromosome. In this autoradiograph of a chromosome (from the salivary gland of the insect *Chironomus tentans*) labeled with 3H-uridine, sites of RNA synthesis are covered with dark silver grains in proportion to their activity. (From C. Pelling, *Chromosoma* 15:71-122, 1964.)


Figure 8-23. Chromosome puffs. A temporal series of photographs illustrating how puffs arise and recede in the polytene chromosomes of *Drosophila melanogaster* during larval development. A region of the left arm of chromosome 3 is shown. It exhibits five very large puffs in salivary gland cells, each active for only a short developmental period. The series of changes shown occur over a period of 22 hours, appearing in a reproducible pattern as the organism develops. (Courtesy of Michael Ashburner.)
Figure 8-24. Autoradiogram of a single puff in a polytene chromosome. The portion of the chromosome indicated is undergoing RNA synthesis and has therefore become labeled with³H-uridine. (Courtesy of Jose Bonner.)
Figure 8-25. Digestion of chromatin with DNase I. The enzyme first cuts at nuclease-hypersensitive sites (not shown, but see Figure 8-12) and then selectively degrades the entire DNA sequence both of genes that are actively being transcribed and of genes that have been activated but are not yet being transcribed.
Figure 8-26. Heterochromatin is transcriptionally inactive. An autoradiograph is shown of a thin section of a nucleus from a cell that has been pulse-labeled with 3H-uridine in order to label sites of RNA synthesis (seen as black silver grains). The *white areas* are regions of heterochromatin, which tend to pack along the inside of the nuclear envelope. Normally, heterochromatin stains unusually darkly in electron micrographs (for example, see Figure 8-71), but because of the particular method used for sample preparation here, areas containing heterochromatin have been bleached. As can be seen, most of the RNA synthesis occurs in the euchromatin that borders these heterochromatic areas. (Courtesy of Stan Fakan.)
Figure 8-27. Drawing of a typical metaphase chromosome. Each sister chromatid contains one of two identical daughter DNA molecules generated earlier in the cell cycle by DNA replication.

Figure 8-28. Scanning electron micrograph of a region near one end of a typical mitotic chromosome. Each knoblike projection is believed to represent the tip of a separate looped domain. Note that the two identical paired chromatids diagrammed in Figure 8-27 can be clearly distinguished. (From M.P. Marsden and U.K. Laemmli, *Cell* 17:849-858, 1979. © Cell Press.)

5 μm
Figure 8-29. Electron micrograph of a single chromatid of a mitotic chromosome. The chromosome (from an insect) was treated to reveal loops of chromatin fibers that emanate from a central axis of the chromatid. Such micrographs support the idea that the chromatin in all chromosomes is folded into a series of looped domains (see Figure 8-18). (Courtesy of Victoria Foe.)
Figure 8-30. Model of chromatin packing. This schematic drawing shows some of the many orders of chromatin packing postulated to give rise to the highly condensed mitotic chromosome.

Figure 8-31. Fluorescence micrographs showing the banding patterns in three pairs of human mitotic chromosomes. In (A) the chromosomes were stained with the A-T-base-pair-specific dye Hoechst 33258, which stains the G bands, and in (B) with the G-C-base-pair-specific dye olivomycin, which stains the R bands. The bars indicate the position of the centromere. Note that these banding patterns are the reverse of each other: the bands that are bright in (A) are dark in (B), and vice versa. The G bands also stain with Giemsa stain - hence their name - while the R bands were so named because they formed the "reverse" of the G-band pattern. (From K.F. Jorgenson, J.H. van de Sande, and C.C. Lin, *Chromosoma* 68:287-302, 1978.)
Figure 8-32. A standard map of the banding pattern of each chromosome in the human karyotype. This map was determined at the prometaphase stage of mitosis. Chromosomes 1 through 22 are labeled in the approximate order of their size; a diploid cell contains two of each of these autosomes plus two sex chromosomes - two X chromosomes (female) or an X and a Y chromosome (male). The 850 bands shown here are G bands, which stain with reagents that appear to be specific for A-T-rich DNA sequences. The *green knobs*on chromosomes 13, 14, 15, 21, and 22 indicate the positions of the genes that encode the large ribosomal RNAs; the *green lines*mark the centromere on each chromosome. (Adapted from U. Franke, *Cytogenet. Cell Genet.* 31:24-32, 1981.)

Chromosome Replication

Introduction

Before a cell can divide, it must produce a new copy of each of its chromosomes, and it does this during a specific part of interphase called the DNA-synthesis phase, or S phase, of the cell-division cycle; the part of interphase preceding S phase is called Gap 1, or G_1, and the part following S phase is called Gap 2, or G_2 (see Figure 17-3). In a typical higher eucaryotic cell the S phase lasts for about 8 hours. By its end each chromosome has been replicated to produce two complete copies, which remain joined together at their centromeres until the M phase that soon follows (see Figure 8-27). Chromosome duplication requires both the replication of the long DNA molecule in each chromosome and the assembly of a new set of chromosomal proteins onto the DNA to form chromatin. In Chapter 6 we discussed the enzymology of DNA replication and described the structure of the *DNA replication fork*, where DNA synthesis occurs by a semi-conservative process (see Figures6-48 and 6-49). In Chapter 17 we consider how entry into the S phase is regulated as part of a more general discussion of how the cell-division cycle is controlled. In this section we describe the timing and pattern of eucaryotic chromosome replication and its relation to

chromosome structure.

Specific DNA Sequences Serve as Replication Origins [19]

We saw in Chapter 6 that replication origins have been precisely defined in bacteria as specific DNA sequences that allow the DNA replication machinery to assemble on the DNA double helix and move in opposite directions to produce *replication forks*. By analogy, one would expect the replication origins in eucaryotic chromosomes to be specific DNA sequences too. As mentioned earlier, the search for replication origins in the chromosomes of eucaryotic cells has been most successful in the yeast *Saccharomyces cerevisiae*. The powerful selection methods that have been devised to find them make use of mutant yeast cells that are defective for an essential gene: they will survive in a selective medium only if they are provided with a plasmid carrying a functional copy of the missing gene. If a bacterial plasmid that carries the essential yeast gene is introduced into the mutant yeast cells, it will not be able to replicate free of the host chromosome because the bacterial replication origin in the plasmid DNA cannot function in a yeast cell. If random pieces of yeast DNA are inserted into the plasmid, however, a small proportion of the plasmid DNA molecules will contain a yeast replication origin and therefore will be able to replicate in the yeast cells. The yeast cells that carry such plasmids will be able to proliferate since they will have been provided with the essential gene (Figure 8-33). A DNA sequence identified by its presence in a plasmid isolated from these cells is called an *autonomously replicating sequence (ARS)*. A number of ARSs recently have been shown to be authentic chromosomal origins of replication, thereby justifying the strategy used to obtain them.

An 11-nucleotide "core consensus sequence" has been shown to be essential for yeast replication-origin function, and all known origins contain multiple near matches of this sequence, spaced throughout a region of about 100 nucleotides. These DNA sequences are recognized by a large protein complex that is thought to function in the initiation process. Although some replication-origin sequences in higher eucaryotic cells have been tentatively identified, the proteins that bind to them are not known.

A Mammalian Cell-free System Replicates the Chromosome of a Monkey Virus [20]

In bacteria a multienzyme complex that includes DNA polymerase, DNA primase, and DNA helicase moves the replication fork (see Figures6-48 and 6-49); this complex assembles at a replication origin in a reaction involving an initiator protein that binds specifically to the origin DNA (see Figure6-52).

Many attempts have been made to reconstitute mammalian DNA replication in a test tube. To do so would make it possible to identify all the enzymes required and to define their actions at a replication fork. The most successful *in vitro* system developed thus far replicates the small circular chromosome of the monkey virus SV40. This virus parasitizes its mammalian host cell for all but one of the proteins that the virus needs to replicate; the one exception is the *SV40 T-antigen*, a large multifunctional protein that allows the virus to bypass normal controls and thereby replicate faster than the host cell. Two hexamers of the T-antigen bind specifically to the SV40 replication origin, recognizing the outside of the DNA double helix. Then, in a process that is not well understood, the bound T-antigen undergoes a conformational change that pulls apart the DNA strands of the origin. This remarkable protein has a third function: utilizing the energy of ATP hydrolysis, it acts as a DNA helicase, moving along the DNA and opening the DNA double helix as it moves, forming a *replication bubble*(Figure 8-34). The cellular components of the replication machinery can now assemble in the bubble to form two replication forks, which then move away from the origin in opposite directions.

Although the replication forks are similar to those of procaryotes, the SV40 experiments have revealed that at least two distinct types of DNA polymerase are needed in eucaryotes: *DNA polymerase a* on the lagging strand and *DNA polymerase delta*on the leading strand (Figure 8-35). In procaryotes, by contrast, a single type of DNA polymerase functions on both strands of the replication fork (see Figure 6-48).

The protein that normally initiates DNA replication of mammalian chromosomes has not yet been discovered. It is therefore not known whether it resembles the T-antigen in functioning as a DNA helicase at the fork or whether, as in procaryotes, a separate initiator protein and DNA helicase are involved.

Replication Origins Are Activated in Clusters on Higher Eucaryotic Chromosomes [21]

In Chapter 6 we describe how in bacteria two replication forks begin at each origin and proceed in opposite directions, moving away from the origin at a rate of about 500 nucleotides per second until all of the DNA in the single circular bacterial

chromosome is replicated. The bacterial genome is so small that these two replication forks can duplicate it in less than 40 minutes. Because of the much larger size of most eucaryotic chromosomes, it seemed unlikely that their replication would begin from a single origin.

A method for determining the general pattern of eucaryotic chromosome replication was developed in the early 1960s. Human cells growing in culture are labeled for a short time with ^{3}H-thymidine so that the DNA synthesized during this period becomes highly radioactive. The cells are then gently lysed, and the DNA is streaked onto the surface of a glass slide, which is coated with a photographic emulsion, so that the pattern of labeled DNA can be determined by autoradiography. Since the time allotted for radioactive labeling is chosen to allow each replication fork to move several micrometers along the DNA, the replicated DNA can be detected in the light microscope as lines of silver grains, even though the DNA molecule itself is too thin to be visible. In this way both the rate and the direction of replication-fork movement can be determined (Figure 8-36). From the rate at which tracks of replicated DNA increase in length with increasing labeling time, the replication forks are estimated to travel at a speed of about 50 nucleotides per second. This is one-tenth the rate at which bacterial replication forks move, possibly reflecting the increased difficulty of replicating DNA that is packaged tightly in chromatin.

As discussed previously, an average human chromosome is composed of a single DNA molecule containing about 150 million nucleotide pairs. To replicate such a DNA molecule from end to end with a single replication fork moving at a rate of 50 nucleotides per second would require $0.02 \times 150 \times 10^6 = 3.0 \times 10^6$ seconds (about 800 hours). As expected, therefore, the autoradiographic experiments just described reveal that many forks are moving simultaneously on each eucaryotic chromosome. Moreover, many forks are often found close together in the same DNA region, while other regions of the same chromosome have none. Further experiments of this type have shown the following: (1) Replication origins tend to be activated in clusters (called *replication units*) of perhaps 20 to 80 origins. (2) New replication units seem to be activated throughout the S phase until all of the DNA is replicated. (3) Within a replication unit, individual origins are spaced at intervals of 30,000 to 300,000 nucleotide pairs from one another. (4) As in bacteria, replication forks are formed in pairs and create a replication bubble as they move in opposite directions away from a common point of origin, stopping only when they collide head-on with a replication fork moving in the opposite direction (or reach a chromosome end). In this way many replication forks can operate independently on each chromosome and yet form two complete daughter DNA helices (see Figure 8-36).

Different Regions on the Same Chromosome Replicate at Distinct Times 22

The replication of DNA in the region between one replication origin and the next should normally require only about an hour to complete, given the rate at which a replication fork moves and the largest distances measured between the replication origins in a replication unit. Yet the S phase usually lasts for about eight hours in a mammalian cell. This implies that the replication origins are not all activated simultaneously and that the DNA in each replication unit (which contains a cluster of perhaps 20 to 80 replication origins) is replicating for only a small part of the total S-phase interval.

Are different replication units activated at random, or is there a specified order in which different regions of the genome are replicated? One way to answer this question is to use the thymidine analogue bromodeoxyuridine (BrdU) to label the newly synthesized DNA in synchronized cell populations for different short periods throughout the S phase. Later, in M phase, those regions of the mitotic chromosomes that have incorporated BrdU into their DNA can be recognized by their altered staining properties or by means of anti-BrdU antibodies. The results show that different regions of each chromosome are replicated in a reproducible order during S phase (Figure 8-37). Moreover, as one would expect from the clusters of replication forks seen in DNA autoradiographs, the timing of replication is coordinated over large regions of the chromosome.

Highly Condensed Chromatin Replicates Late, While Genes in Active Chromatin Replicate Early 23

It seems that the order in which replication origins are activated, at least in part, depends on the chromatin structure in which the origins reside. We have seen, for example, that heterochromatin remains in a highly condensed conformation (similar to that at mitosis) during interphase, while active chromatin has an especially decondensed conformation, which is apparently required to allow RNA synthesis. Heterochromatin is replicated very late in the S phase, suggesting that the timing of replication is related to the packing of the DNA in chromatin. This suggestion is supported by the timing of replication of the two X chromosomes in a female mammalian cell. While these two chromosomes contain essentially the same DNA sequences, one is active for DNA transcription and the other is not (discussed in Chapter 9). Nearly all of the inactive X chromosome is condensed into heterochromatin and its DNA replicates late in the S phase, whereas its active homologue is less condensed and replicates throughout the S phase. These findings support the hypothesis that those regions of the genome whose chromatin is least condensed during interphase, and therefore most accessible to the replication machinery, are replicated first. Autoradiography

shows that replication forks move at comparable rates throughout the S phase, so that the extent of chromosome condensation appears to influence the initiation of replication forks but not their speed once formed.

The suggested relationship between chromatin structure and the time of DNA replication is also supported by studies in which the replication times of specific genes are measured. The results show that so-called "housekeeping" genes, which are those active in all cells, replicate very early in S phase in all cells tested. Genes that are active in only a few cell types, in contrast, generally replicate early in the cells in which the genes are active and later in other types of cells.

The Late-replicating Replication Units Coincide with the A-T-rich Bands on Metaphase Chromosomes 24

Many of the replication units seem to correspond to distinct chromosome bands made visible by the various fixation and staining procedures used for karyotyping. As discussed previously, as many as 2000 dark-staining *A-T-rich bands (G bands)* can be detected early in mitosis in the haploid set of mammalian chromosomes, and these are separated by an equal number of light-staining *G-C-rich bands (R bands)*. It is intriguing that the A-T-rich DNA and the G-C-rich DNA differ in the time of their replication during S phase. Experiments like the one shown in Figure 8-37 suggest that most G-C-rich bands replicate during the first half of S phase, while most A-T-rich bands replicate during the second half of S phase. It has therefore been suggested that housekeeping genes are located mostly in G-C-rich bands, while many cell-type-specific genes - the vast majority of which will be inactive in most cells - are located in A-T-rich bands. As stated earlier, it is a complete mystery why the mammalian genome should be segregated into such large alternating blocks of chromatin - many nearly equal in size to an entire bacterial genome. It is also not known how the many replication origins present in each replication unit are activated all at once. Perhaps the chromatin in a late-replicating unit remains condensed even after the end of M phase and decondenses only in mid S phase, making all the replication origins in the unit simultaneously accessible. If this is the case, the all-or-none coordinated replication of the DNA in a single replication unit could reflect the stepwise decondensation of large chromatin domains.

The Controlled Timing of DNA Replication May Contribute to Cell Memory 25

The S phase is completed extremely rapidly in the cleaving eggs of many species, where large stores of chromatin components (such as histones) are present, as required for the rapid manufacture of new nuclei. As illustrated in Figure 8-38, a short S phase also requires the use of an exceptionally large number of replication origins spaced at intervals of only a few thousand nucleotide pairs (rather than the tens or hundreds of thousands of nucleotide pairs found between the replication origins later in development). Since any foreign DNA injected into a fertilized frog egg is replicated, a specific DNA sequence may not be required to form a replication origin in this cell.

Thus, DNA replication can be viewed as a potentially very rapid process that in most cells is subject to a complex system of regulation that restrains the initiation of replication forks in a way that causes different portions of the genome to replicate at very different times. It has been suggested, for example, that the chromatin that replicates early is assembled in part from a special store of chromosomal proteins produced during the G_1 phase and that once a chromosomal region becomes decondensed into active chromatin, its early replication causes the region to pick up proteins that help it to maintain a decondensed state from one cell generation to the next. In this view, the timing of DNA replication contributes to a cellular memory process that facilitates the continued transcription of expressed genes.

Chromatin-bound Factors Ensure That Each Region of the DNA Is Replicated Only Once 26

In a normal S phase the whole genome must be replicated exactly once and no more. As we have just seen, DNA replication in most eucaryotic cells is an asynchronous process that takes a relatively long time to complete. Because the replication origins are used at different times in different chromosomal regions, in the middle of S phase some parts of a chromosome will not yet have begun replication, while other parts will have replicated completely. An enormous "bookkeeping" problem consequently arises during the middle and late stages of the S phase. Those replication origins already used have been duplicated and, at least with respect to their DNA sequences, are presumably identical to other replication origins not yet used. But each replication origin must be used only once in each S phase. How is this accomplished?

Cell-fusion experiments have provided an important clue. When an S-phase cell is fused with a G_1-phase cell (which has not yet begun S phase), DNA synthesis is induced in the G_1-phase nucleus, suggesting that the transition from G_1 to S phase is mediated by a diffusible activator of DNA synthesis. In contrast, when the S-phase cell is fused with a G_2-phase cell (that is, a cell that has just completed S phase), the G_2 nucleus is not stimulated to synthesize DNA. Since DNA synthesis continues

undisturbed in the S-phase nucleus, this implies that the G_2 nucleus is prevented from entering further rounds of replication because every part of its DNA is somehow blocked. Some nondiffusible inhibitor of replication, for example, may have become tightly bound to its DNA. Such an inhibitor, if applied locally during S phase in the wake of each replication fork, would neatly solve the bookkeeping problem: by modifying the chromatin of freshly replicated DNA, it would ensure that once replicated DNA is not replicated again in the same S period (Figure 8-39A). An equally plausible alternative is that tightly bound initiator proteins, or "licensing factors," required for replication are destroyed or inactivated by the passage of a replication fork (Figure 8-39B). Whatever its nature, the DNA re-replication block must be removed at or near the time of mitosis, since after cell division the DNA in the G_1 nuclei that emerges in the daughter cells is no longer protected.

The fragments of bacterial DNA that replicate when injected into a fertilized frog egg can be shown to be affected by the re-replication block. Therefore, the mechanism responsible for the block cannot require a highly specific replication origin. The block does not affect the SV40 virus, presumably because the T-antigen made by the virus supplies both initiator and DNA helicase functions for replication, substituting for analogous host cell components and thereby evading the controls to which they are subject.

New Histones Are Assembled into Chromatin as DNA Replicates 27

A large amount of new histone, approximately equal in mass to the newly synthesized DNA, is required to make new chromatin in each cell cycle. For this reason most organisms possess multiple copies of the gene for each histone. Vertebrate cells, for example, have about 20 repeated sets, each set containing all five histone genes.

Unlike most proteins, which are made continuously throughout interphase, the histones are synthesized mainly in the S phase, when the level of histone mRNA increases about 50-fold as a result of both increased transcription and decreased mRNA degradation. By a mechanism that depends on special properties of their 3' ends (discussed in Chapter 9), the major histone mRNAs become highly unstable and are degraded within minutes when DNA synthesis stops at the end of S phase (or when inhibitors are added to stop DNA synthesis prematurely). In contrast, the histone proteins themselves are remarkably stable and may survive for the entire life of a cell. The tight linkage between DNA synthesis and histone synthesis may be due, at least in part, to a feedback mechanism that monitors the level of free histone to ensure that the amount of histone made is appropriate for the amount of new DNA synthesized.

Once they are assembled in nucleosomes, histone molecules rarely, if ever, leave the DNA to which they are bound. As a replication fork advances, therefore, it must somehow pass through the parental nucleosomes, which seem to have been designed to allow both transcription and replication to proceed past them. According to one hypothesis, each nucleosome transiently unfolds into two half-nucleosomes during DNA replication, thereby allowing the DNA polymerase to copy the uncoiled nucleosomal DNA (Figure 8-40).

The newly synthesized DNA behind a replication fork inherits some old his-tones, but since the amount of DNA has doubled, it also needs to bind an equal amount of new histones to complete its packaging into chromatin (see Figure 8-40). There is some evidence to suggest that a special nucleosome assembler may travel with the replication fork, packaging the newly synthesized DNA as soon as it emerges from the replication machinery. This newly formed chromatin, however, requires as much as an hour to become fully mature; until then, for example, the new histones are more susceptible than usual to histone-modifying enzymes. The chemical differences between mature and immature chromatin are unknown, although it is thought that maturation involves both covalent modifications of histones and changes in the binding of other proteins to the chromatin.

Telomeres Consist of Short G-rich Repeats That Are Added to Chromosome Ends by Telomerase 28

As discussed earlier, it is not possible for DNA polymerase to replicate the end of a linear DNA molecule completely in the ordinary way, and this has led to the evolution of special DNA sequences, called telomeres, at the ends of eucaryotic chromosomes. These sequences, which are similar in organisms as diverse as protozoa, fungi, plants, and mammals, consist of many tandem repeats of a short sequence that contains a block of neighboring G nucleotides. In humans this sequence is GGGTTA.

The problem of replicating the ends of chromosomes is solved in an ingenious way by an enzyme called telomerase. This enzyme recognizes the G-rich strand of an existing telomere repeat sequence and elongates it in the 5'-to-3' direction. In the absence of a complementary DNA strand, the telomerase synthesizes a new copy of the repeat using an RNA template that is a

component of the enzyme itself. The enzyme thus contains the information used to maintain the characteristic telomere sequences. After several rounds of extension by telomerase, replication of the chromosome end can be completed using these extensions as a template for synthesis of the complementary strand by DNA polymerase (Figure 8-41). Because the processes that shorten and restore the telomere sequence are only approximately balanced, each chromosome end contains a variable number of the tandem repeats, which generally extend for hundreds of nucleotide pairs.

Summary

In vitro studies using the monkey virus SV40 as a model system suggest that, in eucaryotes as in procaryotes, DNA replication begins with the loading of a DNA helicase onto the DNA by an initiator protein bound to a replication origin. A replication bubble forms at such an origin as two replication forks move away from each other. During S phase in higher eucaryotes, neighboring replication origins appear to be activated in clusters known as replication units, with the origins spaced an average of about 100,000 nucleotide pairs apart. Since the replication fork moves at about 50 nucleotides per second, only about an hour should be required to complete the DNA synthesis in a replication unit. Throughout a typical 8-hour S phase different replication units are activated in a sequence determined in part by the structure of the chromatin, the most condensed regions of chromatin being replicated last. The correspondence between replication units and the bands containing millions of nucleotide pairs seen on mitotic eucaryotic chromosomes suggests that replication units may correspond to structurally distinct domains in interphase chromatin.

After the replication fork passes, chromatin structure is re-formed by the addition of new histones and other chromosomal proteins to the old histones inherited on the daughter DNA molecules. A DNA re-replication block of unknown nature acts locally to prevent a second round of replication from occurring until a chromosome has passed through mitosis; this block is needed to ensure that each region of the DNA is replicated only once in each S phase.

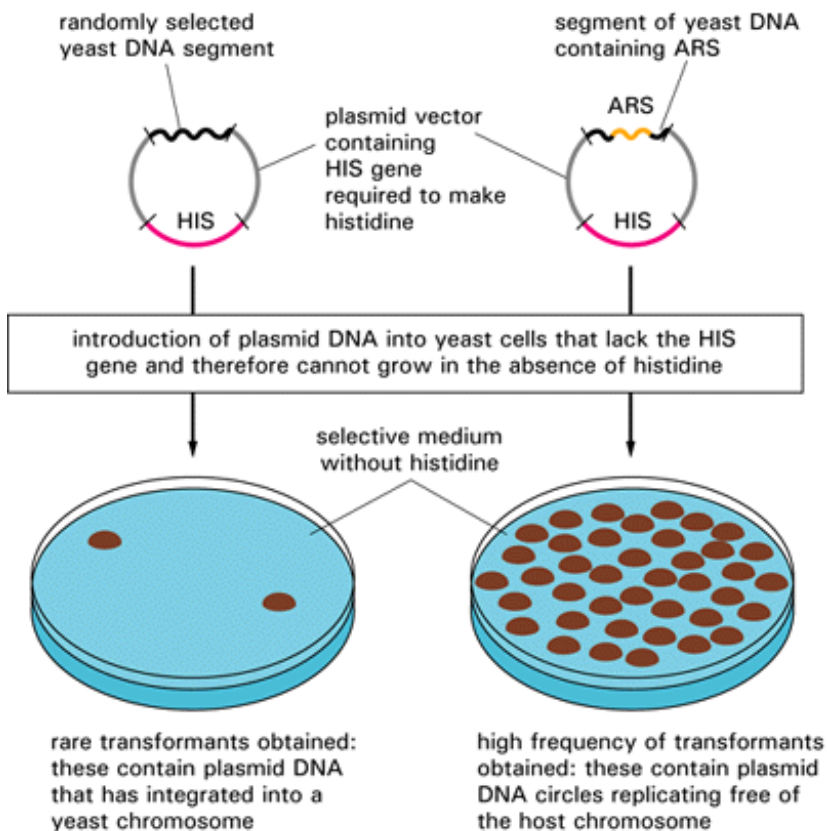
The problem of replicating the ends of chromosomes is solved by a specialized end structure (the telomere) and an enzyme (telomerase) that extends this structure using an RNA template that is part of the telomerase.


Figure 8-33. The strategy used to identify replication origins in yeast cells. A DNA sequence identified in this way was initially called an autonomously replicating sequence (ARS) since it enables a plasmid that contains it to replicate freely in the

host cell without having to be incorporated into its chromosomes.
Figure 8-34. Initiation of DNA replication on the SV40 viral genome. The initiation protein (T-antigen) is encoded by the virus, and it specifically recognizes the viral origin of replication. After opening the DNA double helix at the origin, the T-antigen acts as a DNA helicase, traveling away from the origin and opening the double helix as it moves. Subsequent to the steps depicted, host cell components of the replication machinery assemble in the "replication bubble" to form two replication forks (see Figure 8-35).
Figure 8-35. A mammalian replication fork. The fork is drawn to emphasize its similarity to the bacterial replication fork described in Chapter 6. Although both forks utilize the same basic components, the mammalian fork differs in two important

respects. First, it makes use of two DNA polymerases, one for the leading strand and one for the lagging strand. It seems likely that the leading-strand polymerase is designed to keep a tight hold on the DNA, whereas that on the lagging strand must be able to release the template and then rebind each time that a new Okazaki fragment (see p. 256) is synthesized. Second, the mammalian DNA primase is a subunit of the lagging-strand DNA polymerase, while that of bacteria is associated with the DNA helicase.
Figure 8-36. The experiments that demonstrated the pattern in which replication forks move during the S phase. The new DNA made in human cells in culture was briefly labeled with a pulse of highly radioactive thymidine (^{3}H-thymidine). In the experiment illustrated in (A), the cells were lysed and the DNA was stretched out on a glass slide that was subsequently covered with a photographic emulsion. After several months the emulsion was developed, revealing a line of silver grains over the radioactive DNA. The experiment in (B) was the same except that a further incubation in unlabeled medium allowed additional DNA, with a lower level of radioactivity, to be replicated. The pairs of dark tracks in (B) were found to have silver grains tapering off in opposite directions, demonstrating bidirectional fork movement from a central replication origin (see Figure 6-51). The *red* DNA in this figure is shown only to help with the interpretation of the autoradiograph; the unlabeled DNA is invisible in such experiments. A replication fork is thought to stop only when it encounters a replication fork moving in the opposite direction or when it reaches the end of the chromosome; in this way all the DNA is eventually replicated.

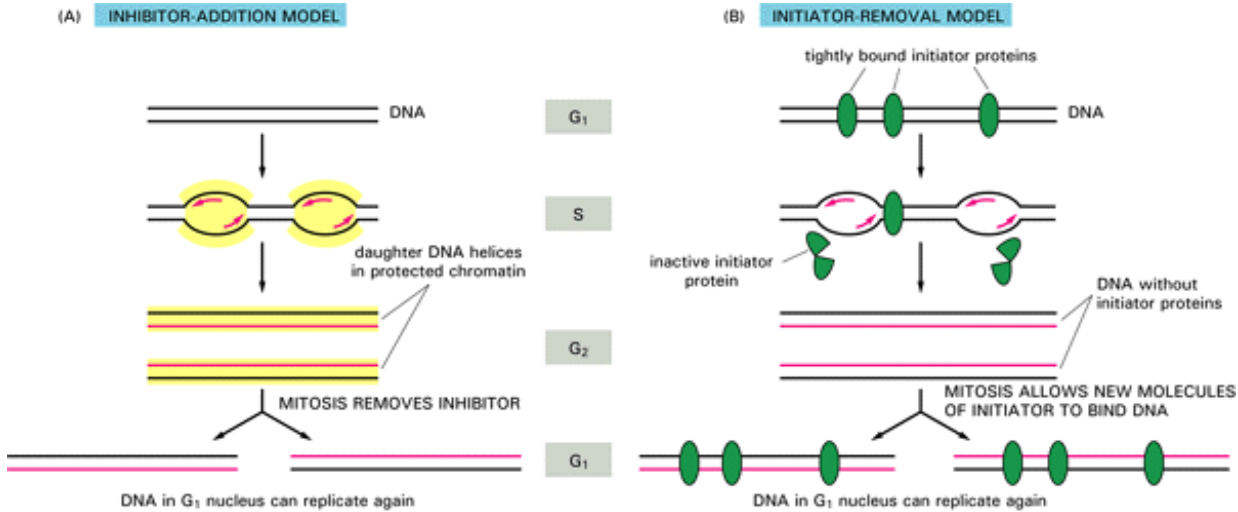
Figure 8-37. Different regions of a chromosome are replicated at different times in S phase. These light micrographs show stained mitotic chromosomes in which the replicating DNA has been differentially labeled during different defined intervals of the preceding S phase. In these experiments cells were first grown in the presence of BrdU (a thymidine analogue) and in the absence of thymidine to label the DNA uniformly. The cells were then briefly pulsed with thymidine in the absence of BrdU during early, middle, or late S phase. Because the DNA made during the thymidine pulse is a double helix with thymidine on one strand and BrdU on the other, it stains more darkly than the remaining DNA (which has BrdU on both strands) and shows up as a bright band (*arrows*) on these negatives. Dashed lines connect corresponding positions on the three copies of the chromosome shown. (Courtesy of Elton Stubblefield.)
Figure 8-38. Large numbers of replication origins operate in rapidly dividing embryonic nuclei. This electron micrograph of spread chromatin from an early *Drosophila* embryo shows that replication bubbles (*arrows*) are extremely closely spaced. Only about 10 minutes elapse between some of the successive nuclear divisions in this embryo. Since the replication origins used here are so closely spaced (separated by a few thousand nucleotide pairs), it should require only about a minute to replicate all the DNA between them. (Courtesy of Victoria Foe.)


Figure 8-39. Two possible mechanisms to explain the "re-replication block". This block, which protects replicated DNA from further replication in the same cell cycle, is crucial to replication bookkeeping, but its molecular nature is not known. Normally, the block is removed at mitosis, but in a few specialized types of cells (the salivary gland cells of *Drosophila* larvae, for example), it is removed without mitosis, leading to the formation of giant *polytene* chromosomes. (A) A model based on the addition of an inhibitor to all newly replicated chromatin; (B) a model based on tightly bound initiator proteins, or "licensing factors," that act only once and that can be added to the DNA only during mitosis.
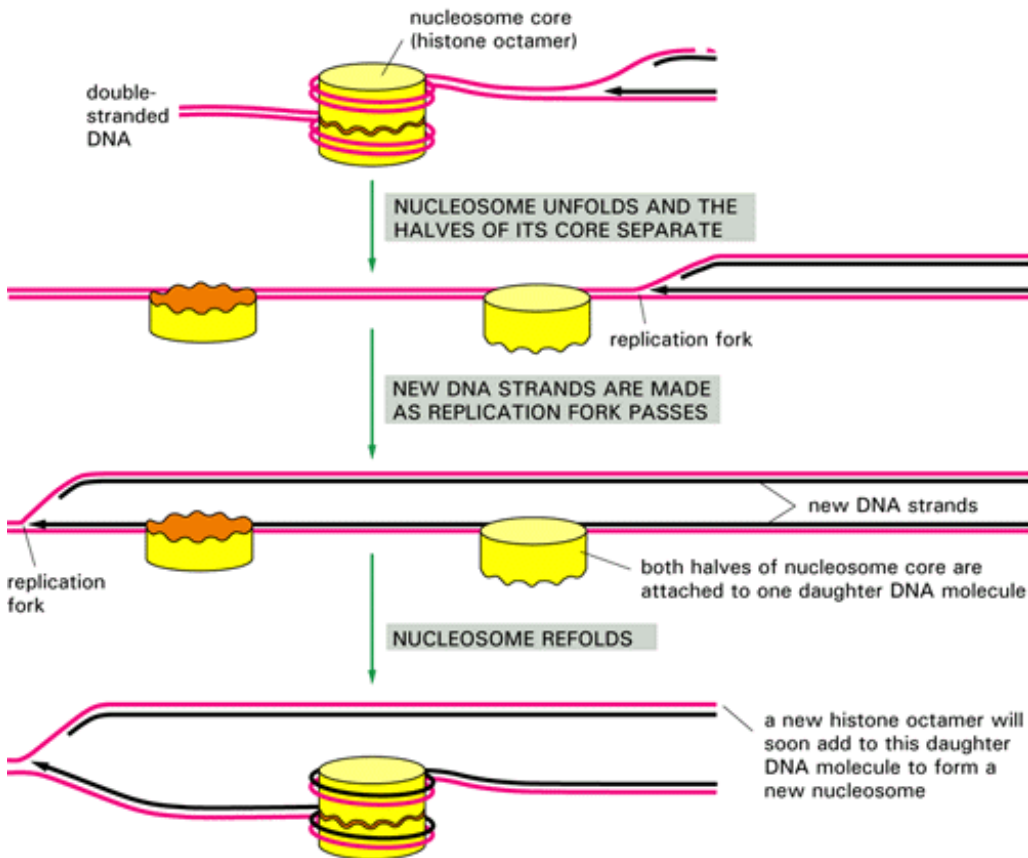

Figure 8-40. Speculative model showing how a nucleosome might open up to permit DNA replication. After the replication fork passes, the nucleosome reassembles. In this way the histones of the nucleosome core remain permanently bound to the DNA. Although in this diagram the old nucleosome has been inherited intact by the DNA helix made on the leading strand, there is evidence that an intact nucleosome can be inherited by either daughter DNA molecule. Moreover, this is only one of many possible models.
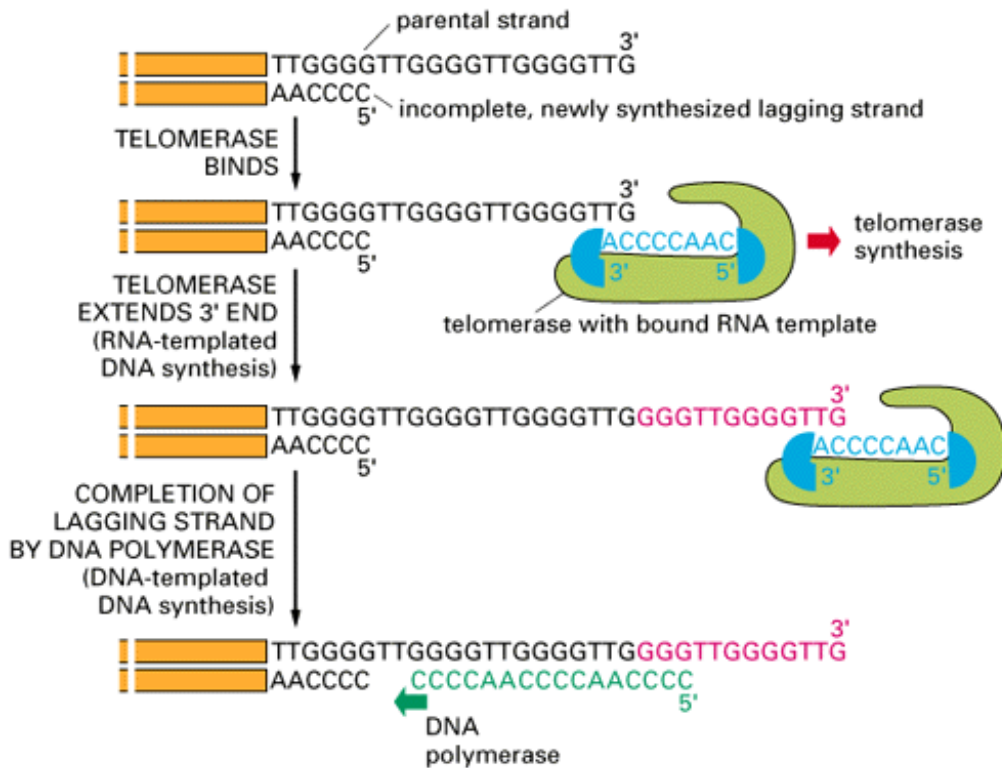

Figure 8-41. Telomere replication. The figure outlines the reactions involved in the formation of the repeating G-rich sequences that form the ends of chromosomes (telomeres) of diverse eucaryotic organisms, as suggested by experiments in the ciliate *Tetrahymena*. The incomplete, newly synthesized strand is the strand made on the lagging side of a replication fork (see Figure6-41). As indicated, the telomerase is a protein-RNA complex that carries an RNA template for synthesizing a repeating, G-rich telomere DNA sequence. These repeats are GGGTTG in *Tetrahymena* but are GGGTTA in humans and $G_{1-3}A$ in the yeast *Saccharomyces cerevisiae*. The lagging strand is presumed to be completed by DNA polymerase a, which carries primase as one of its subunits (see Figure 8-35).

RNA Synthesis and RNA Processing

Introduction

We have thus far considered how chromosomes are organized as very large DNA-protein complexes and how they are duplicated before a cell divides. But the main function of a chromosome is to act as a template for the synthesis of RNA molecules, since only in this way does the genetic information stored in chromosomes become directly useful to the cell. There is a great deal of RNA synthesis in a cell: the total rate at which nucleotides are incorporated into RNA during interphase is about 20 times the rate at which nucleotides are incorporated into DNA during S phase.

RNA synthesis, which is also called DNA transcription, is a highly selective process. In most mammalian cells, for example, only about 1% of the DNA nucleotide sequence is copied into functional RNA sequences (mature messenger RNA or structural RNA). The selectivity occurs at two levels, which we discuss in turn in this section: (1) only part of the DNA sequence is transcribed to produce nuclear RNAs, and (2) only a minor proportion of the nucleotide sequences in nuclear RNAs survives the RNA processing steps that precede the export of RNA molecules to the cytoplasm. We begin by describing *RNA polymerases*, the enzymes that catalyze all DNA transcription.

RNA Polymerase Exchanges Subunits as It Begins Each RNA Chain 29

As described in outline in Chapter 6, transcription begins when an RNA polymerase molecule binds to a promoter sequence on the DNA double helix. Next, in a step that is not well understood, the two strands of the DNA are separated locally to form an *open complex*. At this stage the template strand is exposed, and synthesis of the complementary RNA chain can begin. The

polymerase then moves along the template strand, extending its growing RNA chain in the 5'-to-3' direction by the stepwise addition of ribonucleoside triphosphates until it reaches a *stop (termination) signal*, at which point the newly synthesized RNA chain and the polymerase are released from the DNA. Each RNA molecule thus represents a single-strand copy of the nucleotide sequence of one DNA strand in a relatively short region of the genome (see Figure6-2). This transcribed segment of DNA is called a *transcription unit*.

RNA polymerases are generally formed from multiple polypeptide chains and have masses of 500,000 daltons or more. The enzymes in bacteria and eucaryotes are evolutionarily related (Figure 8-42). Since the bacterial enzyme has been far easier to study, its properties provide a basis for understanding its eucaryotic relatives. The *E. coli* enzyme contains four different subunits, a, b, b', and sigma, there being two copies of a and one each of the others. The complete amino acid sequence of each subunit has been determined from the nucleotide sequence of its gene.

The sigma (s) subunit of the *E. coli* polymerase has a specific role in the initiation of transcription: it enables the enzyme to find promoter sequences to which it binds. After about eight nucleotides of an RNA molecule have been synthesized (step 4 in Figure 8-43), the s subunit dissociates and a number of *elongation factors* - important for chain elongation and termination - become associated with the enzyme instead. The elongation factors include several proteins that function in ways that are incompletely understood. The initiation of transcription is an important control point where the cell can regulate the expression of a gene; for this reason it is discussed in more detail in Chapter 9.

Three Kinds of RNA Polymerase Make RNA in Eucaryotes 30

Although the mechanism of DNA transcription is similar in eucaryotes and procaryotes such as *E. coli*, the machinery is considerably more complex in eucaryotes. In eucaryotes as diverse as yeasts and humans, for example, there are three types of RNA polymerases, each responsible for transcribing different sets of genes. These enzymes - denoted as *RNA polymerases I, II, and III* - are structurally similar to one another and have some common subunits, although other subunits are unique. Each is more complex than *E. coli* RNA polymerase and is thought to contain 10 or more polypeptide chains. Another important distinction between the bacterial and eucaryotic enzymes is that, whereas the purified bacterial enzyme can bind to promoters and initiate transcription on its own, the eucaryotic enzymes require the presence of additional initiation proteins that must bind to the promoter before the enzyme can bind. For this reason it was not until 1979 that systems with all the needed components became available so that eucaryotic initiation mechanisms could be analyzed *in vitro*. Because these initiation proteins and their interactions with the polymerases are intimately involved with the control of transcription initiation, we shall defer discussion of them until Chapter 9.

The three eucaryotic RNA polymerases were initially distinguished by their chemical differences during purification and by their sensitivity to *a-amanitin,* a poison isolated from the deadly toadstool *Amanita phalloides*. RNA polymerase I is unaffected by a-amanitin; RNA polymerase II is very sensitive to this poison; and RNA polymerase III is moderately sensitive to it. The sensitivity of RNA synthesis to a-amanitin is still used to determine which polymerase transcribes a gene. Such studies indicate that RNA polymerase II transcribes the genes whose RNAs will be translated into proteins. The other two polymerases synthesize RNAs that have structural or catalytic roles, chiefly as part of the protein synthetic machinery: polymerase I makes the large ribosomal RNAs, and polymerase III makes a variety of very small, stable RNAs - including the small 5S ribosomal RNA and the transfer RNAs. However, most of the small RNAs that form snRNPs, which we discuss later when we consider RNA processing, are made by polymerase II.

Mammalian cells typically contain 20,000 to 40,000 molecules of each of the RNA polymerases, and studies with cultured cells indicate that the concentrations of these enzymes are regulated individually according to the rate of cell growth.

RNA Polymerase II Transcribes Some DNA Sequences Much More Often Than Others 31

Because RNA polymerase II makes all of the mRNA precursors and thus determines which proteins a cell will make, we shall focus most of our discussion on its activities and on the fate of its products. Although experiments with purified polymerases *in vitro* are essential for establishing the mechanism of transcription, much can also be learned about how the process occurs in a cell by using the electron microscope to examine genes in action, with their bound RNA polymerases caught in the act of transcription.

Ordinary thin-section electron micrographs of interphase nuclei show granular clumps of chromatin (see Figure 8-71) but reveal very little about how genes are transcribed. A much more detailed picture emerges if the nucleus is ruptured and its contents

spilled out onto an electron microscope grid (Figures 8-44 and 8-45). At the farthest point from the center of the lysed nucleus, the chromatin is diluted sufficiently to make individual chromatin strands visible in the expanded, beads-on-a-string form shown previously in Figure 8-9B.

RNA polymerase molecules actively engaged in transcription appear as globular particles with a single RNA molecule trailing behind. Particles representing active RNA polymerase II molecules are usually seen as single units, without nearby neighbors. This observation indicates that most genes are transcribed into mRNA precursors only infrequently, so that one polymerase finishes transcription before another one begins. Occasionally, however, many polymerase molecules (and their associated RNA transcripts) are seen clustered together. These clusters occur on the relatively few genes that are transcribed at high frequency (Figure 8-46). The length of the attached RNA molecules in such a cluster increases in the direction of transcription, producing a characteristic pattern. This pattern defines the RNA polymerase II start site and direction of transcription for a specific transcription unit (Figure 8-47).

Biochemical studies have confirmed and extended the results obtained by electron microscopy, leading to three major conclusions:

1. Eucaryotic RNA polymerase molecules, like those in procaryotes, begin at specific sites on the chromosome.

2. The average length of the complete RNA molecule produced by RNA polymerase II from a single transcription unit is about 7000 nucleotides, and RNA molecules 10,000 to 20,000 nucleotides long are common. These lengths, which are much longer than the 1200 nucleotides of RNA needed to code for an average protein of 400 amino acid residues, reflect the complex structure of eucaryotic genes and, in particular, the presence of long intron sequences, which, as we discuss later, are later removed from the RNA.

3. Although chain *elongation rates* of about 30 nucleotides per second are observed for all RNAs, different RNA polymerase II start sites have different *initiation frequencies,* so that some genes are transcribed at much higher rates than others. As indicated in Table 8-2, the majority of the genes that are transcribed give rise to very few mRNA molecules.

The Precursors of Messenger RNA Are Covalently Modified at Both Ends 32

In eucaryotes mature mRNA is produced in several steps. The RNA molecules freshly synthesized by RNA polymerase II in the nucleus are known as *primary transcripts;* the collection of such transcripts was originally called heterogeneous nuclear RNA (hnRNA) because of the large variation in RNA size, contrasting with the more uniform and smaller size of the RNA sequences actually needed to encode proteins. We shall see shortly that much of this variation is due to the presence of long intron sequences in the primary transcripts. As they are being synthesized, these transcripts are covalently modified at both their 5' end and their 3' end in ways that clearly distinguish them from transcripts made by other RNA polymerases. These modifications will be used later in the cytoplasm as signals that these transcripts are to be translated into protein.

The 5' end of the RNA molecule (which is the end synthesized first during transcription) is first *capped* by the addition of a methylated G nucleotide. Capping occurs almost immediately, after about 30 nucleotides of RNA have been synthesized, and it involves condensation of the triphosphate group of a molecule of GTP with a diphosphate left at the 5' end of the initial transcript (Figure 8-48). This 5' cap will later play an important part in the initiation of protein synthesis; it also seems to protect the growing RNA transcript from degradation.

The 3' end of most polymerase II transcripts is defined not by the termination of transcription but by a second modification in which the growing transcript is cleaved at a specific site and a poly-A tail is added by a separate polymerase to the cut 3' end. The signal for the cleavage is the appearance in the RNA chain of the sequence AAUAAA located 10 to 30 nucleotides upstream from the site of cleavage, plus a less well-defined downstream sequence. Immediately after cleavage, a *poly-A polymerase* enzyme adds 100 to 200 residues of adenylic acid (as *poly A*) to the 3' end of the RNA chain to complete the primary RNA transcript. Meanwhile, the polymerase fruitlessly continues transcribing for hundreds or thousands of nucleotides until termination occurs at one of several later sites; the extra piece of functionless RNA transcript thus generated presumably lacks a 5' cap and is rapidly degraded (Figure 8-49).

The poly-A tail appears to have several functions: (1) as described later, it aids in the export of mature mRNA from the nucleus; (2) it is thought to affect the stability of at least some mRNAs in the cytoplasm; and (3) it seems to serve as a recognition signal for the ribosome that is required for efficient translation of mRNA. The latter feature - in combination with the 5' cap - would

enable a ribosome to determine whether the mRNA was intact before expending energy and precursors to begin its translation.

Even though polymerase II transcripts comprise more than half of the RNA being synthesized by DNA transcription, we shall see below that most of the RNA in these transcripts is unstable and therefore short-lived. Consequently, the hnRNA in the cell nucleus and the cytoplasmic mRNA derived from it constitute only a minor fraction of the total RNA in a cell (Table 8-3). Despite their relative scarcity, these RNA molecules can be readily purified because of their poly-A tails. When the total cellular RNA is passed through a column containing poly dT linked to a solid support, the complementary base-pairing between T and A residues selectively binds the molecules with poly-A tails to the column; the bound molecules can then be released for further analysis. This procedure is widely used to separate the hnRNA and mRNA molecules from the ribosomal and transfer RNA molecules that predominate in cells.

Only RNA polymerase II transcripts have 5' caps and 3' poly-A tails. This seems to be because the capping and cleavage plus poly-A addition reactions are mediated by enzymes that bind selectively to polymerase II. Thus, if a gene that is normally transcribed by polymerase II is separated from its promoter by recombinant DNA methods and fused to a promoter recognized by polymerase I or by polymerase III, the RNA transcripts produced from it by these polymerases are neither capped nor polyadenylated. The requirement for a specific capping and polyadenylation of mRNA precursors may explain why these RNAs are synthesized by a separate type of RNA polymerase molecule in eucaryotes.

RNA Processing Removes Long Nucleotide Sequences from the Middle of RNA Molecules [33]

The discovery of interrupted genes in 1977 was entirely unexpected. Previous studies in bacteria had shown that their genes are composed of a continuous string of the nucleotides needed to encode the amino acids of a protein, and there seemed to be no obvious reason why a gene should be organized in any other way. The first indication that eucaryotic genes are not continuous like bacterial genes came when new methods allowing an accurate comparison of mRNA and DNA sequences were applied to mRNAs produced by a human *adenovirus* (a large DNA virus). The region of the viral DNA producing these RNAs turned out to contain sequences that are not present in the mature RNAs. The possibility that this situation was unique to viruses was quickly eliminated by the finding of similar interruptions in the ovalbumin and b-globin genes of vertebrates. As discussed earlier, the sequences present in the DNA but omitted from the mRNA are called *intron* sequences, while those present in the mRNA are called *exon* sequences (Figures 8-50 and 8-51).

Before the discovery of introns, the significance of hnRNA and its relationship to mRNA had seemed very mysterious. It had long been known that most of the RNA synthesized by RNA polymerase II is rapidly degraded in the nucleus. The hnRNA molecules of cultured cells can be radiolabeled by brief exposure to ^{3}H-uridine and followed over a long period. This sort of experiment showed that the average length of the hnRNA molecules in the labeled population decreases rapidly, starting from about 7000 nucleotides, to reach the size of cytoplasmic mRNA molecules (an average of about 1500 nucleotides) after only about 30 minutes; at about the same time, radioactively labeled RNA molecules begin to leave the nucleus as mRNA molecules. Only about 5% of the mass of the labeled hnRNA ever reaches the cytoplasm, however; the remainder is degraded into small fragments in the nucleus over a period of about an hour. This seemed strangely wasteful. And the puzzle was deepened by the finding that even though the hnRNA molecules became progressively shorter, they retained their 5' caps and their 3' poly-A tails.

With the discovery of introns, the explanation became clear: the primary RNA transcript is a faithful copy of the gene, containing both exon and intron sequences, and the latter sequences are cut out of the middle of the RNA transcript to produce an mRNA molecule that codes directly for a protein (see Figure3-15). Because the coding RNA sequences on either side of an intron sequence are joined to each other after the intron sequence has been cut out, this reaction is known as RNA splicing. RNA splicing occurs in the cell nucleus, out of reach of the ribosomes, and RNA is exported to the cytoplasm only when processing is complete.

Because most mammalian genes contain much more intron than exon sequence (see Table 8-1, p. 340), RNA splicing can account for the conversion of the very long nuclear hnRNA molecules to the much shorter cytoplasmic mRNA molecules.

Before discussing the distribution of introns in eucaryotic genes and some of their consequences for cell function, it is necessary to explain how intron sequences are recognized and removed by the splicing machinery.

hnRNA Transcripts Are Immediately Coated with Proteins and snRNPs [34]

Newly made RNA in eucaryotic cells, unlike that in bacteria, appears to become immediately condensed into a string of closely spaced protein-containing particles. Each particle consists of about 500 nucleotides of RNA wrapped around a protein complex that serves to condense and package each growing RNA transcript in a manner reminiscent of the DNA-protein complexes of nucleosomes. The resulting hnRNP particles (*heterogeneous nuclear ribonucleoprotein particles*) can be purified after nuclei have been treated with ribonucleases at levels just sufficient to destroy the linker RNA between them. Each particle has a diameter of about 20 nm, which is twice that of a nucleosome, and the protein core is more complex and less well characterized, being composed of a set of at least eight different proteins. Except for histones, the proteins in this core are the most abundant proteins in the cell nucleus. Several of them contain a conserved domain of about 80 amino acids, which is often repeated and shared by many other RNA-binding proteins.

The hnRNP particles are generally distorted by the standard spreading techniques used to view gene transcription in the electron microscope (see Figure 8-45). These micrographs, however, reveal especially stable particles of a less common type, whose position on the RNA strongly implicates them in RNA splicing. These particles form very quickly at specific RNA sequences - at or near the junctions between intron and exon sequences - and, as the RNA transcript elongates, they coalesce in pairs to form a larger assembly that is thought to be the *spliceosome* that catalyzes RNA splicing (Figure 8-52).

Biochemical analysis has revealed that the cell nucleus contains many complexes of proteins with small RNAs (generally RNAs of 250 nucleotides or less), which have arbitrarily been designated U1, U2, . . . , U12 RNAs. These complexes, called small nuclear ribonucleoproteins (snRNPs - pronounced "snurps"), resemble ribosomes in that each contains a set of proteins complexed to a stable RNA molecule. They are much smaller than ribosomes, however - only 250,000 daltons compared with 4.5 million daltons for a ribosome. Some proteins are present in several types of snRNPs, whereas others are unique to one type. This was first demonstrated using serum from patients with the autoimmune disease *systemic lupus erythematosus*, who make antibodies directed against one or more of their own snRNP proteins: a single antibody was found that binds the U1, U2, U5, and U4/U6 snRNPs, for example, and we now know that they all contain common proteins.

Individual snRNPs are believed to recognize specific nucleic acid sequences through RNA-RNA base-pairing. Some mediate RNA splicing, one is known to be involved in the cleavage reaction that generates the 3' ends of newly formed histone RNAs, while the function of others is unknown. The evidence for the role of snRNPs in RNA splicing comes from experiments on RNA splicing *in vitro*, as well as from analyses of yeast cells that are mutant in one of the snRNP components.

Intron Sequences Are Removed as Lariat-shaped RNA Molecules 35

Introns range in size from about 80 nucleotides to 10,000 nucleotides or more. Unlike the sequence of an exon, the exact nucleotide sequence of an intron seems to be unimportant. Thus introns have accumulated mutations rapidly during evolution, and it is often possible to alter most of an intron's nucleotide sequence without greatly affecting gene function. This has led to the suggestion that intron sequences have no function at all and are largely genetic "junk," a proposition we shall examine at the end of the chapter. The only highly conserved sequences in introns are those required for intron removal, which are found at or near the ends of an intron and are very similar in all known intron sequences; they generally cannot be altered without affecting the splicing process that normally removes the intron sequence from the primary RNA transcript. These conserved boundary sequences at the 5' splice site (donor site) and the 3' splice site (acceptor site) of introns from higher eucaryotes are shown in Figure 8-53. The RNA breaking and rejoining reactions must be carried out precisely because an error of even one nucleotide would shift the reading frame in the resulting mRNA molecule and make nonsense of its message.

The pathway by which the intron sequences are removed from primary RNA transcripts has been elucidated by *in vitro* studies in which a pure RNA species containing a single intron is prepared by incubating an appropriately designed DNA fragment with an RNA polymerase (see Figure7-36). When these RNA molecules are added to a cell extract, they become spliced in a two-step enzymatic reaction that requires prolonged incubation with ATP, the U1, U2, U5, and U4/U6 snRNPs, and a number of additional proteins; these components assemble into a large multicomponent ribonucleoprotein complex, or spliceosome. Characterization of the RNA species that appear as intermediates during the reaction, as well as the snRNPs required to produce them, led to the discovery that the intron is excised in the form of a *lariat*, according to the splicing pathway shown in Figures 8-54 and 8-55.

Individual roles have been defined for several of the snRNPs. The U1 snRNP, for example, binds to the 5' splice site, guided by a nucleotide sequence in the U1 RNA that forms base pairs complementary to the nine-nucleotide splice site consensus sequence (see Figure 8-53). Since RNA is capable of acting like an enzyme, either the RNA or the protein components of the spliceosome could be responsible for catalyzing the breakage and formation of covalent bonds required for RNA splicing.

Multiple Intron Sequences Are Usually Removed from Each RNA Transcript [36]

Because the spliceosome seems mainly to work by recognizing the consensus sequences that mark the two boundaries of an intron sequence (and for all intron sequences these consensus sequences are alike), the 5' splice site (donor site) at the end of any one intron sequence can in principle be spliced to the 3' splice site (acceptor site) of any other intron sequence. Indeed, when an RNA molecule is created artificially, with donor and acceptor splice sites from different intron sequences inserted into it, the intervening RNA is often recognized by the spliceosome and removed.

In view of this result, it is surprising that vertebrate genes can contain as many as 50 introns (see Table 8-1, p. 340). If *any* two 5' and 3' splice sites were mispaired for splicing, some functional mRNA sequences would be lost, with disastrous consequences. Somehow such mistakes are avoided: the RNA processing machinery normally guarantees that each 5' splice site pairs only with the 3' splice site that is closest to it in the downstream (5'-to-3') direction of the linear RNA sequence (Figure 8-56). How this sequential pairing of splice sites is accomplished is not known, although the assembly of the spliceosome while the RNA transcript is still growing (see Figure 8-52) is presumed to play a major part in ensuring an orderly pairing of the appropriate splice sites. There is also evidence that the exact three-dimensional conformations adopted by the intron and exon sequences in the RNA transcript are important. We shall see in Chapter 9, however, that this simple 5'-to-3' splicing can be altered by specialized control mechanisms that allow a single gene to produce several different mRNAs and hence several different proteins.

Studies of Thalassemia Reveal How RNA Splicing Can Allow New Proteins to Evolve [37]

Recombinant DNA techniques have made humans with inherited diseases an increasingly important source of material for genetic studies of cellular mechanisms. In a group of human genetic diseases called the thalassemia syndromes, for example, patients have an abnormally low level of hemoglobin - the oxygen-carrying protein in red blood cells. The change in the DNA sequence has been determined for more than 50 such mutants, and a large proportion of them have been found to have alterations in the pattern of splicing of globin RNA transcripts. Thus single nucleotide changes have been detected that inactivate a splice site. Surprisingly, analysis of the mRNAs produced in these mutant individuals reveals that the loss of a splice site does not prevent splicing but instead causes its normal partner site to seek out and become joined to a new "cryptic" site nearby; often a number of alternative splices are made in these mutants, causing the mutant gene to produce a set of altered proteins rather than just one (Figure 8-57). Other single nucleotide changes create new splice sites by changing a sequence in an intron or an exon into a consensus splice site. These results demonstrate that RNA splicing is a flexible process in higher eucaryotic cells, and they suggest that changes in the splicing pattern caused by random mutations could be an important pathway in the evolution of genes and organisms.

Spliceosome-catalyzed RNA Splicing Probably Evolved from Self-splicing Mechanisms [38]

When the lariat intermediate in nuclear RNA splicing was first discovered, it puzzled molecular biologists. Why was this bizarre pathway used rather than the apparently simpler alternative of bringing the 5' and 3' splice sites together in an initial step, followed by their direct cleavage and rejoining? The answer seems to lie in the way the spliceosome evolved.

As explained in Chapter 1, it is thought that early cells may have used RNA molecules rather than proteins as their major catalysts and stored their genetic information in RNA rather than DNA sequences. RNA-catalyzed splicing reactions presumably played important roles in these early cells, and some self-splicing RNA introns remain today - for example, in the nuclear rRNA genes of the ciliate *Tetrahymena*, in bacteriophage T4, and in some mitochondrial and chloroplast genes. A self-splicing intron sequence can be identified in a test tube by incubating a pure RNA molecule that contains the intron sequence and observing the splicing reaction; it can also be identified from the RNA sequence, inasmuch as large parts of the intron sequence need to be conserved in order to fold to create a catalytic surface in the RNA molecule. Two major classes of self-splicing intron sequences can be readily distinguished in this way. *Group I intron sequences* begin the splicing reaction by binding a G nucleotide to the intron sequence; the G is thereby activated to form the attacking group that will break the first of the phosphodiester bonds cleaved during splicing (the bond at the 5' splice site). In *group II intron sequences* a specially reactive A residue in the intron sequence is the attacking group, and a lariat intermediate is generated. Otherwise the reaction pathways for the two types of sequences are the same. Both are presumed to represent vestiges of very ancient mechanisms (Figure 8-58).

In the evolution of nuclear RNA splicing, the reaction pathway used by the group II self-splicing intron sequences seems to have been retained, with the catalytic role of the intron sequences being replaced by separate spliceosome components. Thus the

small RNAs U1 and U2, for example, may well be remnants of catalytic RNA sequences that were originally present in intron sequences. Shifting the catalysis from intron sequence to spliceosome presumably lifted most of the constraints on the evolution of introns, allowing many new intron sequences to evolve.

The Transport of mRNAs to the Cytoplasm Is Delayed Until Splicing Is Complete 39

Finished mRNA molecules are thought to be recognized by receptor proteins in the nuclear pore complex and to be transported actively to the cytoplasm (discussed in Chapter 12). The major proteins of the hnRNP particles and various processing molecules bound to the RNA, by contrast, are largely confined to the nucleus, although some of them pass into the cytoplasm with the transported mRNA before being rapidly stripped from the RNA and returned to the nucleus (Figure 8-59).

Studies of mutant yeasts suggest that for RNAs that have splice sites transport out of the nucleus can occur only after the splicing reaction has been completed. When a mutation creates a defect in the splicing machinery so that splicing cannot occur, unspliced mRNA precursors remain in the nucleus, while those mRNAs that do not require splicing (which includes most of the mRNAs in this single-cell eucaryote) are transported normally to the cytosol. This observation suggests that RNAs may be retained in the nucleus by their bound spliceosome components, which seem to form numerous large aggregates throughout the nucleus of higher eucaryotes. These aggregates could serve as "splicing islands" (Figure 8-60); although it is not known how they form or function, they may be analogous to the *nucleolus*, a much larger and more prominent structure in the nucleus, whose organization and function are better understood.

The nucleolus is the site where ribosomal RNA (rRNA) molecules are processed from a larger precursor RNA and assembled into ribosomes by the binding of ribosomal proteins. Before discussing nucleolar structure, however, we need to consider how the precursor rRNA molecules are synthesized from rRNA genes.

Ribosomal RNAs (rRNAs) Are Transcribed from Tandemly Arranged Sets of Identical Genes 40

Many of the most abundant proteins of a differentiated cell, such as hemoglobin in the red blood cell and myoglobin in a muscle cell, are synthesized from genes that are present in only a single copy per haploid genome. These proteins are abundant because each of the many mRNA molecules transcribed from the gene can be translated into as many as 10 protein molecules per minute. This will normally produce more than 10,000 protein molecules per mRNA molecule in each cell generation. Such an amplification step is not available for the synthesis of the intrinsic RNA components of the ribosome, however, since they are the final gene products. Yet a growing higher eucaryotic cell must synthesize 10 million copies of each type of ribosomal RNA molecule in each cell generation in order to construct its 10 million ribosomes. Adequate quantities of ribosomal RNAs, in fact, can be produced only because the cell contains multiple copies of the rRNA genes that code for ribosomal RNAs.

Even *E. coli* needs seven copies of its rRNA genes to keep up with the cell's need for ribosomes. Human cells contain about 200 rRNA gene copies per haploid genome, spread out in small clusters on five different chromosomes, while cells of the frog *Xenopus* contain about 600 rRNA gene copies per haploid genome in a single cluster on one chromosome. In eucaryotes the multiple copies of the highly conserved rRNA genes on a given chromosome are located in a tandemly arranged series in which each gene (8000 to 13,000 nucleotide pairs long, depending on the organism) is separated from the next by a nontranscribed region known as *spacer DNA,* which can vary greatly in length and sequence. We shall see later that such multiple copies of tandemly arranged genes tend to co-evolve.

Because of their repeating arrangement, and because they are transcribed at a very high rate, the tandem arrays of rRNA genes can easily be seen in spread chromatin preparations. The RNA polymerase molecules and their associated transcripts are so densely packed (typically about 100 per gene) that the transcripts stick out perpendicularly from the DNA to give each transcription unit a "Christmas tree" appearance (Figure 8-61). As noted earlier (see Figure 8-47), the tip of each of these "trees" represents the point on the DNA at which transcription begins and where the transcripts are thus shortest, while the other end of the rRNA transcription unit is sharply demarcated by the sudden disappearance of RNA polymerase molecules and their transcripts.

The rRNA genes are transcribed by *RNA polymerase I*, and each gene produces the same primary RNA transcript. In humans this RNA transcript, known as *45S rRNA*, is about 13,000 nucleotides long. Before it leaves the nucleus in assembled ribosomal particles, the 45S rRNA is cleaved to give one copy each of the 28S rRNA (about 5000 nucleotides), the 18S rRNA (about 2000 nucleotides), and the 5.8S rRNA (about 160 nucleotides) of the final ribosome. The derivation of these three rRNAs from the same primary transcript ensures that they will be made in equal quantities. The remaining part of each primary transcript (about

6000 nucleotides) is degraded in the nucleus (Figure 8-62). Some of these extra RNA sequences are thought to play a transient part in ribosome assembly, which begins immediately as specific proteins bind to the growing 45S rRNA transcripts in the nucleus.

Another set of tandemly arranged genes with nontranscribed spacers codes for the 5S rRNA of the large ribosomal subunit (the only rRNA that is transcribed separately). The 5S rRNA genes are only about 120 nucleotide pairs in length, and like a number of other genes encoding small stable RNAs (most notably the transfer RNA [tRNA] genes), they are transcribed by *RNA polymerase III*. Humans have about 2000 5S rRNA genes tandemly arranged in a single cluster far from all the other rRNA genes. It is not known why this one type of rRNA is transcribed separately.

The Nucleolus Is a Ribosome-producing Machine 40

The continuous transcription of multiple gene copies ensures an adequate supply of the rRNAs, which are immediately packaged with ribosomal proteins to form ribosomes. The packaging occurs in the nucleus, in a large, distinct structure called the nucleolus. The nucleolus contains large loops of DNA emanating from several chromosomes, each of which contains a cluster of rRNA genes. Each such gene cluster is known as a nucleolar organizer region. Here the rRNA genes are transcribed at a rapid rate by RNA polymerase I. The beginning of the rRNA packaging process can be seen in electron micrographs of these genes: the 5' tail of each transcript is encased by a protein-rich granule (see Figure 8-61). These granules, which do not appear on other types of RNA transcripts, presumably reflect the first of the protein-RNA interactions that take place in the nucleolus.

The biosynthetic functions of the nucleolus can be traced by briefly labeling newly made RNA with ^{3}H-uridine. After varying intervals of further incubation without ^{3}H-uridine, a cell fractionation procedure can be used to break the rRNA genes free of their chromosomes, thereby allowing the radioactive nucleoli to be isolated in relatively pure form (Figure 8-63). Such experiments show that the intact 45S transcript is first packaged into a large complex containing many different proteins imported from the cytoplasm, where all proteins are synthesized. Most of the 80 different polypeptide chains that will make up the ribosome, as well as the 5S rRNAs, are incorporated at this stage. Other molecules are needed to process the 45S rRNA and to guide the assembly process. Thus the nucleolus also contains other RNA-binding proteins and certain small ribonucleoprotein particles (including U3 snRNP) that are believed to help catalyze the construction of ribosomes. These components remain in the nucleolus when the ribo-somal subunits are exported to the cytoplasm in finished form. An especially notable component is *nucleolin*, an abundant, well-characterized RNA-binding protein that seems to coat only ribosomal transcripts; this protein stains with silver in the characteristic manner of the nucleolus itself.

As the 45S rRNA molecule is processed, it gradually loses some of its RNA and protein and then splits to form separate precursors of the large and small ribosomal subunits (Figure 8-64). Within 30 minutes of radioactive pulse labeling, the first mature small ribosomal subunits, containing their 18S rRNA, emerge from the nucleolus and appear in the cytoplasm. Assembly of the mature large ribosomal subunit, with its 28S, 5.8S, and 5S rRNAs, takes about an hour to complete. The nucleolus therefore contains many more incomplete large ribosomal subunits than small ones.

The last steps in ribosome maturation occur only as these subunits are transferred to the cytoplasm. This delay prevents functional ribosomes from gaining access to the incompletely processed hnRNA molecules in the nucleus.

The Nucleolus Is a Highly Organized Subcompartment of the Nucleus 41

As seen in the light microscope, the large spheroidal nucleolus is the most obvious structure in the nucleus of a nonmitotic cell. Consequently, it was so closely scrutinized by early cytologists that an 1898 review could list some 700 references. By the 1940s cytologists had demonstrated that the nucleolus contains high concentrations of RNA and proteins, but its major function in ribosomal RNA synthesis and ribosome assembly was not discovered until the 1960s.

Some of the details of nucleolar organization can be seen in the electron microscope. Unlike the cytoplasmic organelles, the nucleolus is not bounded by a membrane; instead, it seems to be constructed by the specific binding of unfinished ribosome precursors to one another to form a large network. In a typical electron micrograph three partially segregated regions can be distinguished (Figure 8-65): (1) a pale-staining *fibrillar center*, which contains DNA that is not being actively transcribed; (2) a *dense fibrillar component*, which contains RNA molecules in the process of being synthesized; and (3) *a granular component*, which contains maturing ribosomal precursor particles.

The size of the nucleolus reflects its activity. Its size therefore varies greatly in different cells and can change in a single cell. It is very small in some dormant plant cells, for example, but can occupy up to 25% of the total nuclear volume in cells that are making unusually large amounts of protein. The differences in size are due largely to differences in the amount of the granular component, which is probably controlled at the level of ribosomal gene transcription: electron microscopy of spread chromatin shows that both the fraction of activated ribosomal genes and the rate at which each gene is transcribed can vary according to circumstances.

The Nucleolus Is Reassembled on Specific Chromosomes After Each Mitosis [42]

The appearance of the nucleolus changes dramatically during the cell-division cycle. As the cell approaches mitosis, the nucleolus first decreases in size and then disappears as the chromosomes condense and all RNA synthesis stops, so that generally there is no nucleolus in a metaphase cell. When ribosomal RNA synthesis restarts at the end of mitosis (in telophase), tiny nucleoli reappear at the chromosomal locations of the ribosomal RNA genes (Figure 8-66).

In humans the ribosomal RNA genes are located near the tips of each of 5 different chromosomes, as shown previously in Figure 8-32 (that is, on 10 of the 46 chromosomes in a diploid cell). Correspondingly, 10 small nucleoli form after mitosis in a human cell, although they are rarely seen as separate entities because they quickly grow and fuse to form the single large nucleolus typical of many interphase cells (Figure 8-67).

What happens to the RNA and protein components of the disassembled nucleolus during mitosis? It seems that at least some of them become distributed over the surface of all of the metaphase chromosomes and are carried as cargo to each of the two daughter cell nuclei. As the chromosomes decondense at telophase, these "old" nucleolar components help reestablish the newly emerging nucleoli.

Individual Chromosomes Occupy Discrete Territories in the Nucleus During Interphase [43]

As we have just seen, specific genes from separate interphase chromosomes are brought together at a single site in the nucleus when the nucleolus forms. Are other parts of chromosomes also nonrandomly ordered in the nucleus? First raised by biologists in the late nineteenth century, this fundamental question still has not been answered satisfactorily.

A certain degree of chromosomal order results from the configuration that the chromosomes always have at the end of mitosis. Just before a cell divides, the condensed chromosomes are pulled to each spindle pole by microtubules attached to the centromeres; thus, as the chromosomes move, the centromeres lead the way and the distal arms (terminating in telomeres) lag behind. The chromosomes in many nuclei tend to retain this so-called *Rabl orientation* throughout interphase, with their centromeres facing one pole of the nucleus and their telomeres pointing toward the opposite pole (Figure 8-68A). In some cases the nucleus is specifically oriented in the cell: in the early *Drosophila* embryo, for example, all the centromeres face apically (Figure 8-68B). Such fixed nuclear orientations might have important effects on cell polarity, but it is difficult to design experiments to test this possibility.

In most cells the various chromosomes are indistinguishable from one another during interphase. Consequently, it is difficult to assess their arrangement in more detail than just described. The giant interphase chromosomes of the polytene cells of *Drosophila* larvae, however, are an exception. Here the individual chromosome bands can be resolved clearly enough to determine the precise positions of specific genes in intact nuclei by microscopic optical-sectioning and reconstruction techniques. The results of such analyses suggest that the interphase chromosome set is not highly ordered: although the Rabl orientation tends to be maintained, two apparently identical cells often have different chromosomes as nearest neighbors.

These analyses of polytene chromosomes have also indicated that each chromosome occupies its own territory in the interphase nucleus - that is, the individual chromosomes are not extensively intertwined (Figure 8-69). Other experiments have shown that nonpolytene chromosomes also tend to occupy discrete domains in interphase nuclei. *In situ* hybridization experiments with an appropriate DNA probe, for example, can outline a single chromosome in hybrid mammalian cells grown in culture (Figure 8-70). Most of the DNA of such a chromosome is seen to occupy only a small portion of the interphase nucleus, suggesting that each individual chromosome remains compact and organized while allowing selected portions of its DNA to be active in RNA synthesis.

How Well Ordered Is the Nucleus? [44]

The interior of the nucleus is not a random jumble of its many RNA, DNA, and protein components. We have seen that the nucleolus is organized as an efficient ribosome-construction machine, and clusters of spliceosome components are organized, possibly as discrete RNA-splicing islands (see Figure 8-60). Order is also seen in the electron microscope when one focuses on the regions around nuclear pores: the chromatin that lines the inner nuclear membrane (which is unusually condensed chromatin and therefore clearly visible in electron micrographs) is excluded from a considerable region beneath and around each nuclear pore, clearing a path between the cytoplasm and the nucleoplasm (Figure 8-71). In some special cases, moreover, the nuclear pores are found to be highly organized in the nuclear envelope (Figure 8-72), presumably reflecting a corresponding organization of the nuclear lamina to which the pores are attached.

Is there an intranuclear framework, analogous to the cytoskeleton, on which nuclear components are organized? Many cell biologists believe there is. The *nuclear matrix,* or *scaffold,* has been defined as the insoluble material left in the nucleus after a series of biochemical extraction steps. Some of the proteins that constitute it can be shown to bind specific DNA sequences called *SARs* or *MARs* (for scaffold- or matrix-associated regions). Such DNA sequences have been postulated to form the base of chromosomal loops (see Figure 8-18). By means of such chromosomal attachment sites, the matrix might help organize chromosomes, localize genes, and regulate DNA transcription and replication within the nucleus. Because the structural components of the matrix have not yet been identified, however, it remains uncertain whether the matrix isolated by cell biologists represents a structure that is present in intact cells.

Summary

RNA polymerase, the enzyme that catalyzes DNA transcription, is a complex molecule containing many polypeptide chains. In eucaryotic cells there are three RNA polymerases, designated polymerases I, II, and III; they are evolutionarily related to one another and to bacterial RNA polymerase, and they have some subunits in common. After initiating transcription, each enzyme is thought to release one or more subunits and to bind other subunits that are required for RNA chain elongation and termination.

Most of the cell's mRNA is produced by a complex process beginning with the synthesis of heterogeneous nuclear RNA (hnRNA). The primary hnRNA transcript is made by RNA polymerase II. It is then capped by the addition of a special nucleotide to its 5' end and is cleaved and then polyadenylated at its 3' end. The modified RNA molecules are usually then subjected to one or more RNA splicing events, in which intron sequences are removed from the middle of the RNA molecule by a reaction catalyzed by a large ribonucleoprotein complex known as a spliceosome. In this process most of the mass of the primary RNA transcript is removed and degraded in the nucleus. As a result, although the rate of production of hnRNA typically accounts for about half of a cell's RNA synthesis, the mRNA produced represents only about 3% of the steady-state quantity of RNA in a cell.

