The hexadecimal number system requires that $r = 16$ in Eqs. (86.1) and (86.2), indicating that there are 16 distinguishable characters in the system. By convention, the permissible hexadecimal digits are 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E, and F for decimals 0 through 15, respectively. Examples of the positional and polynomial representations for a hexadecimal number are

$$\begin{aligned} N_{16} &= (h_{n-1} \ldots h_3 h_2 h_1 h_0 \; . \; h_{-1} h_{-2} h_{-3} \ldots h_{-m})_{16} \\ &= (\text{AF3.C8})_{16} \end{aligned}$$

with a decimal value of

$$\begin{aligned} N &= \sum_{i=-m}^{n-1} h_i 16^i \\ &= 10 \times 16^2 + 15 \times 16^1 + 3 \times 16^0 + 12 \times 16^{-1} + 8 \times 16^{-2} \\ &= 2803.78125_{10} \end{aligned}$$

Here, it is seen that a hexadecimal number has been converted to decimal by using Eq. (86.2).

The octal number system requires that $r = 8$ in Eqs. (86.1) and (86.2), indicating that there are eight distinguishable characters in this system. The permissible octal digits are 0, 1, 2, 3, 4, 5, 6, and 7, as one might expect. Examples of the application of Eqs. (86.1) and (86.2) are

$$\begin{aligned} N_8 &= (o_{n-1} \ldots o_3 o_2 o_1 o_0 \; . \; o_{-1} o_{-2} o_{-3} \ldots o_{-m})_8 \\ &= 501.74_8 \end{aligned}$$

with a decimal value of

TABLE 86.3 The BCH and BCO Number Systems

Binary	BCH	BCO	Decimal	Binary	BCH	BCO	Decimal
0000	0	0	0	1010	A	12	10
0001	1	1	1	1011	B	13	11
0010	2	2	2	1100	C	14	12
0011	3	3	3	1101	D	15	13
0100	4	4	4	1110	E	16	14
0101	5	5	5	1111	F	17	15
0110	6	6	6	10000	10	20	16
0111	7	7	7	11011	1B	33	27
1000	8	10	8	110001	31	61	49
1001	9	11	9	1001110	4E	116	78

$$
\begin{aligned}
N &= \sum_{i=-m}^{n-1} o_i 8^i \\
&= 5 \times 8^2 + 0 \times 8^1 + 1 \times 8^0 + 7 \times 8^{-1} + 4 \times 8^{-2} \\
&= 321.9375_{10}
\end{aligned}
$$

When the hexadecimal and octal number systems are used to represent bit patterns in binary, they are called binary-coded hexadecimal (BCH) and binary-coded octal (BCO), respectively. These two number systems are examples of *binary-derived radices*. Table 86.3 lists several selected examples showing the relationships between BCH, BCO, binary, and decimal.

What emerges on close inspection of Table 86.3 is that each hexadecimal digit corresponds to four binary digits and that each octal digit corresponds to three binary digits. The following example illustrates the relationships between these number systems:

$$
\begin{aligned}
10110111111.11011_2 &= \begin{array}{cccccccc} 5 & B & F & . & D & 8 \\ 0101 & 1011 & 1111 & . & 1101 & 1000 \end{array} \\
&= 5BF.D8_{16} \\
&= \begin{array}{cccccccc} 2 & 6 & 7 & 7 & . & 6 & 6 \\ 010 & 110 & 111 & 111 & . & 110 & 110 \end{array} \\
&= 2677.66_8 \\
&= 1471.84375_{10}
\end{aligned}
$$

To separate the binary digits into groups of four (for BCH) or groups of three (for BCO), counting must begin from the radix point and continue outward in both directions. Then, where needed, zeros are added to the leading and trailing ends of the binary representation to complete the MSDs and LSDs for the BCH and BCO forms.

Conversion between Number Systems

It is not the intent of this section to cover all methods for radix (base) conversion. Rather, the plan is to provide general approaches, separately applicable to the integer and fraction portions, followed by specific examples.

Conversion of Integers

Since the polynomial form of Eq. (86.2) is a geometrical progression, the integer portion can be represented in *nested radix* form. In source radix *s*, the nested representation is

$$
\begin{aligned}
N_s &= \left(a_{n-1}s^{n-1} + a_{n-2}s^{n-2} + \cdots + a_1 s^1 + a_0 s^0\right)_s \\
&= a_0 + s(a_1 + s(a_2 + \cdots + a_{n-1})))))_s \\
&= a_0 + s\left(\sum_{i=1}^{n-1} a_i s^{i-1}\right)
\end{aligned}
\tag{86.3}
$$

for digits a_i having integer values from 0 to $s-1$. The nested radix form not only suggests a conversion process but also forms the basis for computerized conversion.

Consider that the number in Eq. (86.3) is to be represented in nested radix r form

$$
\begin{aligned}
N_r &= b_0 + r(b_1 + r(b_2 + \cdots + b_{m-1})))))_r \\
&= b_0 + r\left(\sum_{i=1}^{m-1} b_i r^{i-1}\right)
\end{aligned}
\tag{86.4}
$$

where, in general, $m \neq n$. Then, if N_s is divided by r, the results are of the form

$$
\frac{N_s}{r} = Q + \frac{R}{r} \tag{86.5}
$$

where Q is the integer quotient rearranged as $Q_0 = b_1 + r(b_2 + \cdots + b_{m-1})))_r$ and R is the remainder $R_0 = b_0$. A second division by r yields $Q_0/r = Q_1 + R_1/r$, where Q_1 is arranged as $Q_1 = b_2 + r(b_3 + \cdots + b_{m-1}))_r$ and $R_1 = b_1$. Thus, by repeated division of the integer result Q_i by r, the remainders yield $(b_0, b_1, b_2, \ldots, b_{m-1})_r$ in that order.

The conversion method just described, called the *radix divide method,* can be used to convert between any two integers of different radices. However, the requirement is that *the arithmetic required by N_s/r must be carried out in source radix, s.* Except for source radices 10 and 2, this poses a severe problem for humans. Table 86.4 provides the recommended procedures for integer conversion. The radix divide method is suitable for computer conversion providing, of course, that the computer is programmed to carry out the arithmetic in different radices.

TABLE 86.4 Summary of Recommended Methods for Integer Conversion by Noncomputer Means

Integer Conversion	Conversion Method
$N_{10} \rightarrow N_r$	Radix division by radix r using Eq. (86.5)
$N_s \rightarrow N_{10}$	Eq. (86.2) or Eq. (86.3)
$N_s)_{s\neq 10} \text{—>} N_r)_{r\neq 10}$	$N_s \rightarrow N_{10}$ by Eq. (86.2) or (86.3) $N_{10} \rightarrow N_r$ radix division by r using Eq. (86.5)
Special Cases for Binary Forms	
$N_2 \rightarrow N_{10}$	Positional weighting
$N_2 \rightarrow N_{BCH}$	Partition N_2 into groups of four bits starting from radix point, then apply Table 86.3
$N_2 \rightarrow N_{BCO}$	Partition N_2 into groups of three bits starting from radix point, then apply Table 86.3
$N_{BCH} \rightarrow N_2$	Reverse of $N_2 \rightarrow N_{BCH}$
$N_{BCO} \rightarrow N_2$	Reverse of $N_2 \rightarrow N_{BCO}$
$N_{BCH} \rightarrow N_{BCO}$	$N_{BCH} \rightarrow N_2 \rightarrow N_{BCO}$
$N_{BCO} \rightarrow N_{BCH}$	$N_{BCO} \rightarrow N_2 \rightarrow N_{BCH}$
$N_{NBCD} \rightarrow N_{XS3}$	Add 0011_2 $(= 3_{10})$ to N_{NBCD}
$N_{XS3} \rightarrow N_{NBCD}$	Subtract 0011_2 $(= 3_{10})$ from N_{NBCD}

The integer conversion methods of Table 86.4 can be illustrated by the following simple examples:

Example 1. $139_{10} \rightarrow N_2$

N/r	Q	R	
$139/2 =$	69	1	
$69/2 =$	34	1	
$34/2 =$	17	0	
$17/2 =$	8	1	
$8/2 =$	4	0	
$4/2 =$	2	0	
$2/2 =$	1	0	
$1/2 =$	0	1	$139_{10} = 10001011_2$

Example 2. $10001011_2 \rightarrow N_{10}$. By positional weights,

$$N_{10} = 128 + 8 + 2 + 1 = 139_{10}$$

Example 3. $139_{10} \rightarrow N_8$

N/r	Q	R	
$139/8 =$	17	3	
$17/8 =$	2	1	
$2/8 =$	0	2	$139_{10} = 213_8$

Example 4. $10001011_2 \rightarrow N_{\text{BCO}}$

2	1	3	
010	001	011	$= 213_{\text{BCO}}$

Example 5. $213_{\text{BCO}} \rightarrow N_{\text{BCH}}$

2	1	3			8	B	
$213_{\text{BCO}} =$ 010	001	011	$= 10001011_2 =$	1000	1011	$= 8B_{16}$	

Example 6. $213_8 \rightarrow N_5$

$$213_8 = 2 \times 8^2 + 1 \times 8^1 + 3 \times 8^0 = 139_{10}$$

N/r	Q	R	
$139/5 =$	27	4	
$27/5 =$	5	2	
$5/5 =$	1	0	
$1/5 =$	0	1	$213_8 = 1024_5$

Check: $1 \times 5^3 + 2 \times 5^1 + 4 \times 5^0 = 125 + 10 + 4 = 139_{10}$

Conversion of Fractions

By extracting the fraction portion from Eq. (86.2) one can write

$$\begin{aligned} .N_s &= (a_{-1}s^{-1} + a_{-2}s^{-2} + \cdots + a_{-m}s^{-m})_s \\ &= s^{-1}(a_{-1} + s^{-1}(a_{-2} + \cdots + a_{-m})))))_s \\ &= s^{-1}(a_{-1} + \sum_{i=2}^{m} a_{-i}s^{-i+1})_s \end{aligned} \tag{86.6}$$

in radix s. This is called the *nested inverse radix* form that provides the basis for computerized conversion.

TABLE 86.5 Summary of Recommended Methods for Fraction Conversion by Noncomputer Means

Fraction Conversion	Conversion Method
$.N_{10} \rightarrow .N_r$	Radix multiplication by using Eq. (86.8)
$.N_s \rightarrow .N_{10}$	Equation (86.2) or Eq. (86.6)
$.N_r)_{s\neq 10} \rightarrow .N_r)_{r\neq 10}$	$N_s \rightarrow N_{s10}$ by Eq. (86.2) or Eq. (86.6) $N_{10} \rightarrow N_r$ radix multiply by Eq. (86.8)
Special Cases for Binary Forms	
$.N_2 \rightarrow .N_{BCH}$	Partition $.N_2$ into groups of four bits from radix point, then apply Table 86.3
$.N_2 \rightarrow .N_{BCO}$	Partition $.N_2$ into groups of three bits from radix point, then apply Table 86.3
$.N_{BCH} \rightarrow .N_2$	Reverse of $.N_2 \rightarrow .N_{BCH}$
$.N_{BCO} \rightarrow .N_2$	Reverse of $.N_2 \rightarrow .N_{BCO}$
$.N_{BCH} \rightarrow .N_{BCO}$	$.N_{BCH} \rightarrow .N_2 \rightarrow .N_{BCO}$
$.N_{BCO} \rightarrow .N_{BCH}$	$.N_{BCO} \rightarrow .N_2 \rightarrow .N_{BCH}$

If the fraction in Eq. (86.6) is represented in nested inverse radix r form, then

$$\begin{aligned} .N_r &= r^{-1}(b^{-1} + r^{-1}(b^{-2} + \cdots + b^{-p})))))_r \\ &= r^{-1}(b_{-1} + \sum_{i=2}^{p} b_{-i} r^{-i+1})_r \end{aligned} \tag{86.7}$$

for any fraction represented in radix r. Now, if N_s is multiplied by r, the result is of the form

$$.N_s \times r = I + F \tag{86.8}$$

where I is the product integer, $I_1 = b_{-1}$, and F_0 is the product fraction arranged as $F_1 = r^{-1}(b_{-2} + r^{-1}(b_{-3} + \ldots + b_{-p})))_r$. By repeated multiplication by r of the remaining fractions F_i, the resulting integers yield $(b_{-1}, b_{-2}, b_{-3}, \ldots b_{-m})_r$, in that order.

The conversion just described is called the *radix multiply method* and is perfectly general for converting between fractions of different radices. However, as in the case of integer conversion, the requirement is that *the arithmetic required by $.N_s \times r$ must be carried out in source radix, s.* For noncomputer use by humans, this procedure is usually limited to fraction conversions $N_{10} \rightarrow N_r$, where the source radix is 10 (decimal). The recommended methods for converting between fractions of different radices are given in Table 86.5. The radix multiply method is well suited to computer use.

For any integer of radix s, there exists an exact representation in radix r. This is not the case for a fraction whose conversion is a geometrical progression that never converges. Terminating a fraction conversion at n digits (to the right of the radix point) results in an error or uncertainty. In decimal, this error is given by

$$\begin{aligned} \epsilon_{10} &= a_{-n} r^{-n} + a_{-(n+1)} r^{-(n+1)} + a_{-(n+2)} r^{-(n+2)} + \cdots \\ &= r^{-n} \left[a_{-n} + \sum_{i=1}^{\infty} a_{-(n+i)} r^{-(n+i)} \right]_r \end{aligned}$$

where the quantity in brackets approaches the value of $a_{-n} + 1$. Therefore, terminating a fraction conversion at n digits from the radix point results in an error with bounds

$$0 < \epsilon_{10} \leq r^{-n}(a_{-n} + 1) \tag{86.9}$$

in decimal. Equation (86.9) is useful in deciding when to terminate a fraction conversion.

Often, it is desirable to terminate a fraction conversion at $(n + 1)$ digits and then round off to n from the radix point. A suitable method for rounding to n digits in radix r is: Perform the fraction conversion to $(n + 1)$ digits from the radix point, then drop the $(n + 1)$ digit if $a_{-(n+1)} < r/2$, or add $r^{-(n-1)}$ to the result if $a_{-(n+1)} \geq r/2$.

After rounding off to n digits, the maximum error becomes the difference between the rounded result and the smallest value possible. By using Eq. (86.9), this difference is

$$\begin{aligned}\epsilon_{\max} &= r^{-n}(a_{-n} + 1) - r^{-n}(a_{-n} + a_{-(n+1)}/r) \\ &= r^{-n}(1 - a_{-(n+1)}/r)\end{aligned}$$

Then, by rounding to n digits, there results an error with bounds

$$0 < \epsilon_{10} \leq r^{-n}(1 - a_{-(n+1)}/r) \tag{86.10}$$

in decimal. If $a_{-(n+1)} < r/2$ and the $(n + 1)$ digit is dropped, the maximum error is r^{-n}. Note that for $N_s \rightarrow N_{10} \rightarrow N_r$ type conversions, the bounds of errors aggregate.

The following examples illustrate the fraction conversion methods of Table 86.5.

Example 7. $0.654_{10} \rightarrow N_2$ rounded to eight bits

$.N_s \times r$	F	I	
0.654×2	0.308	1	
0.308×2	0.616	0	
0.616×2	0.232	1	
0.232×2	0.464	0	
0.464×2	0.928	0	
0.928×2	0.856	1	$0.654_{10} = 0.10100111_2$
0.856×2	0.712	1	
0.712×2	0.424	1	
0.424×2	0.848	0	$\epsilon_{\max} = 2^{-8}$

Example 8. $0.654_{10} \rightarrow N_8$ terminated at four digits

$.N_s \times r$	F	I	
0.654×8	0.232	5	
0.232×8	0.856	1	$0.654_{10} = 5166_8$
0.856×8	0.848	6	with error bounds
0.848×8	0.784	6	$0 < \epsilon_{10} \leq 7 \times 8^{-4} = 1.71 \times 10^{-3}$

Example 9. $0.5166_8 \rightarrow N_2$ rounded to eight bits and let $0.5166_8 \rightarrow N_{10}$ be rounded to four decimal places.

$$\begin{aligned}0.5166_8 &= 5 \times 8^{-1} + 1 \times 8^{-2} + 6 \times 8^{-3} + 6 \times 8^{-4} \\ &= 0.625000 + 0.015625 + 0.011718 + 0.001465 \\ &= 0.6538 \text{ rounded to four decimal places; } \epsilon_{10} \leq 10^{-4}\end{aligned}$$

$.N_s \times r$	F	I
0.6538×2	0.3076	1
0.3076×2	0.6152	0
0.6152×2	0.2304	1
0.2304×2	0.4608	0
0.4608×2	0.9216	0

$0.9216 \times 2 \quad 0.8432 \quad 1$
$0.8432 \times 2 \quad 0.6864 \quad 1 \qquad 0.5166_8 = 0.10100111_2$(compare with Example 7)
$0.6864 \times 2 \quad 0.3728 \quad 1$
$0.3728 \times 2 \quad 0.7457 \quad 0 \qquad \epsilon_{10} \leq 10^{-4} + 2^{-8} = 0.0040$

Example 10. $0.10100111_2 \rightarrow N_{BCH}$

$$0.10100111_2 = \underset{\text{A}}{0.1010} \cdot \underset{7}{0111} = 0.\text{A7}_{BCH}$$

Signed Binary Numbers

To this point only unsigned numbers (assumed to be positive) have been considered. However, both positive and negative numbers must be used in computers. Several schemes have been devised for dealing with negative numbers in computers, but only four are commonly used:

- Signed-magnitude representation
- Radix complement representation
- Diminished radix complement representation
- Excess (offset) code representation

Of these, the radix 2 complement representation, called 2's complement, is the most widely used system in computers.

Signed-Magnitude Representation

A signed-magnitude number consists of a magnitude together with a symbol indicating its sign (positive or negative). Such a number lies in the decimal range of $-(r^{n-1} - 1)$ through $+(r^{n-1} - 1)$ for n integer digits in radix r. A fraction portion, if present, would consist of m digits to the right of the radix point.

The most common examples of signed-magnitude numbers are those in the decimal and binary systems. The sign symbols for decimal (+ or –) are well known. In binary it is established practice to use 0 = plus and 1 = minus for the sign symbols and to place one of them in the MSB position for each number. Examples in eight-bit binary are

$$+45.5_{10} = \underset{\text{Sign bit}}{0} \quad \overbrace{101101.1_2} \quad +0_{10} = 0 \;\; 0000000_2$$

$$-123_{10} = \underset{\text{Sign bit}}{1} \quad \overbrace{1111011_2} \quad -0_{10} = 1 \;\; 0000000_2$$

Although the sign-magnitude system is used in computers, it has two drawbacks. There is no unique zero, as indicated by the examples, and addition and subtraction calculations require time-consuming decisions regarding operation and sign as, for example, (–7) minus (–4). Even so, the sign-magnitude representation is commonly used in **floating-point** number systems.

Radix Complement Representation

The *radix complement* of an n-digit number N_r is obtained by subtracting it from r^n, that is $r^n - N_r$. The operation $r^n - N_r$ is equivalent to complementing the number and adding 1 to the LSD. Thus, the radix complement is $\overline{N}_r + 1_{LSD}$ where $\overline{N}_r = r^n - 1 - N_r$ is the complement of a number in radix r. Therefore, one may write

$$\text{Radix complement of } N_r = r^n - N_r$$

$$= \overline{N}_r + 1 \tag{86.11}$$

The complements $\overline{N}_r$ for digits in three commonly used number systems are given in Table 86.6. Notice that the complement of a binary number is formed simply by replacing the 1's with 0's and 0's with 1's as required by $2^n - 1 - N_2$.

With reference to Table 86.6 and Eq. (86.11), the following examples of radix complement representation are offered.

Example 11. The 10's complement of 47.83 is

$$\overline{N}_{10} + 1_{\text{LSD}} = 52.17$$

Example 12. The 2's complement of 0101101.101 is

$$\overline{N}_2 + 1_{\text{LSB}} = 1010010.011$$

Example 13. The 16's complement of A3D is

$$\overline{N}_{16} + 1_{\text{LSD}} = 5\text{C}2 + 1 = 5\text{C}3$$

The decimal value of Eq. (86.11) can be found from the polynomial expression

$$N_{\text{radix compl.}})_{10} = -(a_{n-1}r^{n-1}) + \sum_{i=-m}^{n-2} a_i r^i \tag{86.12}$$

for any n-digit number of radix r. In Eqs. (86.11) and (86.12) the MSD is taken to be the position of the sign symbol.

2's Complement Representation. The radix complement for binary is the 2's complement representation. In 2's complement the MSB is the sign bit, 1 indicating a negative number or 0 if positive. The decimal range of representation for n-integer bits in 2's complement is from $-(2^{n-1})$ through $+(2^{n-1})$. From Eq. (86.11), the 2's complement is formed by

$$N_2)_{\text{2's compl.}} = 2^n - N_2 = \overline{N}_2 + 1 \tag{86.13}$$

A few examples in eight-bit binary are shown in Table 86.7. Notice that application of Eq. (86.13) changes the sign of the decimal value of a binary number (+ to –, and vice versa) and that only one zero representation exists.