Unlike genes that code for proteins, which are transcribed by polymerase II, the genes that code for most structural RNAs are transcribed by polymerase I and III. These genes are usually repeated many times in the genome and are often clustered in tandem arrays. RNA polymerase III makes a variety of small stable RNAs, including the tRNAs and the small 5S rRNA of the ribosome. RNA polymerase I makes the large rRNA precursor molecule (45S rRNA) containing the major rRNAs. Except for the ribosomes in mitochondria and chloroplasts, all the cell's ribosomes are assembled in the nucleolus - a distinct intranuclear organelle that is formed around the tandemly arranged rRNA genes, which are brought together from several chromosomes.

H₂N ☐ COOH

yeast

H₂N ☐ COOH

Drosophila

H₂N ☐ COOH
Figure 8-42. The common origin of bacterial and eucaryotic RNA polymerases. Amino acid sequence similarities between the b' subunit of *E. coli* RNA polymerase and the largest subunit of eucaryotic RNA polymerase II are among the comparisons that reveal a common evolutionary origin for the bacterial and eucaryotic enzymes. The b' subunit is thought to bind to DNA. The regions of the sequence shown as *green bars* are more than 70% identical between yeast and *Drosophila* and more than 40% identical between *Drosophila* and *E. coli*. A uniquely eucaryotic sequence (of seven amino acid residues) is repeated 26 times at the carboxyl terminus of the yeast subunit and more than 40 times in the *Drosophila* subunit (indicated here by *green circles*); these repeats are phosphorylated as part of the process that starts an RNA chain in eucaryotes (see Figure9-30). (After A.L. Greenleaf et al., in RNA Polymerase and the Regulation of Transcription [W.S. Reznikoff et al., eds.], pp. 459-464. New York: Elsevier, 1987.)
Figure 8-43. Schematic diagram of the steps in the initiation of RNA synthesis (DNA transcription) catalyzed by RNA polymerase. The steps indicated have been revealed by studies of the *E. coli* enzyme. A DNA molecule containing a promoter sequence for the *E. coli* polymerase is shown (see Figure6-2). The enzyme first forms a *closed complex* in which the two DNA strands remain fully base-paired. In the next step the enzyme catalyzes the opening of a little more than one turn of the DNA helix to form an *open complex*, in which the template DNA strand is exposed for the initiation of an RNA chain. The polymerase containing the bound s subunit, however, behaves as though it is tethered to the promoter site: it seems unable to proceed with the elongation of the RNA chain and on its own frequently synthesizes and releases short RNA chains. As indicated, the conversion to an actively elongating polymerase requires the release of initiation factors (the sigma subunit in the case of the *E. coli* enzyme) and generally involves the binding of other proteins that serve as elongation factors.

Figure 8-44. A typical cell nucleus visualized by electron microscopy using the procedure shown in Figure 8-45. An enormous tangle of chromatin can be seen spilling out of the lysed nucleus; only the chromatin at the outermost edge of this tangle will be sufficiently dilute for meaningful examination at higher power. (Courtesy of Victoria Foe.)
Figure 8-45. A method for examining chromatin in the electron microscope. The nuclei are first lysed, and then the chromatin is freed from cellular debris and spread out on a grid.
Figure 8-71. Electron micrograph of a mammalian cell nucleus. Note that the condensed chromatin underlying the nuclear envelope is excluded from regions around the nuclear pores. (Courtesy of Larry Gerace.)
Figure 8-46. Electron micrograph of a region of chromatin containing a gene being transcribed at unusually high frequency. Many RNA polymerase II molecules with their growing RNA transcripts are visible. The direction of transcription is from left to right (see Figure 8-47). (From V.E. Foe, L.E. Wilkinson, and C.D. Laird, *Cell* 9:131-146, 1976. © 1976 Cell Press.)
Figure 8-47. An idealized transcription unit. The drawing illustrates how the electron microscope appearance (see Figure 8-46) demonstrates the direction of transcription, as well as the start site of the unit.

Table 8-2. The Population of mRNA Molecules in a Typical Mammalian Cell

	Copies per Cell of Each mRNA Sequence		Number of Different mRNA Sequences in Each Class	Total Number of mRNA Molecules in Each Class
Abundant class	12,000	×	4	= 48,000
Intermediate class	300	×	500	= 150,000
Scarce class	15	×	11,000	= 165,000

This division of mRNAs into just three discrete classes is somewhat arbitrary, and in many cells a more continuous spread in abundances is seen. However, a total of 10,000 to 20,000 different mRNA species is normally observed in each cell, most species being present at a low level (5 to 15 molecules per cell). Most of the total cytoplasmic RNA is rRNA, and only 3% to 5% is mRNA, a ratio consistent with the presence of about 10 ribosomes per mRNA molecule. This particular cell type contains a total of about 360,000 mRNA molecules in its cytoplasm.
Figure 8-48. The reactions that cap the 5' end of each RNA molecule synthesized by RNA polymerase II. The final cap contains a novel 5'-to-5' linkage between the positively charged 7-methyl G residue and the 5' end of the RNA transcript (see Figure 6-26). At least some of the enzymes required for this process are thought to be bound to polymerase II, since polymerase I and III transcripts are not capped and the indicated reaction occurs almost immediately following initiation of each RNA chain. The letter N is used here to represent any one of the four ribonucleotides, although the nucleotide that starts an RNA chain is usually a purine (an A or a G). (After A.J. Shatkin, *Bioessays* 7:275-277, 1987. © ICSU Press.)
Figure 8-49. Synthesis of a primary RNA transcript (an mRNA precursor) by RNA polymerase II. This diagram starts with a polymerase that has just begun synthesizing an RNA chain (step 4 of Figure 8-43). Recognition of a poly-A addition signal in the growing RNA transcript causes the chain to be cleaved and then polyadenylated as shown. In yeasts the polymerase terminates its RNA synthesis almost immediately thereafter, but in higher eucaryotes it often continues transcription for thousands of nucleotides. It seems likely that the polymerase changes its properties once one RNA chain cleavage has occurred. Thus it cannot trigger poly-A addition to its downstream RNA transcript, and it seems to have a greater probability of responding to the sequences that cause chain termination and polymerase release. The simplest hypothesis, represented here, is that an elongation factor (or factors) is released from the polymerase after cleavage of the transcript.

Table 8-3. Selected Data on Amounts of RNA in a Typical Mammalian Cell

	Steady-State Amount (percent of total cell RNA)	Percent of Total RNA Synthesis
Nuclear rRNA precursors	4	39
↓		
Cytoplasmic rRNA	71	-
Nuclear hnRNA	7	58
↓		
Cytoplasmic mRNA	3	-
Small stable RNAs (mostly tRNAs)	15	3

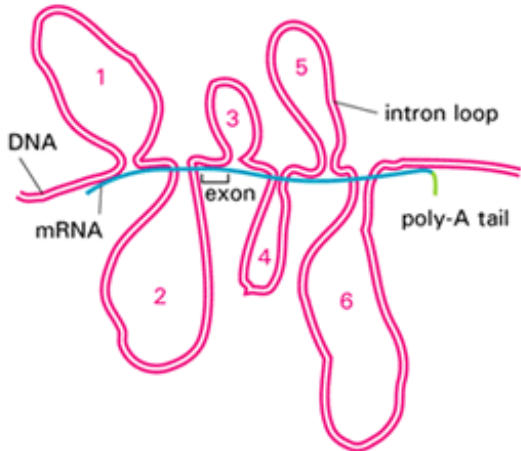
The figures shown here were derived from the analysis of a mouse fibroblast cell line (L cells) in culture. Each cell contained 26 pg of RNA (5×10^{10} nucleotides of RNA), of which about 14% was located in the cell nucleus. (The cell nucleus thus contains about twice as much DNA as RNA.) An average of about 200×10^6 nucleotides is polymerized into RNA every minute during interphase. This is about 20 times the average rate at which DNA is synthesized during S phase. Note that although most of the RNA synthesized is hnRNA, most of this RNA is rapidly degraded in the nucleus. As a result, the mRNA produced from the hnRNA is only a minor fraction of the total RNA in the cell. (Modified from B.P. Brandhorst and E.H. McConkey, *J. Mol. Biol.* 85:451-563, 1974.)


Figure 8-50. Early evidence for the existence of introns in eucaryotic genes. The evidence was provided by the "R-loop technique," in which a base-paired complex between mRNA and DNA molecules is visualized in the electron microscope. An unusually abundant mRNA molecule, such as b-globin mRNA or ovalbumin mRNA, is readily purified from the specialized cells that produce it. When this single-stranded mRNA preparation is annealed in a suitable solvent to a cloned double-stranded DNA molecule containing the gene that encodes the mRNA, the RNA can displace a DNA strand wherever the two sequences match and form regions of RNA-DNA helix. Regions of DNA where no match to the mRNA sequence is possible are clearly visible as large loops of double-stranded DNA. Each of these loops (numbered 1 to 6) represents an intron in the gene sequence.

Figure 8-52. Spliceosomes. (A) Electron micrograph of a chromatin spread showing large ribonucleoprotein particles assembling at the 5' and 3' splice site regions to form a *spliceosome*. The RNA transcripts are being produced from a gene encoding a *Drosophila* chorion protein, and the positions of the splice sites on the primary RNA transcript are known. As indicated in the drawing (B), most of the RNA transcripts have either one or two large RNP particles near their 5' ends; a schematic representation of the gene is shown below the drawing. When there are two particles on a transcript [*open circles* in (B)], they average 25 nm in diameter and occur at or very near the positions of the 5' and 3' splice sites for the single small intron sequence (228 nucleotides long) near the 5' end of the transcripts. The more mature, longer transcripts frequently display a single larger particle [*green circles* in (B)] in the region of the intron, which probably results from the stable association of the two smaller particles and represents the assembled spliceosome. Since in some cases (including the example shown in this figure) splicing occurs while the 3' end of the RNA chain is still being transcribed, the poly A at the 3' end of hnRNA molecules cannot be required for splicing. The hnRNP proteins have been removed from these transcripts by the spreading conditions used. (Adapted from Y.N. Osheim, O.L. Miller, and A.L. Beyer, *Cell* 43:143-151, 1985. © Cell Press.)
Figure 8-53. Consensus sequences for RNA splicing in higher eucaryotes. The sequence given is that for the RNA chain; the nearly invariant GU and AG dinucleotides at either end of the intron sequence are highlighted in *yellow* (see also Figure 8-51).
Figure 8-54. The RNA splicing mechanism. RNA splicing is catalyzed by a spliceosome formed from the assembly of U1, U2, U5, and U4/U6 snRNPs (shown as *green circles*) plus other components (not shown). After assembly of the spliceosome, the reaction occurs in two steps: in step 1 the branch-point A nucleotide in the intron sequence, which is located close to the 3' splice site, attacks the 5' splice site and cleaves it; the cut 5' end of the intron sequence thereby becomes covalently linked to this A nucleotide, forming the branched nucleotide shown in Figure 8-55. In step 2 the 3'-OH end of the first exon sequence, which was created in the first step, adds to the beginning of the second exon sequence, cleaving the RNA molecule at the 3' splice site; the two exon sequences are thereby joined to each other and the intron sequence is released as a lariat. The spliceosome complex sediments at 60S, indicating that it is nearly as large as a ribosome. These splicing reactions occur in the nucleus and generate mRNA molecules from primary RNA transcripts (mRNA precursor molecules).
Figure 8-55. Structure of the branched RNA chain that forms during nuclear RNA splicing. The nucleotide shown in *yellow* is the A nucleotide highlighted in Figure 8-54. The branch is formed in step 1 of the splicing reaction illustrated there, when the 5' end of the intron sequence couples covalently to the 2'-OH ribose group of the A nucleotide, which is located about 30 nucleotides from the 3' end of the intron sequence. The branched chain remains in the final excised intron sequence and is responsible for its lariat form (see Figure 8-54).
Figure 8-56. Splicing the primary RNA transcript from the chicken ovalbumin gene. The drawing shows the organized removal of seven introns required to obtain a functional mRNA molecule. The 5' splice sites (donor sites) are denoted by D, and 3' splice sites (acceptor sites) are denoted by A.

Figure 8-57. Abnormal processing of the b-globin primary RNA transcript in humans with b thalassemia. The site of each mutation is denoted by a *black arrowhead.*The *dark blue boxes*represent the three normal exon sequences illustrated previously in Figure 8-51, and the *red lines*join the 5' and 3' splice sites utilized in splicing the primary RNA transcript produced by the gene. The *light blue boxes*depict new nucleotide sequences included in the final mRNA molecule as a result of a mutation. Note that when a mutation leaves a normal splice site without a partner, one or more abnormal "cryptic" splice sites nearby are used as the partner site, as in (C). (After S.H. Orkin, in The Molecular Basis of Blood Diseases [G. Stamatoyanno-poulos et al., eds.], pp. 106-126. Philadelphia: Saunders, 1987.)
Figure 8-58. The two known classes of self-splicing intron sequences. The group I intron sequences bind a free G nucleotide to a specific site to initiate splicing (see Figure3-21), while the group II intron sequences use a specially reactive A nucleotide in the intron sequence itself for the same purpose. The two mechanisms have been drawn in a way that emphasizes their similarities. Both are normally aided by proteins that speed up the reaction, but the catalysis is nevertheless mediated by the RNA in the intron sequence. The mechanism used by group II intron sequences forms a lariat and resembles the pathway catalyzed by the spliceosome (compare to Figure 8-54). (After T.R. Cech, *Cell* 44:207-210, 1986. © Cell Press.)
Figure 8-59. The transport of mRNA molecules through nuclear pores. (A) Schematic illustration of the change in the proteins bound to the RNA molecule as it moves out of the nucleus. (B) Electron micrograph of a large mRNA molecule produced in an insect salivary gland cell; this molecule (*arrow*) has apparently been caught in the process of moving to the cytosol. (B, from B.J. Stevens and H. Swift, *J. Cell Biol.* 31:55-77, 1966, by copyright permission of the Rockefeller University Press.)
Figure 8-60. Possible splicing islands. This immunofluorescence micrograph shows the staining of a human fibroblast nucleus with a monoclonal antibody that detects the snRNP particles involved in nuclear splicing of mRNA precursor molecules. The snRNP particles are present in large aggregates, which could function as "splicing islands." The antibody detects specific proteins that are present in several of the snRNPs that function in the spliceosome. (Courtesy of N. Ringertz.)
Figure 8-61. Transcription from tandemly arranged rRNA genes, as visualized in the electron microscope. The pattern of alternating transcribed gene and nontranscribed spacer is readily seen in the lower-magnification view in the *upper panel*. The large particles at the 5' end of each rRNA transcript (*lower panel*) are believed to reflect the beginning of ribosome assembly; RNA polymerase molecules are also clearly visible as a series of dots along the DNA. (Upper panel, from V.E. Foe, *Cold Spring Harbor Symp. Quant. Biol.* 42:723-740, 1978; lower panel, courtesy of Ulrich Scheer.)
Figure 8-62. The processing of a 45S rRNA precursor molecule into three separate ribosomal RNAs. Nearly half of the nucleotide sequences in the primary RNA transcript are degraded in the nucleus.
Figure 8-63. The nucleolus. This highly schematic view of a nucleolus in a human cell shows the contributions of loops of chromatin containing rRNA genes from 10 separate chromosomes. Purified nucleoli are very useful for biochemical studies of nucleolar function; to obtain such nucleoli, the loops of chromatin are mechanically sheared from their chromosomes, as shown.
Figure 8-64. The function of the nucleolus in ribosome synthesis. The 45S rRNA transcript is packaged in a large

ribonucleoprotein particle containing many ribosomal proteins imported from the cytoplasm. While this particle remains in the nucleolus, selected pieces are discarded as it is processed into immature large and small ribosomal subunits. These two subunits are thought to attain their final functional form only as each is individually transported through the nuclear pores into the cytoplasm.

The Organization and Evolution of the Nuclear Genome

Introduction

Much of evolutionary history is recorded in the genomes of present-day organisms and can be deciphered from a careful analysis of their DNA sequences. Tens of millions of DNA nucleotides have been sequenced thus far, and we can now see in outline how the genes coding for certain proteins have evolved over hundreds of millions of years. Studies of the occasional changes that occur in present-day chromosomes provide additional clues to the mechanisms that have brought about evolutionary change in the past. In this section we consider some of the general principles that have emerged from such molecular genetic studies, with emphasis on the organization and evolution of the nuclear genome in higher eucaryotes.

Genomes Are Fine-tuned by Point Mutation and Radically Remodeled or Enlarged by Genetic Recombination [45]

DNA nucleotide sequences must be accurately replicated and conserved. In Chapter 6 we discussed the elaborate DNA-replication and DNA-repair mechanisms that enable DNA sequences to be inherited with extraordinary fidelity: only about one nucleotide pair in a thousand is randomly changed every 200,000 years. Even so, in a population of 10,000 individuals, every possible nucleotide substitution will have been "tried out" on about 50 occasions in the course of a million years, which is a short span of time in relation to the evolution of species. Much of the variation created in this way will be disadvantageous to the organism and will be selected against in the population. When a rare variant sequence is advantageous, however, it will be rapidly propagated by natural selection. Consequently, it can be expected that in any given species the functions of most genes will have been optimized by random point mutation and selection.

While point mutation is an efficient mechanism for fine-tuning the genome, evolutionary progress in the long term must depend on more radical types of genetic change. Genetic recombination causes major rearrangements of the genome with surprising frequency: the genome can expand or contract by duplication or deletion, and its parts can be transposed from one region to another to create new combinations. Component parts of genes - their individual exons and regulatory elements - can be shuffled as separate modules to create proteins that have entirely new roles. In addition, duplicated copies of genes tend to diverge by further mutation and become specialized and individually optimized for subtly different functions. By these means the genome

as a whole can evolve to become increasingly complex and sophisticated. In a mammal, for example, multiple variant forms of almost every gene exist - different actin genes for the different types of contractile cells, different opsin genes for the perception of lights of different colors, different collagen genes for the different types of connective tissues, and so on. The expression of each gene is regulated according to its own precise and specific rules. Moreover, DNA sequencing studies reveal that many genes share related modular segments but are otherwise very different: common sequence motifs are frequently found in otherwise unrelated proteins.

Genetic recombination, whereby one chromosome exchanges genetic material with another, is fundamental to the creation of such families of genes and gene segments. In Chapter 6 we discussed the molecular mechanisms of both general recombination and site-specific recombination. Here we consider some of their effects on the genome.

Tandemly Repeated DNA Sequences Tend to Remain the Same 46

Gene duplications are usually attributed to rare accidents catalyzed by some of the enzymes that mediate normal recombination processes. Higher eucaryotes, however, contain an efficient enzymatic system that joins the two ends of a broken DNA molecule together, so that duplications (as well as inversions, deletions, and translocations of DNA segments) can also arise as a consequence of the erratic rejoining of fragments of chromosomes that have somehow become broken in more than one place. When duplicated DNA sequences are joined head to tail, they are said to be *tandemly repeated*. Once a single tandem repeat appears, it can be extended readily into a long series of tandem repeats by unequal crossover events between two sister chromosomes, inasmuch as the large amount of matching sequence provides an ideal substrate for general recombination (Figure 8-73). DNA duplication followed by sequential unequal crossing-over underlies *DNA amplification*, a process that often contributes to the formation of cancer by increasing the number of copies of genes (proto-oncogenes) that promote cancer (see Figure 24-27).

Tandemly repeated genes both increase and decrease in number due to unequal crossing-over (see Figure 8-73). They therefore would be expected to be maintained by natural selection in large numbers only if the extra copies were beneficial to the organism. We have already discussed the hundreds of tandemly repeated genes that code for the vertebrate large ribosomal RNA precursor; these are needed to keep up with a growing cell's demand for new ribosomes. Similarly, vertebrates have clusters of tandemly repeated genes that encode other structural RNAs, including 5S rRNA and the U1 and U2 snRNAs, as well as clusters of repeated histone genes, which produce the large amounts of histones required during each S phase.

One might expect that in the course of evolution the sequences of the genes in a tandem array - and of the nontranscribed *spacer* DNA between them - would drift apart. With many copies of the same gene there should be little selection against random mutations that alter one or a few of the copies, and most nucleotide changes in the long nontranscribed spacer regions would have no functional consequence. In fact, however, the sequences of the tandemly repeated genes and their spacer DNAs are generally almost identical. Two mechanisms are thought to account for this. First, recurring unequal crossing-over events will cause the continued expansion and contraction of tandem arrays, and computer simulations show that this will tend to keep the sequences the same (Figure 8-74A). Second, related DNA sequences can become homogenized through *gene conversion*the process whereby a portion of the DNA sequence is changed by copying a closely similar sequence present at a different site in the genome, as described in Chapter 6 (Figure 8-74B). Although gene conversion does not require that the genes be tandemly repeated, in higher eucaryotes it seems to occur mainly between genes that are close to each other.

The movement of one gene copy in a tandem array to a new chromosomal location will protect it from both of the above homogenizing influences. Thus, in higher eucaryotes accidental gene translocation is an important step in the evolution of new genes: it allows the translocated DNA sequence to begin to evolve independently, so that it can acquire new functions that might benefit the organism.

The Evolution of the Globin Gene Family Shows How Random DNA Duplications Contribute to the Evolution of Organisms 47

In addition to generating a number of sets of tandemly repeated genes, DNA duplications have played a more important general role in the evolution of new proteins. The globin gene family provides a good example because its evolutionary history has been worked out particularly well. The unmistakable homologies in amino acid sequence and structure among the present-day globin genes indicate that they all must derive from a common ancestral gene, even though some now occupy widely separated locations in the mammalian genome.

We can reconstruct some of the past events that produced the various types of oxygen-carrying hemoglobin molecules by considering the different forms of the protein in organisms at different levels on the phylogenetic scale. A molecule like hemoglobin was necessary to allow multicellular animals to grow to a large size, since large animals could no longer rely on the simple diffusion of oxygen through the body surface to oxygenate their tissues adequately. Consequently, hemoglobinlike molecules are found in all vertebrates and in many invertebrates. The most primitive oxygen-carrying molecule in animals is a globin polypeptide chain of about 150 amino acids, which is found in many marine worms, insects, and primitive fish. The hemoglobin molecule in higher vertebrates, however, is composed of two kinds of globin chains. It appears that about 500 million years ago, during the evolution of higher fish, a series of gene mutations and duplications occurred. These events established two slightly different globin genes, coding for the a- and b-globin chains in the genome of each individual. In modern higher vertebrates each hemoglobin molecule is a complex of two a chains and two b chains (Figure 8-75). The four oxygen binding sites in the a_2b_2 molecule interact, allowing a cooperative allosteric change in the molecule as it binds and releases oxygen, which enables hemoglobin to take up and to release oxygen more efficiently than the single-chain version.

Still later, during the evolution of mammals, the b-chain gene apparently underwent mutation and duplication to give rise to a second b-like chain that is synthesized specifically in the fetus. The resulting hemoglobin molecule has a higher affinity for oxygen than adult hemoglobin and thus helps in the transfer of oxygen from the mother to the fetus. The gene for the new b-like chain subsequently mutated and duplicated again to produce two new genes, epsilon and g, the epsilon chain being produced earlier in development (to form $a_2epsilon_2$) than the fetal g chain, which forms a_2g_2 (see Figure9-52). A duplication of the adult b-chain gene occurred still later, during primate evolution, to give rise to a d-globin gene and thus to a minor form of hemoglobin (a_2d_2) found only in adult primates (Figure 8-76). Each of these duplicated genes has been modified by point mutations that affect the properties of the final hemoglobin molecule, as well as by changes in regulatory regions that determine the timing and level of expression of the gene.

The end result of the gene duplication processes that have given rise to the diversity of globin chains is seen clearly in the genes that arose from the original b gene, which are arranged as a series of homologous DNA sequences located within 50,000 nucleotide pairs of one another. A similar cluster of a-globin genes is located on a separate human chromosome. Because the a- and b-globin gene clusters are on separate chromosomes in birds and mammals but are together in the frog *Xenopus*, it is believed that a translocation event separated the two genes about 300 million years ago (see Figure 8-76). As previously discussed, such translocations probably help stabilize duplicated genes with distinct functions by protecting them from the homogenizing processes that act on closely linked genes of similar DNA sequence (see Figure 8-74).

There are several duplicated globin DNA sequences in the a- and b-globin gene clusters that are not functional genes. They are examples of *pseudogenes*. These have a close homology to the functio nal genes but have been disabled by mutations that prevent their expression. The existence of such pseudogenes should not be surprising since not every DNA duplication would be expected to lead to a new functional gene. Moreover, nonfunctional DNA sequences are not rapidly discarded, as indicated by the large excess of noncoding DNA in mammalian genomes, discussed previously.

A great deal of our evolutionary history will be discernible in our chromosomes once the DNA sequences of many gene families have been compared in different animals (see also Figure 7-4).

Genes Encoding New Proteins Can Be Created by the Recombination of Exons [45]

The role of DNA duplication in evolution is not confined to the generation of gene families. It can also be important in generating new single genes. The proteins encoded by genes generated in this way can be recognized by the presence of repeating, similar protein domains, which are covalently linked to one another in series. The immunoglobulins (Figure 8-77) and albumins, for example, as well as most fibrous proteins (such as the collagens) are encoded by genes that have evolved by repeated duplications of a primordial DNA sequence.

In genes that have evolved in this way, as well as in many other genes, each separate exon often encodes an individual protein folding unit, or domain. It is believed that the organization of DNA coding sequences as a series of such exons separated by long introns has greatly facilitated the evolution of new proteins. The duplications necessary to form a single gene coding for a protein with repeating domains, for example, can occur by breaking and rejoining the DNA anywhere in the long introns on either side of an exon encoding a useful protein domain; without introns there would be only a few sites in the original gene at which a recombinational exchange between sister DNA molecules could duplicate the domain. By enabling the duplication to occur at many potential recombination sites rather than at just a few, introns increase the probability of a favorable duplication

event.

For the same reason, the presence of introns greatly increases the probability that a chance recombination event will generate a functional hybrid gene by joining two initially separated DNA sequences that code for different protein domains in such a way that both domains are preserved in the new protein that the hybrid gene encodes (see Figure 8-81, for example). The presumed results of such recombinations are seen in many present-day proteins (see Figure3-43). Thus the large separation between the exons encoding individual domains in higher eucaryotes is thought to accelerate the process by which random genetic-recombination events generate useful new proteins. This could help to explain the successful evolution of these very complex organisms.

Most Proteins Probably Originated from Highly Split Genes [48]

The discovery in 1977 of genes split up by introns was unexpected. Previously all genes analyzed in detail were bacterial genes, which lack introns. Bacteria also lack nuclei and internal membranes and have smaller genomes than eucaryotic cells, and traditionally they were considered to resemble the simpler cells from which eucaryotic cells must have been derived. Not surprisingly, most biologists initially assumed that introns were a bizarre and late evolutionary addition to the eucaryotic line. It now seems likely, however, that split genes are the ancient condition and that bacteria lost their introns only after most of their proteins had evolved.

The idea that introns are very old is consistent with current concepts of protein evolution by the trial-and-error recombination of separate exons that encode distinct protein domains. Moreover, evidence for the ancient origin of introns has been obtained by examination of the gene that encodes the ubiquitous enzyme *triosephosphate isomerase*. Triosephosphate isomerase has an essential role in the metabolism of all cells, catalyzing the interconversion of glyceraldehyde-3 phosphate and dihydroxyacetone phosphate - a central step in glycolysis and gluconeogenesis (see Figure 2-21). By comparing the amino acid sequence of this enzyme in various organisms, it is possible to deduce that the enzyme evolved before the divergence of procaryotes and eucaryotes from a common ancestor; the human and bacterial amino acid sequences are 46% identical. The gene encoding the enzyme contains six introns in vertebrates (chickens and humans), and five of these are in precisely the same positions in maize. This implies that these five introns were present in the gene before plants and animals diverged in the eucaryotic lineage, an estimated 10^9 years ago (Figure 8-78).

In general, small unicellular organisms are under a strong selection pressure to reproduce by cell division at the maximum rate permitted by the levels of nutrients in the environment. To do this, they must minimize the amount of unnecessary DNA that they have to synthesize in each cell-division cycle. For larger organisms that live by predation, where size is an advantage, and for multicellular organisms in general, where rates of cell division are constrained by other requirements, there will not be such strong selection pressure to eliminate superfluous DNA from the genome. This argument may help to explain why bacteria should have lost their introns while eucaryotes have retained them. It also helps to explain why the multicellular fungus *Aspergillus* has five introns in its triosephosphate isomerase gene, whereas its unicellular relative, the yeast *Saccharomyces*, has none.

What is the mechanism by which introns are lost? Precise loss of introns would occur only rarely by piecemeal random deletions of short segments of DNA, yet precise and selective loss of introns seems not uncommon in eucaryotic cells (and perhaps was also frequent in the ancestors of bacteria). Whereas most vertebrates contain only a single insulin gene with two intron sequences, rats, for example, contain a second, neighboring insulin gene with only one intron. The second gene apparently arose by gene duplication relatively recently and subsequently lost one of its introns. Because intron loss requires the exact rejoining of DNA coding sequences, the most likely source of the information needed for such an event is an mRNA transcript of the original gene, from which the intron sequences will have been precisely removed. We know that messenger RNAs may be copied back into DNA through the activity of *reverse transcriptases* (see p. 282), and it is thought that recombination enzymes on occasion allow these DNA copies to become paired with the original sequence, which is then "corrected" to an intronless form by a gene-conversion type of event. This pathway of intron loss has been demonstrated in the laboratory using the powerful genetic tools available in the yeast *S. cerevisiae*.

Reverse transcriptases are not needed for the central genetic pathways, but they are produced in cells by specific transposable elements (see Table 8-4) as well as by all retroviruses. The generation of DNA copies of segments of the genome by reverse transcription has contributed in several ways to the evolution of the genomes of higher organisms, as we discuss later.

A Major Fraction of the DNA of Higher Eucaryotes Consists of Repeated, Noncoding Nucleotide Sequences [49]

Eucaryotic genomes contain not only introns but also large numbers of copies of other seemingly nonessential DNA sequences that do not code for protein. The presence of such repeated DNA sequences in higher eucaryotes was first revealed by a hybridization technique that measures the number of gene copies. In this procedure the genome is broken mechanically into short fragments of DNA double helix about 1000 nucleotide pairs long, and the fragments are then de-natured to produce DNA single strands. The speed with which the single-stranded fragments in the mixture reanneal under conditions in which the double-helical conformation is stable depends on how long it takes each fragment to find a complementary fragment to pair with, which in turn depends on the concentration of suitable fragments in the mixture. For the most part, the reaction is very slow. The haploid genome of a mammalian cell, for example, is represented by about 6 million different 1000-nucleotide-long DNA fragments, and any fragment whose sequence is present in only one copy must randomly collide with 6 million noncomplementary strands for every complementary partner strand that it happens to find.

When the DNA from a human cell is analyzed in this way under conditions that require near perfect matching (high stringency conditions, see Figure7-17), about 70% of the DNA strands reanneal as slowly as one would expect for a large collection of unique (nonrepeated) DNA sequences, requiring days for complete annealing. But most of the remaining 30% of the DNA strands anneal much more quickly. These strands contain sequences that are repeated many times in the genome, and they thus collide with a complementary partner relatively rapidly. Most of these highly repeated DNA sequences do not encode proteins, and they are of two types: about one-third are the tandemly repeated *satellite DNAs*, to be discussed next; the rest are *interspersed repeated DNAs*. As we shall see, most of the latter DNAs derive from a few transposable DNA sequences that have multiplied to especially high copy numbers in the human genome.

Satellite DNA Sequences Have No Known Function 50

The most rapidly annealing DNA strands in an experiment of the type just described usually consist of very long tandem series of repetitions of a short nucleotide sequence (Figure 8-79). The repeat unit in a sequence of this type may be composed of only one or two nucleotides, but most repeats are longer, and in mammals they are typically composed of variants of a short sequence organized into a repeat of a few hundred nucleotides. These tandem repeats of a simple sequence are called satellite DNAs because the first DNAs of this type to be discovered had an unusual ratio of nucleotides that made it possible to separate them by density-gradient centrifugation from the bulk of the cell's DNA as a minor component (or "satellite"). Satellite DNA sequences generally are not transcribed and are located most often in the heterochromatin associated with the centromeric regions of chromosomes. In some mammals a single type of satellite DNA sequence constitutes 10% or more of the DNA and may even occupy a whole chromosome arm, so that the cell contains millions of copies of the basic repeated sequence.

Satellite DNA sequences seem to have changed unusually rapidly and even to have shifted their positions on chromosomes in the course of evolution. When two homologous mitotic chromosomes of any human are compared, for example, some of the satellite DNA sequences usually are found arranged in a strikingly different manner on the two chromosomes. Moreover, in contrast to the high degree of conservation of DNA sequences elsewhere in the genome, generally there are marked differences in the satellite DNA sequences of two closely related species. No function has yet been found for satellite DNA sequences: tests designed to demonstrate a role in chromosome pairing or nuclear organization have failed thus far to reveal any evidence for such a role. It has therefore been suggested that they are an extreme form of "selfish DNA" sequences, whose properties ensure their own retention in the genome but which do nothing to help the survival of the cells containing them. Other sequences that are commonly viewed as selfish are the *transposable elements*, which we discuss next.

The Evolution of Genomes Has Been Accelerated by Transposable Elements 51

Genomes generally contain many varieties of transposable elements. These segments of DNA were first discovered in maize, where several have been sequenced and characterized. Eucaryotic transposable elements have been studied most extensively in *Drosophila*, where more than 30 varieties are known, varying in length between 2000 and 10,000 nucleotide pairs; most are present in 5 to 10 copies per diploid cell.

At least three broad classes of transposable elements can be distinguished by the peculiarities of their sequence organization (Table 8-4). Some elements move from place to place within chromosomes directly as DNA, while many others move via an RNA intermediate, as described in Chapter 6. In either case they can multiply and spread from one site in a genome to a multitude of other sites, sometimes behaving as disruptive parasites.

Transposable elements seem to make up at least 10% of higher eucaryotic genomes. Although most of these elements move only

very rarely, there are so many elements that their movement has a major effect on the variability of a species. More than half of the spontaneous mutations examined in *Drosophila*, for example, are due to the insertion of a transposable element in or near the mutant gene.

Mutations can occur either when an element inserts into a gene or when it exits to move elsewhere. All known transposable elements cause a short "target-site duplication" because of their mechanism of insertion (see Figure 6-70); when they exit, they generally leave behind part of this duplication - often with other local sequence changes as well (Figure 8-80). Thus, as transposable elements move in and out of chromosomes, they cause a variety of short additions and deletions of nucleotide sequences.

Transposable elements have also contributed to genome diversity in another way. When two transposable elements that are recognized by the same site-specific recombination enzyme (*transposase*) integrate into neighboring chromosomal sites, the DNA between them can become subject to transposition by the transposase. Because this provides a particularly effective pathway for the duplication and movement of exons (*exon shuffling*), these elements can help to create new genes (Figure 8-81).

Transposable Elements Often Affect Gene Regulation 52

A DNA sequence rearrangement caused by a transposable element is often observed to alter the timing, level, or spatial pattern of expression of a nearby gene without affecting the sequence of the protein or RNA molecule that the gene encodes. This can change a subtle aspect of animal or plant development, such as the shape of an eye or a flower. While most of these changes in gene regulation would be expected to be detrimental to an organism, some of them will bring benefits and therefore tend to spread through the population by natural selection.

Effects on gene regulation are common, partly because the movement of a transposable element will generally bring with it new sequences that act as binding sites for sequence-specific DNA-binding proteins, including a transposase and the proteins that regulate the transcription of the transposable element DNA. These sequences can thereby act as regulatory sequences called enhancers (see p. 422) to affect the transcription of nearby genes. Similar effects commonly contribute to the evolution of cancer cells, where oncogenes can be created by the transposition of such regulatory sequences into the neighborhood of a proto-oncogene, as we discuss in Chapter 24.

The organization of higher eucaryotic genomes, with long noncoding DNA sequences interspersed with comparatively short coding sequences, provides an accommodating "playground" for the integration and excision of mobile DNA sequences. Because gene transcription can be regulated from distances that are tens of thousands of nucleotide pairs away from a promoter, many of the resulting changes in the genome would be expected to affect gene expression; by contrast, relatively few would be expected to disrupt the short exons that contain the coding sequences.

Might the vast excess of noncoding DNA in higher eucaryotes have been favored by selection during evolution because of the regulatory flexibility that it has provided to organisms with a large variety of transposable elements? What is known about the regulatory systems that control higher eucaryotic genes is consistent with this possibility. Enhancers, like exons, seem to function as separate modules, and the activity of a gene depends on a summation of the influences received at its promoter from a set of enhancers (see Figure9-44). Transposable elements, by moving such enhancer modules around in a genome, may allow gene regulation to be optimized for the long-term survival of the organism.

Transposition Bursts Cause Cataclysmic Changes in Genomes and Increase Biological Diversity 53

Another unique feature that distinguishes transposable elements as mutagens is their tendency to undergo long quiescent periods, during which they remain fixed in their chromosomal positions, followed by a period of intense movement. Their transposition, and therefore their mutagenic action, is activated from time to time in a few individuals in a population of organisms. Such cataclysmic changes in genomes, called *transposition bursts*, can involve near simultaneous transpositions of several types of transposable elements. Transposition bursts were first observed in developing maize plants that were subjected to repeated chromosome breakage. They also are observed in crosses between certain strains of flies - a phenomenon known as *hybrid dysgenesis*. When they occur in the germ line, they induce multiple changes in the genome of an individual progeny fly or plant.

By simultaneously changing several properties of an organism, transposition bursts increase the probability that two new traits that are useful together but of no selective value by themselves will appear in a single individual in a population. In several types of plants there is evidence that transposition bursts can be activated by a severe environmental stress, generating a variety of randomly modified progeny organisms, some of which may be better suited than the parent to survive in the new conditions. It seems that, at least in these plants, a mechanism has evolved to activate transposable elements to serve as mutagens that produce an enhanced range of variant organisms when this variation is most needed. Thus transposable elements are not necessarily just disruptive parasites; rather, they may on occasion act as useful symbionts that aid the long-term survival of the species whose genomes they inhabit.

About 10% of the Human Genome Consists of Two Families of Transposable Elements [54]

Primate DNA is unusual in at least one respect: it contains a remarkably large number of copies of two transposable DNA sequences that seem to have overrun our chromosomes. Both of these sequences move by an RNA-mediated process that requires a reverse transcriptase. One is the L1 transposable element, which resembles the F element in *Drosophila* and the Cin4 element in maize and encodes a reverse transcriptase (see Table 8-4, p. 392). Transposable elements have generally evolved with feedback control systems that severely limit their numbers in each cell (thereby saving the cell from potential disaster); the L1 element in humans, however, constitutes about 4% of the mass of the genome.

Even more abundant is the *Alu* sequence, which is very short (about 300 nucleotide pairs) and moves like a transposable element, creating target-site duplications when it inserts. It was derived, however, from an internally deleted host-cell RNA gene (7SL), which encodes the RNA component of the signal-recognition particle (SRP) that functions in protein synthesis (see Figure 12-39); it is therefore not clear whether the *Alu* sequence should be considered a transposable element or an unusually mobile pseudogene. It is present in about 500,000 copies in the haploid genome and constitutes about 5% of human DNA; thus it is present on average about once every 5000 nucleotide pairs. The *Alu* DNA is transcribed from the 7SL RNA promoter, a polymerase-III promoter that is internal to the transcript, so that it carries the information necessary for its own transcription wherever it moves. It needs a reverse transcriptase encoded elsewhere, however, to transpose.

Comparisons of the sequence and locations of the L1- and *Alu*-like sequences in different mammals suggest that these sequences have multiplied to high copy numbers relatively recently (Figure 8-82). It is hard to imagine that these highly abundant sequences scattered throughout our genome have not had major effects on the expression of many nearby genes. How many of our uniquely human qualities, for example, do we owe to these parasitic elements?

Summary

The functional DNA sequences in the genomes of higher eucaryotes appear to be constructed from small genetic modules of at least two kinds. Modules of coding sequence are combined in many ways to produce proteins, whereas modules of regulatory sequences are scattered throughout long stretches of noncoding sequences and regulate the expression of genes. Both the coding sequences and the regulatory sequences are typically present in modules that are less than a few hundred nucleotide pairs long, which together account for only a small proportion of the total DNA.

A variety of genetic-recombination processes occur in genomes, causing the random duplication and translocation of DNA sequences. Some of these changes create duplicates of entire genes, which can then evolve new functions. Others produce new proteins by shuffling exons or alter the expression of old genes by exposing them to new regulatory sequences. This type of DNA sequence shuffling, which is of great importance for the evolution of organisms, is greatly facilitated by the split structure of higher eucaryotic genes and by the fact that these genes are often controlled by distant regulatory sequences.

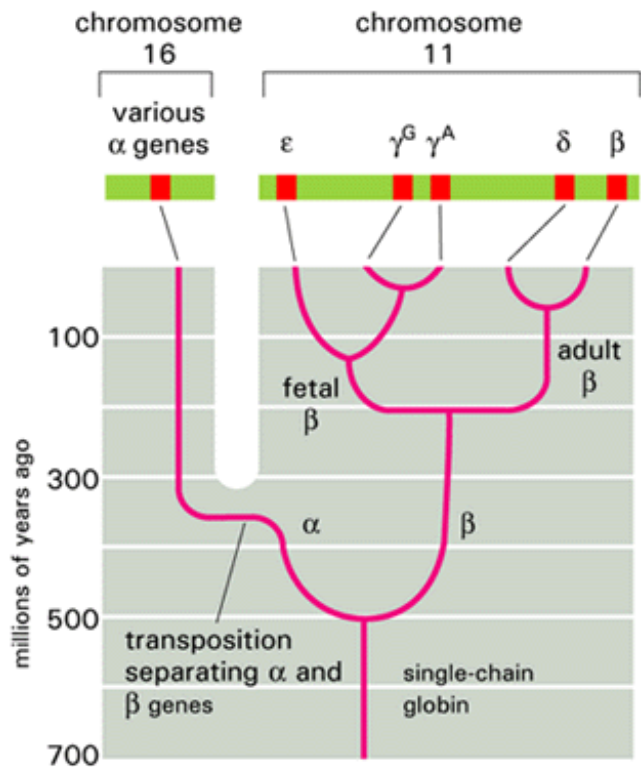
Many types of transposable elements are present in genomes. Collectively, they constitute more than 10% of the mass of bothDrosophila and vertebrate genomes. Occasionally, transposition bursts occur in germ cells and cause many heritable changes in gene expression in the same individual. Transposable elements are thought to have had a special evolutionary role in the generation of organismal diversity.
Figure 8-73. A family of tandemly repeated genes frequently loses and gains gene copies due to unequal crossing-over between sister chromosomes containing the genes. This type of event is frequent because the long regions of homologous DNA sequence are good substrates for the general genetic recombination process (discussed in Chapter 6).
Figure 8-74. Two types of events that help to keep all DNA sequences in a tandem array very similar to one another. (A) The continual expansion and contraction of the number of gene copies in a tandem array caused by unequal crossing-over (see Figure 8-73) tends to homogenize all of the gene sequences in the array. (B) In gene conversion one gene copy acts as a template that passes all or part of its DNA sequence to another gene copy. In higher eucaryotes this process seems to be confined largely to genes that are next to each other on the chromosome; in lower eucaryotes such as fungi, where gene conversion is most readily studied, it is not confined to neighboring genes.
Figure 8-75. A comparison of the structure of one-chain and four-chain globins. The four-chain globin shown is hemoglobin, which is a complex of two a- and two b-globin chains. The one-chain globin in some primitive vertebrates forms a dimer that dissociates when it binds oxygen, representing an intermediate in the evolution of the four-chain globin.


Figure 8-76. An evolutionary scheme for the globin chains that carry oxygen in the blood of animals. The scheme emphasizes the b-like globin gene family. A relatively recent gene duplication of the g-chain gene produced g^G and g ^{A}, which are fetal b-like chains of identical function. The location of the globin genes in the human genome is shown at the top of the figure.
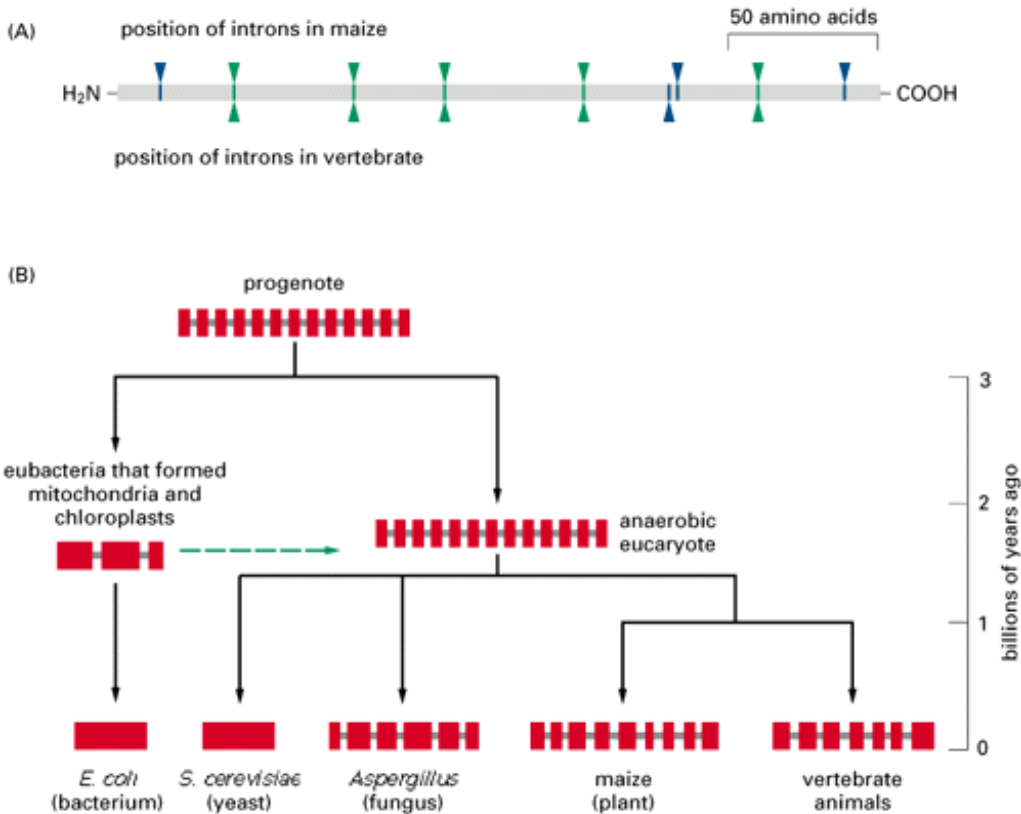
Figure 8-77. Schematic view of an antibody (immunoglobulin) molecule. This molecule is a complex of two identical heavy chains and two identical light chains. Each heavy chain contains four similar, covalently linked domains, while each light chain contains two such domains. Each domain is encoded by a separate exon, and all of the exons are thought to have evolved by the serial duplication of a single ancestral exon.


Figure 8-78. The ancient origin of split genes. (A) A comparison of the exon structure of the *triosephosphate isomerase* gene in plants and animals. The intron positions that are identical in maize (corn) and vertebrates are marked with *green arrowheads,* while the intron positions that differ are marked with *blue arrowheads.* Since plants and animals are thought to have diverged from a common ancestor about a billion years ago, the introns that they share must be of very ancient origin. (B) An outline of how a particular gene may have evolved. The exon sequences are shown in *red* and the intron sequences in *gray.* The gene illustrated here codes for a hypothetical protein that is required in all cells. Like *triosephosphate isomerase*, this protein is assumed to have evolved to its final three-dimensional structure before the eubacterial, archaebacterial, and eucaryotic lineages split off from a common ancestor celldesignated here as a "progenote." The dotted *green* line marks the approximate time of the endosymbiotic events that gave rise to mitochondria and chloroplasts (see pp. 20-21). (A, after W. Gilbert, M. Marchionni, and G. McKnight, *Cell* 46:151-154, 1987. © Cell Press.)

Table 8-4. Three Major Families of Transposable Elements

Structure	Genes in Complete Element	Mode of Movement	Examples
short inverted repeats at each end	encodes transposase	moves as DNA, either excising or following a replicative pathway	P element (*Drosophila*) Ac-Ds (maize) Tn3 and IS1 (*E. coli*) Tam3 (snapdragon)
directly repeated long terminal repeats (LTRs) at ends	encodes reverse transcriptase and resembles retrovirus	moves via an RNA intermediate produced by promoter in LTR	Copia (*Drosophila*) Ty (yeast) THE-1 (human) Bs1 (maize)
Poly A at 3′ end of RNA transcript; 5′ end is often truncated	encodes reverse transcriptase	moves via an RNA intermediate that is presumably produced from a neighboring promotor	F element (*Drosophila*) L1 (human) Cin4 (maize)

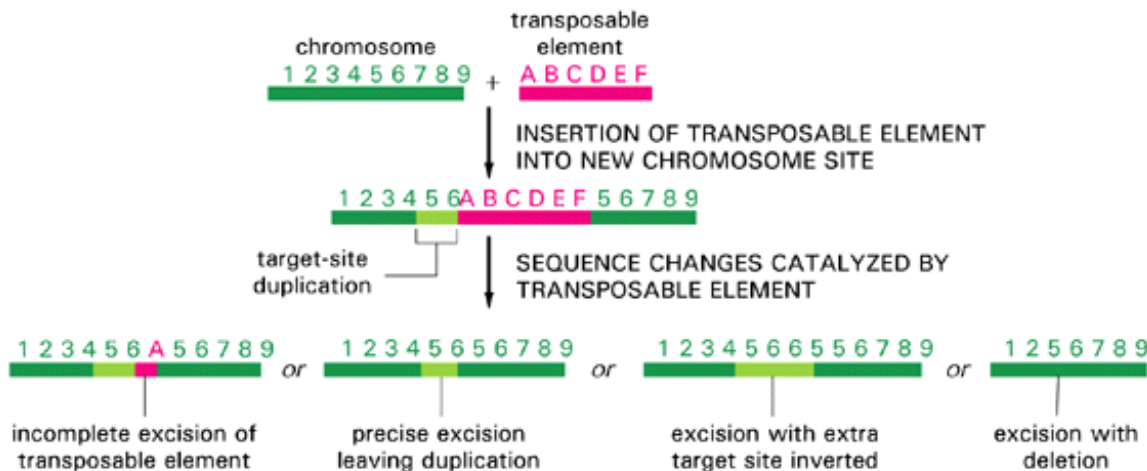
These elements range in length from 2000 to about 12,000 nucleotide pairs; each family contains many members, only a few of which are listed here.
Figure 8-79. Satellite DNA. A simple satellite DNA sequence from *Drosophila* is shown. It consists of many serially arranged repetitions of a sequence seven nucleotide pairs long, and it occurs millions of times in the *Drosophila* haploid genome.


Figure 8-80. Some changes in chromosomal DNA sequences caused by transposable elements. The insertion of a transposable element always produces a short target-site duplication of the chromosomal sequence, which is generally 3 to 12 nucleotide pairs in length depending on the identity of the element. The site-specific recombination enzymes associated with the element can also cause its subsequent excision, which often fails to restore the original chromosomal DNA sequence, as in the four examples shown.
Figure 8-81. An example of the exon shuffling that can be caused by transposable elements. When two elements of the same type (*red* DNA) happen to insert near each other in a chromosome, the transposition mechanism may occasionally use the ends of two different elements (instead of the two ends of the same element) and thereby move the chromosomal DNA between them to a new chromosomal site. Since introns are very large relative to exons, the illustrated insertion of a new exon into a preexisting intron is a frequent outcome.
Figure 8-82. The proposed pattern of evolution of the abundant *Alu* sequence found in the human genome. A related transposable element, *B1*, is found in the mouse genome. Both of these transposable DNA sequences are thought to have evolved from the essential 7SL RNA gene. Based on the species distribution and sequence homology of these highly repeated elements, however, the major expansion in copy numbers seems to have occurred independently in mice and humans. (Adapted from P.L. Deininger and G.R. Daniels, *Trends Gen.* 2:76-80, 1986.)

9. Control of Gene Expression

Introduction

An organism's DNA encodes all of the RNA and protein molecules required to construct its cells. Yet a complete description of the DNA sequence of an organism - be it the few million nucleotides of a bacterium or the few billion nucleotides of a human - would no more enable us to reconstruct the organism than a list of English words would enable us to reconstruct a play by Shakespeare. In both cases the problem is to know how the elements in the DNA sequence or the words on the list are used. Under what conditions is each gene product made, and, once made, what does it do?

In this chapter we discuss the first half of this problem - rules by which a subset of the genes are selectively expressed in each cell. The mechanisms that control the expression of genes operate at a variety of levels, and we discuss the different levels in turn. We begin, however, with an overview of some basic principles of gene control in multicellular organisms.

An Overview of Gene Control

Introduction

The different cell types in a multicellular organism differ dramatically in both structure and function. If we compare a mammalian neuron with a lymphocyte, for example, the differences are so extreme that it is difficult to imagine that the two cells contain the same genome. For this reason, and because cell differentiation is usually irreversible, biologists originally suspected that genes might be selectively lost when a cell differentiates. We now know, however, that cell differentiation generally depends on changes in gene expression rather than on gene loss.

The Different Cell Types of a Multicellular Organism Contain the Same DNA [1]

The cell types in a multicellular organism become different from one another because they synthesize and accumulate different sets of RNA and protein molecules. They generally do this without altering the sequence of their DNA. The best evidence for the preservation of the genome during cell differentiation comes from a classic set of experiments in frogs. When the nucleus of a fully differentiated frog cell is injected into a frog egg whose nucleus has been removed, the injected donor nucleus is capable of programming the recipient egg to produce a normal tadpole. Because the tadpole contains a full range of differentiated cells that derived their DNA sequences from the nucleus of the original donor cell, it follows that the differentiated donor cell cannot have lost any important DNA sequences. A similar conclusion has been reached in experiments done with various plants. Here differentiated pieces of plant tissue are placed in culture and then dissociated into single cells. Often, one of these individual cells can regenerate an entire adult plant (Figure 9-1).

Further evidence that large blocks of DNA are not lost or rearranged during vertebrate development comes from comparing the detailed banding patterns detectable in condensed chromosomes at mitosis (see Figure8-32). By this criterion the chromosome sets of all differentiated cells in the human body appear to be identical. Moreover, comparisons of the genomes of different cells based on recombinant DNA technology have shown, as a general rule, that the changes in gene expression that underlie the development of multicellular organisms are not accompanied by changes in the DNA sequences of the corresponding genes (for an important exception, however, see Figure23-27).

Different Cell Types Synthesize Different Sets of Proteins [2]

As a first step in trying to understand cell differentiation, one would like to know how many differences there are between any one cell type and another. Although we still do not know the answer to this fundamental question, certain general statements can be made.

1. Many processes are common to all cells, and any two cells in a single organism therefore have many proteins in common. These include some abundant proteins that are easy to analyze, such as the major structural proteins of the cytoskeleton and of chromosomes, some of the proteins essential to the endoplasmic reticulum and Golgi membranes, ribosomal proteins, and so on. Many nonabundant proteins, such as various enzymes involved in the central reactions of metabolism, are also the same in all cell types.

2. Some proteins are abundant in the specialized cells in which they function and cannot be detected elsewhere, even by sensitive tests. Hemoglobin, for example, can be detected only in red blood cells.

3. If the 2000 or so most abundant proteins (those present in quantities of 50,000 or more copies per cell) are compared among different cell types of the same organism using two-dimensional polyacrylamide-gel electrophoresis, remarkably few differences are found. Whether the comparison is between two cell lines grown in culture (such as muscle and nerve cells lines) or between cells of two young rodent tissues (such as liver and lung), the great majority of the proteins detected are synthesized in both cell types and at rates that differ by less than a factor of five; only a few percent of the proteins are present in very different amounts in the two cell types.

Studies of the number of different mRNA sequences in a cell suggest that a typical higher eucaryotic cell synthesizes 10,000 to 20,000 different proteins. Most of these are too rare to be detected by two-dimensional gel electrophoresis of cell extracts. If these minor cell proteins differ among cells to the same extent as the more abundant proteins, as is commonly assumed, only a small number of protein differences (perhaps several hundred) suffice to create very large differences in cell morphology and behavior.

A Cell Can Change the Expression of Its Genes in Response to External Signals <u>3</u>

Most of the specialized cells in a multicellular organism are capable of altering their patterns of gene expression in response to extracellular cues. If a liver cell is exposed to a glucocorticoid hormone, for example, the production of several specific proteins is dramatically increased. Glucocorticoids are released during periods of starvation or intense exercise and signal the liver to increase the production of glucose from amino acids and other small molecules; the set of proteins whose production is induced includes enzymes such as tyrosine amino-transferase, which helps to convert tyrosine to glucose. When the hormone is no longer present, the production of these proteins drops to its normal level.

Other cell types respond to glucocorticoids in different ways. In fat cells, for example, the production of tyrosine aminotransferase is reduced, while some other cell types do not respond to glucocorticoids at all. These examples illustrate a general feature of cell specialization - different cell types often respond in different ways to the same extracellular signal. Underlying this specialization are features that do not change, which give each cell type its permanently distinctive character. These features reflect the persistent expression of different sets of genes.

Gene Expression Can Be Regulated at Many of the Steps in the Pathway from DNA to RNA to Protein <u>4</u>

If differences between the various cell types of an organism depend on the particular genes that the cells express, at what level is the control of gene expression exercised? There are many steps in the pathway leading from DNA to protein, and all of them can in principle be regulated. Thus a cell can control the proteins it makes by (1) controlling when and how often a given gene is transcribed (transcriptional control), (2) controlling how the primary RNA transcript is spliced or otherwise processed (RNA processing control), (3) selecting which completed mRNAs in the cell nucleus are exported to the cytoplasm (RNA transport control), (4) selecting which mRNAs in the cytoplasm are translated by ribosomes (translational control), (5) selectively destabilizing certain mRNA molecules in the cytoplasm (mRNA degradation control), or (6) selectively activating, inactivating, or compartmentalizing specific protein molecules after they have been made (protein activity control) (<u>Figure 9-2</u>).

For most genes transcriptional controls are paramount. This makes sense because, of all the possible control points illustrated in <u>Figure9-2</u>, only transcriptional control ensures that no superfluous intermediates are synthesized. In the following sections we discuss the DNA and protein components that regulate the initiation of gene transcription. We return at the end of the chapter to the other ways of regulating gene expression.

Summary

The genome of a cell contains in its DNA sequence the information to make many thousands of different protein and RNA molecules. A cell typically expresses only a fraction of its genes, and the different types of cells in multicellular organisms arise because different sets of genes are expressed. Moreover, cells can change the pattern of genes they express in response to changes in their environment, such as signals from other cells. Although all of the steps involved in expressing a gene can in principle be regulated, for most genes the initiation of RNA transcription is the most important point of control.
Figure 9-1. Regeneration of a whole plant from a single differentiated cell. In many types of plants, differentiated cells retain the ability to "dedifferentiate" so that a single cell can form a clone of progeny cells that can later give rise to an entire plant.
Figure 9-2. Six steps at which eucaryote gene expression can be controlled. Only controls that operate at steps 1 through 5 are discussed in this chapter. The regulation of protein activity (step 6) is discussed in Chapter 5; this includes reversible activation or inactivation by protein phosphorylation as well as irreversible inactivation by proteolytic degradation.

DNA-binding Motifs in Gene Regulatory Proteins 5

Introduction

How does a cell determine which of its thousands of genes to transcribe? As discussed in Chapter 8, the transcription of each gene is controlled by a regulatory region of DNA near the site where transcription begins. Some regulatory regions are simple and act as switches that are thrown by a single signal. Other regulatory regions are complex and act as tiny microprocessors, responding to a variety of signals that they interpret and integrate to switch the neighboring gene on or off. Whether complex or simple, these switching devices consist of two fundamental types of components: (1) short stretches of DNA of defined sequence and (2) *gene regulatory proteins* that recognize and bind to them.

We begin our discussion of gene regulatory proteins by describing how these proteins were discovered.

Gene Regulatory Proteins Were Discovered Using Bacterial Genetics 6

Genetic analyses in bacteria carried out in the 1950s provided the first evidence of the existence of gene regulatory proteins that turn specific sets of genes on or off. One of these regulators, the *lambda repressor,* is encoded by a bacterial virus,

bacteriophage lambda. The repressor shuts off the viral genes that code for the protein components of new virus particles and thereby enables the viral genome to remain a silent passenger in the bacterial chromosome, multiplying with the bacterium when conditions are favorable for bacterial growth (see Figure 6-80). The lambda repressor was among the first gene regulatory proteins to be characterized, and it remains one of the best understood, as we discuss later. Other bacterial regulators respond to nutritional conditions by shutting off genes encoding specific sets of metabolic enzymes when they are not needed. The *lac repressor,* for example, the first of these bacterial proteins to be recognized, turns off the production of the proteins responsible for lactose metabolism when this sugar is absent from the medium.

The first step toward understanding gene regulation was the isolation of mutant strains of bacteria and bacteriophage lambda that were unable to shut off specific sets of genes. It was proposed at the time, and later proved, that most of these mutants were deficient in proteins acting as specific repressors for these sets of genes. Because these proteins, like most gene regulatory proteins, are present in small quantities, it was difficult and time-consuming to isolate them. They were eventually purified by fractionating cell extracts on a series of standard chromatography columns (see pp. 166-169). Once isolated, the proteins were shown to bind to specific DNA sequences close to the genes that they regulate. The precise DNA sequences that they recognized were then determined by a combination of classical genetics, DNA sequencing, and DNA-footprinting experiments (discussed in Chapter 7).

The Outside of the DNA Helix Can Be Read by Proteins 7

As discussed in Chapter 3, the DNA in a chromosome consists of a very long double helix (Figure 9-3). Gene regulatory proteins must recognize specific nucleotide sequences embedded within this structure. It was originally thought that these proteins might require direct access to the hydrogen bonds between base pairs in the interior of the double helix to distinguish between one DNA sequence and another. It is now clear, however, that the outside of the double helix is studded with DNA sequence information that gene regulatory proteins can recognize without having to open the double helix. The edge of each base pair is exposed at the surface of the double helix, presenting a distinctive pattern of hydrogen bond donors, hydrogen bond acceptors, and hydrophobic patches for proteins to recognize in both the major and minor groove (Figure9-4). But only in the major groove are the patterns unique for each of the four base-pair arrangements (Figure 9-5). For this reason gene regulatory proteins generally bind to the major groove, as we shall see.

Although the patterns of hydrogen bond donor and acceptor groups are the most important features recognized by gene regulatory proteins, they are not the only ones: the nucleotide sequence also determines the overall geometry of the double helix.

The Geometry of the DNA Double Helix Depends on the Nucleotide Sequence 8

For 20 years after the discovery of the DNA double helix in 1953, DNA was thought to have the same monotonous structure, with exactly 36° of helical twist between its adjacent nucleotide pairs (10 nucleotide pairs per helical turn) and a uniform helix geometry. This view was based on structural studies of heterogeneous mixtures of DNA molecules, however, and it changed once the three-dimensional structures of short DNA molecules of defined nucleotide sequence were solved by x-ray crystallography and NMR spectroscopy. Whereas the earlier studies provided a picture of an average, idealized DNA molecule, the later studies showed that any given nucleotide sequence had local irregularities, such as tilted nucleotide pairs or a helical twist angle larger or smaller than 36°. These unique features can be recognized by specific DNA-binding proteins.

An especially striking departure from the average structure is seen in the case of nucleotide sequences that cause the DNA double helix to bend. Some sequences (for example, AAAANNN, where N can be any base except A) form a double helix with a pronounced irregularity that causes a slight bend; if this sequence is repeated at 10-nucleotide-pair intervals in a long DNA molecule, the small bends add together so that the DNA molecule appears unusually curved when viewed in the electron microscope (Figure9-6).

A related and equally important variable feature of DNA structure is the extent to which the double helix is deformable. For a protein to recognize and bind to a specific DNA sequence, there must be a tight fit between the DNA and the protein, and often the normal DNA conformation must be distorted to maximize this fit (Figure 9-7). The energetic cost of such distortion depends on the local nucleotide sequence. We encountered an example of this in the discussion of nucleosome assembly in Chapter 8: some DNA sequences can accommodate the tight DNA wrapping required for nucleosome formation better than others. Similarly, a few gene regulatory proteins induce a striking bend in the DNA when they bind to it (Figure 9-8). In general, these proteins recognize DNA sequences that are easily bent.

Short DNA Sequences Are Fundamental Components of Genetic Switches <u>9</u>

We have seen how a specific nucleotide sequence can be detected as a pattern of structural features on the surface of the DNA double helix. Particular nucleotide sequences, each typically less than 20 nucleotide pairs in length, function as fundamental components of genetic switches by serving as recognition sites for the binding of specific gene regulatory proteins. Hundreds of such DNA sequences have been identified, each recognized by a different gene regulatory protein or by a set of related gene regulatory proteins. Some examples of such proteins are listed in <u>Table 9-1</u> along with the DNA sequences that they recognize.

We now turn to the gene regulatory proteins - the second fundamental component of genetic switches - that recognize short, specific DNA sequences contained in a much longer double helix.

Gene Regulatory Proteins Contain Structural Motifs That Can Read DNA Sequences <u>10</u>

Molecular recognition in biology generally relies on an exact fit between the surfaces of two molecules, and the study of gene regulatory proteins has provided some of the clearest examples of this principle. A gene regulatory protein recognizes a specific DNA sequence because the surface of the protein is extensively complementary to the special surface features of the double helix in that region. In most cases the protein makes a large number of contacts with the DNA, involving hydrogen bonds, ionic bonds, and hydrophobic interactions. Although each individual contact is weak, the 20 or so contacts that are typically formed at the protein-DNA interface add together to ensure that the interaction is both highly specific and very strong (<u>Figure 9-9</u>). In fact, DNA-protein interactions are among the tightest and most specific molecular interactions known in biology.

Although each example of protein-DNA recognition is unique in detail, x-ray crystallographic and NMR spectroscopic studies of about 30 gene regulatory proteins complexed with their specific DNA sequence have revealed that many of those proteins contain one of a small set of DNA-binding structural motifs. Each of these motifs uses either a helices or b sheets to bind to the major groove of DNA; this groove, as we have seen, contains sufficient information to distinguish one DNA sequence from any other. The fit is so good that it is tempting to speculate that the dimensions of the basic structural units of nucleic acids and proteins evolved together to permit these molecules to interlock.

The Helix-Turn-Helix Motif Is One of the Simplest and Most Common DNA-binding Motifs <u>11</u>

The first DNA-binding protein motif to be recognized was the helix-turn-helix. Originally identified in bacterial proteins, this motif has since been found in hundreds of DNA-binding proteins from both eucaryotes and procaryotes. It is constructed from two a helices connected by a short extended chain of amino acids, which constitutes the "turn." The two helices are held at a fixed angle, primarily through interactions between the two helices. The more carboxyl-terminal helix is called the *recognition helix* because it fits into the major groove of DNA; its amino acid side chains, which differ from protein to protein, play an important part in recognizing the specific DNA sequence to which the protein binds (<u>Figure 9-10</u>).

Outside the helix-turn-helix region the structure of the various proteins that contain this motif can vary enormously (<u>Figure9-11</u>). Thus each protein "presents" its helix-turn-helix motif to the DNA in a unique way, a feature thought to enhance the versatility of the helix-turn-helix motif by increasing the number of DNA sequences that the motif can be used to recognize. Moreover, in most of these proteins, parts of the polypeptide chain outside the helix-turn-helix domain also make important contacts with the DNA, helping to fine-tune the interaction.

The group of helix-turn-helix proteins shown in <u>Figure 9-11</u>demonstrates a feature that is common to many sequence-specific DNA-binding proteins. They bind as symmetric dimers to DNA sequences that are composed of two very similar "half-sites," which are also arranged symmetrically (<u>Figure 9-12</u>). This arrangement allows each protein monomer to make a nearly identical set of contacts and enormously increases the binding affinity: as a first approximation, doubling the number of contacts doubles the free energy of the interaction but *squares* the affinity constant.

Homeodomain Proteins Are a Special Class of Helix-Turn-Helix Proteins <u>12</u>

Not long after the first gene regulatory proteins were discovered in bacteria, genetic analyses in the fruit fly *Drosophila* led to the characterization of an important class of genes, the *homeotic selector genes,* that play a critical part in orchestrating fly development. As discussed in <u>Chapter 21</u>, they have since proved to have a fundamental role in the development of higher animals as well. Mutations in these genes cause one body part in the fly to be converted into another, showing that the proteins

they encode control developmental switches.

When the nucleotide sequences of several homeotic selector genes were determined in the early 1980s, each proved to contain an almost identical stretch of 60 amino acids that defines this class of proteins and is termed the homeodomain. When the three-dimensional structure of the homeodomain was solved, it was seen to contain a helix-turn-helix motif related to that of the bacterial gene regulatory proteins, providing one of the first indications that the principles of gene regulation established in bacteria are relevant to higher organisms as well. More than 60 homeodomain proteins have now been discovered in *Drosophila* alone, and homeodomain proteins have been identified in virtually all eucaryotic organisms that have been studied, from yeasts to man.

The structure of a homeodomain bound to its specific DNA sequence is shown in Figure 9-13. Whereas the helix-turn-helix motif of bacterial gene regulatory proteins is often embedded in different structural contexts, the helix-turn-helix motif of homeodomains is always surrounded by the same structure (which forms the rest of the homeodomain), suggesting that the motif is always presented to DNA in the same basic manner. Indeed, structural studies show that a yeast homeodomain protein and a *Drosophila* homeodomain protein recognize DNA in almost exactly the same way, although they are identical at only 17 of 60 amino acid positions.

There Are Several Types of DNA-binding Zinc Finger Motifs 13

The helix-turn-helix motif is composed solely of amino acids. A second important group of DNA-binding motifs, by contrast, utilizes one or more molecules of zinc as a structural component. Although all such zinc-coordinated DNA-binding motifs are called zinc fingers, this description refers only to their appearance in schematic drawings dating from their initial discovery (Figure 9-14A). Subsequent structural studies have shown that, in fact, they fall into several groups, only two of which are considered here. The first type was initially discovered in the protein that activates the transcription of a eucaryotic ribosomal RNA. It is a simple structure, consisting of an a helix and a b sheet held together by the zinc (Figure9-14B). This type of zinc finger is often found in a cluster with additional zinc fingers, arranged one after the other so that the a helix of each can contact the major groove of the DNA, forming a nearly continuous stretch of a helix along the groove. In this way a strong and specific DNA-protein interaction is built up through a repeating basic structural unit (Figure9-15). A particular advantage of this motif is that the strength and specificity of the DNA-protein interaction could be adjusted during evolution by changes in the number of zinc finger repeats. By contrast, it is difficult to imagine how any of the other motifs discussed in this section could be formed into repeating chains.

The other type of zinc finger is found in the large family of intracellular receptor proteins (discussed in Chapter 15). It forms a different structure (similar to the procaryotic helix-turn-helix motif) in which two a helices are packed together with two zinc atoms. Like the helix-turn-helix proteins, these proteins form dimers that allow one of the two a helices of each subunit to interact with the major groove of the DNA (Figure 9-16). Although the two types of zinc finger structures are distinct, they share two important features: both use zinc as a structural element, and both use an a helix to recognize the major groove of the DNA.

b Sheets Can Also Recognize DNA 14

In the DNA-binding motifs discussed so far, a helices are used as a primary mechanism to recognize specific DNA sequences. One group of gene regulatory proteins, however, has evolved an entirely different and no less ingenious recognition strategy. In this case the information on the surface of the major groove is read by a two-stranded b sheet, with side chains of the amino acids extending from the sheet toward the DNA as shown in Figure9-17. As in the case of a recognition a helix, this b-sheet motif can be used to recognize many different DNA sequences; the exact DNA sequence recognized depends on the sequence of amino acids that make up the b sheet.

The Leucine Zipper Motif Mediates Both DNA Binding and Protein Dimerization 15

Most gene regulatory proteins recognize DNA as dimers, probably because, as we have seen, this is a simple way of achieving strong specific binding (see Figure 9-12). Usually, the portion of the protein responsible for dimerization is distinct from the portion that is responsible for DNA binding (see Figure9-11). One motif, however, combines these two functions in an elegant and economical way. It is called the leucine zipper motif, so named because of the way the two a helices, one from each monomer, are joined together to form a short coiled-coil (discussed in Chapter 3). The helices are held together by interactions between hydrophobic amino acid side chains (often on leucines) that extend from one side of each helix. Just beyond the

dimerization interface the two a helices separate from each other to form a Y-shaped structure, which allows their side chains to contact the major groove of DNA. The dimer thus grips the double helix like a clothespin on a clothesline (Figure 9-18).

Gene regulatory proteins that contain a leucine zipper motif can form either homodimers, in which the two monomers are identical, or heterodimers, in which the monomers are different. Because heterodimers typically form from two proteins with distinct DNA-binding specificities, the ability of the leucine zipper proteins to form heterodimers greatly expands the repertoire of DNA-binding specificities that these proteins can display. As illustrated in Figure 9-19, for example, three distinct DNA-binding specificities could, in principle, be generated from two types of monomer, while six could be created from three types of monomer, and so on. This is an example of combinatorial control, in which combinations of proteins, rather than individual proteins, control a cellular process. It is one of the most important mechanisms used by eucaryotic cells to control gene expression. As we discuss later, the formation of heterodimeric gene regulatory complexes is only one of several combinatorial mechanisms for controlling gene expression.

There are many types of leucine zipper proteins, and they cannot all form heterodimers with one another. Otherwise the amount of cross-talk between the gene regulatory circuits of a cell would be so great as to cause chaos. Whether or not a particular heterodimer can form depends on how well the hydrophobic surfaces of the two leucine zipper a helices mesh with each other, which, in turn, depends on the exact amino acid sequences of the two zipper regions. Thus each leucine zipper protein in the cell can form dimers with only a small set of other leucine zipper proteins.

The Helix-Loop-Helix Motif Also Mediates Dimerization and DNA Binding 16

Another important DNA-binding motif, related to the leucine zipper, is the helix-loop-helix (HLH) motif, which should not be confused with the *helix-turn-helix* motif discussed earlier. An HLH motif consists of a short a helix connected by a loop to a second, longer a helix. The flexibility of the loop allows one helix to fold back and pack against the other. As shown in Figure 9-20, this two-helix structure binds both to DNA and to the HLH motif of a second HLH protein. As with leucine zipper proteins, the second HLH protein can be the same (resulting in a homodimer) or different (resulting in a heterodimer), and a helices extending from the dimerization interface make specific contacts with DNA.

Several HLH proteins lack the a-helical extension responsible for binding to DNA. These truncated proteins can form heterodimers with full-length HLH proteins, but the heterodimers are unable to bind DNA tightly because they can form only half of the necessary contacts. Thus, in addition to creating active dimers of hybrid DNA specificity, heterodimerization provides a useful control mechanism, enabling a cell to inactivate specific gene regulatory proteins (Figure 9-21).

It Is Not Yet Possible to Predict the DNA Sequence Recognized by a Gene Regulatory Protein 17

The various DNA-binding motifs that we have discussed provide structural frameworks from which specific amino acid side chains extend to contact specific base pairs in the DNA. It is reasonable to ask, therefore, whether there is a simple amino acid–base pair recognition code: is a G-C base pair, for example, always contacted by a particular amino acid side chain? The answer appears to be no. We discussed in Chapter 3 how protein surfaces of virtually any shape and chemistry can be made from just 20 different amino acids, and a gene regulatory protein utilizes different combinations of its side chains to create a surface that is precisely complementary to that of the DNA sequence that it recognizes. It seems, therefore, that the same base pair can be recognized in many ways. Nevertheless, molecular biologists may soon understand protein-DNA recognition well enough to be able to design proteins that will recognize any specified DNA sequence.

A Gel-Mobility Shift Assay Allows Sequence-specific DNA-binding Proteins to Be Detected Readily 18

Genetic analyses, which provided a route to the gene regulatory proteins of bacteria, yeast, and *Drosophila,* are usually not possible in vertebrates. Therefore, the isolation of vertebrate gene regulatory proteins had to await the development of different approaches. Many of these approaches rely on the detection in a cell extract of a DNA-binding protein that specifically recognizes a DNA sequence known to be important in controlling the expression of a particular gene. The most common way to detect sequence-specific DNA-binding proteins is to use a technique that is based on the effect of a bound protein on the migration of DNA molecules in an electric field.

A DNA molecule is highly negatively charged and will therefore move rapidly toward a positive electrode when it is subjected to an electric field. When analyzed by polyacrylamide-gel electrophoresis, DNA molecules are separated according to their size

because smaller molecules are able to penetrate the fine gel meshwork more easily than large ones. Protein molecules bound to a DNA molecule will cause it to move more slowly through the gel; in general, the larger the bound protein, the greater the retardation of the DNA molecule. This phenomenon provides the basis for the *gel-mobility shift assay,* which allows even trace amounts of a sequence-specific DNA-binding protein to be readily detected. In this assay a short DNA fragment of specific length and sequence (produced either by DNA cloning or by chemical synthesis) is radioactively labeled and mixed with a cell extract; the mixture is then loaded onto a polyacrylamide gel and subjected to electrophoresis. If the DNA fragment corresponds to a chromosomal region where, for example, several sequence-specific proteins bind, autoradiography will reveal a series of DNA bands, each retarded to a different extent and representing a distinct DNA-protein complex. The proteins responsible for each band on the gel can then be separated from one another by subsequent fractionations of the cell extract (Figure9-22).

DNA Affinity Chromatography Facilitates the Purification of Sequence-specific DNA-binding Proteins [19]

A particularly powerful purification method called DNA affinity chromatography can be used once the DNA sequence that a gene regulatory protein recognizes has been determined. A double-stranded oligonucleotide of the correct sequence is synthesized by chemical methods and linked to an insoluble porous matrix such as agarose; the matrix with the oligonucleotide attached is then used to construct a column that selectively binds proteins that recognize the particular DNA sequence (Figure 9-23). Purifications as great as 10,000-fold can be achieved by this means with relatively little effort.

Although most proteins that bind to a specific DNA sequence are present in a few thousand copies per higher eucaryotic cell (and generally represent only about one part in 50,000 of the total cell protein), enough pure protein can usually be isolated by affinity chromatography to obtain a partial amino acid sequence. This sequence can then be used to synthesize an oligonucleotide probe that can in turn be used to identify the corresponding cDNA clone because it will specifically hybridize with the sequence that codes for the protein (discussed in Chapter 7). The clone provides the complete amino acid sequence of the protein as well as the means to produce the protein in unlimited amounts.

In some cases a second method, which can be even more powerful than DNA affinity chromatography, can be used more directly to obtain a cDNA clone that encodes a sequence-specific DNA-binding protein. This method begins with a cDNA library cloned in an appropriately designed expression vector (discussed in Chapter 7). An individual colony of bacteria (if the expression vector is a plasmid) or bacteriophage plaque (if the expression vector is a virus) will produce large amounts of the protein that is encoded by the cDNA it contains. To find the rare colony that produces the protein of interest, an oligonucleotide containing the desired protein's recognition sequence is radioactively labeled and used to probe paper-blot replicas of the culture that carry aliquots of thousands of individual colonies (see Figure 7-26). Those few colonies that produce proteins that specifically bind the radiolabeled oligonucleotide are selectively grown and tested further to find the one that produces the desired protein.

Because these powerful methods have only recently been developed, only a fraction of the many thousands of sequence-specific DNA-binding proteins thought to be present in higher eucaryotic cells have been isolated so far.

Summary

Gene regulatory proteins recognize short stretches of double-helical DNA of defined sequence and thereby determine which of the thousands of genes in a cell will be transcribed. Hundreds of gene regulatory proteins have been identified in a wide variety of organisms. Although each of these proteins has unique features, most bind to DNA as homodimers or heterodimers and recognize DNA through one of a small number of structural motifs, including the helix-turn-helix motif, the homeodomain motif, zinc finger motifs, the leucine zipper motif, and the helix-loop-helix motif. The precise amino acid sequence that is folded into the motif determines the particular DNA sequence that is recognized. Several powerful techniques are available that make use of the DNA-sequence specificity of gene regulatory proteins to identify and isolate these proteins and the genes that encode them.
Figure 9-3. Double-helical structure of DNA. The major and minor grooves on the outside of the double helix are indicated. The atoms are colored as follows: carbon, *dark blue;* nitrogen, *light blue;* hydrogen, *white;* oxygen, *red;* phosphorus, *yellow.*
Figure 9-4. How the different base pairs in DNA can be recognized from their edges without the need to open the double helix. The four possible configurations of base pairs are shown, with hydrogen bond donors indicated in *blue,* hydrogen bond acceptors in *red,* and hydrogen bonds themselves as a series of short parallel *red*lines. Methyl groups, which form hydrophobic protuberances, are shown in *yellow,* and hydrogen atoms that are attached to carbons, and are therefore unavailable for hydrogen bonding, are *white.*

Figure 9-6. Electron micrograph of fragments of a highly bent segment of DNA double helix. The DNA fragments are derived from the small, circular mitochondrial DNA molecules of a trypanosome. Although the fragments are only about 200 nucleotide pairs long, many of them have bent to form a complete circle. On average, a normal DNA helix of this length would bend only enough to produce one-fourth of a circle (one smooth right-angle turn). (From J. Griffith, M. Bleyman, C.A. Raugh, P. A. Kitchin, and P.T. Englund, *Cell* 46:717-724, 1986. © Cell Press.)

	GATA-1	TGATAG ACTATC

*. Each protein in this table can recognize a set of closely related DNA sequences; for convenience, only one recognition sequence is given for each protein.

Figure 9-9. The binding of a gene regulatory protein to the major groove of DNA. Only a single type of contact is shown. Typically, the protein-DNA interface would consist of 10 to 20 such contacts, involving different amino acids, each contributing to the binding energy of the protein-DNA interaction.

Figure 9-10. The DNA-binding helix-turn-helix motif. The motif is shown in (A), where each *white* circle denotes the central carbon of an amino acid. The carboxyl-terminal a helix (*red*) is called the recognition helix because it participates in sequence-specific recognition of DNA. As shown in (B), this helix fits into the major groove of DNA, where it contacts the edges of the base pairs (see also Figure 9-4).

Figure 9-11. Some helix-turn-helix DNA-binding proteins. All of the proteins bind DNA as dimers in which the two copies of the recognition helix (*red cylinder*) are separated by exactly one turn of the DNA helix (3.4 nm). The second helix of the helix-turn-helix motif is colored *blue*, as in Figure 9-10. The lambda repressor and cro proteins control bacteriophage lambda gene expression, and the tryptophan repressor and the catabolite activator protein (CAP) control the expression of sets of *E. coli* genes.

Figure 9-12. A specific DNA sequence recognized by the bacteriophage lambda cro protein. The nucleotides labeled in *green* in this sequence are arranged symmetrically, allowing each half of the DNA site to be recognized in the same way by each protein monomer, also shown in *green*.
Figure 9-13. A homeodomain bound to its specific DNA sequence. The homeodomain is folded into three a helices, which are packed tightly together by hydrophobic interactions (A). The part containing helix 2 and 3 closely resembles the helix-turn-helix motif, with the recognition helix (*red*) making important contacts with the major groove (B). The Asn of helix 3, for example, contacts an adenine, as shown in Figure9-9. Nucleotide pairs are also contacted in the minor groove by a flexible arm attached to helix 1. The homeodomain shown here is from a yeast gene regulatory protein, but it is nearly identical to two homeodomains from *Drosophila*, which interact with DNA in a similar fashion. (Adapted from C. Wolberger et al., *Cell* 67:517-
Figure 9-14. One type of zinc finger protein. This protein belongs to the Cys-Cys-His-His family of zinc finger proteins, named after the amino acids that grasp the zinc. This zinc finger is from a frog protein of unknown function. (A) Schematic drawing of the amino acid sequence of the zinc finger. (B) The three-dimensional structure of the zinc finger is constructed from an antiparallel b sheet (amino acids 1 to 10) followed by an a helix (amino acids 12 to 24). The four amino acids that bind the zinc (Cys 3, Cys 6, His 19, and His 23) hold one end of the a helix firmly to one end of the b sheet. (Adapted from M.S. Lee et al., *Science* 245:635-637, 1989. © 1989 the AAAS.)
Figure 9-15. DNA binding by a zinc finger protein. (A) The structure of a fragment of a mouse gene regulatory protein bound to a specific DNA site. This protein recognizes DNA using three zinc fingers of the Cys-Cys-His-His type (see Figure9-14) arranged as direct repeats. (B) The three fingers have similar amino acid sequences and contact the DNA in similar ways. In both (A) and (B) the zinc atom in each finger is represented by a small sphere. (Adapted from N. Pavletich and C. Pabo, *Science*252:810-817, 1991. © 1991 the AAAS.)

Figure 9-16. A zinc finger protein of the intracellular receptor family bound to its specific DNA sequence. This is an example of a Cys-Cys-Cys-Cys zinc finger protein, named after the amino acids that bind the zinc. A dimer of the DNA-binding domain (*red*) is shown, with all side chains omitted except those shown in *yellow,* which form contacts with the DNA (*green*). (Adapted from B.F. Luisi et al., *Nature* 352:497-505, 1991. ©| photo-graph courtesy of Jay Thomas.)

Figure 9-17. The bacterial *met* repressor protein. The bacterial *met* repressor regulates the genes encoding the enzymes that catalyze methionine synthesis. When this amino acid is abundant, it binds to the repressor, causing a change in the structure of the protein that enables it to bind to DNA tightly, shutting off the synthesis of the enzymes. (A) In order to bind to DNA tightly, the *met* repressor must be complexed with S-adenosyl methionine, shown in *red*. One subunit of the dimeric protein is shown in *green*, while the other is shown in *blue*. The two-stranded b sheet that binds to DNA is formed by one strand from each subunit and is shown in *dark green* and *dark blue*. (B) Simplified diagram of the *met* repressor bound to DNA, to show how the two-stranded b sheet of the repressor binds to the major groove of DNA. For clarity, the other regions of the repressor are omitted. (A, adapted from S. Phillips, *Curr. Opin. Struct. Biol.* 1:89-98, 1991. © Current Sciences; B, adapted from W. Somers and S. Phillips, *Nature* 359:387-393, 1992. © 1992 Macmillan Magazines Ltd.)

Figure 9-18. A leucine zipper dimer bound to DNA. Two a-helical DNA-binding domains (*bottom*) dimerize through their a-helical leucine zipper region (*top*) to form an inverted Y-shaped structure. Each arm of the Y is formed by a single a helix, one from each monomer, that mediates binding to a specific DNA sequence in the major groove of DNA. Each a helix binds to one-half of a symmetric DNA structure. (Adapted from T.E. Ellenberger et al., *Cell* 71:1223-1237, 1992. © Cell Press.)
Figure 9-19. Heterodimerization of leucine zipper proteins can alter their DNA-binding specificity. Leucine zipper homodimers bind to symmetric DNA sequences, as shown in the left-hand and center drawings. These two proteins recognize different DNA sequences, as indicated by the *red* and *blue* regions in the DNA. The two different monomers can combine to form a heterodimer, which now recognizes a hybrid DNA sequence, composed from one *red* and one *blue* region.

Permission to reproduce this figure in this web version of *Molecular Biology of the Cell* is either pending or has not been granted.

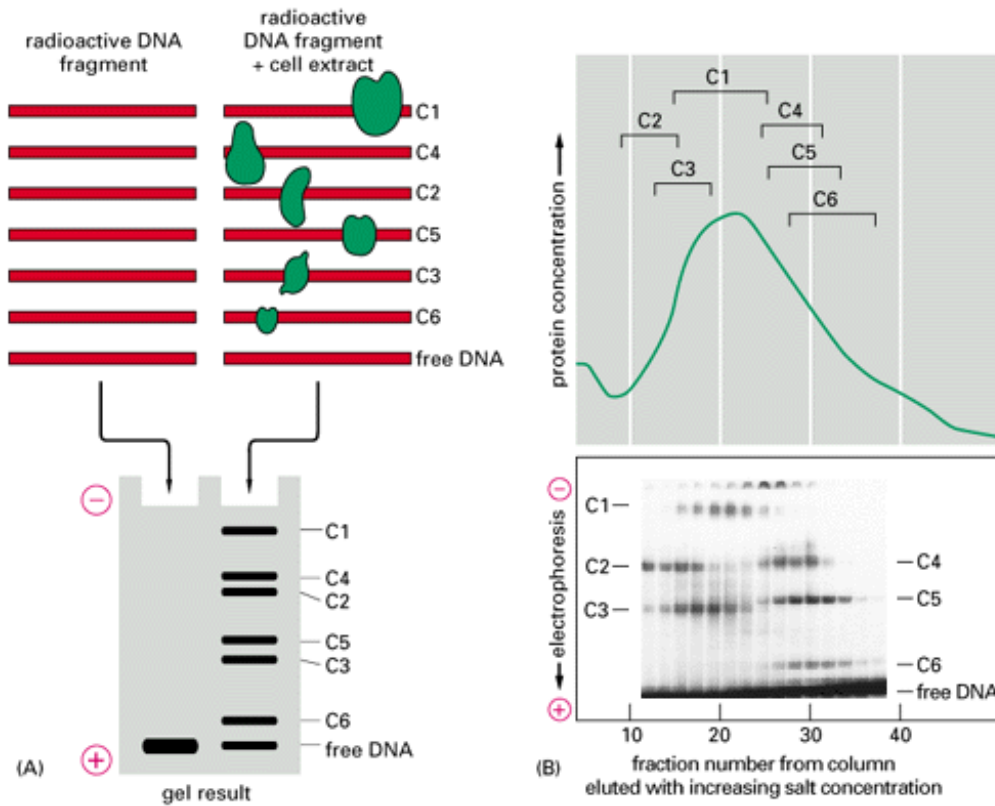
Figure 9-20. A helix-loop-helix dimer bound to DNA. The two monomers are held together in a four-helix bundle: each monomer contributes two a helices connected by a flexible loop of protein (*red*). A specific DNA sequence is bound by the two a helices that project from the four-helix bundle. (Adapted from Ferre-D'Amare et al., *Nature* 363:38-45, 1993. © 1993 Macmillan Magazines Ltd.)
Figure 9-21. Inhibitory regulation by truncated HLH proteins. The HLH motif is responsible for both dimerization and DNA binding. On the left, an HLH homodimer recognizes a symmetric DNA sequence. On the right, the binding of a full-length HLH protein to a truncated HLH protein that lacks the DNA-binding a helix generates a heterodimer that is unable to bind DNA tightly. If present in excess, the truncated protein molecule blocks the homodimerization of the full-length HLH protein and thereby prevents it from binding to DNA.


Figure 9-22. A gel-mobility shift assay. The principle of the assay is shown schematically in (A). In this example an extract of an antibody-producing cell line is mixed with a radioactive DNA fragment containing about 160 nucleotides of a regulatory DNA sequence from a gene encoding the light chain of the antibody made by the cell line. The effect of the proteins in the extract on the mobility of the DNA fragment is analyzed by polyacrylamide-gel electrophoresis followed by autoradiography. The free DNA fragments run rapidly to the bottom of the gel, while those fragments bound to proteins are retarded; the finding of six retarded bands suggests that the extract contains six different sequence-specific DNA-binding proteins (indicated as C1-C6) that bind to this DNA sequence. (For simplicity, any DNA fragments with more than one protein bound have been omitted from the figure.) In (B) the extract was fractionated by a standard chromato-graphic technique (*top*), and each fraction was mixed with the radio-active DNA fragment, applied to one lane of a polyacrylamide gel, and analyzed as in (A). (B, modified from C. Scheidereit, A. Heguy, and R.G. Roeder, *Cell* 51:783-793, 1987. © Cell Press.)
Figure 9-23. DNA affinity chromatography. In the first step all the proteins that can bind DNA are separated from the remainder of the cellular proteins on a column containing a huge number of different DNA sequences. Most sequence-specific DNA-binding proteins have a weak (nonspecific) affinity for bulk DNA and are therefore retained on the column. This affinity is due largely to ionic attractions, and the proteins can be washed off the DNA by a solution that contains a moderate concentration of salt. In the second step the mixture of DNA-binding proteins is passed through a column that contains only DNA of a particular sequence. Typically, all the DNA-binding proteins will stick to the column, the great majority by nonspecific interactions. These are again eluted by solutions of moderate salt concentration, leaving on the column only those proteins (typically one or only a few) that bind specifically and therefore very tightly to the particular DNA sequence. These remaining proteins can be eluted from the column by solutions containing a very high concentration of salt.

How Genetic Switches Work [20]

Introduction

In the previous section we described the basic components of genetic switches - gene regulatory proteins and the specific DNA sequences that these proteins recognize. In this section we discuss how these components operate to turn genes on and off in response to a variety of signals.

Only 40 years ago the idea that genes could be switched on and off was revolutionary. This concept was a major advance, and it came originally from the study of how bacteria adapt to changes in the composition of their growth medium. Parallel studies on the lambda bacteriophage led to many of the same conclusions and helped to establish the basis of our understanding of how gene expression is regulated. The same principles apply to eucaryotic cells, although the enormous complexity of gene regulation in higher organisms, combined with the complication that the DNA in these organisms is packaged into chromatin, creates special challenges and some novel opportunities for control, as we shall see. We begin, however, with the simplest example - an on-off switch in bacteria that responds to a single signal.

The Tryptophan Repressor Is a Simple Switch That Turns Genes On and Off in Bacteria [21]

The chromosome of the bacterium *E. coli,* a single-celled organism, consists of a single circular DNA molecule of about 5×10^6 nucleotide pairs. This DNA is, in principle, sufficient to encode about 4000 proteins, although only a fraction of these are made

at any one time. *E. coli* regulates the expression of many of its genes according to the food sources that are available in the environment. Five *E. coli* genes code for enzymes that manufacture the amino acid tryptophan, and these are arranged in a cluster on the chromosome and are transcribed from a single *promoter* as one long mRNA molecule (Figure9-24). As described in Chapter 6, the promoter is the specific DNA sequence that directs RNA polymerase to bind to DNA, to open the DNA double helix, and to begin synthesizing an RNA molecule. When, however, tryptophan is present in the growth medium and enters the cell (when the bacterium is in the gut of a mammal that has just eaten a meal of protein, for example), these enzymes are no longer needed and their production is shut off.

We now understand the molecular basis for this switch in considerable detail. Within the promoter that directs transcription of the tryptophan biosynthetic genes lies an operator. This operator is simply a short region of regulatory DNA of defined nucleotide sequence that is recognized by a helix-turn-helix gene regulatory protein called the tryptophan repressor (see Figure9-11). The promoter and operator are arranged so that occupancy of the operator by the tryptophan repressor blocks access to the promoter by RNA polymerase, thereby preventing expression of the tryptophan-producing enzymes (Figure9-25). This block is regulated in an ingenious way: the repressor protein can bind to its operator DNA only if the repressor has also bound two molecules of the amino acid tryptophan. As shown in Figure 9-26, tryptophan binding tilts the helix-turn-helix motif of the repressor so that it is presented properly to the DNA major groove; without tryptophan, the motif swings inward and the protein is unable to bind to the operator. Thus the tryptophan repressor is a simple device that switches production of the tryptophan biosynthetic enzymes on and off according to the availability of free tryptophan. Because the active, DNA-binding form of the protein serves to turn genes *off,* this mode of gene regulation is called negative control, and the gene regulatory proteins that function in this way are called *transcriptional repressors* or *gene repressor proteins.*

Transcriptional Activators Turn Genes On 22

We saw in Chapter 6 that purified *E. coli* RNA polymerase can bind to a promoter and initiate DNA transcription. Some bacterial promoters, however, are only marginally functional on their own, either because they are recognized poorly by RNA polymerase or because the polymerase has difficulty opening the DNA helix as it starts transcription. In either case these poorly functioning promoters can be rescued by gene regulatory proteins that bind to a nearby site on the DNA, contacting the RNA polymerase in a way that dramatically increases the probability that a transcript will be initiated. Because the active, DNA-binding form of such a protein turns genes *on,* this mode of gene regulation is called positive control, and the gene regulatory proteins that function in this manner are known as *transcriptional activators* or *gene activator proteins.*

As in negative control by a transcriptional repressor, a transcriptional activator can operate as a simple on-off genetic switch. The bacterial activator protein *CAP (catabolite activator protein),* for example, activates genes that enable *E. coli* to use alternative carbon sources when glucose, its preferred carbon source, is not available. Falling levels of glucose induce an increase in the intracellular signaling molecule cyclic AMP, which binds to the CAP protein, enabling it to bind to its specific DNA sequence near target promoters and thereby turn on the appropriate genes. In this way the expression of a target gene is switched on or off, depending on whether cyclic AMP levels in the cell are high or low, respectively. A summary of the different ways that positive and negative control can be used to regulate genes is shown in Figure9-27.

In many respects transcriptional activators and transcriptional repressors are similar in design. The tryptophan repressor and the transcriptional activator CAP, for example, both use a helix-turn-helix motif and both require a small cofactor in order to bind DNA. In fact, some bacterial proteins (including CAP and the bacteriophage lambda repressor) are known to act as either activators or repressors, depending on the exact placement of the DNA sequence they recognize with respect to the promoter: if the binding site for the protein overlaps the promoter, the polymerase cannot bind and the protein acts as a repressor (Figure 9-28).

A Transcriptional Activator and a Transcriptional Repressor Control the *lac* Operon 23

More complicated types of genetic switches can be constructed by combining positive and negative controls. The *lac operon* in *E. coli,* for example, unlike the *trp* operon, is under both negative and positive transcriptional controls by the lac repressor protein and CAP, respectively. The *lac* operon codes for proteins required to transport the disaccharide lactose into the cell and to break it down. CAP, as we have seen, enables bacteria to use alternative carbon sources such as lactose in the absence of glucose. It would be wasteful, however, for CAP to induce expression of the *lac* operon if lactose is not present, and the lac repressor ensures that the *lac* operon is shut off in the absence of lactose. This arrangement enables the *lac* operon to respond to and integrate two different signals, so that it is expressed only when two conditions are met: lactose must be present and glucose must be absent. Any of the other three possible signal combinations maintain the gene in the off state (Figure9-29).

The simple logic of this genetic switch first attracted the attention of biologists over 50 years ago. As explained above, the molecular basis of the switch was uncovered by a combination of genetics and biochemistry, providing the first insight into how gene expression is controlled. Although the same basic strategies are used to control gene expression in higher organisms, the genetic switches that are used are much more complex.

Regulation of Transcription in Eucaryotic Cells Is Complex 24

The two-signal switching mechanism that regulates the *lac* operon is elegant and simple. However, it is difficult to imagine how additional complexity could be added so that a much larger number of signals could regulate transcription from the operon: one would quickly run out of room to insert new regulatory DNA sequences. How have eucaryotes overcome these limitations to create more complex genetic switches?

The regulation of transcription in eucaryotes differs in two important ways from that typically found in bacteria. First, eucaryotic RNA polymerases cannot initiate transcription on their own. They require a set of proteins called *general transcription factors,* which must be assembled at the promoter before transcription can begin. This assembly process provides multiple steps at which the rate of transcription initiation can be speeded up or slowed down in response to regulatory signals, and many eucaryotic gene regulatory proteins operate by influencing these steps. Second, most gene regulatory proteins in eucaryotes can act even when they are bound to DNA thousands of nucleotide pairs away from the promoter that they influence, which means that a single promoter can be controlled by an almost unlimited number of regulatory sequences scattered along the DNA. We consider these two features of eucaryotic gene regulation in turn.

Eucaryotic RNA Polymerase Requires General Transcription Factors 25

The initial finding that purified eucaryotic RNA polymerase enzymes could not initiate transcription *in vitro* led to the discovery and purification of additional proteins, the general transcription factors, required for this process. These proteins were not simply missing subunits of the polymerase; they had to assemble into a complex on the DNA at the promoter in order to recruit the RNA polymerase to this site.

Figure 9-30shows how the general transcription factors are thought to assemble at promoters utilized by *RNA polymerase II (Pol II),* the polymerase that transcribes the vast majority of eucaryotic genes. The assembly process starts with the binding of TFIID to the *TATA sequence,* a short double-helical DNA sequence primarily composed of T and A nucleotides. The TATA sequence is a component of nearly all promoters utilized by Pol II and is typically located 25 nucleotides upstream from the transcription start site. TFIID is composed of many subunits; that responsible for recognizing the TATA sequence is called TBP (TATA-binding protein) (Figure 9-31). Once TFIID is bound to this DNA site, the other general transcription factors, along with RNA Pol II, are added in turn.

After Pol II has been tethered to the promoter, it must be released from the complex of general transcription factors to begin transcription. A key step in the initiation of transcription is carried out by TFIIH, one subunit of which is a protein kinase that phosphorylates Pol II. For at least some promoters, this phosphorylation is thought to disengage the polymerase and allow transcription to begin.

The other two RNA polymerases found in eucaryotes, RNA polymerase I (Pol I) and RNA polymerase III (Pol III), also require a set of general transcription factors. Although TBP is required for all three polymerases, the other factors are different from those that assemble at Pol II promoters, and the binding of TBP at Pol I and Pol III promoters does not depend on a TATA sequence in the DNA.

Enhancers Control Genes at a Distance 26

It was surprising to many biologists when, in 1979, it was discovered that DNA sequences thousands of nucleotide pairs away from a eucaryotic promoter could activate transcription from the promoter. It is now known that such enhancer sequences serve as specific binding sites for gene regulatory proteins that activate or *enhance* transcription and that this sort of "action-at-a-distance" is the rule rather than the exception for gene regulatory proteins in eucaryotic cells. This phenomenon also occurs, although less commonly, in procaryotes. How do such proteins function over these long distances? Many models have been proposed, but it seems that the simplest of these is correct. The DNA between the enhancer and the promoter loops out to allow the proteins bound to the enhancer to interact directly either with one of the general transcription factors or with RNA

polymerase itself (Figure 9-32). The DNA thus acts as a tether, causing a protein bound to an enhancer even thousands of nucleotide pairs away to collide repeatedly with proteins bound to the promoter. This is the same effect as would be obtained by increasing the protein's local concentration at the promoter (Figure 9-33).

A Eucaryotic Gene Control Region Consists of a Promoter Plus Regulatory DNA Sequences 27

Because eucaryotic gene regulatory proteins can control transcription when bound to DNA far away from the promoter, the DNA sequences that control the expression of a gene can be spread over long stretches of DNA. Here we use the term gene control region to refer to the DNA sequences required to initiate gene transcription plus those required to regulate the rate at which initiation occurs. Thus a eucaryotic gene control region consists of the promoter, where the general transcription factors and the polymerase assemble, plus all of the regulatory sequences to which gene regulatory proteins bind to control the rate of these assembly processes at the promoter (Figure9-34).

In higher eucaryotes it is not unusual to find the regulatory sequences of a gene dotted over distances as great as 50,000 nucleotide pairs, although much of this DNA serves as "spacer" sequence and is not recognized by gene regulatory proteins. In this chapter we use the term gene to refer only to the DNA that is transcribed into RNA (see Figure9-34), although the classical view of a gene would include the gene control region as well. The different definitions arise from the different ways in which genes were historically identified, and modern discoveries have complicated even the narrowly defined sense of the word - a point we return to later in this chapter.

Although most gene regulatory proteins bind to enhancer sequences and activate gene transcription, some function as negative regulators, as we see below. In contrast to the small number of general transcription factors, which are abundant proteins and assemble on the promoters of all genes transcribed by Pol II, there are thousands of different gene regulatory proteins. These vary from gene to gene, and each is usually present in very small amounts in a cell. Most of them recognize their specific DNA sequences using one of the DNA-binding motifs discussed previously. These proteins allow individual genes of an organism to be turned on or off specifically. In a higher eucaryote different selections of gene regulatory proteins are present in different cell types.

Many Gene Activator Proteins Accelerate the Assembly of General Transcription Factors 28

Most gene regulatory proteins that activate gene transcription - that is, most gene activator proteins - have a modular design consisting of at least two distinct domains. One domain usually contains one of the structural motifs discussed previously that recognizes a specific regulatory DNA sequence. In the simplest cases another domain contacts the transcription machinery and accelerates the rate of transcription initiation. This type of modular design was first revealed by experiments in which genetic engineering techniques were used to create a hybrid protein containing the *activation domain* of one protein fused to the *DNA-binding domain* of a different protein (Figure 9-35).

In one class of gene activator proteins the activation domain contains a cluster of negatively charged (acidic) amino acids on its surface. These *acidic activators* work by accelerating the assembly of the general transcription factors at the promoter. In principle, any one of the assembly steps shown in Figure9-30 could be the rate-limiting step of transcription initiation. At some promoters it is the entry of TFIIB into the complex that appears to be the limiting step, and acidic activators are thought to overcome this block by helping TFIIB assemble into the complex (Figure 9-36). Other activator proteins seem to work by loading TFIID onto the DNA, whereas yet others may activate transcription by a different mechanism.

In principle, the protein assembly process at a promoter could have more than one slow step, and a maximal level of transcription could be dependent on several gene activator proteins bound upstream, each speeding up a different step. It is not difficult to see how multiple gene regulatory proteins, each binding to a different regulatory sequence, could control the transcription of a eucaryotic gene. But whatever its precise mechanism of action, a gene regulatory protein must be bound to DNA, either directly or indirectly, to influence transcription of its target promoter.

Gene Repressor Proteins Can Inhibit Transcription in Various Ways 29

Eucaryotic gene activator proteins work in a way that is similar in principle to that described earlier for bacterial gene activators: they catalyze polymerase action by contacting the transcription machinery. Not all eucaryotic gene regulatory proteins activate transcription, however. As mentioned previously, many act as gene repressor proteins to suppress transcription. Unlike bacterial

repressors, most do not act by directly competing with the polymerase for access to the DNA. Although their precise mechanisms of action are not yet understood, it appears that different repressors work in different ways, three of which are described in Figure 9-37.

In addition to gene repressor proteins that act on individual genes, eucaryotic cells utilize another mechanism to shut off the expression of genes in large regions of chromosomes. This mechanism depends on altering chromatin structure, as we discuss later.

Eucaryotic Gene Regulatory Proteins Often Assemble into Small Complexes on DNA 30

Although some eucaryotic gene regulatory proteins may work individually, most act as part of a complex composed of several polypeptides, each with a distinct function. The complex often assembles only in the presence of the appropriate DNA sequence. In some well-studied cases, for example, two gene regulatory proteins with a weak affinity for each other cooperate to bind to a DNA sequence, neither protein being able to bind to the DNA site on its own. Once bound to DNA, the protein dimer creates a distinct surface that is recognized by a third protein that carries an activator domain that stimulates transcription (Figure 9-38). This example illustrates an important general point: protein-protein interactions that are too weak to cause proteins to assemble in solution can cause the proteins to assemble on DNA; in this way the DNA sequence acts as a nucleation site for the assembly of a protein complex.

An individual gene regulatory protein can often participate in more than one type of regulatory complex. A protein might function, for example, in one case as part of a complex that activates transcription and in another case as part of a complex that represses transcription (see Figure 9-38). Thus individual eucaryotic gene regulatory proteins are not necessarily dedicated activators or repressors; instead, they function as regulatory units that are used to generate complexes whose function depends on the final assembly of all of the individual components.

We saw earlier how the formation of gene regulatory heterodimers in solution provides a mechanism for the combinatorial control of gene expression. The assembly of small complexes of gene regulatory proteins on DNA provides a second mechanism for combinatorial control (see Figure 9-38).

Complex Genetic Switches That Regulate *Drosophila* Development Are Built Up from Smaller Modules 31

Given that gene regulatory proteins can be positioned at multiple sites along long stretches of DNA, that these proteins can assemble into complexes at each site, and that the complexes can influence in different ways the ordered assembly of the general transcription factors at the promoter, there would seem to be almost limitless possibilities for creating elaborate switches for the control of eucaryotic gene transcription.

A particularly striking example of such a complex, multicomponent genetic switch is that controlling the transcription of the *Drosophila even-skipped (eve)* gene, whose expression plays an important role in the development of the *Drosophila* embryo. If this gene is inactivated by mutation, many parts of the embryo fail to form, and the embryo dies early in development. As discussed in Chapter 21, at the earliest stage of development where *eve* is expressed, the embryo is a single giant cell containing multiple nuclei in a common cytoplasm. The cytoplasm is not uniform, however: it contains a mixture of gene regulatory proteins that are distributed unevenly along the length of the embryo, thus providing *positional information* that distinguishes one part of the embryo from another (Figure 9-39). (The way these differences are set up is discussed in Chapter 21.) Although the nuclei are initially identical, they rapidly begin to express different genes because they are exposed to different gene regulatory proteins. The nuclei near the anterior end of the developing embryo, for example, are exposed to a set of gene regulatory proteins that is distinct from the set that influences nuclei at the posterior end of the embryo.

The regulatory DNA sequences of the *eve* gene are designed to read the concentrations of gene regulatory proteins at each position along the length of the embryo and to interpret this information in such a way that the *eve* gene is expressed in seven stripes, each initially five to six nuclei wide and positioned precisely along the anterior-posterior axis of the embryo (Figure 9-40). How is this remarkable feat of information processing carried out? Although the molecular details are not yet understood, several general principles have emerged from studies of *eve* and other *Drosophila* genes that are similarly regulated.

The regulatory region of the *eve* gene is very large (approximately 20,000 nucleotide pairs). It is formed from a series of relatively simple regulatory modules, each of which contains multiple regulatory sequences and is responsible for specifying a particular stripe of *eve* expression along the embryo. This modular organization of the *eve* gene control region is revealed by

experiments in which a particular regulatory module (say, that specifying stripe 2) is removed from its normal setting upstream of the *eve* gene, placed in front of a reporter gene, and reintroduced into the *Drosophila* genome (Figure9-41A). When developing embryos derived from flies carrying this genetic construct are examined, the reporter gene is found to be expressed in precisely the position of stripe 2 (Figure 9-41B). Similar experiments reveal the existence of other regulatory modules, each of which specifies one of the other six stripes.

The *Drosophila eve* Gene Is Regulated by Combinatorial Controls 32

A detailed study of the stripe 2 regulatory module has provided insights into how it reads and interprets positional information. It contains recognition sequences for two gene regulatory proteins (Bicoid and Hunchback) that activate *eve* transcription and two (Krüppel and Giant) that repress it (Figure 9-42). (The gene regulatory proteins of *Drosophila* often have colorful names reflecting the phenotype that results if the gene encoding the protein is inactivated by mutation.) The relative concentrations of these four proteins determine whether protein complexes form at the stripe 2 module that turn on transcription of the *eve* gene. Figure 9-43 shows the distributions of the four gene regulatory proteins across the region of a *Drosophila* embryo where stripe 2 forms. Although the precise details are not known, it seems likely that either one of the two repressor proteins, when bound to the DNA, will turn off the stripe 2 module, whereas *both* Bicoid and Hunchback must bind for maximal activation of the module. This simple regulatory unit thereby integrates these four positional signals so as to turn on the stripe 2 module (and therefore the expression of the *eve* gene) only in those nuclei that are located where the levels of both Bicoid and Hunchback are high and both Krüppel and Giant are absent. This combination of activators and repressors occurs only in one region of the early embryo; everywhere else, therefore, the stripe 2 module is off (and therefore silent).

We have previously discussed two mechanisms of combinatorial control of gene expression - heterodimerization of gene regulatory proteins in solution (see Figure 9-19) and the assembly of combinations of gene regulatory proteins into small complexes on DNA (see Figure 9-38). It is likely that both mechanisms participate in the complex regulation of *eve* expression. In addition, the regulation of stripe 2 just described illustrates a third type of combinatorial control. Because the individual regulatory sequences in the *eve* stripe 2 module are strung out along the DNA, many sets of gene regulatory proteins can be bound simultaneously and influence the promoter of a gene. The promoter integrates the transcriptional cues provided by all of the bound proteins (Figure9-44).

The regulation of *eve*expression is an extreme example of combinatorial control. Seven combinations of gene regulatory proteins - one combination for each stripe - activate *eve* expression, while many other combinations (all those found in the interstripe regions) keep the stripe elements silent. The other stripe regulatory modules are thought to be constructed along lines similar to those described for stripe 2, being designed to read positional information provided by other combinations of gene regulatory proteins. The entire gene control region is strung out over 20,000 nucleotide pairs of DNA and binds more than 20 different proteins. A large and complex control region is thereby built from a series of smaller modules, each of which consists of a unique arrangement of short DNA sequences recognized by specific gene regulatory proteins. An important requirement of this strategy is the absence of cross-talk between the modules: the state of one module should not affect that of the others. How this molecular insulation is achieved is unknown. In this way, however, a single gene can respond to an enormous number of combinatorial inputs.

Complex Mammalian Gene Control Regions Are Also Constructed from Simple Regulatory Modules 33

It has been estimated that several percent of the coding capacity of a mammalian genome is devoted to the synthesis of proteins that serve as regulators of gene transcription. This reflects the exceedingly complex controls that regulate the expression of mammalian genes. It is not unusual, for example, to find a gene with a control region that is 50,000 nucleotide pairs in length, in which many modules, each containing a number of regulatory sequences that bind gene regulatory proteins, are interspersed with long stretches of spacer DNA.

One of the best-understood examples of a complex mammalian regulatory region is found in the human b-globin gene, which is expressed exclusively in red blood cells and at a specific time in their development. A complex array of gene regulatory proteins controls the expression of the gene, some acting as activators and others as repressors (Figure 9-45). The concentrations (or activities) of many of these gene regulatory proteins are thought to change during development, and only a particular combination of all the proteins triggers transcription of the gene. We see later that the b-globin gene is also subject to a second, higher layer of control that involves global changes in chromatin structure.

The Activity of a Gene Regulatory Protein Can Itself Be Regulated 34

The strategies for regulating the *eve* gene and the human b-globin gene are similar in that the gene control regions respond to a bewildering array of gene regulatory proteins. *Drosophila* is unusual, however, in the way that the spatial distribution of gene regulatory proteins in the cytoplasm controls gene expression. As discussed previously, the early *Drosophila* embryo is a single giant cell that contains thousands of nuclei in a common cytoplasm, and the gene regulatory proteins themselves are distributed in complex spatial patterns so that different nuclei are exposed to different concentrations of the proteins. These gene regulatory proteins enter the nuclei directly to activate or repress transcription of their target genes. In most embryos of other organisms, individual nuclei are in separate cells, and extracellular positional information must either pass across the plasma membrane or, more usually, generate signals in the cytosol in order to influence the genome.

The mechanisms by which extracellular signals communicate their message across the plasma membrane to gene regulatory proteins inside the cell are discussed in Chapter 15. Here we need deal only with the final steps in the intracellular signaling cascades activated by extracellular signals - the steps in which the activity of gene regulatory proteins is altered. In many cases the gene regulatory protein is present in the cell in an inactive form and a signal alters the protein so as to activate it. The protein may be activated by phosphorylation catalyzed by a protein kinase, for example, or it may be released from a tight complex with a second protein that otherwise holds the gene regulatory protein in the cytosol, preventing it from entering the nucleus. These and some other ways of controlling the activity of gene regulatory proteins are illustrated in Figure 9-46.

Bacteria Use Interchangeable RNA Polymerase Subunits to Help Regulate Gene Transcription 35

We have seen the importance of gene regulatory proteins that bind to regulatory sequences in DNA and signal to the transcription apparatus whether or not to start the synthesis of an RNA chain. Although this is the main way of controlling transcriptional initiation in both eucaryotes and procaryotes, some bacteria and their viruses use an additional strategy based on interchangeable subunits of RNA polymerase. As described in Chapter 8, a *sigma subunit* is required for the bacterial RNA polymerase to recognize a promoter. Some bacteria make several different sigma subunits, each of which can interact with the RNA polymerase core and direct it to different specific promoters. This scheme permits one large set of genes to be turned off and a new set to be turned on simply by replacing one sigma subunit with another. The strategy is efficient because it bypasses the need to deal with the genes one by one, and it is often used by bacterial viruses to activate several sets of genes rapidly and sequentially (Figure9-47).

In a sense, eucaryotes employ an analogous strategy through the use of three distinct RNA polymerases (I, II, and III) that share some of their subunits. Procaryotes, in contrast, use only one type of core RNA polymerase molecule but modify it with different sigma subunits.

Gene Switches Have Gradually Evolved

We have seen that the control regions of eucaryotic genes are often spread out over long stretches of DNA, whereas those of procaryotic genes are typically closely packed around the start point of transcription. Several bacterial gene regulatory proteins, however, recognize DNA sequences that are located many nucleotide pairs away from the promoter. The example of DNA looping in *E. coli* shown previously in Figure 9-32 resembles the way that eucaryotic gene regulatory proteins act at a distance. In fact, this case provided one of the first examples of DNA looping in gene regulation and greatly influenced later studies of eucaryotic gene regulatory proteins.

It seems likely that the close-packed arrangement of bacterial genetic switches developed from more extended forms of switches in response to the evolutionary pressure on bacteria to maintain a small genome size. (The same argument has been used to explain the lack of introns in bacteria, as discussed in Chapter 8.) This compression comes at a price, however, as it is difficult to imagine how the compact switches could be easily altered to incorporate new levels of control. The extended form of eucaryotic control regions, in contrast, with discrete regulatory modules separated by long stretches of spacer DNA, would be expected to facilitate reshuffling of modules during evolution, both to create new regulatory circuits and to modify old ones. Unraveling the history of how gene control regions evolved presents a fascinating challenge, and many clues can be found in present-day DNA sequences (Figure9-48).

Summary

The transcription of individual genes is switched on and off in cells by gene regulatory proteins. In procaryotes these proteins

usually bind to specific DNA sequences close to the RNA polymerase start site and, depending on the nature of the regulatory protein and the precise location of its binding site relative to the start site, either activate or repress transcription of the gene. The flexibility of the DNA helix, however, also allows proteins bound at distant sites to affect the RNA polymerase at the promoter by the looping out of the intervening DNA. Such action at a distance is extremely common in eucaryotic cells, where gene regulatory proteins bound to sequences thousands of nucleotide pairs from the promoter can control gene expression.

Although procaryotic RNA polymerases can initiate transcription on their own, eucaryotic polymerases require the prior assembly of general transcription factors at the promoter. These factors assemble in a particular order, beginning with the binding of TFIID to the TATA box, a DNA sequence found just upstream of most eucaryotic RNA polymerase start sites. The ordered assembly of general transcription factors provides several steps at which the initiation of transcription can be regulated, and many eucaryotic gene regulatory proteins are thought to work by facilitating (positive control) or hindering (negative control) the assembly process.

Whereas the transcription of a typical procaryotic gene is controlled by only one or two gene regulatory proteins, the regulation of higher eucaryotic genes is much more complex, commensurate with the larger genome size and the large variety of cell types. The control region of the Drosophila eve gene, for example, encompasses 20,000 nucleotide pairs of DNA and has binding sites for over 20 gene regulatory proteins. Some of these proteins are transcriptional activators, while others are transcriptional repressors. These proteins bind to regulatory sequences organized in a series of regulatory modules strung together along the DNA.
Figure 9-24. The clustered genes in *E. coli* that code for enzymes that manufacture the amino acid tryptophan. These five genes are transcribed as a single mRNA molecule, a feature that allows their expression to be controlled coordinately. Clusters of genes transcribed as a single mRNA molecule are common in bacteria. Each such cluster is called an *operon.*
Figure 9-25. Switching the tryptophan genes on and off. If the level of tryptophan inside the cell is low, RNA polymerase binds to the promoter and transcribes the five genes of the tryptophan (*trp*) operon. If the level of tryptophan is high, however, the tryptophan repressor is activated to bind to the operator, where it blocks the binding of RNA polymerase to the promoter. Whenever the level of intracellular tryptophan drops, the repressor releases its tryptophan and becomes inactive, allowing the polymerase to begin transcribing these genes.

Permission to reproduce this figure in this web version of *Molecular Biology of the Cell* is either pending or has not been granted.

Figure 9-26. The binding of tryptophan to the tryptophan repressor protein changes the conformation of the repressor. The conformational change enables this gene regulatory protein to bind tightly to a specific DNA sequence (the operator), thereby blocking transcription of the genes encoding the enzymes required to produce tryptophan (the *trp* operon). The three-dimensional structure of this bacterial helix-turn-helix protein, as determined by x-ray diffraction with and without tryptophan bound, is illustrated. Tryptophan binding increases the distance between the two recognition helices in the homodimer, allowing the repressor to fit snugly on the operator. (Adapted from R. Zhang et al., *Nature*327:591-597, 1987. © 1987 Macmillan Magazines Ltd.)
Figure 9-27. Summary of the mechanisms by which specific gene regulatory proteins control gene transcription in procaryotes. (A) Negative regulation; (B) positive regulation. Note that the addition of an inducing ligand can turn on a gene either by removing a gene repressor protein from the DNA (*upper left panel*) or by causing a gene activator protein to bind (*lower right panel*). Likewise, the addition of an inhibitory ligand can turn off a gene either by removing a gene activator protein from the DNA (*upper right panel*) or by causing a gene repressor protein to bind (*lower left panel*).
Figure 9-28. Some bacterial gene regulatory proteins act as either transcriptional activators or repressors, depending on the precise placement of their binding sites in DNA. An example is the bacteriophage lambda repressor. The protein acts as a transcriptional activator by providing a favorable contact for RNA polymerase (*top*). At the bottom of the figure the operator is located one base pair closer to the promoter, and, instead of helping polymerase, the repressor now competes with it for binding to the DNA. The lambda repressor recognizes its operator by a helix-turn-helix motif, as shown in Figure 9-11.

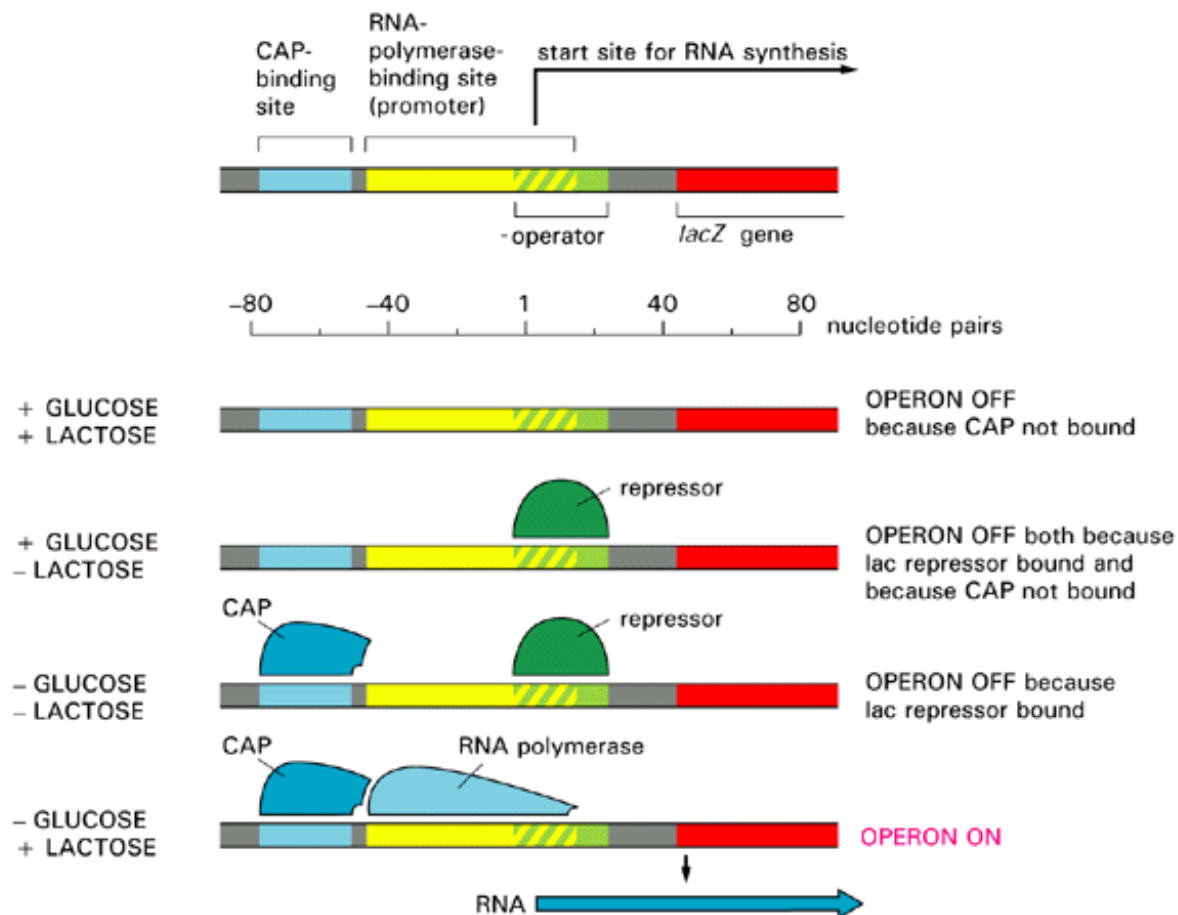
RNA ━━━━━━━➤


Figure 9-29. Dual control of the *lac* operon. Glucose and lactose levels control the initiation of transcription of the *lac* operon through their effects on the lac repressor protein and CAP. Lactose addition increases the concentration of allolactose, which binds to the repressor protein and removes it from the DNA. Glucose addition decreases the concentration of cyclic AMP; because cyclic AMP no longer binds to CAP, this gene activator protein dissociates from the DNA, turning off the operon. As shown in <u>Figure9-8</u>, CAP is known to induce a bend in the DNA when it binds; for simplicity, the bend is not shown here. *LacZ,* the first gene of the *lac* operon, encodes the enzyme b-galactosidase, which breaks down lactose to galactose and glucose.
Figure 9-30. Assembly of the general transcription factors required for the initiation of transcription by RNA polymerase II. In the first step, TFIID binds specifically to a TATA sequence. Next, TFIIB enters the complex, followed by RNA polymerase II (Pol II) escorted by TFIIF. TFIIE and TFIIH then assemble into the complex. In the presence of ATP, TFIIH phosphorylates Pol II, which releases the polymerase so that it can initiate transcription. The site of phosphorylation is a long polypeptide tail that extends from the largest subunit of Pol II. In mammals it is composed of 52 repeats of the amino acid sequence YSPTSPS (see <u>Figure8-42</u>), and it is the serine (S) and threonine (T) side chains in the repeat that are phosphorylated. The general transcription factors have been highly conserved in evolution: some of those isolated from human cells, for example, can be replaced in biochemical experiments by the equivalent factors from yeast.

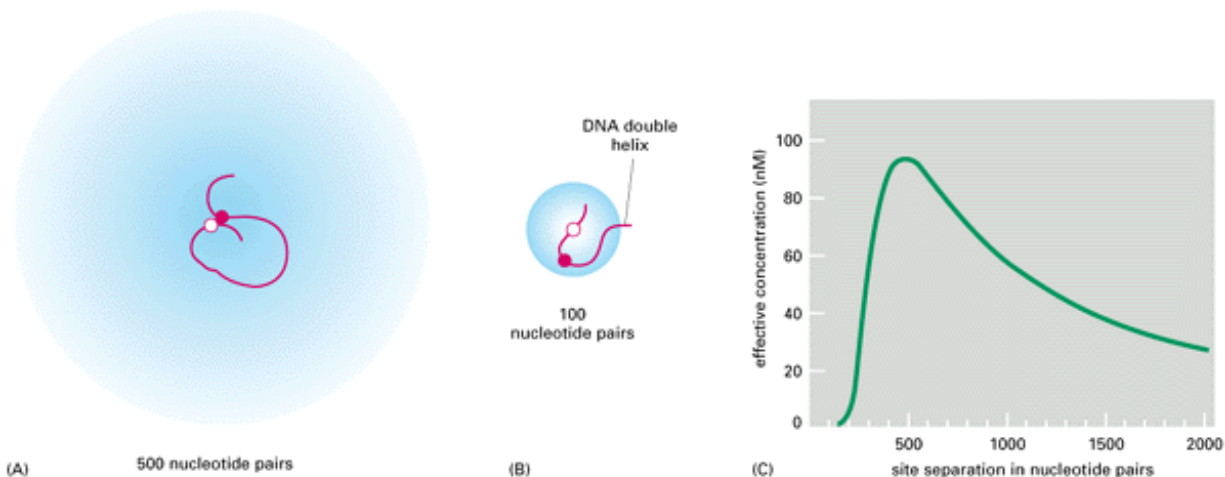
Figure 9-31. Three-dimensional structure of TBP. The structure of this subunit of TFIID resembles a saddle that fits over the DNA double helix. Although the protein is organized with twofold symmetry, it is a single polypeptide chain. It seems likely that this protein was once a symmetric dimer and that the gene encoding the original monomer duplicated and fused during evolution. TBP recognizes DNA using a motif that is distinct from those discussed earlier in the chapter. No other protein is known to bind DNA in this way, reflecting, perhaps, TBP's unique role in the cell: it participates in the initiation of transcription of all genes. Although not shown in the figure, the DNA is severely deformed when TBP is bound. This deformationtwo kinks separated by partially unwound DNAmay provide a landmark that helps to attract the other general transcription factors. (Adapted from D.B. Nikolov et al., *Nature* 360:40-45, 1992. ©1992 Macmillan Magazines Ltd.)
Figure 9-32. Gene activation at a distance. (A) NtrC is a bacterial gene regulatory protein that activates transcription by facilitating the transition between closed and open RNA polymerase complexes (discussed in Chapter 8). Although not usually the case for procaryotic RNA polymerases, the transition stimulated by NtrC requires the energy produced by ATP hydrolysis. (B) The interaction of NtrC and RNA polymerase, with the intervening DNA looped out, can be seen in the electron microscope. Although transcriptional activation by DNA looping is unusual in bacteria, it is typical of eucaryotic gene regulatory proteins. (B, courtesy of Harrison Echols.)


Figure 9-33. Binding of two proteins to separate sites on the DNA double helix can greatly increase their probability of interacting. (A) The tethering of one protein to the other via an intervening DNA loop of 500 nucleotide pairs increases their frequency of collision. The intensity of *blue* coloring reflects the probability that the *red* protein will be located at each position in space relative to the *white* protein. (B) The flexibility of DNA is such that an average sequence makes a smoothly graded 90° bend (a curved turn) about once every 200 nucleotide pairs. Thus, when two proteins are tethered by only 100 nucleotide pairs, their contact is relatively restricted. In such cases the protein interaction is facilitated when the two protein-binding sites are separated by a multiple of about 10 nucleotide pairs, which places both proteins on the same side of the DNA helix (which has 10 nucleotides per turn) and thus on the inside of the DNA loop, where they can best reach each other. (C) Theoretical effective concentration of the *red* protein at the site where the *white* protein is bound as a function of their separation. (C, courtesy of Gregory Bellomy, modified from M.C. Mossing and M.T. Record, *Science* 233:889-892, 1986. © 1986 the AAAS.)
Figure 9-34. The gene control region of a typical eucaryotic gene. The *promoter* is the DNA sequence where the general transcription factors and the polymerase assemble. The most important feature of the promoter is the TATA box, a short sequence of T-A and A-T base pairs that is recognized by the general transcription factor TFIID. The start point of transcription is typically located about 25 nucleo-tide pairs downstream from the TATA box. The *regulatory sequences* serve as binding sites for gene regulatory proteins, whose presence on the DNA affects the rate of transcription initiation. These sequences can be located adjacent to the promoter, far upstream of it, or even downstream of the gene. DNA looping is thought to allow gene regulatory proteins bound at any of these positions to interact with the proteins that assemble at the promoter. Whereas the general transcription factors that assemble at the promoter are similar for all polymerase II transcribed genes, the gene regulatory proteins and the locations of their binding sites relative to the promoter are different for each gene.
Figure 9-35. The modular structure of a gene activator protein. Outline of a domain-swap experiment that reveals the presence of independent DNA-binding and transcription-activating domains in the yeast gene activator protein GAL4. A functional activator can be reconstituted from the carboxyl-terminal portion of the GAL4 protein if it is attached to the DNA-binding domain of a bacterial gene regulatory protein (the lexA protein) by gene fusion techniques. When the resulting bacterial-yeast hybrid protein is produced in yeast cells, it will activate transcription from yeast genes provided that the specific DNA-binding site for the bacterial protein has been inserted next to them. (A) The normal activation of gene transcription produced by the GAL4 protein. (B) The chimeric gene regulatory protein requires the lexA-protein DNA-binding site for its activity. GAL4 is normally responsible for activating the transcription of yeast genes that code for the enzymes that convert galactose to glucose. For the experiments shown here, the control region for one of these genes was fused to the *E. coli lacZ* gene, which codes for the enzyme b-galactosidase (see Figure 9-29). b-galactosidase is very simple to detect biochemically and thus provides a convenient way to monitor the expression level specified by a gene control region; *lacZ* thus serves as a *reporter gene* (see p. 321).
Figure 9-36. A model for the action of acidic activators. The GAL4 gene activator protein, bound to DNA in the rough vicinity of the promoter, facilitates the addition of TFIIB to the nascent complex of general transcription factors. DNA-bound activator proteins typically increase the rate of transcription by up to 1000-fold, which is consistent with a relatively weak and nonspecific interaction between the activator and the general transcription factors (a 1000-fold change in affinity corresponds to

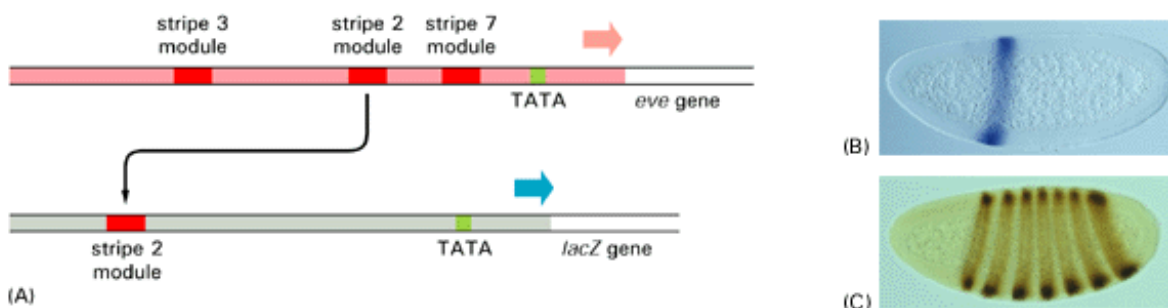
a change in DG of ~4 kcal/mole, which could be accounted for by only a few weak, noncovalent bonds).
Figure 9-37. Three ways in which eucaryotic gene repressor proteins can operate. In the first (A) gene activator proteins and gene repressor proteins compete for binding to the same regulatory DNA sequence. In the second (B) both proteins can bind DNA, but the repressor complexes with the activation domain of the activator protein and thereby prevents it from contacting the transcription machinery. In the third (C) the repressor interacts with an early stage of the assembling complex of general transcription factors, blocking further assembly. A fourth mechanism of negative control - inactivation of a transcriptional activator by heterodimerization - was illustrated in Figure9-21.
Figure 9-38. Eucaryotic gene regulatory proteins often assemble into small complexes on DNA. Five gene regulatory proteins are shown in (A). The nature and function of the complex they form depends on the specific DNA sequence that nucleates their assembly. In (B) one complex that assembles activates gene transcription, while another represses transcription. Note that the *green* protein is shared by both the activating and the repressing complexes.
Figure 9-39. The nonuniform distribution of four gene regulatory proteins in an early *Drosophila* embryo. At this stage the embryo is a syncytium, with multiple nuclei in a common cytoplasm. Although it is not clear in these drawings, all of these proteins are concentrated in the nuclei.
Figure 9-40. The seven stripes of the protein encoded by the *even-skipped (eve)* gene in a developing *Drosophila* embryo. Two and one-half hours after fertilization, the egg was fixed and stained with antibodies that recognize the Eve protein (*green*) and antibodies that recognize the Giant protein (*red*). Where Eve and Giant proteins are both present, the staining appears *yellow*. At this point in development, the egg contains approximately 4000 nuclei. The Eve and Giant proteins are both located in the nuclei, and the *eve*stripes are about four nuclei wide. The staining pattern of the giant protein is also shown in Figure9-39. (Courtesy of Michael Levine.)


Figure 9-41. Experiment demonstrating the modular construction of the *eve* gene regulatory region. (A) A 480-nucleotide-pair piece of the *eve* regulatory region was removed and inserted upstream of a test promoter that directs the synthesis of the enzyme b-galactosidase (the product of the *E. coli lacZ* gene). (B) When this artificial construct was reintroduced into the genome of *Drosophila* embryos, the embryos expressed b-galactosidase (detectable by histo-chemical staining) precisely in the position of the second of the seven *eve* stripes (C). (B and C, courtesy of Stephen Small and Michael Levine.)
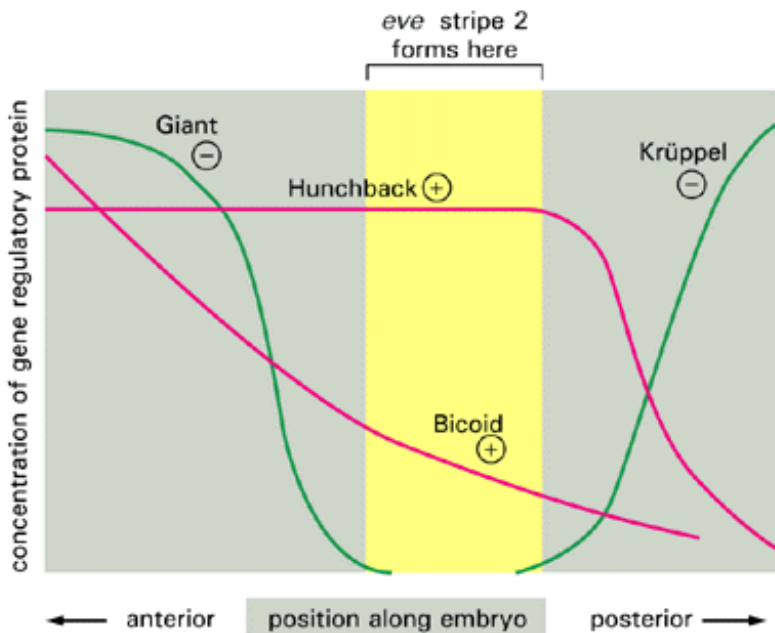
Figure 9-42. Close-up view of the *eve* stripe 2 unit. The segment of the *eve* gene control region identified in the previous figure contains regulatory sequences, each of which binds one or another of four gene regulatory proteins. It is known from genetic experiments that these four regulatory proteins are responsible for the proper expression of stripe 2 of *eve*. Flies that are deficient in the two gene activators Bicoid and Hunch-back, for example, fail to express stripe 2 of *eve* efficiently. In flies deficient in either of the two gene repressors, Giant and Krüppel, stripe 2 expands and covers an abnormally broad region of the embryo. The DNA-binding sites for these gene reg-ulatory proteins were determined by cloning the genes encoding the pro-teins, overexpressing the proteins in *E. coli,* purifying them, and perform-ing DNA-footprinting experiments as described in Chapter 7. The top diagram indicates that, in some cases, the binding sites for the gene regula-tory proteins overlap and the proteins can compete for binding to the DNA. For example, the binding of Krüppel and Bicoid to the site at the far right is thought to be mutually exclusive.


Figure 9-43. Distribution of the gene regulatory proteins responsible for ensuring that *eve* is expressed in stripe 2. The distributions of these proteins were visualized by staining a developing *Drosophila* embryo with antibodies directed against each of the four proteins (Figure 9-39). The expression of *eve* in stripe 2 occurs only at the position where the two activators (Bicoid and Hunchback) are present and the two repressors (Giant and Krüppel) are absent. In fly embryos that lack Krüppel, for example, stripe 2 expands posteriorly. Likewise, stripe 2 expands posteriorly if the DNA-binding sites for Krüppel in the stripe 2 module (see Figure9-41) are inactivated by mutation and this regulatory region is reintroduced into the genome.The *eve* gene itself encodes a gene regulatory protein, which, after its pattern of expression is set up in seven stripes, in turn regulates the expression of other *Drosophila* genes. As development proceeds, the embryo is thus subdivided into finer and finer regions that

eventually give rise to the different body parts of the adult fly, as discussed in Chapter 21.
Figure 9-44. Integration at a promoter. Multiple sets of gene regulatory proteins can work together to influence a promoter, as they do in the *eve* stripe 2 module illustrated previously in Figure9-42. It is not yet understood in detail how the integration of multiple inputs is achieved.
Figure 9-45. Model for the control of the human b-globin gene. The diagram shows some of the gene regulatory proteins thought to control expression of the gene during red blood cell development (see Figure9-52). Some of the gene regulatory proteins shown, such as CP1, are found in many types of cells, while others, such as GATA-1, are present in only a few types of cells including red blood cells and therefore are thought to contribute to the cell-type specificity of b-globin gene expression. As indicated by the double-headed arrows, several of the binding sites for GATA-1 overlap those of other gene regulatory proteins; it is thought that occupancy of these sites by GATA-1 excludes binding of other proteins. (Adapted from B. Emerson, In Gene Expression: General and Cell-Type-Specific [M. Karin, ed.], pp. 116-161. Boston: Birkhauser, 1993.)
Figure 9-46. Some ways in which the activity of gene regulatory proteins is regulated in eucaryotic cells. (A) The protein is synthesized only when needed and is rapidly degraded by proteolysis so that it does not accumulate. (B) Activation by ligand binding. (C) Activation by phosphorylation. (D) Formation of a complex between a DNA-binding protein and a separate protein with a transcription-activating domain. (E) Unmasking of an activation domain by the phosphorylation of an inhibitor protein. (F) Stimulation of nuclear entry by removal of an inhibitory protein that otherwise keeps the regulatory protein from entering the nucleus.
Figure 9-47. Interchangeable RNA polymerase subunits as a strategy to control gene expression in a bacterial virus. The bacterial virus SPO1, which infects the bacterium *B. subtilis,* uses the bacterial polymerase to transcribe its early genes. One of the early genes, called 28, encodes a sigmalike factor that binds to RNA polymerase and displaces the bacterial sigma factor. This new form of polymerase specifically initiates transcription of the SPO1 "middle" genes. One of the middle genes encodes a second sigmalike factor that displaces the 28 product and directs RNA polymerase to transcribe the "late" genes. This last set of genes produces the proteins that package the virus chromosome into a virus coat and lyse the cell. Thus, by this strategy, sets of virus genes are expressed in a particular order, allowing for rapid, yet temporally controlled, viral replication.
Figure 9-48. A comparison of part of the control region upstream from the *engrailed* gene in two species of *Drosophila*. A DNA sequence comparison between *Drosophila melanogaster* and *Drosophila virilis* is shown, with regions of 90% sequence conservation shown in *red*. One example of an actual sequence match is illustrated in detail at the top. The conserved sequences presumably mark the sites where important gene regulatory proteins bind, whereas loops indicate places where insertions or deletions of nucleotides have occurred since these two species evolved from a common ancestor about 60 million years ago. (Courtesy of Judith A. Kassis and Patrick H. O'Farrell.)

Introduction

As discussed in Chapter 8, the genomes of eucaryotes are highly compacted to allow the very long DNA molecules to fit inside the cell and to be managed easily. The first level of compaction is the wrapping of DNA around histones to form nucleosomes. In a second level of compaction nucleosomes are packed into 30-nm filaments. Finally, an even higher order of packing (still poorly understood) is observed in heterochromatin, which is confined to selected regions of the genome that show an unusually condensed interphase structure.

How do gene regulatory proteins and the general transcription factors gain access to DNA that is packed into these compact protein-DNA structures, and how does the packing affect the control of gene expression? We see in this section that two general principles have emerged from studies of chromatin structure and its influence on gene expression. First, nucleosomes do not usually present a serious obstruction to either gene regulatory proteins or RNA polymerases. Enhancers can still function despite them, histones that block a promoter can be displaced, and, once transcription has begun, Pol II can transcribe through the nucleosomes without dislodging them. Even bacterial polymerases, which do not encounter nucleosomes *in vivo,* can transcribe through them, suggesting that the nucleosome is built to be traversed easily (Figure9-49). The second general principle is that some forms of higher-order DNA packaging render the DNA inaccessible both to gene regulatory proteins and to the general transcription factors. Higher-order DNA packaging thus plays a crucial part in the control of gene expression in eucaryotes, serving to silence large sections of the genome - in some cases reversibly, in other cases not.

Transcription Can Be Activated on DNA That Is Packaged into Nucleosomes 37

In the previous section we described a simple model for how transcription of a eucaryotic gene is activated by a gene regulatory protein (see Figure9-36). How must this model be modified to take account of the presence of nucleosomes? To begin with the first step, how do nucleosomes affect the binding of a gene activator protein to its regulatory DNA sequence? In some cases the regulatory sequences reside in short nucleosome-free regions, and so no problem arises. It is uncertain how such nucleosome-free regions are maintained, but, as discussed in Chapter 8, some stretches of DNA are too stiff to accommodate the tight folding necessary for nucleosome formation. In other cases, however, the regulatory sequence is packaged into a nucleosome and yet at least some gene activator proteins can still recognize and bind to it. Once bound, the regulatory proteins appear to destabilize the nucleosome, which is then at least partially disassembled. Which types of gene regulatory proteins can achieve this feat and how they accomplish it remain unknown.

The general transcription factors, in contrast, seem unable to assemble onto a promoter that is packaged into a nucleosome. In fact, such packaging may have evolved in part to ensure that leaky, or basal, transcription initiation (that is, initiation without a gene activator protein bound upstream) does not occur. The binding of a gene activator protein thousands of nucleotide pairs away from a nucleosome-packaged promoter, however, can apparently displace a nucleosome from a promoter and thereby allow the assembly of the general transcription factors. The displacement either could be due to a separate activity of the gene activator protein or could be an indirect consequence of the activator contacting the general transcription factors to facilitate their assembly on the DNA (Figure 9-50).

Some Forms of Chromatin Silence Transcription 38

Although transcription can occur on DNA that is packaged into nucleosomes, the DNA in some special forms of chromatin appears to be inaccessible to gene activator proteins. These *inactive* forms of chromatin, including the especially highly condensed form called *heterochromatin* (discussed in Chapter 8), are assumed to contain special proteins that make the DNA unusually inaccessible.

An observation in the yeast *S. cerevisiae* illustrates how some types of chromatin can shut off gene transcription. The *ADE2* gene, whose expression is particularly easy to monitor, is expressed when present at its normal chromosomal location. When this gene is experimentally relocated to the end of a chromosome, however, its transcription is turned off, even though the cell contains all of the proteins required to transcribe the gene. The DNA near the ends of yeast chromosomes (the *telomeres*) is packaged into an especially inaccessible form of chromatin, and it is this packaging that is thought to be responsible for maintaining the translocated *ADE2* gene in an inactive state, a process called *silencing.* The silencing of genes located near

chromosome ends extends for approximately 10,000 nucleotide pairs and applies to many genes in addition to *ADE2*; the silencing seems to weaken gradually with distance from the telomere. The mechanism of silencing is not known, but it seems likely to involve a cooperative assembly of proteins on the DNA that, once established, is heritable following DNA replication (Figure 9-51A).

The silencing of the *ADE2* gene is an example of a position effect, in which the activity of a gene is dependent on its position in the genome. Position effects were first recognized in *Drosophila* (Figure9-51B), but they have now been observed in a number of other organisms and are thought to reflect the different states of chromatin present at different locations in the genome and the tendency of these states to spread to encompass nearby genes. We revisit this topic later in the chapter when we analyze mechanisms of cell memory.

An Initial Decondensation Step May Be Required Before Mammalian Globin Genes Can Be Transcribed 39

Another example of how highly condensed chromatin can prevent gene expression comes from studies of chick and human b-globin gene clusters. The five genes of the cluster, spread over 50,000 nucleotide pairs of DNA, are transcribed exclusively in erythroid cells (that is, cells of the red blood cell lineage). Moreover, each gene is turned on at a different stage of development (Figure 9-52) and in different organs: the epsilon-globin gene is expressed in the embryonic yolk sac, gamma in the yolk sac and the fetal liver, and delta and b primarily in the adult bone marrow. We previously described a series of gene regulatory proteins that are necessary to turn on the human b-globin gene at the appropriate time and place (see Figure 9-45), and each of the other globin genes has a similar set of regulatory proteins, many of which are shared among these genes. In addition to the individual regulation of each of the globin genes, however, the entire cluster appears to be subject to an on-off control that involves global changes in chromatin structure.

Some of the first evidence for such changes came from studies of the sensitivity of the globin genes in isolated nuclei to digestion by the nuclease enzyme DNaseI. In cells where the globin genes are not expressed, the DNA in these genes is resistant to DNaseI, indicating that they are tightly packaged into chromatin. In erythroid cells, by contrast, the entire gene cluster is sensitive to DNaseI, indicating that the chromatin has changed to make the DNA more accessible to the enzyme. The DNA is still folded into nucleosomes, but the higher-order packing of the chromatin has loosened. This change in DNA packing occurs even before the individual globin genes are transcribed, suggesting that the genes are regulated in two steps. In the first step the chromatin of the entire globin locus is decondensed, which is presumed to allow some of the gene regulatory proteins access to the DNA. In the second step the remaining gene regulatory proteins assemble on the DNA and direct the expression of individual genes (Figure 9-53).

The extensive change in chromatin structure that occurs in the first step is thought to require a region of DNA (called the *locus control region,* or *LCR*) that lies far upstream from the gene clusters (see Figure 9-52). The importance of the LCR can be seen in patients with a certain type of thalassemia, a severe genetic form of anemia. In these patients the b-globin locus is found to have undergone deletions that remove all or part of the LCR, and although the b-globin gene and its nearby regulatory regions are intact, the gene remains silent in erythroid cells. Moreover, the b-globin gene in the erythroid cells remains DNaseI resistant, indicating that it fails to undergo the normal chromatin decondensation step during erythroid cell development.

Subsequent experiments in transgenic mice have confirmed the profound effects of the LCR on the expression of globin genes. When, for example, the human b-globin gene plus its local regulatory sequences (the region shown in Figure 9-45) is inserted into different positions in the mouse genome, it is expressed at low levels that depend on the site of insertion. This behavior is typical for mammalian genes, and it indicates that local position effects influence the expression of the gene (Table 9-2). When the LCR is included with the gene, however, b-globin is expressed at high levels in erythroid cells regardless of the site of insertion, indicating that the LCR can override these position effects.

Although several proteins that specifically bind to the LCR have been identified, the mechanism that alters the chromatin structure of the entire b-globin locus is not known. Some ideas for how such changes may be brought about are discussed in the next section.

The Mechanisms That Form Active Chromatin Are Not Understood

The hypothetical model for globin activation outlined in Figure 9-53 implies that eucaryotes may contain sequence-specific DNA-binding proteins that function to decondense the chromatin in a local chromosomal domain that extends for tens of thousands of DNA nucleotide pairs. Alternatively, the observed differences in the chromatin structure of active genes could be

an automatic consequence of the assembly of transcription factors or RNA polymerase (or both) onto a promoter rather than being a prerequisite for these events. We saw earlier that the assembly of the general transcription factors at promoters appears to be accompanied by changes in nucleosome distribution at the assembly site; perhaps this small perturbation can spread for long distances by some unknown propagation mechanism.

Whether or not eucaryotes turn out to have proteins that are specifically designed to decondense domains of chromatin, it is worth speculating on how proteins might accomplish this task. At present we can only guess at the mechanism. Three possibilities are outlined in Figure9-54. These very different types of models indicate how far we are from understanding the transition from inactive to active chromatin.

Superhelical Tension in DNA Allows Action at a Distance 40

One of the three models outlined in Figure9-54 invokes topological changes in a closed loop of DNA double helix that can lead to the formation of DNA supercoils, a conformation that DNA adopts in response to *superhelical tension.* DNA supercoiling is most readily studied in small circular DNA molecules, such as the chromosomes of some viruses and plasmids. The same considerations apply, however, to any region of DNA bracketed by two ends that are unable to rotate freely - as, for example, in a loop of chromatin that is tightly clamped at its base.

A simple way of visualizing the topological constraints that cause DNA supercoiling is illustrated in Figure 9-55. In a DNA double helix with two fixed ends, one DNA supercoil forms to compensate for each 10 nucleotide pairs that are opened (unwound) in the helix; the formation of this supercoil is energetically favorable because it restores the normal helical twist to the base-paired regions that remain.

In bacteria such as *E. coli* a special type II DNA topoisomerase, called *DNA gyrase,* uses the energy of ATP hydrolysis to pump supercoils continuously into the DNA, thereby maintaining the DNA under constant tension. These supercoils are *negative supercoils,* having the opposite handedness from the *positive supercoils,* shown in Figure9-55, that form when a region of DNA helix opens. Therefore, rather than creating a positive supercoil, a negative supercoil is removed from bacterial DNA when a region of helix opens. Because superhelical tension in the DNA is reduced during this event, the opening of the DNA helix in *E. coli* is energetically favored compared to helix opening in DNA that is not supercoiled.