Application of Eq. (86.12) gives the decimal value of any 2's complement number, including those containing a radix point. For example, the pattern $N_{\text{2's compl.}} = 11010010.011$ has a decimal value

$$\begin{aligned} N_{\text{2's compl.}})_{10} &= -1 \times 2^7 + 1 \times 2^6 + 1 \times 2^4 + 1 \times 2^1 + 1 \times 2^{-2} + 1 \times 2^{-3} \\ &= -128 + 64 + 16 + 2 + 0.25 + 0.125 \\ &= -45.625_{10} \end{aligned}$$

The same result could have easily been obtained by first applying Eq. (86.13) to $N_{\text{2's compl.}}$ followed by the use of positional weighting to obtain the decimal value. Thus,

TABLE 86.6 Complements for Three Commonly Used Number Systems

	Complement ($-N_r$)		
Digit	Binary	Decimal	Hexadecimal

C			3
D			2
E			1
F			0

TABLE 86.7 Examples of Eight-Bit 2's and 1's Complement Representations (MSB = Sign Bit)

Decimal Value	2's Complement	1's Complement
–128	10000000	
–127	10000001	10000000
–31	11100001	11100000
–16	11110000	11101111
–15	11110001	11110000
–3	11111101	11111100
–0	00000000	11111111
+0	00000000	00000000
+3	00000011	00000011
+15	00001111	00001111
+16	00010000	00010000
+31	00011111	00011111
+127	01111111	01111111
+128		

$$\begin{aligned} N_{\text{2's compl.}} &= 00101101.101 \\ &= 32 + 8 + 5 + 0.5 + 0.125 \\ &= 45.625_{10} \end{aligned}$$

which is known to be a negative number, -45.625_{10}.

Negative NBCD numbers can be represented in 2's complement. The foregoing discussion on 2's complement applies to NBCD with consideration of how NBCD is formed from binary. As an example, -59.24_{10} is represented by

$$0101\ \ 1001.0010\ \ 0100)_{\text{NBCD}} = 10100110.11011100)_{\text{2's compl. NBCD}}$$

In a similar fashion, negative NBCD numbers can also be represented in 1's complement following the procedure given in the next paragraph. Sign-magnitude representation of a negative NBCD number simply requires the addition of a sign bit to the NBCD magnitude.

Diminished Radix Complement Representation

The diminished radix complement of a number is obtained by

$$\begin{aligned} N_r)_{\text{dim. rad. compl.}} &= r^n - N_r - 1 \qquad (86.14) \\ &= \overline{N}_{\text{r}} \end{aligned}$$

Thus, the complement of a number is its diminished radix complement. It also follows that the radix complement of a number is the diminished radix complement with 1 added to the LSD as in Eq. (86.13). The range of representable numbers is $-(r^{n-1} - 1)$ through $+(r^{n-1} - 1)$ for radix r.

In the binary and decimal number systems, the diminished radix complement representations are the 1's complement and 9's complement, respectively. Examples of 1's complement are shown in Table 86.7 for comparison with those of 2's complement. Notice that in 1's complement there are two representations for zero, one for +0 and the other for –0. This fact limits the usefulness of the 1's complement representation for computer arithmetic.

Excess (Offset) Representations

Other systems for representing negative numbers use *excess* or *offset* codes. Here, a bias B is added to the true value N_r of the number to produce an excess number N_{xs} given by

$$N_{xs} = N_r + B \tag{86.15}$$

When $B = r^{n-1}$ exceeds the usable bounds of negative numbers, N_{xs} remains positive. Perhaps the most common use of the excess representation is in floating-point number systems—the subject of the next section.

Two examples are given below in eight-bit excess 128 code.

Example 14.

-43_{10}	11010101	$N_{2\text{'s compl.}}$
$+128_{10}$	10000000	B
85_{10}	01010101	$N_{xs} = -43_{10}$ in excess 128 code

Example 15.

27_{10}	00011011	$N_{2\text{'s compl.}}$
$+128_{10}$	10000000	B
155_{10}	10011011	$N_{xs} = 27_{10}$ in excess 128 code

The representable decimal range for an excess 2^{n-1} number system is -2^{n-1} through $+(2^{n-1} - 1)$ for an n-bit binary number. However, if $N_2 + B > 2^{n-1} - 1$, *overflow* occurs and 2^{n-1} must be subtracted from $(N_2 + B)$ to give the correct result in excess 2^{n-1} code.

Floating-Point Number Systems

In fixed-point representation [Eq. (86.1)], the radix point is assumed to lie immediately to the right of the integer field and at the left end of the fraction field. The fixed-point system is the most commonly used system for representing bounded orders of magnitude. For example, with 32 bits a binary number could represent decimal numbers with upper and lower bounds of the order of $\pm 10^{10}$ and $\pm 10^{-10}$. However, for greatly expanded bounds of representation, as in scientific notation, the *floating-point* representation is needed.

A floating-point number (FPN) in radix r has the general form

$$\text{FPN})_r = F \times r^E \tag{86.16}$$

where F is the *fraction* (or **mantissa**) and E is the *exponent*. Only fraction digits are used for the mantissa! Take, for example, Planck's constant $h = 6.625 \times 10^{-34}$ J·s. This number can be represented many different ways in floating point notation:

$$\begin{aligned} \text{Planck's constant } h &= 0.625 \times 10^{-33} \\ &= 0.0625 \times 10^{-32} \\ &= 0.00625 \times 10^{-31} \end{aligned}$$

All three adhere to the form of Eq. (86.16) and are, therefore, legitimate floating-point numbers in radix 10. Thus, as the radix point *floats* to the left, the exponent is *scaled* accordingly. The first form for h is said to be *normalized* because the MSD of F is nonzero, a means of standardizing the radix point position. Notice that the sign for F is positive while that for E is negative.

In computers the FPN is represented in binary where the normalized representation requires that the MSB for F always be 1. Thus, the range in F in decimal is

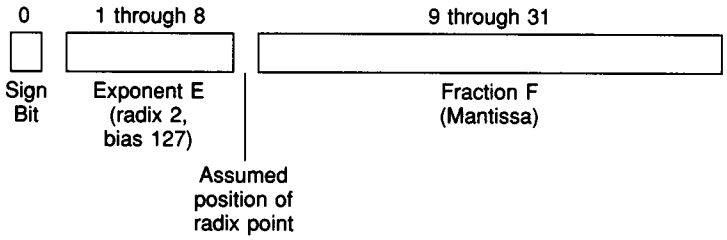

FIGURE 86.1 IEEE standard bit format for normalized floating-point representation.

$$0.5 \le F < 1$$

Also, the mantissa F is represented in sign-magnitude from. The normalized format for a 32-bit floating-point number in binary, which agrees with the IEEE standard [IEEE, 1985], is shown in Fig. 86.1. Here, the sign bit (1 if negative or 0 if positive) is placed at bit position 0 to indicate the sign of the fraction. Notice that the radix point is assumed to lie between bit positions 8 and 9 to separate the E bit-field from the F bit-field.

Before two FPNs can be added or subtracted in a computer, the E fields must be compared and equalized and the F fields adjusted. The decision-making process can be simplified if all exponents are converted to positive numbers by using the excess representation given by Eq. (86.15). For a q-digit number in radix r, the exponent in Eq. (86.16) becomes

$$E_{xs} = E_r + r^{q-1} \tag{86.17}$$

where E is the actual exponent augmented by a bias of $B = r^{q-1}$. The range in the actual exponent E_r is usually taken to be

$$-(r^{q-1} - 1) \le E_r \le +(r^{q-1} - 1)$$

In the binary system, required for computer calculations, Eq. (86.17) becomes

$$E_{xs} = E_2 + 2^{q-1} \tag{86.18}$$

with a range in actual exponent of $-(2^{q-1}-1) \le E_2 \le +(2^{q-1} - 1)$. In 32-bit normalized floating-point form, the exponent is stored in excess 128 code, while the number is stored in sign-magnitude form.

There still remains the question of how the number 0 is to be represented. If the F field is zero, then the exponent can be anything and the number will be zero. However, in computers the normalized FPN_2 limits F to $0.5 \le F < 1$ since the MSB for F is always 1. The solution to this problem is to assume that the number is zero if the exponent bits are all zero regardless of the value of the mantissa. This leads, however, to a discontinuity in normalized FPN_2 representation at the low end.

The IEEE standard for normalized FPN_2 representation attempts to remove the problem just described. The IEEE system stores the exponent in excess $2^{q-1} - 1$ code and limits the decimal range of the actual exponent to

$$-(2^{q-1} - 2) \le E_2 \le +(2^{q-1} - 1)$$

For 32-bit FPN representation, the exponent is stored in excess 127 code as indicated in Fig. 86.1. Thus, the allowable range of representable exponents is from

$$-126_{10} = 00000001_2 \quad \text{through} \quad +127_{10} = 11111110_2$$

This system reserves the use of all 0's or all 1's in the exponent for special conditions [IEEE, 1985; Pollard, 1990]. So that the F field magnitude can diminish linearly to zero when $E = -126$, the MSB = 1 for F is not specifically represented in the IEEE system but is implied.

The following example attempts to illustrate the somewhat confusing aspects of the IEEE normalized representation:

The number 101101.11001_2 is to be represented in IEEE normalized FPN_2 notation.

$$101101.11001_2 = .10110111001 \times 2^6$$

$$\text{Sign bit} = 0 \text{ (positive)}$$

$$E_{xs} = 6 + 127 = 133_{10} = 10000101_2$$

$$F = 0110111001\ldots00 \text{ (the MSB} = 1 \text{ is not shown)}$$

Therefore, the IEEE normalized FPN is

$$FPN_2 = 0 \quad 10000101 \quad 0110111001\ldots0$$

Still other forms of FPNs are in use. In addition to the IEEE system, there are the IBM, Cray, and DEC systems of representation, each with its own single- and double-precision forms.

Defining Terms

Binary: Representation of quantities in base 2.
Complement: Opposite form of a number system.
Floating point: Similar to "scientific notation" except used to represent binary operations in a computer.
Hexadecimal: Base 16 number system.
Mantissa: Fraction portion of a floating-point number.
Octal: Base 8 number system.
Radix: Base to which numbers are represented.

86.2 Computer Arithmetic

Vojin G. Oklobdzija

As the ability to perform computation increased from the early days of computers up to the present, so has the knowledge of how to utilize the hardware and software to perform computation. Digital computer arithmetic emerged from that period in two ways: as an aspect of logic design and as a development of efficient **algorithms** to utilize the available hardware.

Given that numbers in a digital computer are represented as a string of zeros and ones and that hardware can perform only a relatively simple and primitive set of Boolean operations, all the arithmetic operations performed are based on a hierarchy of operations that are built upon the very simple ones.

What distinguishes computer arithmetic is its intrinsic relation to technology and the ways things are designed and implemented in a digital computer. This comes from the fact that the value of a particular way to compute, or a particular algorithm, is directly evaluated from the actual speed with which this computation is performed. Therefore, there is a very direct and strong relationship between the technology in which digital logic is implemented to compute and the way the computation is structured. This relationship is one of the guiding principles in the development of computer arithmetic.

The subject of computer arithmetic can be, for simpler treatment, divided into number representation; basic, arithmetic operations (such as addition, multiplication, and division), and evaluation of functions.

Number Representation

The only way to represent information in a digital computer is via a string of bits, i.e., zeros and ones. The number of bits being used depends on the length of the *computer word,* which is a quantity of bits on which hardware is capable of operating (sometimes also a quantity that is brought to the CPU from memory in a single access). The first question is what relationship to use in establishing correspondence between those bits and a number. Second, we need to make sure that certain properties that exist in the corresponding **number representation system** are satisfied and that they directly correspond to the operations being performed in hardware over the taken string of bits.

This relationship is defined by the rule that associates one numerical value designated as X (in the text we will use capital X for the numerical value) with the corresponding bit string designated as x.

$$x = \{x_{n-1}, x_{n-2}, \ldots, x_0\}$$

where

$$x_i \in 0, 1$$

In this case the associated word (the string of bits) is n bits long.

When for every value X there exists one and only one corresponding bit string x, we define the number system as **nonredundant.** If however, we could have more than one bit string x that represents the same value X, the number system is **redundant.**

Most commonly we are using numbers represented in a *weighted* number system, where a numerical value is associated with the bit string x according to the equation

$$x = \sum_{i=0}^{n-1} x_i w_i$$

where

$$w_0 = 1 \qquad \text{and} \qquad w_i = (w_i - 1)(r_i - 1)$$

TABLE 86.8 The Relationship between the Implicit Value and the Explicit Value

Implied Attributes: Radix Point, Negative Number Representation, Others	Expression for Implicit Value X_i as a Function of Explicit Value x_e	Numerical Implicit Value X_i (in Decimal)
Integer magnitude	$X_i = x_e$	27
Integer, two's complement	$X_i = -2^5 + x_e$	–5
Integer, one's complement	$X_i = -(2^5 - 1) + x_e$	–4
Fraction, magnitude	$X_i = -2^{-5}x_e$	27/32
Fraction, two's complement	$X_i = -2^{-4}(2^{-5} + x_e)$	–5/16
Fraction, one's complement	$X_i = -2^{-4}(2^{-5} + 1 + x_e)$	–4/16

Source: A. Avizienis, "Digital computer arithmetic: A unified algorithmic specification," in *Symp. Computers and Automata,* Polytechnic Institute of Brooklyn, April 13–15, 1971.

The value r_i is an integer designated as the *radix*, and in a nonredundant number system it is an integer equal to the number of allowed values for x_i. In general x_i could consist of more than one bit. The numerical value associated with x is designated as the *explicit value* of x_e. In conventional number systems the radix r_i is the same positive integer for all the digit positions x_i and with the canonical set of digit values

$$\sum i = \{0, 1, 2, 3, \ldots, r_i - 1\} \qquad \text{for } 0 \le i \le n - 1$$

An example of a weighted number system with a mixed radix would be the representation of time in weeks, days, hours, minutes, and seconds with a range for representing 100 weeks:

$$r = 10, 10, 7, 24, 60, 60$$

In digital computers the radices encountered are 2, 4, 10, and 16, with 2 being the most commonly used one.

The digit set x_i can be *redundant* and *nonredundant.* If the number of different values x_i can assume is $n_x \le r$, then we have a *nonredundant* digit set. Otherwise, if $n_x > r$, we have a *redundant* digit set. Use of the *redundant* digit set has its advantages in efficient implementation of algorithms (multiplication and division in particular).

Other number representations of interest are *nonweighted* number systems, where the relative position of the digit does not affect the weight so that the appropriate interchange of any two digits will not change the value x. The best example of such a number system is the residue number system (RNS).

We also define **explicit value x_e** and **implicit value X_i** of a number represented by a bit string x. The *implicit value* is the only value of interest to the user, while the *explicit value* provides the most direct interpretation of the bit string x. Mapping of the *explicit value* to the *implicit value* is obtained by an arithmetic function that defines the number representation used. It is a task of the arithmetic designer to devise algorithms that result in the correct implicit value of the result for the operations on the operand digits representing the explicit values. In other words, the arithmetic algorithm needs to satisfy the *closure* property.

The relationship between the *implicit value* and the *explicit value* is best illustrated by Table 86.8.

Representation of Signed Integers

The two most common representations of signed integers are sign and magnitude (SM) representation and true and complement (TC) representation. While SM representation might be easier to understand and convert to and from, it has its own problems. Therefore, we will find TC representation to be more commonly used.

Sign and Magnitude Representation (SM). In SM representation signed integer X_i is represented by sign bit x_s and magnitude x_m (x_s, x_m). Usually 0 represents the positive sign (+) and 1 represents the negative sign (–). The magnitude of the number x_m can be represented in any way chosen for the representation of positive integers. A disadvantage of SM representation is that two representations of zero exist, positive and negative zero: $x_s = 0$, $x_m = 0$ and $x_s = 1$, $x_m = 0$.

True and Complement Representation (TC). In TC representation there is no separate bit used to represent the sign. Mapping between the explicit and implicit value is defined as

TABLE 86.9 True and Complement Mapping

x_e	X_i
0	0
1	1
2	2
M	M
$C/2 - 1$	$C/2 - 1$
$C/2 + 1$	$-(C/2 + 1)$
M	M
$C - 2$	-2
$C - 1$	-1
C	0

TABLE 86.10 Mapping of the Explicit Value x_e into RC and DRC Number Representations

x_e	X_i(RC)	X_i(DRC)
0	0	0
1	1	1
2	2	2
M	M	M
$1/2\,r^n - 1$	$1/2\,r^n - 1$	$1/2\,r^n - 1$
$1/2\,r^n$	$-1/2\,r^n$	$-(1/2\,r^n - 1)$
M	M	M
$r^n - 2$	-2	-1
$r^n - 1$	-1	0

$$X_i = \begin{cases} x_e & x_e < C/2 \\ x_e - C & x_e > C/2 \end{cases}$$

The illustration of TC mapping is given in Table 86.9. In this representation positive integers are represented in the *true form*, while negative integers are represented in the *complement form*.

With respect to how the complementation constant C is chosen, we can further distinguish two representations within the TC system. If the complementation constant is chosen to be equal to the range of possible values taken by x_e, $C = r^n$ in a conventional number system where $0 \le x_e \le r^n - 1$, then we have defined the *range complement* (RC) system. If, on the other hand, the complementation constant is chosen to be $C = r^n - 1$, we have defined the *diminished radix complement* (DRC) (also known as the *digit complement* [DC]) number system. Representations of the RC and DRC number representation systems are shown in Table 86.10.

As can be seen from Table 86.10, the RC system provides for one unique representation of zero because the complementation constant $C = r^n$ falls outside the range. There are two representations of zero in the DRC system, $x_e = 0$ and $r^n - 1$. The RC representation is not symmetrical, and it is not a closed system under the change of sign operation. The range for RC is $[-1/2\,r^n, 1/2\,r^n - 1]$. The DC is symmetrical and has the range of $[-(1/2\,r^n - 1), 1/2\,r^n - 1]$.

For the radix $r = 2$, RC and DRC number representations are commonly known as *two's complement* and *one's complement* number representation systems, respectively. Those two representations are illustrated by an example in Table 86.11 for the range of values $-(4 \le X_i \le 3)$.

Algorithms for Basic Arithmetic Operations

The algorithms for the arithmetic operation are dependent on the number representation system used. Therefore, their implementation should be examined for each number representation system separately, given that the complexity of the algorithm, as well as its hardware implementation, is dependent on it.

Addition and Subtraction in Sign and Magnitude System

In the *SM number system* addition/subtraction is performed on pairs (u_s, u_m) and (w_s, w_m) resulting in a sum (s_s, s_m), where u_s and w_s are sign bits and u_m and w_m are magnitudes. The algorithm is relatively complex because it requires comparisons of the signs and magnitudes as well. Extending the addition algorithm in order to perform subtraction is relatively easy because it only involves change of the sign of the operand being subtracted. Therefore, we will consider only the addition algorithm.

The algorithm can be described as

if $u_s = w_s$ (signs are equal) **then**
$s_s = u_s$ and $s_m = u_m + w_m$ (operation includes checking for the overflow)

TABLE 86.11 Two's Complement and One's Complement Representation

	Two's Complement, $C = 8$		One's Complement, $C = 7$	
X_i	x_e	X_i (2's complement)	x_e	X_i (1's complement)
3	3	011	3	011
2	2	010	2	010
1	1	001	1	001
0	0	000	0	000
–0	0	000	7	111
–1	7	111	6	110
–2	6	110	5	101
–3	5	101	4	100
–4	4	100	3	—

if $u_s \neq w_s$ **then**
  if $u_m > w_m$: $s_m = u_m - w_m$ $s_s = u_s$
  else: $s_m = w_m - u_m$ $s_s = w_s$

Addition and Subtraction in True and Complement System

Addition in the *TC system* is relatively simple. It is sufficient to perform modulo addition of the explicit values; therefore,

$$s_e = (u_e + w_e) \bmod C$$

Proof will be omitted.

In the *RC number system* this is equivalent to passing the operands through an adder and discarding the carry-out of the most significant position of the adder which is equivalent to performing the modulo addition (given that $C = r^n$).

In the *DRC number system* the complementation constant is $C = r^n - 1$. Modulo addition in this case is performed by subtracting r^n and adding 1. It turns out that this operation can be performed by simply passing the operands through an adder and feeding the carry-out from the most significant digit position into the carry-in at the least significant digit position. This is also called addition with *end-around carry.*

Subtracting two numbers is performed by simply changing the sign of the operand to be subtracted preceding the addition operation.

Change of Sign Operation. The change of sign operation involves the following operation:

$$W_i = -Z_i$$
$$w_e = (-z_e) = (-z_e) \bmod C = C - Z_i \bmod C = C - z_e$$

which means that the change of sign operation consists of subtracting the operand z_e from the complementation constant C.

In the *DRC system* complementation is performed by simply complementing each digit of the operand Z_i with respect to $r - 1$. In the case of $r = 2$, this results in a simple inversion of bits.

In the *RC system* the complementation is performed by complementing each digit of the operand Z_i with respect to $r - 1$ and adding 1 to the resulting z_e.