The eucaryotic type II DNA topoisomerases remove superhelical tension rather than generate it (discussed in Chapter 8). Consequently, most of the DNA in eucaryotic cells is not under tension. But helix unwinding is associated with the initiation step of transcription. Moreover, a moving RNA polymerase molecule (as well as other proteins that unwind DNA) will tend to generate positive superhelical tension in the DNA in front of it and negative superhelical tension behind it (Figure 9-56). Through such topological effects an event that occurs at a single DNA site can produce forces that are felt throughout an entire domain of chromatin. It is not yet known, however, whether an effect of this kind is involved in creating large-scale changes in chromatin structure.

Summary

The genomes of eucaryotic organisms are packaged into chromatin. Some forms of chromatin are so highly compacted that the packaged genes are transcriptionally silent. Although the structural details of this type of packaging are not well understood, it is thought to be a device utilized by cells to silence large regions of their genomes. In some cases, this silencing can be reversed and the packaged genes activated, but the way this happens is also not understood.

In less compacted forms of chromatin the DNA is still packaged in nucleosomes. Nucleosomes positioned at the start point of transcription block the assembly of the general transcription factors. These nucleosomes appear to be displaced by an unknown mechanism when transcription is activated by gene regulatory proteins.
Figure 9-49. A tentative model to account for the ability of RNA polymerases to transcribe through nucleosomes without causing their displacement. The polymerase first displaces an H2A-H2B dimer (see Figure 8-10), allowing the polymerase to enter the nucleosome. In the next step the polymerase pulls the DNA away from the H3-H4 dimer it next encounters and continues transcribing. The displaced H2A-H2B dimer is recaptured by the nucleosome, and the second, symmetrically disposed H2A-H2B dimer is now displaced, allowing the process to repeat and permitting the polymerase to exit from the nucleosome. (After K.E. van Holde et al., *J. Biol. Chem.* 267:2837-2840, 1992.)
Figure 9-50. One model to explain the displacement of nucleosomes during the initiation of transcription in eucaryotes. A

bound gene activator protein possesses a separate activity that directly removes nucleosomes from the promoter, exposing the promoter to the general transcription factors and enabling them to assemble. In a different model (not shown) nucleosome displacement occurs as an indirect consequence of the activator protein promoting the assembly of the general transcription factors; the activator protein, for example, could permit the general factors to begin to assemble in the presence of a nucleosome, and, once partially assembled, these factors would destabilize the nucleosome. The process underlying nucleosome displacement is poorly understood. The histones may simply leave the DNA or, according to an alternative model, they may disassemble but remain bound to DNA (see Figure8-40).

Figure 9-51. Position effects on gene expression. (A) The yeast *ADE2* gene at its normal chromosomal location is expressed in all cells. When moved near the end of a yeast chromosome, the gene is silenced in most but not all cells of the population. The absence of the *ADE2* gene product results in a block in the adenine biosynthetic pathway, which leads to the accumulation of a red pigment. The founder cell for the sectored colony shown had its *ADE2* gene shut off, so most of the colony is *red*. Normally, yeast colonies are white. The *white* sectors at the edges of the *red* colony are clones of cells where the *ADE2* gene has spontaneously become active. The finding of such sectoring indicates that the active and inactive states of *ADE2* expression are heritable when this gene is near the telomere, a topic discussed in more detail in the next section.(B) Position effects can also be observed for the *Drosophila white* gene. Wild-type flies with a normal *white* gene have red eyes. If the *white* gene is inactivated by mutation, the eyes become white (hence the name of the gene). In flies with a chromosomal inversion that moves the *white* gene near a heterochromatic region, the eyes are mottled, with red and white patches. The white patches represent cells where the *white* gene is silenced and red patches represent cells that express the *white* gene. The difference is thought to arise from variations in how far along the chromosome the heterochromatin spreads early in eye development. As in the case of yeast *ADE2* gene, once established, the state of *white* expression is heritable, producing patches of many cells that express *white* as

well as patches of cells where *white* is silenced. (After L.L. Sandell and V.A. Zakian, *Trends Cell Biol.* 2:10-14, 1992.)
Figure 9-52. The cluster of b-like globin genes in humans. (A) The large chromosomal region shown spans 100,000 nucleotide pairs and contains the five globin genes and a locus control region (discussed in the text). (B) Changes in the expression of the b-like globin genes at various stages of human development. Each of the globin chains encoded by these genes combines with an a-globin chain to form the hemoglobin in red blood cells. (A, after F. Grosveld, G.B. van Assendelft, D.R. Greaves, and G. Kollias, *Cell* 51:975-985, 1987. © Cell Press.)
Figure 9-53. The two stages postulated to be involved in some gene activations, such as that of the human globin gene cluster. In stage 1 the structure of a large local region of chromatin is modified to decondense it in preparation for transcription. In stage 2 gene regulatory proteins (represented by a single protein in this simplified figure) bind to specific sites on the altered chromatin to induce RNA synthesis (transcription).

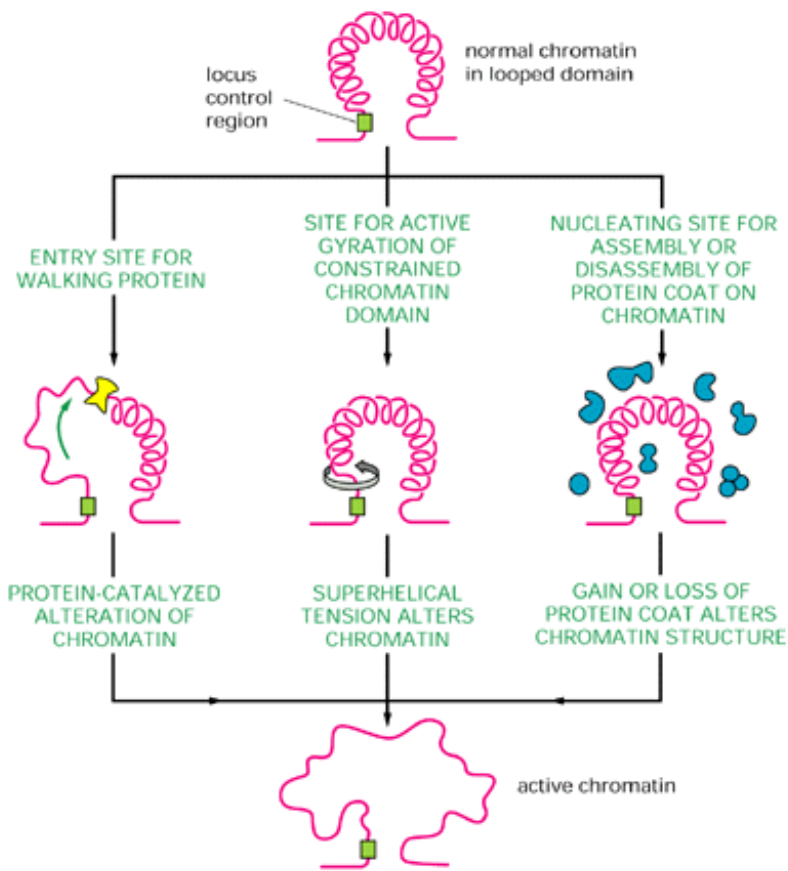
Table 9-2. Permission to reproduce this table in this web version of *Molecular Biology of the Cell* is either pending or has not been granted.


Figure 9-54. Three models proposed to explain the long-range influence of a locus control region (LCR) on gene activity. The loop of chromatin shown usually is postulated to represent an entire chromosomal looped domain (discussed in Chapter 8), which can contain 100,000 or more nucleotide pairs of DNA. Each model proposes a different function for the LCR site. The actual mechanism that causes long-range effects is unknown, and other mechanisms are also conceivable.
Figure 9-55. Superhelical tension in DNA causes DNA supercoiling. (A) For a DNA molecule with one free end (or a nick in one strand that serves as a swivel), the DNA double helix rotates by one turn for every 10 nucleotide pairs opened. (B) If rotation is prevented, superhelical tension is introduced into the DNA by helix opening. One way to accommodate this tension would be to increase the helical twist from 10 to 11 nucleotide pairs per turn in the double helix that remains in this example; the DNA helix, however, resists such a deformation in a springlike fashion, preferring to relieve the superhelical tension by bending into supercoiled loops. As a result, one DNA supercoil forms in the DNA double helix for every 10 nucleotide pairs opened. The supercoil formed in this case is a *positive supercoil*(see Figure 9-56).
Figure 9-56. Supercoiling of a DNA segment induced by a protein tracking through the DNA double helix. The two ends of the DNA shown here are unable to rotate freely relative to each other, and the protein molecule is assumed also to be prevented from rotating freely as it moves. Under these conditions the movement of the protein will cause an excess of helical turns to accumulate in the DNA helix ahead of the protein and a deficit of helical turns to arise in the DNA behind the protein, as shown. Experimental evidence suggests that a moving RNA polymerase molecule causes supercoiling in this way; the positive superhelical tension ahead of it makes the DNA helix more difficult to open, but this tension should facilitate the unwrapping of the DNA in nucleosomes, as the release of DNA from the histone core helps to relax positive superhelical tension.

The Molecular Genetic Mechanisms That Create Specialized Cell Types [41]

Introduction

Although unicellular organisms must be able to switch genes on and off, multicellular organisms require special gene switching mechanisms for generating and maintaining their different types of cells. In particular, once a cell in a multi-cellular organism becomes committed to differentiate into a specific cell type, the choice of fate is generally maintained through many subsequent cell generations, which means that the changes in gene expression involved in the choice must be remembered. This phenomenon of *cell memory* is a prerequisite for the creation of organized tissues and for the maintenance of stably differentiated cell types. In contrast, the simplest changes in gene expression in both eucaryotes and procaryotes are only transient; the tryptophan repressor, for example, switches off the tryptophan genes in bacteria only in the presence of tryptophan; as soon as tryptophan is removed from the medium, the genes are switched back on, and the descendants of the cell will have no memory that their ancestors had been exposed to tryptophan. Even in procaryotes, however, some changes in gene expression can be stably inherited.

In this section we examine how gene regulatory devices can be combined to form switches that, once thrown, are remembered by subsequent cell generations. We begin by considering some of the best-understood genetic mechanisms of cell differentiation, which operate in bacterial and yeast cells.

DNA Rearrangements Mediate Phase Variation in Bacteria [42]

We have seen that cell differentiation in higher eucaryotes usually occurs without detectable changes in DNA sequence. In some procaryotes, in contrast, a stably inherited pattern of gene regulation is achieved by DNA rearrangements that activate or inactivate specific genes. Since changes in DNA sequence are faithfully copied during subsequent DNA replications, an altered state of gene activity will be inherited by all the progeny of the cell in which the rearrangement occurred. Some of these rearrangements are reversible and produce an alternating pattern of gene activity that can be detected by observations over long time periods and many generations.

A well-studied example of this differentiation mechanism, known as phase variation, occurs in *Salmonella* bacteria. Although

this mode of differentiation has no known counterpart in higher eucaryotes, it can nevertheless have considerable impact on them because it is an important means whereby disease-causing bacteria evade detection by the immune system. The switch in *Salmonella* gene expression is brought about by the occasional inversion of a specific 1000-nucleotide-pair piece of DNA and affects the expression of the cell-surface protein flagellin, for which the bacterium has two different genes. The inversion is catalyzed by a site-specific recombination enzyme and changes the orientation of a promoter that is within the 1000 nucleotide pairs. With the promoter in one orientation, the bacteria synthesize one type of flagellin; with the promoter in the other orientation, they synthesize the other (Figure9-57). Because inversions occur only rarely, whole clones of bacteria will grow up with one type of flagellin or the other.

Phase variation almost certainly evolved because it protects the bacterial population against the immune response of its vertebrate host. If the host makes antibodies against one type of flagellin, a few bacteria whose flagellin has been altered by gene inversion will still be able to survive and multiply.

Bacteria isolated from the wild very often exhibit phase variation for one or more phenotypic traits. These "instabilities" are usually lost with time from standard laboratory strains of bacteria, and only some of the underlying mechanisms have been studied. Not all involve DNA inversion. A bacterium that causes a common sexually transmitted human disease (*Neisseria gonorrhoeae*), for example, avoids immune attack by means of an inherited variation in its surface properties that is generated by *gene conversion* (discussed in Chapter 6) rather than by gene inversion. This mechanism is dependent on the recA recombination protein, and it transfers DNA sequences to an expressed gene from a set of silent "gene cassettes"; it has the advantage of creating more than 100 variants of the major bacterial surface protein.

Several Gene Regulatory Proteins Determine Cell Type Identity in Yeasts 43

Because they are so easy to grow and to manipulate genetically, yeasts have been analyzed in great detail as model organisms for studying the mechanisms of gene control in eucaryotic cells. The common baker's yeast, *Saccharomyces cerevisiae,* has been especially illuminating because of its ability to differentiate into three cell types, even though the control mechanism differs in some basic ways from that used generally by animal and plant cells. *S. cerevisiae* is a single-celled eucaryote that exists in either a haploid or a diploid state. Diploid cells form by a process known as mating, in which two haploid cells fuse. In order for two haploid cells to mate, they must differ in *mating type* (sex). In *S. cerevisiae* there are two mating types, a and **a**, which are specialized for mating with each other. Each produces a specific diffusible signaling molecule (mating factor) and a receptor protein that jointly enable the cell to recognize and fuse with its opposite cell type. The resulting diploid cells, called **a**/a, are distinct from either parent: they are unable to mate but can form spores (sporulate) when they run out of food, giving rise to haploid cells by meiosis.

The mechanisms by which these three cell types are established and maintained illustrate several of the strategies we have discussed for changing the pattern of gene expression. The mating type of the haploid cell is determined by a single locus, the mating-type (*MAT*) locus, which in an **a**-type cell encodes a single gene regulatory protein, **a**1, and in an a cell encodes two gene regulatory proteins, a1 and a2. The **a**1 protein has no effect in the **a**-type haploid cell that produces it but becomes important later in the diploid cell that results from mating; meanwhile, the **a**-type haploid cell produces the proteins specific to its mating type by default. In contrast, the a2 protein acts in the a cell as a transcriptional repressor that turns off the **a**-specific genes, while the a1 protein acts as a transcriptional activator that turns on the a-specific genes. Once cells of the two mating types have fused, the combination of the **a**1 and a2 regulatory proteins generates a completely new pattern of gene expression, unlike that of either parent cell. The mechanism by which the mating-type-specific genes are expressed in different patterns in the three cell types is illustrated in Figure9-58. It was among the first examples of combinatorial gene control to be identified and remains one of the best understood at the molecular level.

Although in most laboratory strains of *S. cerevisiae* the **a** and a cell types are stably maintained through many cell divisions, some strains isolated from the wild can switch repeatedly between the **a** and a cell types by a mechanism of gene rearrangement whose effects are reminiscent of phase variation in *N. gonorrhoeae,* although the exact mechanism seems to be peculiar to yeast. On either side of the *MAT* locus in the yeast chromosome, there is a silent locus encoding the mating-type gene regulatory proteins: the silent locus on one side encodes a1 and a2; the silent locus on the other side encodes **a**1. Every other cell division, the active gene in the *MAT* locus is excised and replaced by a newly synthesized copy of the silent locus determining the opposite mating type. Because the change involves the removal of one gene from the active "slot" and its replacement by another, this mechanism is called the *cassette mechanism.* The change is reversible because, although the original gene at the *MAT* locus is discarded, a silent copy remains in the genome. New DNA copies made from the silent genes function as disposable cassettes that will be inserted in alternation into the *MAT* locus, which serves as the "playing head" (Figure 9-59).

Genetic tests suggest that the silent cassettes are maintained in a transcriptionally inactive form by the same mechanism that is responsible for silencing genes located at the ends of the yeast chromosomes (see Figure9-51A): the DNA at a silent locus appears to be packaged into inactive chromatin.

Two Proteins That Repress Each Other's Synthesis Determine the Heritable State of Bacteriophage Lambda 44

The observation that a whole vertebrate or plant can be specified by the genetic information present in a single somatic cell nucleus (see Figure9-1) eliminates the possibility that *irreversible* change in DNA sequence is the major mechanism in the differentiation of higher eucaryotic cells (although such changes are a crucial part of lymphocyte differentiation - discussed in Chapter 23). *Reversible* DNA sequence changes, resembling those just described for *Salmonella* and yeasts, in principle could still be responsible for some of the inherited changes in gene expression observed in higher organisms, but there is currently no evidence that such mechanisms are used.

Other mechanisms that we have touched upon in this chapter, however, are also capable of producing an inherited pattern of gene regulation with discrete stable states. None of these mechanisms is fully understood in any vertebrate system, but studies on bacteriophage lambda have provided insight at the molecular level into a switch that can flip-flop between two stable self-maintaining states, which could be a model for some similar switches that operate in the development of higher eucaryotes.

We mentioned earlier that this bacterial virus can in favorable conditions become integrated into the *E. coli* cell DNA, to be replicated automatically each time the bacterium divides instead of multiplying in the cytoplasm and killing its host. The switch between these two states is mediated by proteins encoded by the bacteriophage genome. The genome contains a total of about 50 genes, which are transcribed in very different patterns in the two states. A virus destined to integrate, for example, must produce the lambda *integrase* protein, which is needed to insert the lambda DNA into the bacterial chromosome, but must repress production of the viral proteins responsible for virus multiplication. Once one transcriptional pattern or the other has been established, it is stably maintained.

We cannot discuss the details of this complex gene regulatory system here, but we outline a few of its general features. At the heart of the system are two gene regulatory proteins synthesized by the virus: the lambda repressor protein (*cI protein*), which we have already encountered, and the cro protein. These proteins repress each other's synthesis, an arrangement giving rise to just two stable states. In state 1 (the *prophage state*) the lambda repressor occupies the operator, blocking the synthesis of cro and also activating its own synthesis. In state 2 (the *lytic state*) the cro protein occupies a different site in the operator, blocking the synthesis of repressor but allowing its own synthesis (Figure9-60). In the prophage state most of the DNA of the stably integrated bacteriophage is not transcribed; in the lytic state this DNA is extensively transcribed, replicated, packaged into new bacteriophage, and released by host cell lysis.

When the host bacteria are growing well, an infecting virus tends to adopt state 1, allowing the DNA of the virus to multiply along with the host chromosome. When the host cell is damaged, an integrated virus converts from state 1 to state 2 in order to multiply in the cell cytoplasm and make a quick exit. This conversion is signaled by bacterial regulatory proteins that inactivate the repressor protein. In the absence of such interference, however, the lambda repressor both turns off production of the cro protein and turns on its own synthesis, and this *positive feedback loop* helps to maintain the prophage state. Positive feedback loops are a feature of many cell memory circuits (Figure9-61).

Bacteriophage lambda illustrates an important general principle: a sophisticated pattern of inherited behavior can be achieved with only a few gene regulatory proteins that reciprocally affect one another's synthesis and activities. We know that variations of this simple strategy are used by eucaryotic cells to establish and maintain heritable patterns of gene transcription. Several gene regulatory proteins that are involved in establishing the *Drosophila* body plan (discussed in Chapter 21), for example, stimulate their own transcription, thereby creating a positive feedback loop that promotes their continued synthesis; at the same time these proteins repress the transcription of genes encoding other important gene regulatory proteins.

Expression of a Critical Gene Regulatory Protein Can Trigger Expression of a Whole Battery of Downstream Genes 45

In general, a combination of multiple gene regulatory proteins, rather than a single protein, determines where and when a gene is transcribed in eucaryotes. But even if control is combinatorial, a single gene regulatory protein can be decisive in switching a cell from one developmental pathway or state of differentiation to another. A striking example comes from experiments on muscle cell differentiation *in vitro*.

A mammalian skeletal muscle cell is typically extremely large and contains many nuclei. It is formed by the fusion of many muscle precursor cells called *myoblasts.* The mature muscle cell is distinguished from other cells by a large number of characteristic proteins, including specific types of actin, myosin, tropomyosin, and troponin (all part of the contractile apparatus), creatine phosphokinase (for the specialized metabolism of muscle cells), and acetylcholine receptors (to make the membrane sensitive to nerve stimulation). In proliferating myoblasts these muscle-specific proteins and their mRNAs are absent or are present in very low concentrations. As myoblasts begin to fuse with one another, the corresponding genes are all switched on coordinately as part of a general transformation of the pattern of gene expression.

This entire program of muscle differentiation can be triggered in cultured skin fibroblasts and certain other cell types by introducing any one of a family of helix-loop-helix proteins - the so-called *myogenic proteins* (MyoD, Myf5, or myogenin, for example) - normally expressed only in muscle cells (Figure9-62). Binding sites for these regulatory proteins can be detected in the regulatory DNA sequences adjacent to many muscle-specific genes. From studies in transgenic mice, it seems likely that MyoD and Myf5 act by turning on myogenin: if the myogenin gene is eliminated by targeted gene disruption, muscle cells fail to differentiate.

It is probable that the fibroblasts and other cell types that are converted to muscle cells by myogenic proteins have already accumulated a number of gene regulatory proteins that can cooperate with the myogenic proteins to switch on muscle-specific genes. In this view it is a specific *combination* of gene regulatory proteins, rather than a single protein, that determines muscle differentiation. This idea is consistent with the finding that some cell types fail to be converted to muscle by myogenin or its relatives; these cells presumably have not accumulated the other gene regulatory proteins required.

As we see next, combinatorial gene control has important implications for both the evolution and the development of multicellular organisms.

Combinatorial Gene Control Is the Norm in Eucaryotes 46

We have already discussed how multiple gene regulatory proteins can act in combination to regulate the expression of an individual gene. But, as the example of the myogenic proteins shows, combinatorial gene control means more than this: not only does each gene have many gene regulatory proteins to control it, but each regulatory protein contributes to the control of many genes. Moreover, although some gene regulatory proteins, like MyoD or myogenin, are specific to a single cell type, more typically production of a given gene regulatory protein is itself switched on in a variety of cell types, at several sites in the body, and at several times in development. This point is illustrated schematically in Figure9-63, which shows how combinatorial gene control makes it possible to generate a great deal of biological complexity with relatively few gene regulatory proteins.

With combinatorial control, a given gene regulatory protein does not necessarily have a single, simply definable function as commander of a particular battery of genes or specifier of a particular cell type. Instead, it may serve many purposes that overlap with those of other gene regulatory proteins. These proteins can be likened to the words of a language: they are used with different meanings in a variety of contexts and rarely alone; it is the well-chosen combination that conveys the information that specifies a gene regulatory event.

A consequence of combinatorial gene control is that the effect of adding a new gene regulatory protein to a cell will depend on the cell's past history, since this history will determine which gene regulatory proteins are already present. Thus during development a cell can accumulate a series of gene regulatory proteins that need not initially alter gene expression. When the final member of the requisite combination of gene regulatory proteins is added, however, the regulatory message is completed, leading to large changes in gene expression. Such a scheme, as we have seen, could explain how the addition of a single regulatory protein to a fibroblast can produce the dramatic transformation of the fibroblast into a muscle cell. It also can account for the important difference, discussed in Chapter 21, between the process of *cell determination,* where a cell becomes committed to a particular developmental fate, and the process of *cell differentiation,* where a committed cell expresses its specialized character. It is an essential feature of this scheme that once a gene regulatory protein has been made, it may act to maintain its own expression, thereby contributing to *cell memory,* which we discuss further below.

Combinatorial gene control also has an important consequence for evolution. Because gene regulatory proteins are not dedicated to a particular circuit or to a particular target gene, a subtle change in one gene regulatory protein can affect the expression pattern of many genes and thereby cause a substantial change in cell behaviors.

An Inactive X Chromosome Is Inherited 47

We saw earlier how gene regulatory proteins can produce heritable patterns of gene expression in both procaryotic and eucaryotic cells. One possible mechanism, based on positive feedback in the control of gene expression, was illustrated in Figure 9-61. An additional mechanism operates only in eucaryotes, where long-range patterns of chromatin structure can be stably inherited. Perhaps the most dramatic example known is the inactivation of one of the two X chromosomes in female mammalian cells.

The X and Y chromosomes are the *sex chromosomes* of mammals: female cells contain two X chromosomes, while male cells contain one X and one Y chromosome. Presumably because a double dose of X-chromosome products would be lethal, the female cells have evolved a mechanism for permanently inactivating one of the two X chromosomes in each cell. In mice this occurs between the third and the sixth day of development, when, at random, one or other of the two X chromosomes in each cell becomes highly condensed into heterochromatin. This chromosome is seen in the light microscope during interphase as a distinct structure known as a *Barr body,* located near the nuclear membrane, and it replicates late in S phase. Most of its DNA is not transcribed. Because the inactive state of this X chromosome is faithfully inherited, every female is a mosaic composed of a mixture of clonal groups of cells in which only the paternally inherited X chromosome (X_p) is active and a roughly equal number of clonal groups of cells in which only the maternally inherited X chromosome (X_m) is active. In general, the cells expressing X_p and those expressing X_m are distributed in small clusters in the adult animal, reflecting the tendency of sister cells to remain close neighbors during the later stages of embryonic development and growth (Figure 9-64).

The process that forms the condensed chromatin (the heterochromatin) in an X chromosome tends to spread continuously along the chromosome. This can be seen in studies with mutant animals in which one of the X chromosomes has become joined to a portion of an *autosome* (a nonsex chromosome). In such hybrid chromosomes regions of the autosome adjacent to an inactivated X chromosome are often condensed into heterochromatin, causing the genes they contain to be inactivated in a heritable way. This suggests that X-chromosome inactivation occurs by a cooperative process that can be thought of as a chromatin "crystallization" event that spreads linearly along the DNA from a nucleation site on the X chromosome. In fact, a unique *inactivation center* has been located genetically on the X chromosome: broken fragments of X chromosome do not undergo inactivation unless they include this center.

Once the condensed chromatin structure is established on an X chromosome, some unknown process causes the structure to be faithfully inherited during all subsequent replications of the DNA. The change is not absolutely permanent, however, as the condensed X chromosome is reactivated in the formation of germ cells in the female.

Drosophila and Yeast Genes Can Also Be Inactivated by Heritable Features of Chromatin Structure 48

Earlier we discussed two examples of *position effects* on gene expression - one in *Drosophila* and one in yeast - that seem in many ways to be analogous to X-chromosome inactivation (see Figure 9-51). In both cases a specifically condensed form of chromatin prevents the expression of genes, and in both cases the condensed state of chromatin is heritable.

In flies with chromosomal rearrangements, breaking and rejoining events that place the middle of a region of heterochromatin next to a region of normal chromatin (*euchromatin*) tend to inactivate the nearby euchromatic genes. The situation is analogous to fusing a mammalian autosome to an inactive X chromosome, as just described, and the inactivation events are similarly patterned: the zone of inactivation spreads from the chromosome breakpoint to involve one or more adjacent genes. Moreover, while the extent of the spreading effect is different in different cells, the inactivated zone established in an embryonic cell is stably inherited by all of the cell's progeny (Figure9-65). The example of position effect in yeast described previously in Figure9-51 also shares some of the features of X-chromosome inactivation, including the spreading effect and the heritability of the condensed chromatin state.

It has not yet been proved that X-chromosome inactivation and the position effects in flies and yeast all occur by related mechanisms. Nevertheless, the parallels are striking. The recent identification and cloning of several *Drosophila* and yeast genes required for the position effects have provided an experimental entry point for exploring the molecular mechanisms involved. Figure9-66 shows one hypothetical scheme that could, in principle, account for both the spreading effect and the heritable nature of the condensed chromatin state.

Regardless of its molecular basis, the packing of selected regions of the genome into condensed chromatin is a type of genetic

regulatory mechanism that is not available to bacteria. The crucial feature of this uniquely eucaryotic form of gene regulation is the storing of the stable memory of gene states in an inherited chromatin structure rather than in a stable feedback loop of self-regulating gene regulatory proteins that can diffuse from place to place in the nucleus. Whether mechanisms of this type operate only to inactivate large regions of chromosomes or whether they can also operate at the level of one or a few genes is not known.

The Pattern of DNA Methylation Can Be Inherited When Vertebrate Cells Divide 49

The nucleotides in DNA can be covalently modified, and in vertebrate cells the methylation of cytosine seems to provide an important mechanism for distinguishing genes that are active from those that are not. The covalently modified *5-methylcytosine (5-methyl C)* has the same relation to cytosine that thymine has to uracil and likewise has no effect on base-pairing (Figure9-67). The methylation in vertebrate DNA is restricted to cytosine (C) nucleotides in the sequence CG, which is base-paired to exactly the same sequence (in opposite orientation) on the other strand of the DNA helix. Consequently, a simple mechanism permits the existing pattern of DNA methylation to be inherited directly by the daughter DNA strands. An enzyme called *maintenance methylase* acts preferentially on those CG sequences that are base-paired with a CG sequence that is *already* methylated. As a result, the pattern of DNA methylation on the parental DNA strand will act as a template for the methylation of the daughter DNA strand, causing this pattern to be inherited directly following DNA replication (Figure9-68).

Bacteria produce enzymes that are useful for studying methylation in vertebrate cells. They use the methylation of either an A or a C at a specific site to protect themselves from the action of their own restriction nucleases. The restriction nuclease HpaII, for example, cuts the sequence CCGG but fails to cleave it if the central C is methylated. Thus the susceptibility of a DNA molecule to cleavage by HpaII can be used to detect whether CG sequences at specific DNA sites are methylated. The inheritance of methylation patterns can be studied in vertebrate cells in culture by first using bacterial methylating enzymes to introduce methyl groups on cytosines and then using bacterial restriction nucleases to follow the inheritance of these groups. The enzyme used to introduce 5-methyl C bases into specific CG sequences is the HpaII-methylase that normally protects the bacterium against its own HpaII restriction nuclease. If this enzyme is used to methylate the central C in the sequence CCGG on a cloned DNA molecule that is introduced into cultured vertebrate cells, the maintenance methylase can be shown to work as expected: each individual methylated CG is generally retained through many cell divisions, whereas unmethylated CG sequences remain unmethylated.

The maintenance methylase explains the automatic inheritance of 5-methyl C nucleotides, but since it normally does not methylate fully unmethylated DNA, it leaves unanswered the question of how the methyl group is first added in a vertebrate organism. If a fully unmethylated DNA molecule is injected into a fertilized mouse egg, methyl groups will be added to nearly every CG site (an important exception will be described below). This is presumed to reflect the presence of a novel *establishment methylase* activity in the egg. As we shall see, *de novo* methylation can also occur during the differentiation of specialized cell types, although it is not known how it occurs.

DNA Methylation Reinforces Developmental Decisions in Vertebrate Cells 50

Although DNA methylation was once proposed to play a dominant part in generating different mammalian cell types, it is now viewed as having a more subtle role. In some invertebrates, including *Drosophila,* DNA methylation does not occur, yet the control of gene expression and the diversification of cell types appear to be similar in *Drosophila* and vertebrates. Several observations are consistent with the idea that DNA methylation in vertebrates is associated with gene inactivation but that it usually only reinforces decisions that are first brought about by other mechanisms. Thus tests with the HpaII restriction nuclease indicate that in general the DNA of inactive genes is more heavily methylated than that of active genes. When an inactive gene that contains methylated DNA is turned on during the course of normal development, however, it generally loses most of its methyl groups only after the gene has been activated. Conversely, the female X chromosome, discussed above, is first condensed and inactivated and only later acquires an increased level of methylation on some of its genes.

What, then, does methylation do, and why is it useful to the organism? There are at least two important clues. First, the DNA corresponding to a muscle-specific actin gene can be prepared in both its fully methylated and its fully unmethylated form. When these two versions of the gene are introduced into cultured muscle cells, both are transcribed at the same high rate. When, however, they are introduced into fibroblasts, which normally do not transcribe the gene, the unmethylated gene is transcribed at a low rate, whereas neither the exogenously added methylated gene nor the endogenous gene of the fibroblast (which is also methylated) is transcribed at all. Second, biochemical experiments have identified a vertebrate protein that binds tightly to DNA that contains clustered 5-methyl C nucleotides. The binding of this protein is thought to package the methylated DNA in a way that makes it unusually resistant to the transcriptional activation machinery. These two observations suggest that DNA

methylation is used in vertebrates mainly to ensure that once a gene is turned off, it stays completely off (Figure 9-69).

Experiments designed to test whether a DNA sequence that is transcribed at high levels in one vertebrate cell type is transcribed at all in another have demonstrated that rates of gene transcription can differ between two cell types by a factor of more than 10^6. Thus unexpressed vertebrate genes are much less "leaky" in terms of transcription than are unexpressed genes in bacteria, in which the largest known differences in transcription rates between expressed and unexpressed gene states are about 1000-fold. DNA methylation of unexpressed vertebrate genes may account for at least part of this difference. In addition, as we discuss next, DNA methylation is required for at least one special type of cellular memory.

Genomic Imprinting Requires DNA Methylation 51

Mammalian cells are diploid, containing one set of genes inherited from the father and one set from the mother. In a few cases the expression of a gene has been found to depend on whether it is inherited from the mother or the father. This phenomenon is called genomic imprinting. Although not originally discovered in this way, genomic imprinting has been dramatically illustrated in experiments in transgenic mice. It is possible, for example, to make transgenic mice in which one of the two normal copies of the gene coding for *insulinlike growth factor-2 (IGF-2)* has been inactivated by mutation. These heterozygous mice develop normally if it is the maternally derived *Igf-2* gene that is defective, whereas if the paternally derived *Igf-2* gene is defective, they are stunted, growing to less than half the size of normal mice. Further analysis of these and normal mice provided an explanation. In both the transgenic and the wild-type mice only the paternally derived *Igf-2* gene is transcribed, while the maternally derived gene is silent; the maternally derived gene in this case is said to be *imprinted.*

Although the mechanism of imprinting is uncertain, it seems very likely that DNA methylation is involved. Thus, in transgenic mice defective in the maintenance methylase, the imprinting of the maternal *Igf-2* gene does not occur, implying that the mechanism that distinguishes between the paternal and maternal copies of the *Igf-2* gene requires DNA methylation. Interestingly, the mice lacking the maintenance methylase die as young embryos. This could result from defective imprinting, but it is also conceivable that a failure to reinforce developmental decisions by methylation is the primary defect, leading to leaky transcription of the many thousands of genes that are normally turned off in each vertebrate cell.

CG-rich Islands Are Associated with About 40,000 Genes in Mammals 52

Because of the way DNA repair enzymes work, methylated C nucleotides in the genome tend to be eliminated in the course of evolution. Accidental deamination of an unmethylated C gives rise to U, which is not normally present in DNA and thus is recognized easily by the DNA repair enzyme uracil DNA glycosylase, excised, and then replaced with a C (discussed in Chapter 6). But accidental deamination of a 5-methyl C cannot be repaired in this way, for the deamination product is a T and so indistinguishable from the other, nonmutant T nucleotides in the DNA. Although a special repair system exists to remove these mutant Ts (see p. 250), many of the deaminations escape detection, so that those C nucleotides in the genome that are methylated tend to mutate to T over evolutionary time.

During the course of evolution, more than three out of every four CGs have been lost in this way, leaving vertebrates with a remarkable deficiency of this dinucleotide. The CG sequences that remain are very unevenly distributed in the genome; they are present at 10 to 20 times their average density in selected regions, called CG islands, that are 1000 to 2000 nucleotide pairs long. These islands, with some important exceptions, seem to remain unmethylated in all cell types. They are thought to surround the promoters of the so-called *housekeeping genes*those genes that code for the many proteins that are essential for cell viability and are therefore expressed in most cells (Figure 9-70). In addition, many *tissue-specific genes,* which code for proteins needed only in selected types of cells, are also associated with CG islands.

The distribution of CG islands can be explained if we assume that CG methylation was adopted in vertebrates as a way of hindering the initiation of transcription in inactive segments of the genome (Figure 9-71). In the germ line of vertebrates - the cell lineage giving rise to eggs and sperm - most of the genome is inactive and methylated. Over long periods of evolutionary time, the methylated CG sequences in these inactive regions have presumably been lost through accidental deamination events that were not correctly repaired. The CG sequences in the regions surrounding the promoters of many genes, however, including all housekeeping genes, are kept demethylated in cells of the germ line, and so they can be readily repaired after spontaneous deamination events. Such regions are preserved as CG islands.

The mammalian genome (about 3×10^9 nucleotide pairs) contains an estimated 40,000 CG islands. Most of the islands mark the

5' ends of a transcription unit and thus, presumably, a gene. It is possible to clone specifically the DNA surrounding the CG islands, and this technique provides a convenient way of finding new genes.

Summary

The many types of cells in animals and plants are created largely through mechanisms that cause different genes to be transcribed in different cells. Since many specialized animal cells can maintain their unique character when grown in culture, the gene regulatory mechanisms involved in creating them must be stable once established and heritable when the cell divides, endowing the cell with a memory of its developmental history. Procaryotes and yeasts provide unusually accessible model systems in which to study gene regulatory mechanisms, some of which may be relevant to the creation of specialized cell types in higher eucaryotes. One such mechanism involves a competitive interaction between two (or more) gene regulatory proteins, each of which inhibits the synthesis of the other; this can create a flip-flop switch that switches a cell between two alternative patterns of gene expression. Direct or indirect positive feedback loops, which enable gene regulatory proteins to perpetuate their own synthesis, provide a general mechanism for cell memory.

In eucaryotes gene transcription is generally controlled by combinations of gene regulatory proteins. It is thought that each type of cell in a higher eucaryotic organism contains a specific combination of gene regulatory proteins that ensures the expression of only those genes appropriate to that type of cell. A given gene regulatory protein may be expressed in a variety of circumstances and typically is involved in the regulation of many genes.

In addition to diffusible gene regulatory proteins, inherited states of chromatin condensation are also utilized by eucaryotic cells to regulate gene expression. In vertebrates DNA methylation also plays a part, mainly as a device to reinforce decisions about gene expression that are made initially by other mechanisms.
Figure 9-57. Switching gene expression by DNA inversion in bacteria. Alternating transcription of two flagellin genes in a *Salmonella* bacterium is caused by a simple site-specific recombination event that inverts a small DNA segment containing a promoter that in one orientation (A) activates transcription of the H2 flagellin gene as well as a repressor protein that blocks the expression of the H1 flagellin gene. When the promoter is inverted, it no longer turns on H2 or the repressor, and the H1 gene, which is thereby released from repression, is expressed instead (B). The recombination mechanism is activated only rarely (about once every 10^5 cell divisions). Therefore, the production of one or other flagellin tends to be faithfully inherited in each

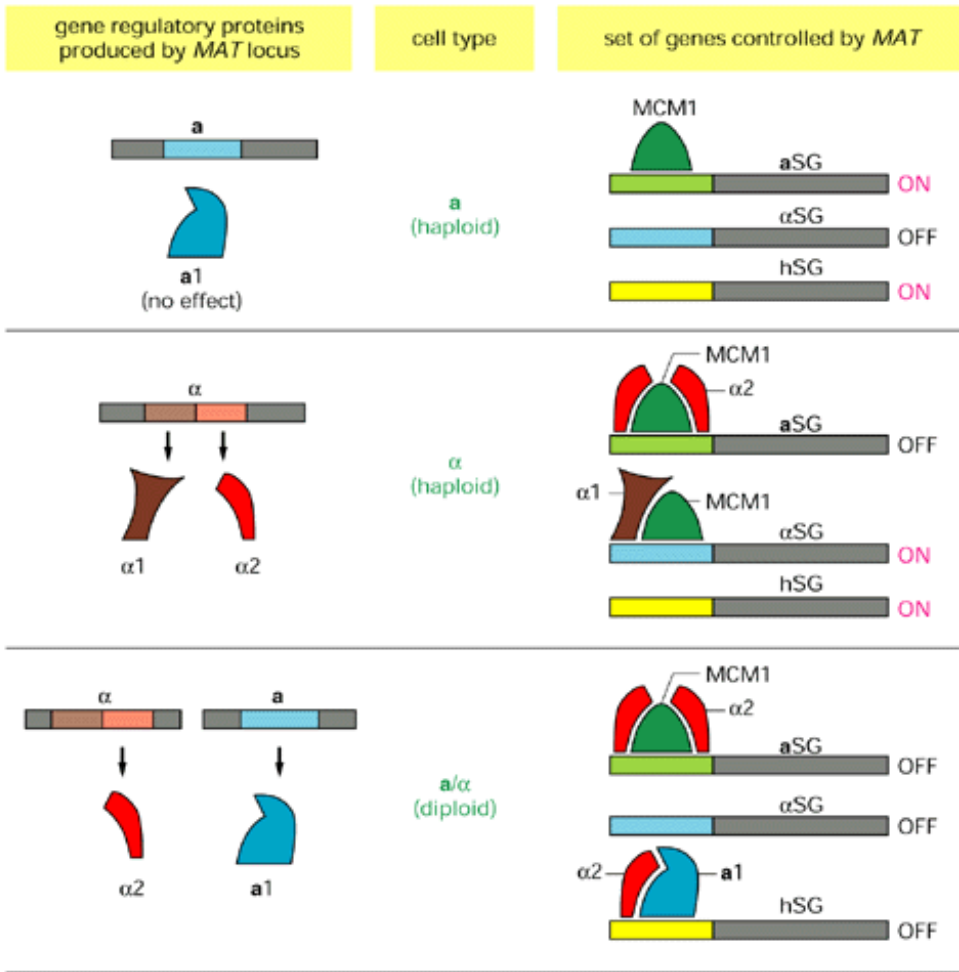
clone of cells.


Figure 9-58. Control of cell type in yeasts. Yeast cell type is determined by three gene regulatory proteins (a1, a2, and **a**1) produced by the *MAT* locus. Different sets of genes are transcribed in haploid cells of type **a**, in haploid cells of type a, and in diploid cells (type **a**/a). The haploid cells express a set of haploid-specific genes (hSG) and either a set of a-specific genes (aSG) or a set of **a**-specific genes (**a**SG). The diploid cells express none of these genes. The a1, a2, and **a**1 proteins control many target genes in each type of cell by binding, in various combinations, to specific regulatory sequences upstream of these genes. Note that the a1 protein is a gene activator protein, whereas the a2 protein is a gene repressor protein, and both work in combination with a ubiquitous gene regulatory protein called MCM1. In the diploid cell type a2 and **a**1 form a heterodimer that turns off a different set of genes (including the gene encoding the a1 activator protein) from that turned off by the a2 and MCM1 proteins. This relatively simple system of gene regulatory proteins is an example of combinatorial control of gene expression (see Figure 9-38). The **a**1 and a2 proteins both recognize their DNA-binding sites by using the homeodomain motif (see Figure9-13).
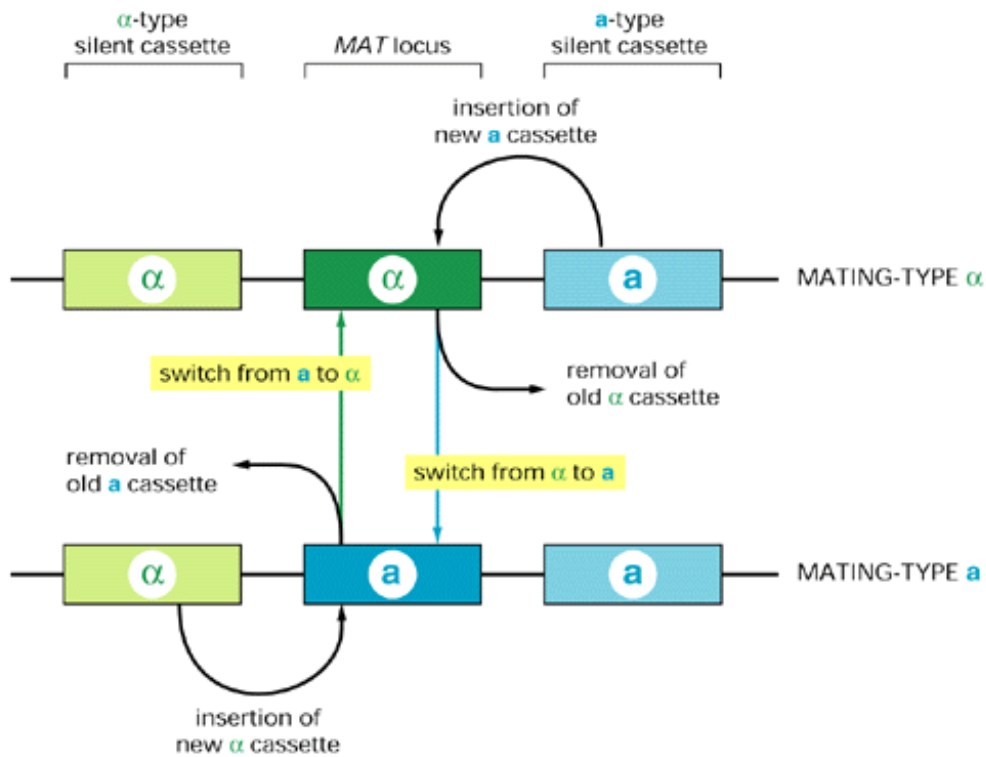

Figure 9-59. Cassette model of yeast mating-type switching. Cassette switching occurs by a gene-conversion process that involves a specialized enzyme that makes a double-stranded cut at a specific DNA sequence in the *MAT* locus. The DNA near the cut is then excised and replaced by a copy of the silent cassette of opposite mating type.
Figure 9-60. A simplified version of the regulatory system that determines the mode of growth of bacteriophage lambda in the *E. coli* host cell.. In stable state 1 (the prophage state) the bacteriophage synthesizes a repressor protein, which activates its own synthesis and turns off the synthesis of several other bacteriophage proteins, including the cro protein. In stable state 2 (the lytic state) the bacteriophage synthesizes the cro protein, which turns off the synthesis of the repressor protein, so that many bacteriophage proteins are made and the viral DNA replicates freely in the *E. coli* cell, eventually producing many new bacteriophage particles and killing the cell. This example shows how two gene regulatory proteins can be combined in a circuit to produce two heritable states. As shown in Figure 9-11, both the lambda repressor and the cro protein recognize the operator through a helix-turn-helix motif.
Figure 9-61. Schematic diagram showing how a positive feedback loop can create cell memory. Protein A is a gene regulatory protein that activates its own transcription. All of the descendants of the original cell will therefore "remember" that the progenitor cell had experienced a transient signal that initiated the production of the protein.

Figure 9-62. The effect of expressing the MyoD protein in fibroblasts. As shown in this immuno-fluorescence micrograph, skin fibroblasts from a chick embryo have been converted to muscle cells by the experimentally induced expression of the *myoD* gene. The fibroblasts were grown in culture and transfected three days earlier with a recombinant DNA plasmid containing the *myoD* coding sequence. Although only a few percent of the fibroblasts take up the DNA and produce the MyoD protein, these cells have fused to form elongated myotubes, which are stained here with an antibody that detects a muscle-specific protein. The stained cells are intermixed with a confluent layer of fibroblasts, whose nuclei are barely visible in this micrograph. Control

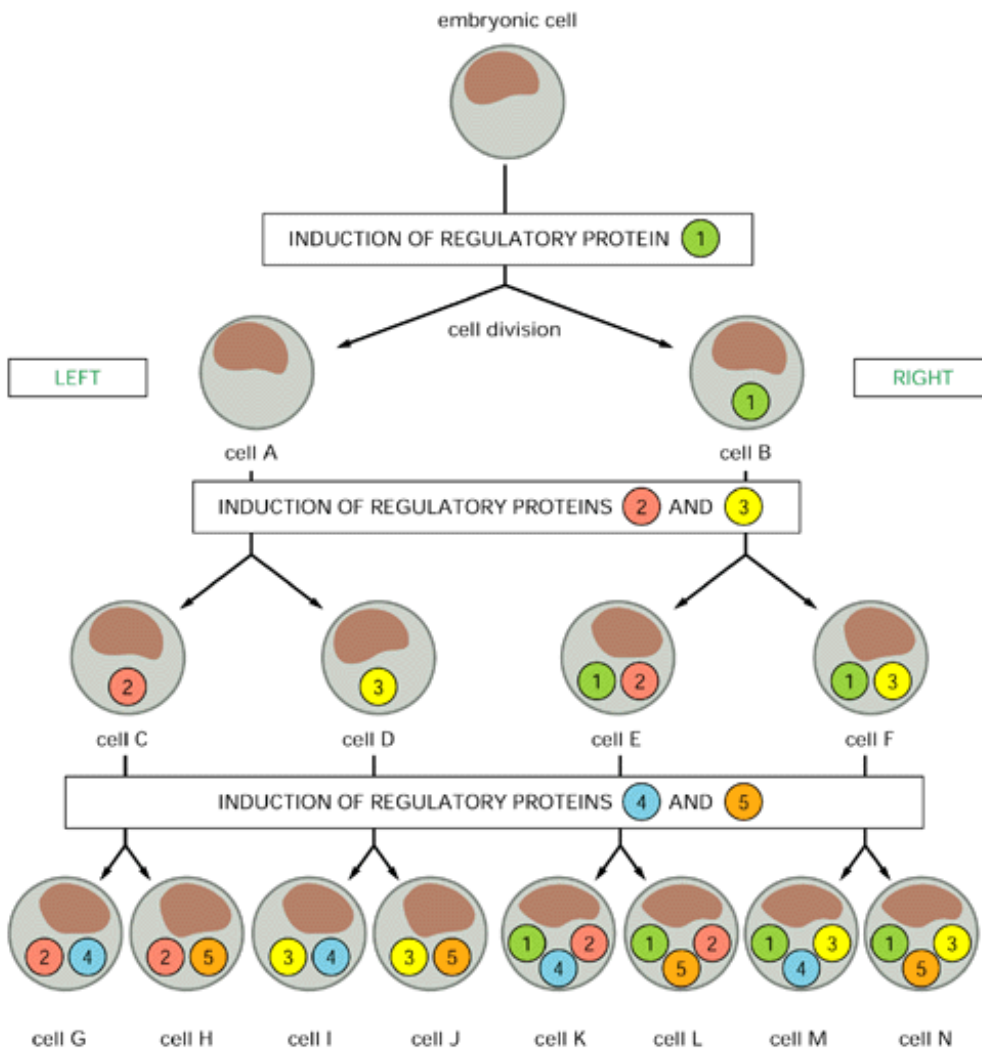
cultures transfected with another plasmid contain no muscle cells. (Courtesy of Stephen Tapscott and Harold Weintraub.)


Figure 9-63. The importance of combinatorial gene control for development. A highly schematic scheme illustrating how combinations of a few gene regulatory proteins can generate many cell types during development. In this simple scheme a "decision" to make one of a pair of different gene regulatory proteins (shown as numbered circles) is made after each cell division. Sensing its relative position in the embryo, the daughter cell toward the left side of the embryo is always induced to synthesize the even-numbered protein of each pair, while the daughter cell toward the right side of the embryo is induced to synthesize the odd-numbered protein. The production of each gene regulatory protein is assumed to be self-perpetuating (thereby contributing to cell memory). Therefore, the cells in the enlarging clone contain an increasing number of regulatory proteins. Note that, in this purely hypothetical example, eight cell types (G through N) have been created with 5 different gene regulatory proteins. With continuation of such a scheme, more than 10,000 cell types could have been specified by only 25 different gene regulatory proteins.

(A)

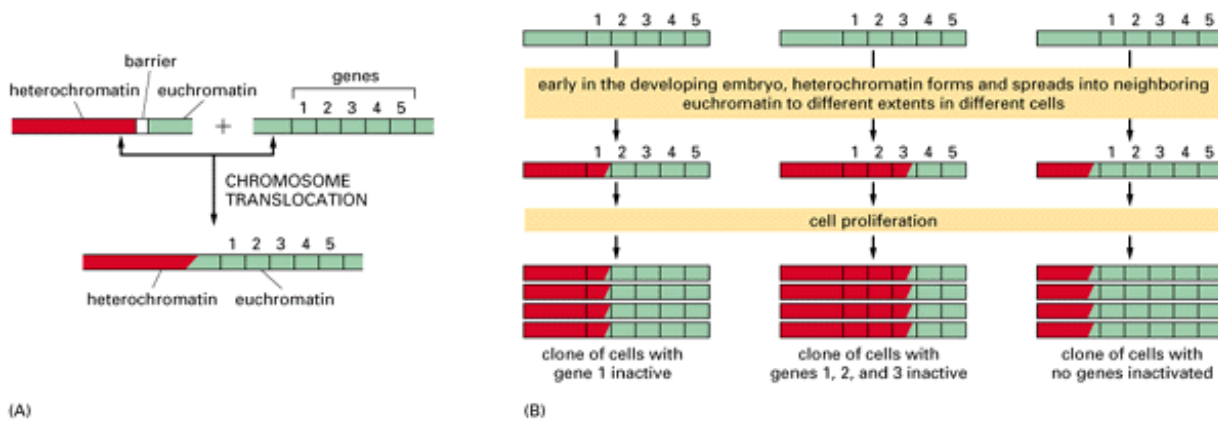
(B)


Figure 9-65. Position-effect variegation in *Drosophila*. (A) Heterochromatin (*red*) is normally prevented from spreading into adjacent regions of euchromatin (*green*) by special barrier sequences of unknown nature. In flies that inherit certain chromosomal translocations, however, this barrier is no longer present. (B) During the early development of such flies, the heterochromatin now spreads into neighboring chromosomal DNA, proceeding for different distances in different cells. The spreading soon stops, but the established pattern of heterochromatin is inherited, so that large clones of progeny cells are produced that have the same neighboring genes condensed into heterochromatin and thereby inactivated (hence the "variegated" appearance of some of these flies; see Figure 9-51B). This phenomenon shares many features with X-chromosome inactivation in mammals.
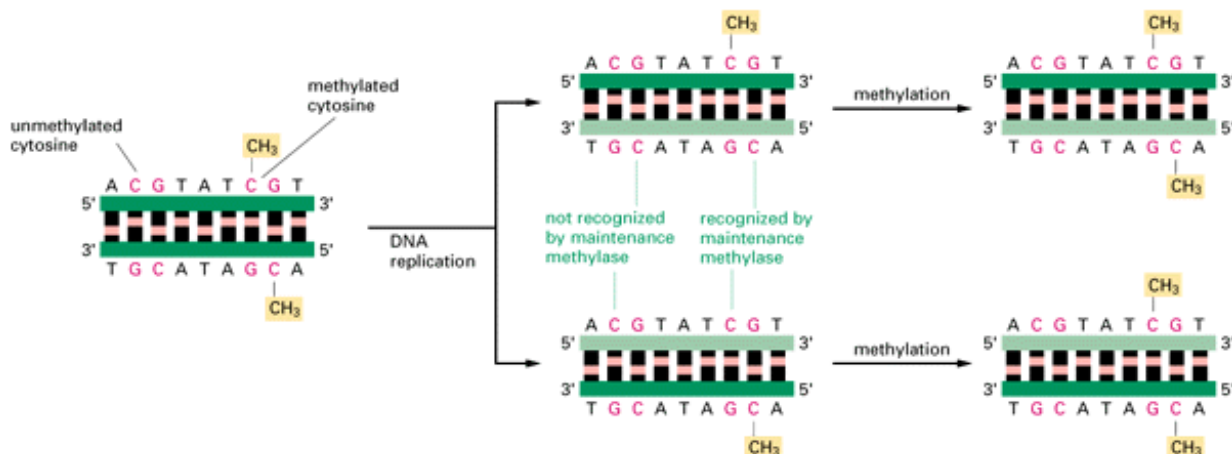
Figure 9-66. A general scheme that permits the direct inheritance of states of gene expression during DNA replication. In this hypothetical model, portions of a cooperatively bound cluster of chromosomal proteins are transferred directly from the parental DNA helix (*top left*) to both daughter helices. The inherited cluster then causes each of the daughter DNA helices to bind additional copies of the same proteins. Because the binding is cooperative, DNA synthesized from an identical parental DNA helix that lacks the bound proteins (*top right*) will remain free of them. If the bound proteins turn off gene transcription, then the inactive gene state will be directly inherited, as illustrated. If the cooperative protein binding requires specific DNA sequences, these events will be limited to specific gene control regions; if the binding can be propagated all along the chromosome, however, it could account for the spreading effect associated with the heritable chromatin states discussed in the text.
Figure 9-67. Formation of 5-methylcytosine occurs by methylation of a cytosine base in the DNA double helix. In vertebrates this event is confined to selected cytosine (C) nucleotides located in the sequence CG.


Figure 9-68. How DNA methylation patterns are faithfully inherited. In vertebrate DNAs a large fraction of the cytosine nucleotides in the sequence CG are methylated (see Figure 9-67). Because of the existence of a methyl-directed methylating

enzyme (the maintenance methylase), once a pattern of DNA methylation is established, each site of methylation is inherited in the progeny DNA, as shown. This means that changes in DNA methylation patterns will be perpetuated in all of the progeny of a cell.

Posttranscriptional Controls

Introduction

Although controls on the initiation of gene transcription are the predominant form of regulation for most genes, other controls can act later in the pathway from RNA to protein to modulate the amount of gene product that is made. Although these posttranscriptional controls, which operate after RNA polymerase has bound to the gene's promoter and begun RNA synthesis, are less common than *transcriptional control,* for many genes they are crucial. It seems that every step in gene expression that could be controlled in principle is likely to be regulated under some circumstances for some genes.

We consider the varieties of posttranscriptional regulation in temporal order, according to the sequence of events that might be experienced by an RNA molecule after its transcription has begun (Figure9-72).

Transcription Attenuation Causes the Premature Termination of Some RNA Molecules 53

In bacteria the expression of certain genes is inhibited by premature termination of transcription, a phenomenon called transcription attenuation. In some of these cases the nascent RNA chain adopts a structure that causes it to interact with the RNA polymerase in such a way as to abort its transcription. When the gene product is required, regulatory proteins bind to the nascent RNA chain and interfere with attenuation, allowing the transcription of a complete RNA molecule.

In eucaryotes transcription attenuation can occur by a number of distinct mechanisms. In both adenovirus and HIV (the human AIDS virus), for example, the proteins that assemble at the promoter seem to determine whether or not the polymerase will be able to pass through specific sites of attenuation downstream. These proteins can differ from one cell type to the next, and the cell can control the degree of attenuation for particular genes.

Alternative RNA Splicing Can Produce Different Forms of a Protein from the Same Gene 54

As discussed in Chapter 8, many genes are first transcribed as long mRNA precursors that are then shortened by a series of processing steps to produce the mature mRNA molecule. One of these steps is *RNA splicing,* in which the intron sequences are removed from the mRNA precursor. Often a cell can splice the primary transcript in different ways and thereby make different polypeptide chains from the same gene—a process called alternative RNA splicing (Figure 9-73). A substantial proportion of higher eucaryotic genes produce multiple proteins in this way. When different splicing possibilities exist at several positions in the transcript, a single gene can produce dozens of different proteins. Usually, however, the splice alternatives are more limited, and only a few kinds of proteins are synthesized from each transcription unit.

In some cases alternative RNA splicing occurs because there is an "intron sequence ambiguity": the standard spliceosome mechanism for removing intron sequences (discussed in Chapter 8) is unable to distinguish cleanly between two or more alternative pairings of 5' and 3' splice sites, so that different choices are made haphazardly on different occasions. Where such *constitutive alternative splicing* occurs, several versions of the protein encoded by the gene are made in all cells in which the gene is expressed.

In many cases, however, alternative RNA splicing is *regulated* rather than constitutive. In the simplest examples regulated splicing is used to switch from the production of a nonfunctional protein to the production of a functional one. The transposase that catalyzes the transposition of the *Drosophila* P element, for example, is produced in a functional form in germ cells and a nonfunctional form in somatic cells of the fly, allowing the P element to spread throughout the genome of the fly without causing damage in somatic cells. The difference in transposon activity has been traced to the presence of an intron sequence in the transposase RNA that is removed only in germ cells.

RNA splicing can be regulated either negatively, by a regulatory molecule that prevents the splicing machinery from gaining access to a particular splice site on the RNA, or positively, by a regulatory molecule that directs the splicing machinery to an otherwise overlooked splice site (Figure9-74). In the case of the *Drosophila* transposase, the key splicing event is blocked in somatic cells by negative regulation.

In addition to switching from the production of a functional protein to the production of a nonfunctional one, the regulation of RNA splicing can generate different versions of a protein in different cell types, according to the needs of the cell. The tyrosine protein kinase encoded by the *src* proto-oncogene, for example, is produced in a specialized form in nerve cells by this mechanism (Figure 9-75). Cell-type-specific forms of many other proteins are produced in the same way.

Sex Determination in *Drosophila* Depends on a Regulated Series of RNA Splicing Events 55

In *Drosophila* the primary signal for determining whether the fly develops as a male or female is the X chromosome/autosome ratio. Individuals with an X chromosome/autosome ratio of 1 (normally two X chromosomes and two sets of autosomes) develop as females, while those with a ratio of 0.5 (normally one X chromosome and two sets of autosomes) develop as males. This ratio is somehow assessed early in development and is remembered by each cell thereafter. Three crucial gene products are involved in transmitting information about this ratio to the many other genes that specify male and female characteristics (Figure 9-76). As explained in Figure9-77, sex determination in *Drosophila* depends on a cascade of regulated RNA splicing events that involves these three gene products.

Drosophila sex determination provides the best-understood example of a regulatory cascade based on RNA splicing. It is not clear why the fly should use this strategy. Other organisms (the nematode, for example) use an entirely different scheme for sex

determination - one based on transcriptional and translational controls. Moreover, the *Drosophila* male-determination pathway requires that a number of nonfunctional RNA molecules be continually produced, which seems unnecessarily wasteful. One speculation is that this RNA-splicing cascade is an ancient control device, left over from a stage of evolution where RNA was the predominant biological molecule and controls of gene expression had to be based almost entirely on RNA-RNA interactions.

A Change in the Site of RNA Transcript Cleavage and Poly-A Addition Can Change the Carboxyl Terminus of a Protein 56

In eucaryotes the 3' end of an mRNA molecule is not determined by the termination of RNA synthesis by the RNA polymerase as it is in bacteria. Instead, it is determined by an RNA cleavage reaction that is catalyzed by additional factors while the transcript is elongating (see Figure8-49). A cell can control the site of this cleavage so as to change the carboxyl terminus of the resultant protein (which is encoded by the 3' end of the mRNA).

A well-studied example is the switch from the synthesis of membrane-bound to secreted antibody molecules that occurs during the development of B lymphocytes. Early in the life history of a B lymphocyte, the antibody it produces is anchored in the plasma membrane, where it serves as a receptor for antigen. Antigen stimulation causes these cells to multiply and to start secreting their antibody. The secreted form of the antibody is identical to the membrane-bound form except at the extreme carboxyl terminus. In this part of the protein the membrane-bound form has a long string of hydrophobic amino acids that traverses the lipid bilayer of the membrane, whereas the secreted form has a much shorter string of hydrophilic amino acids. The switch from membrane-bound to secreted antibody therefore requires a different nucleotide sequence at the 3' end of the mRNA; this difference is generated through a change in the length of the primary RNA transcript caused by a change in the site of RNA cleavage, as described in Figure 9-78.

The Definition of a Gene Has Had to Be Modified Since the Discovery of Alternative RNA Splicing 57

The discovery that eucaryotic genes usually contain introns and that their coding sequences can be put together in more than one way raised new questions about the definition of a gene. A gene was first clearly defined in molecular terms in the early 1940s from work on the biochemical genetics of the fungus *Neurospora*. Until then, a gene had been defined operationally as a region of the genome that segregates as a single unit during meiosis and gives rise to a definable phenotypic trait, such as a red or a white eye in *Drosophila* or a round or wrinkled seed in peas. The work on *Neurospora* showed that most genes correspond to a region of the genome that directs the synthesis of a single enzyme. This led to the hypothesis that one gene encodes one polypeptide chain. The hypothesis proved fruitful for subsequent research; and, as more was learned about the mechanism of gene expression in the 1960s, a gene became identified as that stretch of DNA that was transcribed into the RNA coding for a single polypeptide chain (or a single structural RNA such as a tRNA or an rRNA molecule). The discovery of split genes in the late 1970s could be readily accommodated by the original definition of a gene, provided that a single polypeptide chain was specified by the RNA transcribed from any one DNA sequence. But it is now clear that many DNA sequences in higher eucaryotic cells produce two or more distinct proteins by means of alternative RNA splicing. How then is a gene to be defined?

In those relatively rare cases in which two very different eucaryotic proteins are produced from a single transcription unit, the two proteins are considered to be produced by distinct genes that overlap on the chromosome. It seems unnecessarily complex, however, to consider most of the protein variants produced by alternative RNA splicing as being derived from overlapping genes. A more sensible alternative is to modify the original definition to include as a gene any DNA sequence that is transcribed as a single unit and encodes one set of closely related polypeptide chains (*protein isoforms*). This definition of a gene also accommodates those DNA sequences that encode protein variants produced by posttranscriptional processes other than RNA splicing, such as ribosomal frameshifting and RNA editing, which we discuss later.

RNA Transport from the Nucleus Can Be Regulated 58

An average primary RNA transcript seems to be at most 10 times longer than the mature mRNA molecule generated from it by RNA splicing. Yet it has been estimated that only about one-twentieth of the total mass of RNA made ever leaves the nucleus. It seems, therefore, that a substantial fraction of the primary transcripts (perhaps half) may be completely degraded in the nucleus without ever generating an RNA molecule that reaches the cytoplasm. The discarded RNAs may consist of sequences that are never made into an mRNA molecule; on the other hand, some may represent potential mRNA molecules that are functional in some cell types but in others fail to get delivered to the cytoplasm. This might be either because they are selectively targeted for intranuclear degradation or because their exit from the nucleus is selectively blocked.

Although there is very little solid evidence for either form of control, each of them remains a real possibility. In particular, RNA export through the nuclear pores is an active process, and for most RNAs it requires a specific nucleotide cap at the 5' end of the RNA molecule and a poly-A tail at the 3' end (discussed in Chapter 8). A requirement of this type makes sense, since it keeps junk RNA fragments (such as the intron sequences removed by RNA splicing) out of the cytosol. But having the proper types of ends is not enough for transport: each mRNA precursor molecule remains tethered to sites inside the nucleus until all of the spliceosome components have dissociated from it (see Figure8-54). Therefore, any mechanism that prevents the completion of RNA splicing on particular RNA molecules could, in principle, block the exit of those RNAs from the nucleus.

Some mRNAs Are Localized to Specific Regions of the Cytoplasm 59

Once a newly made eucaryotic mRNA molecule has passed through a nuclear pore and entered the cytosol, it encounters ribosomes that translate it into a polypeptide chain. If the mRNA encodes a protein that is destined to be secreted or expressed on the cell surface, it will be directed to the endoplasmic reticulum (ER) by a signal sequence at the protein's amino terminus; the signal sequence will be recognized as soon as it emerges from the ribosome by components of the cell's protein-sorting apparatus. This apparatus then directs the entire complex of ribosome, mRNA, and nascent protein to the membrane of the ER, where the remainder of the polypeptide chain is synthesized, as discussed in Chapter 12. In other cases the entire protein is synthesized by free ribosomes in the cytosol, and signals in the completed polypeptide chain may then direct the protein to other sites in the cell.

In still other cases, however, mRNAs are directed to specific intracellular locations by signals in the mRNA sequence itself, before the sequence has been translated into an amino acid sequence. The signal is typically located in the 3' *untranslated region (UTR)* of the mRNA molecule - a region that extends from the stop codon, which terminates protein synthesis, to the start of the poly-A tail (see Figure 9-78). A striking example is seen in the *Drosophila* egg, where the mRNA encoding the bicoid gene regulatory protein is attached to the cortical cytoskeleton at the anterior tip of the developing egg. When the translation of this mRNA is triggered by fertilization, a gradient of the bicoid protein is generated that plays a crucial part in directing the development of the anterior part of the embryo (shown in Figure 9-39 and discussed in more detail in Chapter 21). Some mRNAs in somatic cells are localized in a similar way. The mRNA that encodes actin, for example, is localized to the actin-filament-rich cell cortex in mam-malian fibroblasts by means of a 3' UTR signal, presumably because it is advantageous for the cell to position its mRNAs close to the sites where the protein produced from the mRNA is required. This form of posttranscriptional gene regulation, where mRNA is specifically localized to one part of the cell, has been recognized only recently, and it is still unclear how many mRNAs are localized in this way. The role of the UTR in localizing mRNAs to a particular region of the cytoplasm is illustrated in Figure 9-79.

RNA Editing Can Change the Meaning of the RNA Message 60

The molecular mechanisms used by cells are a continual source of surprises. An example is the phenomenon of *trans* RNA splicing, which occurs in all transcripts in the trypanosomes (the parasitic protozoa responsible for sleeping sickness). All mRNAs in trypanosomes possess a common 5' capped leader sequence that is transcribed separately and added to the 5' ends of RNA transcripts by splicing of two initially unconnected RNA molecules. *Trans*splicing is also used to add a 5' leader to several mRNAs in nematodes and to combine the separate RNA transcripts that form the coding sequence of some chloroplast and mitochondrial proteins in plant cells. Cutting and pasting between RNA transcripts could speed up the evolution of new proteins, and the few cases where exons are known to be joined in this way are suspected to be evolutionary remnants of a much more extensive process that dominated ancient cells.

Another startling discovery is the process of RNA editing, whereby the nucleotide sequences of RNA transcripts are altered. In this process, discovered in RNA transcripts that code for proteins in the mitochondria of trypanosomes, one or more U nucleotides are inserted (or, less frequently, removed) from selected regions of a transcript, causing major modifications in both the original reading frame and the sequence, thereby changing the meaning of the message. For some genes the editing is so extensive that over half of the nucleotides in the mature mRNA are U nucleotides that were inserted during the editing process. The information that specifies exactly how the initial RNA transcript is to be altered is contained in a set of 40- to 80-nucleotide-long RNA molecules that are separately transcribed. These so-called *guide RNAs* have a 5' end that is complementary in sequence to one end of the region of the transcript to be edited; this is followed by a sequence that specifies the set of nucleotides to be inserted into the transcript and then a continuous run of U nucleotides. The editing mechanism is surprisingly complex, with the U nucleotides at the 3' end of the guide RNA being transferred directly into the transcript, as illustrated in Figure 9-80.

Extensive editing of mRNA sequences has also been found in the mitochondria of many plants, with nearly every mRNA being edited to some extent. In this case, however, bases are changed from C to U in the RNA, without nucleotide insertions or deletions. Often many of the Cs in an mRNA are affected by editing, changing 10% or more of the amino acids that the mRNA encodes.

We can only speculate as to why the mitochondria of trypanosomes and plants make use of such extensive RNA editing. The suggestions that seem most reasonable are based on the premise that mitochondria contain a primitive genetic system. There is evidence that editing is regulated to produce different mRNAs under different conditions, so that RNA editing can be viewed as a primitive way to change the expression of genes. Trypanosomes are extremely ancient single-celled eucaryotes, which diverged very early on from the lineage leading to plants, animals, and yeasts (see Figure1-16). Perhaps, therefore, the extreme version of RNA editing found in their mitochondria is a holdover from very ancient cells, where most catalyses were carried out by RNA molecules rather than by proteins.

RNA editing of a much more limited kind occurs in mammals. The first case discovered involved the *apolipoprotein-B* gene, where RNA editing produces two types of transcripts: in one of these a DNA-encoded C is changed to a U, creating a stop codon that causes a truncated version of this large protein to be made in a tissue-specific manner. In another case a nucleotide change in the middle of an mRNA molecule changes a single amino acid in a transmitter-gated ion channel in the brain, significantly altering the channel's permeability to Ca^{2+}. For apolipoprotein-B the editing is catalyzed in a very straightforward way: a protein binds to a specific sequence in the mRNA and then catalyzes the deamination of a C to a U. It is not known whether the other cases of mammalian and plant RNA editing are protein-mediated in this way or whether, instead, they make use of short RNA templates, as in trypanosomes.

We now turn to controls that operate on the translation of mRNAs into proteins.

Procaryotic and Eucaryotic Cells Use Different Strategies to Specify the Translation Start Site on an mRNA Molecule 61

In bacterial mRNAs a conserved stretch of six nucleotides, the *Shine-Dalgarno sequence,* is always found a few nucleotides upstream of the initiating AUG codon. This sequence forms base pairs with the 16S RNA in the small ribosomal subunit and thereby correctly positions the initiating AUG codon in the ribosome. This interaction makes a major contribution to the efficiency of initiation and provides the bacterial cell with a simple way to regulate protein synthesis. Many translational control mechanisms in procaryotes involve blocking the Shine-Dalgarno sequence, either by covering it with a bound protein or by incorporating it into a base-paired region in the mRNA molecule.

Eucaryotic mRNAs do not contain a Shine-Dalgarno sequence. Instead, the selection of an AUG codon as a translation start site is largely determined by its proximity to the cap at the 5' end of the mRNA molecule, which is the site at which the small ribosomal subunit binds to the mRNA and begins scanning for an initiating AUG codon (discussed in Chapter 6). The nucleotides immediately surrounding the start site in eucaryotic mRNAs also influence the efficiency of AUG recognition during the scanning process. If this recognition site is poor enough, scanning ribosomal subunits will ignore the first AUG codon in the mRNA and skip to the second or third AUG codon instead. This phenomenon, known as "leaky scanning," is a strategy frequently used to produce two or more proteins, differing in their amino termini, from the same mRNA. It allows some genes to produce the same protein with and without a signal sequence attached at its amino terminus, for example, so that the protein is directed to two different compartments in the cell.

Another important difference between eucaryotic and procaryotic translation is that eucaryotic ribosomes dissociate rapidly from the mRNA when translation terminates. Thus reinitiation at an internal AUG codon after translation of a preceding open reading frame is much less efficient in eucaryotes than in procaryotes. Together, these differences - scanning from the 5' cap and a limited ability to reinitiate at internal AUG codons - explain why the vast majority of eucaryotic mRNAs encode only a single protein and why the first AUG codon from the 5' end is usually the functional start site for translation.

A few eucaryotic cell and viral mRNAs initiate translation by an alternative mechanism that involves internal initiation rather than scanning. These mRNAs contain complex nucleotide sequences, called *internal ribosome entry sites,* where ribosomes bind in a cap-independent fashion and start translation at the next AUG codon downstream. The details of this mechanism are not known.

The Phosphorylation of an Initiation Factor Regulates Protein Synthesis 62

Eucaryotic cells decrease their overall rate of protein synthesis in response to a variety of situations, including the deprivation of growth factors, infection by viruses, heat shock, and entry into M phase of the cell cycle. Much of this regulation is thought to involve the initiation factor eIF-2, which is phosphorylated by specific protein kinases to decrease the overall rate of protein synthesis.

The normal function of eIF-2 is outlined in Figure 9-81. This protein forms a complex with GTP and mediates the binding of the methionyl initiator tRNA to the small ribosomal subunit, which then binds to the 5' cap of the mRNA and begins scanning along the mRNA. After an AUG codon is recognized, the bound GTP is hydrolyzed to GDP by the eIF-2 protein, causing a conformational change in the protein and releasing it from the small ribosomal subunit. The large ribosomal subunit then joins the small one to form a complete ribosome that begins protein synthesis.

Because eIF-2 binds very tightly to GDP, a guanine nucleotide releasing protein (see Figure 15-50), designated eIF-2B, is required to cause GDP release so that a new GTP molecule can bind and eIF-2 can be reused (Figure9-82A). The reuse of eIF-2 is inhibited when it is phosphorylated because phosphorylated eIF-2 binds to eIF-2B unusually tightly, preventing the completion of nucleotide exchange. There is more eIF-2 than eIF-2B in cells, and even a fraction of phosphorylated eIF-2 can trap nearly all of the available eIF-2B, thereby preventing the reuse of even the nonphosphorylated eIF-2 and greatly slowing protein synthesis (Figure 9-82B).

When the activity of a general translation factor, such as eIF-2, is reduced by phosphorylation, one might expect that the translation of all mRNAs would be reduced equally. Contrary to this expectation, however, the phosphorylation of eIF-2 can have selective effects, even enhancing the translation of specific mRNAs. This can enable yeast cells, for example, to adapt to starvation for specific nutrients by shutting down the synthesis of all proteins except those that are required for synthesis of the missing nutrients. The details have been worked out for a specific yeast mRNA that encodes a protein called GCN4, a gene regulatory protein that is required for the activation of many genes encoding proteins that are important for amino acid synthesis. The GCN4 protein is produced by a specific activation of the translation of its mRNA following amino acid starvation that is induced when eIF-2 becomes phosphorylated. By a complex mechanism depending on competition between correct and incorrect ("decoy") sites of initiation of translation near the 5' end of the GCN4 mRNA, the reduction of eIF-2 activity actually leads to an increase in the synthesis of the GCN4 protein.

Regulation of the level of eIF-2 is also important in mammalian cells as part of the mechanism by which they can be induced to enter a nonproliferating, resting state (called G_0) in which the rate of protein synthesis is reduced to about one-fifth the rate in proliferating cells (discussed in Chapter 17).

Proteins That Bind to the 5' Leader Region of mRNAs Mediate Negative Translational Control 63

The translation of some mRNA molecules is blocked by specific *translation repressor proteins* that bind near the 5' end of the mRNAs, where translation would otherwise begin. This type of mechanism is called negative translation control (Figure 9-83). It was first discovered in bacteria, where it enables excess ribosomal proteins to repress the translation of their own mRNAs - a form of negative feedback regulation.

In eucaryotic cells a particularly well-studied form of negative translational control allows the synthesis of the intracellular iron storage protein *ferritin* to be increased rapidly if the level of soluble iron atoms in the cytosol rises. The iron regulation depends on a sequence of about 30 nucleotides in the 5' leader of the ferritin mRNA molecule. This *iron-response element* folds into a stem-loop structure that binds a translation repressor protein called *aconitase,* which blocks the translation of any RNA sequence downstream (see Figure 9-83). Aconitase is an iron-binding protein, and exposure of the cell to iron causes it to dissociate from the ferritin mRNA, releasing the block to translation and increasing the production of ferritin by as much as 100-fold.

Gene Expression Can Be Controlled by a Change in mRNA Stability 64

Most mRNAs in a bacterial cell are very unstable, having a half-life of about 3 minutes. Because bacterial mRNAs are both rapidly synthesized and rapidly degraded, a bacterium can adapt quickly to environmental changes.

The mRNAs in eucaryotic cells are more stable. Some, such as that encoding b-globin, have a half-life of more than 10 hours. Others, however, have a half-life of 30 minutes or less. The unstable mRNAs often code for regulatory proteins, such as growth

factors and gene regulatory proteins, whose production levels change rapidly in cells (Figure 9-84). Many of these RNAs are unstable because they contain specific sequences that stimulate their degradation. A long sequence rich in A and U nucleotides in the 3' untranslated region (UTR) of several mRNAs, for example, can, if transferred to other stable mRNAs by recombinant DNA techniques, cause them to be unstable. This AU-rich sequence appears to accelerate mRNA degradation by stimulating the removal of the poly-A tail found at the 3' end of almost all eucaryotic mRNAs. Other unstable mRNAs contain recognition sites in their 3' UTR for specific endonucleases that cleave the mRNA (Figure 9-85).

The stability of an mRNA can be changed in response to extracellular signals. Steroid hormones, for example, affect a cell not only by increasing the transcription of specific genes, but also by increasing the stability of several of the mRNAs encoded by these genes. Conversely, the addition of iron to cells decreases the stability of the mRNA that encodes the receptor protein that binds the iron-transporting protein transferrin, causing less of this receptor to be made. Interestingly, the stability of the transferrin receptor mRNA seems to be modulated by the iron-sensitive RNA-binding protein aconitase, which, as we discussed above, also controls ferritin mRNA translation. Here aconitase binds to the 3' UTR of the transferrin receptor mRNA and causes an increase in receptor production, presumably by inhibiting the function of sequences that otherwise cause rapid degradation of the mRNA. On the addition of iron, aconitase is released from the mRNA, decreasing mRNA stability (Figure 9-86).

Selective mRNA Degradation Is Coupled to Translation 65

The control of mRNA stability in eucaryotic cells is best understood for the mRNAs that encode histones. These mRNAs have a half-life of about 1 hour during the DNA synthesis (S) phase of the cell cycle, when new histones are needed, but become unstable and are degraded within minutes when DNA synthesis stops. If DNA synthesis during S phase is inhibited with a drug, histone mRNAs immediately become unstable, perhaps because the accumulation of free histones in the absence of new DNA for them to bind increases the degradation rate of their mRNAs.

The regulation of histone mRNA stability depends on a short 3' stem-and-loop structure that replaces the poly-A tail present at the 3' end of other mRNAs (see Figure 9-84). A special cleavage reaction, which requires base-pairing to a small RNA in a ribonucleoprotein particle, creates this 3' end after the histone mRNA is synthesized by RNA polymerase II. If the 3' end is transferred to other mRNAs by recombinant DNA methods, they also become unstable when DNA synthesis stops. Thus, as for other types of mRNAs, the degradation rate of histone mRNA is strongly influenced by signals near the 3' end, where mRNA degradation is thought to begin.

If a stop codon is inserted into the middle of a coding sequence in a histone mRNA, the mRNA is no longer rapidly degraded. It has therefore been suggested that the nuclease responsible for degrading mRNAs is bound to the ribosome and that most of the histone mRNA has to be translated before the nuclease can begin digesting the 3' end of the mRNA. This hypothesis would explain why most unstable mRNAs are selectively stabilized when cells are treated with the protein synthesis inhibitor cycloheximide. Coupling the degradation of mRNA to translation may be a mechanism for ensuring that newly synthesized mRNA molecules in eucaryotic cells are not destroyed before they have been translated at least once.

Cytoplasmic Control of Poly-A Length Can Affect Translation in Addition to mRNA Stability 66

The initial polyadenylation of an RNA molecule (discussed in Chapter 8) occurs in the nucleus apparently automatically for nearly all eucaryotic mRNA precursors (the exception being the histone mRNAs discussed above). Once in the cytosol, the 200-nucleotide-long poly-A tails on most mRNAs gradually shorten over the course of days. Tails shorter than about 30 As, however, are not observed, suggesting that this is the minimum tail length required for mRNA stability. In addition, the poly-A tail length of some mRNAs is specifically controlled - either by selective poly-A addition or by selective poly-A removal (Figure 9-87A).

Maturing oocytes and eggs provide a striking example of the control of gene expression by means of poly-A addition to specific mRNAs. Many of the normal mRNA degradation pathways seem to be disabled in these giant cells, so that the cells can build up large stores of mRNAs in preparation for fertilization. Many mRNAs are stored with only 10 to 30 As at their 3' end, and in this form they are not translated. At specific times during oocyte maturation and postfertilization, when the proteins encoded by these mRNAs are required, poly A is added to selected mRNAs, greatly stimulating the initiation of their translation. A model that explains how poly A added at the 3' end can affect the initiation of translation near the 5' end of the mRNA is illustrated in Figure 9-87B.

A Few mRNAs Contain a Recoding Signal That Interrupts the Normal Course of Translation 67

The translational controls thus far discussed affect the rate at which new protein chains are initiated on an mRNA molecule. Usually, the completion of the synthesis of a protein is automatic once this synthesis has begun. In special cases, however, a process called translational recoding can alter the final protein that is made.

The most frequently observed form of recoding is *translational frameshifting.* This type of recoding is commonly used by retroviruses, where it allows more than one protein to be synthesized from a single mRNA. These viruses commonly make both the capsid proteins (*Gag proteins*) and the viral reverse transcriptase and integrase (*Pol proteins*) from the same RNA transcript. The virus needs many more copies of the Gag proteins than it does of the Pol proteins, and many viruses achieve this quantitative adjustment by having the *gag* and *pol* genes in different reading frames, with a stop codon at the end of the *gag* coding sequence that can be eliminated by a rare translational frameshift. The frameshift occurs at a particular codon in the mRNA and requires a specific *recoding signal,* thought to be a structural feature of the RNA sequence downstream of this site (Figure 9-88).

Similar principles are used more rarely in other forms of recoding at specific mRNA sites. Thus recoding signals have been discovered in some mRNAs that can cause a +1 frameshift, rather than the -1 frameshift shown in Figure9-88that operates in the viral RNA. In other cases a specific nucleotide sequence around a stop codon causes the stop codon to be leaky, so that additional amino acids are often inserted at the end of the polypeptide chain. More surprising is the recently discovered mechanism that inserts the modified amino acid *selenocysteine* into a protein chain. Selenocysteine, which is essential for the function of some enzymes, contains a selenium atom in place of the sulfur atom of cysteine and is attached to a special tRNA molecule. The tRNA has an affinity for a recoding signal present in those mRNA molecules that code for proteins utilizing selenocysteine. Selenocysteine is incorporated at special UGA codons, which in most other settings would serve as a stop codon to terminate protein synthesis.

RNA-catalyzed Reactions in Cells Are Likely to Be of Extremely Ancient Origin 68

All of the posttranscriptional control mechanisms discussed in this section depend on a particular RNA molecule being specifically recognized for special treatment, such as splicing, editing, or degradation. In some cases this recognition is accomplished by specialized RNA-binding proteins. In other cases, however, the recognition of specific RNA sequences is carried out by other RNA molecules, which use complementary RNA-RNA base-pairing as part of their recognition mechanism. RNA-RNA pairings, for example, are known to play a central part in translation, in RNA splicing, in several other forms of RNA processing, and in the RNA editing that occurs in trypanosomes. In attempting to dissect posttranscriptional mechanisms, we have largely entered an RNA world.

RNA molecules also have other regulatory roles in cells. The *antisense RNA* strategy for experimentally manipulating cells so that they fail to express a particular gene (see p. 326) mimics a normal mechanism that is known to regulate the expression of a few selected genes in bacteria and may be used much more widely than is now realized. A well-understood example of this kind of mechanism provides a feedback control on the initiation of DNA replication for a large family of bacterial DNA plasmids. The control system limits the number of copies of the plasmid made in the cell, thereby preventing the plasmid from killing its host cell by overreplicating (Figure 9-89).

Studies of RNA-catalyzed reactions are of special interest from an evolutionary perspective. As discussed in Chapter 1, the first cells are thought to have lacked DNA and may have contained very few, if any, proteins. Many of the RNA-catalyzed reactions in present-day cells seem to represent molecular fossils - descendants of the complex network of RNA-mediated reactions that are presumed to have dominated cell metabolism more than 3.5 billion years ago. Recombinant DNA technology has allowed large amounts of pure RNAs of any sequence to be produced *in vitro* with purified RNA polymerases (see Figure7-36), making it possible to study the detailed chemistry of RNA-catalyzed reactions. From an understanding of many such reactions, biologists hope to be able to trace the path by which a living cell first evolved.

Summary

Many steps in the pathway from RNA to protein are regulated by cells to control gene expression. Most genes are thought to be regulated at multiple levels, although control of the initiation of transcription (transcriptional control) usually predominates. Some genes, however, are transcribed at a constant level and turned on and off solely by posttranscriptional regulatory processes. These processes include (1) attenuation of the RNA transcript by its premature termination, (2) alternative RNA splice-site selection, (3) control of 3'-end formation by cleavage and poly-A addition, (4) control of transport from the nucleus to

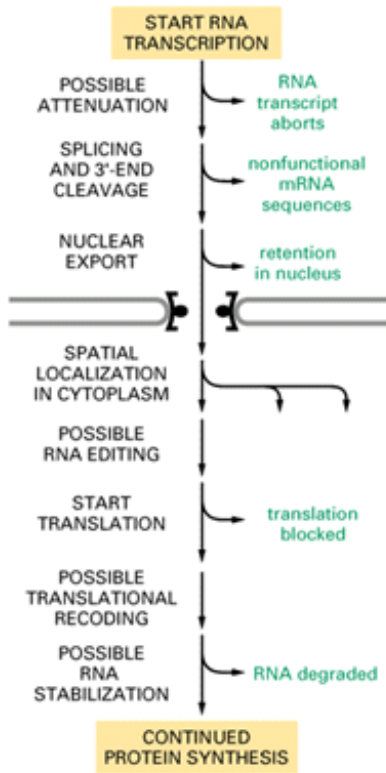
the cytosol, (5) localization of mRNAs to particular parts of the cell, (6) RNA editing, (7) control of translational initiation, (8) regulated mRNA degradation, and (9) translational recoding. Most of these control processes require the recognition of specific sequences or structures in the RNA molecule being regulated. This recognition can be accomplished by either a regulatory protein or a regulatory RNA molecule.


Figure 9-72. Possible post-transcriptional controls on gene expression. Only a few of these controls are likely to be used for any one gene.

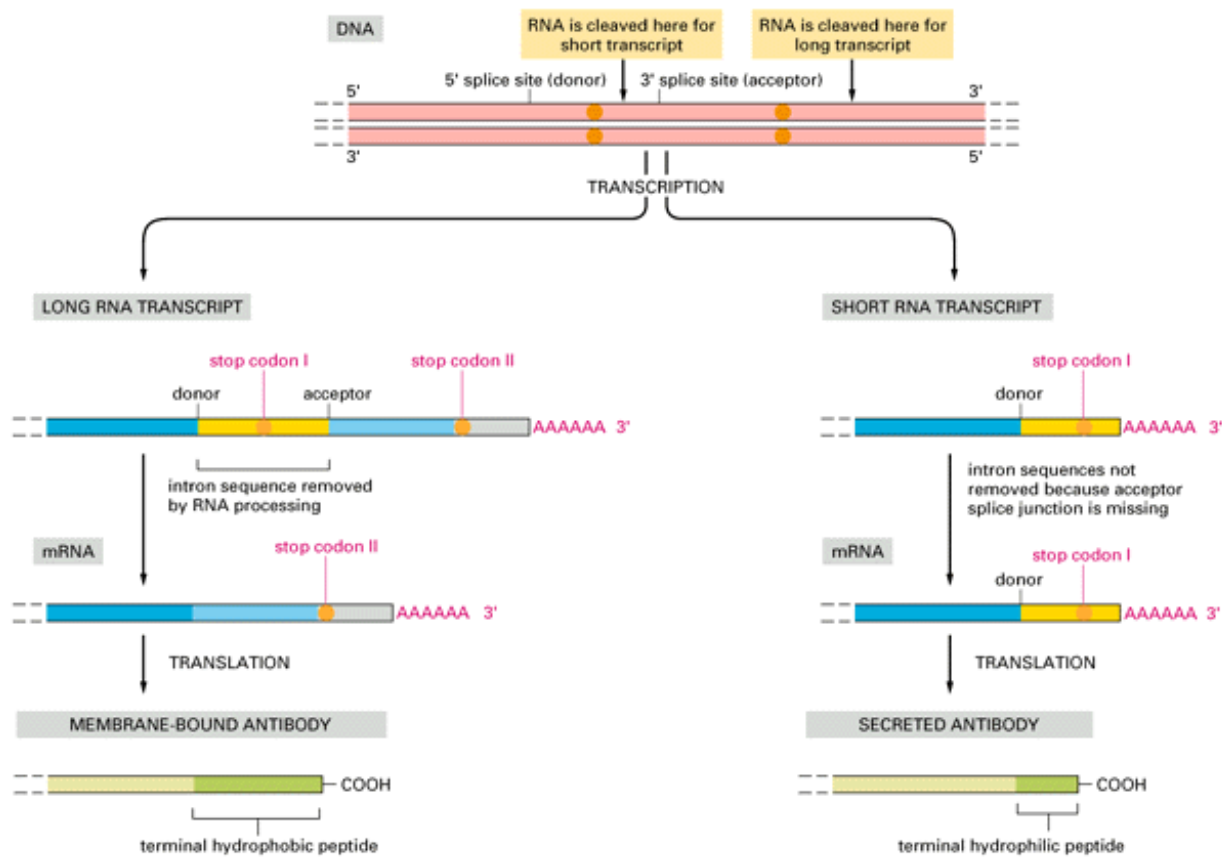
Figure 9-73. Four patterns of alternative RNA splicing. In each case a single type of RNA transcript is spliced in two alternative ways to produce two distinct mRNAs (1 and 2). The *dark blue boxes* mark exon sequences that are retained in both mRNAs. The *light blue boxes* mark possible exon sequences that are included in only one of the mRNAs; these boxes are joined by *red lines* to indicate where intron sequences (*yellow*) are removed. (Adapted with permission from A. Andreadis, M.E. Gallego, and B. Nadal-Ginard, *Annu. Rev. Cell Biol.* 3:207-242, 1987. © 1987 Annual Reviews, Inc.)
Figure 9-74. Negative and positive control of alternative RNA splicing. (A) Negative control, in which a repressor protein binds to the primary RNA transcript in tissue 2, thereby preventing the splicing machinery from removing an intron sequence. (B) Positive control, in which the splicing machinery is unable to remove a particular intron sequence without assistance from an activator protein.
Figure 9-75. Regulated alternative RNA splicing produces cell-type-specific forms of a gene product. Here two slightly different tyrosine protein kinases are produced from the *src* gene because exon sequence A is included only in nerve cells. The neural form of the Src protein contains an extra site for phospho-rylation and is also thought to have a higher specific activity. Only the protein-coding exons (*colored*) are shown in this diagram (exon 1, which forms the 5' leader on the mRNA, is not shown). (After J.B. Levy et al., *Mol. Cell Biol.* 7:4142-4145, 1987.)
Figure 9-76. Sex determination in *Drosophila*. The gene products shown act in a sequential cascade to determine the sex of the fly according to the X chromosome/autosome ratio. The genes are called *sex-lethal (Sxl), transformer (tra),* and *doublesex (dsx)* because of the phenotypes that result when the gene is inactivated by mutation. The function of these gene products is to transmit the information about the X chromo-some/autosome ratio to the many other genes that are involved in creating the sex-related phenotypes. These other genes function as two alternative sets: those that specify female features and those that specify male features (see Figure 9-77).
Figure 9-77. The cascade of changes in gene expression that determines the sex of a fly depends on alternative RNA splicing. An X chromosome/autosome ratio of 0.5 results in male development. Male is the "default" pathway in which the *Sxl* and *tra* genes are both transcribed, but the RNAs are spliced constitutively to produce only nonfunctional RNA molecules, and the *dsx* transcript is spliced to produce a protein that turns off the genes that specify female characteristics. An X chromosome/autosome ratio of 1 triggers the female differentiation pathway in the embryo by transiently activating a promoter within the *Sxl* gene that causes a functional Sxl protein to be synthesized. Sxl is a splicing regulatory protein with two sites of action: (1) it binds to a constitutively produced *Sxl* RNA transcript, causing a female-specific splice that continues the production of a functional Sxl protein, and (2) it binds to the constitutively produced *tra* RNA and causes an alternative splice of this transcript, which now produces an active Tra regulatory protein. The Tra protein acts with the constitutively produced Tra-2 protein to produce the female-specific spliced form of the *dsx* transcript; this encodes the female form of the Dsx protein, which turns off the genes that specify male features. The components in this pathway were all initially identified through the study of *Drosophila* mutants that are altered in their sexual development. The *dsx* gene, for example, derives its name (*doublesex*) from the observation that a fly lacking this gene product expresses both male- and female-specific features. Note that, whereas both the Sxl and Tra proteins bind to specific RNA sites, Sxl is a repressor that acts negatively to block a splice, whereas the Tra proteins are activators that act positively to induce a splice (see Figure 9-74).


Figure 9-78. Regulation of the site of RNA cleavage and poly-A addition determines whether an antibody molecule is secreted or remains membrane-bound. In unstimulated B lymphocytes (*left*) a long RNA transcript is produced, and the intron sequence near its 3' end is removed by RNA splicing to give rise to an mRNA molecule that codes for a membrane-bound antibody molecule. In contrast, after antigen stimulation (*right*) the primary RNA transcript is cleaved upstream from the splice site in front of the last exon sequence. As a result, some of the intron sequence that is removed from the long transcript remains as coding sequence in the short transcript. These are the sequences that encode the hydrophilic carboxyl-terminal portion of the secreted antibody molecule.
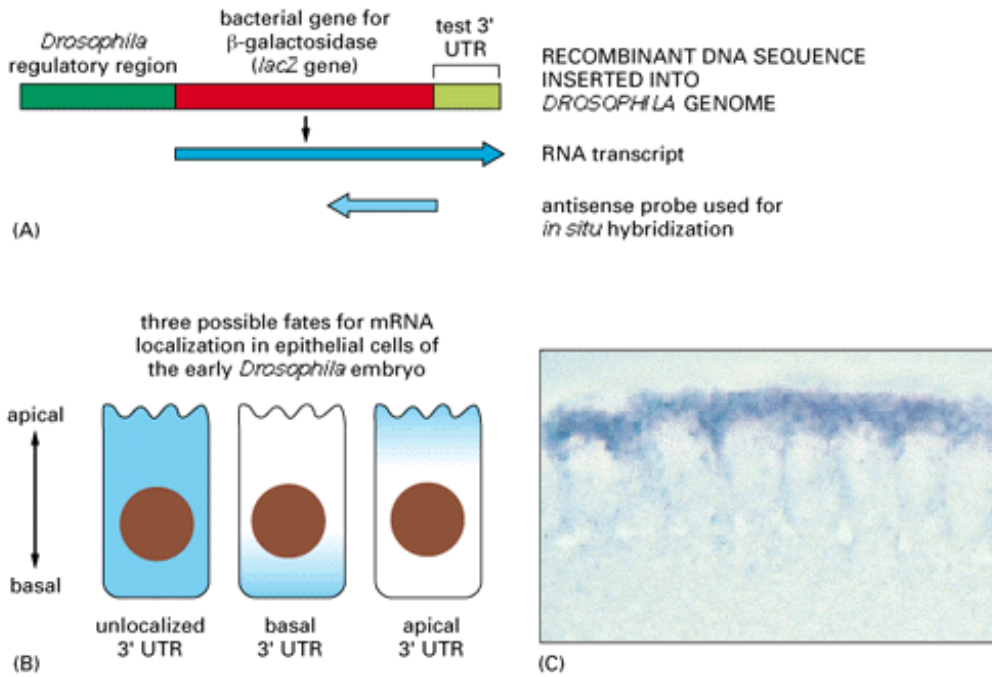

Figure 9-79. The importance of the UTR in localizing mRNAs to specific regions of the cytoplasm. *Drosophila* can be transfected with a recombinant DNA molecule coding for an mRNA in which a bacterial reporter sequence (encoding b-galactosidase) is linked to a chosen 3' UTR sequence. According to the choice of 3' UTR, the mRNA may be unlocalized in the embryonic cells, localized at their basal ends, or localized at their apical ends. (A) The recombinant DNA molecule used to test the effects of different 3' UTRs. (B) *In situ* hybridization (for b-galactosidase RNA sequences) shows that the 3' UTR determines the localization of the mRNA in the embryonic cells. (C) Photograph of an apically localized mRNA detected by *in situ* hybridization. The cells containing this mRNA are arranged in stripes along the axis of the embryo. (C, courtesy of David Ish-Horowitz.)
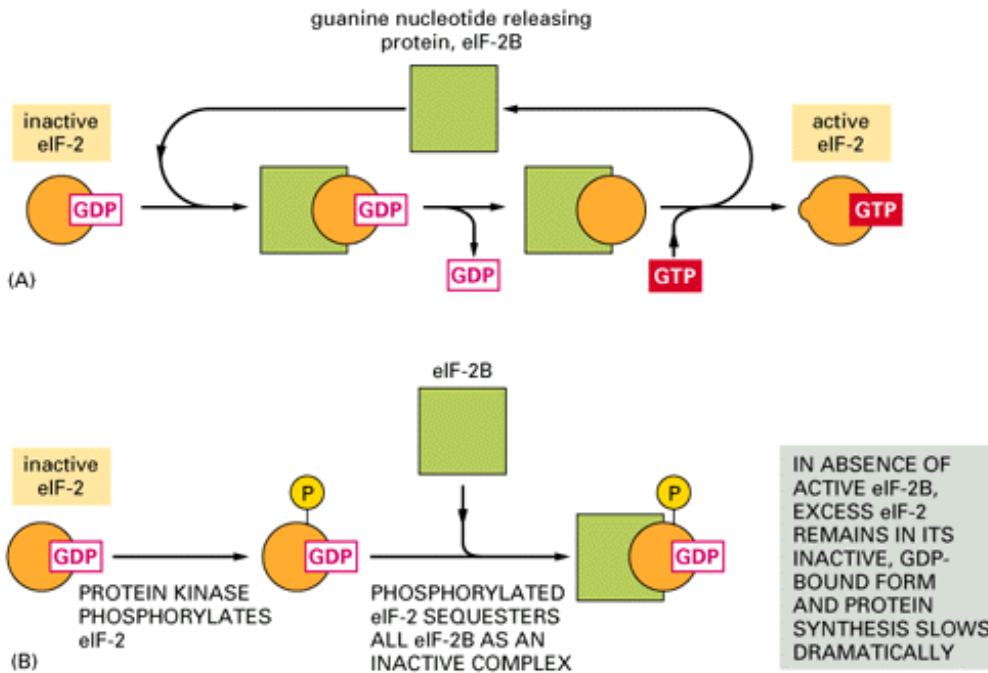
Figure 9-80. RNA editing in the mitochondria of trypanosomes. Guide RNAs contain at their 3' end a stretch of poly U, which donates U nucleotides to sites on the RNA transcript that mispair with the guide RNA; thus the poly-U tail gets shorter as editing proceeds (not shown). Editing generally starts near the 3' end and progresses toward the 5' end of the RNA transcript, as shown, because the "anchor sequence" at the 5' end of most guide RNAs can pair only with edited sequences.
The role of eIF-2 in the initiation of protein synthesis.


Figure 9-82. The eIF-2 cycle. (A) The recycling of used eIF-2 by a guanine nucleotide releasing protein (eIF-2B). (B) eIF-2 phosphorylation controls protein synthesis rates by tying up eIF-2B.
Figure 9-83. Negative translational control. This form of control is mediated by a sequence-specific RNA-binding protein that acts as a trans-lation repressor. Binding of the protein to an mRNA molecule decreases the translation of the mRNA. Several cases of this type of translational control are known; the illustration is modeled on the mechanism that causes more ferritin (an iron storage protein) to be synthesized when the free iron concentration in the cytosol rises; the iron-sensitive translation repressor protein is called aconitase (see also Figure9-86).

THE STABILITY OF NATURAL mRNAs
Figure 9-84. RNA stability. Three normal mRNAs with very different half-lives. The continuous rapid degradation of the mRNA molecules that encode various growth factors allows their concentration to be changed rapidly in response to extracellular signals. A signal for rapid degradation in the 3' untranslated region (UTR) determines the half-life of the growth factor RNA (see Figure9-85). Histones are needed mainly to form the new chromatin produced during DNA synthesis; a large change in the stability of their mRNAs helps to confine histone synthesis to the S phase of the cell cycle.

TWO MECHANISMS OF EUCARYOTIC mRNA DECAY

an evolutionarily conserved 50-nucleotide AU-rich sequence in the 3' UTR promotes the removal of the poly-A tail and causes the mRNA to become unstable

a repeated sequence in the 3' UTR promotes cleavage of the 3' UTR by a specific endonuclease. The fragments are rapidly degraded
Figure 9-85. Control of RNA degradation. Special sequences in the 3' untranslated region (UTR) of unstable mRNAs are responsible for their unusually rapid degradation. As indicated, AU-rich sequences found in the 3' UTR of many short-lived mRNAs cause a rapid removal of the poly-A tail, which in turn makes the RNA unstable. Other mRNAs contain sequences in their 3' UTR that serve as sites for specific endonucleolytic cleavage.

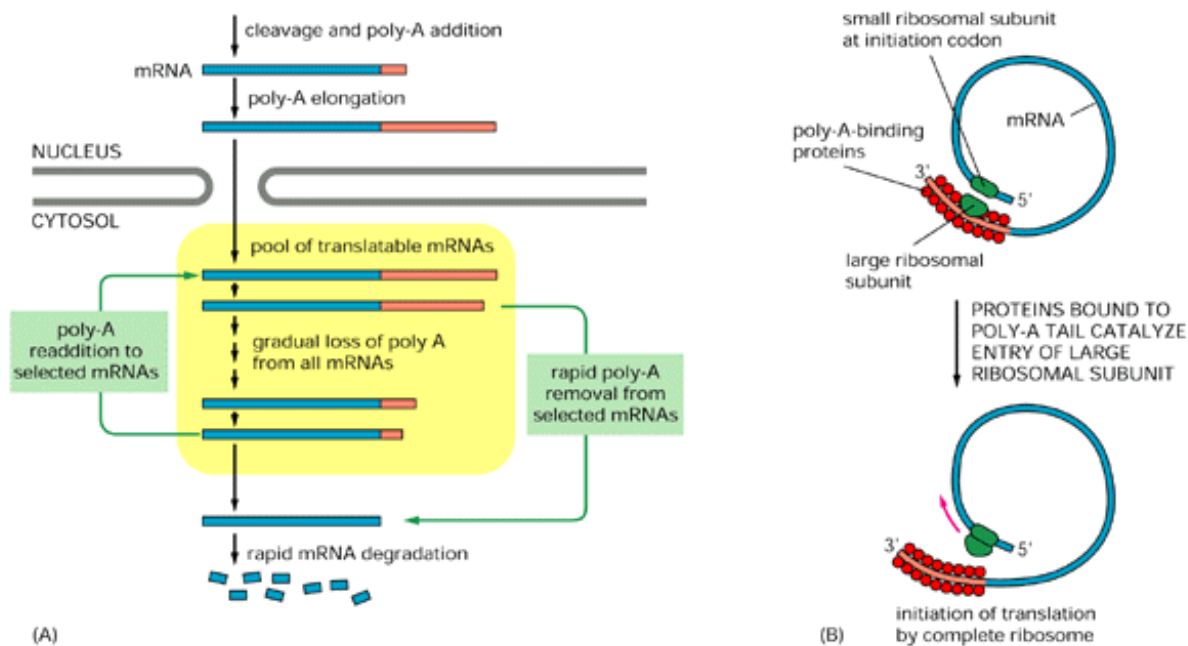
Figure 9-86. Two posttranslational controls mediated by iron. In response to an increase in iron concentration in the cytosol, a cell increases its synthesis of ferritin in order to bind the extra iron (A) and decreases its synthesis of transferrin receptors in order to import less iron (B). Both responses are mediated by the same iron-responsive regulatory protein, aconitase, which recognizes common features in a stem-and-loop structure in the mRNAs encoding ferritin and transferrin receptor. Aconitase dissociates from the mRNA when it binds iron. Because the transferrin receptor and ferritin are regulated by different types of mechanisms, their levels respond oppositely to iron concentrations even though they are regulated by the same iron-responsive regulatory protein. (Adapted from M.W. Hentze et al., *Science* 238:1570-1573, 1987; J.L. Casey et al., *Science* 240:924-928, 1988.)


Figure 9-87. Control of the poly-A tail length affects both mRNA stability and mRNA translation. (A) Most translated mRNAs have poly-A tails that exceed a minimum length of about 30 As. The tails on selected mRNAs can be either elongated or rapidly cleaved in the cytosol, and this will have an effect on the translation of these mRNAs. (B) A model proposed to explain the observed stimulation of translation by an increase in poly-A tail length. The large ribosomal subunits, on finishing a protein chain, may be directly recycled from near the 3' end of an mRNA molecule back to the 5' end to start a new protein by special poly-A-binding proteins (*red*).
Figure 9-88. Translational frameshifting is necessary to produce the reverse transcriptase and integrase of a retrovirus. The viral reverse transcriptase and integrase are produced by cleavage of the large Gag-Pol fusion protein, whereas the viral capsid proteins are produced by cleavage of the more abundant Gag protein. Both the Gag and fusion proteins start identically, but the Gag protein terminates at an in-frame stop codon (not shown); the indicated frameshift eliminates this stop codon, allowing the synthesis of the longer fusion protein. The frameshift occurs because features in the local RNA structure (including the RNA loop shown) cause the tRNA^{Leu} attached to the carboxyl terminus of the growing polypeptide chain occasionally to slip backward by one nucleotide on the ribosome, so that it pairs with a UUU codon instead of the UUA codon that had specified its incorporation; the next codon (AGG) in the new reading frame specifies an arginine rather than a glycine. The sequence shown is from the AIDS virus, HIV. (Adapted from T. Jacks et al., *Nature* 331:280-283, 1988.)
Figure 9-89. Antisense RNA strategy for regulating plasmid numbers in bacteria. A regulatory interaction between two RNA molecules maintains a constant plasmid copy number in the ColE1 family of bacterial DNA plasmids. RNA I (about 100 nucleotides long) is a regulatory RNA that inhibits the activity of RNA II (about 500 nucleotides long), which normally helps initiate plasmid DNA replication. The concentration of RNA I increases in proportion to the number of plasmid DNA molecules in the cell, so that as plasmid numbers increase, plasmid replication is inhibited. RNA I is complementary in sequence to the 5' end of RNA II. In RNA II sequence 2 is complementary to both sequence 1 and sequence 3, and it is displaced from one to the other by the binding of RNA I; RNA I thereby alters the conformation of sequence 4, inactivating RNA II. (After H. Masukata and J. Tomizawa, *Cell* 44:125-136, 1986.)

III. Internal Organization of the Cell

10. Membrane Structure

Introduction

Cell membranes are crucial to the life of the cell. The plasma membrane encloses the cell, defines its boundaries, and maintains the essential differences between the cytosol and the extracellular environment. Inside the cell the membranes of the endoplasmic reticulum, Golgi apparatus, mitochondria, and other membrane-bounded organelles in eucaryotic cells maintain the characteristic differences between the contents of each organelle and the cytosol. Ion gradients across membranes, established by the activities of specialized membrane proteins, can be used to synthesize ATP, to drive the transmembrane movement of selected solutes, or, in nerve and muscle cells, to produce and transmit electrical signals. In all cells the plasma membrane also contains proteins that act as sensors of external signals, allowing the cell to change its behavior in response to environmental cues; these protein sensors, or *receptors*, transfer information rather than ions or molecules across the membrane.

Despite their differing functions, all biological membranes have a common general structure: each is a very thin film of lipid and protein molecules, held together mainly by noncovalent interactions. Cell membranes are dynamic, fluid structures, and most of their molecules are able to move about in the plane of the membrane. The lipid molecules are arranged as a continuous double layer about 5 nm thick (Figure 10-1). This *lipid bilayer* provides the basic structure of the membrane and serves as a relatively impermeable barrier to the passage of most water-soluble molecules. Protein molecules "dissolved" in the lipid bilayer mediate most of the other functions of the membrane, transporting specific molecules across it, for example, or catalyzing membrane-associated reactions, such as ATP synthesis. In the plasma membrane some proteins serve as structural links that connect the membrane to the cytoskeleton and/or to either the extracellular matrix or an adjacent cell, while others serve as receptors to detect and transduce chemical signals in the cell's environment. As would be expected, cell membranes are asymmetrical structures: the lipid and protein compositions of the outside and inside faces differ from one another in ways that reflect the different functions performed at the two surfaces of the membrane.

In this chapter we consider the structure and organization of the two main constituents of biological membranes - the lipids and the proteins. Although we shall focus mainly on the plasma membrane, most of the concepts discussed are applicable to the various internal membranes in cells as well. The functions of cell membranes are considered in later chapters. Their role in ATP synthesis, for example, is discussed in Chapter 14; their role in the transmembrane transport of small molecules, in Chapter 11; and their roles in cell signaling and cell adhesion in Chapters 15 and 19, respectively. In Chapters 12 and 13 we discuss the internal membranes of the cell and the protein traffic through and between them.

Introduction

The lipid bilayer has been firmly established as the universal basis for cell-membrane structure. It is easily seen by ordinary electron microscopy, although specialized techniques, such as x-ray diffraction and freeze-fracture electron microscopy, are needed to reveal the details of its organization. The bilayer structure is attributable to the special properties of the lipid molecules, which cause them to assemble spontaneously into bilayers even in simple artificial conditions.

Membrane Lipids Are Amphipathic Molecules, Most of Which Spontaneously Form Bilayers <u>1</u>

Lipid molecules are insoluble in water but dissolve readily in organic solvents. They constitute about 50% of the mass of most animal cell membranes, nearly all of the remainder being protein. There are approximately 5×10^6 lipid molecules in a 1 μm × 1 μm area of lipid bilayer, or about 10^9 lipid molecules in the plasma membrane of a small animal cell. All of the lipid molecules in cell membranes are *amphipathic* (or amphiphilic) - that is, they have a *hydrophilic*("water-loving," or *polar*) end and a *hydrophobic*("water-hating," or *nonpolar*) end. The most abundant are the phospholipids. These have a polar *head group* and two hydrophobic *hydrocarbon tails* (Figure 10-2). The tails are usually fatty acids, and they can differ in length (they normally contain between 14 and 24 carbon atoms). One tail usually has one or more *cis*-double bonds (that is, it is *unsaturated*), while the other tail does not (that is, it is *saturated*). As indicated in Figure10-2, each double bond creates a small kink in the tail. Differences in the length and saturation of the fatty acid tails are important because they influence the ability of phospholipid molecules to pack against one another, and for this reason they affect the fluidity of the membrane (discussed below).

It is the shape and amphipathic nature of the lipid molecules that cause them to form bilayers spontaneously in aqueous solution. When lipid molecules are surrounded on all sides by water, they tend to aggregate so that their hydrophobic tails are buried in the interior and their hydrophilic heads are exposed to water. Depending on their shape, they can do this in either of two ways: they can form spherical *micelles,* with the tails inward, or they can form bimolecular sheets, or *bilayers,* with the hydrophobic tails sandwiched between the hydrophilic head groups (Figure 10-3).

Because of their cylindrical shape, membrane phospholipid molecules spontaneously form bilayers in aqueous environments. Moreover, these lipid bilayers tend to close on themselves to form sealed compartments, thereby eliminating free edges where the hydrophobic tails would be in contact with water. For the same reason compartments formed by lipid bilayers tend to reseal when they are torn.

A lipid bilayer has other characteristics besides its self-sealing properties that make it an ideal structure for cell membranes. One of the most important of these is its fluidity, which is crucial to many membrane functions.

The Lipid Bilayer Is a Two-dimensional Fluid <u>2</u>

It was only in the early 1970s that it was first recognized that individual lipid molecules are able to diffuse freely within lipid bilayers. The initial demonstration came from studies of synthetic lipid bilayers. Two types of synthetic bilayers have been very useful in experimental studies: (1) bilayers made in the form of spherical vesicles, called liposomes, which can vary in size from about 25 nm to 1 micron in diameter depending on how they are produced (Figure10-4); and (2) planar bilayers, called black membranes, formed across a hole in a partition between two aqueous compartments (Figure10-5).

Various techniques have been used to measure the motion of individual lipid molecules and their different parts. One can construct a lipid molecule, for example, whose polar head group carries a "spin label," such as a nitroxyl group (>N-O); this contains an unpaired electron whose spin creates a paramagnetic signal that can be detected by electron spin resonance (ESR) spectroscopy. (The principles of this technique are similar to those of nuclear magnetic resonance, which is discussed in Chapter 4.) The motion and orientation of a spin-labeled lipid in a bilayer can be deduced from the ESR spectrum. Such studies show that phospholipid molecules in synthetic bilayers very rarely migrate from the monolayer on one side to that on the other. This process, called "flip-flop," occurs less than once a month for any individual molecule. On the other hand, lipid molecules readily exchange places with their neighbors *within*a monolayer (~10^7 times a second). This gives rise to a rapid lateral diffusion, with a diffusion coefficient (*D*) of about 10^{-8}cm^2/sec, which means that an average lipid molecule diffuses the length of a large bacterial cell (~2 μm) in about 1 second. These studies have also shown that individual lipid molecules rotate very rapidly about

their long axis and that their hydrocarbon chains are flexible (Figure10-6).

Similar studies have been carried out with labeled lipid molecules in isolated biological membranes and in relatively simple whole cells such as mycoplasmas, bacteria, and nonnucleated red blood cells. The results are generally the same as for synthetic bilayers, and they demonstrate that the lipid component of a biological membrane is a two-dimensional liquid in which the constituent molecules are free to move laterally; as in synthetic bilayers, individual phospholipid molecules are normally confined to their own monolayer. This confinement creates a problem for their synthesis. Phospholipid molecules are synthesized in only one monolayer of a membrane, mainly being produced in the cytosolic monolayer of the endoplasmic reticulum (ER) membrane; if none of these newly made molecules could migrate to the other half of the lipid bilayer, new bilayer could not be made. The problem is solved by a special class of ER-membrane-bound enzymes called *phospholipid translocators*, which catalyze the rapid flip-flop of specific phospholipids from the monolayer where they are made to the opposite monolayer, as discussed in Chapter 12.

The Fluidity of a Lipid Bilayer Depends on Its Composition 3

The precise fluidity of cell membranes is biologically important. Certain membrane transport processes and enzyme activities, for example, can be shown to cease when the bilayer viscosity is experimentally increased beyond a threshold level. The fluidity of a lipid bilayer depends on both its composition and temperature, as is readily demonstrated in studies of synthetic bilayers. A synthetic bilayer made from a single type of phospholipid changes from a liquid state to a rigid crystalline (or gel) state at a characteristic freezing point. This change of state is called a *phase transition,* and the temperature at which it occurs is lower (that is, the membrane becomes more difficult to freeze) if the hydrocarbon chains are short or have double bonds. A shorter chain length reduces the tendency of the hydrocarbon tails to interact with one another, and *cis*-double bonds produce kinks in the hydrocarbon chains that make them more difficult to pack together, so that the membrane remains fluid at lower temperatures (Figure10-7). Bacteria, yeast, and other organisms whose temperatures fluctuate with that of their environment adjust the fatty acid composition of their membrane lipids so as to maintain a relatively constant fluidity; as the temperature falls, for instance, fatty acids with more *cis*-double bonds are synthesized, so that the decrease in bilayer fluidity that would otherwise result from the drop in temperature is avoided.

The lipid bilayer of many cell membranes is not composed exclusively of phospholipids, however; it often also contains *cholesterol* and *glycolipids.* Eucaryotic plasma membranes contain especially large amounts of cholesterol (Figure 10-8) - up to one molecule for every phospholipid molecule. The cholesterol molecules enhance the permeability-barrier properties of the lipid bilayer. They orient themselves in the bilayer with their hydroxyl groups close to the polar head groups of the phospholipid molecules; their rigid, platelike steroid rings interact with - and partly immobilize - those regions of the hydrocarbon chains that are closest to the polar head groups (Figure10-9). By decreasing the mobility of the first few CH_2 groups of the hydrocarbon chains of the phospholipid molecules, cholesterol makes the lipid bilayer less deformable in this region and thereby decreases the permeability of the bilayer to small water-soluble molecules. Although cholesterol tends to make lipid bilayers less fluid, at the high concentrations found in most eucaryotic plasma membranes it also prevents the hydrocarbon chains from coming together and crystallizing. In this way it inhibits possible phase transitions.

The lipid compositions of several biological membranes are compared in Table 10-1. Note that bacterial plasma membranes are often composed of one main type of phospholipid and contain no cholesterol; the mechanical stability of these membranes is enhanced by the overlying cell wall (see Figure 11-14). The plasma membranes of most eucaryotic cells, by contrast, are more varied, not only in containing large amounts of cholesterol, but also in containing a mixture of different phospholipids. Four major phospholipids predominate in the plasma membrane of many mammalian cells: *phosphatidylcholine, sphingomyelin, phosphatidylserine,* and *phosphatidylethanolamine.* The structures of these molecules are shown in Figure 10-10. Note that only phosphatidylserine carries a net negative charge, the importance of which we shall see later; the other three are electrically neutral at physiological pH, carrying one positive and one negative charge. Together these four phospholipids constitute more than half the mass of lipid in most membranes (see Table 10-1). Other phospholipids, such as the *inositol phospholipids*, are present in smaller quantities but are functionally very important. The inositol phospholipids have a crucial role in cell signaling, as discussed in Chapter 15.

One might wonder why eucaryotic membranes contain such a variety of phospholipids, with head groups that differ in size, shape, and charge. One can begin to understand why if one thinks of the membrane lipids as constituting a two-dimensional solvent for the proteins in the membrane, just as water constitutes a three-dimensional solvent for proteins in an aqueous solution. As we shall see, some membrane proteins can function only in the presence of specific phospholipid head groups, just as many enzymes in aqueous solution require a particular ion for activity.

The Lipid Bilayer Is Asymmetrical [4]

The lipid compositions of the two halves of the lipid bilayer in those membranes that have been analyzed are strikingly different. In the human red blood cell membrane, for example, almost all of the lipid molecules that have choline - $(CH_3)_3N$ $^+CH_2CH_2OH$ - in their head group (that is, phosphatidylcholine and sphingomyelin) are in the outer half of the lipid bilayer, whereas almost all of the phospholipid molecules that contain a terminal primary amino group (phosphatidylethanolamine and phosphatidylserine) are in the inner half (Figure 10-11). Because the negatively charged phosphatidylserine is located in the inner monolayer, there is a significant difference in charge between the two halves of the bilayer.

Most of the membranes in a eucaryotic cell, including the plasma membrane, are synthesized in the endoplasmic reticulum (ER), and it is here that the phospholipid asymmetry is generated by the phospholipid translocators in the ER that move specific phospholipid molecules from one monolayer to the other (discussed in Chapter 12). This lipid asymmetry can be functionally important. The enzyme *protein kinase C*, for example, is activated in response to various extracellular signals; it binds to the cytoplasmic face of the plasma membrane, where phosphatidylserine is concentrated, and requires this negatively charged phospholipid in order to act. Similarly, specific inositol phospholipids are concentrated in the cytoplasmic half of the plasma membrane of the eucaryotic cell. These minor phospholipids are cleaved into two fragments by specific enzymes that are activated by extracellular signals. Both fragments then act inside the cell as diffusible mediators to help relay the signal into the cell interior, as we discuss in Chapter 15.

Glycolipids Are Found on the Surface of All Plasma Membranes [5]

The lipid molecules that show the most striking and consistent asymmetry in distribution in cell membranes are the sugar-containing lipid molecules called glycolipids. These intriguing molecules are found exclusively in the noncyto-plasmic half of the lipid bilayer, where they are thought to self-associate into microaggregates by forming hydrogen bonds with one another. In the plasma membrane their sugar groups are exposed at the cell surface (see Figure 10-11), suggesting some role in interactions of the cell with its surroundings. The asymmetric distribution of glycolipids in the bilayer results from the addition of sugar groups to the lipid molecules in the lumen of the Golgi apparatus, which is topologically equivalent to the exterior of the cell (discussed in Chapter 13).

Glycolipids probably occur in all animal cell plasma membranes, generally constituting about 5% of the lipid molecules in the outer monolayer. They are also found in some intracellular membranes. The most complex of the glycolipids, the gangliosides, contain oligosaccharides with one or more sialic acid residues, which give gangliosides a net negative charge (Figure 10-12). Gangliosides are most abundant in the plasma membrane of nerve cells, where they constitute 5-10% of the total lipid mass, although they are also found in much smaller quantities in most cell types. So far more than 40 different gangliosides have been identified.

There are only hints as to what the functions of glycolipids might be. A possible clue comes from their localization: in the plasma membrane of epithelial cells, for example, glycolipids are confined to the apical surface, where they may help to protect the membrane from the harsh conditions (such as low pH and degradative enzymes) frequently found there. Charged glycolipids, such as gangliosides, may be important for their electrical effects: their presence will alter the electrical field across the membrane and the concentrations of ions - especially Ca^{2+} - at its external surface. Glycolipids may also play a role in electrical insulation, since in the myelin membrane, which electrically insulates nerve cell axons, the noncytoplasmic half of the bilayer is filled with them. They are also thought to function in cell-recognition processes. The ganglioside G_{M1} (see Figure 10-12), for example, acts as a cell-surface receptor for the bacterial toxin that causes the debilitating diarrhea of cholera. Cholera toxin binds to and enters only those cells that have G_{M1} on their surface, including intestinal epithelial cells. Its entry into a cell leads to a prolonged increase in the concentration of intracellular cyclic AMP (discussed in Chapter 15), which in turn causes a large efflux of Na^+ and water into the intestine. Although binding bacterial toxins cannot be the *normal* function of gangliosides, such observations suggest that these glycolipids might also serve as receptors for normal extracellular molecules. This suggestion is supported by increasing evidence that glycolipids can help cells to bind to the extracellular matrix, as well as to other cells, as we discuss later.

Summary

Biological membranes consist of a continuous double layer of lipid molecules in which various membrane proteins are

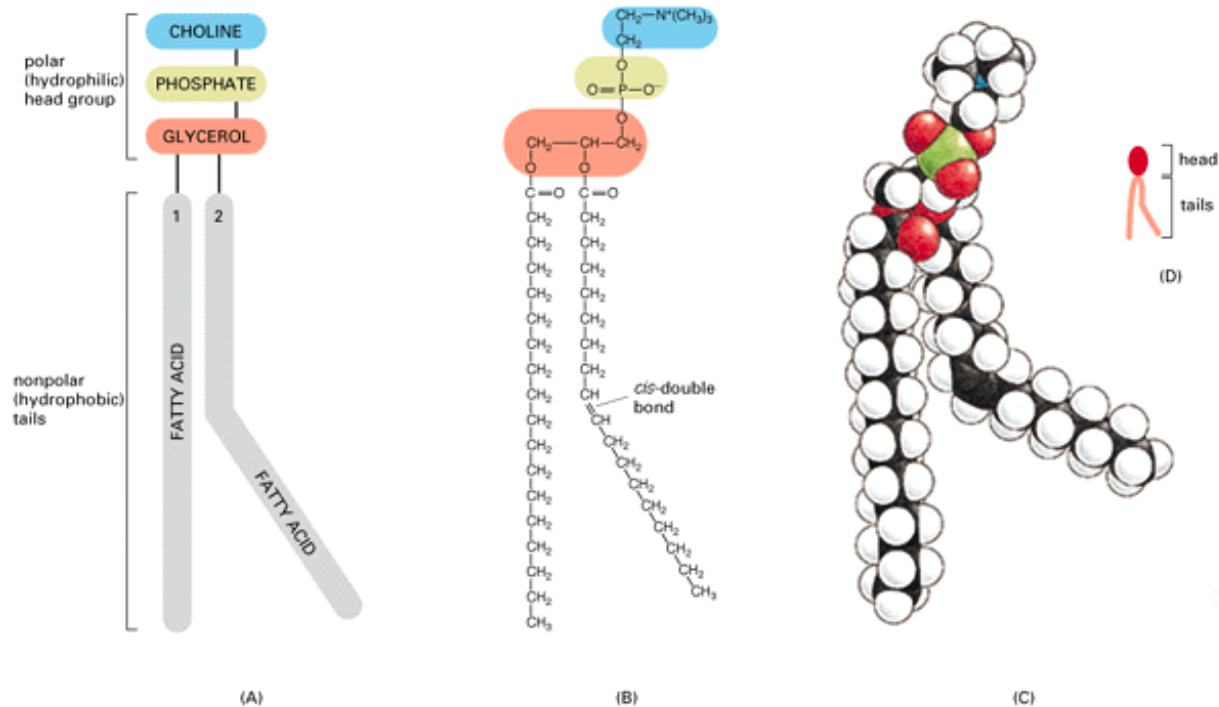
embedded. This lipid bilayer is fluid, with individual lipid molecules able to diffuse rapidly within their own monolayer. Most types of lipid molecules, however, very rarely flip-flop spontaneously from one monolayer to the other. Membrane lipid molecules are amphipathic, and some of them (the phospholipids) assemble spontaneously into bilayers when placed in water; the bilayers form sealed compartments that reseal if torn. There are three major classes of membrane lipid molecules - phospholipids, cholesterol, and glycolipids - and the lipid compositions of the inner and outer monolayers are different, reflecting the different functions of the two faces of a cell membrane. Different mixtures of lipids are found in the membranes of cells of different types, as well as in the various membranes of a single eucaryotic cell. Some membrane-bound proteins require specific lipid head groups in order to function, which is thought to explain, in part at least, why eucaryotic membranes contain so many kinds of lipid molecules.


Figure 10-2. The parts of a phospholipid molecule. Phosphatidylcholine, represented schematically (A), in formula (B), as a space-filling model (C), and as a symbol (D). The kink due to the *cis*-double bond is exaggerated in these drawings for emphasis.
Figure 10-3. A lipid micelle and a lipid bilayer seen in cross-section. Lipid molecules form such structures spontaneously in water. The shape of the lipid molecule determines which of these structures is formed. Wedge-shaped lipid molecules (*above*) form micelles, whereas cylinder-shaped phospholipid molecules (*below*) form bilayers.

Table 10-1. Approximate Lipid Compositions of Different Cell Membranes

	Percentage of Total Lipid by Weight					
Lipid	Liver Plasma Membrane	Erythrocyte Plasma Membrane	Myelin	Mitochondrion (inner and outer membranes)	Endoplasmic Reticulum	E. coli
Cholesterol	17	23	22	3	6	0
Phosphatidyl-ethanolamine	7	18	15	35	17	70
Phosphatidylserine	4	7	9	2	5	trace
Phosphatidyl-choline	24	17	10	39	40	0
Sphingomyelin	19	18	8	0	5	0
Glycolipids	7	3	28	trace	trace	0
Others	22	13	8	21	27	30
Figure 10-10. Four major phospholipids in mammalian plasma membranes. Note that different head groups are represented by different symbols in this figure and the next. All of the lipid molecules shown are derived from glycerol except for sphingomyelin, which is derived from serine.
Figure 10-11. The asymmetrical distribution of phospholipids and glycolipids in the lipid bilayer of human red blood cells. The symbols used for the phospholipids are those introduced in Figure 10-10. In addition, glycolipids are drawn with hexagonal polar head groups (*blue*). Cholesterol (not shown) is thought to be distributed about equally in both monolayers.
Figure 10-12. Glycolipid molecules. Galactocerebroside (A) is called a *neutral glycolipid* because the sugar that forms its head group is uncharged. A ganglioside (B) always contains one or more negatively charged sialic acid residues (also called *N*-acetylneuraminic acid, or NANA), whose structure is shown in (C). Whereas in bacteria and plants almost all glycolipids are derived from glycerol, as are most phospholipids, in animal cells they are almost always produced from sphingosine, an amino alcohol derived from *serine*, as is the case for the phospholipid sphingomyelin (see Figure10-10). Gal = galactose; Glc = glucose, GalNAc = *N*-acetylgalactos-amine; these three sugars are uncharged.

Membrane Proteins 6

Introduction

Although the basic structure of biological membranes is provided by the lipid bilayer, most of the specific functions are carried out by proteins. Accordingly, the amounts and types of proteins in a membrane are highly variable: in the myelin membrane, which serves mainly as electrical insulation for nerve cell axons, less than 25% of the membrane mass is protein, whereas in the membranes involved in energy transduction (such as the internal membranes of mito-chondria and chloroplasts), approximately 75% is protein. The usual plasma membrane is somewhere in between, with about 50% of its mass as protein. Because lipid molecules are small in comparison to protein molecules, there are always many more lipid molecules than protein molecules in membranes - about 50 lipid molecules for each protein molecule in a membrane that is 50% protein by mass. Like membrane lipids, membrane proteins often have oligosaccharide chains attached to them. Thus the surface that the cell presents to the exterior consists largely of carbohydrate, which forms a *glycocalyx* or *cell coat* (discussed later).

Membrane Proteins Can Be Associated with the Lipid Bilayer in Various Ways 7

Different membrane proteins are associated with the membranes in different ways, as illustrated in Figure 10-13. Many membrane proteins extend through the lipid bilayer, with part of their mass on either side (see examples 1 and 2 in Figure 10-13). Like their lipid neighbors, these transmembrane proteins are amphi-pathic, having regions that are hydrophobic and regions that are hydrophilic. Their hydrophobic regions pass through the membrane and interact with the hydrophobic tails of the lipid molecules in the interior of the bilayer. Their hydrophilic regions are exposed to water on one or the other side of the membrane. The hydrophobicity of some of these membrane proteins is increased by the covalent attachment of a fatty acid chain that is

inserted in the cytoplasmic leaflet of the lipid bilayer (see example 1 in Figure 10-13). Other membrane proteins are located entirely in the cytosol and are associated with the bilayer only by means of one or more covalently attached fatty acid chains or other types of lipid chains called *prenyl groups*(see example 3 in Figure10-13 and Figure10-14). Yet other membrane proteins are entirely exposed at the external cell surface, being attached to the bilayer only by a covalent linkage (via a specific oligosaccharide) to phosphatidylinositol in the outer lipid monolayer of the plasma membrane (see example 4 in Figure 10-13). The lipid-linked proteins in example 3 are made as soluble proteins in the cytosol and are subsequently directed to the membranes by the covalent attachment of a lipid group (Figure10-14). The proteins in example 4, however, are made as single-pass transmembrane proteins in the ER; while still in the ER, the transmembrane segment of the protein is cleaved off and a glycosylphosphatidylinositol (GPI) anchor is added, leaving the protein bound to the noncytoplasmic surface of the membrane solely by this anchor (discussed in Chapter 12). Proteins bound to the membrane by a GPI anchor can be readily distinguished by the use of the enzyme phosphatidylinositol-specific phospholipase C, which specifically cuts these proteins free from their anchors and thereby releases them from the membrane.

Some proteins that do not extend into the hydrophobic interior of the lipid bilayer at all are bound to one or the other face of the membrane by noncovalent interactions with other membrane proteins (see examples 5 and 6 in Figure10-13). Many of these can be released from the membrane by relatively gentle extraction procedures, such as exposure to solutions of very high or low ionic strength or extreme pH, which interfere with protein-protein interactions but leave the lipid bilayer intact; these proteins are referred to operationally as peripheral membrane proteins. By contrast, transmembrane proteins, many proteins held in the bilayer by lipid groups, and some other tightly bound proteins cannot be released in these ways and therefore are called integral membrane proteins.

How a membrane-bound protein is associated with the lipid bilayer usually reflects the function of the protein. Thus only transmembrane proteins can function on both sides of the bilayer or transport molecules across it. Some cell-surface receptors, for example, are transmembrane proteins that bind signaling molecules in the extracellular space and generate different intracellular signals on the opposite side of the plasma membrane. Proteins that function on only one side of the lipid bilayer, by contrast, are often associated exclusively with either the lipid monolayer or a protein domain on that side. A number of proteins involved in intracellular signaling, for example, are bound to the cytosolic half of the plasma membrane by one or more covalently attached lipid groups.

In Most Transmembrane Proteins the Polypeptide Chain Is Thought to Cross the Lipid Bilayer in an a-helical Conformation 6, 8

A transmembrane protein always has a unique orientation in the membrane. This reflects both the asymmetrical manner in which it is synthesized and inserted into the lipid bilayer in the ER and the different functions of its cytoplasmic and noncytoplasmic domains. These domains are separated by the membrane-spanning segments of the polypeptide chain, which contact the hydrophobic environment of the lipid bilayer and are composed largely of amino acid residues with nonpolar side chains. Because the peptide bonds themselves are polar and because water is absent, all peptide bonds in the bilayer are driven to form hydrogen bonds with one another. The hydrogen bonding between peptide bonds is maximized if the polypeptide chain forms a regular a helix as it crosses the bilayer, and this is how the great majority of the membrane-spanning segments of polypeptide chains are thought to traverse the bilayer (Figure10-15): in single-pass transmembrane proteins, the polypeptide crosses only once (see example 1 in Figure 10-13), whereas in multipass transmembrane proteins, the polypeptide chain crosses multiple times (see example 2 in Figure 10-13). An alternative way for the peptide bonds in the lipid bilayer to satisfy their hydrogen-bonding requirements is for multiple transmembrane strands of polypeptide chain to be arranged as a b sheet in the form of a closed barrel (a so-called *b barrel*). This form of multipass transmembrane structure is seen in *porin* proteins, which we discuss later. The strong drive to maximize hydrogen bonding in the absence of water also means that a polypeptide chain that enters the bilayer is likely to pass entirely through it before changing direction, since chain bending requires a loss of regular hydrogen-bonding interactions. Probably for this reason, there is still no established example of a membrane protein in which the polypeptide chain extends only partway across the lipid bilayer.

Because transmembrane proteins are notoriously difficult to crystallize, only a few have been studied in their entirety by x-ray crystallography (discussed later); the folded three-dimensional structures of almost all of the others are uncertain. DNA cloning and sequencing techniques, however, have revealed the amino acid sequences of large numbers of transmembrane proteins, and it is often possible to predict from an analysis of the protein's sequence which parts of the polypeptide chain extend across the lipid bilayer as an a helix. Segments containing about 20-30 amino acid residues with a high degree of hydrophobicity are long enough to span a membrane as an a helix, and they can often be identified by means of a *hydropathy plot* (Figure 10-16). Because ten or fewer residues are sufficient to traverse a lipid bilayer as an extended b strand, the same strategy is unlikely to

identify the membrane-spanning segments of a b barrel.

The great majority of transmembrane proteins are glycosylated. As in the case of glycolipids, the sugar residues are added in the lumen of the endoplasmic reticulum and Golgi apparatus (discussed in Chapters 12 and 13), and for this reason the oligosaccharide chains are always present on the noncytoplasmic side of the membrane. A further asymmetry arises as a result of the reducing environment of the cytosol, which prevents the formation of intrachain (and interchain) disulfide (S - S) bonds between cysteine residues on the cytosolic side of membranes. These bonds do form on the noncytosolic side, where they can play an important part in stabilizing either the folded structure of the polypeptide chain (Figure 10-17) or its association with other polypeptide chains.

Membrane Proteins Can Be Solubilized and Purified in Detergents 9

In general, transmembrane proteins (and some other tightly bound membrane proteins) can be solubilized only by agents that disrupt hydrophobic associations and destroy the lipid bilayer. The most useful among these for the membrane biochemist are detergents, which are small amphipathic molecules that tend to form micelles in water (Figure 10-18). When mixed with membranes, the hydrophobic ends of detergents bind to the hydrophobic regions of the membrane proteins, thereby displacing the lipid molecules. Since the other end of the detergent molecule is polar, this binding tends to bring the membrane proteins into solution as detergent-protein complexes (although some tightly bound lipid molecules may also remain) (Figure 10-19). The polar (hydrophilic) ends of detergents can be either charged (ionic), as in the case of *sodium dodecyl sulfate (SDS),* or uncharged (nonionic), as in the case of the *Triton* detergents. The structures of these two commonly used detergents are illustrated in Figure 10-20.

With strong ionic detergents, such as SDS, even the most hydrophobic membrane proteins can be solubilized. This allows them to be analyzed by *SDS polyacrylamide-gel electrophoresis* (discussed in Chapter 4), a procedure that has revolutionized the study of membrane proteins. Such strong detergents unfold (denature) proteins by binding to their internal "hydrophobic cores," thereby rendering the proteins inactive and unusable for functional studies. Nonetheless, proteins can be readily purified in their SDS-denatured form, and in some cases the purified protein can be renatured, with recovery of functional activity, by removing the detergent.

Many hydrophobic membrane proteins can be solubilized and then purified in an active, if not entirely normal, form by the use of mild detergents, such as Triton X-100, that bind to the membrane-spanning segments of the protein. In this way functionally active membrane protein systems can be reconstituted from purified components, providing a powerful means to analyze their activities (Figure 10-21).

The Cytoplasmic Side of Membrane Proteins Can Be Readily Studied in Red Blood Cell Ghosts 10

More is known about the plasma membrane of the human red blood cell (Figure 10-22) than about any other eucaryotic membrane. There are a number of reasons for this. Red blood cells are availabl e in large numbers (from blood banks, for example) relatively uncontaminated by other cell types. Since they have no nucleus or internal organelles, the plasma membrane is their only membrane, and it can be isolated without contamination by internal membranes (thus avoiding a serious problem encountered in plasma membrane preparations from other cell types in which the plasma membrane typically constitutes less than 5% of the cell's membrane). It is easy to prepare empty red blood cell membranes, or "ghosts," by putting the cells in a medium with a lower salt concentration than the cell interior. Water then flows into the red cells, causing them to swell and burst (lyse) and release their hemoglobin (the major nonmembrane protein). Membrane ghosts can be studied while they are still leaky (in which case any reagent can interact with molecules on both faces of the membrane), or they can be allowed to reseal so that water-soluble reagents cannot reach the internal face. Moreover, since sealed *inside-out* vesicles can also be prepared from red blood cell ghosts (Figure 10-23), the external side and internal (cytoplasmic) side of the membrane can be studied separately. The use of sealed and unsealed red cell ghosts led to the first demonstration that some membrane proteins extend across the lipid bilayer (discussed below) and that the lipid compositions of the two halves of the bilayer are different. Like most of the basic principles initially demonstrated in red blood cell membranes, these findings were later extended to the membranes of nucleated cells.

The "sidedness" of a membrane protein can be determined in several ways. One is to use a covalent labeling reagent (for example, one carrying a radioactive or fluorescent marker) that is water soluble and therefore cannot penetrate the lipid bilayer; such a marker will attach covalently only to the portion of the protein on the exposed side of the membrane. The membranes are then solubilized with detergent and the proteins separated by SDS polyacrylamide-gel electrophoresis. The labeled proteins can

be detected either by their radioactivity (by autoradiography of the gel) or by their fluorescence (by exposing the gel to ultraviolet light). By using such *vectorial labeling*, it is possible to determine how a particular protein, detected as a band on a gel, is oriented in the membrane: for example, if it is labeled from both the external side (when intact cells or sealed ghosts are labeled) and the internal (cytoplasmic) side (when sealed inside-out vesicles are labeled), then it must be a transmembrane protein. An alternative approach is to expose either the external or internal surface to membrane-impermeant proteolytic enzymes: if a protein is partially digested from both surfaces, it must be a transmembrane protein. In addition, labeled antibodies that bind only to one part of a protein can be used to determine if that part of a transmembrane protein is exposed on one side of the membrane or the other.

When the plasma membrane proteins of the human red blood cell are studied by SDS polyacrylamide-gel electrophoresis, approximately 15 major protein bands are detected, varying in molecular weight from 15,000 to 250,000. Three of these proteins - *spectrin, glycophorin,* and *band 3* - account for more than 60% (by weight) of the total membrane protein (Figure10-24). Each of these proteins is arranged in the membrane in a different manner. We shall, therefore, use them as examples of three major ways that proteins are associated with membranes, not only in red blood cells, but in other cells as well.

Spectrin Is a Cytoskeletal Protein Noncovalently Associated with the Cytoplasmic Side of the Red Blood Cell Membrane 11

Most of the protein molecules associated with the human red blood cell membrane are peripheral membrane proteins associated with the cytoplasmic side of the lipid bilayer. The most abundant of these proteins is spectrin, a long, thin, flexible rod about 100 nm in length that constitutes about 25% of the membrane-associated protein mass (about 2.5×10^5 copies per cell). It is the principal component of the protein meshwork (the *cytoskeleton*) that underlies the red blood cell membrane, maintaining the structural integrity and biconcave shape of this membrane (see Figure 10-22): if the cytoskeleton is dissociated from red blood cell ghosts in low-ionic-strength solutions, the membrane fragments into small vesicles.

Spectrin is a heterodimer formed from two large, structurally similar subunits (Figure 10-25). The heterodimers self-associate head-to-head to form 200-nm-long tetramers. The tail ends of four or five tetramers are linked together by binding to short actin filaments and to other cytoskeletal proteins (including the *band 4.1 protein*) in a "junctional complex." The final result is a deformable, netlike meshwork that underlies the entire cytoplasmic surface of the membrane (Figure 10-26). It is this spectrin-based cytoskeleton that enables the red cell to withstand the stress on its membrane as it is forced through narrow capillaries. Mice and humans with genetic abnormalities of spectrin are anemic and have red cells that are spherical (instead of concave) and abnormally fragile; the severity of the anemia increases with the degree of the spectrin deficiency.

The protein mainly responsible for attaching the spectrin cytoskeleton to the red cell plasma membrane was identified by monitoring the binding of radiolabeled spectrin to red cell membranes from which spectrin and various other peripheral proteins had been removed. These experiments showed that the binding of spectrin depends on a large intracellular attachment protein called ankyrin, which attaches both to spectrin and to the cytoplasmic domain of the transmembrane protein band 3 (see Figure10-26). By connecting some of the band 3 molecules to spectrin, ankyrin links the spectrin network to the membrane; it also greatly reduces the rate of diffusion of these band 3 molecules in the lipid bilayer. The spectrin-based cytoskeleton is also attached to the membrane by a second mechanism, which depends on the band 4.1 protein mentioned above. This protein, which binds to spectrin and actin, also binds to the cytoplasmic domain of both band 3 and *glycophorin*, the other major transmembrane protein in red blood cells.

An analogous but much more elaborate and complicated cytoskeletal network exists beneath the plasma membrane of nucleated cells. This network, which constitutes the cortical region (or *cortex*) of the cytoplasm, is rich in actin filaments, which are thought to be attached to the plasma membrane in numerous ways. Proteins that are structurally homologous to spectrin, ankyrin, and band 4.1 are present in the cortex of nucleated cells, but their organization and functions are less well understood than they are in red blood cells. The cortical cytoskeleton in nucleated cells and its interactions with the plasma membrane are discussed in Chapter 16.

Glycophorin Extends Through the Red Blood Cell Lipid Bilayer as a Single a Helix 10

Glycophorin is one of the two major proteins exposed on the outer surface of the human red blood cell and was the first membrane protein for which the complete amino acid sequence was determined. Like the model transmembrane protein shown in Figure 10-17, glycophorin is a small, single-pass transmembrane glycoprotein (131 amino acid residues) with most of its mass on the external surface of the membrane, where its hydrophilic amino-terminal end is located. This part of the protein

carries all of the carbohydrate (about 100 sugar residues in 16 separate oligosaccharide side chains), which accounts for 60% of the molecule's mass. In fact, the great majority of the total red blood cell surface carbohydrate (including more than 90% of the sialic acid and, therefore, most of the negative charge of the surface) is carried by glycophorin molecules. The hydrophilic carboxyl-terminal tail of glycophorin is exposed to the cytosol, while a hydrophobic a-helical segment 23 amino acid residues long spans the lipid bilayer (see Figure 10-16A).

Despite there being nearly a million glycophorin molecules per cell, their function remains unknown. Indeed, individuals whose red blood cells lack a major subset of these molecules appear to be perfectly healthy. Although glycophorin itself is found only in red blood cells, its structure is representative of a common class of membrane proteins that traverse the lipid bilayer as a single a helix. Many cell-surface receptors, for example, belong to this class.

Band 3 of the Red Blood Cell Is a Multipass Membrane Protein That Catalyzes the Coupled Transport of Anions [12]

Unlike glycophorin, the band 3 protein is known to play an important part in the function of red blood cells. It derives its name from its position relative to the other membrane proteins after electrophoresis in SDS polyacrylamide gels (see Figure 10-24). Like glycophorin, band 3 is a transmembrane protein, but it is a multipass membrane protein, traversing the membrane in a highly folded conformation: the polypeptide chain (about 930 amino acids long) is thought to extend across the bilayer up to 14 times. Each red blood cell contains about 10^6 band 3 polypeptide chains, which are arranged as dimers in the membrane.

The main function of red blood cells is to carry O_2 from the lungs to the tissues and to help carry CO_2 from the tissues to the lungs. The band 3 protein is crucial for the second of these functions. CO_2 is only sparingly soluble in water and so it is carried in the blood plasma as bicarbonate (HCO_3^-), which is formed and broken down inside red blood cells by an enzyme that catalyzes the reaction $H_2O + CO_2 \leftrightarrow HCO_3^- + H^+$. The band 3 protein acts as an *anion transporter*, which allows HCO_3^- to cross the membrane in exchange for Cl^-. By making the red cell membrane freely permeable to HCO_3^-, this transporter increases the amount of CO_2 that the blood can deliver to the lungs.

Band 3 proteins can be seen as distinct *intramembrane particles* by the technique of freeze-fracture electron microscopy, in which cells are frozen in liquid nitrogen and the resulting block of ice is fractured with a knife. The fracture plane tends to pass through the hydrophobic middle of membrane lipid bilayers, separating them into their two monolayers (Figure 10-27). The exposed *fracture faces* are then shadowed with platinum, and the resulting platinum replica is examined with an electron microscope. When examined in this way, human red blood cell membranes are studded with intramembrane particles that are relatively homogeneous in size (7.5 nm in diameter) and randomly distributed (Figure 10-28). The particles are thought to be principally band 3 molecules: when synthetic lipid bilayers are reconstituted with purified band 3 protein molecules, typical 7.5-nm intramembrane particles are observed when the bilayers are fractured. Figure 10-29 illustrates why band 3 molecules are seen in freeze-fracture electron microscopy of red blood cell membranes but glycophorin molecules probably are not.

In Chapter 11 we consider how a multipass transmembrane protein such as band 3 could, in principle, mediate the passive transport of polar molecules across the nonpolar lipid bilayer. But a detailed understanding of how a membrane transport protein actually works requires precise information about its three-dimensional structure in the bilayer. The first plasma membrane transport protein for which such detail became known was *bacteriorhodopsin,* a protein that serves as a light-activated proton (H^+) pump in the plasma membrane of certain bacteria. The structure of bacteriorhodopsin is similar to that of many other membrane proteins, and it merits a brief digression here.

Bacteriorhodopsin Is a Proton Pump That Traverses the Lipid Bilayer as Seven a Helices [13]

The "purple membrane" of the bacterium *Halobacterium halobium* is a specialized patch in the plasma membrane that contains a single species of protein molecule, bacteriorhodopsin (Figure10-30). Each bacteriorhodopsin molecule contains a single light-absorbing group, or chromophore (called *retinal*), which gives the protein its purple color; retinal is related to vitamin A and is identical to the chromophore found in rhodopsin of the photoreceptor cells of the vertebrate eye (discussed in Chapter 15). Retinal is covalently linked to a lysine side chain of the protein; when activated by a single photon of light, the excited chromophore immediately changes its shape and causes a series of small conformational changes in the protein that results in the transfer of one H^+ from the inside to the outside of the cell (see Figure14-36). In bright light each bacteriorhodopsin molecule can pump several hundred protons per second. The light-driven proton transfer establishes an H^+ gradient across the plasma membrane, which in turn drives the production of ATP by a second protein in the cell's plasma membrane. Thus

bacteriorhodopsin is part of a solar energy transducer that provides energy to the bacterial cell.

To understand the function of a multipass transmembrane protein in molecular detail, it is necessary to locate each of its atoms precisely, which generally requires x-ray diffraction studies of large three-dimensional crystals of the protein. But because of their amphipathic nature, these proteins are extremely difficult to crystallize. The numerous bacteriorhodopsin molecules in the purple membrane, however, are arranged as a planar two-dimensional crystal, which has made it possible to determine their three-dimensional structure and orientation in the membrane to a resolution of about 0.3 nm by an alternative approach, which uses a combination of electron microscopy and electron diffraction analysis. This procedure (referred to as *electron crystallography*) is analogous to the study of three-dimensional crystals of soluble proteins by x-ray diffraction analysis, although less structural detail has so far been obtained. As illustrated in Figure 10-31, these studies have shown that each bacteriorhodopsin molecule is folded into seven closely packed a helices (each containing about 25 amino acids), which pass roughly at right angles through the lipid bilayer.

Bacteriorhodopsin is a member of a very large superfamily of membrane proteins with similar structures but different functions. The light receptor protein *rhodopsin* in rod cells of the vertebrate retina, for example, and many cell-surface receptor proteins that bind extracellular signaling molecules are also folded into seven transmembrane a helices. These proteins function as signal transducers rather than as transporters: each responds to an extracellular signal by activating another protein inside the cell, which generates chemical signals in the cytosol, as we discuss in Chapter 15.

Porins Are Pore-forming Transmembrane Proteins That Cross the Lipid Bilayer as a b Barrel [14]

As discussed earlier, some multipass transmembrane proteins have their transmembrane segments arranged as a closed b sheet (a *b barrel*) rather than as a helices. The best studied examples of such proteins are the porins, which are found in the outer membrane of many bacteria. They are among the few transmembrane proteins whose complete atomic structure has been solved by x-ray crystallography.

Many bacteria, including *E. coli*, have an *outer membrane* surrounding their plasma membrane (see Figure11-14). The outer membrane is penetrated by various pore-forming porin proteins, which allow selected hydrophilic solutes of up to 600 daltons to diffuse across the outer lipid bilayer. The porins (and the structurally related pore-forming proteins in the outer membrane of mitochondria and chloroplasts) have a b sheet instead of an a helix as the major transmembrane motif.

The atomic structure of a porin protein isolated from a photosynthetic bacterium was determined by x-ray crystallography in 1990. It consists of a trimer in which each monomer forms a tubular b barrel, which traverses the lipid bilayer and has a water-filled pore at its center. The barrel is formed from a 16-stranded antiparallel b sheet, which is sufficiently curved to roll up into a cylindrical structure (Figure 10-32). Polar side chains line the aqueous channel on the inside, while nonpolar side chains project from the outside of the barrel to interact with the hydrophobic core of the lipid bilayer.