Implementation of Addition

Carry Look-Ahead Adder (CLA)

The first significant speed improvement in the implementation of a parallel adder was a carry-look-ahead adder (CLA) developed by Weinberger and Smith [1958] in 1958. The CLA is one of the fastest schemes used for the addition of two numbers even today given that the delay incurred to add two numbers is logarithmically

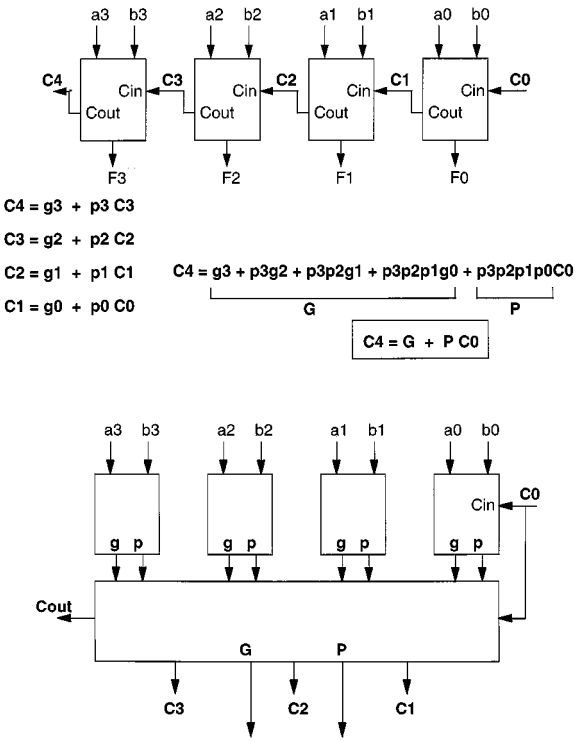

FIGURE 86.2 Carry Look-Ahead adder structure. (a) Generation of carry generate and propagate signals and (b) generation of group signals G, P and intermediate carries.

dependent on the size of the operands (delay = log[N]). The concept of CLA is illustrated in Fig. 86.2a and b. For each bit position of the adder, a pair of signals (p_i, g_i) is generated in parallel. It is possible to generate local carries using (p_i, g_i) as seen in the equations. Those signals are designated as: p_i = carry-propagate and g_i = carry-generate because they take part in propagation and generation of carry signal C_{i-1}. However, each bit position requires an incoming carry signal C_{i-1} in order to generate the outgoing carry C_i. This makes the addition slow because the carry signal has to ripple from stage to stage as shown in Fig. 86.2a. The adder can be divided into the groups and the carry-generate and carry-propagate signals can be calculated for the entire group (G,P). This will take an additional time equivalent to and AND-OR delay of the logic. However, now we can calculate each group's carry signals in an additional AND-OR delay. for the generation of the carry signal from the adder only the incoming carry signal into the group is now required. Therefore, the rippling of the carry is limited only to the groups. In the next step we may calculate generate and propagate signals for the group of groups (G*, P*) and continue in that fashion until we have only one group left generating the C_{out} signal from the adder. This process will terminate in log number of steps given that we are generating a tree structure for generation of carries. The computation of carries within the groups is done individually as illustrated in Fig. 86.2a and this process requires only the incoming carry into the group.

The logarithmic dependence on the delay (delay = log[N]) is only valid under the assumption that the gate delay is constant without depending on the fan-out and fan-in of the gate. In practice this is not true and even when the bipolar technology (which does not exhibit strong dependence on the fan-out) is used to implement CLA structure, the further expansion of the carry-block is not possible given the practical limitations on the fan-in of the gate.

In CMOS technology this situation is much different given that CMOS gate has strong dependency not only on fan-in but on fan-out as well. This limitation takes away much of the advantages gained by using the CLA scheme. However, by clever optimization of the critical path and appropriate use of dynamic logic the CLA scheme can still be advantageous, especially for the adders of a larger size.

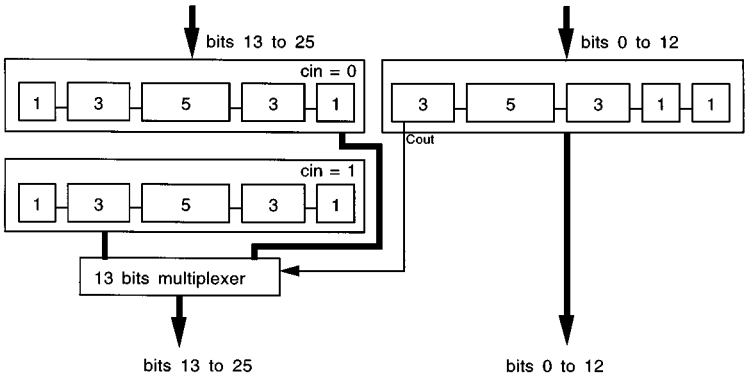

FIGURE 86.3 26-bit carry-select adder.

Conditional-Sum Addition

Another one of the fast schemes for addition of two numbers that predates CLA is conditional-sum addition (CSA) proposed by Sklansky [1960] in 1960. The essence of the CSA scheme is the realization that we can add two numbers without waiting for the carry signal to be available. Simply, the number were added in two instances: one assuming $C_{in} = 0$ and the other assuming $C_{in} = 1$. The results: Sum_0, Sum_1 and $Carry_0$, $Carry_1$ are presented at the input of a multiplexer. The final values are being selected at the time C_{in} arrives at the "select" input of a multiplexer. As in CLA the input bits are divided into groups which are added "conditionally".

It is apparent that starting from the least significant bit (LSB) position the hardware complexity starts to grow rapidly. Therefore, in practice, the full-blown implementation of the CSA is not often seen.

However, the idea of adding the most significant bit (MSB) portion conditionally and selecting the results once the carry-in signal is computed in the LSB portion is attractive. Such a scheme (which is a subset of CSA) is known as "carry-select adder". A 26-b carry-select adder consisting of two 13-bit portions is shown in Fig. 86.3.

Multiplication Algorithm

The multiplication operation is performed in a variety of forms in hardware and software. In the beginning of computer development any complex operation was usually programmed in software or coded in the microcode of the machine. Some limited hardware assistance was provided. Today it is more likely to find full hardware implementation of the multiplication for reasons of speed and reduced cost of hardware. However, in all of them, multiplication shares the basic algorithm with some adaptations and modifications to the particular implementation and number system used. For simplicity we will describe a basic multiplication algorithm that operates on positive n-bit-long integers X and Y resulting in the product P, which is $2n$ bits long:

$$P = XY = X \times \sum_{i=0}^{n-1} y_i r^i = \sum_{i=0}^{n-1} X \times y_i r^i$$

This expression indicates that the multiplication process is performed by summing n terms of a *partial product*: $X \times y_i r^i$. This product indicates that the ith term is obtained by a simple arithmetic left shift of X for the i positions and multiplication by the single digit y_i. For the binary radix $r = 2$, y_i is 0 or 1 and multiplication by the digit y_i is very simple to perform. The addition of n terms can be performed at once, by passing the partial products through a network of adders (which is the case of full hardware multiplier), or sequentially, by passing the *partial product* through an adder n times. The algorithm to perform multiplication of X and Y can be described as [Ercegovac, 1985]

$$p^{(0)} = 0$$
$$p^{j+1} = 1/r(p^j + r^n X y_j) \qquad \text{for } j = 0, \ldots, n-1$$

It can be easily proved that this recurrence results in $p^{(n)} = XY$.

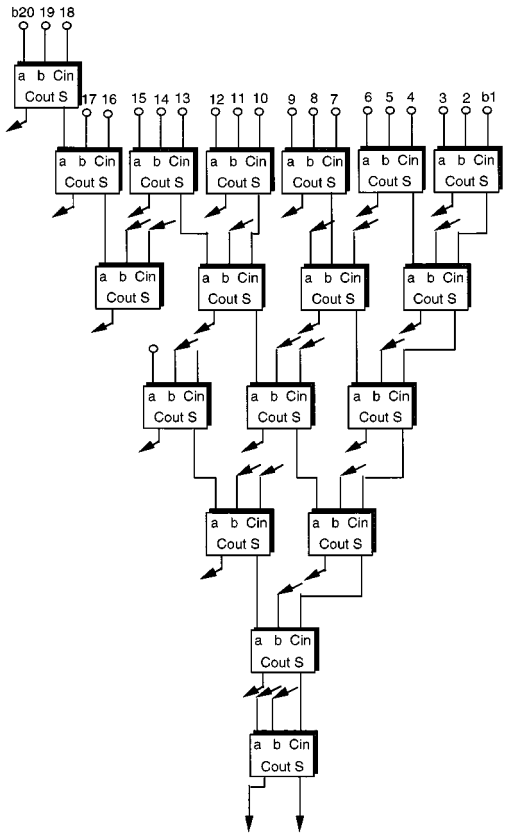

FIGURE 86.4 Wallace Tree.

Various modifications of the multiplication algorithm exist; one of the most famous is the *modified Booth recoding algorithm* described by Booth in 1951. This algorithm allows for the reduction of the number of partial products, thus speeding up the multiplication process. Generally speaking, the Booth algorithm is a case of using the redundant number system with the radix higher than 2.

Implementation of the Multiplication Algorithm

Speed of multiply operation is of utmost importance in digital signal processors (DSP) today as well as in the general purpose processors. Therefore, research in building a fast parallel multiplier has been going on since such a paper was published by Wallace [1964] in 1964. In his historic paper, Wallace introduced a way of summing the partial product bits in parallel using a tree of carry-save adders which became generally known as the "Wallace Tree" (Fig. 86.4).

A suggestion for speed improvement of such a process of adding partial product bits in parallel followed in the paper published by Dadda [1965]. In his 1965 paper, Dadda introduced a notion of a counter structure that will take a number of bits p in the same bit position (of the same "weight") and output a number q that represents the count of ones in the input. Dadda has introduced a number of ways to compress the partial product bits using such a counter, which later became known as Dadda's counter.

The quest for making the parallel multiplier even faster continued for almost 30 years. The search for producing a fastest "counter" did not result in a general structure that yielded a faster partial product summation than that which used a full-adder (FA) cell, or 3:2 counter. Therefore, the use of the Wallace Tree was almost prevalent in the implementation of the parallel multipliers. In 1981, Weinberger disclosed a structure he called "4-2 carry-save module". This structure contained a combination of FA cells in an intricate interconnection structure that was yielding faster partial product compression than the use of 3:2 counters.

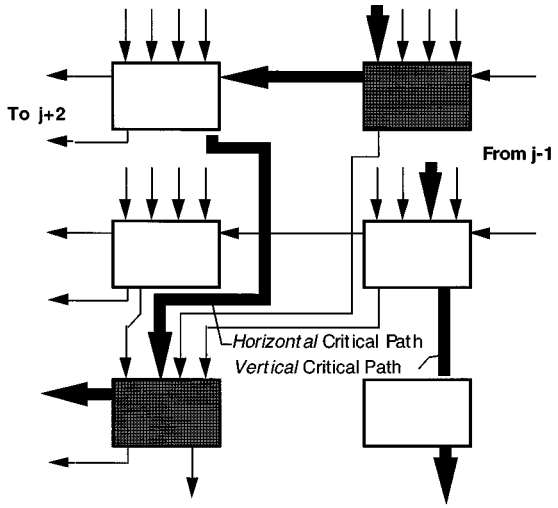

FIGURE 86.5 4:2 compressor.

The 4:2 compressor (Fig. 86.5) actually compresses five partial product bits into three; however, it is connected in such a way that four of the inputs are coming from the same bit position of the weight *j* while one bit is fed from the neighboring position *j*-1 (known as carry-in). The output of such a 4-2 module consists of one bit in the position *j* and two bits in the position *j*+1. This structure does not represent a counter (though it became erroneously known as a "4-2 counter") but a "compressor" which would compress four partial product bits into two (while using one bit laterally connected between adjacent 4-2 compressors). The efficiency of such a structure is higher (it reduces the number of partial product bits by one half). The speed of such a 4-2 compressor has been determined by the speed of 3 XOR gates in series (in the redesigned version of 4-2 compressor) making such a scheme more efficient that the one using 3:2 counters in a regular Wallace Tree. The other equally important feature of the use of a 4-2 compressor is that the interconnections between such cells follow more regular patterns than in the case of the Wallace Tree.

Booth Encoding

Booth's algorithm [Booth, 1951] is widely used in the implementations of hardware or software multipliers because its application makes it possible to reduce the number of partial products. It can be used for both sign-magnitude numbers as well as 2's complement numbers with no need for a correction term or a correction step.

A modification of the Booth algorithm was proposed by MacSorley [1961] in which a triplet of bits is scanned instead of two bits. This technique has the advantage of reducing the number of partial products by one half regardless of the inputs. This is summarized in Table 86.12.

TABLE 86.12 Modified Booth Recoding

$x_{i+2}x_{i+1}x_i$	Add to Partial Product
000	+0Y
001	+1Y
010	+1Y
011	+2Y
100	–2Y
101	–1Y
110	–1Y
111	–0Y

The recoding is performed within two steps: encoding and selection. The purpose of the encoding is to scan the triplet of bits of the multiplier and define the operation to be performed on the multiplicand, as shown in Table 86.8. This method is actually an application of a sign-digit representation in radix 4. The Booth-MacSorley algorithm, usually called the Modified Booth algorithm or simply the Booth algorithm, can be generalized to any radix.

Booth recoding necessitates the internal use of 2's complement representation in order to efficiently perform subtraction of the partial products as well as additions. However, floating point standard specifies sign magnitude representation which is followed by most of the non-standard floating point numbers in use today. The advantage of Booth recoding is that it generates only a half of the partial products as compared to the multiplier implementation which does not use Booth recoding. However, the benefit achieved comes at the expense of

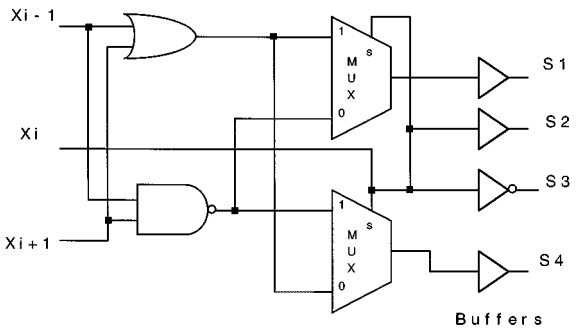

FIGURE 86.6 Booth encoder.

increased hardware complexity. Indeed, this implementation requires hardware for the encoding and for the selection of the partial products (0, ±Y, ±2Y). An optimized encoding is shown in Fig. 86.6.

Division Algorithm

Division is a more complex process to implement because, unlike multiplication, it involves *guessing* the digits of the quotient. Here, we will consider an algorithm for division of two positive integers designated as *dividend* Y and *divisor* X resulting in a *quotient* Q and an integer *remainder* Z according to the relation given by

$$Y = XQ + Z$$

In this case the dividend contains $2n$ integers and the divisor has n digits in order to produce a quotient with n digits.

The algorithm for division is given with the following recurrence relationship [Ercegovac, 1985]:

$$z^{(0)} = Y$$
$$z^{(j+1)} = rz^{(j)} - Xr^{n}Q_{n-1-j} \qquad \text{for } j = 0, \ldots, n-1$$

this recurrence relation yields

$$z^{(n)} = r^{n}(Y - XQ)$$
$$Y = XQ + z^{(n)}r^{-n}$$

which defines the division process with remainder $Z = z^{(n)}r^{-n}$.

The selection of the quotient digit is done by satisfying that $0 \le Z < X$ at each step in the division process. This selection is a crucial part of the algorithm, and the best known are *restoring* and *nonrestoring* division algorithms. In the former the value of the *tentative partial remainder* $z^{(j)}$ is restored after the wrong guess is made of the quotient digit q_j. In the latter this correction is not done in a separate step, but rather in the step following. The best-known division algorithm is the so-called SRT algorithm independently developed by Sweeney, Robertson, and Tocher. Algorithms for a higher radix were further developed by Robertson and his students, most notably Ercegovac.

Defining Terms

4:2 Compressor: A structure used in the partial product reduction tree of a parallel multiplier for achieving faster and more efficient reduction of the partial product bits.

Algorithm: Decomposition of the computation into subcomputations with an associated precedence relation that determines the order in which these subcomputations are performed [Ercegovac, 1985].

Booth-MacSorley algorithm: An algorithm used for recoding of the multiplier such that the number of partial products is roughly reduced by a factor of two. It is a special case of the application of the redundant number system to represent the multiplier.

Carry look-ahead adder: An implementation technique of addition that accelerates the propagation of the carry signal, thus increasing the speed of addition operation.

Dadda's counter: A generalized structure used to produce a number (count) representing the number of bits that are "one". It is used for efficient reduction of the partial products in a parallel multiplier.

Explicit value x_e: A value associated with the bit string according to the rule defined by the number representation system being used.

Implicit value X_i: The value obtained by applying the arithmetic function defined for the interpretation of the explicit value x_e.

Nonredundant number system: The system where for each bit string there is one and only one corresponding numerical value x_e.

Number representation system: A defined rule that associates one numerical value x_e with every *valid* bit string x.

Redundant number system: The system in which the numerical value x_e could be represented by more than one bit string.

SRT algorithm: An algorithm for division of binary numbers which uses redundant number representation.

Wallace tree: A technique for summing the partial product bits of a parallel multiplier in a carry-save fashion using full-adder cells.

86.3 Architecture[1]

V. Carl Hamacher, Zvonko G. Vranesic, and Safwat G. Zaky

Computer architecture can be defined here to mean the functional operation of the individual hardware units in a computer system and the flow of information and control among them. This is a somewhat more general definition than is sometimes used. For example, some articles and books refer to instruction set architecture or the system bus architecture.

The main functional units of a single-processor system, a basic way to interconnect them, and features that are used to increase the speed with which the computer executes programs will be described. Following this, a brief introduction to systems that have more than one processor will be provided.

Functional Units

A digital computer, or simply a computer, accepts digitized input information, processes it according to a list of internally stored *machine instructions,* and produces the resultant output information. The list of instructions is called a *program*, and internal storage is called *computer memory.*

A computer has five functionally independent main parts: input, memory, arithmetic and logic, output, and control. The input unit accepts digitally encoded information from human operators, through electromechanical devices such as a keyboard, or from other computers over digital communication lines. The information received is usually stored in the memory and then operated on by the arithmetic and logic unit circuitry under the control of a program. Results are sent back to the outside world through the output unit. All these actions are coordinated by the control unit. The arithmetic and logic unit, in conjunction with the main control unit, are referred to as the **processor.**

Input and output equipment is usually combined under the term **input-output unit** (*I/O unit*). This is reasonable because some standard equipment provides both input and output functions. The simplest example of this is the video terminal consisting of a keyboard for input and a cathode-ray tube for output. The control circuits of the computer recognize two distinct devices, even though the human operator may associate them as being part of the same physical unit.

The **memory unit** stores programs and data. There are two main classes of memory devices called *primary* and *secondary* memory. Primary storage, or main memory, is an electronic storage device, constructed from integrated circuits that consist of millions of semiconductor storage cells, each capable of storing one bit of information. These cells are accessed in groups of fixed size called *words.* The main memory is organized so that the contents of one word can be stored or retrieved in one basic operation called a *memory cycle.*

To provide direct access to any word in the main memory in a short and fixed amount of time, a distinct address number is associated with each word location. A given word is accessed by specifying its address and issuing a control command that starts the storage or retrieval process. The number of bits in a word is called the *word length* of the computer. Word lengths vary from 16 to 64 bits. Small machines such as personal computers or workstations, may have only a few million words in the main memory, while larger machines have tens of millions of words. The time required to access a word for reading or writing is less than 100 ns.

Although primary memory is essential, it tends to be expensive and volatile. Thus cheaper, more permanent, magnetic media secondary storage is used for files of information that contain programs and data. A wide selection of suitable devices is available, including magnetic disks, drums, diskettes, and tapes.

Execution of most operations within a computer takes place in the **arithmetic and logic unit** (ALU) of a processor. Consider a typical example. Suppose that two numbers located in the main memory are to be added, and the sum is to be stored back into the memory. Using a few instructions, each consisting of a few basic steps, determined by the **control unit**, the operands are first fetched from the memory into the processor. They are then added in the ALU, and the result is stored back in memory. Processors contain a number of high-speed storage elements called *registers,* which are used for temporary storage of operands. Each register contains one

The First Digital Computers

Of all the new technologies to emerge from World War II, none was to have such profound and pervasive impacts as the digital computer. As early as the 1830s, the Englishman Charles Babbage conceived of an "Analytical Engine" that would perform mathematical operations using punched cards, hundreds of gears, and steam power. Babbage's idea was beyond the capabilities of 19th-century technology, but his vision represented a goal that many were to pursue in the next century and a half.

In the mid-1920s, MIT electrical engineer Vannevar Bush devised the "product integraph", a semi-automatic machine for solving problems in determining the characteristics of complex electrical systems. This was followed a few years later by the "differential analyzer", the first general equation-solving machine. These machines were mechanical, analog devices, but at the same time that they were being built and copied, the principles of electrical, digital machines were being laid out.