Membrane Proteins Often Function as Large Complexes [15]

By far the most complex transmembrane protein structure that has been studied by x-ray crystallography to date is a bacterial *photosynthetic reaction center*, whose atomic structure was solved in 1985. It was the first transmembrane protein to be crystallized and analyzed by x-ray diffraction. The results of this analysis were of general importance to membrane biology because they showed for the first time how multiple polypeptides can associate in a membrane to form a complex protein machine (Figure 10-33). In Chapter 14 we discuss how such photosynthetic complexes function to capture light energy and use it to pump H$^+$ across the membrane. Membrane proteins are often arranged in large complexes, not only for harvesting various forms of energy, but also for transducing extracellular signals into intracellular ones (discussed in Chapter 15).

Many Membrane Proteins Diffuse in the Plane of the Membrane [16]

Like membrane lipids, membrane proteins do not tumble (*flip-flop*) across the bilayer, but they do rotate about an axis perpendicular to the plane of the bilayer (*rotational diffusion*). In addition, many membrane proteins are able to move laterally within the membrane (*lateral diffusion*). The first direct evidence that some plasma membrane proteins are mobile in the plane of the membrane was provided in 1970 by an experiment in which mouse cells were artificially fused with human cells to produce hybrid cells (*heterocaryons*). Two differently labeled antibodies were used to distinguish selected mouse and human plasma membrane proteins. Although at first the mouse and human proteins were confined to their own halves of the newly

formed heterocaryon, the two sets of proteins diffused and mixed over the entire cell surface within half an hour or so (Figure 10-34). Further evidence for membrane protein mobility was soon provided by the discovery of the processes called *patching* and *capping*. When ligands, such as antibodies, that have more than one binding site (so-called *multivalent* ligands) bind to specific proteins on the surface of cells, the proteins tend to become aggregated, through cross-linking, into large clusters (or "patches"), indicating that the protein molecules are able to diffuse laterally in the lipid bilayer. Once such clusters have formed on the surface of a cell capable of locomotion, such as a white blood cell, they are actively moved to one pole of the cell to form a "cap" (Figure 10-35).

The lateral diffusion rates of membrane proteins can be measured using the technique of *fluorescence recovery after photobleaching (FRAP).* The method usually involves marking the cell-surface protein of interest with a specific fluorescent ligand, such as a fluorescent antibody. (It is important that monovalent fragments of antibodies, which have only one antigen-binding site, be used to avoid cross-linking neighboring molecules.) The fluorescent ligand is then bleached in a small area by a laser beam, and the time taken for adjacent membrane proteins carrying unbleached fluorescent ligand to diffuse into the bleached area is measured (Figure 10-36). From such measurements diffusion coefficients can be calculated for the particular cell-surface protein that was marked. The values of the diffusion coefficients for different membrane proteins in different cells are highly variable, but they are typically about one-tenth or one-hundredth of the corresponding values for the phospholipid molecules in the same membrane.

Cells Can Confine Proteins and Lipids to Specific Domains Within a Membrane [17]

The recognition that biological membranes are two-dimensional fluids was a major advance in understanding membrane structure and function. It has become clear, however, that the picture of a membrane as a lipid sea in which all proteins float freely is greatly oversimplified. Many cells have ways of confining membrane proteins to specific domains in a continuous lipid bilayer. In epithelial cells, such as those that line the gut or the tubules of the kidney, for example, certain plasma membrane enzymes and transport proteins are confined to the apical surface of the cells, whereas others are confined to the basal and lateral surfaces (Figure 10-37). This asymmetric distribution of membrane proteins is often essential for the function of the epithelium, as we discuss in Chapter 11. The lipid compositions of these two membrane domains are also different, demonstrating that epithelial cells can prevent the diffusion of lipid as well as protein molecules between the domains. Experiments with labeled lipids, however, suggest that only lipid molecules in the outer monolayer of the membrane are confined in this way. The separation of both protein and lipid molecules is thought to be maintained, at least in part, by the barriers set up by a specific type of intercellular junction (called a *tight junction,* discussed in Chapter 19). Clearly, the membrane proteins that form these intercellular junctions cannot be allowed to diffuse laterally in the interacting membranes.

A cell can also create membrane domains without using intercellular junctions. The mammalian spermatozoon, for instance, is a single cell that consists of several structurally and functionally distinct parts covered by a continuous plasma membrane. When a sperm cell is examined by immunofluorescence microscopy using a variety of antibodies that react with cell-surface antigens, the plasma membrane is found to consist of at least three distinct domains (Figure 10-38). In some cases, the antigens are able to diffuse within the confines of their own domain; it is not known how they are prevented from leaving it.

In the two examples just considered, the diffusion of protein and lipid molecules is confined to specialized domains within a continuous plasma membrane. Cells also have more drastic ways of immobilizing certain membrane proteins. One is exemplified by the purple membrane of *Halobacterium.* There the bacteriorhodopsin molecules assemble into large two-dimensional crystals in which the individual protein molecules are relatively fixed in relationship to one another; large aggregates of this kind diffuse very slowly. A more common way of restricting the lateral mobility of specific membrane proteins is to tether them to macromolecular assemblies either inside or outside the cell. We have seen that some red blood cell membrane proteins are anchored to the cytoskeleton inside; in other cell types plasma membrane proteins can be anchored to the cytoskeleton, or to the extracellular matrix, or to both. The four known ways of immobilizing specific membrane proteins are summarized in Figure 10-39.

The Cell Surface Is Coated with Sugar Residues [18]

Plasma membrane proteins, as a rule, do not protrude naked from the exterior of the cell but are decorated, clothed, or hidden by carbohydrates, which are present on the surface of all eucaryotic cells. These carbohydrates occur both as oligosaccharide chains covalently bound to membrane proteins (glycoproteins) and lipids (glycolipids) and as polysaccharide chains of *integral membrane proteoglycan* molecules. Proteoglycans, which consist of long polysaccharide chains linked covalently to a protein core, are found mainly outside the cell as part of the extracellular matrix (discussed in Chapter 19); but in the case of integral

membrane proteoglycans, the protein core either extends across the lipid bilayer or is attached to the bilayer by a glycosylphosphotidylinositol (GPI) anchor.

The term *cell coat*, or *glycocalyx*, is often used to describe the carbohydrate-rich zone on the cell surface. This zone can be visualized by a variety of stains, such as ruthenium red (Figure 10-40), as well as by its affinity for carbohydrate-binding proteins called lectins, which can be labeled with a fluorescent dye or some other visible marker. Although most of the carbohydrate is attached to intrinsic plasma membrane molecules, the glycocalyx usually also contains both glycoproteins and proteoglycans that have been secreted into the extracellular space and then adsorbed onto the cell surface (Figure10-41). Many of these adsorbed macromolecules are components of the extracellular matrix, so that where the plasma membrane ends and the extracellular matrix begins is largely a matter of semantics.

The oligosaccharide side chains of glycoproteins and glycolipids are enormously diverse in their arrangement of sugars. Although they usually contain fewer than 15 sugar residues, they are often branched, and the sugars can be bonded together by a variety of covalent linkages, unlike the amino acid residues in a polypeptide chain, which are all linked by identical peptide bonds. Even three sugar residues can be put together to form hundreds of different trisaccharides. In principle, both the diversity and the exposed position of these oligosaccharides on the cell surface make them especially well suited to function in specific cell-recognition processes, but for many years there was little evidence for this suspected function. It seemed that the role of the cell coat might be merely to protect against mechanical and chemical damage and to keep foreign objects and other cells at a distance, preventing undesirable protein-protein interactions. Indeed, this probably is an important part of its function. Recently, however, plasma-membrane-bound lectins have been identified that recognize specific oligosaccharides on cell-surface glycolipids and glycoproteins to mediate a variety of transient cell-cell adhesion processes, including those occurring in sperm-egg interactions, blood clotting, lymphocyte recirculation, and inflammatory responses.

Selectins Are Cell-Surface Carbohydrate-binding Proteins That Mediate Transient Cell-Cell Adhesions in the Bloodstream [19]

One of the best understood examples of protein-carbohydrate recognition occurs in inflammatory responses, when white blood cells (of the class called *neutrophils*) are recruited from the blood into a site of inflammation in a tissue, usually to help combat a local infection. Initially, the neutrophils adhere weakly to the endothelial cells lining the blood vessels at the site, and then they adhere more strongly and migrate out of the blood vessels by crawling between adjacent endothelial cells. It is the initial adhesion process that involves protein-carbohydrate recognition. Local chemical mediators released by cells at the site of inflammation signal the endothelial cells in the region to express a transmembrane glycoprotein called *P-selectin*, which belongs to the selectin family of cell-cell adhesion molecules. The selectins contain a carbohydrate-binding lectin domain at the end of an extended protein "stalk" that extends from the cell surface (Figure 10-42A). The lectin domain of P-selectin recognizes the specific oligosaccharide as shown in Figure 10-42B. Because this oligosaccharide is expressed on both glycolipid and glycoprotein molecules on the surface of neutrophils, the neutrophils stick specifically to the endothelial cells lining blood vessels at the inflamed site.

The binding of each lectin domain to its specific oligosaccharide is of relatively low affinity, and it seems that both the association and the subsequent dissociation of the domain from the oligosaccharide occur rapidly. This enables the selectins to bind the passing blood cells to the vessel wall, while at the same time allowing the attached cells to roll along the endothelium at the inflamed site, propelled by the flow of blood. The rolling continues until another cell-cell adhesion mechanism, mediated by a different class of transmembrane proteins, called *integrins*(discussed in Chapter 19), is activated and strengthens the adhesion, allowing the neutrophils to stop rolling and crawl out of the blood vessel into the tissue. A similar sequence of selectin-mediated and integrin-mediated adhesion events occurs when lymphocytes migrate out of the bloodstream into a lymph node (see Figure 23-9).

Various selectins are expressed on the surface of white blood cells, platelets, and endothelial cells, where they function in a wide range of transient cell-cell interactions in the bloodstream.

Summary

Whereas the lipid bilayer determines the basic structure of biological membranes, proteins are responsible for most membrane functions, serving as specific receptors, enzymes, transport proteins, and so on. Many membrane proteins extend across the lipid bilayer: in some of these transmembrane proteins the polypeptide chain crosses the bilayer as a single a helix (single-pass proteins); in others, including those responsible for the transmembrane transport of ions and other small water-soluble

molecules, the polypeptide chain crosses the bilayer multiple times, either as a series of a helices or as a b sheet in the form of a closed barrel (multipass proteins). Other membrane-associated proteins do not span the bilayer but instead are attached to one or the other side of the membrane. Many of these are bound by noncovalent interactions with transmembrane proteins, but others are bound via covalently attached lipid groups. Like the lipid molecules in the bilayer, many membrane proteins are able to diffuse rapidly in the plane of the membrane. On the other hand, cells have ways of immobilizing specific membrane proteins and of confining both membrane protein and lipid molecules to particular domains in a continuous lipid bilayer.

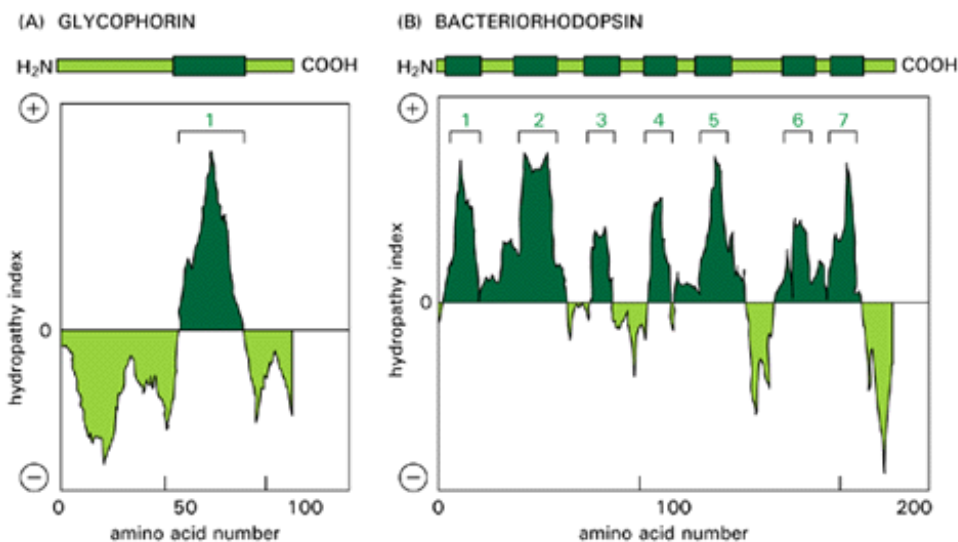
In the plasma membrane of all eucaryotic cells most of the proteins exposed on the cell surface and some of the lipid molecules in the outer lipid monolayer have oligosaccharide chains covalently attached to them. Some plasma membranes also contain integral proteoglycan molecules with surface-exposed polysaccharide chains. This sugar coating helps to protect the cell surface from mechanical and chemical damage, and some of the oligosaccharide chains are recognized by cell-surface carbohydrate-binding proteins (lectins) that mediate specific, transient, cell-cell adhesion events.
Figure 10-13. Six ways in which membrane proteins associate with the lipid bilayer. Most trans-membrane proteins are thought to extend across the bilayer as a single a helix (1) or as multiple a helices (2); some of these "single-pass" and "multipass" proteins have a covalently attached fatty acid chain inserted in the cytoplasmic monolayer (1). Other membrane proteins are attached to the bilayer solely by a covalently attached lipid - either a fatty acid chain or prenyl group - in the cytoplasmic monolayer (3) or, less often, via an oligosaccharide, to a minor phospholipid, phosphatidylinositol, in the noncytoplasmic monolayer (4). Finally, many proteins are attached to the membrane only by noncovalent interactions with other membrane proteins (5) and (6). How the structure in (3) is formed is illustrated in Figure10-14. The details of how membrane proteins become associated with the lipid bilayer in these different ways are discussed in Chapter 12.
Figure 10-14. The covalent attachment of either of two types of lipid groups can help localize a water-soluble protein to a membrane after its synthesis in the cytosol. (A) A fatty acid chain (either myristic or palmitic acid) is attached via an amide linkage to an amino-terminal glycine. (B) A prenyl group (either farnesyl or a longer geranylgeranyl group - both related to cholesterol) is attached via a thioether linkage to a cysteine residue that is four residues from the carboxyl terminus. Following this prenylation, the terminal three amino acids are cleaved off and the new carboxyl terminus is methylated before insertion into the membrane. The structures of two lipid anchors are shown underneath: (C) a myristyl anchor (a 14-carbon saturated fatty acid chain), and (D) a farnesyl anchor (a 15-carbon unsaturated hydrocarbon chain).
Figure 10-15. A segment of a transmembrane polypeptide chain crossing the lipid bilayer as an a helix. Only the a-carbon backbone of the polypeptide chain is shown, with the hydrophobic amino acids in *green* and *yellow*. The polypeptide segment shown is part of the bacterial photo-synthetic reaction center illustrated in Figure 10-33, the structure of which was determined by x-ray diffraction. (Based on data from J. Deisenhofer et al., *Nature* 318:618-624, 1985, and H. Michel et al., *EMBO J.* 5:1149-1158, 1986.)


Figure 10-16. Localization of potential a-helical membrane-spanning segments in a polypeptide chain through the use of hydropathy plots. The free energy needed to transfer successive segments of a polypeptide chain from a nonpolar solvent to water is calculated from the amino acid composition of each segment using data on model compounds. This calculation is made for segments of a fixed size (usually around 10 amino acid residues), beginning with each successive amino acid in the chain. The "hydropathy index" of the segment is plotted on the Y axis as a function of its location in the chain. A positive value indicates that free energy is required for transfer to water (that is, the segment is hydrophobic), and the value assigned is an index of the amount of energy needed. Peaks in the hydropathy index appear at the positions of hydrophobic segments in the

amino acid sequence. Two examples of membrane proteins that we discuss later in this chapter are shown: (A) glycophorin has a single membrane-spanning a helix and one corresponding peak in the hydropathy plot; (B) bacteriorhodopsin has seven membrane-spanning a helices and seven corresponding peaks in the hydropathy plot. (Adapted from D. Eisenberg, *Annu. Rev. Biochem.* 53:595-624, 1984.)
Figure 10-17. A typical single-pass transmembrane protein. Note that the polypeptide chain traverses the lipid bilayer as a right-handed a helix and that the oligosaccharide chains and disulfide bonds are all on the noncytosolic surface of the membrane. Disulfide bonds do not form between the sulfhydryl groups in the cytoplasmic domain of the protein because the reducing environment in the cytosol maintains these groups in their reduced (-SH) form.
Figure 10-18. A detergent micelle in water, shown in cross-section. Because they have both polar and nonpolar ends, detergent molecules are amphipathic.
Figure 10-19. Solubilizing membrane proteins with a mild detergent. The detergent disrupts the lipid bilayer and brings the proteins into solution as protein-lipid-detergent complexes. The phospholipids in the membrane are also solubilized by the detergent.
Figure 10-20. The structures of two commonly used detergents. Sodium dodecyl sulfate (SDS) is an anionic detergent, and Triton X-100 is a nonionic detergent. The hydrophobic portion of each detergent is shown in *green*, and the hydrophilic portion is shown in *blue*. Note that the bracketed portion of Triton X-100 is repeated about eight times.
Figure 10-21. The use of mild detergents for solubilizing, purifying, and reconstituting functional membrane protein systems. In this example functional Na$^+$-K$^+$ ATPase molecules are purified and incorporated into phospholipid vesicles. The Na$^+$-K$^+$ ATPase is an ion pump that is present in the plasma membrane of most animal cells; it uses the energy of ATP hydrolysis to pump Na$^+$ out of the cell and K$^+$ in, as discussed in Chapter 11.
Figure 10-22. A scanning electron micrograph of human red blood cells. The cells have a biconcave shape and lack nuclei. (Courtesy of Bernadette Chailley.)
Figure 10-23. The preparation of sealed and unsealed red blood cell ghosts and of right-side-out and inside-out vesicles. As indicated, the red cells tend to rupture in only one place, giving rise to ghosts with a single hole in them. The smaller vesicles are produced by mechanically disrupting the ghosts; the orientation of the membrane in these vesicles can be either right-side-out or inside-out, depending on the ionic conditions used during the disruption procedure.
Figure 10-24. SDS polyacrylamide-gel electrophoresis pattern of the proteins in the human red blood cell membrane. The gel in (A) is stained with Coomassie blue. The positions of some of the major proteins in the gel are indicated in the drawing in (B); glycophorin is shown in *red* to distinguish it from band 3. Other bands in the gel are omitted from the drawing. The large amount of carbohydrate in glycophorin molecules slows their migration so that they run almost as slowly as the much larger band 3 molecules. (A, courtesy of Ted Steck.)
Figure 10-25. Spectrin molecules from human red blood cells. The protein is shown schematically in (A) and in electron micrographs in (B). Each spectrin heterodimer consists of two antiparallel, loosely intertwined, flexible polypeptide chains called a and b these are attached noncovalently to each other at multiple points, including both ends. The phosphorylated "head" end, where two dimers associate to form a tetramer, is on the left. Both the a and b chains are composed largely of repeating domains 106 amino acids long. In (B) the spectrin molecules have been shadowed with platinum. (A, adapted from D.W. Speicher and V.T. Marchesi, *Nature* 311:177-180, 1984; B, courtesy of D.M. Shotton, with permission from D.M. Shotton, B.E. Burke, and D. Branton, *J. Mol. Biol.* 131:303-329, 1979, © Academic Press Inc. [London] Ltd.)
Figure 10-26. The spectrin-based cytoskeleton on the cytoplasmic side of the human red blood cell membrane. The structure is shown schematically in (A) and in an electron micrograph in (B). The arrangement shown in (A) has been deduced mainly from studies on the interactions of purified proteins *in vitro*. Spectrin dimers associate head-to-head to form tetramers that are linked together into a netlike meshwork by junctional complexes composed of short actin filaments (containing 13 actin monomers), tropomyosin, which probably determines the length of the actin filaments, band 4.1, and adducin (enlarged in the box on the *left*). The cytoskeleton is linked to the membrane by the indirect binding of spectrin tetramers to some band 3 proteins via ankyrin molecules, as well as by the binding of band 4.1 proteins to both band 3 and glycophorin (not shown). The electron micrograph in (B) shows the cytoskeleton on the cytoplasmic side of a red blood cell membrane after fixation and negative staining. The spectrin meshwork has been purposely stretched out to allow the details of its structure to be seen; in the normal cell the meshwork shown would occupy only about one-tenth of this area. (B, courtesy of T. Byers and D. Branton, *Proc. Natl. Acad. Sci. USA* 82:6153-6157, 1985.)
Figure 10-27. Freeze-fracture electron microscopy. The drawing shows how the technique provides images of the hydrophobic interior of the cytoplasmic (or protoplasmic) half of the bilayer (called the P face) and the external half of the bilayer (called the E face). After the fracturing process shown here, the exposed fracture faces are shadowed with platinum and carbon, the organic material is digested away, and the resulting platinum replica is examined in the electron microscope (see also Figure4-27).
Figure 10-28. Freeze-fracture electron micrograph of human red blood cells. Note that the density of intramembrane particles on the protoplasmic (P) face is higher than on the external (E) face. (Courtesy of L. Engstrom and D. Branton.)
Figure 10-29. Probable fates of band 3 and glycophorin molecules in the human red blood cell membrane during freeze-fracture. When the lipid bilayer is split, either the inside or outside half of each trans-membrane protein is pulled out of the frozen monolayer with which it is associated; the protein tends to remain with the monolayer that contains the main bulk of the protein. For this reason band 3 molecules usually remain with the inner (P) fracture face; since they have sufficient mass above the fracture plane, they are readily seen as intramembrane particles. Glycophorin molecules usually remain with the outer (E) fracture face, but it is thought that their cytoplasmic tails have insufficient mass to be seen.

Figure 10-30. Schematic drawing of the bacterium *Halobacterium halobium* showing the patches of purple membrane that contain bacteriorhodopsin molecules. These bacteria, which live in saltwater pools where they are exposed to a large amount of sunlight, have evolved a variety of light-activated proteins, including bacteriorhodopsin, which is a light-activated proton pump in the plasma membrane.
Figure 10-31. The three-dimensional structure of a bacteriorhodopsin molecule. The polypeptide chain crosses the lipid bilayer as seven a helices. The location of the chromophore and the probable pathway taken by protons during the light-activated pumping cycle are shown. When activated by a photon, the chromophore is thought to pass an H^+ to the side chain of aspartic acid 85 (*pink sphere marked 85*). Subsequently, three other H^+ transfers are thought to complete the cyclefrom aspartic acid 85 to the extra-cellular space, from aspartic acid 96 (*pink sphere marked 96*) to the chromophore, and from the cytosol to aspartic acid 96 (see Figure 14-36). (Adapted from R. Henderson et al. *J. Mol. Biol.*213:899-929, 1990.)
Figure 10-32. The three-dimensional structure of a porin trimer of *Rhodobacter capsulatus* determined by x-ray crystallography. (A) Each monomer consists of a 16-stranded antiparallel b barrel that forms a transmembrane water-filled channel. (B) The monomers tightly associate to form trimers, which have three separate channels for the diffusion of small solutes through the bacterial outer membrane. A long loop of polypeptide chain (shown in *red*), which connects two b strands, protrudes into the lumen of each channel, narrowing it to a cross-section of 0.6 x 1 nm. (Adapted from M.S. Weiss et al., *FEBS Lett.*280: 379-382, 1991.)
Figure 10-33. The three-dimensional structure of the photosynthetic reaction center of the bacterium *Rhodopseudomonas viridis*. The structure was determined by x-ray diffraction analysis of crystals of this transmembrane protein complex. The complex consists of four subunits, L, M, H, and a cytochrome. The L and M subunits form the core of the reaction center, and each contains five a helices that span the lipid bilayer. The locations of the various electron carrier coenzymes are shown in *black*. (Adapted from a drawing by J. Richardson based on data from J. Deisenhofer, O. Epp, K. Miki, R. Huber, and H. Michel, *Nature* 318:618-624, 1985.)
Figure 10-34. Experiment demonstrating the mixing of plasma membrane proteins on mouse-human hybrid cells. The mouse and human proteins are initially confined to their own halves of the newly formed heterocaryon plasma membrane, but they intermix with time. The two antibodies used to visualize the proteins can be distinguished in a fluorescence microscope because fluorescein is green whereas rhodamine is red. (Based on observations of L.D. Frye and M. Edidin, *J. Cell Sci.* 7:319-335, 1970, by permission of The Company of Biologists.)
Figure 10-35. Antibody-induced patching and capping of a cell-surface protein on a white blood cell. The bivalent antibodies cross-link the protein molecules to which they bind. This causes them to cluster into large patches, which are actively swept to the tail end of the cell to form a "cap." The centrosome, which governs the head-tail polarity of the cell, is shown in *orange*.
Figure 10-36. Measuring the rate of lateral diffusion of a plasma membrane protein by the FRAP technique. A specific protein is labeled on the cell surface with a fluorescent monovalent antibody that binds only to that protein (for simplicity, no other proteins are shown). After the antibodies are bleached in a small area using a laser beam, the fluorescence intensity recovers as the bleached molecules diffuse away and unbleached molecules diffuse into the irradiated area (shown in side view in A and top view in B). (C) A graph showing the rate of recovery. The greater the diffusion coefficient of the membrane protein, the faster the recovery.
Figure 10-37. Diagram of an epithelial cell showing how a plasma membrane protein is restricted to a particular domain of the membrane. Protein A (in the apical membrane) and protein B (in the basal and lateral membranes) can diffuse laterally in their own domains but are prevented from entering the other domain, at least partly by the specialized cell junction called a *tight junction.* Lipid molecules in the outer (noncytoplasmic) monolayer of the plasma membrane are likewise unable to diffuse between the two domains; lipids in the inner (cytoplasmic) monolayer, however, are able to do so (not shown).
Figure 10-38. Three domains in the plasma membrane of guinea pig sperm defined with monoclonal antibodies. A guinea pig sperm is shown schematically in (A), while each of the three pairs of micrographs shown in (B), (C), and (D) shows cell-surface immunofluorescence staining with a different monoclonal antibody (on the *right*) next to a phase-contrast micrograph (on the *left*) of the same cell. The antibody shown in (B) labels only the anterior head, that in (C) only the posterior head, whereas that in (D) labels only the tail. (Courtesy of Selena Carroll and Diana Myles.)

(D)
Figure 10-39. Four ways in which the lateral mobility of specific plasma membrane proteins can be restricted. The proteins can self-assemble into large aggregates (such as bacteriorhodopsin in the purple membrane of *Halobacterium*) (A); they can be tethered by interactions with assemblies of macromolecules outside (B) or inside (C) the cell; or they can interact with proteins on the surface of another cell (D).

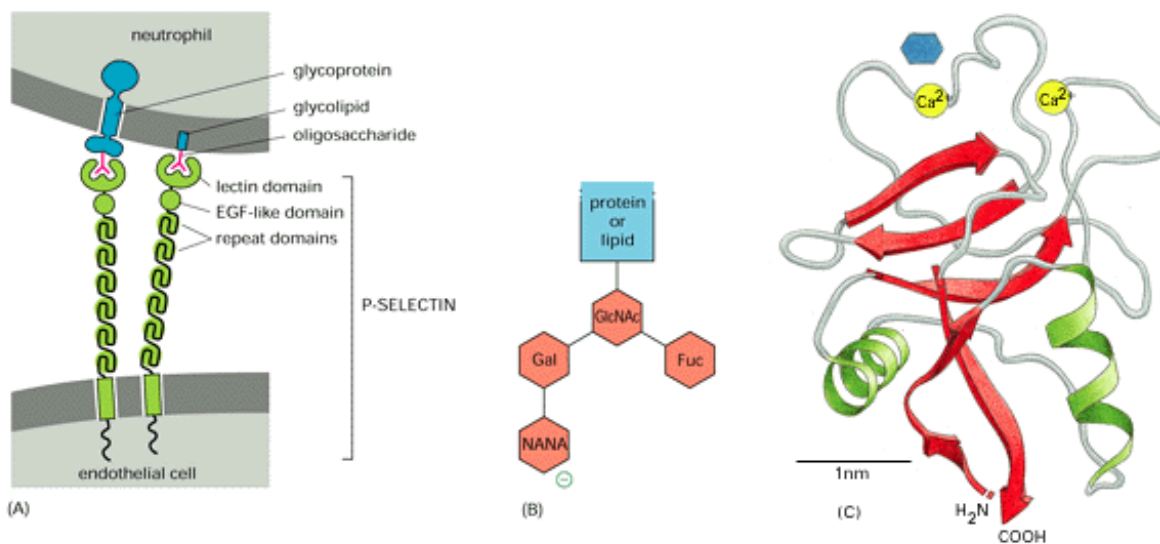
Figure 10-40. The cell coat, or glycocalyx. Electron micrograph of the surface of a lymphocyte stained with ruthenium red to show the cell coat. (Courtesy of A.M. Glauert and G.M.W. Cook.)
Figure 10-41. Simplified diagram of the cell coat (glycocalyx). The cell coat is made up of the oligosaccharide side chains of glycolipids and integral membrane glycoproteins and the polysaccharide chains on integral membrane proteoglycans. In addition, adsorbed glycoproteins and adsorbed proteoglycans (not shown) contribute to the glycocalyx in many cells. Note that all of the carbohydrate is on the noncytoplasmic surface of the membrane.


Figure 10-42. The protein-carbohydrate interaction that initiates the transient adhesion of neutrophils to endothelial cells at sites of inflammation. (A) The lectin domain of P-selectin binds to the specific oligosaccharide shown in (B), which is present on both cell-surface glycoprotein and glycolipid molecules. The lectin domain of the selectins is homologous to lectin domains found on many other carbohydrate-binding proteins in animals; because the binding to their specific sugar ligand requires extracellular Ca^{2+}, they are called *C-type lectins*. A three-dimensional structure of one of these lectin domains, determined by x-ray crystallography, is shown in (C); its bound sugar is colored *blue*. Gal = galactose; GlcNAc = *N*-acetylglucosamine; Fuc = fucose; NANA = sialic acid.

11. Membrane Transport of Small Molecules and the Ionic Basis of Membrane Excitability

Introduction

Because of its hydrophobic interior, the lipid bilayer of cell membranes serves as a barrier to the passage of most polar molecules. This barrier function is crucially important as it allows the cell to maintain concentrations of solutes in its cytosol that are different from those in the extracellular fluid and in each of the intracellular membrane-bounded compartments. To make use of this barrier, however, cells have had to evolve ways of transferring specific water-soluble molecules across their membranes in order to ingest essential nutrients, excrete metabolic waste products, and regulate intracellular ion concentrations. Transport of inorganic ions and small water-soluble organic molecules across the lipid bilayer is achieved by specialized transmembrane proteins, each of which is responsible for the transfer of a specific ion or molecule or a group of closely related ions or molecules. Cells can also transfer macromolecules and even large particles across their membranes, but the mechanisms involved in most of these cases are different from those used for transferring small molecules, and they are discussed in Chapters 12 and 13. The importance of membrane transport is indicated by the fact that almost 20% of the genes identified so far in *E. coli* are associated with such transport processes.

We begin this chapter by considering some general principles that will guide our discussion of how small water-soluble molecules traverse cell membranes. We then consider, in turn, the two main classes of membrane proteins that mediate the transfer: *carrier proteins,* which have moving parts to shift specific molecules across the membrane, and *channel proteins,* which form a narrow hydrophilic pore, allowing the passive movement of small inorganic ions. Carrier proteins can be coupled to a source of energy to catalyze active transport, and a combination of selective passive permeability and active transport creates large differences in the composition of the cytosol compared with either the extracellular fluid (Table 11-1) or the fluid

within membrane-bounded organelles. In particular, by generating ionic concentration differences across the lipid bilayer, cell membranes are able to store potential energy in the form of electrochemical gradients, which are used to drive various transport processes, to convey electrical signals in electrically excitable cells, and (in mitochondria, chloroplasts, and bacteria) to make most of the cell's ATP. We focus the discussion mainly on transport across the plasma membrane, but similar mechanisms operate across the other membranes of the eucaryotic cell, as discussed in later chapters. In the last part of this chapter we concentrate mainly on the functions of ion channels in nerve cells, for it is in these cells that channel proteins perform at their highest level of sophistication, enabling networks of nerve cells to carry out all of the astonishing feats that the human brain is capable of.

Table 11-1. Comparison of Ion Concentrations Inside and Outside a Typical Mammalian Cell

Component	Intracellular Concentration (mM)	Extracellular Concentration (mM)
Cations		
Na^+	5-15	145
K^+	140	5
Mg^{2+}	0.5	1-2
Ca^{2+}	10^{-4}	1-2
H^+	7×10^{-5} ($10^{-7.2}$ M or pH 7.2)	4×10^{-5} ($10^{-7.4}$ M or pH 7.4)
Anions*		
Cl^-	5-15	110

*. The cell must contain equal quantities of + and - charges (that is, be electrically neutral). Thus, in addition to Cl^-, the cell contains many other anions not listed in this table; in fact, most cellular constituents are negatively charged (HCO_3^-, PO_4^{3-}, proteins, nucleic acids, metabolites carrying phosphate and carboxyl groups, etc.). The concentrations of Ca^{2+} and Mg^{2+} given are for the free ions. There is a total of about 20 mM Mg^{2+} and 1-2 mM Ca^{2+} in cells, but this is mostly bound to proteins and other substances and, in the case of Ca^{2+}, stored within various organelles.

Principles of Membrane Transport [1]

Introduction

We begin this section by describing the permeability properties of protein-free, synthetic lipid bilayers. We then introduce some of the terms used to describe the various forms of membrane transport and some strategies for characterizing the proteins and processes involved.

Protein - free Lipid Bilayers Are Highly Impermeable to Ions [2]

Given enough time, virtually any molecule will diffuse across a protein-free lipid bilayer down its concentration gradient. The rate at which it does so, however, varies enormously, depending partly on the size of the molecule and mostly on its relative solubility in oil. In general, the smaller the molecule and the more soluble it is in oil (that is, the more hydrophobic, or nonpolar, it is), the more rapidly it will diffuse across a bilayer. *Small nonpolar* molecules, such as O_2 (32 daltons) and CO_2 (44 daltons), readily dissolve in lipid bilayers and therefore rapidly diffuse across them. *Uncharged polar* molecules also diffuse rapidly across a bilayer if they are small enough. Water (18 daltons), ethanol (46 daltons), and urea (60 daltons), for example, cross rapidly; glycerol (92 daltons) diffuses less rapidly; and glucose (180 daltons), hardly at all (Figure11-1).

By contrast, lipid bilayers are highly impermeable to *charged* molecules (ions), no matter how small: the charge and high degree of hydration of such molecules prevents them from entering the hydrocarbon phase of the bilayer. Thus synthetic bilayers are

10^9 times more permeable to water than to even such small ions as Na^+ or K^+ (Figure11-2).

There Are Two Main Classes of Membrane Transport Proteins - Carriers and Channels [1]

Like synthetic lipid bilayers, cell membranes allow water and nonpolar molecules to permeate by simple diffusion. Cell membranes, however, also have to allow passage of various polar molecules, such as ions, sugars, amino acids, nucleotides, and many cell metabolites that pass across synthetic lipid bilayers only very slowly. Special membrane proteins are responsible for transferring such solutes across cell membranes. These proteins, referred to as membrane transport proteins, occur in many forms and in all types of biological membranes. Each protein transports a particular class of molecule (such as ions, sugars, or amino acids) and often only certain molecular species of the class. The specificity of transport proteins was first indicated in the mid-1950s by studies in which single gene mutations were found to abolish the ability of bacteria to transport specific sugars across their plasma membrane. Similar mutations have now been discovered in humans suffering from a variety of inherited diseases that affect the transport of a specific solute in the kidney or intestine or both. Individuals with the inherited disease *cystinuria,* for example, are unable to transport certain amino acids (including cystine, the disulfide-linked dimer of cysteine) from either the urine or the intestine into the blood; the resulting accumulation of cystine in the urine leads to the formation of cystine stones in the kidneys.

All membrane transport proteins that have been studied in detail have been found to be multipass transmembrane proteins - that is, their polypeptide chains traverse the lipid bilayer multiple times. By forming a continuous protein pathway across the membrane, these proteins are thought to enable the specific hydrophilic solutes to cross the membrane without coming into direct contact with the hydrophobic interior of the lipid bilayer.

There are two major classes of membrane transport proteins: *carrier proteins* and *channel proteins*. Carrier proteins (also called *carriers, permeases,* or *transporters*) bind the specific solute to be transported and undergo a series of conformational changes in order to transfer the bound solute across the membrane. Channel proteins, on the other hand, need not bind the solute. Instead, they form hydrophilic pores that extend across the lipid bilayer; when these pores are open, they allow specific solutes (usually inorganic ions of appropriate size and charge) to pass through them and thereby cross the membrane (Figure11-3). Not surprisingly, transport through channel proteins occurs at a very much faster rate than transport mediated by carrier proteins.

Active Transport Is Mediated by Carrier Proteins Coupled to an Energy Source [1], [3]

All channel proteins and many carrier proteins allow solutes to cross the membrane only passively ("downhill") - a process called passive transport (or facilitated diffusion). If the transported molecule is uncharged, it is simply the difference in its concentration on the two sides of the membrane (its *concentration gradient*) that drives passive transport and determines its direction. If the solute carries a net charge, however, both its concentration gradient and the electrical potential difference across the membrane (the *membrane potential*) influence its transport. The concentration gradient and the electrical gradient can be combined to calculate a net driving force, or electrochemical gradient, for each charged solute. We discuss this in more detail in Chapter 14. In fact, almost all plasma membranes have an electrical potential difference (voltage gradient) across them, with the inside usually negative with respect to the outside. This potential difference favors the entry of positively charged ions into the cell but opposes the entry of negatively charged ions.

Cells also require transport proteins that will actively pump certain solutes across the membrane against their electrochemical gradient ("uphill"); this process, known as active transport, is always mediated by carrier proteins. In active transport the pumping activity of the carrier protein is directional because it is tightly coupled to a source of metabolic energy, such as ATP hydrolysis or an ion gradient, as discussed later. Thus transport by carrier proteins can be either active or passive, whereas transport by channel proteins is always passive (Figure 11-4).

Recombinant DNA Technology Has Revolutionized the Study of Membrane Transport Proteins [4]

Because of the difficulty in obtaining three-dimensional crystals of multipass membrane proteins for x-ray crystallographic studies, the detailed three-dimensional structures of the membrane transport proteins we shall discuss are not known. We therefore do not understand the molecular mechanisms they use to transport specific solutes across the lipid bilayer. But important insights have been gained by other methods, especially by the use of recombinant DNA technology.

Once the DNA encoding a transport protein has been cloned and sequenced, the amino acid sequence of the polypeptide can be

deduced and the number of transmembrane a helices can be estimated by analysis of a hydropathy plot (discussed in Chapter 10). Antibodies made against synthetic peptides corresponding to specific segments of the polypeptide chain can be used to help determine which segments are exposed on one or the other side of the membrane. The DNA sequence encoding specific parts of the protein can be altered by site-specific mutagenesis, and the corresponding mutant mRNA can be injected into cultured mammalian cells or *Xenopus* oocytes, where it will direct the synthesis of a mutant protein whose transport function can be readily assessed. In this way functionally important amino acid residues and protein segments can be identified. One must interpret the results of such studies with caution, however, as a small change in one part of a protein can sometimes have large effects on the protein's overall folded conformation and, therefore, on its function, even when the altered part is not directly involved in that function. Nonetheless, this strategy is proving to be invaluable, as we shall see.

Recombinant DNA technology has also contributed to our understanding of membrane transport proteins in a second way. Once the DNA encoding a protein has been isolated, it is often a relatively simple matter to use this DNA as a probe to isolate related DNA sequences encoding homologous proteins. Such studies have revealed that membrane transport is mediated by a surprisingly small number of protein families, whose members have related structures and, presumably, related mechanisms of action and a common evolutionary origin. A family, however, can contain a very large number of different proteins, and, even for a specific family member, there are often many variants (called *isoforms*) produced either from different genes or from differently processed RNA transcripts from a single gene. In some cases the isoforms differ in their transport activity, time of expression in development, tissue distribution, location in the cell, or any combination of these properties. In other cases the significance of the heterogeneity is unclear.

Before discussing in detail the different classes of membrane transport proteins and the insights gained by these techniques, we pause briefly to consider another class of molecules that can selectively increase the permeability of lipid bilayers. These molecules provide a simple illustration of some of the principles discussed earlier.

Ionophores Can Be Used as Tools to Increase the Permeability of Membranes to Specific Ions 5

Ionophores are small hydrophobic molecules that dissolve in lipid bilayers and increase their permeability to specific inorganic ions. Most are synthesized by microorganisms (presumably as biological weapons against competitors or prey). They are widely used by cell biologists as tools to increase the ion permeability of membranes in studies on synthetic bilayers, cells, or cell organelles. There are two classes of ionophores - mobile ion carriers and channel formers (Figure 11-5). Both types operate by shielding the charge of the transported ion so that it can penetrate the hydrophobic interior of the lipid bilayer. Since ionophores are not coupled to energy sources, they permit net movement of ions only down their electrochemical gradients.

Valinomycin is an example of a mobile ion carrier. It is a ring-shaped polymer that transports K^+ down its electrochemical gradient by picking up K^+ on one side of the membrane, diffusing across the bilayer, and releasing K^+ on the other side. The ionophore *A23187* is another example of a mobile ion carrier, but it transports divalent cations such as Ca^{2+} and Mg^{2+}. It normally acts as an ion-exchange shuttle, carrying two H^+ out of the cell for every divalent cation it carries in. When cells are exposed to A23187, Ca^{2+} enters the cytosol from the extracellular fluid down a steep electrochemical gradient. Accordingly, this ionophore is widely used in cell biology to increase the concentration of free Ca^{2+} in the cytosol, thereby mimicking certain cell-signaling mechanisms (discussed in Chapter 15).

Gramicidin A is an example of a channel-forming ionophore. As a linear peptide of only 15 amino acid residues, all with hydrophobic side chains, it is the simplest and best characterized ion channel. Two gramicidin molecules are thought to come together end to end across the bilayer to form a transmembrane channel (Figure 11-6), which selectively allows monovalent cations to flow down their electrochemical gradients. These dimers are unstable and are constantly forming and dissociating, so that the average open time for a channel is about 1 second. With a large electrochemical gradient, gramicidin A can transport about 20,000 cations per open channel each millisecond, which is 1000 times more ions than can be transported by a single mobile carrier molecule in the same time. Gramicidin is made by certain bacteria, perhaps to kill other microorganisms by collapsing the H^+, Na^+, and K^+ gradients that are essential for cell survival, and it has been useful as an antibiotic.

Summary

Lipid bilayers are highly impermeable to most polar molecules. In order to transport small water-soluble molecules into or out of cells or intracellular membrane-bounded compartments, cell membranes contain various transport proteins, each of which is responsible for transferring a particular solute or class of solutes across the membrane. There are two classes of membrane

transport proteinscarriers and channels; both form continuous protein pathways across the lipid bilayer. Whereas transport by carrier proteins can be either active or passive, transport by channel proteins is always passive. Ionophores, which are small hydrophobic molecules made by microorganisms, can be used as tools to increase the permeability of cell membranes to specific inorganic ions in studies on cells or organelles.
Figure 11-1. The relative permeability of a synthetic lipid bilayer to different classes of molecules. The smaller the molecule and, more important, the fewer hydrogen bonds it makes with water, the more rapidly the molecule diffuses across the bilayer.
Figure 11-2. Permeability coefficients (cm/sec) for the passage of various molecules through synthetic lipid bilayers. The rate of flow of a solute across the bilayer is directly proportional to the difference in its concentration on the two sides of the membrane. Multiplying this concentration difference (in mol/cm^3) by the permeability coefficient (cm/sec) gives the flow of solute in moles per second per square centimeter of membrane. A concentration difference of tryptophan of 10^{-4} mol/cm^3($10^{-4}/10^{-3}$ L = 0.1 M), for example, would cause a flow of 10^{-4} mol/cm^3 x 10^{-7} cm/sec = 10^{-11} mol/sec through 1 cm^2 of membrane, or 6 x 10^4 molecules/sec through 1 μ^2 of membrane.

(A) CARRIER PROTEIN   (B) CHANNEL PROTEIN
Figure 11-3. A schematic view of the two classes of membrane transport proteins. A *carrier protein* is thought to alternate between two conformations, so that the solute binding site is sequentially accessible on one side of the bilayer and then on the other. In contrast, a *channel protein* is thought to form a water-filled pore across the bilayer through which specific ions can diffuse.
Figure 11-4. Comparison of passive transport down an electrochemical gradient with active transport against an electrochemical gradient. Whereas simple diffusion and passive transport by membrane transport proteins (facilitated diffusion) occur spontaneously, active transport requires an input of metabolic energy. Only carrier proteins can carry out active transport, but both carrier proteins and channel proteins can mediate facilitated diffusion.
Figure 11-5. A mobile ion carrier and a channel-forming ionophore. In both cases net ion flow occurs only down an electrochemical gradient.
Figure 11-6. The structure of a gramicidin channel. The channel is formed by the association of two identical peptides at their amino-terminal ends. Each chain is folded into a b helix, which resembles a rolled-up b pleated sheet. (A) is a side view and (B) a top view. The peptide backbones that line the channel are shown in *blue* and *dark green*, while the *light green* represents the protruding hydrophobic side chains. The lipid bilayer is shown in *gray*. (C) shows the size of unhydrated K^+ions, while (D) shows a membrane-spanning a helix in top view for comparison with the b helix. Note that the a helix does not contain a pore and, therefore, cannot, on its own, form a channel. (After S. Weinstein, B.A. Wallace, E.R. Blout, J.S. Morrow, and W. Veatch, *Proc. Natl. Acad. Sci.* 76:4230, 1979.)

Carrier Proteins and Active Membrane Transport [1], [6]

Introduction

The process by which a carrier protein transfers a solute molecule across the lipid bilayer resembles an enzyme-substrate reaction, and the carriers involved behave like specialized membrane-bound enzymes. Each type of carrier protein has one or more specific binding sites for its solute (substrate). When the carrier is saturated (that is, when all these binding sites are occupied), the rate of transport is maximal. This rate, referred to as V_{max}, is characteristic of the specific carrier. In addition, each carrier protein has a characteristic binding constant for its solute, K_M, equal to the concentration of solute when the transport rate is half its maximum value (Figure 11-7). As with enzymes, the binding of solute can be blocked specifically by competitive inhibitors (which compete for the same binding site and may or may not be transported by the carrier) or by noncompetitive inhibitors (which bind elsewhere and specifically alter the structure of the carrier). In contrast with ordinary enzyme-substrate reactions, however, the transported solute is usually not covalently modified by the carrier protein.

Some carrier proteins simply transport a single solute from one side of the membrane to the other at a rate determined as above by V_{max} and K_M; they are called uniporters. Others, with more complex kinetics, function as coupled transporters, in which the transfer of one solute depends on the simultaneous or sequential transfer of a second solute, either in the same direction (symport) or in the opposite direction (antiport) (Figure11-8). Most animal cells, for example, take up glucose from the extracellular fluid, where its concentration is high relative to that in the cytosol, by *passive* transport through glucose carriers that operate as uniporters. There are a variety of these glucose carriers, all belonging to the same family of homologous proteins with 12 putative transmembrane a helices. By contrast, intestinal and kidney cells take up glucose from the lumen of the intestine and kidney tubules, respectively, where the concentration of the sugar is low. These cells actively transport glucose across their plasma membrane by symport with Na^+. As discussed in Chapter 10, the band 3 protein of the human red blood cell is an anion carrier that operates as an antiporter to exchange Cl^- for HCO_3^-.

Although the molecular details are unknown, carrier proteins are thought to transfer the solute across the lipid bilayer by undergoing reversible conformational changes that alternately expose the solute binding site first on one side of the membrane and then on the other. A schematic model of how such a carrier protein might operate is shown in Figure11-9. Because carriers are now known to be multipass transmembrane proteins, it is highly unlikely that they ever tumble in the membrane or shuttle back and forth across the lipid bilayer as was once believed.

As we discuss below, it requires only a relatively minor modification of the model shown in Figure 11-9 to link the carrier protein to a source of energy (such as ATP hydrolysis [see Figure 11-11] or an ion gradient) in order to pump a solute uphill against its electrochemical gradient. In fact, comparison of some bacterial carrier proteins with mammalian ones supports the idea that there need be little difference in molecular design between carrier proteins that mediate active transport and those that operate passively. Some carriers that in bacteria use the energy stored in the H^+gradient across the bacterial plasma membrane to drive the active uptake of various sugars are structurally similar to the passive glucose carriers of animal cells. This suggests an evolutionary relationship between these carrier proteins; and given the importance of sugars as an energy source, it would not be surprising if this superfamily of sugar carriers were an ancient one.

We begin our discussion of active transport by considering a carrier protein that plays a crucial part in generating and maintaining the Na^+ and K^+ gradients across the plasma membrane of animal cells.

The Plasma Membrane Na^+-K^+Pump Is an ATPase [7]

The concentration of K^+ is typically 10 to 20 times higher inside cells than outside, whereas the reverse is true of Na^+ (see Table

These concentration differences are maintained by a Na^+-K^+ pump that is found in the plasma membrane of virtually all animal cells. The pump operates as an antiporter, actively pumping Na^+ out of the cell against its steep electrochemical gradient and pumping K^+ in. As explained below, the Na^+ gradient produced by the pump regulates cell volume through its osmotic effects and is also exploited to drive transport of sugars and amino acids into the cell. Almost one-third of the energy requirement of a typical animal cell is consumed in fueling this pump; in electrically active nerve cells, which, as we shall see, are repeatedly gaining small amounts of Na^+ and losing small amounts of K^+ during the propagation of nerve impulses, this figure approaches two-thirds of the cell's energy requirement.

A major advance in understanding the Na^+-K^+ pump came with the discovery in 1957 of an enzyme that hydrolyzes ATP to ADP and phosphate and requires Na^+ and K^+ for maximal activity. An important clue linking this Na^+-K^+ ATPase with the Na^+-K^+ pump was the observation that a known inhibitor of the pump, *ouabain,* also inhibits the ATPase. But the crucial evidence that ATP hydrolysis provides the energy for driving the pump came from studies of resealed red blood cell ghosts, in which the concentrations of ions, ATP, and drugs on either side of the membrane could be varied and the effects on ion transport and ATP hydrolysis observed. It was found that (1) the transport of Na^+ and K^+ is tightly coupled to ATP hydrolysis, so that one cannot occur without the other; (2) ion transport and ATP hydrolysis can occur only when Na^+ and ATP are present inside the ghosts and K^+ is present on the outside; (3) ouabain is inhibitory only when present outside the ghosts, where it competes for the K^+-binding site; and (4) for every molecule of ATP hydrolyzed (100 ATP molecules can be hydrolyzed by each ATPase molecule each second), three Na^+ ions are pumped out and two K^+ ions are pumped in (Figure 11-10).

Although these experiments provided compelling evidence that ATP supplies the energy for pumping Na^+ and K^+ ions across the plasma membrane, they did not explain how ATP hydrolysis is coupled to ion transport. A partial explanation was provided by the finding that, during the pumping cycle, the terminal phosphate group of the ATP is transferred to an aspartic acid residue of the ATPase and is subsequently removed, as explained in Figure 11-11.

The Na^+-K^+ pump in red blood cell ghosts can be driven in reverse to produce ATP: when the Na^+ and K^+ gradients are experimentally increased to such an extent that the energy stored in their electrochemical gradients is greater than the chemical energy of ATP hydrolysis, these ions move down their electrochemical gradients and ATP is synthesized from ADP and phosphate by the Na^+-K^+ ATPase. Thus the phosphorylated form of the ATPase (step 2 in Figure 11-11) can relax either by donating its phosphate to ADP (step 2 to step 1) or by changing its conformation (step 2 to step 3). Whether the overall change in free energy is used to synthesize ATP or to pump Na^+ out of the ghost depends on the relative concentrations of ATP, ADP, and phosphate and on the electrochemical gradients for Na^+ and K^+.

The Na^+-K^+ ATPase has been purified and found to consist of a large, multipass, transmembrane catalytic subunit (about 1000 amino acids long) and an associated smaller, single-pass glycoprotein. The former has binding sites for Na^+ and ATP on its cytoplasmic surface and a binding site for K^+ on its external surface, and is reversibly phosphorylated and dephosphorylated during the pumping cycle. The function of the glycoprotein is uncertain, except that it is required for the intracellular transport of the catalytic subunit to the plasma membrane. A functional Na^+-K^+ pump can be reconstituted from the purified complex: the ATPase is solubilized in detergent, purified, and mixed with appropriate phospholipids. When the detergent is removed, membrane vesicles are formed that pump Na^+ and K^+ in opposite directions in the presence of ATP (see Figure 10-22).

The Na^+-K^+ ATPase Is Required to Maintain Osmotic Balance and Stabilize Cell Volume 8

Since the Na^+-K^+ ATPase drives three positively charged ions out of the cell for every two it pumps in, it is *electrogenic;* that is, it drives a net current across the membrane, tending to create an electrical potential, with the inside negative relative to the outside. This effect of the pump, however, seldom contributes more than 10% to the membrane potential. The remaining 90%, as we shall see later, depends on the pump only indirectly.

On the other hand, the Na^+-K^+ ATPase does have a direct role in regulating cell volume: it controls the solute concentration inside the cell, thereby regulating the osmotic forces that can make a cell swell or shrink (Figure 11-12). As explained in Panel 11-1, cells contain a high concentration of solutes, including numerous negatively charged organic molecules that are confined inside the cell (the so-called *fixed anions*) and their accompanying cations that are required for charge balance, and this creates a large osmotic gradient that tends to "pull" water into the cell. For animal cells this effect is counteracted by an opposite osmotic gradient due to a high concentration of inorganic ions - chiefly Na^+ and Cl^- - in the extracellular fluid. The Na^+-K^+ ATPase maintains osmotic balance by pumping out the Na^+ that leaks in down its steep electrochemical gradient; the Cl^- is kept out by

the membrane potential.

The importance of the Na^+-K^+ ATPase in controlling cell volume is indicated by the observation that many animal cells swell, and sometimes burst, if they are treated with ouabain, which inhibits the Na^+-K^+ ATPase. There are, of course, other ways for a cell to cope with its osmotic problems. Plant cells and many bacteria are prevented from bursting by the semirigid cell wall that surrounds their plasma membrane; in amoebae the excess water that flows in osmotically is collected in contractile vacuoles, which periodically discharge their contents to the exterior (see Panel 11-1). But for most animal cells, the Na^+-K^+ ATPase is crucial.

Some Ca^{2+} Pumps Are Also Membrane-bound ATPases 9

Eucaryotic cells maintain very low concentrations of free Ca^{2+} in their cytosol (~10^{-7} M) in the face of very much higher extracellular Ca^{2+} concentrations (~10^{-3}M). Even a small influx of Ca^{2+} significantly increases the concentration of free Ca^{2+} in the cytosol, and the flow of Ca^{2+} down its steep concentration gradient in response to extracellular signals is one means of transmitting these signals rapidly across the plasma membrane. The maintenance of a steep Ca^{2+} gradient is therefore important to the cell. The Ca^{2+} gradient is in part maintained by Ca^{2+} pumps in the plasma membrane that actively transport Ca^{2+} out of the cell. One of these is an ATPase, while the other is an antiporter that is driven by the Na^+ electrochemical gradient.

The best-understood Ca^{2+}pump is a membrane-bound ATPase in the *sarcoplasmic reticulum* of muscle cells. The sarcoplasmic reticulum - a specialized type of endoplasmic reticulum - forms a network of tubular sacs in the cytoplasm of muscle cells and serves as an intracellular store of Ca^{2+}. (When an action potential depolarizes the muscle cell membrane, Ca^{2+} is released from the sarcoplasmic reticulum into the cytosol, stimulating the muscle to contract, as discussed in Chapter 16.) The Ca^{2+} pump, which accounts for about 90% of the membrane protein of the organelle, is responsible for pumping Ca^{2+} from the cytosol into the sarcoplasmic reticulum. (The endoplasmic reticulum of nonmuscle cells contains a similar Ca^{2+} ATPase, but in smaller quantities, so that it is harder to purify.)

The Ca^{2+} ATPase can be analyzed biochemically by the same methods as the Na^+-K^+ ATPase and is found to function in a closely similar way. DNA sequencing studies show, in fact, that the Na^+-K^+ ATPase and Ca^{2+} ATPases are homologous proteins. In each case the large catalytic subunit exists in multiple isoforms, is thought to have about 10 putative membrane-spanning a helices, and is phosphorylated and dephosphorylated during the pumping cycle.

Membrane-bound Enzymes That Synthesize ATP Are Transport ATPases Working in Reverse 10

The plasma membrane of bacteria, the inner membrane of mitochondria, and the thylakoid membrane of chloroplasts all contain an enzyme that is analogous to the transport ATPases discussed above, but it normally works in reverse. Instead of ATP hydrolysis driving ion transport, H^+ gradients across these membranes drive the synthesis of ATP from ADP and phosphate. The H^+ gradients are generated during the electron-transport steps of oxidative phosphorylation (in aerobic bacteria and mitochondria) or photosynthesis (in chloroplasts) or by the light-activated H^+ pump (bacteriorhodopsin) in *Halobacterium.* The enzyme that normally synthesizes ATP, called *ATP synthase,* can, like the transport ATPases, work in either direction, depending on the conditions: it can hydrolyze ATP and pump H^+ across the membrane, or it can synthesize ATP when H^+ flows through the enzyme in the reverse direction. ATP synthase is responsible for producing nearly all of the ATP in most cells and is discussed in detail in Chapter 14.

Active Transport Can Be Driven by Ion Gradients 11

Many active transport systems are driven by the energy stored in ion gradients rather than by ATP hydrolysis. The free energy released during the movement of an inorganic ion down an electrochemical gradient is used as the driving force to pump other solutes uphill, against their electrochemical gradient. Thus all of these proteins function as coupled transporters - some as symporters, others as antiporters. In the plasma membrane of animal cells Na^+ is the usual co-transported ion whose electrochemical gradient provides the driving force for the active transport of a second molecule. The Na^+ that enters the cell during transport is subsequently pumped out by the Na^+-K^+ ATPase, which, by maintaining the Na^+ gradient, indirectly drives the transport. (For this reason ion-driven carriers are said to mediate *secondary active transport*, whereas transport ATPases are said to mediate *primary active transport*.) Intestinal and kidney epithelial cells, for instance, contain a variety of symport

systems that are driven by the Na^+ gradient across the plasma membrane; each system is specific for importing a small group of related sugars or amino acids into the cell. In these systems the solute and Na^+ bind to different sites on a carrier protein; because the Na^+ tends to move into the cell down its electrochemical gradient, the sugar or amino acid is, in a sense, "dragged" into the cell with it. The greater the electrochemical gradient for Na^+, the greater the rate of solute entry; conversely, if the Na^+ concentration in the extracellular fluid is reduced, solute transport decreases.

In bacteria and yeasts, as well as in many membrane-bounded organelles of animal cells, most active transport systems driven by ion gradients depend on H^+ rather than Na^+ gradients, reflecting the predominance of H^+ ATPases and the virtual absence of Na^+-K^+ ATPases in these membranes. The active transport of many sugars and amino acids into bacterial cells, for example, is driven by the electrochemical H^+ gradient across the plasma membrane.

Na^+-driven Carrier Proteins in the Plasma Membrane Regulate Cytosolic pH [12]

The structure and function of most macromolecules are greatly influenced by pH, and most proteins operate optimally at a particular pH. Lysosomal enzymes, for example, function best at the low pH (~5) found in lysosomes, whereas cytosolic enzymes function best at the close to neutral pH (~7.2) found in the cytosol. It is crucial, therefore, that cells be able to control the pH of their intracellular compartments.

Most cells have one or more types of Na^+-driven antiporters in their plasma membrane that regulate intracellular (cytosolic) pH (pH_i), keeping it at about 7.2. These proteins use the energy stored in the Na^+ gradient to reduce acidity by getting rid of excess H^+, which either leaks in or is produced in the cell by acid-forming reactions. Two mechanisms are used: either H^+ is directly transported out of the cell or HCO_3^- is brought into the cell to neutralize H^+ in the cytosol. One of these antiporters, which uses the first mechanism, is a *Na^+-H^+ exchanger*, which couples an influx of Na^+ to an efflux of H^+. Another, which uses a combination of the two mechanisms, is a *Na^+-driven Cl^--HCO_3^- exchanger* that couples an influx of Na^+ and HCO_3^- to an efflux of Cl^- and H^+ (so that $NaHCO_3$ goes in and HCl comes out). The Na^+-driven Cl^--HCO_3^- exchanger is twice as effective as the Na^+-H^+ exchanger, in the sense that it pumps out one H^+ and neutralizes another for each Na^+ that enters the cell. If HCO_3^- is available, as is usually the case, this antiporter is the most important carrier protein regulating pH_i. Both exchangers are regulated by pH_i and increase their activity as pH_i falls.

In some cells a third Na^+-dependent transporter plays a part in pH_i regulation. This *$Na^+HCO_3^-$ symporter* transports one Na^+ into the cell together with two or more HCO_3^- ions. In contrast with the other two transporters just described, this symporter, therefore, is *electrogenic* and has the net effect of carrying a negative charge into the cell. The lower the voltage inside the cell, the harder it is for the symporter to operate. Consequently, the pH_i in cells with this symporter - notably glial cells in the nervous system - is sensitive to changes in the membrane potential. This sensitivity is thought to allow these cells to help regulate extracellular pH locally in the brain in response to changes in electrical activity.

A Na^+-independent *Cl^--HCO_3^- exchanger*, similar to the band 3 protein in the membrane of red blood cells discussed in Chapter 10, also plays an important part in pH_i regulation in some nucleated cells. Like the Na^+-dependent transporters, the Cl^--HCO_3^- exchanger is regulated by pH_i, but the movement of HCO_3^- in this case is normally *out* of the cell, down its electrochemical gradient. The rate of HCO_3^- efflux and Cl^- influx increases as pH_i rises, thereby decreasing pH_i whenever the cytosol becomes too alkaline.

As discussed in Chapter 13, the low pH in lysosomes, as well as in endosomes and secretory vesicles, is maintained by *H^+ ATPases,* which use the energy of ATP hydrolysis to pump H^+ into these organelles from the cytosol.

An Asymmetrical Distribution of Carrier Proteins in Epithelial Cells Underlies the Transcellular Transport of Solutes [13]

In epithelial cells, such as those involved in absorbing nutrients from the gut, carrier proteins are distributed asymmetrically in the plasma membrane and thereby contribute to the transcellular transport of absorbed solutes. As shown in Figure 11-13, Na^+-linked symporters located in the apical (absorptive) domain of the plasma membrane actively transport nutrients into the cell, building up substantial concentration gradients, while Na^+-independent transport proteins in the basal and lateral (basolateral)

domain allow nutrients to leave the cell passively down these concentration gradients. The Na$^+$-K$^+$ ATPase that maintains the Na$^+$ gradient across the plasma membrane of these cells is located in the basolateral domain. Related mechanisms are thought to be used by kidney and intestinal epithelial cells to pump water from one extracellular space to another.

In many of these epithelial cells the plasma membrane area is greatly increased by the formation of thousands of microvilli, which extend as thin, fingerlike projections from the apical surface of each cell (see Figure 11-13). Such microvilli can increase the total absorptive area of a cell by as much as 25-fold, thereby greatly increasing its transport capabilities.

Some Bacterial Transport ATPases Are Homologous to Eucaryotic Transport ATPases Involved in Drug Resistance and Cystic Fibrosis: The ABC Transporter Superfamily 14

The last type of carrier protein that we discuss is a family of transport ATPases that are of great clinical importance, even though their normal functions in eucaryotic cells are only just beginning to be discovered. The first of these proteins to be characterized were found in bacteria. We have already mentioned that the plasma membranes of all bacteria contain carrier proteins that use the H$^+$ gradient across the membrane to pump a variety of nutrients into the cell. Many also have transport ATPases that use the energy of ATP hydrolysis to import certain sugars, amino acids, and small peptides. In bacteria such as *E. coli,* which have double membranes (Figure11-14), the transport ATPases are located in the inner membrane, and an auxiliary mechanism exists to capture the nutrients and deliver them to the transporters (Figure 11-15).

The transport ATPases in the bacterial plasma membrane belong to the largest and most diverse family of transport proteins known. It is called the ABC transporter superfamily because each member contains a highly conserved ATP-binding cassette (Figure 11-16). Over 50 ABC transporters have been described, and although each one is usually specific for a particular substrate or class of substrates, the variety of substrates transported by this superfamily is great and includes amino acids, sugars, inorganic ions, polysaccharides, peptides, and even proteins. Whereas most family members have been described in procaryotes, an increasing number are being discovered in eucaryotes. The first of these to be identified were discovered because of their ability to pump hydrophobic drugs out of eucaryotic cells. One of these is the multidrug resistance (MDR) protein, whose overexpression in human cancer cells can make these cells simultaneously resistant to a variety of chemically unrelated cytotoxic drugs that are widely used in cancer chemotherapy. Treatment with any one of these drugs can result in the selection of cells that overexpress the MDR transport protein; the transporter pumps the drugs out of the cell, thereby reducing their toxicity and conferring resistance to a wide variety of therapeutic agents. A related and equally sinister phenomenon occurs in the protist *Plasmodium falciparum*, which causes malaria. More than 200 million people are infected with this parasite, which remains a major cause of human death, killing more than a million people a year. The control of malaria is hampered by the development of resistance to the antimalarial drug *chloroquine*, and resistant *P. falciparum* have been shown to have amplified a gene that encodes an ABC transporter that pumps out the chloroquine.

The number of known members of the ABC superfamily of transporters in eucaryotic cells is growing rapidly, and the normal functions of some of them are becoming apparent. In yeasts an ABC transporter is responsible for exporting a mating pheromone (which is a peptide 13 amino acids long) across the yeast cell plasma membrane. In most vertebrate cells an ABC transporter in the endoplasmic reticulum (ER) membrane actively transports a wide variety of peptides, produced by protein degradation, from the cytosol into the ER. This is the first step in a pathway of great importance in the surveillance of cells by the immune system (discussed in Chapter 23). The transported protein fragments, having entered the ER, are eventually carried to the cell surface, where they are displayed for scrutiny by cytotoxic T lymphocytes, which will kill the cell if the fragments appear foreign (as they will if they derive from a virus inside the cell). Yet another member of the ABC family has been discovered through studies of the common genetic disease *cystic fibrosis*. This disease is caused by a mutation in a gene encoding an ABC transporter that functions as a Cl$^-$ channel in the plasma membrane of epithelial cells. The channel is unusual in that it requires both ATP hydrolysis and cyclic-AMP-dependent phosphorylation in order to open. As there is evidence that the MDR protein may also function as a Cl$^-$ channel in some cells (in this case, regulated by cell volume rather than by cyclic AMP), it seems clear that at least some ABC transporters can function as both carriers and ion channels. How ABC transporters can function in these two different ways and transfer such diverse types of molecules across a membrane is a mystery.

Some of the families of structurally related carrier proteins that we have discussed are summarized in Table 11-2.

Summary

Carrier proteins bind specific solutes and transfer them across the lipid bilayer by undergoing conformational changes that

expose the solute binding site sequentially on one side of the membrane and then on the other. Some carrier proteins simply transport a single solute "downhill," whereas others can act as pumps to transport a solute "uphill" against its electrochemical gradient, using energy provided by ATP hydrolysis or by a "downhill" flow of another solute (such as Na$^+$) to drive the requisite series of conformational changes. DNA cloning and sequencing studies show that carrier proteins belong to a small number of families, each of which comprises proteins of similar amino acid sequence that are thought to have evolved from a common ancestral protein and to operate by a similar mechanism. The family of cation-transporting ATPases, which includes the ubiquitous Na$^+$-K$^+$ pump, is an important example; each of these ATPases contains a large catalytic subunit that is sequentially phosphorylated and dephosphorylated during the pumping cycle. The superfamily of ABC transporters is especially important clinically: it includes proteins that are responsible for cystic fibrosis, as well as for drug resistance in cancer cells and in malaria-causing parasites.
Figure 11-7. Kinetics of simple diffusion compared to carrier-mediated diffusion. Whereas the rate of the former is always proportional to the solute concentration, the rate of the latter reaches a maximum (V_{max}) when the carrier protein is saturated. The solute concentration when transport is at half its maximal value approximates the binding constant (K_M) of the carrier for the solute and is analogous to the K_M of an enzyme for its substrate. The graph applies to a carrier transporting a single solute; the kinetics of coupled transport of two or more solutes (see text) are more complex but show basically similar phenomena.
Figure 11-8. Three types of carrier-mediated transport. The schematic diagram shows carrier proteins functioning as uniports, symports, and antiports.
Figure 11-9. A hypothetical model showing how a conformational change in a carrier protein could mediate the facilitated diffusion of a solute. The carrier protein shown can exist in two conformational states: in state "pong" the binding sites for solute A are exposed on the outside of the bilayer; in state "ping" the same sites are exposed on the other side of the bilayer. The transition between the two states is proposed to occur randomly and to be completely reversible. Therefore, if the concentration of A is higher on the outside of the bilayer, more A will bind to the carrier protein in the pong conformation than in the ping conformation, and there will be a net transport of A down its electrochemical gradient.
Figure 11-11. A schematic model of the pumping cycle of the Na+-K+ ATPase. The binding of Na+ (1) and the subsequent phosphorylation by ATP of the cytoplasmic face of the ATPase (2) induce the protein to undergo a conformational change that transfers the Na+ across the membrane and releases it on the outside (3). Then the binding of K+on the extracellular surface (4) and the subsequent dephosphorylation (5) return the protein to its original conformation, which transfers the K+ across the membrane and releases it into the cytosol (6). These changes in conformation are analogous to the ping⇌pong transitions shown in Figure 11-9 except that here the Na+-dependent phosphorylation and the K+-dependent dephosphorylation of the protein cause the conforma-tional transitions to occur in an orderly manner, enabling the protein to do useful work. Although for simplicity only one Na+- and one K+-binding site are shown, in the real pump there are thought to be three Na+- and two K+-

binding sites. Moreover, although the ATPase is shown as alternating between two conformational states, there is evidence that it goes through a more complex series of conformational changes during the actual pumping cycle.
Figure 11-10. The Na+-K+ ATPase. This carrier protein actively pumps Na+ out of and K+ into a cell against their electrochemical gradients. For every molecule of ATP hydrolyzed inside the cell, three Na+ are pumped out and two K+ are pumped in. The specific pump inhibitor ouabain and K+ compete for the same site on the external side of the ATPase.
Figure 11-12. **Response of a human red blood cell to changes in osmolarity (also called *tonicity*) of the extracellular fluid.** Because the plasma membrane is freely permeable to water, water will move into or out of cells down its concentration gradient, a process called *osmosis.* If cells are placed in a *hypotonic solution* (i.e., a solution having a low solute concentration and therefore a high water concentration), there will be a net movement of water into the cells, causing them to swell and burst (lyse). Conversely, if cells are placed in a *hypertonic solution,* they will shrink.

Panel 11-1: Intracellular water balance: the problem and its solution.

SOURCES OF INTRACELLULAR OSMOLARITY
Macromolecules themselves contribute very little to the osmolarity of the cell interior since, despite their large size, each one counts only as a single molecule and there are relatively few of them compared to the number of small molecules in the cell. However, most biological macromolecules are highly charged, and they attract many inorganic ions of opposite charge. Because of their large numbers, these counterions make a major contribution to intracellular osmolarity.

As the result of active transport and metabolic processes, the cell contains a high concentration of small organic molecules, such as sugars, amino acids, and nucleotides, to which its plasma membrane is impermeable. Because most of these metabolites are charged, they also attract counterions. Both the small metabolites and their counterions make a further major contribution to intracellular osmolarity.
The osmolarity of the extracellular fluid is usually due mainly to small inorganic ions. These leak slowly across the plasma membrane into the cell. If they were not pumped out, and if there were no other molecules inside the cell that interacted with them so as to influence their distribution, they would eventually come to equilibrium with equal concentrations inside and outside the cell. However, the presence of charged macromolecules and metabolites in the cell that attract these ions gives rise to the Donnan effect: it causes the total concentration of inorganic ions (and therefore their contribution to the osmolarity) to be greater inside than outside the cell at equilibrium.

THE PROBLEM

Because of the above factors, a cell that does nothing to control its osmolarity will have a higher concentration of solutes inside than outside. As a result, water will be higher in concentration outside the cell than inside. This difference in water concentration across the plasma membrane will cause water to move continuously into the cell by osmosis, causing it to rupture.

THE SOLUTION

Animal cells and bacteria control their intracellular osmolarity by actively pumping out inorganic ions, such as Na$^+$, so that their cytoplasm contains a lower total concentration of inorganic ions than the extracellular fluid, thereby compensating for their excess of organic solutes.
Plant cells are prevented from swelling by their rigid walls and so can tolerate an osmotic difference across their plasma membranes: an internal turgor pressure is built up, which at equilibrium forces out as much water as enters.
Many protozoa avoid becoming swollen with water, despite an osmotic difference across the plasma membrane, by periodically extruding water from special contractile vacuoles.
Figure 11-13. The transcellular transport of glucose across an intestinal epithelial cell depends on the asymmetrical distribution of transport proteins in the cell's plasma membrane. The process shown results in the transport of glucose from the gut lumen to the extracellular fluid (from where it passes into the blood). Glucose is pumped into the cell through the apical domain of the membrane by a Na^+-powered glucose symport, and glucose passes out of the cell (down its concentration gradient) by facilitated diffusion mediated by a different glucose carrier protein in the basal and lateral membrane domains. The Na^+ gradient driving the glucose symport is maintained by the Na^+-K^+ ATPase in the basal and lateral plasma membrane domains, which keeps the internal concentration of Na^+ low. Adjacent cells are connected by impermeable junctions (called *tight junctions*). The junctions have a dual function in the transport process illustrated: they prevent solutes from crossing the epithelium between cells, allowing a concentration gradient of glucose to be maintained across the cell sheet, and they also serve as diffusion barriers within the plasma membrane, which help confine the various carrier proteins to their respective membrane domains (see Figure 10-37).
Figure 11-14. Schematic view of a small section of the double membrane of an *E. coli* bacterium.. The inner membrane is the cell's plasma membrane. Between the inner and outer lipid bilayer membranes there is a highly porous, rigid peptidoglycan composed of protein and polysaccharide that constitutes the bacterial cell wall; it is attached to lipoprotein molecules in the

outer membrane and fills the *periplasmic space*(only a little of the peptido-glycan is shown). This space also contains a variety of soluble protein molecules. The dashed green threads at the top represent the polysaccharide chains of the special lipopolysaccharide molecules that form the external monolayer of the outer membrane; for clarity, only a few of these chains are shown.Bacteria with double membranes are called *gram negative* because they do not retain the dark blue dye used in the gram staining procedure. Bacteria with single membranes (but thicker cell walls), such as staphylo-cocci and streptococci, retain the blue dye and therefore are called *gram positive*; their single membrane is analogous to the inner (plasma) membrane of gram-negative bacteria.
Figure 11-15. The auxiliary transport system associated with transport ATPases in bacteria with double membranes. The solute diffuses through channel-forming proteins (called *porins*) in the outer membrane and binds to a *periplasmic substrate-binding protein*. As a result, the substrate-binding protein undergoes a conformational change that enables it to bind to a transport ATPase in the plasma membrane, which then picks up the solute and actively transfers it across the bilayer in a reaction driven by ATP hydrolysis. The peptidoglycan is omitted for simplicity; its porous structure allows the substrate-binding proteins and water-soluble solutes to move through it by simple diffusion.
Figure 11-16. A schematic drawing of a typical ABC transporter. (A) Topology diagram. (B) Hypothetical arrangement of the polypeptide chain in the membrane. The transporter consists of four domains: two highly hydrophobic domains, each with six putative membrane-spanning segments that somehow form the translocation pathway, and two ATP-binding catalytic domains (or cassettes). In some cases the two halves of the transporter are formed by a single polypeptide (*as shown*), whereas in other cases they are formed by two separate polypeptides.