In 1937, Claude Shannon published in the *Transactions* of the AIEE the circuit principles for an "electric adder to the base of two", and George Stibitz of Bell Labs built such an adding device on his own kitchen table. In that same year, Howard Aiken, then a student at Harvard, proposed a gigantic calculating machine that could be used for everything from vacuum tube design to problems in relativistic physics. With support from Thomas J. Watson, president of IBM, Aiken was able to build his machine, the "Automatic Sequence Controlled Calculator", or "Mark I". When it was finished in 1944, the Mark I was quickly pressed into war service, calculating ballistics problems for the Navy.

In 1943, the government contracted with John W. Mauchly and J. Presper Eckert of the University of Pennsylvania to build the "Electronic Numerical Integrator and Computer"—the first true electronic digital computer. When the ENIAC was finally dedicated in February 1946, it was both a marvel and a monster—weighing 30 tons, consuming 150 kW of power, and using 18,000 vacuum tubes. With all of this, it could perform 5,000 additions or 400 multiplications per second, which was about one thousand

word of data and its access time is about 10 times faster than main memory access time. Large-scale micro-electronic fabrication techniques allow whole processors to be implemented on a single semiconductor chip containing a few million transistors.

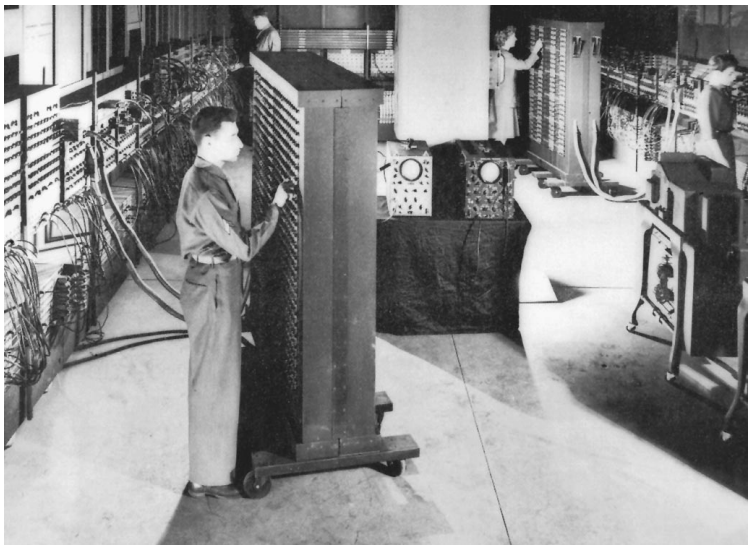
Basic Operational Concepts

To perform a given computational task, an appropriate program consisting of a set of machine instructions is stored in the main memory. Individual instructions are brought from the memory into the processor for execution. Data used as operands are also stored in the memory. A typical instruction may be

MOVE MEMLOC, Ri

This instruction loads a copy of the operand at memory location MEMLOC into the processor register Ri. The instruction requires a few basic steps to be performed. First, the instruction must be transferred from the memory into the processor, where it is decoded. Then the operand at location MEMLOC must be fetched into the processor. Finally, the operand is placed into register R1. After operands are loaded into the processor registers in this way, instructions such as ADD Ri, Rj, Rk can be used to add the contents of registers Ri and Rj, and then place the result into register Rk.

Instruction set design has been intensively studied in recent years to determine the effectiveness of the various alternatives. See Patterson and Hennessey [1994] for a thorough discussion.



The ENIAC, pictured above, was the first true electronic digital computer. Early programmers set up problems by plugging in cables and setting switches. ENIAC could perform calculations about one thousand times faster than any other machine of its day. (Photo courtesy of the IEEE Center for the History of Electrical Engineering.)

times faster than any other machine of the day. The ENIAC showed the immense possibilities of digital electronic computers.

These possibilities occupied engineers and mathematicians for the coming decades. For electrical engineers, the computer represented a challenge and responsibility for the most powerful new machine of the twentieth century. (Courtesy of the IEEE Center for the History of Electrical Engineering.)

The connection between the main memory and the processor that allows for the transfer of instructions and operands is called the **bus**, as shown in Fig. 86.7. A bus consists of a set of address, data, and control lines. The bus also allows program and data files to be transferred from their long-term location on magnetic disk storage to the main memory. Long distance digital communication with other computers is also enabled by transfers over the bus to the Communication Line Interface, as shown in the figure. The bus interconnects a number of devices, but only two devices (a sender and a receiver) can use it at any one time. Therefore, some control circuitry is needed to manage the orderly use of the bus when a number of devices wish to use it.

Normal execution of programs may sometimes be preempted if some I/O device requires urgent control action or servicing. For example, a monitoring device in a computer-controlled industrial process may detect a dangerous condition that requires the execution of a special service program dedicated to the device. To cause this service program to be executed, the device sends an *interrupt* signal to the processor. The processor temporarily suspends the program that is being executed and executes the special *interrupt service routine.* After providing the required service, the processor switches back to the interrupted program. To appreciate the complexity of the computer system software programs needed to control such switching from one program task to another and to manage the general movement of programs and data between primary and secondary storage, consult Tanenbaum [1990].

The need often arises during program loading and execution to transfer blocks of data between the main memory and a disk or other secondary storage I/O devices. Special control circuits are provided to manage these transfers without detailed control actions from the main processor. Such transfers are referred to as *direct memory access* (DMA). Assuming that accesses to the main memory from both I/O devices (such as disks) and

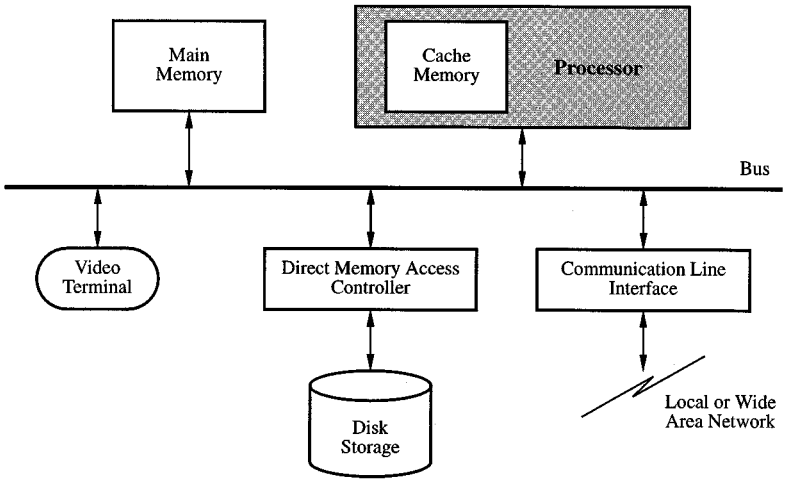


FIGURE 86.7 Interconnection of major components in a computer system.

the main processor can be appropriately interwoven over the bus, I/O-memory transfers and computation in the main processor can proceed in parallel, and performance of the overall system is improved.

Performance

A major performance measure for computer systems is the time, T, that it takes to execute a complete program for some task. Suppose N machine instructions need to be executed to perform the task. A program is typically written in some high-level language, translated by a compiler program into machine language, and stored on a disk. An operating system software routine then loads the machine language program into the main memory, ready for execution. Assume that, on average, each machine language instruction requires S basic steps for its execution. If basic steps are executed at the rate of R steps per second, then the time to execute the program is

$$T = (N \times S)/R$$

The main goal in computer architecture is to develop features that minimize T.

We will now give an outline of main memory and processor design features that help to achieve this goal. The first concept is that of a **memory hierarchy**. We have already noted that access to operands in processor registers is significantly faster than access to the main memory. Suppose that when instructions and data are first loaded into the processor, they are stored in a small, fast, **cache memory** on the processor chip itself. If instructions and data in the cache are accessed repeatedly within a short period of time, as happens often with program loops, then program execution will be speeded up. The cache can only hold small parts of the executing program. When the cache is full, its contents are replaced by new instructions and data as they are fetched from the main memory. A variety of *cache replacement algorithms* are in use. The objective of these algorithms is to maximize the probability that the instructions and data needed for program execution are found in the cache. This probability is known as the cache *hit ratio*. A higher hit ratio means that a larger percentage of the instructions and data are being found in the cache, and do not require access to the slower main memory. This leads to a reduction in the memory access basic step time components of S, and hence to a smaller value of T.

The basic idea of a cache can be applied at different points in a computer system, resulting in a hierarchy of storage units. A typical memory hierarchy is shown in Fig. 86.8. Some systems have two levels of cache to take the best advantage of size/speed/cost tradeoffs. The main memory is usually not large enough to contain all of the programs and their data. Therefore, the highest level in the memory hierarchy is usually magnetic disk storage. As the figure indicates, it has the largest capacity, but the slowest access time. Segments of a program, often called *pages*, are transferred from the disk to the main memory for execution. As other pages are needed, they may replace the pages already in the main memory if the main memory is full. The orderly,

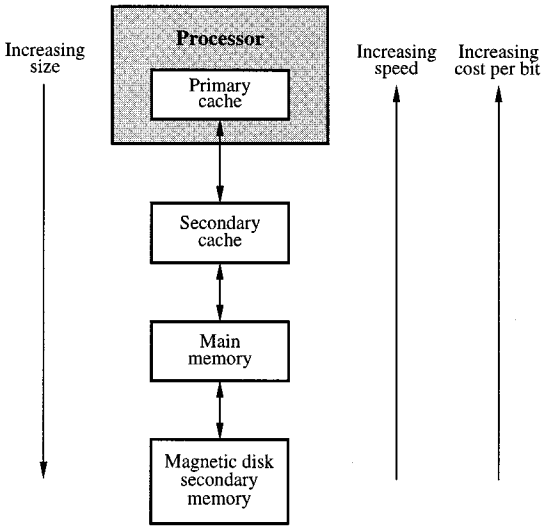

FIGURE 86.8 Memory hierarchy.

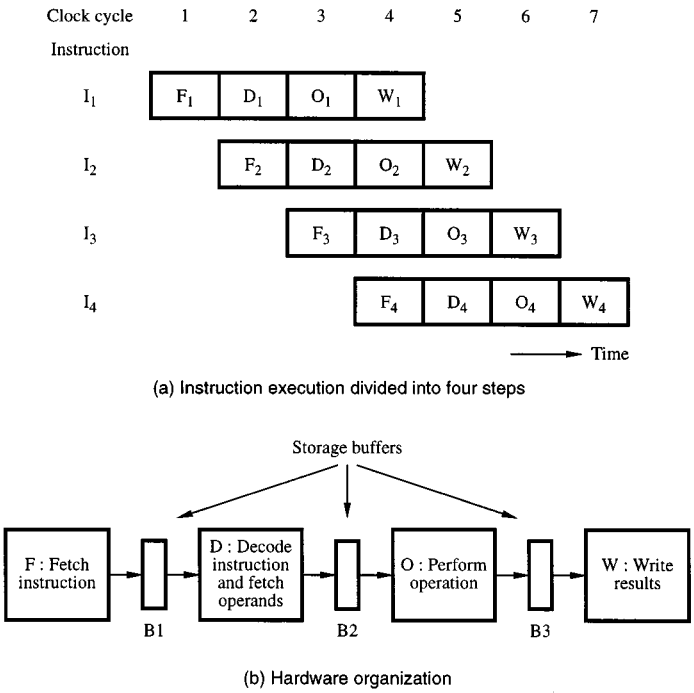

FIGURE 86.9 Pipelining of instruction execution.

automatic movement of large program and data segments between the main memory and the disk, as programs execute, is managed by a combination of operating system software and control hardware. This is referred to as **memory management**.

We have implicitly assumed that instructions are executed one after another. Most modern processors are designed to allow the execution of successive instructions to overlap, using a technique known as **pipelining**. In the example in Fig. 86.9, each instruction is broken down into 4 basic steps—fetch, decode, operate, and write—and a separate hardware unit is provided to perform each of these steps. As a result, the execution of

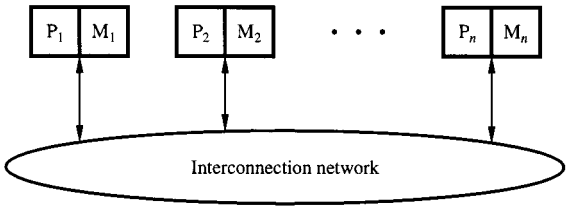

FIGURE 86.10 A multiprocessor system.

successive instructions can be overlapped as shown, resulting in an instruction completion rate of one per basic time step. If the execution overlap pattern shown in the figure can be maintained for long periods of time, the effective value of S tends toward 1.

When the execution of some instruction I depends on the results of a previous instruction, J, which is not yet completed, instruction I must be delayed. The pipeline is said to be *stalled,* waiting for the execution of instruction J to be completed. While it is not possible to eliminate such situations altogether, it is important to minimize the probability of their occurrence. This is a key consideration in the design of the instruction set of modern processors and the design of the compilers that translate high-level language programs into machine language.

Now, imagine that multiple functional units are provided in the processor so that more than one instruction can be in the operate stage. This *parallel* execution capability, when added to pipelining of the individual instructions, means that execution rates of more than one instruction completion per basic step time can be achieved. This mode of enhanced processor performance is called **superscalar processing**.

The rate, R, of performing basic steps in the processor is usually referred to as the processor clock rate; and it is of the order of 100 to 200 million steps per second in current high-performance VLSI processors. This rate is determined by the technology used in fabricating the processors, and is strongly related to the size or area occupied by individual transistors. This size feature, which is currently in the submicron range, has been steadily decreasing as fabrication techniques improve, allowing increases in R to be achieved.

Multiprocessors

Physical limits on electronic speeds prevent single processors from being speeded up indefinitely. A major design trend has seen the development of systems that consist of a large number of processors. Such multiprocessors can be used to speed up the execution of large programs by executing subtasks in parallel. The main difficulty in achieving this type of speedup is in being able to decompose a given task into its parallel subtasks and assign these subtasks to the individual processors in such a way that communication among the subtasks can be done efficiently. Fig. 86.10 shows a block diagram of a multiprocessor system, with the interconnection network needed for data sharing among the processors Pi. Parallel paths are needed in this network in order for parallel activity to proceed in the processors as they access the global memory space represented by the multiple memory units Mi.

Defining Terms

Arithmetic and logic unit: The logic gates and register storage elements used to perform the basic operations of addition, subtraction, multiplication, and division of numeric operands, and the comparison, shifting, and alignment operations on more general forms of numeric and nonnumeric data.

Bus: The collection of data, address, and control lines that enables exchange of information, usually in word-size quantities, among the various computer system units. In practice, a large number of units can be connected to a single bus. These units contend in an orderly way for the use of the bus for individual transfers.

Cache memory: A high-speed memory for temporary storage of copies of the sections of program and data from the main memory that are currently active during program execution.

Computer architecture: The functional operation of the individual hardware units in a computer system and the flow of information and control among them.

Control unit: The circuits required for sequencing the basic steps needed to execute machine instructions.

Input-output unit (I/O): The equipment and controls necessary for a computer to interact with a human operator, to access mass storage devices such as disks and tapes, or to communicate with other computer systems over communication networks.

Memory hierarchy: The collection of cache, primary, and secondary memory units that comprise the total storage capability in the computer system.

Memory management: The combination of operating system software and hardware controls that is needed to access and move program and data segments up and down the memory hierarchy during program execution.

Memory unit: The unit responsible for storing programs and data. There are two main types of units: primary memory, consisting of millions of bit storage cells fabricated from electronic semiconductor integrated circuits, used to hold programs and data during program execution; and secondary memory, based on magnetic disks, diskettes, and tapes, used to store permanent copies of programs and data.

Multiprocessor: a computer system comprising multiple processors and main memory unit modules, connected by a network that allows parallel activity to proceed efficiently among these units in executing program tasks that have been sectioned into subtasks and assigned to the processors.

Pipelining: The overlapped execution of the multiple steps of successive instructions of a machine language program, leading to a higher rate of instruction completion than can be attained by executing instructions strictly one after another.

Processor: The arithmetic and logic unit combined with the control unit needed to sequence the execution of instructions. Some cache memory is also included in the processor.

Superscalar processing: The ability to execute instructions at a completion rate that is faster than the normal pipelined rate, by providing multiple functional units in the pipeline to allow a small number of instructions to proceed through the pipeline process in parallel.

86.4 Microprogramming

Jacques Raymond

Since the 1950s when Wilkes et. al. [1958] defined the term and the concept, microprogramming has been used as a clean and systematic way to define the instruction set of a computer. It has also been used to define a virtual architecture out of a real hardwired one.

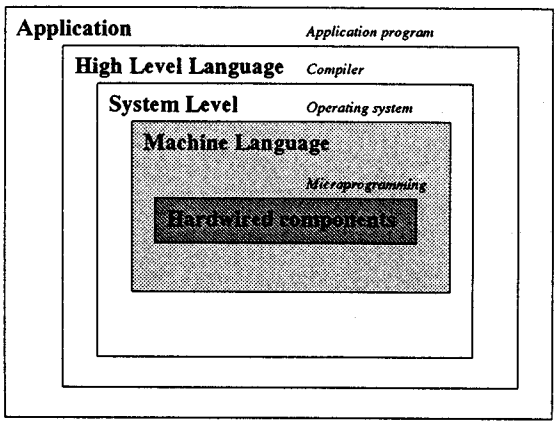

FIGURE 86.11 Levels of programming in a computer system.

Levels of Programming

In Fig. 86.12, we see that a computer application is usually realized by programming a given algorithm in a high-level language. A system offering a high-level language capability is implemented at the system level via a compiler. The operating system is (usually) implemented in a lower-level language. The machine instruction set can be hardwired (in a hardware implementation) or implemented via microprogramming (Fig. 86.11).

Therefore, microprogramming is simply an extra level in the general structure. Since it is used to define the machine instruction set, it can be considered at the *hardware* level. Since this definition is done via a program at a low level, but still eventually modifiable, it can also be considered to be at the *software* level. For these reasons, the term **firmware** has been coined to name sets of microprograms. In short, **microinstructions** that specify hardware functions (*microoperations* such as Open a path, Select operation) are used to form a more complex instruction (Convert to binary, Add decimal). The machine instruction set is defined via a set of microprogram routines and a microprogrammed instruction decoder.

In a microprogrammed machine, the hardware is designed in terms of its capabilities (ALU, data paths, I/O, processing units) with little concern for how these capabilities will have to be accessed by the programmers. The microoperations are decoded from microinstructions. The way programmers *view* the machine is defined at the microprogramming level.

This approach offers some differences over the hardwired approach. The advantages are that it is more systematic in implementation, modifiable, economical on most designs, and easier to debug. The disadvantages are that it is uneconomical on simple machines, slower, and needs support software. Like all programs, microprograms reside in memory. The term "control memory" is commonly used for microprograms.

Microinstruction Structure

On a given hardware, many processing functions are available. In general a subset *O* of these functions can be performed in parallel, for example, carrying on an addition between two registers while copying a register on an I/O bus. These functions are called **microcommands.**

Horizontal Microinstructions

Each of the fields **f** of a microinstruction specifies a microcommand. If the format of the microinstruction is such that all possible microcommands can be specified, the instruction is called *horizontal*. Most of the time, it is wasteful in memory as, in a microprogram, not every possible microcommand is specified in each microinstruction. However, it permits the microprogrammer to fully take advantage of all possible parallelisms and to build faster machines.

For example, the horizontal specification of an ALU operation,

ALUOperation	SourcePathA	SourcePathB	ResultPath	CvtDecimal

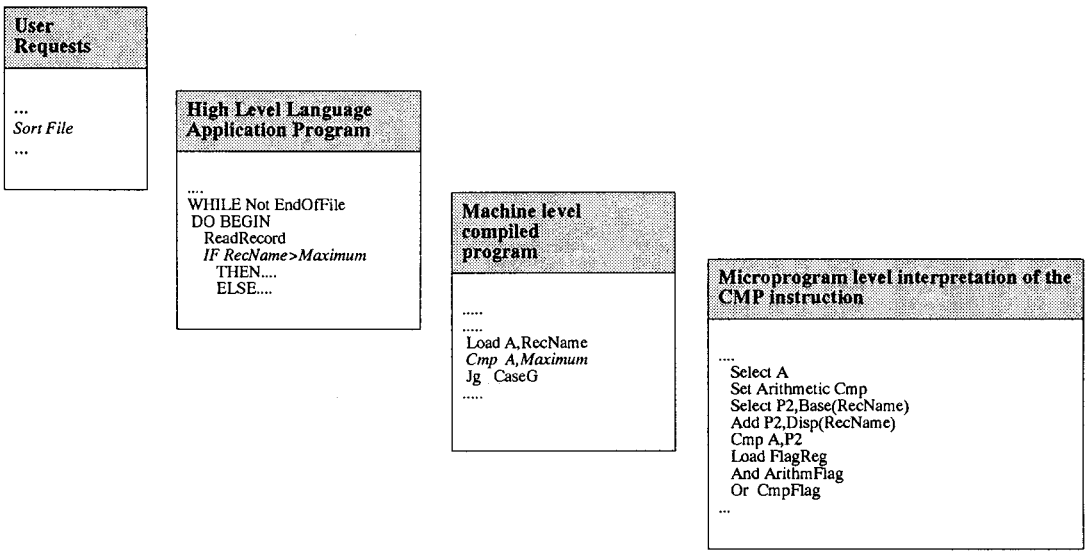

FIGURE 86.12 A view of computer system levels.

specifies both operands, which register will contain the result, whether or not the result is to be converted to decimal, and the operation to be performed. If this instruction is, for example, part of a microprogram defining a 32-bit addition instruction, assuming a 16-bit path, it is wasteful to specify twice the source and result operands.

In some cases, it is possible to design a microinstruction that specifies more microcommands than can be executed in parallel. In that case, the execution of the microcommand is carried out in more than one clock cycle. For this reason they are called *polyphase* microinstructions (as opposed to *monophase*).

Vertical Microinstructions

At the other extreme, if the microinstruction allows only the specification of a single microcommand at a time, the instruction is then called *vertical*. In that case, only the necessary commands for a particular program are specified, resulting in smaller **control memory** requirements. However, it is not possible to take advantage of possible parallelism offered by the hardware, since only one microcommand is executed at a time. For example, the vertical specification of an ALU operation is as follows:

SourceA	Reg#	1st Operand
SourceB	Reg#	2nd Operand
Result	Reg#	Result
ALU	Op	Operation

Diagonal Microinstructions

Most cases fit in between these two extremes (see Fig. 86.13). Some parallelism is possible; however, microcommands pertaining to a given processing unit are regrouped. This results in shorter microprograms than in the vertical case and may still allow some optimization. For example, a diagonal specification of an ALU operation is as follows:

SelectSources	RegA#	RegB#	Select Operands
SelectResult	Reg#	Dec/Bin	Result place and format
Select ALU Operation			Perform the operation

Optimization

Time and space optimization studies can be performed before designing the microinstruction format. The reader is referred to Das et al. [1973] and Agerwala [1976] for details and more references.

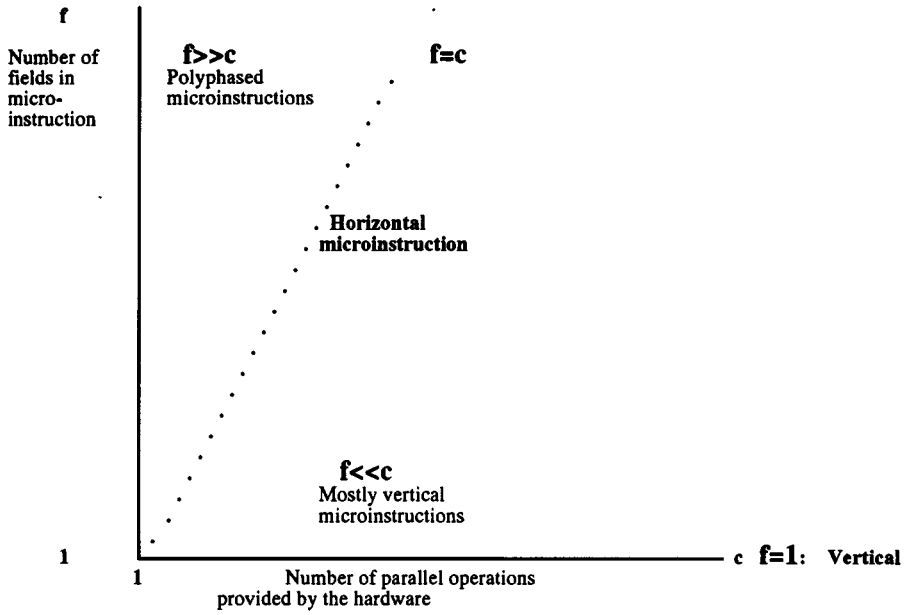

FIGURE 86.13 Microinstruction fields versus microcommands.

Microprogram Development

Microassemblers

The first level of specification of microinstructions is, just like its counterpart at the machine level, the assembler. Although the process and philosophy is exactly the same, it is traditionally called a microassembler. A microassembler is a software program (it is not relevant to know in which language it is written) whose function is to translate a source program into the binary code equivalent. Obviously, to write a source program, a language has to be designed. At assembly level, languages are usually very close to the hardware structure, and the objects defined are microregisters, gate level controls, and paths. Operations are the microoperations (sometimes slightly more sophisticated with a microassembler with macrofacilities).

This level provides an easily readable microprogram and does much to help avoid syntax errors. In binary, only the programmer can catch a faulty 1 or 0; the microassembler can catch syntax errors or some faulty register specifications. No microassembler exists that can catch all logic errors in the implementation of a given instruction algorithm. It is still very easy to make mistakes. It should be noted that this level is a good compromise between convenience and cost.

The following is a typical example of a microprogram in the microassembler (it implements a 16-bit add on an 8-bit path and ALU):

```
CLC   Clear Carry
Lod   A       Get first part of first operand
Add   B       Add to first part of second operand
Sto   C       Give low byte of final result
Lod   a       Get second part of first operand
Adc   b       Add to second part of second operand and to carry bit
Sto   c       Give high byte of final result
JCS   Error   Jump to error routine if Result >65536
Jmp   FetchNext
```

High-Level Languages for Microprogramming

Many higher-level languages have been designed and implemented; see a discussion of some design philosophies in Malik and Lewis [1978]. In principle, a high-level language program is oriented toward the application it supports and is farther away from the hardware-detailed implementation of the machine it runs on. The applications supported are mostly other machine definitions (**emulators**) and implementations of some algorithms.

The objects defined and manipulated by high-level languages for microprogramming are therefore the virtual components of virtual machines. They are usually much the same as their real counterparts: registers, paths, ALUs, microoperations, etc. Furthermore, writing a microprogram is usually defining a machine architecture. It involves a lot of intricate and complicated details, but the algorithms implemented are mostly quite simple. The advantages offered by high-level languages to write better algorithms without getting lost in implementation details are therefore not exploited.

Firmware Implementation

Microprogramming usually requires the regular phases of design, coding, test, conformance acceptance, documentation, etc. It differs from other programming activities when it comes to the deliverable. The usual final product takes the form of hardware, namely, a control memory, PROM, ROM, or other media, containing the bit patterns equivalent to the firmware. These implementation steps require special hardware and software support. They include a linker, loader, PAL programmer, or ROM burner; a test program in a control memory test bench is also necessary.

Supporting Software

It is advisable to test the microprogram before its actual hard implantation, if the implantation process is irreversible or too costly to repeat. Software simulators have been implemented to allow thorough testing of the newly developed microprogram. Needless to say these tools are very specialized to a given environment and therefore costly to develop, as their development cost cannot be distributed over many applications.

Emulation

Concept

In a microprogrammed environment, a computer architecture is softly (or firmly) defined by the microprogram designed to implement its operations, its data paths, and its machine-level instructions. It is easy to see that if one changes the microprogram for another one, then a new computer is defined. In this environment, the desired operation is simulated by the execution of the firmware, instead of being the result of action on real hardwired components.

Since the word *simulation* was already in use for simulation of some system by software, the word *emulation* was chosen to mean simulation of an instruction set by firmware. Of course, "simulation" by hardware is not a simulation but the *real thing*.

The general structure of an emulator consists of the following pseudocode algorithm:

```
BEGIN
Initialize Machine Components
Repeat
Fetch Instruction
Emulate Operation of the current instruction
Process interrupts
Update instruction counter
Until MachineIsOff
Perform shutdown procedure
END
```

Many variations exist, in particular to process interrupts within the emulation of a lengthy operation or to optimize throughput, but the general principle and structure are fairly constant.

Emulation of CPU Operation

One of the advantages of microprogramming is that the designer can implement his or her *dream instructions* simply by emulating its operation. We have seen already the code for a typical 16-bit adder, but it is not difficult to code a parity code generator, a cyclic redundancy check calculator, or an instruction that returns the eigenvalues of an $n \times n$ matrix. This part is straight programming. One consideration is to make sure that the machine is still listening to the outside world (interruptions) or actively monitoring it (I/O flags) in order not to loose asynchronous data while looking for a particular pattern in a 1 megabyte string. Another consideration is to optimize memory usage by combining common processes for different operations. For example, emulating a 32-bit add instruction and emulating a 16-bit add instruction have common parts. This is, however, a programming concern not specific to emulation.

I/O System and Interrupts

Programming support for I/Os and interrupts is more complicated than for straight machine instructions. This is due to the considerable speed differences between I/O devices and a CPU, the need for synchronization, the need for not losing any external event, and the concerns for optimizing processing time. Microprogramming offers considerable design flexibility, as these problems are more easily handled by programming than with hardware components.

Applications of Microprogramming

The main application of microprogramming is the emulation of a virtual machine architecture on a different host hardware machine. It is, however, easy to see that the concept of emulation can be broadened to other functions than the traditional hardware operation.

It is mainly a matter of point of view. Emulation and simulation are essentially the same process but viewed from different levels. Realizing a 64-bit addition and implementing a communication controller are qualitatively the same type of task. Once this is considered, there are theoretically no limits to the uses of microprogramming.

From the programmer's point of view, programming is the activity of producing, in some language, an implementation of some algorithm. If the language is at the very lowest level, as is the case with microprogramming, and at the same time the algorithm is filled with intricate data structures and complex decisions, the task might be enormous, but nothing says it cannot be done (except, maybe, experience). With this perspective of the field, we now look at some existing applications of microprogramming.

Operating System Support

One of the first applications, besides emulation, was to support some operating system functions. Since microprograms are closer to the hardware and programming directly in microcode removes the overhead of decoding machine-level instructions, it was thought that directly coding operating system (OS) functions would improve their performance. Success was achieved in some areas, such as virtual memory. In general, people write most OS functions in assembly language, probably because the cost is not offset by the benefits, especially with rapidly changing OS versions. The problems raised by the human side of programming have changed the question "Should it be in microcode or in assembler?" to the question "Should it be in assembler or in C?" This parallels the CISC/RISC debate.

High-Level Languages Support

Early research was done also in the area of support for high-level languages. Support can be in the form of microprogrammed implementations of some language primitive (for example, the trigonometric functions) or support for the definition and processing of data structures (for example, trees and lists primitives). Many interesting research projects have led to esoteric laboratory machines. More common examples include the translate instructions, string searches and compares, or indexing multidimensional arrays.

Paging, Virtual Memory

An early and typical application of microprogramming is the implementation of the paging algorithm for a virtual memory system. It is a typical application since it is a low-level function that must be time optimized and is highly hardware dependent. Furthermore, the various maintenance functions which are required by the

paging algorithms and the disk I/Os can be done during the idle time of the processing of other functions or during part of that processing in order to avoid I/O delays.

Diagnostics

Diagnostic functions have also been an early application of microprogramming. A firmware implementation is ideally suited to test the various components of a computer system, since the gates, paths, and units can be exercised in an isolated manner, therefore allowing one to precisely pinpoint the trouble area.

Controllers

Real-time controllers benefit from a microprogrammed implementation, due to the speed gained by programming only the required functions, therefore avoiding the overhead of general-purpose instructions. Since the microprogrammer can better make use of the available parallelism in the machine, long processes can still support the asynchronous arrival of data by incorporating the interrupt polling at intervals in these processes.

High-Level Machines

Machines that directly implement the constructs of high-level languages can be easily implemented via microprogramming. For example, Prolog machines and Lisp machines have been tried. It is also possible to conceive an application directly microcoded. Although this could provide a high performance hardware, human errors and software engineering practice seem to make such a machine more of a curiosity than a maintainable system.

Defining Terms

Control memory: A memory containing a set of microinstructions (a microprogram) that defines the instruction set and operations of a CPU.

Emulator: The firmware that simulates a given machine architecture.

Firmware: Meant as an intermediate between software, which can be modified very easily, and hardware, which is practically unchangeable (once built); the word *firmware* was coined to represent the microprogram in control memory, i.e., the modifiable representation of the CPU instruction set.

High-level language for microprogramming: A high-level language more or less oriented toward the description of a machine. Emulators can more easily be written in a high-level language; the source code is compiled into the microinstructions for actual implementation.

Horizontal microinstruction: Theoretically, a completely horizontal microinstruction is made up of all the possible microcommands available in a given CPU. In practice, some encoding is provided to reduce the length of the instruction.

Microcommand: A small bit field indicating if a gate is open or closed, if a function is enabled or not, if a control path is active or not, etc. A microcommand is therefore the specification of some action within the control structure of a CPU.

Microinstruction: The set of microcommands to be executed or not, enabled or not. Each field of a microinstruction is a microcommand. The instruction specifies the new state of the CPU.

Vertical microinstruction: A completely vertical microinstruction would contain one field and therefore would specify one microcommand. An Op code is used to specify which microcommand is specified. In practice, microinstructions that typically contain three or four fields are called vertical.

87.1 Assembly Language

James M. Feldman and Edward W. Czeck

The true language of computers is a stream of 1s and 0s—bits. Everything in the computer, be it numbers or text or program, spreadsheet or database or 3-D rendering, is nothing but an array of bits. The meaning of the bits is in the "eye of the beholder"; it is determined entirely by context. Bits are not a useful medium for human consumption. Instead, we insist that what *we* read be formatted spatially and presented in a modest range of visually distinguishable characters. 0 and 1 arranged in a dense, page-filling array do not fulfill these requirements *in any way*. The several languages that are presented in this handbook are all intended to make something readable to two quite different readers. On the one hand, they serve the human reader with his/her requirements on symbols and layout; on the other, they provide a grammatically regular language for interpretation by a **compiler**. A compiler, of course, is normally a program running on a computer, but human beings can and sometimes do play both sides of this game. They want to play with both the input and output. Such accessibility requires that not only the input but the output of the compilation process be comfortably readable by humans. The language of the input is called a **high-level language (HLL)**. Examples are C, Pascal, Ada and Modula II. They are designed to express both regularly and concisely the kinds of operations and the kinds of constructs that programmers manipulate. The output end of the compiler generates **object code**—a generally unreadable, binary representation of machine language, lacking only the services of a **linker** to turn it into true machine language. The language that has been constructed to represent object code for human consumption is *assembly language*. That is the subject of this section.

Some might object to our statement of purpose for assembly language. While few will contest the concept of assembly language as the readable form of object code, some see writing assembly code as the way to "get their hands on the inner workings of the machine." They see it as a "control" issue. Since most HLLs today give the user reasonably direct ways to access hardware, where does the "control" issue arise? What assembly proponents see as the essential reason for having an assembly language is the option to optimize the "important" sections of a program by doing a better job of machine code generation than the compiler does. This perspective was valid enough when compilers were mediocre optimizers. It was not unlike the old days when a car came with a complete set of tools because you needed them. The same thing that has happened to cars has happened to compilers. They are engineered to be "fuel efficient" and perform their assigned functions with remarkable

ability. When the cars or compilers get good enough and complex enough, the tinkerer may do more harm than good. IBM's superscalar RISC computer—the RS6000—comes with superb compilers *and no* ***assembler*** *at all.* The Pentagon took a long look at their costs of programming their immense array of computers. Contrary to popular legend, they decided to save money. The first amendment not withstanding, their conclusion was: "Thou shalt not assemble."

The four principal reasons for *not* writing assembly language are

- Any sizable programming job gets done at least four times faster in a HLL.
- Most modern compilers are good optimizers of code; some are superb.
- Almost all important code goes through revisions—maintenance. Reworking old assembly code is similar to breaking good encryption; it takes forever.
- Most important of all is portability. To move any program to a different computer, you must generate machine code for that new platform. With a program in a HLL, a new platform is almost free; all it requires is another pass through the compiler for the target platform. With assembly code, you are back to square one. Assembly code is unique to the platform.

Given all of that, the question naturally arises: Why have an article on assembly language? We respond with two reasons, both of which we employ in our work as teachers and programmers:

- An essential ingredient in understanding computer hardware and in designing new computer systems and compilers is a detailed appreciation of the operations of central processing units (CPUs). These are best expressed in assembly language. Our undergraduate Computer Engineering courses include a healthy dose of assembly language programming for this specific reason.
- If you are concerned about either CPU design or compiler effectiveness, you have to be able to look in great detail at the interface between them—*machine language.* As we have said, the easiest way to read machine language is by translating it to assembly language. This is one way to get assembly language, not by writing in it as a source of code but by running the object code itself through a backward translator called a **disassembler**. While many compilers will oblige you by providing an assembly listing if asked, often that listing does not include optimizations that occur only when the several modules are linked together, providing opportunities for truly global optimization. Some compilers "help" the reader by using **macros** (names for predefined blocks of code) in place of the real machine instructions and register assignments. The absence of the optimizations and the inclusion of unexpected macros can make the assembly listing almost useless for obtaining insight into the program's fine detail. The compilers that we have used on the DECstations and SPARC machines do macro inclusion. To see what is really going on in these machines, you must disassemble the machine code. That is precisely what the Think C® compiler on the Macintosh does when you ask for machine code. It disassembles what it just did in compiling and linking the whole program. What you see is what is really there. The code we present for the 68000 was obtained in that way.

These are important applications. Even if most or all other programming needs can be better met in HLLs, these applications are sufficient reason for many engineers to want to know something about assembly language.

There are other applications of assembly language, but they tend to be specific to rather specialized and infrequent tasks. For example, the back end of most HLL compilers is a machine code generator. To write one of those, you certainly must know something about assembly language. On rare occasions, you may find some necessary machine-specific transaction which is not supported by the HLL of choice or which requires some special micro optimization. A "patch" of assembly code is a way to fit this inexpressible thought into the program's vocabulary. These are rare events. The reason why we recommend to you this section on assembly code is that it improves your understanding of HLLs and of computer architecture.

We will take a single subroutine which we express in C and look at the machine code that is generated on two representative machines. The machines include two widely used *complex instruction set computers* (**CISCs**) and one *reduced instruction set computer* (**RISC**). These are the 68000®, the VAX®, and a SPARC®. We will have two objectives:

- To see how a variety of paradigms in HLLs are translated (or, in other words, to see what is really going on when you ask for a particular HLL operation)
- To compare the several architectures to see how they are the same and how they differ

The routine attempts to get a count of the number of numbers which occur in a block of text. Since we are seeking numbers and not *digits*, the task is more complex than you might first assume. This is why we say "attempts." The function that we present below handles all of the normal text forms:

- Integers, such as 123 or –17
- Numbers written in a fixed-point format, such as 12.3 or 0.1738
- Numbers written in a floating-point format, such as –12.7e+19 or 6.781E2

If our program were to scan the indented block of code above, it would report finding six numbers. The symbols that the program recognizes as potentially part of a number include the digits 0 to 9 and the symbols 'e', 'E', ' . ', '–' and '+'. Now it is certainly possible to include other symbols in legitimate numbers, such as HEX numbers or the like, but this little routine will not properly deal with them. Our purpose was not to handle all comers but to provide a routine with some variety of expression and possible application. Let us begin.

NumberCount( )

We enter the program at the top with one pointer passed from the calling routine and a set of local variables comprising two integers and eight Boolean variables. Most of the Boolean variables will be used in pairs. The first element of a pair, for instance, *ees* of *ees* and *latche*, indicates that the current character is one of a particular class of non-numeric characters which might be found inside a number. If you consider that the number begins at the first digit, then these characters can occur legally only once within a given number. *ees* will be set true if the current character is the *first instance* of either 'e' or 'E'. The paired variable, *latche*, is set true if there has ever been one of those characters in the current number. The other pairs are *period* and *latchp* and *sign* and *latchs*.

There is also a pair of Booleans which indicate if the current character is a *digit* and if the scanner is currently *inside* a number. Were you to limit your numbers to integers, these two are the only Booleans which would be needed. At the top of the program, all Booleans are reset (made FALSE). Then we step through the block looking for numbers. The search stops when we encounter the first null [char(0)] marking the end of the block. Try running through the routine with text containing the three forms of number. You will quickly convince yourself that the routine works with all normal numbers. If someone writes "3..14" or "3.14ee6", the program will count 2 numbers. That is probably right in the first two cases. Who knows in the third?

Let us look at this short routine in C.

```
# define blk_length 20001
int NumberCount(char block[])
{  int count=0,inside=0,digit;
   int ees=0, latche=0, latchp=0, period=0, latchs=0, sign=0;
   char *source;

   source = block;
   do {
     digit = (*source >= '0') && (*source <= '9');
     period = (*source=='.') && inside && !latchp; && !latche;
     latchp = (latchp || period);
     ees = ((*source=='E') || (*source=='e')) && inside && !latche;
     latche = (latche || ees);
     sign = ((*source=='+') || (*source=='-')) && inside && latche && !latchs;
     latchs = (latchs || sign);
     if (inside) {
       if (!(digit || ees || period || sign)) inside=latchp=latche=latchs=0;
     }
     else if (digit) {
```

```
    count++;
    inside = 1;
   }
 source++;
 }
 while ((*source != '\0') && ((source-block)<blk_length+1));
 return count;
 }
```

To access values within the character array, the normal C paradigm is to step a pointer along the array. *Source* points at the current character in the array; **source* is the character ("what *source* points at"). *source* is initialized at the top of the program before the loop (source = block;) and incremented (source++;) at the bottom of the loop. Note the many repetitions of **source*. Each one means the same current character. If you read that expression as *the character which source is pointing to*, it looks like an invitation to fetch the same character from memory eight times. A compiler that optimizes by removing *common subexpressions* should eliminate all but the first such fetch. This optimization is one of the things that we want to look for.

For those less familiar with C, the meanings of the less familiar symbols are:

`==`	equal (in the logical sense)
`!`	not
`!=`	not equal
`&&`	and
`||`	or
`count++`	increment *count* by 1 unit (after using it)

C uses 0 as FALSE and anything else as TRUE.