Table 11-2. Some Carrier Protein Families

Family*	Representative Members
Sugar transporters	passive glucose transporters in mammalian cells some H^+-driven sugar transporters in bacteria
Cation-transporting ATPases	Na^+-K^+ ATPases; Ca^{2+} ATPases
ABC transporters	multidrug resistance (MDR) ATPase in mammalian cells; periplasmic substrate-binding-protein-dependent ATPases in bacteria; chloroquine-resistance ATPase in *P. falciparum*; mating pheromone exporter in yeast; peptide pump in vertebrate ER membrane; cystic fibrosis transmembrane regulator (CFTR) protein
Anion (Cl^--HCO_3^-) antiporters	band 3 in red blood cells; anion exchangers in other cells
Cation antiporters	Na^+-H^+exchanger
Cation/anion antiporters	Na-dependent Cl^--HCO_3^- exchanger
Na^+-driven symporters	Na^+-glucose symporter in intestinal cells; Na^+-proline symporter in bacteria; Na^+-HCO_3^- symporter in glial cells

*. The members of a family are similar in amino acid sequence and, therefore, are thought to have evolved from a common ancestral protein.

Ion Channels and Electrical Properties of Membranes <u>15</u>

Introduction

Unlike carrier proteins, channel proteins form hydrophilic pores across membranes. One class of channel proteins found in virtually all animal phyla forms *gap junctions* between two adjacent cells; each plasma membrane contributes equally to the formation of the channel, which connects the cytoplasm of the two cells. These channels are discussed in <u>Chapter 19</u> and will not be considered further here. Both gap junctions and *porins*, the channel-forming proteins of the outer membranes of bacteria, mitochondria, and chloroplasts (discussed in <u>Chapter 10</u>), have relatively large and permissive pores, which would be disastrous if they directly connected the inside of a cell to an extracellular space. In contrast, most channel proteins in the plasma membrane of animal a nd plant cells connect the cytosol to the cell exterior and necessarily have narrow, highly selective pores. These proteins are concerned specifically with inorganic ion transport and so are referred to as ion channels. For transport efficiency, channels have an advantage over carriers in that more than 1 million ions can pass through one channel each second, which is a rate 1000 times greater than the fastest rate of transport mediated by any known carrier protein. On the other hand, channels cannot be coupled to an energy source to carry out active transport, so the transport they mediate is always passive ("downhill"). Thus the function of ion channels is to allow specific inorganic ions, mainly Na^+, K^+, Ca^{2+}, or Cl^-, to diffuse rapidly down their electrochemical gradients across the lipid bilayer, although this does not mean that the transport through ion channels cannot be regulated. Indeed, we shall see that the ability to control ion fluxes in this way is essential for many cell functions. Nerve cells, in particular, have made a specialty of using ion channels, and we shall consider how they utilize a diversity of such channels for receiving, conducting, and transmitting signals.

Ion Channels Are Ion Selective and Fluctuate Between Open and Closed States <u>15</u>

Two important properties distinguish ion channels from simple aqueous pores. First, they show *ion selectivity,* permitting some inorganic ions to pass but not others. This suggests that their pores must be narrow enough in places to force permeating ions into intimate contact with the walls of the channel so that only ions of appropriate size and charge can pass. It is thought that the permeating ions have to shed most of their associated water molecules in order to pass, in single file, through the narrowest part of the channel; this limits their rate of passage. Thus, as ion concentrations are increased, the flux of ions through a channel increases proportionally but then levels off (saturates) at a maximum rate.

The second important distinction between ion channels and simple aqueous pores is that ion channels are not continuously open. Instead, they have "gates," which open briefly and then close again, as shown schematically in <u>Figure 11-17</u>. In most cases the gates open in response to a specific stimulus. The main types of stimuli that are known to cause ion channels to open are a change in the voltage across the membrane (*voltage-gated channels*), a mechanical stress (*mechanically gated channels*), or the binding of a ligand (*ligand-gated channels*). The ligand can be either an extracellular mediator - specifically, a *neurotransmitter* (*transmitter-gated channels*) - or an intracellular mediator, such as an ion (*ion-gated channels*), or a nucleotide (*nucleotide-gated channels*) (<u>Figure11-18</u>). The activity of many ion channels is regulated in addition by protein phos-phorylation and dephosphorylation; this type of channel regulation is discussed, together with nucleotide-gated ion channels, in <u>Chapter 15</u>.

More than 100 types of ion channels have been described thus far, and new ones are still being discovered. They are responsible for the electrical excitability of muscle cells, and they mediate most forms of electrical signaling in the nervous system. A single nerve cell might typically contain 10 kinds of ion channels or more, located in different domains of its plasma membrane. But ion channels are not restricted to electrically excitable cells. They are present in all animal cells and are found in plant cells and microorganisms: they propagate the leaf-closing response of the mimosa plant, for example, and allow the single-celled paramecium to reverse direction after a collision.

Perhaps the most common ion channels are those that are permeable mainly to K^+. These channels are found in the plasma membrane of almost all animal cells. An important subset of K^+ channels are open even in an unstimulated or "resting" cell and are hence sometimes called *K^+ leak channels.* Although this term covers a variety of different K^+ channels depending on the cell type, they serve a common function: by making the plasma membrane much more permeable to K^+ than to other ions, they play a critical part in maintaining the *membrane potential*the voltage difference that is present across all plasma membranes.

The Membrane Potential in Animal Cells Depends Mainly on K^+ Leak Channels and the K^+ Gradient Across the Plasma Membrane <u>15</u>, <u>16</u>

A membrane potential arises when there is a difference in the electrical charge on the two sides of a membrane, due to a slight excess of positive ions over negative on one side and a slight deficit on the other. Such charge differences can result both from active electrogenic pumping (see p. 515) and from passive ion diffusion. We shall see in Chapter 14 that most of the membrane potential of the mitochondrion is generated by electrogenic H^+ pumps in the mitochondrial inner membrane. Electrogenic pumps also generate most of the electrical potential across the plasma membrane in plants and fungi. In typical animal cells, however, passive ion movements make the largest contribution to the electrical potential across the plasma membrane.

As explained earlier, the Na^+-K^+ ATPase helps to maintain osmotic balance across the animal cell membrane by keeping the intracellular concentration of Na^+ low. Because there is little Na^+ inside the cell, other cations have to be plentiful there to balance the charge carried by the cell's fixed anions - the negatively charged organic molecules that are confined inside the cell. This balancing role is performed largely by K^+, which is actively pumped into the cell by the Na^+-K^+ ATPase and can also move freely in or out through the K^+ leak channels in the plasma membrane. Because of the presence of these channels, K^+ comes almost to an equilibrium, where an electrical force exerted by an excess of negative charges attracting K^+ into the cell balances the tendency of K^+ to leak out down its concentration gradient. The membrane potential is the manifestation of this electrical force, and its equilibrium value can be calculated from the steepness of the K^+ concentration gradient. The following argument may help to make this clear.

Suppose that initially there is no voltage gradient across the plasma membrane (the membrane potential is zero), but the concentration of K^+ is high inside the cell and low outside. K^+ will tend to leave the cell through the K^+ leak channels, driven by its concentration gradient. As K^+ moves out, it will leave behind unbalanced negative charge, thereby creating an electrical field, or membrane potential, which will tend to oppose the further efflux of K^+. The net efflux of K^+ will halt when the membrane potentialreaches a value where this electrical driving force on K^+ exactly balances the effect of its concentration gradient - that is, when the electrochemical gradient for K^+ is zero. Although Cl^- ions also equilibrate across the membrane, because their charge is negative, the membrane potential keeps most of these ions out of the cell. The equilibrium condition, in which there is no net flow of ions across the plasma membrane, defines the resting membrane potential for this idealized cell. A simple but very important formula, the Nernst equation, expresses the equilibrium condition quantitatively and, as explained in Panel 11-2, makes it possible to calculate the theoretical resting membrane potential if the ratio of internal and external ion concentrations is known. As the plasma membrane of a real cell is not exclusively permeable to K^+ and Cl^-, however, the actual resting membrane potential is usually not exactly equal to that predicted by the Nernst equation for K^+ or Cl^-.

The Resting Potential Decays Only Slowly When the Na^+-K^+ Pump Is Stopped [15], [16]

The number of ions that must move across the plasma membrane to set up the membrane potential is minute. Thus one can think of the membrane potential as arising from movements of charge that leave ion *concentrations* practically unaffected and result in only a very slight discrepancy in the number of positive and negative ions on the two sides of the membrane (Figure11-19). Moreover, these movements of charge are generally rapid, taking only a few milliseconds or less.

It is illuminating to consider what happens to the membrane potential in a real cell if the Na^+-K^+ ATPase is suddenly inactivated. First, there is an immediate slight drop in the membrane potential. This is because the pump is electrogenic and, when active, makes a small direct contribution to the membrane potential by pumping out three Na^+ for every two K^+ that it pumps in. Switching off the pump, however, does not abolish the major component of the resting potential, which is generated by the K^+ equilibrium mechanism outlined above. This component persists as long as the Na^+ concentration inside the cell stays low and the K^+ ion concentration high - typically for many minutes. The plasma membrane, however, is somewhat permeable to all small ions, including Na^+. Therefore, without the Na^+-K^+ ATPase, the ion gradients set up by pumping will eventually run down, and the membrane potential established by diffusion through the K^+ leak channels will fall as well. As Na^+ enters, the osmotic balance is upset, and water seeps into the cell (see Panel 11-1, p. 517). But if the cell does not burst, it eventually comes to a new resting state where Na^+, K^+, and $Cl^-$are all at equilibrium across the membrane. The membrane potential in this state is much less than it was in the normal cell with an active Na^+-K^+ pump.

The potential difference across the plasma membrane of an animal cell at rest varies between -20 mV and -200 mV, depending on the organism and cell type. Although the K^+ gradient always has a major influence on this potential, the gradients of other ions (and the disequilibrating effects of ion pumps) also have a significant effect: the more permeable the membrane for a given ion, the more strongly the membrane potential tends to be driven toward the equilibrium value for that ion. Consequently,

almost any change of a membrane's permeability to ions causes a change in the membrane potential. This is the key principle relating the electrical excitability of cells to the activities of ion channels.

Nerve cells, or *neurons*, have made a profession of electrical excitability, and most of what we know about the topic has come from studies of these remarkable cells. To put the following account of electrical excitability in context, therefore, we must digress to review briefly how a typical neuron is organized.

The Function of a Nerve Cell Depends on Its Elongated Structure 15

The fundamental task of the neuron is to receive, conduct, and transmit signals. To perform these functions, neurons in general are extremely elongated: a single nerve cell in a human being, extending, say, from the spinal cord to a muscle in the foot, may be a meter long. Every neuron consists of a *cell body* (containing the nucleus) with a number of long, thin processes radiating outward from it. Usually there is one long axon, to conduct signals away from the cell body toward distant targets, and several shorter branching dendrites, which extend from the cell body like antennae and provide an enlarged surface area to receive signals from the axons of other nerve cells (Figure11-20). Signals are also received on the cell body itself. The axon commonly divides at its far end into many branches and so can pass on its message to many target cells simultaneously. Likewise, the extent of branching of the dendrites can be very great - in some cases sufficient to receive as many as 100,000 inputs on a single neuron.

Despite the varied significance of the signals carried by different classes of neurons, the form of the signal is always the same, consisting of changes in the electrical potential across the neuron's plasma membrane. Communication occurs because an electrical disturbance produced in one part of the cell spreads to other parts. Such a disturbance becomes weaker with increasing distance from its source unless energy is expended to amplify it as it travels. Over short distances this attenuation is unimportant; in fact, many small neurons conduct their signals passively, without amplification. For long-distance communication, however, passive spread is inadequate. Thus larger neurons employ an active signaling mechanism, which is one of their most striking features: an electrical stimulus that exceeds a certain threshold strength triggers an explosion of electrical activity that is propagated rapidly along the neuron's plasma membrane and is sustained by automatic amplification all along the way. This traveling wave of electrical excitation, known as an action potential, or *nerve impulse*, can carry a message without attenuation from one end of a neuron to the other at speeds as great as 100 meters/second or more. Action potentials are the direct consequence of the properties of voltage-gated cation channels, as we shall now see.

Voltage-gated Cation Channels Are Responsible for the Generation of Action Potentials in Electrically Excitable Cells 15, 17

The plasma membrane of all electrically excitable cells - not only neurons but also muscle, endocrine, and egg cells - contains voltage-gated cation channels, which are responsible for generating the action potentials. An action potential is triggered by a *depolarization* of the plasma membrane - that is, by a shift in the membrane potential to a less negative value. (We shall see later how this may be caused by the action of a neurotransmitter.) In nerve and skeletal muscle cells a stimulus that causes sufficient depolarization promptly causes voltage-gated Na^+ channels to open, allowing a small amount of Na^+ to enter the cell down its electrochemical gradient. The influx of positive charge depolarizes the membrane further, thereby opening more Na^+ channels, which admit more Na^+ ions, causing still further depolarization. This process continues in a self-amplifying fashion until, within a fraction of a second, the electrical potential in the local region of membrane has shifted from its resting value of about -70 mV almost as far as the Na^+ equilibrium potential of about +50 mV (see Panel 11-2, p. 526). At this point, when the net electrochemical driving force for the flow of Na^+ is almost zero, the cell would come to a new resting state, with all of its Na^+ channels permanently open, if the open conformation of the channel were stable.

The cell is saved from such a permanent electrical spasm because the Na^+ channels have an automatic inactivating mechanism, which causes the channels to reclose rapidly even though the membrane is still depolarized. The Na^+ channels remain in this *inactivated* state, unable to reopen, until a few milliseconds after the membrane potential returns to its initial negative value. A schematic illustration of these three distinct states of the voltage-gated Na^+ channel - closed, open, and inactivated - is shown in Figure 11-21. How they contribute to the rise and fall of the action potential is shown in Figure11-22.

The description just given of an action potential concerns only a small patch of plasma membrane. The self-amplifying depolarization of the patch, however, is sufficient to depolarize neighboring regions of membrane, which then go through the same cycle. In this way the action potential spreads as a traveling wave from the initial site of depolarization to involve the

entire plasma membrane, as shown in Figure 11-23.

In addition to the inactivation of Na$^+$ channels, in many nerve cells a second mechanism operates to help bring the activated plasma membrane more rapidly back toward its original negative potential, ready to transmit a second impulse. Voltage-gated K$^+$ channels open, so that the transient influx of Na$^+$ is rapidly overwhelmed by an efflux of K$^+$, which quickly drives the membrane back toward the K$^+$ equilibrium potential, even before the inactivation of the Na$^+$ channels is complete. These K$^+$ channels respond to changes in membrane potential in much the same way as the Na$^+$ channels do, but with slightly slower kinetics; for this reason they are sometimes called *delayed K$^+$channels.*

The electrochemical mechanism of the action potential was first established by a famous series of experiments carried out in the 1940s and 1950s. Because the techniques for studying electrical events in small cells had not yet been developed, the experiments exploited the giant neurons in the squid. Despite the many technical advances made since then, the logic of the original analysis continues to serve as a model for present-day work. Panel11-3 outlines some of the key original experiments.

Myelination Increases the Speed and Efficiency of Action Potential Propagation in Nerve Cells 15, 18

The axons of many vertebrate neurons are insulated by a myelin sheath, which greatly increases the rate at which an axon can conduct an action potential. The importance of myelination is dramatically demonstrated by the demyelinating disease *multiple sclerosis*, in which myelin sheaths in some regions of the central nervous system are destroyed by an unknown mechanism; where this happens, the propagation of nerve impulses is greatly slowed, often with devastating neurological consequences.

Myelin is formed by specialized supporting, or *glial,* cells - *Schwann cells* in peripheral nerves and *oligodendrocytes* in the central nervous system. These glial cells wrap layer upon layer of their own plasma membrane in a tight spiral around the axon (Figure 11-24), thereby insulating the axonal membrane so that almost no current leaks across it. The sheath is interrupted at regularly spaced *nodes of Ranvier,* where almost all the Na$^+$ channels in the axon are concentrated. Because the ensheathed portions of the axon membrane have excellent cable properties (i.e., they behave electrically much like well-designed undersea telegraph cables), a depolarization of the membrane at one node almost immediately spreads passively to the next node. Thus an action potential propagates along a myelinated axon by jumping from node to node, a process called *saltatory conduction.* This type of conduction has two main advantages: action potentials travel faster, and metabolic energy is conserved because the active excitation is confined to the small regions of axonal plasma membrane at nodes of Ranvier.

Patch-Clamp Recording Indicates That Individual Na$^+$ Channels Open in an All-or-Nothing Fashion 15, 19

Neuron and skeletal muscle cell plasma membranes contain many thousands of voltage-gated Na$^+$ channels, and the current crossing the membrane is the sum of the currents flowing through all of these. This aggregate current can be recorded with an intracellular microelectrode, as shown in Figure11-23. Remarkably, however, it is also possible to record current flowing through individual channels. This is achieved by means of patch-clamp recording, a method that has revolutionized the study of ion channels by allowing transport through a single molecule of channel protein to be studied in a small patch of membrane covering the mouth of a micropipette (Figure11-25). With this simple but powerful technique, the detailed properties of ion channels can be studied in all sorts of cell types, and this has led to the discovery that even cells that are not electrically excitable usually have a variety of gated ion channels in their plasma membrane. Many of these cells, such as yeasts, are too small to be investigated by the traditional electrophysiologist's method of impalement with an intracellular microelectrode.

Patch-clamp recording indicates that individual voltage-gated Na$^+$ channels open in an all-or-nothing fashion: the times of its opening and closing are random, but when open, the channel always has the same very large conductance, allowing more than 8000 ions to pass per millisecond. Therefore, the aggregate current crossing the membrane of an entire cell does not indicate the *degree* to which a typical individual channel is open but rather the *total number* of channels in its membrane that are open at any one time (Figure 11-26).

The phenomenon of voltage gating can be understood in terms of simple physical principles. The interior of the resting neuron or muscle cell is at an electric potential about 50-100 mV more negative than the external medium. Although this potential difference seems small, it exists across a plasma membrane only about 5 nm thick, so that the resulting voltage *gradient* is about 100,000 V/cm. Proteins in the membrane are thus subjected to a very large electrical field. These proteins, like all others, have a number of charged groups on their surface, as well as polarized bonds between their various atoms. The electrical field therefore exerts forces on the molecular structure. For many membrane proteins the effects of changes in the membrane electrical field are

probably insignificant, but voltage-gated ion channels can adopt a number of alternative conformations whose stabilities depend on the strength of the field. Each conformation can "flip" to another conformation if given a sufficient jolt by the random thermal movements of the surroundings, and it is the relative stability of the closed, open, and inactivated conformations against flipping that is altered by changes in the membrane potential (see Figure 11-21).

Voltage-gated Cation Channels Are Evolutionarily and Structurally Related 20

Na^+ channels are not the only kind of voltage-gated cation channel that can generate an action potential: the action potentials in some muscle, egg, and endocrine cells, for example, depend on *voltage-gated Ca^{2+} channels* rather than on Na^+ channels. Moreover, voltage-gated Na^+, K^+, or Ca^{2+} channels of unknown function are found in some cell types that are not normally electrically active. There is a surprising amount of structural and functional diversity within each of these three classes of voltage-gated cation channels, which is generated both by multiple genes and by alternative splicing of RNA transcripts produced from the same gene. Nonetheless, the amino acid sequences of the known voltage-gated Na^+, K^+, and Ca^{2+} channels show striking similarities, suggesting that they all belong to a large superfamily of evolutionarily and structurally related proteins.

Each type of voltage-gated cation channel is composed of either four homologous protein domains (in the case of Na^+ and Ca^{2+} channels) or four identical subunits (in the case of K^+ channels). These four domains or subunits are thought to be arranged like staves of a barrel surrounding a central pore, as illustrated for a voltage-gated K^+ channel in Figure 11-27. The K^+ channels are especially convenient for studying the relationship between the structure and function of voltage-gated cation channels because they are formed from relatively small identical subunits rather than from a single large polypeptide chain. The amino acid sequence suggests that each subunit of a K^+ channel contains six membrane-spanning a helices, but, unexpectedly, none of these seems to line the ion-conducting pore. Studies of K^+ channel proteins that have been modified by the use of recombinant DNA techniques suggest that a 20 amino acid segment of polypeptide chain extends across the membrane as an antiparallel b sheet to line the pore: when this segment is exchanged between two K^+ channels with differing permeability properties, the permeability characteristics are found to depend solely on this segment.

A similar approach has been used to identify two other important functional regions of voltage-gated K^+ channel proteins. The amino-terminal 19 amino acid residues of at least one such protein are involved in rapid *channel inactivation.* If this region is altered, the kinetics of channel inactivation are changed, and if the region is entirely removed, inactivation is abolished. Amazingly, in the latter case, inactivation can be restored by exposing the cytoplasmic face of the plasma membrane to a small synthetic peptide corresponding to the missing amino terminus. These findings suggest that the amino terminus of each K^+ channel subunit acts like a tethered ball that occludes the cytoplasmic end of the pore soon after it opens (Figure 11-28); a similar mechanism is thought to operate in the rapid inactivation of voltage-gated Na^+ channels, although a different segment of the protein seems to be involved. Finally, one of the transmembrane a helices that is highly conserved in all known voltage-gated cation channels contains regularly spaced, positively charged amino acid residues (see Figure 11-27A). This helix has been implicated as the *voltage sensor* in these channels: if any of these charged residues are changed, the response of the channel to shifts in membrane potential is altered.

The same type of analysis, combining recombinant DNA technology and electrophysiological techniques, has been used to characterize another class of ion channels. These channels open in response to the binding of a specific *neuro-transmitter* rather than to a change in membrane potential.

Transmitter-gated Ion Channels Convert Chemical Signals into Electrical Ones at Chemical Synapses 15

Neuronal signals are transmitted from cell to cell at specialized sites of contact known as synapses. The usual mechanism of transmission is indirect. The cells are electrically isolated from one another, the *presynaptic cell* being separated from the *postsynaptic cell* by a narrow *synaptic cleft*. A change of electrical potential in the presynaptic cell triggers it to release a small signaling molecule known as a neurotransmitter, which is stored in membrane-bounded *synaptic vesicles* and is released by exocytosis. The neurotransmitter rapidly diffuses across the synaptic cleft and provokes an electrical change in the postsynaptic cell by binding to *transmitter-gated ion channels* (Figure 11-29). After the neurotransmitter has been secreted, it is rapidly removed, either by specific enzymes in the synaptic cleft or by re-uptake - either by the nerve terminal that released it or by surrounding glial cells. Re-uptake is mediated by a variety of Na^+-dependent neurotransmitter carrier proteins. Rapid removal ensures both spatial and temporal precision of signaling at a synapse: it prevents the neurotransmitter from influencing neighboring cells and clears the synaptic cleft before the next pulse of neurotransmitter is released, so that the timing of

repeated, rapid signaling events can be accurately communicated to the postsynaptic cell. As we shall see, signaling via such *chemical synapses* is far more versatile and adaptable than direct electrical coupling via gap junctions at *electrical synapses* (discussed in <u>Chapter 19</u>), which are also used by neurons but to a much lesser extent.

Transmitter-gated ion channels are specialized for rapidly converting extracellular chemical signals into electrical signals at chemical synapses. The channels are concentrated in the plasma membrane of the postsynaptic cell in the region of the synapse and open transiently in response to the binding of neuro-transmitter molecules, thereby producing a brief permeability change in the membrane (see <u>Figure 11-29</u>). Unlike the voltage-gated channels responsible for action potentials, transmitter-gated channels are relatively insensitive to the membrane potential and, therefore, cannot by themselves produce a self-amplifying excitation. Instead, they produce local permeability changes, and hence changes of membrane potential, that are graded according to how much neuro-transmitter is released at the synapse and how long it persists there. An action potential can be triggered from this site only if the local membrane potential increases enough to open a sufficient number of nearby voltage-gated cation channels that are present in the same target cell membrane.

Chemical Synapses Can Be Excitatory or Inhibitory <u>15</u>, <u>21</u>

Transmitter-gated ion channels differ from one another in several important ways. First, as receptors, they have a highly selective binding site for the neuro-transmitter that is released from the presynaptic nerve terminal. Second, as channels, they are selective as to the type of ions that they let pass across the plasma membrane; this determines the nature of the postsynaptic response. Excitatory neurotransmitters, such as *acetylcholine*, *glutamate,* and *serotonin*, open cation channels, causing an influx of Na^+ that depolarizes the postsynaptic membrane toward the threshold potential for firing an action potential. Inhibitory neuro-transmitters, such as *g-aminobutyric acid (GABA)* and *glycine,* by contrast, open Cl^- channels, and this suppresses firing by keeping the postsynaptic membrane polarized.

We have already discussed how the opening of cation channels depolarizes a membrane. The effect of opening Cl^- channels can be understood as follows. The concentration of Cl^- is much higher outside the cell than inside (see <u>Table 11-1</u>, p. 508). For this reason opening Cl^- channels will tend to hyperpolarize the membrane by letting more negatively charged chloride ions into the cell, unless the membrane potential is already so negative that it is sufficient to counter the steep Cl^- gradient. (In fact, for many neurons, the equilibrium potential for Cl^- is close to the resting potentialor even more negative.) In either case the opening of Cl^- channels makes it more difficult to depolarize the membrane and hence to excite the cell. The importance of the inhibitory neurotransmitters is demonstrated by the effects of toxins that block their action: strychnine, for example, by binding to glycine receptors and blocking the action of glycine, causes muscle spasms, convulsions, and death.

Not all chemical signaling in the nervous system, however, operates through ligand-gated ion channels. Many of the signaling molecules that are secreted by nerve terminals, including a large variety of *neuropeptides*, bind to receptors that regulate ion channels only indirectly. These so-called *G-protein-linked receptors* and *enzyme-linked receptors* are discussed in detail in <u>Chapter 15</u>. Whereas signaling mediated by excitatory and inhibitory neurotransmitters binding to transmitter-gated ion channels is generally immediate, simple, and brief, signaling mediated by ligands binding to G-protein-linked receptors and enzyme-linked receptors tends to be far slower and more complex and longer lasting in its consequences.

The Acetylcholine Receptors at the Neuromuscular Junction Are Transmitter-gated Cation Channels <u>22</u>

The best-studied example of a transmitter-gated ion channel is the acetylcholine receptor of skeletal muscle cells. This channel is opened transiently by acetylcholine released from the nerve terminal at a neuromuscular junction - the specialized chemical synapse between a motor neuron and a skeletal muscle cell (<u>Figure 11-30</u>). This synapse has been intensively investigated because it is readily accessible to electrophysiological study, unlike most of the synapses in the central nervous system.

The acetylcholine receptor has a special place in the history of ion channels. It was the first ion channel to be purified, the first to have its complete amino acid sequence determined, the first to be functionally reconstituted in synthetic lipid bilayers, and the first for which the electrical signal of a single open channel was recorded. Its gene was also the first channel protein gene to be cloned and sequenced. There were at least two reasons for the rapid progress in purifying and characterizing this receptor. First, there is an unusually rich source of the receptor in the electric organs of electric fish and rays (these organs are modified muscles designed to deliver a large electric shock to prey). Second, there are neurotoxins (such as *a-bungarotoxin*) in the venom of certain snakes that bind with high affinity ($K_a = 10^9$ liters/mole) and specificity to the receptor and therefore can be used to purify it by affinity chromatography. Fluorescent or radiolabeled a-bungarotoxin can also be used to localize and count

acetylcholine receptors. In this way it has been shown that the receptors are densely packed in the muscle cell plasma membrane at a neuromuscular junction (about 20,000 such receptors/μm^2), with relatively few receptors elsewhere in the same membrane.

The acetylcholine receptor of skeletal muscle is composed of five transmembrane polypeptides, two of one kind and three others, encoded by four separate genes. The four genes are strikingly similar in sequence, implying that they evolved from a single ancestral gene. The two identical polypeptides in the pentamer each have binding sites for acetylcholine. When two acetylcholine molecules bind to the pentameric complex, they induce a conformational change that opens the channel. The channel remains open for about 1 millisecond and then closes; like that of the voltage-gated Na^+ channel, the open form of the acetylcholine receptor channel is short-lived and quickly flips to a closed state of lower free energy (Figure 11-31). Subsequently, the acetylcholine molecules dissociate from the receptor and are hydrolyzed by a specific enzyme (acetylcholinesterase) located in the neuromuscular junction. Once freed of its bound neurotransmitter, the acetylcholine receptor reverts to its initial resting state.

The general shape of the acetylcholine receptor and the likely arrangement of its subunits have been determined by a combination of electron microscopy and low-angle x-ray diffraction of two-dimensional crystals: the five subunits are arranged in a ring to form a water-filled transmembrane channel that consists of a narrow pore through the lipid bilayer bounded by wide cylindrical entrances (Figure 11-32). Clusters of negatively charged amino acid residues at either end of the pore help to exclude negative ions and to encourage any positive ion of diameter less than 0.65 nm to pass through. The normal traffic consists chiefly of Na^+ and K^+, together with some Ca^{2+}. Thus, unlike voltage-gated cation channels, there is little selectivity among cations, and the relative contributions of the different cations to the current through the channel depend chiefly on their concentrations and on the electrochemical driving forces. When the muscle cell membrane is at its resting potential, the net driving force for K^+ is near zero, since the voltage gradient nearly balances the K^+ concentration gradient across the membrane (see Panel11-2, p. 526). For Na^+, on the other hand, the voltage gradient and the concentration gradient both act in the same direction to drive the ion into the cell. (The same is true for Ca^{2+}, but the extracellular concentration of Ca^{2+} is so much lower than that of Na^+ that Ca^{2+} makes only a small contribution to the total inward current.) Therefore, the opening of the acetylcholine receptor channels leads to a large net influx of Na^+ (peak rate of about 30,000 ions per channel each millisecond). This influx causes a membrane depolarization that signals the muscle to contract, as discussed below.

Transmitter-gated Ion Channels Are Major Targets for Psychoactive Drugs [23]

The ion channels that open directly in response to the neurotransmitters acetylcholine, serotonin, GABA, and glycine contain subunits that are structurally similar, suggesting that they are evolutionarily related and probably form transmembrane pores in the same way, even though their neurotransmitter-binding specificities and ion selectivities are distinct. Glutamate-gated ion channels are constructed from a distinct family of subunits but, nonetheless, seem to have a similar overall structure. In each case the channel is formed by homologous polypeptide subunits, which probably form a pentamer resembling the acetylcholine receptor (see Figure 11-32). Comparison of Figures 11-27 and 11-32 emphasizes the contrast with voltage-gated cation channels, which are constructed from a ring of four subunits (or domains). Perhaps as a result, the transmitter-gated channels have wider pores, which are correspondingly less stringent in their ion selectivity. Gap junctions, which are constructed from a ring of six subunits, have even wider pores, which permit the passage of small organic molecules in addition to inorganic ions (discussed in Chapter 19). This possible relationship between subunit number and pore width is illustrated in Figure 11-33.

For each class of transmitter-gated ion channels, alternative forms of each type of subunit exist, either encoded by distinct genes or generated by alternative RNA splicing of the same gene product. These combine in different combinations to form an extremely diverse set of distinct channel subtypes, with different ligand affinities, different channel conductances, different rates of opening and closing, and different sensitivities to drugs and toxins. Vertebrate neurons, for example, have acetylcholine-gated ion channels that differ from those of muscle cells in that they are formed usually from two subunits of one type and three of another; but there are at least seven genes coding for different versions of the first type of subunit and at least three coding for different versions of the second, with further diversity due to alternative RNA splicing. Subsets of acetylcholine-sensitive neurons serving different functions in the brain are characterized by different combinations of these subunits. This, in principle and already to some extent in practice, makes it possible to design drugs targeted against narrowly defined groups of neurons or synapses, thereby influencing particular brain functions specifically. Indeed, transmitter-gated ion channels have for a long time been important targets for drugs. A surgeon, for example, can make muscles relax for the duration of an operation by blocking the acetylcholine receptors on skeletal muscle cells with *curare*, a drug from a plant that was originally used by South American Indians to poison arrows. Most drugs used in the treatment of insomnia, anxiety, depression, and schizophrenia exert their effects at chemical synapses, and many of these act by binding to transmitter-gated channels: both barbiturates and tranquilizers

such as Valium and Librium, for example, bind to GABA receptors, potentiating the inhibitory action of GABA by allowing lower concentrations of this neurotransmitter to open Cl⁻ channels. The new molecular biology of ion channels, by revealing both their diversity and the details of their structure, holds out the hope of designing a new generation of psychoactive drugs that will act still more selectively to alleviate the miseries of mental illness.

Ion channels are the basic molecular components from which neuronal devices for signaling and computation are built. To provide a glimpse of how sophisticated the functions of these devices can be, we consider several examples that demonstrate how groups of ion channels work together in synaptic communication between electrically excitable cells.

Neuromuscular Transmission Involves the Sequential Activation of Five Different Sets of Ion Channels [15]

The importance of ion channels to electrically excitable cells can be illustrated by following the process whereby a nerve impulse stimulates a muscle cell to contract. This apparently simple response requires the sequential activation of five different sets of ion channels - all within a few milliseconds (Figure 11-34).

1. The process is initiated when the nerve impulse reaches the nerve terminal and depolarizes the plasma membrane of the terminal. The depolarization transiently opens voltage-gated Ca^{2+} channels in this membrane. As the Ca^{2+} concentration outside cells is more than 1000 times greater than the free Ca^{2+} concentration inside, Ca^{2+} flows into the nerve terminal. The increase in Ca^{2+} concentration in the cytosol of the nerve terminal triggers the localized release of acetylcholine into the synaptic cleft.

2. The released acetylcholine binds to acetylcholine receptors in the muscle cell plasma membrane, transiently opening the cation channels associated with them. The resulting influx of Na^+ causes a localized membrane depolarization.

3. The local depolarization of the muscle cell plasma membrane opens voltage-gated Na^+ channels in this membrane, allowing more Na^+ to enter, which further depolarizes the membrane. This, in turn, opens neighboring voltage-gated Na^+ channels and results in a self-propagating depolarization (an action potential) that spreads to involve the entire plasma membrane (see Figure 11-23).

4. The generalized depolarization of the muscle cell plasma membrane activates voltage-gated Ca^{2+} channels in specialized regions (the transverse [T] tubules - discussed in Chapter 16) of this membrane. This, in turn, causes *Ca^{2+} release channels* in an adjacent region of the sarcoplasmic reticulum membrane to open transiently and release the Ca^{2+} stored in the sarcoplasmic reticulum into the cytosol. It is the sudden increase in the cytosolic Ca^{2+} concentration that causes the myofibrils in the muscle cell to contract. It is not certain how the activation of the voltage-gated Ca^{2+} channels in the T-tubule membrane leads to the opening of the Ca^{2+} release channels in the sarcoplasmic reticulum membrane. The two membranes are closely apposed, however, with the two types of channels joined together in a specialized structure (see Figure 16-92). It is possible, therefore, that a voltage-induced change in the conformation of the plasma membrane Ca^{2+} channel directly opens the Ca^{2+} release channel in the sarcoplasmic reticulum through a mechanical coupling (discussed in Chapter 16).

While the activation of muscle contraction by a motor neuron is complex, an even more sophisticated interplay of ion channels is required for a neuron to integrate a large number of input signals at synapses and compute an appropriate output, as we now discuss.

The Grand Postsynaptic Potential in a Neuron Represents a Spatial and Temporal Summation of Many Small Postsynaptic Potentials [15], [24]

In the central nervous system a single neuron can receive inputs from thousands of other neurons. Several thousand nerve terminals, for example, make synapses on an average motor neuron in the spinal cord; its cell body and dendrites are almost completely covered with them (Figure11-35). Some of these synapses transmit signals from the brain or spinal cord; others bring sensory information from muscles or from the skin. The motor neuron must combine the information received from all these sources and react either by firing action potentials along its axon or by remaining quiet.

Of the many synapses on a neuron, some will tend to excite it, others to inhibit it. Neurotransmitter released at an excitatory synapse causes a small depolarization in the postsynaptic membrane called an *excitatory postsynaptic potential (excitatory PSP),* while neurotransmitter released at an inhibitory synapse generally causes a small hyperpolarization called an *inhibitory PSP.* Because the membrane of the dendrites and cell body of most neurons contains few voltage-gated Na^+ channels, an

individual excitatory PSP generally does not trigger an action potential. Instead, each incoming signal is reflected in a local PSP of graded magnitude, which decreases with distance from the site of the synapse. If signals arrive simultaneously at several synapses in the same region of the dendritic tree, the total PSP in that neighborhood will be roughly the sum of the individual PSPs, with inhibitory PSPs making a negative contribution to the total. The PSPs from each neighborhood spread passively and converge on the cell body. Because the cell body is small compared with the dendritic tree, its membrane potential will be roughly uniform and will be a composite of the effects of all the signals impinging on the cell, weighted according to the distances of the synapses from the cell body. The grand postsynaptic potential (grand PSP) of the cell body is thus said to represent a *spatial summation* of all the stimuli being received. If excitatory inputs predominate, the grand PSP will be a depolarization; if inhibitory inputs predominate, it will usually be a hyperpolarization.

While spatial summation combines the effects of signals received at different sites on the membrane, temporal summation combines the effects of signals received at different times. If an action potential arrives at a synapse and triggers neurotransmitter release before a previous PSP at the synapse has decayed completely, the second PSP adds to the remaining tail of the first. If many action potentials arrive in quick succession, each PSP adds to the tail of the preceding PSP, building up to a large sustained average PSP whose magnitude reflects the rate of firing of the presynaptic neuron (Figure11-36). This is the essence of *temporal summation*: it translates the *frequency* of incoming signals into the *magnitude* of a net PSP.

Temporal and spatial summation together provide the means by which the rates of firing of many presynaptic neurons jointly control the membrane potential (the grand PSP) in the body of a single postsynaptic cell. The final step in the neuronal computation made by the postsynaptic cell is the generation of an output, usually in the form of action potentials, to relay a signal to other cells. The output signal reflects the magnitude of the grand PSP in the cell body. While the grand PSP is a continuously graded variable, however, action potentials are always all-or-nothing and uniform in size. The only variable in signaling by action potentials is the time interval between one action potential and the next. For long-distance transmission the magnitude of the grand PSP is therefore translated, or *encoded,* into the *frequency* of firing of action potentials (Figure11-37). This encoding is achieved by a special set of gated ion channels that are present at high density at the base of the axon, adjacent to the cell body, in a region known as the *axon hillock* (see Figure11-35).

Neuronal Computation Requires a Combination of At Least Three Kinds of K^+ Channels [15], [25]

We have seen that the intensity of stimulation received by a neuron is encoded for long-distance transmission as the frequency of action potentials the neuron fires: the stronger the stimulation, the higher the frequency of action potentials. Action potentials are initiated at the axon hillock, a unique region of each neuron where voltage-gated Na^+ channels are plentiful. But to perform its special function of encoding, the membrane of the axon hillock also contains at least four other classes of ion channels - three selective for K^+ and one selective for Ca^{2+}. The three varieties of K^+ channels have different properties; we shall refer to them as the *delayed,* the *early,* and the *Ca $^{2+}$ -activated K $^+$ channels.* To understand the need for multiple types of channels, consider first what would happen if the only voltage-gated ion channels present in the nerve cell were the Na^+ channels. Below a certain threshold level of synaptic stimulation, the depolarization of the axon hillock membrane would be insufficient to trigger an action potential. With gradually increasing stimulation, the threshold would be crossed; the Na^+ channels would open; and an action potential would fire. The action potential would be terminated in the usual way by inactivation of the Na^+ channels. Before another action potential could fire, these channels would have to recover from their inactivation. But that would require a return of the membrane voltage to a very negative value, which would not occur as long as the strong depolarizing stimulus (from PSPs) was maintained. An additional channel type is needed, therefore, to repolarize the membrane after each action potential to prepare the cell to fire again. This task is performed by the delayed K^+ channels, which we discussed previously in relation to the propagation of the action potential (see p. 529). They are voltage-gated, but because of their slower kinetics, they open only during the falling phase of the action potential, when the Na^+ channels are inactive. Their opening permits an efflux of K^+ that drives the membrane back toward the K^+ equilibrium potential, which is so negative that the Na^+ channels rapidly recover from their inactivated state. Repolarization of the membrane also causes the delayed K^+ channels to close. The axon hillock is now reset so that the depolarizing stimulus from synaptic inputs can fire another action potential. In this way, sustained stimulation of the dendrites and cell body leads to repetitive firing of the axon.

Repetitive firing in itself, however, is not enough. The frequency of the firing has to reflect the intensity of the stimulation, and a simple system of Na^+ channels and delayed K^+ channels is inadequate for this purpose. Below a certain threshold level of steady stimulation, the cell will not fire at all; above that threshold it will abruptly begin to fire at a relatively rapid rate. The early K^+ channels solve the problem. These too are voltage-gated and open when the membrane is depolarized, but their specific voltage sensitivity and kinetics of inactivation are such that they act to reduce the rate of firing at levels of stimulation that are only just

above the threshold required for firing. Thus they remove the discontinuity in the relationship between the firing rate and the intensity of stimulation. The result is a firing rate that is proportional to the strength of the depolarizing stimulus over a very broad range (see Figure11-37).

The process of encoding is usually further modulated by the two other types of ion channels in the axon hillock that were mentioned at the outset - *voltage-gated Ca $^{2+}$ channels* and *Ca $^{2+}$ -activated K $^+$ channels.* They act together to decrease the response of the cell to an unchanging, prolonged stimulation - a process called adaptation. The Ca^{2+} channels are similar to the Ca^{2+} channels that mediate release of neurotransmitter from presynaptic axon terminals; they open when an action potential fires, transiently allowing Ca^{2+} into the axon hillock. The Ca^{2+}-activated K^+ channel is both structurally and functionally different from any of the channel types described earlier. It opens in response to a raised concentration of Ca^{2+} at the cytoplasmic face of the nerve cell membrane. Suppose that a strong depolarizing stimulus is applied for a long time, triggering a long train of action potentials. Each action potential permits a brief influx of Ca^{2+} through the voltage-gated Ca^{2+} channels, so that the intracellular Ca^{2+} concentration gradually builds up to a level high enough to open the Ca^{2+}-activated K^+ channels. Because the resulting increased permeability of the membrane to K^+ makes the membrane harder to depolarize, it increases the delay between one action potential and the next. In this way a neuron that is stimulated continuously for a prolonged period becomes gradually less responsive to the constant stimulus. Such adaptation, which can also occur by other mechanisms, allows a neuron, and indeed the nervous system generally, to react sensitively to *change,* even against a high background level of steady stimulation. It is one of the strategies that help us, for example, to feel a light touch on the shoulder and yet ignore the constant pressure of our clothing. We discuss adaptation in more detail in Chapter 15.

Other neurons do different computations, reacting to their synaptic inputs in myriad ways, reflecting the different assortments of members of the various ion channel families that they have in their membranes. There are, for example, at least five known types of voltage-gated Ca^{2+} channels in the vertebrate nervous system and at least four known types of voltage-gated K^+ channels. The multiplicity of genes evidently allows for a host of different types of neurons, whose electrical behavior is specifically tuned to the particular tasks they must perform.

One of the crucial properties of the nervous system is its ability to learn and remember, which seems to depend largely on long-term changes in specific synapses. We end this chapter by considering a remarkable type of ion channel that has a special role in some forms of learning and memory. It is located at many synapses in the central nervous system, where it is gated by both voltage and the excitatory neurotransmitter glutamate. It is also the site of action of the psychoactive drug phencyclidine, or angel dust.

Long-term Potentiation in the Mammalian Hippocampus Depends on Ca^{2+} Entry Through NMDA-Receptor Channels 26

Practically all animals can learn, but mammals seem to learn exceptionally well (or so we like to think). In a mammal's brain the *hippocampus*, a part of the cerebral cortex, plays a special role in learning: when it is destroyed on both sides of the brain, the ability to form new memories is largely lost, although previous long-established memories remain. Correspondingly, some synapses in the hippocampus show dramatic functional alterations with repeated use: whereas occasional single action potentials in the presynaptic cells leave no lasting trace, a short burst of repetitive firing causes long-term potentiation (LTP), such that subsequent single action potentials in the presynaptic cells evoke a greatly enhanced response in the postsynaptic cells. The effect lasts hours, days, or weeks, according to the number and intensity of the bursts of repetitive firing. Only the synapses that were activated show the potentiation; synapses that have remained quiet on the same postsynaptic cell are not affected. But if, while the cell is receiving a burst of repetitive stimulation via one set of synapses, a single action potential is delivered at *another* synapse on its surface, that latter synapse also will undergo long-term potentiation, even though a single action potential delivered there at another time would leave no such lasting trace.

The underlying rule in the hippocampus seems to be that *long-term potentiation occurs on any occasion where a presynaptic cell fires (once or more) at a time when the postsynaptic membrane is strongly depolarized* (either through recent repetitive firing of the same presynaptic cell or by other means). There is good evidence that this rule reflects the behavior of a particular class of ion channels in the postsynaptic membrane. Glutamate is the main excitatory neurotransmitter in the mammalian central nervous system, and in the hippocampus, as elsewhere, most of the depolarizing current responsible for excitatory PSPs is carried by glutamate-gated ion channels that operate in the standard way. But the current has in addition a second and more intriguing component, which is mediated by a separate subclass of glutamate-gated ion channels, known as NMDA receptors because they are selectively activated by the artificial glutamate analog N-methyl-D-aspartate. The NMDA-receptor channels

are doubly gated, opening only when two conditions are satisfied simultaneously: glutamate must be bound to the receptor, and the membrane must be strongly depolarized. The second condition is required to release Mg^{2+} that normally blocks the resting channel, and it means that NMDA receptors are normally only activated when conventional glutamate-gated ion channels are activated as well and depolarize the membrane. The NMDA receptors are critical for long-term potentiation. When they are selectively blocked with a specific inhibitor, long-term potentiation does not occur, even though ordinary synaptic transmission continues. An animal treated with this inhibitor shows specific deficits in its learning abilities but behaves almost normally otherwise.

How do the NMDA receptors mediate such a remarkable effect? The answer is that these channels, when open, are highly permeable to Ca^{2+}, which acts as an intracellular mediator in the postsynaptic cell, triggering a cascade of changes that are responsible for long-term potentiation. Thus long-term potentiation is prevented when Ca^{2+} levels are held artificially low in the postsynaptic cell by injecting the Ca^{2+} chelator EGTA into it and can be induced by transiently raising extracellular Ca^{2+} levels artificially high.

The long-term changes, although initiated in the postsynaptic cell, affect the presynaptic cell as well so that it releases more glutamate than normal when it is activated subsequently. The nature of the lasting change in the presynaptic cell is uncertain, but it is clear that some message must pass retrogradely from the postsynaptic cell to the presynaptic cell when long-term potentiation is induced. The nature of the retrograde signal is also unknown, although both nitric oxide and carbon monoxide have been suggested as candidates. A tentative model of some of the steps in the induction of long-term potentiation is presented in Figure 11-38. In addition to the long-lasting changes in the presynaptic cell illustrated in Figure 11-38, there are also long-lasting changes in the postsynaptic cell that contribute to long-term potentiation.

There is evidence that NMDA receptors play an important part in learning and related phenomena in other parts of the brain as well as in the hippocampus. In Chapter 21 we shall see, moreover, that NMDA receptors have a crucial role in adjusting the anatomical pattern of synaptic connections in the light of experience during the development of the nervous system.

Thus neurotransmitters released at synapses, besides relaying transient electrical signals, can also alter concentrations of intracellular mediators that bring about lasting changes in the efficacy of synaptic transmission. It is still uncertain, however, how these changes endure for weeks, months, or a lifetime in the face of the normal turnover of cell constituents.

Some of the ion channel families that we have discussed are summarized in Table 11-3.

Summary

Channel proteins form aqueous pores across the lipid bilayer and allow inorganic ions of appropriate size and charge to cross the membrane down their electrochemical gradients at rates that are about 1000 times greater than those achieved by any known carrier. These ion channels are "gated" and usually open transiently in response to a specific perturbation in the membrane, such as a change in membrane potential (voltage-gated channels) or the binding of a neurotransmitter (transmitter-gated channels).

K^+-selective leak channels play an important part in determining the resting membrane potential across the plasma membrane in most animal cells. Voltage-gated cation channels are responsible for the generation of self-amplifying action potentials in electrically excitable cells such as neurons and skeletal muscle cells. Transmitter-gated ion channels convert chemical signals to electrical signals at chemical synapses: excitatory neurotransmitters, such as acetylcholine and glutamate, open transmitter-gated cation channels and thereby depolarize the postsynaptic membrane toward the threshold potential for firing an action potential; inhibitory neurotransmitters, such as GABA and glycine, open transmitter-gated Cl^- channels and thereby suppress firing by keeping the postsynaptic membrane polarized. A subclass of glutamate-gated ion channels, called NMDA-receptor channels, are highly permeable to Ca^{2+}, which can trigger the long-term changes in synapses that are thought to be involved for some forms of learning and memory.

Ion channels work together in complex ways to control the behavior of electrically excitable cells. A typical neuron, for example, receives thousands of excitatory and inhibitory inputs, which combine by spatial and temporal summation to produce a grand postsynaptic potential (PSP) in the cell body. The magnitude of the grand PSP is translated into the rate of firing of action potentials by a mixture of cation channels in the membrane of the axon hillock.
Figure 11-17. Schematic drawing of a typical ion channel, which fluctuates between closed and open conformations. A transmembrane protein complex, seen in cross-section, forms a hydrophilic pore across the lipid bilayer only when the gate is open. Polar amino acid side chains are thought to line the wall of the pore, while hydrophobic side chains interact with the lipid bilayer. The pore narrows to atomic dimensions in one region (the "ion-selective filter"), where the ion selectivity of the channel is largely determined.
Figure 11-18. Gated ion channels. Schematic drawing of the different ways in which ion channels are gated.

Panel 11-2: The derivation of the Nernst equation

THE NERNST EQUATION AND ION FLOW

The flow of any ion through a membrane channel protein is driven by the electrochemical gradient for that ion. This gradient represents the combination of two influences: the voltage gradient and the concentration gradient of the ion across the membrane. When these two influences just balance each other the electrochemical gradient for the ion is zero and there is no *net* flow of the ion through the channel. The voltage gradient (membrane potential) at which this equilibrium is reached is called the equilibrium potential for the ion. It can be calculated from an equation that will be derived below, called the Nernst equation.

The Nernst equation is

$$V = \frac{RT}{zF} \ln \frac{C_o}{C_i}$$

where

V = the equilibrium potential in volts (internal potential minus external potential)

C_o and C_i = outside and inside concentrations of the ion, respectively

R = the gas constant (2 cal mol^{-1} °K^{-1})

T = the absolute temperature (°K)

F = Faraday's constant (2.3 x 10^4 cal V^{-1} mol^{-1})

z = the valence (charge) of the ion

$\ln$ = logarithm to the base e

The Nernst equation is derived as follows:

A molecule in solution (a solute) tends to move from a region of high concentration to a region of low concentration simply due to the pressure of numbers. Consequently, movement down a concentration gradient is accompanied by a favorable free-energy change ($\Delta G < 0$), whereas movement up a concentration gradient is accompanied by an unfavorable free-energy change ($\Delta G > 0$). (Free energy is introduced and discussed in Panel 14–1, pp. 668–669.) The free-energy change per mole of solute moved across the plasma membrane (ΔG_{conc}) is equal to $-RT \ln C_o / C_i$. If the solute is an ion, moving it into a cell across a membrane whose inside is at a voltage V relative to the outside will cause an additional free-energy change (per mole of solute moved) of $\Delta G_{volt} = zFV$. At the point where the concentration and voltage gradients just balance, $\Delta G_{conc} + \Delta G_{volt} = 0$ and the ion distribution is at equilibrium across the membrane. Thus,

$$zFV - RT \ln \frac{C_o}{C_i} = 0$$

and, therefore,

$$V = \frac{RT}{zF} \ln \frac{C_o}{C_i} = 2.3 \frac{RT}{zF} \log_{10} \frac{C_o}{C_i}$$

For a univalent ion,

$$2.3 \frac{RT}{F} = 58 \text{ mV at } 20°C \quad \text{and} \quad 61.5 \text{ mV at } 37°C$$

Thus, for such an ion at 37°C, $V = + 61.5$ mV for $C_o / C_i = 10$, whereas $V = 0$ for $C_o / C_i = 1$.

The K$^+$ equilibrium potential (V_K), for example, is $61.5 \log_{10}([K^+]_o / [K^+]_i)$ millivolts (–89 mV for a typical cell where $[K^+]_o = 5$ mM and $[K^+]_i = 140$ mM). At V_K, there is no net flow of K$^+$ across the membrane. Similarly, when the membrane potential has a value of $61.5 \log_{10}([Na^+]_o /[Na^+]_i)$, the Na$^+$ equilibrium potential (V_{Na}), there is no net flow of Na$^+$.

For any particular membrane potential, V_M, the net force tending to drive a particular type of ion out of the cell, is proportional to the difference between V_M and the equilibrium potential for the ion: hence, for K$^+$ it is $V_M - V_K$ and for Na$^+$ it is $V_M - V_{Na}$.

The number of ions that go to form the layer of charge adjacent to the membrane is minute compared with the total number inside the cell. For example, the movement of 6000 Na$^+$ ions across 1 μm^2 of membrane will carry sufficient charge to shift the membrane potential by about 100 mV. Because there are about 3 x 10^7 Na$^+$ ions in 1 μm^3 of bulk cytoplasm, such a movement of charge will generally have a negligible effect on the ion concentration gradients across the membrane.
exact balance of charges on each side of the membrane; membrane potential = 0
a few of the positive ions (*red*) cross the membrane from right to left, leaving their negative counterions (*red*) behind; this sets up a nonzero membrane potential

Figure 11-19. A small flow of ions carries sufficient charge to cause a large change in the membrane potential. The ions that give rise to the membrane potential lie in a thin (<1nm) surface layer close to the membrane, held there by their electrical attraction to their oppositely charged counterparts (counterions) on the other side of the membrane. For a typical cell 1 microcoulomb of charge (6 x 10^{12} univalent ions) per square centimeter of membrane, transferred from one side of the membrane to the other, will change the membrane potential by roughly 1 V. This means, for example, that in a spherical cell of diameter 10 mm, the number of K$^+$ ions that have to flow out to alter the membrane potential by 100 mV is only about 1/100,000 of the total number of K$^+$ ions in the cytosol.

cell body

dendrites

axon (less than 1mm to more than 1m in length)

terminal branches of axon
Figure 11-20. Schematic diagram of a typical vertebrate neuron. The arrows indicate the direction in which signals are conveyed. The single axon conducts signals away from the cell body, while the multiple dendrites receive signals from the axons of other neurons. The nerve terminals end on the dendrites or cell body of other neurons or on other cell types, such as muscle or gland cells.
Figure 11-21. The voltage-gated Na⁺ channel can adopt at least three conformations (states). Internal forces, represented here by attractions between charges on different parts of the channel, stabilize each state against small disturbances, but a sufficiently violent collision with other molecules can cause the channel to flip from one of these states to another. The state of lowest energy depends on the membrane potential because the different conformations have different charge distributions. When the membrane is at rest (highly polarized), the closed conformation has the lowest free energy and is therefore most stable; when the membrane is depolarized, the energy of the *open* conformation is lower and so the channel has a high probability of opening. But the free energy of the *inactivated* conformation is lower still, and so, after a randomly variable period spent in the open state, the channel becomes inactivated. Thus the open conformation corresponds to a metastable state that can exist only transiently. The *red arrows* indicate the sequence that follows a sudden depolarization, while the *black arrow* indicates the return to the original conformation as the lowest energy state after the membrane is repolarized.
Figure 11-22. An action potential. The action potential is triggered by a brief pulse of current (shown in the *upper graph*), which partially depolarizes the membrane, as shown in the plot of membrane potential versus time (*middle graph*). The *green curve* shows how the membrane potential would have simply relaxed back to the resting value after the initial depolarizing stimulus if there had been no voltage-gated ion channels in the membrane; this relatively slow return of the membrane potential to its initial value of -70 mV in the absence of open Na⁺ channels is automatic because of the efflux of K⁺ through K⁺ channels, which drives the membrane back toward the K⁺ equilibrium potential. The *red curve* shows the course of the action potential

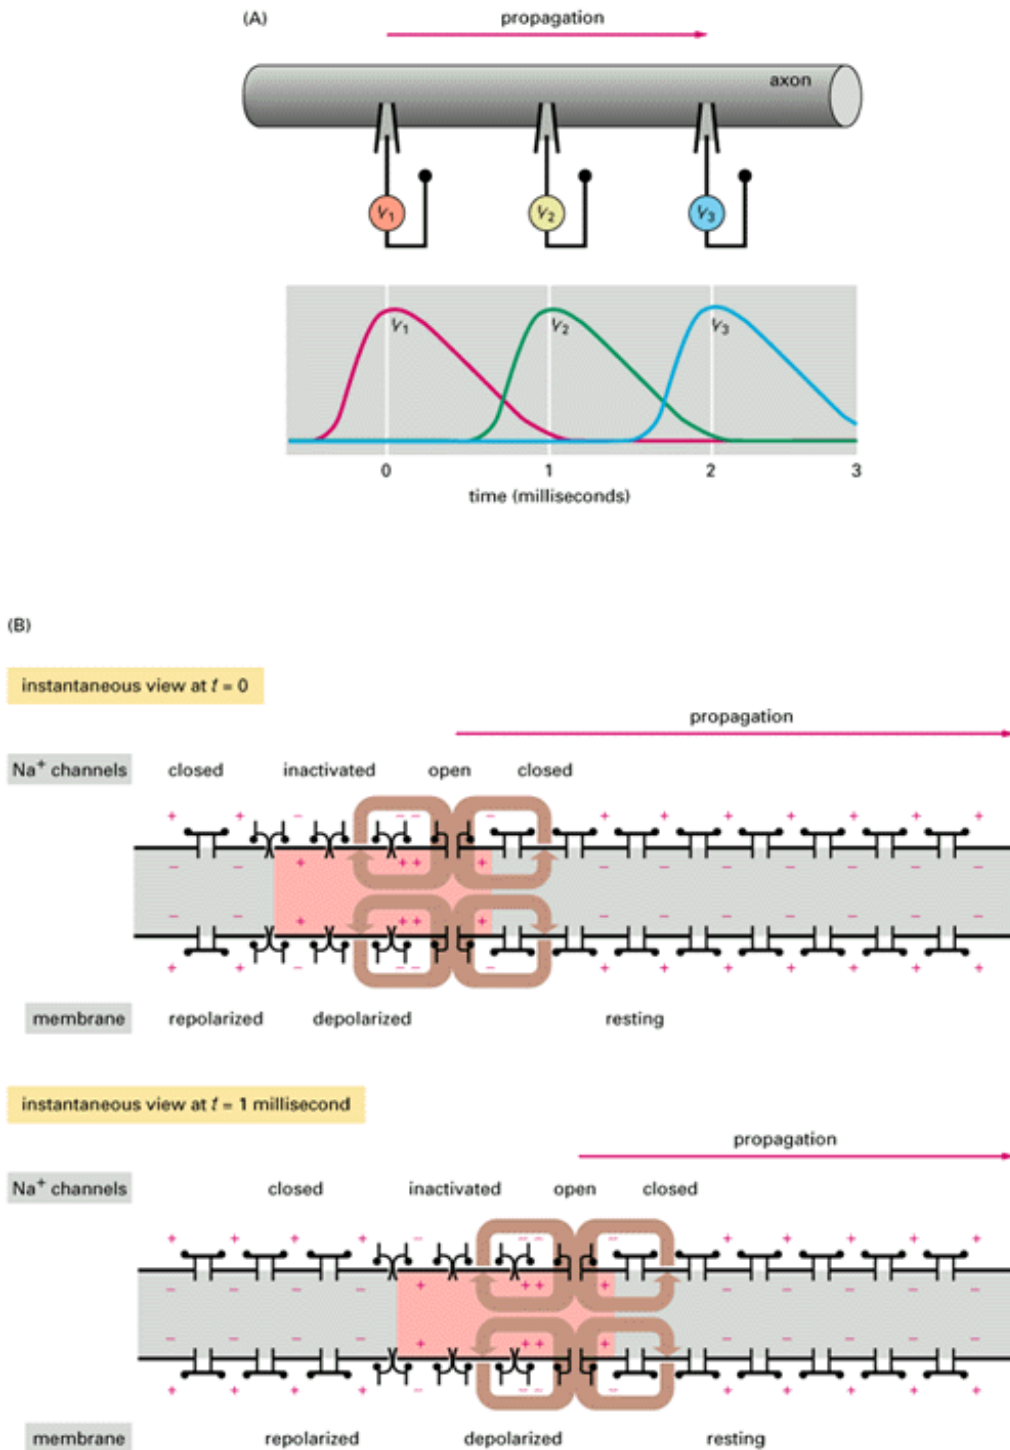
that is caused by the opening and subsequent inactivation of voltage-gated Na$^+$ channels, whose state is shown at the bottom. The membrane cannot fire a second action potential until the Na$^+$ channels have returned to the closed conformation (see Figure11-21); until then the membrane is refractory to stimulation.


Figure 11-23. The propagation of an action potential along an axon. (A) shows the voltages that would be recorded from a set of intracellular electrodes placed at intervals along the axon. (B) shows the changes in the Na$^+$ channels and the current flows (*brown lines*) that give rise to the traveling disturbance of the membrane potential. The region of the axon with a depolarized membrane is shaded in *red*. Note that an action potential can only travel away from the site of depolarization because Na$^+$-channel inactivation prevents the depolarization from spreading backward. (See also Figure 11-22.)

Panel 11-3: Some classical experiments on the squid giant axon

1. Action potentials are recorded with an intracellular electrode

The squid giant axon is about 0.5–1 mm in diameter and several centimeters long. An electrode in the form of a glass capillary tube containing a conducting solution can be thrust down the axis of the axon so that its tip lies deep in the cytoplasm. With its help, one can measure the voltage difference between the inside and the outside of the axon—that is, the membrane potential—as an action potential sweeps past the electrode. The action potential is triggered by a brief electrical stimulus to one end of the axon. It does not matter which end, because the excitation can travel in either direction; and it does not matter how big the stimulus is, as long as it exceeds a certain threshold: the action potential is all or none.
2. Action potentials depend only on the neuronal plasma membrane and on gradients of Na⁺ and K⁺ across it

The three most plentiful ions, both inside and outside the axon, are Na^+, K^+, and Cl^-. As in other cells, the Na^+-K^+ pump maintains a concentration gradient: the concentration of Na^+ is about 9 times lower inside the axon than outside, while the concentration of K^+ is about 20 times higher inside than outside. Which ions are important for the action potential?

The squid giant axon is so large and robust that it is possible to extrude the cytoplasm from it, like toothpaste from a tube, and then
to perfuse it internally with pure artificial solutions of Na^+, K^+, and Cl^- or SO_4^{2-}. Remarkably, if (and only if) the concentrations of Na^+ and K^+ inside and outside approximate those found naturally, the axon will still propagate action potentials of the normal form. The important part of the cell for electrical signaling, therefore, must be the plasma membrane; the important ions are Na^+ and K^+; and a sufficient source of free energy to power the action potential must be provided by their concentration gradients across the membrane, because all other sources of metabolic energy have presumably been removed by the perfusion.
3. At rest, the membrane is chiefly permeable to K⁺; during the action potential, it becomes transiently permeable to Na⁺

At rest the membrane potential is close to the equilibrium potential for K^+. When the external concentration of K^+ is changed, the resting potential changes roughly in accordance with the Nernst equation for K^+ (see Panel 11–2). At rest, therefore, the membrane is chiefly permeable to K^+: K^+ leak channels provide the main ion pathway through the membrane.

If the external concentration of Na^+ is varied, there is no effect on the resting potential. However, the height of the peak of the action potential varies roughly in accordance with the Nernst equation for Na^+. During the action potential, therefore, the membrane appears to be chiefly permeable to Na^+: Na^+ channels have opened. In the aftermath of the action potential, the membrane potential reverts to a negative value that

depends on the external concentration of K^+ and is even closer to the K^+ equilibrium potential than the resting potential is: the membrane has lost most of its permeability to Na^+ and has become even more permeable to K^+ than before—that is, Na^+ channels have closed, and additional K^+ channels have opened.
The form of the action potential when the external medium contains 100%, 50%, or 33% of the normal concentration of Na^+.

4. Voltage clamping reveals how the membrane potential controls opening and closing of ion channels

The membrane potential can be held constant ("voltage clamped") throughout the axon by passing a suitable current through a bare metal wire inserted along the axis of the axon while monitoring the membrane potential with another intracellular electrode. When the membrane is abruptly shifted from the resting potential and held in a depolarized state (A), Na^+ channels rapidly open until the Na^+ permeability of the membrane is much greater than the K^+ permeability; they then close again spontaneously, even though the membrane potential is clamped and unchanging. K^+ channels also open but with a delay, so that the K^+ permeability increases as the Na^+ permeability falls (B). If the experiment is now very promptly repeated, by returning the membrane briefly to the resting potential and then quickly depolarizing it again, the response is different: prolonged depolarization has caused the Na^+ channels to enter an inactivated state, so that the second depolarization fails to cause a rise and fall similar to the first. Recovery from this state requires

a relatively long time—about 10 milliseconds—spent at the repolarized (resting) membrane potential.

In a normal unclamped axon, an inrush of Na^+ through the opened Na^+ channels produces the spike of the action potential; inactivation of Na^+ channels and opening of K^+ channels bring the membrane rapidly back down to the resting potential.
Figure 11-24. Myelination. (A) Schematic diagram of a myelinated axon from a peripheral nerve. Each Schwann cell wraps its plasma membrane concentrically around the axon to form a segment of myelin sheath about 1 mm long. For clarity, the layers of myelin are not shown compacted together as tightly as they are in reality (see part B). (B) Electron micrograph of a section from a nerve in the leg of a young rat. Two Schwann cells can be seen: one (*below*) is just beginning to myelinate its axon; the other has formed an almost mature myelin sheath. (B, from C. Raine, in Myelin [P. Morell, ed.]. New York: Plenum, 1976.)
Figure 11-25. The technique of patch-clamp recording. Because of the extremely tight seal between the micropipette and the membrane, current can enter or leave the micropipette only by passing through the channels in the *patch* of membrane covering its tip. The term *clamp* is used because an electronic device is employed to maintain, or "clamp," the membrane potential at a set value while recording the ionic current through individual channels. Recordings of the current through these channels can be made with the patch still attached to the rest of the cell, as in (A), or detached, as in (B). The advantage of the detached patch is that it is easy to alter the composition of the solution on either side of the membrane to test the effect of various solutes on channel behavior. A detached patch can also be produced with the opposite orientation, so that the cytoplasmic surface of the

membrane faces the inside of the pipette. (See also Figures 4-54and 4-55.)
Figure 11-26. Patch-clamp measurements for a single voltage-gated Na$^+$ channel. A tiny patch of plasma membrane was detached from an embryonic rat muscle cell as in Figure 11-25. The membrane was depolarized by an abrupt shift of potential, as indicated in (A). The three current records shown in (B) are from three experiments performed on the same patch of membrane. Each major current step in (B) represents the opening and closing of a single channel. Comparison of the three records shows that, whereas the times of channel opening and closing vary greatly, the rate at which current flows through an open channel is practically constant. The minor fluctuations in the current records arise largely from electrical noise in the recording apparatus. The sum of the currents measured in 144 repetitions of the same experiment is shown in (C). This aggregate current is equivalent to the usual Na$^+$ current that would be observed flowing through a relatively large region of membrane containing 144 channels. Comparison of (B) and (C) reveals that the time course of the aggregate current reflects the probability that any individual channel will be in the open state; this probability decreases with time as the channels in the depolarized membrane adopt their inactivated conformation. (Data from J. Patlak and R. Horn, *J. Gen. Physiol.* 79:333-351, 1982, by copyright permission of the Rockefeller University Press.)
Figure 11-27. A model for the structure of a voltage-gated K+ channel. (A) A topology diagram showing the major functional domains of the polypeptide chain of one subunit, with the six putative transmembrane a helices labeled 1 to 6. Four such subunits, each having about 600 amino acids, are thought to assemble to form a transmembrane pore; only two are shown in (B). In voltage-gated Na+ and Ca^{2+} channels the four subunits are domains of a single very large polypeptide chain, but otherwise the overall structure is thought to be similar. The 20 amino acid segment (shown in *red*), contained in the region linking helices 5 and 6, is thought to extend across the membrane as two antiparallel b strands to line the pore as shown. The fourth a helix (*blue*) has positively charged residues at every third position, which is thought to allow this helix to serve as a *voltage sensor*. In at least some K+ channels, the amino-terminal domain is involved in rapid channel inactiva-tion, as illustrated in Figure 11-28.
Figure 11-28. The "ball-and-chain" model of rapid inactivation for a voltage-gated K+channel. When the membrane is depolarized, the channel opens and begins to conduct ions. The open channel is then susceptible to occlusion (inactivation) by the amino-terminal 19 amino acid "ball," which is linked to the channel proper by a segment of unfolded polypeptide chain that serves as the "chain." For simplicity, only two balls are shown; in fact there are four, one from each subunit. A similar mechanism, using a different segment of the polypeptide chain, is thought to operate in Na+ channel inactivation.

RESTING CHEMICAL SYNAPSE

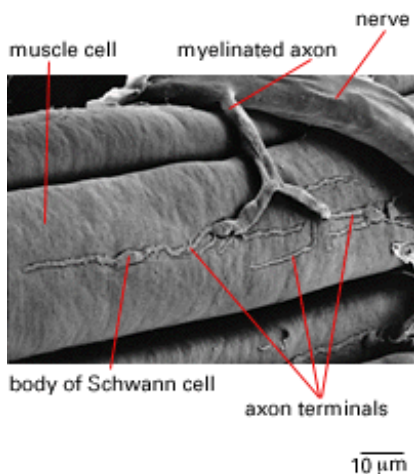
ACTIVE CHEMICAL SYNAPSE
Figure 11-29. A chemical synapse. When an action potential reaches the nerve terminal, it stimulates the terminal to release its neurotrans-mitter; the neurotransmitter is contained in synaptic vesicles and is released to the cell exterior when the vesicles fuse with the plasma membrane of the nerve terminal. The released neurotransmitter binds to and opens the transmitter-gated ion channels concentrated in the plasma membrane of the target cell at the synapse. The resulting ion flows alter the membrane potential of the target cell, thereby transmitting a signal from the excited nerve.


Figure 11-30. Low-magnification scanning electron micrograph of a neuromuscular junction in a frog. The termination of a single axon on a skeletal muscle cell is shown. (From J. Desaki and Y. Uehara, *J. Neurocytol.* 10:101-110, 1981, by permission of Chapman & Hall.)
Figure 11-31. Three conformations of the acetylcholine receptor. The binding of two acetylcholine molecules opens this transmitter-gated ion channel. But even with acetylcholine bound, the receptor is thought to stay in the open conformation only briefly, before the channel recloses. The acetylcholine then dissociates from the receptor, which enables the receptor to return to its original conformation.
Figure 11-32. A model for the structure of the acetylcholine receptor. Five homologous subunits (a, a, b, g, d) combine to form a transmembrane aqueous pore. The pore is lined by a ring of five transmembrane a helices, one contributed by each subunit. The ring of a helices is probably surrounded by a continuous rim of transmembrane b sheet, made up of the other transmembrane segments of the five subunits. In its closed conformation the pore is thought to be occluded by the hydrophobic side chains of five leucine residues, one from each a helix, which form a gate near the middle of the lipid bilayer. The negatively charged side chains at either end of the pore ensure that only positively charged ions pass through the channel. Both of the a subunits contain an acetylcholine binding site; when acetylcholine binds to both sites, the channel undergoes a conformational change that opens the gate, possibly by causing the leucine residues to move outward. Figure 11-34. The system of ion channels at a neuromuscular junction. These gated ion channels are essential for the stimulation of muscle contraction by a nerve impulse. The various channels are numbered in the sequence in which they are activated, as described in the text.
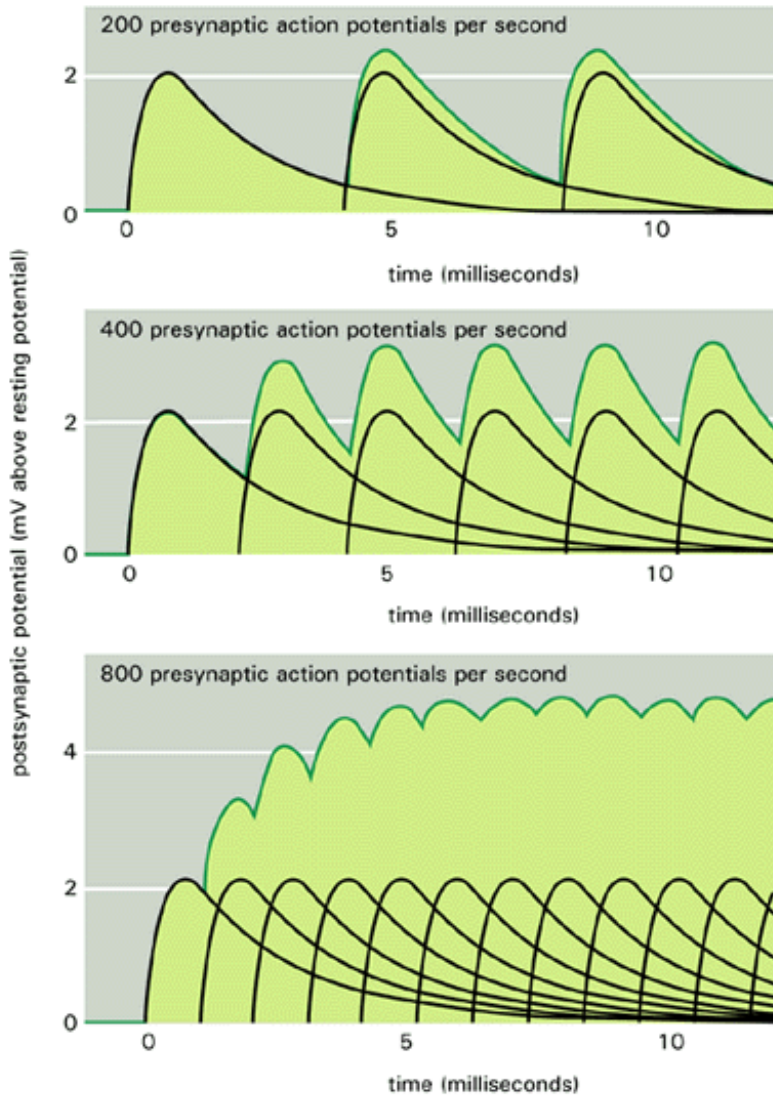
Figure 11-35. A motor neuron cell body in the spinal cord. Many thousands of nerve terminals synapse on the cell body and dendrites. These deliver signals from other parts of the organism to control the firing of action potentials along the single axon of this large cell.