Comparisons Down on the Factory Floor

Now let us see what we can learn by running this program through compilers on several quite different hosts. The items that we wish to examine include:

I. Subroutine operations comprising:
   A. Building the call block
   B. The call itself
   C. Obtaining memory space for local variables
   D. Accessing the call block
   E. Returning the function value
   F. Returning to the calling routine

II. Data operations
   A. Load and store
   B. Arithmetic
   C. Logical
   D. Text

III. Program control
   A. Looping
   B. if and the issue of multiple tests

Our objectives are to build three quite different pictures:

- An appreciation for the operations underlying the HLL statements
- An overview of the architectures of several important examples of CISC and RISC processors
- An appreciation for what a HLL optimizer should be doing for you

We will attempt to do all three all of the time.

Let us begin with the calling operations. Our first machine will be the MC68000, one of the classical and widely available CISC processors. It or one of its progeny is found in many machines and forms the heart of the Macintosh (not the PowerMac) and the early Sun workstations. Programmatically, the 68000 family shares a great deal with the very popular VAX family of processors. Both of these CISC designs derive in rather linear fashion from DEC's PDP-11 machines that were so widely used in the 1970s. Comparisons to that style of machine will be done with the SPARC, a RISC processor found in Sun, Solbourne, and other workstations.

Memory and Registers

All computers will have data stored in memory and some space in the CPU for manipulating data. Memory can be considered to be a long list of bytes (8-bit data blocks) with *addresses* (locations in the list) spanning some large range of numbers from 0 to typically 4 billion (4 GB). The memory is constructed physically by grouping chips so that they appear to form enormously deep columns of bytes, as shown in Fig. 87.1. Since each column can deliver one byte on each request, the number of adjacent columns determines the number of bytes which may be obtained from a single request. Machines today have 1, 2, 4, or 8 such columns. (Some machines, the 68000 being our current example, have only 2 columns but arrange to have the CPU ask for two successive transfers to get a total of 4 bytes.) In general, the CPU may manipulate in a single step a datum as wide as the memory. For all of the machines which we will consider, that maximum datum size is 32 bits or 4 bytes. While convention would have us call this biggest datum a *word*, historical reason has led both the VAX and MC68000 to call it a *longword*. Then, 2 bytes is either a *halfword* or a *word*. We will use the VAX/68000 notation (longword, word, and byte) wherever possible to simplify the reading. To load data from memory, the CPU sends the address and the datum size to the memory and gets the datum as the reply. To store data, the address is sent and then the datum and datum size.

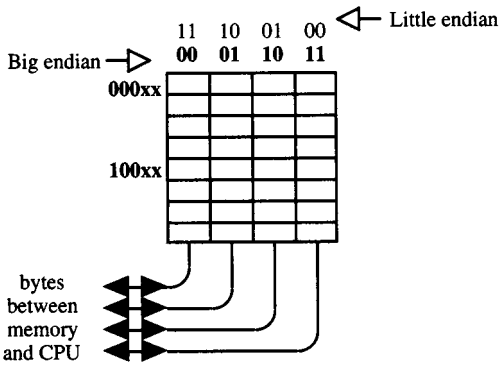

FIGURE 87.1 Memory arranged as 4 columns of bytes. The binary addresses are shown in the two formats widely used in computers. The illustration shows only 32 bytes in a 4 3 8 array, but a more realistic span would be 4 3 1,000,000 or 4 3 4,000,000 (4 MB to 16 MB).

Some machines require that the datum be properly aligned with the stacking order of the memory columns in Fig. 87.1. Thus, on the SPARC, a longword must have an address ending in 00 (xxx00 in Fig. 87.1), and a word address must end in 0. The programmer who arranges to violate this rule will be greeted with an **address error**. Since the MC68000 has only two columns, it complains only if you ask for words or longwords with odd addresses. Successor models of that chip (68020, 30, and 40), like the VAX, accept any address and have the CPU read two longwords and do the proper repacking.

The instruction explicitly specifies the size and indicates how the CPU should calculate the address. An instruction to load a byte, for example, is `LB`, `MOVE.B`, or `MOVB` on the SPARC, MC68000, and VAX, respectively. These are followed immediately by an expression which specifies an address. We will discuss how to specify an address later. First, we must introduce the concept of a register.

The space for holding data and working on it in the CPU is the *register set*. Registers are a very important resource. Bringing data in from memory is quite separate from any operations on that data. Data in memory must first be fetched, then acted upon. Data in registers can be acted on immediately. Thus, the availability of registers to store very active variables and intermediate results makes a processor inherently faster. In some machines, most or all of the registers are tied to specific uses. The most prevalent example would be Intel's 80x86 processors, which power the ubiquitous PC. Such architectures, however, are considered quite old-fashioned. All of the machines that we are considering are of a type called *general register machines* in that they have a large group of registers which may be used for any purpose. The machines that we include have either 16 or 32 registers, with only a few tied to specific machine operations.

Table 87.1 shows the general register resources in the three machines. The SPARC is a little strange. The machine provides eight *global* registers and then a *window blind* of 128 registers which sits behind a frame

TABLE 87.1 General Registers in the Three Machines

	Reg	Special	Names	Comments
MC68000	16	1	D0..D7 A0..A7	A(ddress) register operations are 32 bits wide. Address generation uses A registers as bases. D (data) registers allow byte, word, and longword operations. A7 is SP.
VAX	16	4	r0..r11 AP, FP, SP, PC	AP,FP,SP and PC hold the addresses of the argument block, the frame, the stack and the current place in the program, respectively. All data instructions can use any register.
SPARC	32 (136)	4	zero, g1..g7, i0..i5, FP, RA, l0..l7, o0..o5, SP, o7	The 4 groups of eight registers comprise: global (g), incoming parameters (i), local (l) and outgoing parameters (o). g0 is a hardwired 0 as a data source and a wastebasket as a destination. The registers are arranged as a window blind (see text) with the g's always visible and the others moveable in multiple overlapping frames of 24.

The special registers are within the set of general registers. Where a PC is not listed, it exists as a special register and can be used as an address when the program uses *program-relative* addressing.

which exposes 24 of the 128. A program can ask the machine to raise or lower the blind by 16 registers. That leaves an overlap of eight between successive yanks or rewinds. This arrangement is called a *multiple overlapping register set* (MORS). If you think of starting with register r8 at the bottom and r31 at the top, a yank of 16 on the blind will now have r49 at the top and r24 at the bottom. r24 to r31 are shared between the old set and the new. To avoid having to keep track of which registers are showing, the set of 24 are divided into what came *in* from the last set, those that are only *local*, and those that will go *out* to the next set. These names apply to going toward increasing numbers. In going the other direction, the *ins* of the current set will become the *outs* of the next set. Almost all other machines keep their registers screwed down to the local masonry, but you will see in a moment how useful a MORS can be. (Like other useful but expensive accessories, the debate is always on whether it is worth it [Patterson and Hennessy, 1989].)

Stack. Most subroutines define a number of local variables. NumberCount in C, for example, defines 10 local variables. While these local variables will often be created and kept in register, there is always some need for a bit of memory for each *invocation of* (call to) a subroutine. In the "good old days," this local storage was often tied to the block of code comprising the subroutine. However, such a fixed block means that a subroutine could never call itself or be called by something that it called. To avoid that problem (and for other purposes) a memory structure called a *stack* was invented which got its name because it behaved like the spring-loaded plate stack in a restaurant. Basically, it is a *last-in-first-out* (LIFO) structure whose top is defined by a pointer (address) which resides in a register commonly called the *stack pointer* or SP.

Heap. When a subroutine needs space to store local variables, it acquires that space on the stack. When the subroutine finishes, it returns that stack space for use by other routines. Thus, local variable allocations live and die with their subroutines. It is often necessary to create a data structure which is passed to other routines whose lives are independent of the creating routine. This kind of storage must be independent of the creator. To meet this need, the *heap* was invented. This is an expandable storage area managed by the system. You get an allocation by asking for it [*malloc* (*structure_size*) in C]. You get back a pointer to the allocation and the routine can pass that pointer to any other routine and then go away. When it comes time to dispose of the allocation—that is, return the space for other uses—the program must do that actively by a deallocation call [*free*(*pointer*) in C]. Thus, one function can create a structure, several may use it, and another one can return the memory for other uses, all by passing the pointer to the structure from one to another.

Both heap and stack provide a mechanism to obtain large (or small) amounts of storage dynamically. Thus, large structures which are created only at run time need not have static space stored for them in programs that are stored on disk nor need they occupy great chunks of memory when the program does not need them. Dynamic allocation is very useful and all modern HLLs provide for it.

Since there are two types of dynamic storage, there must be some way to lay out memory so that unpredictable needs in either stack or heap can be met at all times. The mechanism is simplicity itself. The program is stuffed into low addresses in memory along with any static storage (e.g., globals) which are declared in the program. The entire remaining space is then devoted to dynamic storage. The heap starts right after the program and

grows toward higher addresses; the stack goes in at the top of memory and grows down. The system is responsible to see that they never collide (a *stack crash*). When it all goes together, it looks like Fig. 87.2 [Aho et al., 1986].

There is one last tidbit that an assembly programmer must be aware of in looking at memory. Just as some human alphabets are written left to right and some right to left (not to mention top to bottom), computer manufacturers have chosen to disagree on how to arrange words in memory. The two schemes are called *big-endian* and *little-endian* (after which end of a number goes in the lowest-numbered byte and also after a marvelous episode in *Gulliver's Travels*). The easiest way to perceive how it is done in the two systems is to think of all numbers as being written in conventional order (left to right), but for big-endian you start counting on the upper left of the page and on little-endian you start counting on the upper right (see Fig. 87.1). Since each character in a text block is *a number* of length 1 byte, this easy description makes big-endian text read in normal order (left to right) but little-endian text reads from right to left. Figure 87.3 shows the sentence "This is a sentence" followed by the two hexadecimal (HEX) numbers 01020304 and 0A0B0C0D written to consecutive bytes in the two systems. Why must we bring this up? Because anyone working in assembly language must know how the bytes are arranged. Furthermore, two of the systems we are considering are big-endian and one (the VAX) is little-endian. Which is the better system? Either one. It is having both of them that is a nuisance.

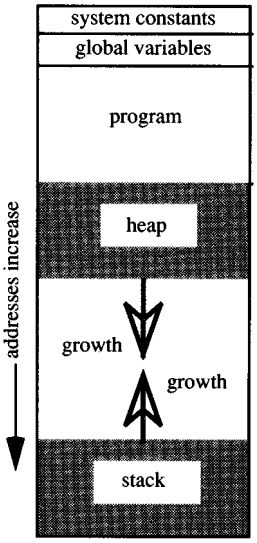

FIGURE 87.2 Layout of a program, static storage, and dynamic storage in memory.

As you look at Fig. 87.3, undoubtedly you will prefer big-endian, but that is only because it appeals to your prejudices. In truth, either works well. What is important is that you be able to direct your program to go fetch the item of choice. In both systems, you use the lowest-numbered byte to indicate the item of choice. Thus, for the number 01020304, the address will be 13. For the big-endian system, 13 will point to the byte containing 04 and for the little-endian system, it will point at the byte containing 01.

Figure 87.3 contains a problem for some computers which we alluded to in the discussion of Fig. 87.1. We have arranged the bytes to be four in a row as in Fig. 87.1. That is the way that the memory is arranged in two of our three machines. (In the 68000, there are only two columns.) A good way to look at the fetch operation is that the memory always delivers a whole row and then the processor must acquire the parts that it wants and then properly arrange them. (This is the effect if not always the method.) Some processors—the VAX being a conspicuous example—are willing to undertake getting a longword by fetching two longwords and then piecing together the parts that it wants. Others (in our case, the 68000 and the SPARC) are not so accommodating. Those machines opt for simplicity and speed and require that the program keep its data aligned. To use one of those machines, you (or the compiler or assembler) must rearrange Fig. 87.3 by inserting a null byte into Fig. 87.2. This modification is shown in Fig. 87.4. With this modification, all three machines could fetch the two numbers in one operation without rearrangement.

Look closely at the numbers 01020304 and 0A0B0C0D in Fig. 87.4. Notice that for both configurations, the numbers read from left to right and that (visually) they appear to be in the same place. Furthermore, as pointed out in the discussion of Fig. 87.3, the "beginning" or address of each of the numbers is identical. However, the byte that is pointed at by the address is not the same and the internal bytes do not have the same addresses. Getting big-endian and little-endian machines in a conversation is not easy. It proves to be even more muddled than these figures suggest. A delightful and cogent discussion of the whole issue is found in Cohen [1981].

The principal objective in this whole section has been accomplished if looking at Fig. 87.4 and given the command to load a byte from location 0000 0019, you get the number 0B in the big-endian machine and 0C in the little-endian machine.

If you are not already familiar with storing structures in memory, look at the string (sentence) and ask how those letters get in memory. To begin with, every typeable symbol and all of the unprintable actions such as tabbing and carriage returns have been assigned a numerical value from the *ASCII code*. Each assignment is a byte-long number. What "This" really looks like (HEX, left to right) is 54 68 69 73. The spaces are HEX 20; the period 2E. With the alignment null byte at the end, this list of characters forms a proper C string. It is a structure of 20 bytes. A structure of any number of bytes can be stored, but from the assembly point of view,

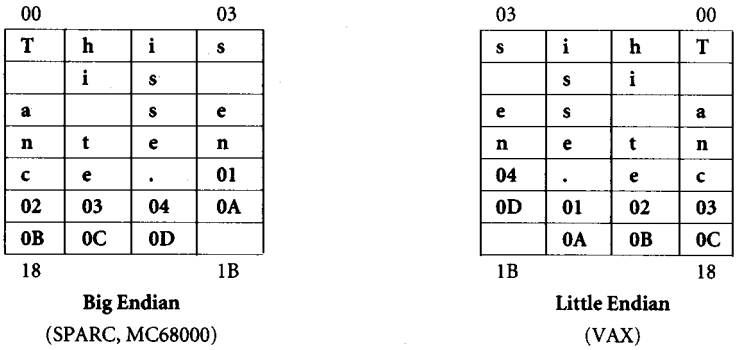

FIGURE 87.3 Byte numbering and number placement for big- and little-endian systems. Hexadecimal numbers are used for the memory addresses.

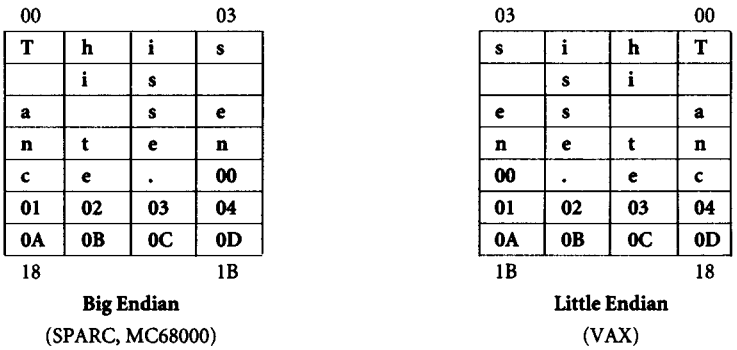

FIGURE 87.4 The same items as in Fig. 87.3, but with justification of the long integers to begin on a longword boundary.

it is all just a list of bytes. You may access them two at a time, four at a time, or one at a time. Any interpretation of those bytes is entirely up to the program. Unlike the HLL which requires that you tell it what each named variable is, assembly language knows only bytes and groups of bytes. In assembly language, the "T" can be thought of as a letter or the number 54 (HEX). Your choice. Or, more importantly, your program's choice.

Addressing

Now that we have both memory and addresses, we should next consider how these processors require that programmers specify the data that is to be acted upon by the instructions.

All of these machines have multiple modes of address. The VAX has the biggest vocabulary; the SPARC the smallest. Yet all can accomplish the same tasks. Four general types of address specification are quite common among assembly languages. These are shown in Table 87.2. They are spelled out in words in the table, but their usage is really developed in the examples which follow in this and the succeeding sections.

In Table 87.2, formats 1.4 and 1.5 and the entries in 4 require some expansion. The others will be clear in the examples we will present. Base-index addressing is the mechanism for dealing with subscripts. The base points at the starting point of a data structure, such as a string or a vector; the index measures the offset from the start of the structure to the element in question. For most machines, the index is simply a separate register which counts the bytes from the base to the item in question. If the items in the list are 4 bytes long, then to increment the index, you add 4. While that is not hard to remember, the VAX does its multiplication by the item length for you. Furthermore, it allows you to index any form of address that you can write. To show you what that means, consider expanding numbers stored in words into numbers stored in longwords. The extension is to preserve sign. The VAX provides specific instructions for conversions. If we were moving these words in one array to longwords in another array, we would write:

TABLE 87.2 Addressing Modes

1.	**Explicit addresses**	**Example**	
	1.1. Absolute addressing	765	The actual address written into the instruction.
	1.2. Register indirect	(r3)	Meaning "the address is in register 3."
	1.3. Base-displacement	–12(r3)	Meaning "12 bytes before the address in register 3."
	1.4. Base-index	(r3,r4)	Meaning make an address by adding the contents of r3 and r4. This mode has many variations which are discussed below.
	1.5. Double indirect	@5(r4)	Very uncommon! Means calculate an address as in 1.3, then fetch the longword there, and then use it as the address of what you really want.
2.	**Direct data specification**		
	2.1. Immediate/literal	#6 or 6	Meaning "use 6 as the datum." In machines which use #6, 6 without # means address 6. This is called "absolute addressing."
3.	**Program-relative**		
	3.1. Labels	loop:	The label (typically an alphanumeric ending in a colon) is a marker in the program which the assembler and linker keep track of. The common uses are to jump to a labeled spot or to load labeled constants stored with the program.
4.	**Address-modifying forms** (CISC only)		
	4.1. Postincrement	(sp)+	Same as 1.2 except that, after the address is used, it is incremented by the size of the datum in bytes and returned to the register from which it came.
	4.2. Predecrement	–(sp)	The value in SP is decremented by the size of the datum in bytes, used as the address and returned to the register from which it came.

```
CVTWL (r4)[r5],(r6)[r5]    ;convert the words starting at (r4) to longwords starting at (r6)
```

Note that the same index, [r5], is used for both arrays. On the left, the contents of r5 are multiplied by 2 and added to r4 to get the address; on the right, the address is r5*4+r6. You would be saying: "Convert the 4th word to the 4th longword." This is undoubtedly compact and sometimes convenient. It is also unique to the VAX.

For the 68000, the designers folded both base-displacement and base-index into one mode and made room for word or longword indices. It looks like:

```
add.1 64(A3,D2.w),D3    ;address = (A3+64) +sign-extended(D2)
```

The 68000 limits the displacement to a signed byte, but other than that, it is indeed a rather general indexing format. If you do not want the displacement, set it to 0.

For the powerful but simple SPARC, the simple base-index form shown in 1.4 is all that you have (or need).

The double-indirect format, 1.5, is so rarely used that it has been left out of almost all designs but the VAX. What makes it occasionally useful is that subroutines get pointers to "pass by pointer" variables. Thus, if you want to get the variable, first you must load the address and then the variable. The VAX allows you to do this in one instruction. While that sounds compact, it is expensive in memory cycles. If you want to use that pointer again, it pays to have it in register.

The two items under heading 4 are strange at first. Their principal function is adding items to and removing them from a dynamic stack, or for C, to execute the operation *X++ or *(– –X). The action may be viewed with the code below and the illustration of memory in Fig. 87.2:

```
movl r4, –(sp)          ;make room on the stack (subtract 4 from SP) and put
                         the contents of r4 in that spot

movl (sp)+, r4          ;take a longword off the stack, shorten the stack by 4
                         bytes, and put the longword in r4
```

RISCs abhor instructions which do two unrelated things. Instead of using a dynamic stack, they use a quasi-static stack. If a subroutine needs 12 bytes of stack space, it explicitly subtracts 12 from SP. Then it works from there with the base-displacement format (1.3) to reference any place in the block of bytes just defined. If you want to use a pointer and then increment the pointer, RISCs will do that as two independent instructions.

Let us consider one short section of MC68000 code from our sample program in C to see how these modes work and to sample some of the flavor of the language:

```
;ees = ((*source=='E') || (*source=='e')) && inside && !latche;

            CMPI.B      #$45,(A4)   ; 'E'   "compare immediate"    literal hex 45,
                                                                    what A4 points at
            BEQ         first       ;       "branch if equal"     to label first
            CMPI.B      #$65,(A4)   ; 'e'   "compare immediate"    literal hex 65,
                                                                    what A4 points at
            BNE         second      ;       "branch if not equal" to label second
first:
            TST.W       D6          ;       "test word" (subtract 0) D6 ('inside')
            BEQ         second      ;       "branch if equal"     to label second
            TST.W       D3          ;       "test word" (subtract 0) D3 ('latche')
            BEQ         third       ;       "branch if equal"     to label third
second:
            MOVEQ       #00,D0      ;       "move quick"          literal 0 to D0
            BRA         fourth      ;       "branch always"       to label fourth
third:
            MOVEQ       #$01,D0     ;       "move quick"          literal 1 to D0
fourth:
            MOVE.W      D0,-6(A6)   ;       "move word"           from D0 to -6(FP)
```

There are all sorts of little details in this short example. For example, a common way to indicate a comment is to start with a ";". The assembler will ignore your comments. The "#" indicates a literal, and the "$" that the literal is written in hexadecimal notation. The VAX would use #^x to express the same idea. "Compare" means "subtract but save only the **condition codes** of the result" (*v* or *overflow*, *n* or *negative*, *z* or *zero*, and *c* or *carry*). Thus, the first two lines do a subtraction of whatever A4 is pointing at (*source) from the ASCII value for 'E' and then, if the two were equal (the result, zero), the program jumps to line 5. If *source is not 'E', then it simply goes to the next line, line 3. The instruction, TST.W D6, is quite equivalent to CMPI.W D6, #0, but the TST instruction is inherently shorter and faster. On a SPARC, where it would be neither shorter nor faster, TST does not exist.