Figure 11-36. The principle of temporal summation. Each presynaptic action potential arriving at a synapse produces a small postsynaptic potential, or PSP (*black lines*). When successive action potentials arrive at the same synapse, each PSP produced adds to the tail of the preceding one to produce a larger combined PSP (*green lines*). The greater the frequency of incoming action potentials, the greater the size of the combined PSP.
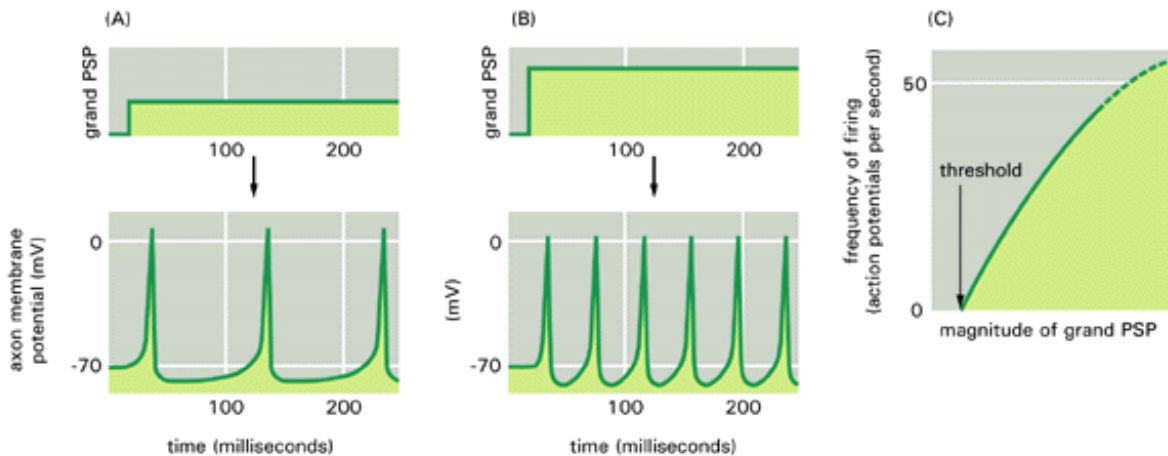

Figure 11-37. The encoding of the grand PSP in the form of the frequency of firing of action potentials by an axon. A comparison of (A) and (B) shows how the firing frequency of an axon increases with an increase in the grand PSP, while (C)

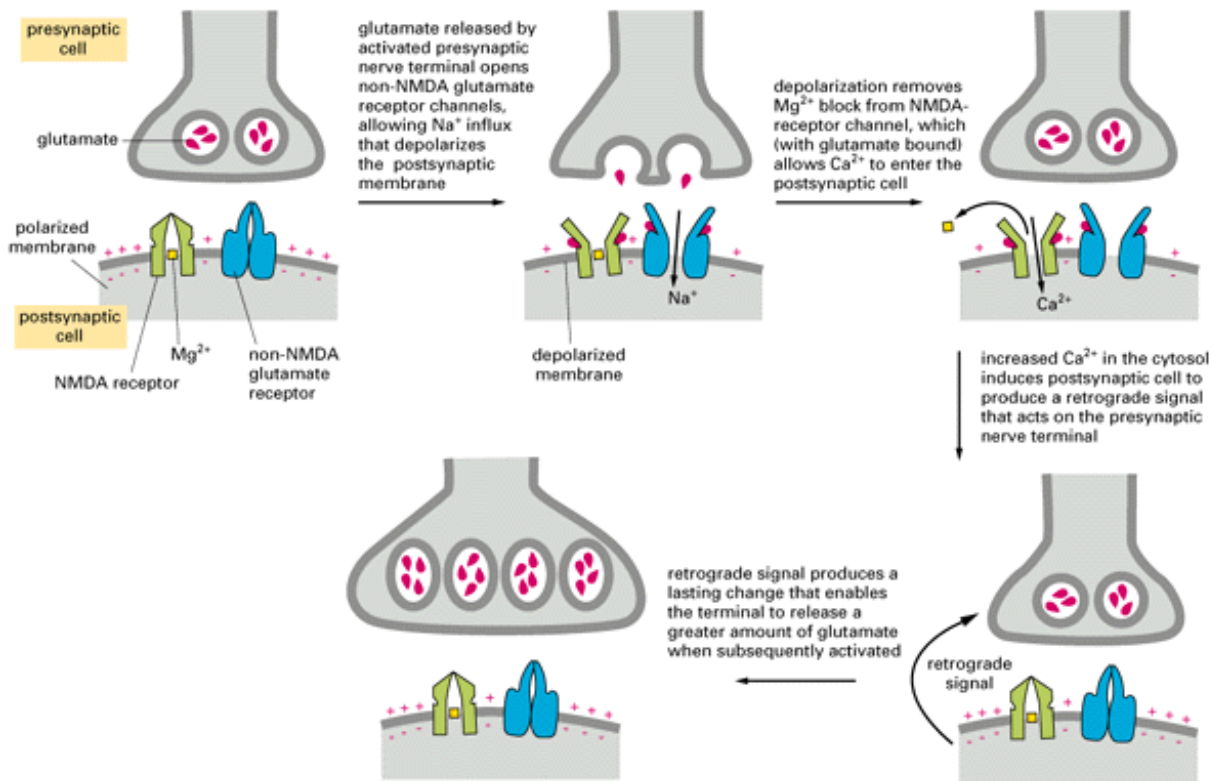
summarizes the general relationship.


The signaling events in long-term potentiation.

Table 11-3. Some Ion Channel Families

Family*	Representative Subfamilies	
Voltage-gated cation channels	voltage-gated Na⁺ channels voltage-gated K⁺ channels (including delayed and early) voltage-gated Ca²⁺ channels	
Transmitter-gated ion channels	acetylcholine-gated cation channels serotonin-gated cation channels glutamate-gated cation channels**	excitatory
	GABA-gated Cl⁻ channels glycine-gated Cl⁻ channels	inhibitory

*The members of a family are similar in amino acid sequence and, therefore, are thought to have derived from a common ancestor; within subfamilies the resemblances are usually even closer.
**These channels are formed by a distinct family of subunits but are thought to have a similar overall structure to the other transmitter-gated ion channels.

12. Intracellular Compartments and Protein Sorting

Introduction

Unlike a bacterium, which generally consists of a single intracellular compartment surrounded by a plasma membrane, a eucaryotic cell is elaborately subdivided into functionally distinct, membrane-bounded compartments. Each compartment, or organelle, contains its own characteristic set of enzymes and other specialized molecules, and complex distribution systems transport specific products from one compartment to another. To understand the eucaryotic cell, it is essential to know what occurs in each of these compartments, how molecules move between them, and how the compartments themselves are created and maintained.

Proteins play a central part in the compartmentalization of a eucaryotic cell. They catalyze the reactions that occur in each organelle and selectively transport small molecules into and out of its interior, or *lumen*. Proteins also serve as organelle-specific surface markers that direct new deliveries of proteins and lipids to the appropriate organelle. A mammalian cell contains about 10 billion (10^{10}) protein molecules of perhaps 10,000 kinds, and the synthesis of almost all of them begins in the cytosol. Each newly synthesized protein is then delivered specifically to the cell compartment that requires it. We shall make the intracellular transport of proteins the central theme of this chapter as well as of the next. By tracing the protein traffic from one compartment to another, one can begin to make sense of the otherwise bewildering maze of intracellular membranes.

The Compartmentalization of Higher Cells

Introduction

In this introductory section we give a brief overview of the compartments of the cell and of the relationships between them. In doing so, we organize the organelles conceptually into a small number of discrete families, discussing how proteins are directed to specific organelles and how they cross organelle membranes.

All Eucaryotic Cells Have the Same Basic Set of Membrane-bounded Organelles [1]

Many vital biochemical processes take place in or on membrane surfaces. Lipid metabolism, for example, is catalyzed mostly by membrane-bound enzymes, and oxidative phosphorylation and photosynthesis both require a membrane in order to couple the transport of H^+ to the synthesis of ATP. Intracellular membrane systems, however, do more for the cell than just provide increased membrane area: they create enclosed compartments that are separate from the cytosol, thus providing the cell with functionally specialized aqueous spaces. Because the lipid bilayer of organelle membranes is impermeable to most hydrophilic molecules, the membrane of each organelle must contain transport proteins that are responsible for the import and export of specific metabolites. Each organelle membrane must also have a mechanism for importing, and incorporating into the organelle, the specific proteins that make the organelle unique.

The major intracellular compartments common to eucaryotic cells are illustrated in Figure 12-1. The *nucleus* contains the main genome and is the principal site of DNA and RNA synthesis. The surrounding *cytoplasm* consists of the *cytosol* and the cytoplasmic organelles suspended in it. The cytosol constitutes a little more than half the total volume of the cell and is the site of protein synthesis and of most of the cell's intermediary metabolism - that is, the many reactions by which some small molecules are degraded and others are synthesized to provide the building blocks of macromolecules (discussed in Chapter 2).

About half the total area of membrane in a cell encloses the labyrinthine spaces of the *endoplasmic reticulum (ER)*. The ER has many ribosomes bound to its cytosolic surface; these are engaged in the synthesis of integral membrane proteins and soluble proteins, most of which are destined for secretion or for other organelles. We shall see that this reflects an important difference between how proteins are directed to the ER and how they are directed to other cytoplasmic organelles: whereas proteins are translocated into other organelles only after their synthesis is complete, they are translocated into the ER during their synthesis, and hence the ribosomes on which they are made are tethered to the ER membrane. The ER also produces the lipid for the rest of the cell and functions as a store for Ca^{2+} ions. The *Golgi apparatus* consists of organized stacks of disclike compartments called Golgi *cisternae;* it receives lipids and proteins from the ER and dispatches them to a variety of destinations, usually covalently modifying them en route .

Mitochondria and (in plants) *chloroplasts* generate most of the ATP used to drive cellular reactions that require an input of free energy. *Lysosomes* contain digestive enzymes that degrade defunct intracellular organelles, as well as macromolecules and particles taken in from outside the cell by endocytosis. On their way to lysosomes, endocytosed material must first pass through a series of compartments called *endosomes. Peroxisomes* (also known as *microbodies*) are small vesicular compartments that contain enzymes utilized in a variety of oxidative reactions. In general, each membrane-bounded organelle carries out the same set of basic functions in all cell types but varies in abundance and can have additional properties that differ from cell type to cell type according to the specialized functions of differentiated cells.

On average, the membrane-bounded compartments together occupy nearly half the volume of a cell (Table 12-1), and a large amount of intracellular membrane is required to make them all. In the two mammalian cells analyzed in Table 12-2, for example, the endoplasmic reticulum has a total membrane surface area that is, respectively, 25 times and 12 times that of the plasma membrane. In terms of its area and mass the plasma membrane is only a minor membrane in most eucaryotic cells (Figure 12-2).

Membrane-bounded organelles are not randomly distributed in the cytosol; instead they often have characteristic positions. In most cells, for example, the Golgi apparatus is located close to the nucleus, whereas the network of ER tubules extends from the nucleus throughout the entire cytosol. These characteristic distributions seem to depend on interactions of the organelles with the cytoskeleton: the localization of both the ER and the Golgi apparatus, for example, is dependent on an intact microtubule array; if the microtubules are experimentally depolymerized with a drug, the Golgi apparatus fragments and disperses throughout the cell and the ER network collapses toward the cell center, or *centrosome*, from which the microtubule array emanates (discussed in Chapter 16).

The Topological Relationships of Membrane-bounded Organelles Can Be Interpreted in Terms of Their Evolutionary Origins [2]

To understand the relationships between the compartments of the cell, it is helpful to consider how they might have evolved. The precursors of the first eucaryotic cells are thought to have been simple organisms that resembled bacteria, which generally have a plasma membrane but no internal membranes. The plasma membrane in such cells therefore provides all membrane-dependent functions, including the pumping of ions, ATP synthesis, protein secretion, and lipid synthesis. Typical present-day eucaryotic cells are 10 to 30 times larger in linear dimension and 1000 to 10,000 times greater in volume than a typical bacterium such as *E. coli*. The profusion of internal membranes can be seen in part as an adaptation to this increase in size: the eucaryotic cell has a much smaller ratio of surface to volume, and its area of plasma membrane is presumably too small to sustain the many vital functions for which membranes are required.

The evolution of internal membranes evidently has gone hand in hand with specialization of membrane function. Some present-day bacteria have specialized patches of plasma membrane in which a selected set of membrane proteins coalesce to carry out a group of related functions (Figure 12-3A). These specialized membrane patches, such as the "purple membrane" containing bacterio-rhodopsin in *Halobacterium* (discussed in Chapter 10) and the chromatophores in photosynthetic bacteria (discussed in Chapter 14), represent primitive organelles. In some photosynthetic bacteria the patches have become elaborated into extensive invaginations of the plasma membrane (Figure 12-3B); in others the invaginations seem to have pinched off completely, forming sealed membrane-bounded vesicles specialized for photosynthesis (Figure 12-3C).

A eucaryotic organelle that originated by the type of pathway illustrated in Figure 12-3 might be expected to have an interior that is topologically equivalent to the exterior of the cell. We shall see that this is the case for the ER, Golgi apparatus, endosome, and lysosome - as well as for the many vesicular intermediates (*transport vesicles*) in the secretory and endocytic pathways. We can therefore think of all of these organelles as members of the same family, and, as we discuss in detail in the next chapter, their interiors communicate extensively with one another and with the outside of the cell via transport vesicles that bud off from one organelle and fuse with another (Figure 12-4). Ribosomes are found attached to the cytosolic side of the plasma membrane in bacteria, and so the evolutionary origin of the ER membrane from the plasma membrane may explain why ribosomes are attached to the ER membrane in eucaryotic cells.

This evolutionary scheme also offers a reasonable explanation for the architecture of the cell nucleus with its double membrane. In bacteria the single chromosome is attached at special sites to the inside of the plasma membrane. It is possible therefore that the double-layered nuclear envelope originated as a deep invagination of the plasma membrane, as shown in Figure 12-5A. This scheme would explain why the nuclear compartment is topologically equivalent to the cytosol. In fact, in higher eucaryotic cells the nuclear envelope breaks down during mitosis, allowing the nuclear contents to disperse in the cytosol, a situation that never

occurs for the contents of any other membrane-bounded organelle. As the scheme in Figure 12-5A also predicts, the space between the two nuclear membranes is topologically equivalent to the exterior of the cell and is continuous with the lumen of the ER.

As discussed in Chapter 14, mitochondria and plastids (of which chloroplasts are one form) differ from the other membrane-bounded organelles in that they contain their own genomes. The nature of these genomes and the close resemblance of the proteins in these organelles to those in some present-day bacteria strongly suggest that mitochondria and plastids evolved from bacteria that were engulfed by other cells with which they initially lived in symbiosis (discussed in Chapters 1 and 14). According to the hypothetical scheme shown in Figure 12-5B, the inner membrane of mitochondria and plastids corresponds to the original plasma membrane of the bacterium, while the lumen of these organelles evolved from the bacterial cytosol. As might be expected from such origins, these two organelles remain isolated from the extensive vesicular traffic that connects the interiors of most of the other membrane-bounded organelles to one another and to the outside of the cell.

This evolutionary scheme groups the intracellular compartments in eucaryotic cells into five distinct families: (1) the nucleus and the cytosol, which communicate through the nuclear pores and are thus topologically continuous (although functionally distinct); (2) all organelles that function in the secretory and endocytic pathways - including the ER, Golgi apparatus, endosomes, lysosomes, and numerous classes of transport vesicles; (3) the mitochondria; (4) the plastids (in plants only); and (5) the peroxisomes (whose evolutionary origins are discussed later).

Proteins Can Move Between Compartments in Different Ways 3

All proteins begin being synthesized on ribosomes in the cytosol, except for the few that are synthesized on the ribosomes of mitochondria and plastids. Their subsequent fate depends on their amino acid sequence, which can contain sorting signals that direct their delivery to locations outside the cytosol. Most proteins do not have a sorting signal and consequently remain in the cytosol as permanent residents. Many others, however, have specific sorting signals that direct their transport from the cytosol into the nucleus, the ER, mitochondria, plastids (in plants), or peroxisomes; sorting signals can also direct the transport of proteins from the ER to other destinations in the cell.

To understand the general principles by which sorting signals operate, it is important to distinguish three fundamentally different ways by which proteins move from one compartment to another. (1) The protein traffic between the cytosol and nucleus occurs between topologically equivalent spaces, which are in continuity through the nuclear pore complexes. This process is called gated transport because the nuclear pore complexes function as selective gates that can actively transport specific macromolecules and macromolecular assemblies, although they also allow free diffusion of smaller molecules. (2) In transmembrane transport membrane-bound *protein translocators* directly transport specific proteins across a membrane from the cytosol into a space that is topologically distinct. The transported protein molecule usually must unfold in order to snake through the membrane. The initial transport of selected proteins from the cytosol into the ER lumen or into mitochondria, for example, occurs in this way. (3) In vesicular transport, *transport vesicles* ferry proteins from one compartment to another. The vesicles become loaded with a cargo of molecules derived from the lumen of one compartment as they pinch off from its membrane; they discharge their cargo into a second compartment by fusing with its membrane. The transfer of soluble proteins from the ER to the Golgi apparatus, for example, occurs in this way. Because the transported proteins do not cross a membrane, they move only between compartments that are topologically equivalent (Figure 12-6). We discuss vesicular transport in more detail in Chapter 13. The three ways in which proteins are transported between different compartments are summarized in Figure 12-7.

Each of the three modes of protein transfer is usually selectively guided by sorting signals in the transported protein that are recognized by complementary receptor proteins in the target organelle. If a large protein is to be imported into the nucleus, for example, it must possess a sorting signal that is recognized by receptor proteins associated with the nuclear pore complex. If a protein is to be transferred directly across a membrane, it must possess a sorting signal that is recognized by the translocator in the membrane to be crossed. Likewise, if a protein is to be incorporated into certain types of transport vesicles or to be retained in certain organelles, its sorting signal must be recognized by a complementary receptor in the appropriate membrane.

Signal Peptides and Signal Patches Direct Proteins to the Correct Cellular Address 4

There are at least two types of sorting signals on proteins. One type resides in a continuous stretch of amino acid sequence, typically 15 to 60 residues long. This signal peptide is often (but not always) removed from the finished protein by a specialized signal peptidase once the sorting process has been completed. The other type consists of a specific three-dimensional arrangement of atoms on the protein's surface that forms when the protein folds up. The amino acid residues that comprise this

signal patch can be distant from one another in the linear amino acid sequence, and they generally remain in the finished protein (Figure 12-8). Signal peptides are used to direct proteins from the cytosol into the ER, mitochondria, chloroplasts, peroxisomes, and nucleus, and they are also used to retain soluble proteins in the ER. Signal patches identify certain enzymes that are to be marked with specific sugar residues that then direct them from the Golgi apparatus into lysosomes; signal patches are also used in other sorting steps that have been less well characterized.

Different types of signal peptides are used to specify different destinations in the cell. Proteins destined for initial transfer to the ER usually have a signal peptide at their amino terminus, which characteristically includes a sequence composed of about 5 to 10 hydrophobic amino acids. Most of these proteins will in turn pass from the ER to the Golgi apparatus, but those with a specific sequence of four amino acids at their carboxyl terminus are retained as permanent ER residents. Proteins destined for mitochondria have signal peptides of yet another type, in which positively charged amino acids alternate with hydrophobic ones. Proteins destined for peroxisomes usually have a specific signal sequence of three amino acids at their carboxyl terminus. Many proteins destined for the nucleus carry a signal peptide formed from a cluster of positively charged amino acids, which is commonly found at internal sites of the polypeptide chain. Some typical signal peptides are listed in Table 12-3.

The importance of each of these signal peptides for protein targeting has been shown by experiments in which the peptide is transferred from one protein to another by genetic engineering techniques: placing the amino-terminal ER signal peptide at the beginning of a cytosolic protein, for example, redirects the protein to the ER. Even though their amino acid sequences can vary greatly, the signal peptides of all proteins having the same destination are functionally interchangeable: physical properties, such as hydrophobicity, often appear to be more important in the signal-recognition process than the exact amino acid sequence.

Signal patches are far more difficult to analyze than signal peptides, and so less is known about their structure. Because they result from a complex three-dimensional protein-folding pattern, they cannot be easily transferred experimentally from one protein to another.

The main ways of studying how proteins are directed from the cytosol to a specific compartment and how they are translocated across membranes are illustrated in Panel 12-1 (pp. 559).

Cells Cannot Construct Their Membrane-bounded Organelles *de Novo:* They Require Information in the Organelle Itself 5

When a cell reproduces by division, it has to duplicate its membrane-bounded organelles. In general, cells do this by enlarging the existing organelles by incorporating new molecules into them; the enlarged organelles then divide and are distributed to the two daughter cells. Thus each daughter cell inherits from its mother a complete set of specialized cell membranes. This inheritance is essential because a cell could not make such membranes *de novo.* If the ER were completely removed from a cell, for example, how could the cell reconstruct it? The membrane proteins that define the ER and carry out many of its functions are themselves products of the ER. A new ER could not be made without an existing ER or, at the very least, a membrane that contains the translocators required to import specific proteins into the ER (and lacks the translocators required to import the proteins that function in other organelles).

Thus it seems that the information required to construct a membrane-bounded organelle does not reside exclusively in the DNA that specifies the organelle's proteins. *Epigenetic*information in the form of at least one distinct protein that preexists in the organelle membrane is also required, and this information is passed from parent cell to progeny cell in the form of the organelle itself. Presumably, such information is essential for the propagation of the cell's compartmental organization, just as the information in DNA is essential for the propagation of its nucleotide and amino acid sequences.

Summary

Eucaryotic cells contain intracellular membranes that enclose nearly half the cell's total volume in separate intracellular compartments called organelles. The main types of membrane-bounded organelles that are present in all eucaryotic cells are the endoplasmic reticulum, Golgi apparatus, nucleus, mitochondria, lysosomes, endosomes, and peroxisomes; plant cells also contain plastids, such as chloroplasts. Each organelle contains a distinct set of proteins that mediates its unique functions.

Each newly synthesized organelle protein finds its way from the ribosome where it is made to the organelle where it functions by following a specific pathway, guided by signals in its amino acid sequence that function as signal peptides or signal patches. The signal peptides and patches are recognized by complementary receptor proteins in the target organelle. Proteins that

function in the cytosol do not contain signal peptides or signal patches and therefore remain in the cytosol after they are synthesized.
Figure 12-1. The major intracellular compartments of an animal cell. The cytosol (*gray*), endoplasmic reticulum, Golgi apparatus, nucleus, mitochondrion, endosome, lysosome, and peroxisome are distinct compartments isolated from the rest of the cell by at least one selectively permeable membrane.

Table 12-1. The Relative Volumes Occupied by the Major Intracellular Compartments in a Liver Cell (Hepatocyte)

Intracellular Compartment	Percent of Total Cell Volume	Approximate Number per Cell*
Cytosol	54	1
Mitochondria	22	1700
Rough ER cisternae	9	1
Smooth ER cisternae plus Golgi cisternae	6	
Nucleus	6	1
Peroxisomes	1	400
Lysosomes	1	300
Endosomes	1	200

*. All the cisternae of the rough and smooth endoplasmic reticulum are thought to be joined to form a single large compartment. The Golgi apparatus, in contrast, is organized into a number of discrete sets of stacked cisternae in each cell, and the extent of interconnection between these sets has not been clearly established.

Table 12-2. Relative Amounts of Membrane Types in Two Types of Eucaryotic Cells

Membrane Type	Percent of Total Cell Membrane	
	Liver Hepatocyte*	Pancreatic Exocrine Cell*
Plasma membrane	2	5
Rough ER membrane	35	60
Smooth ER membrane	16	<1
Golgi apparatus membrane	7	10
Mitochondria		
Outer membrane	7	4
Inner membrane	32	17
Nucleus		
Inner membrane	0.2	3
Secretory vesicle membrane	not determined	3
Lysosome membrane	0.4	not determined
Peroxisome membrane	0.4	not determined
Endosome membrane	0.4	not determined

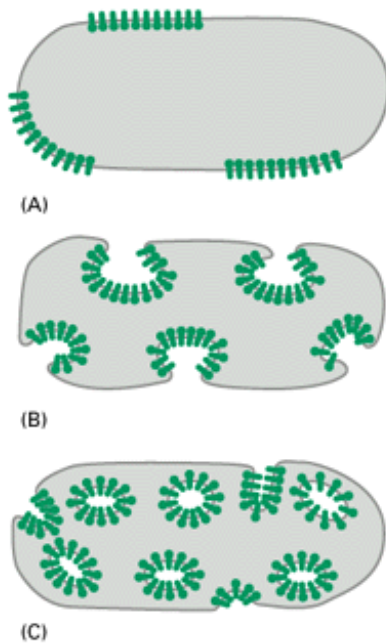
*. These two cells are of very different sizes, since the average hepatocyte has a volume of about 5000 μm^3 compared with about 1000 μm^3 for the pancreatic exocrine cell. Total cell membrane areas are estimated at about 110,000 μm^2 and 13,000 μm^2, respectively.
Figure 12-2. Electron micrograph of part of a liver cell seen in cross-section. Examples of most of the major intracellular compartments are indicated. (Courtesy of Daniel S. Friend.)


Figure 12-3. Organization of specialized membranes in bacteria. (A) Membrane patches on the cell surface consisting of clusters of specialized membrane proteins. (B) Invaginated patches of plasma membrane that increase the amount of membrane available for a specialized function such as photosynthesis. (C) Internalization of the specialized invaginated membrane to form vesicles, whose interior surface is topologically equivalent to the exterior surface of the cell. Membrane-bounded vesicles of this type are present in some types of photosynthetic bacteria; their topological relationship to the cell surface is similar to that of the ER, Golgi apparatus, endosomes, and lysosomes in eucaryotic cells.
Figure 12-4. Topological relationships between compartments in a eucaryotic cell. Topologically equivalent spaces are shown in *red*. In principle, cycles of vesicle budding and fusion permit any lumen to communicate with any other and with the cell exterior. The *blue arrows* indicate the outward direction of vesicle traffic from the ER to Golgi apparatus to plasma membrane (or lysosomes), and the *black dots* represent protein molecules that are secreted by the cell. Some organelles, most notably mitochondria and (in plant cells) chloroplasts, however, do not take part in this vesicular communication and so are isolated from the traffic between organelles shown here.
Figure 12-5. Hypotheses for the evolutionary origins of some membrane-bounded organelles. The origins of mitochondria, chloroplasts, ER, and the cell nucleus could explain the topological relationships of these intracellular compartments in eucaryotic cells. (A) A possible pathway for the evolution of the cell nucleus and the ER. In some bacteria the single DNA molecule is attached to an invagination of the plasma membrane, called a *mesosome*. Such an invagination in a very ancient procaryotic cell could have spread to form an envelope around the DNA while still allowing access of the DNA to the cell cytosol (as is required for DNA to direct protein synthesis). This envelope is presumed to have eventually pinched off completely from the plasma membrane, producing a nuclear compartment surrounded by a double membrane. As illustrated, the nuclear envelope is organized by a fibrous shell called the *nuclear lamina* and is penetrated by communicating channels called *nuclear pore complexes*. Because it is surrounded by two membranes that are in continuity where they are penetrated by these pores, the nuclear compartment is topologically equivalent to the cytosol. The lumen of the ER is continuous with the space between the inner and outer nuclear membranes and topologically equivalent to the extracellular space. (B) Mitochondria (and chloroplasts) are thought to have originated when a bacterium was engulfed by a larger pre-eucaryotic cell. They retain their autonomy. This may explain why the lumens of these organelles remain isolated from the vesicular traffic that interconnects the lumens of many other intracellular compartments.
Figure 12-6. The "sidedness" of membranes is preserved during vesicular transport. Note that the original orientation of both proteins and lipids in the donor-compartment membrane is preserved in the target-compartment membrane and that soluble molecules are transferred from lumen to lumen.

KEY: ▮ = gated transport
▮ = transmembrane transport
▮ = vesicular transport
Figure 12-7. A simplified "road map" of protein traffic. Proteins can move from one compartment to another by gated transport (*red*), trans-membrane transport (*blue*), or vesicular transport (*green*). The signals that direct a given protein's movement through the system, and thereby determine its eventual location in the cell, are contained in its amino acid sequence. The journey begins with the synthesis of a protein on a ribosome and terminates when the final destination is reached. At each intermediate station (*boxes*) a decision is made as to whether the protein is to be retained or transported further. In principle, a signal could be required either for retention in or for exit from each of the compartments shown, with the alternative fate being the *default pathway* (one that requires no signal). The vesicular transport of proteins from the ER through the Golgi apparatus to

the cell surface, for example, appears not to require any specific sorting signals; specific sorting signals therefore are required to retain in the ER and the Golgi apparatus those specialized proteins that are resident there.We shall use this figure repeatedly as a guide throughout this chapter and the next, highlighting the particular pathway being discussed.
Figure 12-8. Two ways that a sorting signal can be built into a protein. (A) The signal resides in a single discrete stretch of amino acid sequence, called a *signal peptide,* that is exposed in the folded protein. Signal peptides often occur at the end of the polypeptide chain (as shown), but they can also be located elsewhere. (B) A *signal patch* can be formed by the juxtaposition of amino acids from regions that are physically separated before the protein folds (as shown); alternatively, separate patches on the surface of the folded protein that are spaced a fixed distance apart could form the signal. In either case the transport signal depends on the three-dimensional conformation of the protein, which makes it difficult to locate the signal precisely.

Table 12-3. Some Typical Signal Peptides

Function of Signal Peptide	Example of Signal Peptide
Import into ER	⁺H₃N-Met-Met-Ser-Phe-Val-Ser- Leu-Leu-Leu-Val Gly-Ile-Leu-Phe-Trp-Ala -Thr-Glu-Ala-Glu- Gln-Leu-Thr-Lys-Cys-Glu-Val-Phe-Gln-
Retain in lumen of ER	-Lys-Asp-Glu-Leu-COO⁻
Import into mitochondria	⁺H₃N-Met-Leu-Ser-Leu-Arg-Gln-Ser-Ile-Arg-Phe- Phe-Lys-Pro-Ala-Thr-Arg-Thr-Leu-Cys-Ser- Ser-Arg-Tyr-Leu-Leu-
Import into nucleus	-Pro-Pro-Lys-Lys-Lys-Arg-Lys-Val-
Import into peroxisomes	-Ser-Lys-Leu-
Attach to membranes via the covalent linkage of a myristic acid to the amino terminus	⁺H₃N-Gly-Ser-Ser-Lys-Ser-Lys-Pro-Lys-

Positively charged amino acids are shown in *red* and negatively charged amino acids in *green*. An extended block of hydrophobic amino acids is enclosed in a *yellow* box. H₃N⁺ indicates the amino terminus of a protein; COO⁻ indicates the carboxyl terminus.

Panel 12-1: Approaches to studying signal sequences and protein translocation across membranes

A transfection approach for defining signal sequences

One way to show that a signal sequence is required and sufficient to target a protein to a specific intracellular compartment is to create a fusion protein in which the signal sequence is attached by genetic engineering techniques to a protein that is normally resident in the cytosol. After the cDNA encoding this protein is transfected into cells, the location of the fusion protein is determined by immunostaining or by cell fractionation.

signal sequence a or b gene encoding cytosolic protein

plasmid used to transfect cells

signal sequence a (▭) directs fusion protein to organelle A

signal sequence b (▪) directs fusion protein to organelle B
By altering the signal sequence using site-directed mutagenesis, one can determine which structural features are important for its function.

A biochemical approach for studying the mechanism of protein translocation

In this approach a labeled protein containing a specific signal sequence is transported into isolated organelles *in vitro*. The labeled protein is usually produced by cell-free translation of a purified mRNA encoding the protein; radioactive amino acids are used to label the newly synthesized protein so that it can be distinguished from the many other proteins that are present in the *in vitro* translation system.

Three methods are commonly used to test if the labeled protein has been translocated into the organelle:

1. The labeled protein co-fractionates with the organelle during centrifugation.

signal sequence

radioactively labeled protein

protein transported into isolated organelle
2. The signal sequence is removed by a specific protease that is present inside the organelle.

incubated without organelle
incubated with organelle

radioactive proteins on SDS gel
3. The protein is protected from digestion when proteases are added to the incubation medium but is susceptible if a detergent is first added to disrupt the organelle membrane.

protease

protein

no detergent   plus detergent
By exploiting such *in vitro* assays, one can determine what components (proteins, ATP, GTP, etc.) are required for the translocation process.

Genetic approaches for studying the mechanism of protein translocation

wild-type yeast cell

histidinol   histidine

enzyme in cytosol: cell lives without histidine as nutrient

ER

translocation apparatus

engineered yeast cell

histidinol

enzyme targeted to ER: cell dies without histidine as nutrient

mutant engineered cell

histidinol   histidine

not all enzyme taken up into ER: cell lives without histidine as nutrient

mutant translocation apparatus
Yeast cells with mutations in genes that encode components of the translocation machinery have been useful for studying protein translocation. Because mutant cells that cannot translocate proteins across their membranes will die, the trick is to design a strategy that allows weak mutations that cause only a partial defect in protein translocation to be isolated.

One way uses genetic engineering to design special yeast cells. The enzyme histidinol dehydrogenase, for example, normally resides in the cytosol, where it is required to produce the essential amino acid histidine from its precursor histidinol. A yeast strain is constructed in which the histidinol dehydrogenase gene is replaced by a re-engineered gene encoding a fusion protein with an added signal sequence that misdirects the enzyme into the endoplasmic reticulum (ER). When such cells are grown without histidine, they die because all of the histidinol dehydrogenase is sequestered in the ER, where it is of no use. Cells with a mutation that partially inactivates the mechanism for translocating proteins from the cytosol to the ER, however, will survive because enough of the dehydrogenase will be retained in the cytosol to produce histidine. Often one obtains a cell in which the mutant protein still functions partially at normal temperature but is completely inactive at higher temperature. A cell carrying such a temperature-sensitive mutation dies at higher temperature, whether or not histidine is present, as it cannot transport any protein into the ER. This allows the normal gene that was disabled by the mutation to be identified by transfecting the mutant cells with a yeast plasmid vector into which random yeast genomic DNA fragments have been cloned: the specific DNA fragment that rescues the mutant cells when they are grown at high temperature should encode the wild-type version of the mutant gene.

The Transport of Molecules into and out of the Nucleus [6]
Introduction

The nuclear envelope encloses the DNA and defines the nuclear compartment. It is formed from two concentric membranes that, as we have seen, are continuous with the endoplasmic reticulum. Although the inner and outer nuclear membranes are continuous, the two membranes maintain distinct protein compositions. The inner nuclear membrane contains specific proteins that act as binding sites for the feltlike *nuclear lamina*that supports it. The inner membrane is surrounded by the outer nuclear membrane, which closely resembles the membrane of the rough endoplasmic reticulum (Figure 12-9). Like the membrane of the rough ER, the outer nuclear membrane is studded with ribosomes engaged in protein synthesis. The proteins made on these ribosomes are transported into the space between the inner and outer nuclear membranes (the *perinuclear space*), which is continuous with the ER lumen (see Figure 12-9).

Bidirectional traffic occurs continuously between the cytosol and the nucleus. The many proteins that function in the nucleus - including histones, DNA and RNA polymerases, gene regulatory proteins, and RNA-processing proteins - are selectively imported into the *nuclear compartment* from the cytosol where they are made. At the same time, tRNAs and mRNAs are synthesized in the nuclear compartment and then exported to the cytosol. Like the import process, the export process is selective; mRNAs, for example, are exported only after they have been properly modified by RNA-processing reactions in the nucleus. In some cases the transport process is complex: ribosomal proteins, for instance, are made in the cytosol, imported into the nucleus - where they assemble with newly made ribosomal RNA into particles - and then exported again to the cytosol as part of a ribosomal subunit; each of these steps involves selective transport across the nuclear envelope.

Nuclear Pores Perforate the Nuclear Envelope [7]

The nuclear envelope in all eucaryotes, from yeasts to humans, is perforated by *nuclear pores*. Each pore is formed by a large, elaborate structure known as the nuclear pore complex, which has an estimated molecular mass of about 125 million and is thought to be composed of more than 100 different proteins, arranged with a striking octagonal symmetry (Figures12-10 and 12-11).

Each pore complex contains one or more open aqueous channels through which water-soluble molecules that are smaller than a certain size can passively diffuse. The effective size of these channels has been determined by injecting labeled molecules (that are not nuclear components) into the cytosol and then measuring their rate of diffusion into the nucleus. Small molecules (5000 daltons or less) diffuse in so fast that the nuclear envelope can be considered to be freely permeable to them. A protein of 17,000 daltons takes 2 minutes to equilibrate between the cytosol and nucleus, while a protein of 44,000 daltons takes 30 minutes. A globular protein larger than about 60,000 daltons seems hardly able to enter the nucleus at all. A quantitative analysis of such data suggests that the nuclear pore complex contains a pathway for free diffusion equivalent to a water-filled cylindrical channel about 9 nm in diameter and 15 nm long; such a channel would occupy only a small fraction of the total pore volume (Figure 12-12).

Because many cellular proteins are too large to pass by diffusion through the nuclear pores, the nuclear envelope allows the nuclear compartment and the cytosol to maintain different complements of proteins. Mature cytosolic ribosomes, for example, are about 30 nm in diameter and thus cannot diffuse through the 9-nm channels; their exclusion from the nucleus ensures that all protein synthesis is confined to the cytosol. But how does the nucleus export newly made ribosomal subunits or import large molecules, such as DNA and RNA polymerases, which have subunit molecular weights of 100,000 to 200,000? As we discuss next, these and many other protein and RNA molecules bind to specific receptor proteins located in the pore complexes and are then actively transported across the nuclear envelope through the complexes.

Nuclear Localization Signals Direct Nuclear Proteins to the Nucleus [8]

In general, the more active the nucleus is in transcription, the greater the number of pore complexes its envelope contains. The nuclear envelope of a typical mammalian cell contains 3000 to 4000 pore complexes. If the cell is synthesizing DNA, it needs to import about 10^6 histone molecules from the cytosol every 3 minutes in order to package newly made DNA into chromatin, which means that, on average, each pore complex needs to transport about 100 histone molecules per minute. If the cell is growing rapidly, each pore complex also needs to transport about 6 newly assembled large and small ribosomal subunits per minute from the nucleus, where they are produced, to the cytosol, where they are used. And that is only a very small part of the total traffic that passes through the nuclear pores.

When proteins are experimentally extracted from the nucleus and micro-injected back into the cytosol, even the very large ones efficiently reaccumulate in the nucleus. The selectivity of this nuclear protein import resides in nuclear localization signals, which are present only in nuclear proteins. The signals have been precisely defined in many nuclear proteins using recombinant DNA technology. They can be located almost anywhere in the amino acid sequence and generally consist of a short sequence (typically from four to eight amino acids) that varies for different nuclear proteins but is rich in the positively charged amino acids lysine and arginine and usually contains proline. In many nuclear proteins this sequence is split into two blocks of two to four amino acids each, with the blocks separated from each other by about ten amino acids. The signals are thought to form loops on the protein surface.

Nuclear localization signals were first identified in the large viral protein called *T-antigen*, which is encoded by the SV40 virus and is needed for viral DNA replication in the host cell nucleus. The T-antigen normally accumulates in the nucleus shortly after being synthesized in the cytosol. A mutation in a single amino acid, however, prevents nuclear import (Figure 12-13). On the assumption that this mutation is in a nuclear localization signal sequence, short lengths of the DNA encoding this region of the normal T-antigen were fused to a gene coding for a cytosolic protein. The shortest sequence that caused the resulting fusion protein to be imported into the nucleus encoded a stretch of eight contiguous amino acids, which is normally located in an internal region of the T-antigen polypeptide chain (see Figure 12-13). Further experiments showed that the signal sequence could function even when it was linked as a short peptide to selected lysine side chains on the surface of a cytosolic protein, suggesting that the precise location of a nuclear localization signal within the amino acid sequence of a nuclear protein is not important. In fact, many nuclear proteins contain more than one nuclear localization signal.

Macromolecules Are Actively Transported into and out of the Nucleus Through Nuclear Pores [9]

The active transport of nuclear proteins through nuclear pore complexes can be directly visualized by coating gold particles with a nuclear protein, injecting the particles into the cytosol, and then following their fate by electron microscopy (Figures 12-14 and 12-15).

The initial interaction of a nuclear protein with the nuclear pore complex requires one or more cytosolic proteins that bind to the nuclear localization signals and help direct the nuclear protein to the pore complex, where it appears to bind to the fibrils that project from the rim of the complex. The nuclear protein then moves to the center of the pore complex, where it is actively transported across the nuclear envelope by a process that requires ATP hydrolysis (Figure 12-16). Studies with various sizes of gold beads indicate that the opening can dilate up to about 26 nm in diameter during the transport process: a poorly defined structure in the center of the nuclear pore complex appears to function like a close-fitting diaphragm that opens just the right amount when activated by a signal on an appropriate large protein (see Figure 12-12). The molecular basis of this mechanism, and how it operates to pump macromolecules both into and out of the nucleus, is a mystery.

It seems likely that the export of new ribosomal subunits and messenger RNA molecules through the nuclear pores also depends on a selective transport system. If 20-nm-diameter gold spheres, similar to those used in the experiments shown in Figure 12-15, are coated with small RNA molecules (tRNA or 5S RNA) and then injected into the nucleus of a frog oocyte, they are rapidly

transported through the nuclear pores into the cytosol. If they are injected into the cytosol of the oocyte, on the other hand, they remain there. Thus it seems that, in addition to receptors that recognize nuclear protein import signals, the pore contains one or more receptors that recognize RNA molecules (or the proteins bound to them) destined for the cytosol. Using differently sized gold particles, one set coated with RNA and injected into the nucleus and the other set coated with nuclear protein import signals, it can be shown that a single pore complex allows traffic in both directions.

The mechanism of macromolecular transport across nuclear pores is fundamentally different from the transport mechanisms involved in the transfer of proteins across the membranes of other organelles in that it occurs through a large, regulated aqueous pore rather than through a protein transporter that spans one or more lipid bilayers. It is thought that a nuclear protein is transported through the pores while it is in a fully folded conformation, just as a newly formed ribosomal subunit is transported as an assembled particle; by contrast, proteins have to be unfolded during their transport into other organelles, as we discuss later.

The Nuclear Envelope Is Disassembled During Mitosis 10

The nuclear lamina is a meshwork of interconnected protein subunits called nuclear lamins. These are a special class of intermediate filament proteins (discussed in Chapter 16) that polymerize into a two-dimensional lattice (Figure 12-17). The nuclear lamina is thought to give shape and stability to the nuclear envelope, to which it is anchored by attachment to both the nuclear pore complexes and the inner nuclear membrane. As the chromatin is also thought to interact directly with the nuclear lamina, the lamina provides a structural link between the DNA and the nuclear envelope.

When a nucleus disassembles during mitosis, the nuclear lamina depolymerizes, at least partly as a consequence of the phosphorylation of the nuclear lamins at the onset of mitosis. At the same time the nuclear pore complexes disassemble into their various components. Depolymerization of the nuclear lamina is probably a prerequisite for the nuclear envelope to break up into membrane vesicles, which, together with the nuclear contents, disperse throughout the cytosol. Reassembly of the lamina occurs when the nuclear lamins are dephosphorylated and, as a result, repolymerize on the surface of the chromosomes; the re-assembled lamina then binds the vesicles of nuclear envelope membrane, which fuse with one another to re-form an envelope around each chromosome or group of chromosomes. During this process the nuclear pore complexes also re-assemble. The enveloped chromosomes then come together, and their membranes fuse to form a single nuclear envelope, which actively reimports all those proteins that contain nuclear localization signals (Figure 12-18). Because the new nuclear envelope is so closely applied to the surface of the chromosomes, it excludes all of the proteins in the cell except those bound to the mitotic chromosomes. Thus large proteins are kept out of the interphase nucleus unless they contain nuclear localization signals.

Nuclear localization signals are not cleaved off after transport into the nucleus. This is presumably because nuclear proteins need to be imported repeatedly, once after every cell division. In contrast, once a protein molecule has been imported into any of the other membrane-bounded organelles, it is passed on from generation to generation within that compartment and need never be translocated again; the signal peptide on these molecules is often removed following protein translocation.

Transport Between Nucleus and Cytosol Can Be Regulated by Preventing Access to the Transport Machinery 11

As discussed in Chapter 9, the activity of some gene regulatory proteins is controlled by keeping them out of the nuclear compartment until they are needed there. The nuclear localization signal of some of these proteins can be inactivated by phosphorylation. Others are bound to inhibitory cytosolic proteins that either anchor them in the cytosol - presumably through interactions with the cytoskeleton or specific organelles - or mask their nuclear localization signals. When the cell receives an appropriate stimulus, the protein is released from its cytosolic anchor or mask and is transported into the nucleus (Figure 12-19).

Export of RNA from the nucleus may be controlled in a similar way. Like active import into the nucleus, export also requires a signal: in the case of most messenger RNA molecules, this is provided by a unique modification, the cap structure, at the 5' end of the RNA (discussed in Chapter 8). Incompletely processed pre-messenger RNAs include this cap but are anchored to the nuclear transcription and splicing machinery, which releases an RNA molecule only after its processing is completed: genetic studies in yeast have shown that mutations that prevent the pre-messenger RNA from properly engaging with the splicing machinery lead to the export of the unspliced RNA. Other RNAs, like transfer RNA or ribosomal RNA, which lack a 5' cap, must first be assembled with proteins and are then exported as part of these complexes. Presumably, nuclear export signals are contained in the protein subunits of these complexes, and these signals become activated after proper assembly with the RNA components, but the nature of these signals is not known.

Summary

The nuclear envelope consists of an inner and an outer nuclear membrane. The outer membrane is continuous with the ER membrane, and the space between it and the inner membrane is continuous with the ER lumen. RNA molecules, which are made in the nucleus, and ribosomal subunits, which are assembled there, are exported to the cytosol, while all of the proteins that function in the nucleus are synthesized in the cytosol and are then imported. The extensive traffic of materials between nucleus and cytosol occurs through nuclear pores that provide a direct passageway across the nuclear envelope.

Proteins containing nuclear localization signals are actively transported inward through the pores, while RNA molecules and newly made ribosomal subunits are actively transported outward through the pores. Because the nuclear localization signals are not removed, nuclear proteins can be imported repeatedly, as is required each time the nucleus reassembles following mitosis. The transport of nuclear proteins and RNA molecules through the pores can be regulated by denying these molecules access to the transport machinery in the nuclear pore complexes.
Figure 12-9. The nuclear envelope. The double-membrane envelope is penetrated by nuclear pores and is continuous with the endoplasmic reticulum. The ribosomes that are bound to the cytosolic surface of the ER membrane and outer nuclear membrane are not shown.

Permission to reproduce this figure in this web version of *Molecular Biology of the Cell* is either pending or has not been granted.

Figure 12-10. The arrangement of the nuclear pore complexes in the nuclear envelope. (A) A sketch showing a small region of the nuclear envelope. In cross-section the nuclear pore complex appears composed of three parts: (1) a column component which forms the bulk of the pore wall; (2) an annular component, which extends "spokes" toward the center of the pore; and (3) a luminal component, which is formed by a large transmembrane glycoprotein that is thought to help anchor the complex to the nuclear membrane. In addition, fibrils protrude from both the cytosolic and nuclear sides of the complex. On the nuclear side the fibrils converge to form cagelike structures, which are shown in a scanning electron micrograph of the nuclear side of the nuclear envelope of an oocyte in (B). (B, from M.W. Goldberg and T.D. Allen, *J. Cell Biol.* 119:1429-1440, 1992, by copyright permission of the Rockefeller University Press.)
Figure 12-11. Electron micrograph and computer reconstruction of nuclear pore complexes. (A) and (B) Negatively stained views of nuclear pore complexes released from the envelope by detergent. In (B) some nuclear pore complexes can be seen on their side. (C) Three-dimensional computer reconstructions showing top, tilted, and side views of pore complexes. (From J.E. Hinshaw and R. Milligan, *Cell* 69:1133-1141, 1992. © Cell Press.)
Figure 12-12. Possible paths for free diffusion through the nuclear pore complex. The drawing shows a hypothetical diaphragm inserted into the pore to restrict the size of the open channel to 9 nm, which is the pore size estimated from diffusion measurements. Nine nanometers is a much smaller diameter than that of the central opening apparent on the images of the nuclear pore complex derived from electron micrographs (or from that measured during active transport when the pore dilates to allow transport of particles of up to 26 nm in diameter). Thus it is likely that some pore components are lost during the preparation of specimens for electron microscopy and that these normally restrict free diffusion through the central opening. Such components may form a diaphragm (or plug) that opens and closes to allow passage of large objects during active transport, which is mediated by a sorting signal (discussed below). Although plugs can be seen in some preparations, it is not clear whether they are components of the pore complex or material that is being transported through it. Three-dimensional computer reconstructions suggest that the channels permitting free diffusion might not be located at the center of the pore complex but near its rim between the column components (see Figure 12-10A); this would mean that passive diffusion and active transport take place through different parts of the pore complex.

Figure 12-13. The function of a nuclear localization signal. Immunofluorescence micrographs showing the cellular location of SV40 virus T-antigen containing or lacking a short peptide that serves as a nuclear localization signal. The wild-type T-antigen protein contains the lysine-rich sequence indicated and is imported to its site of action in the nucleus, as indicated by immunofluorescence staining with antibody against the T-antigen (A). T-antigen with an altered nuclear localization signal (a threonine replacing a lysine) remains in the cytosol (B). (From D. Kalderon, B. Roberts, W. Richardson, and A. Smith, *Cell* 39:499-509, 1984. © Cell Press.)
Figure 12-14. The uptake of nuclear proteins via nuclear pores. *Nucleoplasmin* is a large nuclear protein with distinct head and tail domains. The heads can be cleaved from the tails by limited proteolysis. When injected into the cytosol of a frog oocyte, intact nucleoplasmin molecules rapidly accumulate in the nucleus even though they are too large to diffuse passively through the pore complex. The signal for this nuclear import resides in the tail domains, since injected tails are taken up by the nucleus but heads are not. The role of nuclear pores in this signal-directed import is demonstrated by electron microscopy using nucleoplasmin tails coupled to spheres of colloidal gold, which are easily visualized because of their high electron density. The attached nucleoplasmin tails direct the entry of the gold particles into the nucleus via nuclear pores (see Figure 12-15).
Figure 12-15. Visualizing the specific import of a protein through nuclear pores. This electron micrograph shows colloidal gold spheres coated with nucleoplasmin (see Figure 12-14) entering the nucleus by means of nuclear pores (indicated by *red brackets*). The same result is obtained when the gold spheres are coated with the tail regions of nucleoplasmin molecules. These gold particles are much larger in diameter than the diffusion channel in the pore complex, implying that a pore has been induced to widen to permit their passage. Because the gold particles line up in the cytosol before they contact and enter the pore complex, it has been suggested that the fibrils that extend into the cytosol from the pore complex (see Figure 12-10A) guide the particles to their destination (From C. Feldherr, E. Kallenbach, and N. Schultz, *J. Cell Biol.* 99:2216-2222, 1984, by copyright permission of the Rockefeller University Press.)
Figure 12-16. Highly schematic view of the mechanism of active transport through nuclear pores. The proteins and

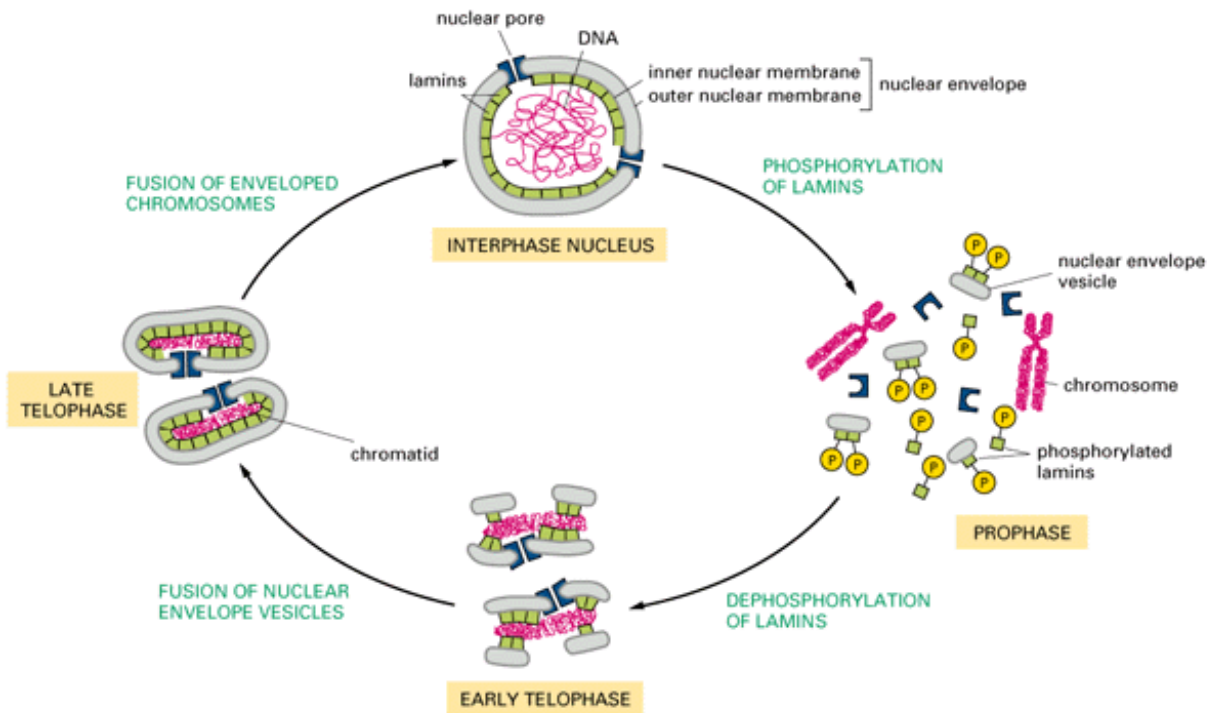
structures involved in the active transport process are not known. A diverse set of related cytosolic proteins, however, is required for the initial binding of nuclear proteins to the complex. These proteins, called *nucleoporins,* contain a simple sugar (*N*-acetylglucosamine) that aided their identification through the use of lectins and specific antibodies. The fibrils that project from the pore complex and are thought to help guide nuclear proteins to the center of the pore are not shown.
Figure 12-17. The nuclear lamina. Electron micrograph of a portion of the nuclear lamina in a *Xenopus* oocyte prepared by freeze drying and metal shadowing. The lamina is formed by a regular lattice of specialized intermediate filaments. (Courtesy of Ueli Aebi.)


Figure 12-18. Breakdown and re-formation of the nuclear envelope during mitosis. The phosphorylation of the lamins is thought to help trigger the disassembly of the nuclear lamina, which in turn causes the nuclear envelope to break up into vesicles. Dephosphorylation of the lamins is thought to help reverse the process.
Figure 12-19. The nuclear import of the glucocorticoid receptor. The glucocorticoid receptor is a gene regulatory protein that, in the non-hormone-treated cell, is bound in the cytosol to the chaperone protein hsp90. When activated by the binding of the appropriate steroid hormone, it is released from hsp90 and is directed into the nucleus by a nuclear localization signal; once in the nucleus, it binds to specific DNA sequences and regulates the transcription of a discrete set of genes (discussed in Chapters 9 and 15).

The Transport of Proteins into Mitochondria and Chloroplasts 12

Introduction
As discussed in Chapter 14, mitochondria and chloroplasts are double-membrane-bounded organelles that specialize in the synthesis of ATP, using energy derived from electron transport and oxidative phosphorylation in mitochondria and from photosynthetic phosphorylation in chloroplasts. Although both organelles contain their own DNA, ribosomes, and other machinery for protein synthesis, most of their proteins are encoded in the cell nucleus and imported from the cytosol. Moreover, each imported protein must reach the particular organelle subcompartment in which it functions. For mitochondria there are two subcompartments: the internal matrix space and the intermembrane space. These compartments are formed by the two distinct mitochondrial membranes: the inner membrane, which encloses the matrix space, and the outer membrane, which is in contact with the cytosol (Figure 12-20A). Chloroplasts have the same two subcompartments plus an additional subcompartment, the *thylakoid space,* which is surrounded by the *thylakoid membrane* (Figure 12-20B). Each of the subcompartments contains a distinct set of proteins. The growth of mitochondria and chloroplasts by the import of proteins from the cytosol is therefore a major feat, requiring that proteins be translocated across a number of membranes in succession and end up in the appropriate place.

The relatively few proteins encoded by the genomes of these organelles are located mostly in the inner membrane in mitochondria and in the thylakoid membrane in chloroplasts. These organelle-encoded polypeptides generally form subunits of protein complexes whose other subunits are encoded by nuclear genes and are imported from the cytosol. The formation of such

hybrid protein complexes requires a balanced synthesis of the two types of subunits; how protein synthesis is coordinated on different types of ribosomes located two membranes apart is still largely a mystery.

Translocation into the Mitochondrial Matrix Depends on a Matrix Targeting Signal [13]

Proteins imported into the mitochondrial matrix are usually taken up from the cytosol within a minute or two of their release from polyribosomes. These mitochondrial precursor proteins almost always have a signal peptide (20-80 residues long) at their amino terminus that is rapidly removed after import by a protease (the *signal peptidase*) in the mitochondrial matrix. The signal peptide can be remarkably simple. Molecular genetic experiments in which the signal peptide is progressively reduced in length have shown that, for one mitochondrial protein, only 12 amino acids at the amino terminus are needed to signal mitochondrial import. These 12 residues can be attached to any cytosolic protein and will direct the protein into the mitochondrial matrix. Physical studies of full-length signal peptides suggest that they can form amphipathic alpha-helical structures in which positively charged residues are clustered on one side of the helix while uncharged hydrophobic residues are clustered on the opposite side (Figure 12-21). This configuration is thought to be recognized by specific receptor proteins on the mitochondrial surface.

Translocation into the Mitochondrial Matrix Requires Both the Electrochemical Gradient Across the Inner Membrane and ATP Hydrolysis [14]

Almost everything we know about the molecular mechanism of protein import into mitochondria has been learned from analysis of cell-free, reconstituted transport systems. Mitochondria are first purified by differential centrifugation of homogenized cells and are then incubated with radiolabeled mitochondrial precursor proteins. The precursor proteins are generally taken up rapidly and efficiently into such mitochondria during a brief *in vitro* incubation. By changing the conditions in these experiments *in vitro,* it is possible to establish the biochemical requirements for protein transport into the mitochondria.

Vectorial movement and transport require energy. In most biological systems the energy is supplied by ATP hydrolysis. In the case of mitochondrial import, however, an electrochemical gradient across the inner mitochondrial membrane is required in addition to ATP hydrolysis. This gradient is maintained by the pumping of H^+ from the matrix to the intermembrane space, driven by electron transport processes in the inner membrane. The mitochondrial outer membrane, like that of gram-negative bacteria (see Figure 11-14), contains large amounts of a pore-forming protein called *porin* and is thus freely permeable to inorganic ions and metabolites (but not to most proteins), so that no gradient can be maintained across it. The energy in the electrochemical gradient across the inner membrane is tapped to help drive most of the cell's ATP synthesis, but it is also used to drive the translocation of proteins bearing a mitochondrial import signal peptide: when ionophores that collapse the mitochondrial membrane potential are added, import is blocked. It is still uncertain how the electrochemical gradient contributes to protein translocation. The role of ATP hydrolysis is much better understood, as we see below.

Mitochondrial Proteins Are Imported into the Matrix in a Two-Stage Process at Contact Sites That Join the Inner and Outer Membranes [15]

As a first step in mitochondrial import, the mitochondrial precursor proteins have to bind to receptor proteins that reside in the mitochondrial outer membrane and recognize the mitochondrial signal peptides. The next step is the translocation process itself.

A protein could reach the mitochondrial matrix by crossing the two membranes one at a time, or it could pass through both at once. To distinguish these possibilities, a cell-free import system is cooled to a low temperature, arresting the proteins at an intermediate step in the translocation process. The proteins that accumulate at this step have already had their amino-terminal signal peptide removed by the matrix signal peptidase, indicating that their amino terminus must be in the matrix space; yet the bulk of the protein can still be attacked from outside the mitochondria by externally added proteolytic enzymes (Figure 12-22). This result demonstrates that the precursor proteins can pass through both mitochondrial membranes at once to enter the matrix. It is thought that there are two protein translocators, one in the outer membrane and one in the inner membrane, whose functions are usually coupled to allow translocation across both membranes at the same time. Electron microscopists have noted numerous contact sites at which the inner and outer mitochondrial membranes appear to be joined, and it seems likely that translocation occurs at or near these sites.

Although precursor proteins are transported through both membranes at once, it is clear from the experiments described in Figure 12-22 that the import process occurs in two distinct stages, only the second of which is arrested at a low temperature. Of these, it is only the initial penetration, which is not affected by low temperatures, that requires the membrane potential: when

cooled mitochondria containing partly translocated intermediates are warmed up, import is rapidly completed (see Figure 12-22) even if the potential across the inner membrane is collapsed. This second stage of the transport process, however, requires ATP. Thus the first stage, which involves the insertion of the signal peptide and adjoining sequences into both mitochondrial membranes, is driven by the electrochemical gradient, and the second stage, in which the remainder of the polypeptide chain moves into the matrix, requires both ATP hydrolysis and a physiological temperature (Figure 12-23).

Proteins Are Imported into the Mitochondrial Matrix in an Unfolded State 16

Transport of mitochondrial precursor proteins across the two mitochondrial membranes at a contact site is guided by members of the chaperone family of proteins, which are discussed in Chapter 5. It is difficult to envisage how a folded, water-soluble protein could straddle two (or even one) lipid bilayer while retaining its native three-dimensional conformation. It is now known that cytosolic chaperone proteins (called *chaperonins*) belonging to the hsp70 family, as well as helping to ensure the correct folding of cytosolic proteins, play an essential part in protein import into both mitochondria and the ER by binding the precursor in its unfolded state during translocation. As discussed in Chapter 5, the release of newly synthesized polypeptides from the hsp70 family of chaperone proteins requires ATP hydrolysis, and this partly accounts for the ATP dependence of the later stages of mitochondrial import.

The essential role of the chaperone proteins in translocation across internal cellular membranes was first indicated by genetic studies in yeasts. When the genes encoding certain members of the hsp70 family of chaperone proteins are inactivated, mitochondrial precursor proteins fail to be imported into mitochondria and accumulate in the cytosol instead. It is thought that newly synthesized precursor proteins, as they are released from polyribosomes in the cytosol, bind to hsp70 proteins, which prevent the precursor proteins from aggregating or folding up spontaneously before they bind to the protein translocator in the target membrane. The energy liberated by the hydrolysis of ATP is used to release the bound hsp70 proteins as the translocated protein is passed across the membrane. Experimentally, the requirement for hsp70 and ATP in the cytosol can be bypassed if the precursor proteins are artificially unfolded, for example, by a denaturation step in a concentrated solution of urea.

Sequential Binding of the Imported Protein to Mitochondrial hsp70 and hsp60 Drives Its Translocation and Assists Protein Folding 17

Imported proteins are not only delivered to the mitochondrion by chaperone proteins: once they are extruded into the interior, they are received by closely related hsp70 proteins in the matrix space. *Mitochondrial hsp70* is crucial to the import process, as mitochondria containing mutant forms of the protein fail to import precursor proteins. Like its cytosolic cousin, mitochondrial hsp70 has a high affinity for unfolded polypeptide chains, and it binds tightly to an imported protein as soon as it emerges from the translocator. The hsp70 then releases the protein in an ATP-dependent step. This energy-driven cycle of binding and subsequent release could provide the driving force for protein import after the protein has initially inserted into the translocator (Figure 12-24): the sequential binding of multiple mitochondrial hsp70 proteins may pull the unfolded protein through a transmembrane channel into the matrix.

After the initial interaction with mitochondrial hsp70, many imported proteins are passed on to another chaperone protein, *mitochondrial hsp60*. As discussed in Chapter 5, hsp60 attaches to the unfolded polypeptide chain and facilitates its folding in an ATP-consuming reaction. Much of our current understanding of the function of hsp60 in facilitating protein folding is derived from studies on import of proteins into mitochondria.

Protein Transport into the Mitochondrial Inner Membrane and the Intermembrane Space Requires Two Signals 18

Many of the functions of mitochondria require proteins that either are integrated into the mitochondrial inner membrane or operate in the intermembrane space. These proteins are transported from the cytosol by the same mechanism that transports proteins into the matrix, but they are then prevented by various means from ending their journey in the matrix. In many cases the precursor proteins are first transferred all the way into the matrix, as was illustrated in Figure 12-23. A very hydrophobic amino acid sequence, however, is strategically placed after the amino-terminal signal peptide that initiates import. Once the amino-terminal signal is cleaved by the matrix signal peptidase, the hydrophobic sequence can function as a new amino-terminal signal peptide to translocate the protein back again from the matrix into or across the inner membrane. Presumably, the final step in this pathway involves a mechanism that is also used to direct proteins encoded in the mitochondrion to the inner membrane (Figure 12-25A), and we see later that a similar mechanism is used for translocating proteins into or across the ER membrane and the procaryotic plasma membrane, where it has been more extensively investigated.

An alternative route to the inner membrane may avoid the excursion into the matrix space altogether. The translocator in the inner membrane binds to the hydrophobic sequence that follows the amino-terminal signal peptide that initiates import and prevents further translocation across the inner membrane. The two translocators in the outer and inner membranes become uncoupled, which causes the remainder of the protein to be pulled into the intermembrane space (Figure 12-25B). Different proteins may use one or the other of these two pathways to the inner membrane or intermembrane space. It is not clear which one is more commonly used.

After proteins destined for the intermembrane space have been inserted via their hydrophobic signal peptides into the inner membrane, some are cleaved by a signal peptidase in the intermembrane space to release the mature polypeptide chain as a soluble protein (Figure 12-25C). Many of these proteins ultimately become attached as peripheral membrane proteins to the outer surface of the inner membrane, where they form subunits of protein complexes that also contain transmembrane proteins.

Two Signal Peptides Are Required to Direct Proteins to the Thylakoid Membrane in Chloroplasts [19]

Protein transport into chloroplasts resembles transport into mitochondria in many respects: both occur posttranslationally, both require energy, and both utilize amphipathic amino-terminal signal peptides that are removed after use. There is at least one important difference, however: mitochondria exploit the electrochemical gradient across their inner membrane to help drive the transport, whereas chloroplasts, which have an electrochemical gradient across their thylakoid but not their inner membrane, appear to employ only ATP hydrolysis to power import across their double-membrane outer envelope.

Although the signal peptides for import into chloroplasts resemble those for import into mitochondria, mitochondria and chloroplasts are both present in the same plant cells, and proteins must choose appropriately between them. In plants, for example, a bacterial enzyme is directed specifically to mitochondria if it is experimentally joined to an amino-terminal signal sequence of a mitochondrial protein; the same enzyme joined to an amino-terminal signal sequence of a chloroplast protein ends up in chloroplasts. The different signal sequences, therefore, can be distinguished, presumably by the import receptors on each organelle.

Chloroplasts have an extra membrane-bounded compartment, the thylakoid. Many chloroplast proteins, including protein subunits of the photosynthetic system and of the ATP synthase, are embedded in the membrane of the thylakoid compartment. Like the precursors of some mitochondrial proteins, these proteins are transported from the cytosol to their final destination in two steps. First, they pass across the double membrane at contact sites into the matrix space of the chloroplast (termed the stroma), and then they are translocated into the thylakoid membrane (or across this membrane into the thylakoid space). The precursors of these proteins have a hydrophobic thylakoid signal peptide following the amino-terminal chloroplast signal peptide. After the amino-terminal signal peptide has been used to import the protein into the stroma, it is removed by a stromal signal peptidase (analogous to the matrix signal peptidase in mitochondria). This cleavage unmasks the thylakoid signal peptide, which then initiates transport across the thylakoid membrane (Figure 12-26). As with mitochondria, the second step is the pathway used to insert chloroplast-encoded proteins into the thylakoid membrane; the protein translocator required presumably originated in the chloroplast's bacterial ancestor.

Summary

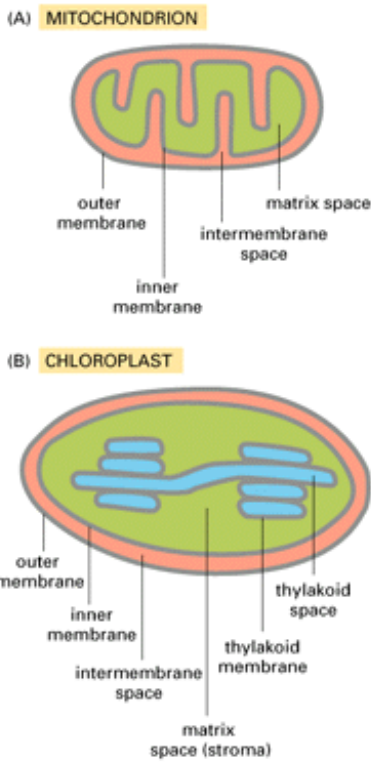
Although mitochondria and chloroplasts have their own genetic systems, they produce only a small proportion of their own proteins. Instead, the two organelles import most of their proteins from the cytosol using similar mechanisms. The transport processes involved have been most extensively studied in mitochondria, especially in yeasts. A protein is translocated into the mitochondrial matrix space by passing through sites of adhesion between the outer and inner membranes called contact sites. Translocation into mitochondria is driven by both ATP hydrolysis and the electrochemical gradient across the inner membrane, whereas translocation into chloroplasts is driven by ATP hydrolysis alone. The transported protein crosses the membranes of the mitochondrion or chloroplast in an unfolded state. Chaperone proteins of the cytosolic hsp70 family maintain the precursor proteins in an unfolded, translocation-competent state. Mitochondrial hsp70 in the matrix binds to the incoming polypeptide chain and is thought to pull the protein chain into the matrix. Once the protein is in the matrix, another stress protein, hsp60, helps the translocated protein fold up. Only proteins that contain a specific signal peptide are translocated into mitochondria or chloroplasts. The signal peptide is usually located at the amino terminus and is cleaved off after import. Transport across or into the inner membrane can occur as a second step if a hydrophobic signal peptide is also present in the imported protein; this second signal peptide is unmasked when the first signal peptide is removed. In the case of chloroplasts, import from the stroma into the thylakoid likewise requires a second signal peptide.


Figure 12-20. The subcompartments of mitochondria and chloroplasts. The topology of the chloroplast can be derived from that of the mitochondrion in a simple way: pinching off the invaginations of the inner mitochondrial membrane to create vesicles would generate a compartment that is topologically equivalent to the thylakoid vesicle in chloroplasts. Thylakoid vesicles may have evolved in this way.
Figure 12-21. A signal peptide for mitochondrial protein import. Cytochrome oxidase is a large multiprotein complex located in the mitochondrial inner membrane, where it functions as the terminal enzyme in the electron-transport chain (discussed in Chapter 14). (A) The first 12 amino acids of the precursor to subunit IV of this enzyme serve as a signal peptide for the import of the subunit into the mitochondrion. (B) When the full-length signal peptide is folded as an alpha helix with 3.6 residues per turn and viewed from the top, the positively charged residues (*red*) are seen to be clustered on one face of the helix while the nonpolar residues (*green*) are clustered on the opposite face. Mitochondrial signal peptide sequences always have the

potential to form such an amphipathic helix, which is thought to be recognized by specific receptor proteins on the mitochondrial surface.
Figure 12-22. Proteins transiently span both the inner and outer mitochondrial membranes during their translocation into the matrix. When isolated mitochondria are incubated with a precursor protein at 5°C, the precursor is only partially translocated. The amino-terminal signal peptide (*red*) is cleaved off in the matrix; most of the polypeptide chain remains outside the mitochondria, where it is accessible to proteolytic enzymes. Upon warming to 25°C, the translocation is completed. Once inside the mitochondrion, the polypeptide chain is protected from externally added proteolytic enzymes unless detergents are added to disrupt the mitochondrial membranes, which allows the imported proteins to be digested.
Figure 12-23. Protein import by mitochondria. The amino-terminal signal peptide of the precursor protein is recognized by receptors that reside in the outer membrane. The protein is thought to be translocated across both mitochondrial membranes at or near special contact sites, driven first by the electrochemical gradient across the inner membrane and then by ATP hydrolysis. The signal peptide is cleaved off by a signal peptidase in the matrix to form the mature protein; the free signal peptide is rapidly degraded.
Figure 12-24. Protein import into the mitochondrial matrix requires hsp70 proteins on both sides of the mitochondrial double membrane. After the initial insertion of the signal peptide and of adjacent portions of the polypeptide chain, the unfolded chain slides in a channel that spans both membranes. Bound *cytosolic hsp70* is released from the protein in a step that depends on ATP hydrolysis; concomitantly, *mitochondrial hsp70* binds to regions of the polypeptide chain as they become exposed in the matrix, thereby pulling the protein into the interior of the mitochondrion.
Figure 12-25. Import of proteins from the cytosol to the mitochondrial intermembrane space or inner membrane. (A) A pathway that requires two signal peptides and two translocation events is thought to be used to move some proteins from the cytosol to the inner membrane. The protein is first imported into the matrix space as in Figure 12-23. Cleavage of the signal peptide (*red*) used for the initial translocation, however, unmasks an adjacent hydrophobic signal peptide (*orange*) at the new amino terminus. This signal causes the protein to be integrated into the inner membrane by the same pathway that is used to insert proteins encoded by the mitochondrial genome into this membrane. (B) In an alternative mechanism, the hydrophobic sequence that follows the matrix targeting signal binds to the translocator and stops the translocation across the inner membrane. The remainder of the protein is then pulled into the intermembrane space and the hydrophobic sequence is released into the inner membrane. This mechanism is called the stop-transfer pathway and is discussed in detail later. (C) Some soluble proteins of the intermembrane space may also use the pathways shown in (A) and (B) before they are released into the intermembrane space by a second signal peptidase (with its active site in the intermembrane space), which removes the hydrophobic signal peptide.
Figure 12-26. Translocation into the thylakoid space of chloroplasts. The precursor polypeptide contains an amino-terminal chloroplast signal peptide (*red*) followed immediately by a thylakoid signal peptide (*orange*). The chloroplast signal peptide initiates translocation into the stroma through a membrane contact site by a mechanism similar to that used for translocation into the mitochondrial matrix. The signal peptide is then cleaved off, unmasking the thylakoid signal peptide, which initiates translocation across the thylakoid membrane.

Peroxisomes [20]
Introduction

Peroxisomes differ from mitochondria and chloroplasts in many ways. Most notably, they are surrounded by only a single membrane, and they do not contain DNA or ribosomes. In spite of these differences, peroxisomes are thought to acquire their proteins by a similar process of selective import from the cytosol. Because peroxisomes have no genome, however, *all* of their proteins must be imported. Peroxisomes thus resemble the ER in being self-replicating membrane-bounded organelles that exist without genomes of their own.

Because we do not discuss peroxisomes elsewhere, we shall digress to consider some of the functions of this diverse family of organelles before discussing their biosynthesis. Peroxisomes are found in all eucaryotic cells. They contain oxidative enzymes, such as *catalase* and *urate oxidase,* at such high concentrations that in some cells the peroxisomes stand out in electron micrographs because of the presence of a crystalloid core, largely composed of urate oxidase (Figure 12-27).

Like the mitochondrion, the peroxisome is a major site of oxygen utilization. One hypothesis is that the peroxisome is a vestige of an ancient organelle that carried out all of the oxygen metabolism in the primitive ancestors of eucaryotic cells. When the oxygen produced by photosynthetic bacteria first began to accumulate in the atmosphere, it would have been highly toxic to

most cells. Peroxisomes might have served to lower the intracellular concentration of oxygen while also exploiting its chemical reactivity to carry out useful oxidative reactions. According to this view, the later development of mitochondria rendered the peroxisome largely obsolete because many of the same reactions - which had formerly been carried out in peroxisomes without producing energy - were now coupled to ATP formation by means of oxidative phosphorylation. The oxidative reactions carried out by peroxisomes in present-day cells would therefore be those that have important functions not taken over by mitochondria.

Peroxisomes Use Molecular Oxygen and Hydrogen Peroxide to Carry Out Oxidative Reactions [21]

Peroxisomes are so called because they usually contain one or more enzymes that use molecular oxygen to remove hydrogen atoms from specific organic substrates (designated here as R) in an oxidative reaction that produces *hydrogen peroxide (H_2O_2):*
$$RH_2 + O_2 \rightarrow R + H_2O_2$$

Catalase utilizes the H_2O_2 generated by other enzymes in the organelle to oxidize a variety of other substrates - including phenols, formic acid, formaldehyde, and alcohol - by the "peroxidative" reaction: $H_2O_2 + R'H_2 \rightarrow R' + 2H_2O$. This type of oxidative reaction is particularly important in liver and kidney cells, whose peroxisomes detoxify various toxic molecules that enter the bloodstream. About a quarter of the ethanol we drink is oxidized to acetaldehyde in this way. In addition, when excess H_2O_2 accumulates in the cell, catalase converts it to H_2O ($2H_2O_2 \rightarrow 2H_2O + O_2$).

A major function of the oxidative reactions carried out in peroxisomes is the breakdown of fatty acid molecules. In a process called *b oxidation,* the alkyl chains of fatty acids are shortened sequentially by blocks of two carbon atoms at a time that are converted to acetyl CoA and exported from the peroxisomes to the cytosol for reuse in biosynthetic reactions. b oxidation in mammalian cells occurs both in mitochondria and peroxisomes; in yeast and plant cells, however, this essential reaction is exclusively found in peroxisomes.

Peroxisomes are unusually diverse organelles and even in the different cells of a single organism may contain very different sets of enzymes. They also can adapt remarkably to changing conditions. Yeast cells grown on sugar, for example, have small peroxisomes. But when some yeasts are grown on methanol, they develop large peroxisomes that oxidize methanol; and when grown on fatty acids, they develop large peroxisomes that break down fatty acids to acetyl CoA by b oxidation.