Exactly what the assembler or linker does to replace the label references with proper addresses, while interesting, is not particularly germane to our current topic. Note that the range of the branch is somewhat limited. In the 68000, the maximum branch is ±32K and in the VAX a mere +127 to –128. If you need to go further, you must combine a branch with a jump. For example, if you were doing BEQ farlabel, you would instead do:

```
    BNE     nearlabel
    jmp     farlabel    ;   this instruction can go any distance
nearlabel:
```

Follow through the example above until the short steps of logic and the addressing modes are clear. Then progress to the next section where we use the addressing modes to introduce the general topic of subroutine calling conventions.

Calling Conventions

Whenever you invoke a subroutine in a HLL, the calling routine (*caller*) must pass to the called routine (*callee*) the parameters that the subroutine requires. These parameters are defined at compile time to be either *pass-by-value* or *pass-by-pointer* (or *pass-by-reference*), and they are listed in some particular order. The convention for passing the parameters varies from architecture to architecture and HLL to HLL, but basically it always consists of building a *call block* which contains all of the parameters and which will be found where the recipient expects to find it.

Along with the passing of parameters, for each system, a convention is defined for register and stack use which establishes:

- Which registers must be returned from callee to caller with the same contents that the callee received (such registers are said to be *preserved across a call*)
- Which registers may be used without worrying about their contents (such registers are called *scratch registers*)
- Where the return address is to be found
- Where the value returned by a function will be found

The convention may be supported by hardware or simply a gentlemanly rule of the road. However the rules come into being, they define the steps which must be accomplished coming into and out of a subroutine. The whole collection of such rules forms the *calling convention* for that machine. In this section, we look at our three different machines to see how all accomplish the same tasks but by rather different mechanisms.

The two CISCs do almost all of their passing and saving on the stack. The call block will be built on the stack; the return address will be put on the stack; saved registers will be put on the stack. Only a few stack references are passed forward in register; the value returned by the function will be passed back in register.

How different is the SPARC! The parameters to be passed are placed in the *out* registers (six are available for this purpose). Only the overflow, if any, would go on the stack. In general, registers are saved by window-blinding rather than moving them to the stack. On return, data is returned in the *in* registers and the registers restored by reverse window-blinding.

MC68000 Call and Return. Let us look at the details for two of the machines. We start with the 68000, because that is the most open and "conventional." We continue with the function NumberCount. Only a single parameter must be passed—the pointer to the text block. The HLL callee sees NumberCount(block) as an integer (i.e., what will be returned), but the assembly program must do a call and then use the returned integer as instructed. A typical assembly routine would be:

```
MOVE.L    A2,-(SP)       ; move pointer to block onto the stack
JSR       NumberCount    ; save return address on the stack and start
                         ; executing NumberCount
                         ; do something with value returned in D0
```

The first instruction puts the pointer to the block, which is in A2, on the stack. It first must make room, so the "–" in –(A7) first subtracts 4 from A7 (making room for the longword) and then moves the longword into the space pointed to by the now-modified A7. The one instruction does two things: the decrementing of SP and the storing of the longword in memory.

```
MOVE.L    A2,–(A7)     A7 ⇐ A7–4      ;A7 = SP
                       M(A7) ⇐ A2     ;M(x) = memory(address x)
```

The next instruction, *jump subroutine* (JSR), does three things. It decrements SP (i.e., A7) by 4, stores the return address on the top of the stack, and puts the address of NumberCount in the *program counter*. We have just introduced two items which need specific definition:

Return address (RA): This will always be the address of the instruction which the callee should return to. In the 68000 and the VAX (and all other CISCs), the RA points to the first instruction after the JSR. In the SPARC and almost any RISC, RA will point to the second instruction after JSR. That curious difference will be discussed later.

Program counter (PC): This register (which is a *general register* on the VAX but a special register on the other machines) points to the place (memory location) in the machine language instruction stream where the program is currently operating. As each instruction is fetched, the PC is automatically incremented. The action of the JSR is to save the last version of the PC—the one for the next fetch—and replace it with the starting address of the routine to be jumped to.

Summing up these transactions in algebraic form:

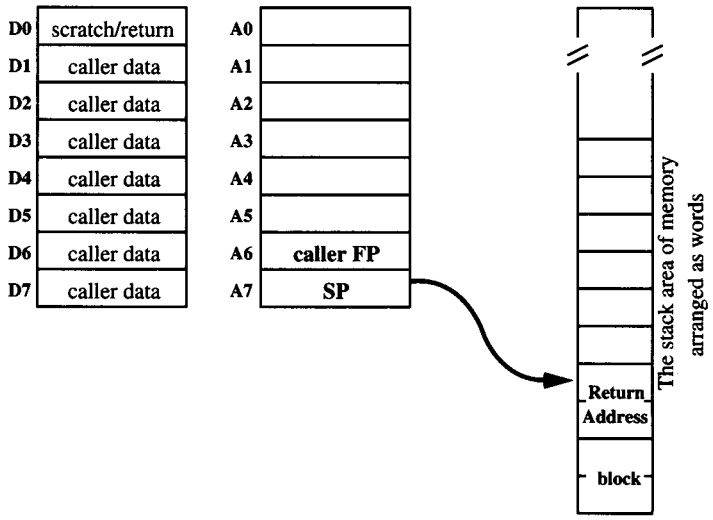

FIGURE 87.5 The stack area of the 68000's memory and the register assignments that the called subroutine sees as it is entered at the top. The registers all hold longwords, the size of an address. In typical PC/Macintosh compilers, integers are defined as 16-bit words. Accordingly, the stack area of memory is shown as words, or half the width of a register.

```
JSR NumberCount     SP ⇐ SP-4      ;A7 = SP
                    M(SP) ⇐ PC     ;M(x) = memory(address x)
                    PC ⇐ address of NumberCount
```

Should you wonder how the address of NumberCount gets in there, the *linker*, which assigns each section of code to its proper place in memory and therefore knows where all the labels are, will insert the proper address in place of the name.

This completes the call as far as building the call block, doing the call itself, and picking up the result. Had there been more parameters to pass, that first instruction would have been replicated enough times to *push* all of the parameters, one at a time, onto the stack. Now let us look at the conventions from the point of view of the callee. The callee has more work.

When the callee picks up the action, the stack and registers are as shown in Figure 87.5. With the exception of D0 and A7, the callee has no registers . . . yet. The callee must make room for local variables in either register or memory. If it wants to use registers, it must save the user's data from the registers. The subroutine can get whatever space it needs on the stack. Only after the setup will it get down to work. The entire section of stack used for local variables and saving registers is called the callee's frame. It is useful to have a pointer (FP) to the bottom of the frame to provide a static reference to the return address, the passed parameters, and the subroutine's local variable area on the stack. In the 68000, the convention is to use A6 as FP. When our routine, NumberCount, begins, the address in A6 points to the start of the caller's frame. The first thing the callee must do is to establish a local frame. It does that with the instruction LINK.

Typical of a CISC, each instruction does a large piece of the action. The whole entry operation for the 68000 is contained in two instructions:

```
LINK      A6,#$FFF8
MOVEM.L   D3-D7/A4,-(SP)
```

The first instruction does the frame making; the second does the saving of registers. There are multiple steps in each. Each double step of decrementing SP and moving a value onto the stack will be called a *push*. The steps are as follows:

```
LINK      A6,#$FFF8        ;push A6 (A7 ‹ A7-4, M(A7) ‹ A6)
                           ;move A7 to A6 (SP to FP)
                           ;add FFF8 (-8) to SP (4 words for local variables)
```

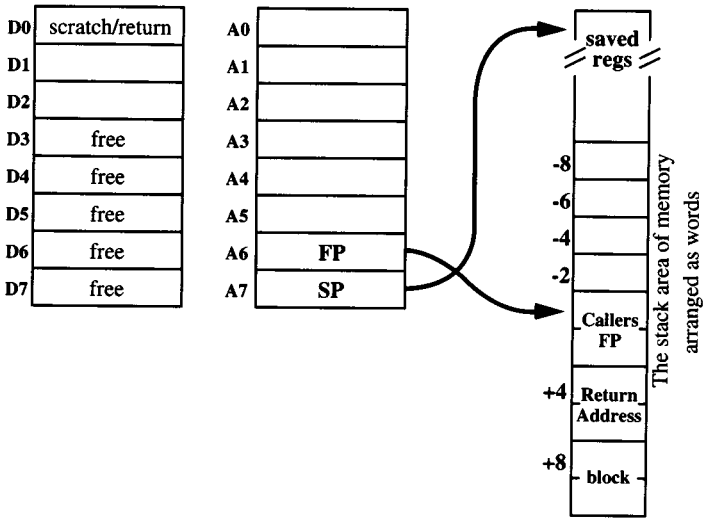

FIGURE 87.6 The stack area of the 68000's memory and the register situation just after MOVEM has been executed. The memory area between the two arrows is the subroutine's *frame*.

```
MOVEM.L   D3-D7/A4,-(A7)   ;push 5 data registers (3..7) and 1 address
                           ;register (A4)
```

At this point, the stack looks like Fig. 87.6.

The subroutine is prepared to proceed. How it uses those free registers and the working space set aside on the stack is the subject of the section on optimization in this chapter. For the moment, however, we simply assume that it will do its thing in exemplary fashion, get the count of the numbers, and return. We continue in this section by considering the rather simple transaction of getting back.

The callee is obliged to put the answer back where the caller expects to find it. Two paradigms for return are common. The one that our compiler uses is to put the answer in D0. The other common paradigm is to put the answer back on the stack. The user will have left enough room for that answer at FP+8, whether or not that space was also used for transferring parameters in. Using our paradigm, the return becomes:

```
MOVE.W $FFFC(A6),D0        ;answer from callee's stack frame [-4(FP)] to D0
MOVEM.L (A7)+,D3-D7/A4     ;registers restored to former values
UNLK A6                    ;SP ‹ FP, FP ‹ M(SP), SP ‹ SP+4
RTS                        ;PC ‹ M(SP), SP ‹ SP+4
```

When all of this has transpired, the machine is back to the caller with SP pointing at *block*. The registers look like Fig. 87.5 except for two important changes. SP is back where the caller left it and D0 contains the answer that the caller asked for.

Transactional Paradigms

The final topic in this section is the description of some of the translations of the simple and ordinary phrases of the HLLs into assembly language. We will show some in each of our three machines to show both the similarities and slightly different flavors that each machine architecture gives to the translation.

The paradigms that we will discuss comprise:

- Arithmetic
- Replacement
- Testing and branching, particularly multiple Boolean expressions
- Stepping through a structure

Many studies have shown that most computer arithmetic is concerned with addressing, testing, and indexing. In NumberCount there are several examples of each. For example, near the bottom of the program, there are statements such as:

```
count++;
```

For all three machines, the basic translation is the same: Add an *immediate* (a constant stored right in the instruction) to a number in register. However, for the CISCs, one may also ask that the number be brought in and even put back in memory. The three translations of this pair comprise:

MC68000	**VAX**	**SPARC**
ADDQ.W #$1,$FFFE(A6)	INCL R0	add %o2,1,%o2

Typical of the VAX, it makes a special case out of adding 1. There is no essential difference in asking it to add 1 by saying "1," but if one has a special instruction, it saves a byte of program length. With today's inexpensive memories, a byte is no longer a big deal, but when the VAX first emerged (1978), they were delivered with less memory than a PC or Mac would have today. The VAX, of course, can say ADDL #1, r0 just like the 68000, and for any number other than 1 or 0, it would. Note also that the VAX compiler chose to keep *count* in register, while in Think C® decided to put it on the stack (–2(SP)). A RISC has no choice. If you want arithmetic, your numbers must be in register. However, once again, we are really talking about the length of the code, not the speed of the transaction. *All* transactions take place from registers. The only issues are whether the programmer can see the registers and whether a single instruction can include both moving the operands and doing the operand arithmetic. The RISC separates the address arithmetic (e.g., –2(SP)) from the operand arithmetic, putting each in its own instruction. Both get the job done.

The next items we listed were *replacement* and *testing and branching*. We have both within the statement:

```
digit = (*source >= '0') && (*source <= '9');
```

The translation requires several statements:

MC68000	**VAX**	**SPARC**
MOVE.B (A4),D3	clrb r1	add %g0,0,%o1
CMPI.B #$30,D3	cmpb @4(ap),#48	ldsb [%o2],%o0
BLT ZERO	blss ZERO	subcc %o0, 47,%g0
CMPI.B #$39,D3	cmpb @4(ap),#57	ble ZERO
BLE ONE	bgtr ZERO	nop
	incb r1	subcc %o0,57,%g0
		bg ZERO
		nop
		add %g0, 1,%o1
		add %o1,0,%l3
ZERO:	**ZERO:**	**ZERO:**
MOVEQ #$00,D0		
BRA DONE		
ONE:		
MOVEQ #$01,D0		
DONE:		
MOVE.W D0,$FFF6(A6)		

To begin with, all three do roughly the same thing. The only noticeable difference in concept is that the SPARC compiler chose to compare the incoming character (*source) to 47 (the character before '0') and then branch if the result showed the letter to be "less than or equal," while the other two compared it to '0' as asked and then branched if the result was "less than." No big deal. But let us walk down the several columns to see the specific details. Prior to beginning, note that all three must bring in the character, run one or two tests, and then set an integer to either *zero* (false) or *not zero* (true). Also, let it be said that each snatch of code is

purportedly optimized, but at least with the small sample that we have, it looks as if each could be better. We begin with three parallel walkdowns. Notes as needed are provided below.

MC68000	**VAX**	**SPARC**
character from M → D#	Set (byte) DIGIT to 0	Set (byte) DIGIT to 0
Is (D3-'0') <=0?	Is (*source-'0') <=0?	character from Mfi out1
If <, branch to label ZERO	If <, branch to ZERO	Is (*source-'/') <=0?
Is (D3-'9')<=0?	Is (*source-'9') <=0?	If <=, branch to ZERO
If <=. branch to label ONE	If neither, branch to ZERO	Is (*source-'9') <=0?
	Add (byte) 1 to DIGIT	If neither, branch to
ZERO:	**ZERO:**	Add 1 to DIGIT
Put a longword 0 in D0		**ZERO:**
Branch to label DONE		
ONE:		
Put a longword 1 in D0		
DONE:		
Put value in D0 into DIGIT		

Notes:

1. Moving the character into register to compare it with '0' and '9':
   a. The first 68000 line moves the next character *as a byte* into register D3. The other 3 bytes will be ignored in the byte operations. Remember that the program had already moved the pointer to the string into A4.
   b. The SPARC does the same sort of thing with a pointer in %o2, except with the difference that it sign-extends the byte to a longword. Sign extension simply copies the *sign-bit* into the higher-order bits, effectively making 3E into 0000 003E or C2 into FFFF FFC2. That is what the mnemonic means: "LoaD Signed Byte."
   c. The VAX compiler takes a totally different approach—a rather poor one, actually. It leaves not only the byte in memory but even the pointer to the byte. Thus, every time it wants to refer to the byte—and it does so numerous times—it must first fetch the address from memory and then fetch the byte itself. This double memory reference is what @4(ap) means: "At the address you will find at address 4(ap)." The only thing that makes all this apparent coming and going even remotely acceptable is that the VAX will cache (place in a fast local memory) both the address and the character the first time that it gets them. Then, it can refer to them rapidly again. Cache references, however, are not as fast as register references.
2. Testing the character:
   The next line (3rd for the SPARC) does a comparison between 48 (or 47) and the character. *Compare* is an instruction which subtracts one operand from the other, but instead of putting the results somewhere, it stores only the facts on whether the operation delivered a negative number or zero or resulted in either an overflow or a carry. These are stored in **flags**, single bits associated with the arithmetic unit. The bits can contain only one result at a time. The 68000 and VAX must test immediately after the comparison or they will lose the bits. The SPARC changes the bits only when the instruction says so (the CC on the instruction — "change condition codes"). Thus, the subtraction can be remote from the test-and-branch.

   The SPARC is explicit about where to store the subtraction—in %g0. %g0 is a pseudo-register. It is always a 0 as a source and is a garbage can as a destination. The availability of the 0 and the garbage can serves all the same functions that the special instructions for zeros and comparisons do on the CISCs.
3. The differences in the algorithm to do the tests:
   There are two different paradigms expressed in these three examples. One says: "Figure out which thing you want to do and then do that one thing." The other says: "First set the result false and then figure out if you should set it true." While the second version would seem to do a lot of unnecessary settings to zero, the other algorithm will execute one less branch. That would make it roughly equivalent.

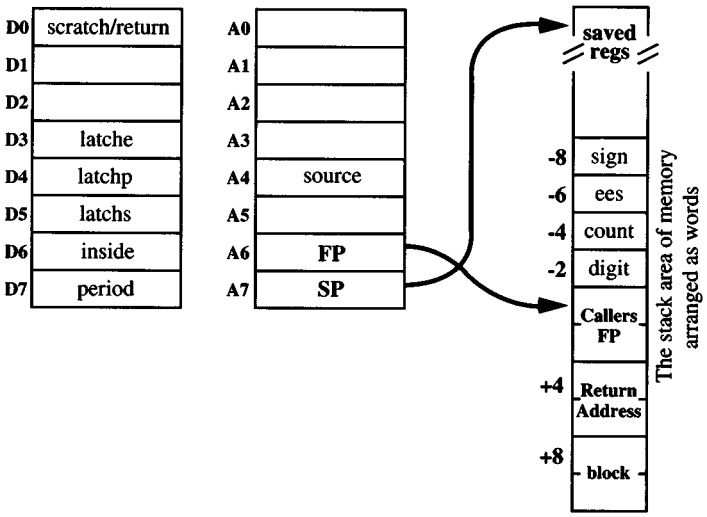

FIGURE 87.7 The stack area of the 68000's memory and the register assignments that the Think C® compiler made with global optimization *turned off*. The stack is shown just after the MOVEM instruction. The items in bold are as they would be after that instruction. While the registers all hold longwords, in typical PC/Macintosh compilers, integers are defined as words. This figure is the programmatic successor to Fig. 87.6.

> However, the 68000 algorithm is definitely longer—uses more memory for code. That is not really much of an issue, but why put the result first into a temporary register and then where you really want it?

Compiler Optimization and Assembly Language

Compiler Operations

To understand the optimizing features of compilers and their relation to assembly language, it is best to understand some of the chores for the compiler. This section examines variable allocation and how it can be optimized, and the optimization task of constant expression removal. Examples of how compilers perform these operations are taken from the various systems used in the article.

Variable Allocation. Variables in high-level languages are an abstraction of memory cells or locations. One of the compiler's tasks is to assign the abstract variables into physical locations—either registers within the processor or locations within memory. Assignment strategies vary, but an easy and often-used strategy is to place *all* variables in memory. Easy, indeed, but wasteful of execution time in that it requires memory fetches for all HLL variables. Another assignment strategy is to assign as many variables to the registers as possible and then assign any remaining variables to memory; this method is typically sufficient, except when there is a limited number of registers, such as in the 68000. In these cases, the best assignment strategy is to assign registers to the variables which have the greatest use and then assign any remaining variables to memory. In examining the compilers and architecture used in this article, we find examples of all these methods.

In the unoptimized mode, VAX and Sparc compilers are among the many which take the easy approach and assign variables only to memory locations. In Figs. 87.6 and 87.7, the variable assignments are presented for the unoptimized and optimized options. Note that only one or two registers are used, both as scratch pads, in the unoptimized option, whereas the optimization assigns registers to all variables. The expected execution time savings is approximately 42 of the 50 memory references per loop iteration. That does not include additional savings caused by compact code. Detailed comparisons are not presented since the interpretation of architectural comparisons is highly subjective.

Unlike the VAX and Sparc compilers, the 68000 compiler assigns variables to registers in both the unoptimized and unoptimized options; these assignments are depicted in Figs. 87.7 and 87.8. Since there are only eight general-purpose data registers in the 68000 and two are assigned as scratch pads, only six of the program's ten

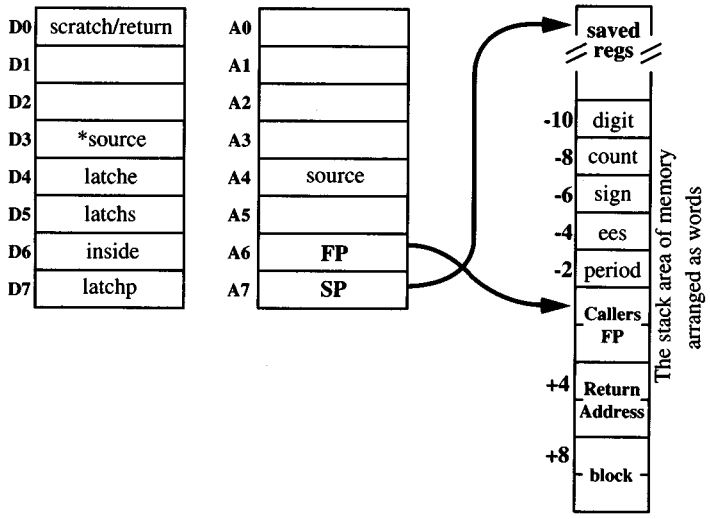

FIGURE 87.8 The stack area of the 68000's memory and the register assignments that the Think C® compiler made with global optimization *turned on*. The stack is shown just after the MOVEM instruction. The items in bold are as they would be after that instruction. This figure should be compared with Fig. 87.7.

variables can be assigned to registers. The question is how the 68000 compiler chose which variables to assign to registers and which to leave in memory. As might be expected, the compiler assigned registers based on their usage for the unoptimized option as well as the optimized. The exact counting strategy is unknown. However, a fair estimate, which yields the same assignment as the compiler, is to count only the variable's usage in the loop—the likely place for the program to spend most of its execution time. There are other ways to estimate the variable usage such as assigning weights to a reference based on its placement within a loop, its placement within a conditional (if-then-else) statement, etc. These estimates and how they are applied within a compiler can change the variable allocation as well as the efficiency of the code.

In the optimized case, a slightly different register assignment is used. This is because the optimizer created another character variable—*source—which it assigned to a register. The motivation for its creation and its assignment to a register is shown in the next section on constant expression removal.

Even though the assignment of variables to registers gives an improvement in performance, it is not always possible to assign a variable to a register. In C, one operation is to assign the address of a variable to a pointer-type variable (e.g., ip = & i). If i were assigned to a register, the operation would become invalid, because a register does not have a memory address. Although this example appears limited to the C language, the use of a variable's address is widespread when subroutine parameters are passed by reference. (Variables sent to a subroutine are either passed by reference, where the address of the variable is passed to the subroutine, allowing modifications to the original variable, or they are passed by value, where a copy of the variable is passed to the subroutine.) When a parameter is passed by reference its address must be obtained and passed to the subroutine, an action commonly found in most languages. This action compounds the task of selecting candidate variables for register assignment.

Constant Expression Removal. The task of allocating program variables to physical locations is accomplished by all compilers; we have shown that there are many ways to achieve this goal with varying ease or run-time performance. This section explores a compiler task which is done strictly for optimization—the removal of constant expressions. In exploring this task, we show strategies for the recognition of this optimization and also some caveats in their application.

Constant expressions are subexpressions within a statement which are unchanged during its execution. An obvious example is the expression *vector[x]* in the following conditional statement.

```
if (vector[x] < 100) && (vector[x] > 0) then ...
```

SPARC GCC no optimization

```
L2:   add 0, %g0, %o0          ; put 0 in o0 — i.e., assume a false result
      ld [%fp-92], %o1         ; get source from memory
      ldsb [%o1], %o1          ; get *source
      add 47, %g0, %o2         ; move 47 into o2
      subcc %o1, %o2, %g0      ; compare *source to '0'
      ble L5                   ; branch if less then, digit is false
      nop
      ld [%fp-92], %o1         ; get source again
      ldsb [%o1], %o1          ; get *source again
      add 57, %g0, %o2         ;
      subcc %o1, %o2, %g0      ; compare to '9'
      bg L5
      nop
      add 1, %g0, %o0          ; results is a true, change temporary
L5:                            ; jump target if result is false
      st %o0, [%fp-36]         ; move the result to variable.
```

SPARC GCC optimization

```
L2:   add 0, %g0, %o1          ; assume a false result from statement.
      ldsb [%o2], %o0          ; get *source save in register o0
      addcc -47, %o0, %g0      ; compare to '0'
      ble L5
      nop
      addcc -57, %o0, %g0      ; reuse *source and compare to '9'
      bg L5
      nop
      add 1, %g0, %o1          ; results is a true, so change temporary
L5:                            ; jump target if result is false
      add %o1, %g0, %l3        ; move the result to variable.

FIGURE 87.9 SPARC register assignments.

An astute coder who does not trust compilers would not allow two memory references for vector[x] in the same conditional statement and would rewrite the code by assigning vector[x] to a temporary variable and using that variable in the conditional. An astute compiler would also recognize the constant expression and assign vector[x] to a scratch pad register and use this register for both comparisons. This type of optimization, where small sections of code (typically one source line) are optimized, is called *peep-hole* optimization.

Within the example program, the assignment statement which checks if the character is a digit within the range from '0' to '9' is a statement which can benefit from this type of optimization. The C code lines, with the unoptimized and optimized SPARC assembly code, are listed below. Note that in addition to the constant expression removal the optimized code also assigns variables to registers.

```
digit = (*source >= '0') && (*source <= '9') ;
```

In translating this line on the SPARC, Fig. 87.9 shows the 32 registers visible at any moment in the window-blinding SPARC. The top 24 shift by 16 in a normal call. The eight globals remain the same. The shift of the registers is accompanied by copying SP to o6 and the call instruction puts the return address into o7. Accordingly, a call wipes out the caller's o7. Register g0 serves as a 0 (as a source) and as a *wastebasket* (as a destination). *ld* loads a longword, and *ldsb* sign-extends a byte into a longword. The instruction after a branch is executed whether the branch is taken or not (delayed branching). An instruction such as add 47, %g0, %o2 adds a constant to 0 and puts it in the register. This is equivalent to move.l #47, d4 on the 68000. An *add* or *sub* with *cc* appended changes the condition codes. To do a *compare*, one uses *addcc* or *subcc* and puts the result in g0 (the wastebasket).

The same type of constant expression can be found and removed with a global perspective, typically from within loops. A simple example is the best way to describe how they can be removed and to offer some caveats when the compiler cannot see the global picture. The following example code updates each element in the vector by adding the first element scaled by a constant y. An observation shows that the subexpression, vector[0] * y, is constant throughout all executions of the loop. An obvious improvement in code is to calculate the product of vector[0] * y outside of the loop and store its value in a temporary variable. This is done in the second example.

Constant expression present	**Constant expression removed**
for(i= 0 ; i < size; i++) { vector[i] = vector[i] + (vector[0] * y); }	temp = vector[0] * y ; for(i= 0 ; i < size; i++) { vector[i] = vector[i] + temp ; }

Ideally, the compiler should find and remove these constant expressions from loops, but this is not as obvious as it may seem. Consider the above example if the following line were inserted in the loop:

```
y = vector[i-1] + vector[i+1]
```

If each source line is taken in isolation, y appears constant, but y is dependent on the loop index i. Hence before removing constant expressions, the compiler must map the dependencies of each variable on the other variables and the loop index. Additionally, other not-so-obvious dependencies—such as when two pointers modify the same structure—are difficult to map and can result in erroneous object code. This is one of the difficulties in optimizing compiler operation and why its extent is limited.

A subtle example for constant expression removal is found in our sample program in the reference to *source. In these statements, the character referenced (addressed) by source is obtained from memory. The pointer (address) *source* is changed only at the bottom of the loop and the memory contents addressed by *source* are static. A global optimization should obtain the character once at the top of each pass of the loop and save on subsequent memory references throughout. The 68000 C compiler with the optimization option determined *source to be constant throughout the loop and assigned register D3 to hold its contents. This saved seven of the eight memory accesses to *source in each loop pass. The unoptimized 68000 option, the SPARC, and the VAX compilers did not use global constant expression removal and must fetch the operand from memory before its use.

The Problems. With optimization yielding more efficient code resulting in improved system performance, why would you not use it? Our favorite, among the several reasons, is the following quote from compiler documentation: "Compiling with optimization may produce incorrect object code." Problems are caused by assumptions used by the compiler which are not held by the programmer. For example, an optimization which assumes that memory contents do not change with time is erroneous for multi-tasking systems which share memory structures and also for memory- mapped I/O devices, where memory contents are changed by external events. For these cases, the data in register may not match the newer data in memory.

Additionally, HLL debuggers do not always work well with the optimization option since the one-to-one correspondence between HLL code and the object code may have been removed by optimization. Consider the reassignment of *source to a data register which is performed by the 68000 C compiler. If a debugger were to modify the contents of *source, then it would have to know about the two locations where it is stored: the memory and the register. Other types of optimizations which may cause problems are when unneeded variables are removed or when code is resequenced. If a HLL debugger tries to single-step through HLL code, there may not be corresponding assembly code, and its execution will appear erroneous.

High-Level Language and Assembly Language Relations

In comparing the various assembly languages from the compiler-generated code, we have not presented a full vocabulary of assembly languages or the minutiae of the underlying machines. Exploring only the code generated by the compilers may lead one to believe that all assembly languages and processor architectures are pretty much the same. This is not really the case. What we have shown is that compilers typically use the same assembly language instructions regardless of the underlying machines. The compiler writer's motivation for this apparent similarity is not because all architectures are the same, but because it is difficult—arguably even nonproductive—for the compiler to take advantage of the complex features which some CPU architectures offer. An argument may be made that compilers generate the best code by developing code rather independently of the

underlying architecture. Only in the final stages of code generation is the underlying platform's hardware architecture specifically considered [see Aho et al., 1986]. Differences in the architectures and assembly languages are plentiful; compilers typically do not and probably should not take advantage of such features.

The VAX is one of the best examples of an architecture having an almost extraordinary vocabulary, which is why it is often considered the prototypical *CISC* machine. What were the motivations for having this rich vocabulary if compilers simply ignore it? Early computer programming was accomplished through slightly alphabetized machine language—mnemonics for opcodes and sometimes for labels. Assembly language represented a vast improvement in readability, but even though FORTRAN, COBOL and Algol were extant at the same time as assembly language, their crude or absent optimization abilities led to the popular belief that *really good* programming was always done in assembly. This was accepted lore until early studies of optimization began to have an impact on commercial compilers. It is fair to say that this impact did not occur until the early 1980s. The VAX and the 68000 were products of the middle and late 1970s. It is no great surprise then to find that CISC computer architectures were designed to enable and assist the assembly language programmer. Such an objective promotes the inclusion of many complex features which the programmer might want to utilize. However, two facts emerged in the late 1970s which suggested that this rich vocabulary was provided at too high a cost for its benefit (for a more complete discussion of the emergence of the RISC concept, which really began with Seymour Cray in the 1960s, see [Feldman and Retter, 1994]):

- It was widely observed that the generation, testing, and maintenance of large programs in assembly code was extremely expensive when compared to doing the same task in a HLL. Furthermore, the compilers were improving to the point where they competed quite well with typical assembly code.
- Although initially not widely accepted, it was observed that the rich vocabulary made it very difficult to set up an efficient processing pipeline for the instruction stream. In essence, the assembly line was forced to handle too many special cases and slowed down under the burden. When the analysis of compiled programs showed that only a limited span of instructions was being used, these prescient designers decided to include only the heavily used instructions and to restrict even these instructions so that they would flow in unblemished, uniform streams through the production line. Because this focus resulted in noticeably fewer instructions— though that was not the essential objective—the machines were called *RISC*, a sobriquet that came out of a VLSI design project at Berkeley [Patterson and Hennessy, 1989].

Even though RISC hardware designs have increased performance in essence by reducing the complexity and richness of the assembly language, back at the ranch the unrepentant assembly language programmer still desired complex features. Some of these features were included in the assembly languages not as native machine instructions but essentially as a *high-level* extension to assembly language. A universal extension is the inclusion of *macros*. In some sense, a macro looks like a subroutine, but instead of a call to a distant block of code, the macro results in an inline insertion of a predefined block of code. Formally, a macro is a name which identifies a particular sequence of assembly instructions. Then, wherever the name of the macro appears in the text, it is replaced by the lines of code in the macro definition. In some sense, macros make assembly language a little more like a HLL. It makes code more readable, makes code maintenance a little faster and more reliable (fix the macro definition and you fix all of the invocations of the macro), and it speeds up the programmer's work.

Another extension to some assembly languages is extended mnemonics. Here the coder places a mnemonic in place of specific assembly language instructions; during code assembly the mnemonic is automatically translated to an optimal and correct instruction or instruction sequence. These free the coder from the management of low-level details, leaving the task to a program where it is better suited. Examples of extended mnemonics include *get* and *put*, which generate memory transfers by selecting the addressing mode as well as the specific instructions based on the operand locations. An increasingly common feature of assembly languages is the inclusion of structured control statements which emulate high-level language control-flow constructs such as: `if .. then .. else`, `for` loops, `while .. do` loops, `repeat .. until` loops, `break`, and `next`. These features remove the tedium from the programmer's task, allow for a more readable code, and reduce the cost of code development. An amusing set of examples are found in the assemblers that we have used on the SPARC. Architecture not withstanding, the assembly programmers wanted VAX assembly code! In spite of the absence of such constructs in the SPARC architecture, you find expressions such as CMP (compare) and MOV. Since these are easily translated to single lines of real SPARC code, their only raison d'etre

is to keep the old assembly language programmers happy. Presumably, those who knew not the VAX are not writing SPARC assembly code.

Summary

After all this fuss over compilers and how they generate assembly code, the obvious question is "Why bother to write any assembly code at all?" Three reasons why "some assembly may be required" follow.

- A human writing directly in assembly language is probably better than an optimizing compiler in extracting the last measure of resources (e.g., performance, hardware usage) from the machine. That inner loop—the code where the processor spends most of its execution cycles—may need to be hand-optimized to achieve acceptable performance. Real-time systems, where the expedient delivery of the data is as critical as its correctness, are another area where the required optimization may be greater than that achievable by compilers. The disparity in performance between human optimizers and their machine competitors comes from two special capabilities of the human programmer. These are the ability to know what the program will be doing—forward vision based on the program's intent rather than its structure—and the ability to take advantage of special quirks or tricks that have no general applicability. If you really need to extract this last full measure of performance, assembly language is the route. The cost of doing such hand-optimization is much greater than the hours spent in doing it and getting it debugged. Special quirks and tricks expressible only in assembly language will not translate to another machine and may disappear even in an "upgrade" of the intended processor.
- There is overhead in using HLL conventions, some of which can be eliminated by directly coding in assembly language. A typical embedded processor does not need the full span of HLL conventions and support, such as parameter passing or memory and stack allocation. One can *get away with* such dangerous things as global variables which do not have to be passed at all. By eliminating these conventions, increased performance is obtained. It should be pointed out that code written without such standard conventions is likely to be *very* peculiar, bug-prone, and hard to maintain.
- HLLs provide only limited access to certain hardware features of the underlying machine. Assembly language may be required to access these features. Again, this makes the code unportable and hard to maintain, but small stubs of assembly code may be required to invoke hardware actions which have no representation in a HLL. For example, setting or clearing certain bits in a special register may not be expressible in C. While any address can be explicitly included in C code, how do you reference a register which has no address? An example of such usage is writing or reading into or out of the status register. Some machines map these transactions into special addresses so that C could be used to access them, but for the majority of machines which do not provide this route to the hardware, the only way to accomplish these actions is with assembly code. To this end, some C compilers provide an inline assembler. You can insert a few lines of assembly language right in the C code, get your datum into or out of the special register, and move right back to HLL. Those compilers which provide this nonstandard extension also provide a rational paradigm for using HLL variable names in the assembly statements. Where necessary, the name gets expanded to allow the variable to be fetched and then used.

These reasons are special; they are not valid for most applications. Using assembly language loses development speed, loses portability, and increases the maintenance costs. While this caveat is well taken and widely accepted, at least for the present, few would deny the existence of situations where assembly language programming provides the best or only solution.

Defining Terms

Address error: An exception (error interrupt) caused by a program's attempt to access unaligned words or longwords on a processor which does not accommodate such requests. The address error is detected within the CPU. This contrasts with problems which arise in accessing the memory itself, where a logic circuit external to the CPU itself must detect and signal the error to cause the CPU to process the exception. Such external problems are called *bus errors.*

Assembler: A computer program (*application*) for translating an assembly-code text file to an *object* file suitable for linking to become an executable image (*application*) in machine language. Some HLL compilers include an inline assembler, allowing the programmer to drop into and out of assembly language in the midst of a HLL program.

CISC: *Complex instruction set computer,* a name to mean "not a RISC," but generally one that offers a very rich vocabulary of computer operations at a cost of making the processor which must handle this variety of operations more complex, expensive, and often slower than a RISC designed for the same task. One of the benefits of a CISC is that the code tends to be very compact. When memory was an expensive commodity, this was a substantial benefit. Today, speed of execution rather than compactness of code is the dominant force.

Compiler: A computer program (*application*) for translating a HLL text file to an *object* file suitable for linking to become an executable image (*application*) in machine language. Some compilers do both compilation and linking, so their output is an application.

Condition codes: Many computers provide a mechanism for saving the characteristics of results of a particular calculation. Such characteristics as *sign, zero result, carry* or *borrow,* and *overflow* are typical of integer operations. The program may reference these flags to determine whether to branch or not.

Disassembler: A computer program which can take an executable image and convert it back into assembly code. Such a reconstruction will be true to the machine language but normally loses much of the convenience factors, such as *macros* and name equivalencies, that an original assembly language program may contain.

Executable image: A program in pure machine code and including all of the necessary header information that allows an operating system to load it and start running it. Since it can be run directly, it is *executable.* Since it represents the original HLL or assembly program it is an *image.*

Flags: See *Condition codes.*

High-level language (HLL): A computer programming language generally designed to be efficient and succinct in expressing human programming concepts and paradigms. To be contrasted with low-level programming languages such as *assembly language.*

Linker: A computer program which takes one or more object files, assembles them into blocks which are to fit in particular blocks in memory, and resolves all external (and possibly internal) references to other segments of a program and to libraries of precompiled subroutines. The output of the linker is a single file called an *executable image* which has all addresses and references resolved and which the operating system can load and run on request.

Macro: A single line of code-like text, defined by the programmer, which the assembler will then recognize and which will result in an inline insertion of a predefined block of code. In most cases, the assembler allows both hidden and visible local variables and local labels to be used within a macro. Macros also appear in some HLLs, such as C (the *define* paradigm).

Object code: A file comprising an intermediate description of a segment of a program. The object file contains binary data, machine language for program, tables of offsets with respect to the beginning of the segment for each label in the segment, and data that would be of use to debugger programs.

RISC: *Reduced instruction set computer,* a name coined by Patterson et al. at the University of California at Berkeley to describe a computer with an instruction set designed for maximum execution speed on a particular class of computer programs. Such designs are characterized by requiring separate instructions for load/store operations and arithmetic operations on data in registers. The earliest computers explicitly designed by these rules were designs by Seymour Cray at CDC in the 1960s. The earliest development of the RISC philosophy of design was given by John Cocke in the late 1970s at IBM. See *CISC* above for the contrasting approach.

87.2 High-Level Languages

Ted G. Lewis

High-level languages (**HLLs**), also known as higher-order languages (**HOLs**), have a rich history in the annals of computing. From their inception in the 1950s until advances in the 1970s, HLLs were thought of as simple mechanical levers for producing machine-level instructions (see Table 87.3). Removing the details of the underlying machine, and automatically converting from a HLL statement to an equivalent machine-level statement, releases the programmer from the drudgery of the computer, allowing one to concentrate on the solution to the problem at hand.

TABLE 87.3 Each Statement of a HLL Translates into More than One Statement in a Machine-Level Language Such as Assembler

Language	Typical Number of Machine-Level Statements
FORTRAN	4–8
COBOL	3–6
Pascal	5–8
APL	12–15
C	3–5

Over the years, HLLs evolved into a field of study of their own, finding useful applications in all areas of computing. Some HLLs are designed strictly for solving numerical problems, and some for symbolic problems. Other HLLs are designed to control the operation of the computer itself, and yet even more novel languages have been devised to describe the construction of computer hardware. The number of human-crafted languages has multiplied into the hundreds, leading to highly special-purpose HLLs.

This evolution is best characterized as a shift away from the mechanical lever view of a HLL toward HLLs as notations for encoding **abstractions**. An abstraction is a model of the real world whose purpose is to de-emphasize mundane details and highlight the important parts of a problem, system, or idea. Modern HLLs are best suited to expressing such abstractions with little concern for the underlying computer hardware.

Abstraction releases the HLL designer from the bounds of a physical machine. A HLL can adopt a metaphor or arbitrary model of the world. Such unfettered languages provide a new interface between human and computer, allowing the human to use the machine in novel and powerful ways. Abstractions rooted in logic, symbolic manipulation, database processing, or operating systems, instead of the instruction set of a central processing unit (CPU), open the engineering world to new horizons. Thus, the power of computers depends on the expressiveness of HLLs.

To illustrate the paradigm shifts brought on by HLLs over the past 30 years, consider PROLOG, LISP, SQL, C++, and various operating system command languages. PROLOG is based on first-order logic. Instead of computing a numerical answer, PROLOG programs derive a conclusion. LISP is based on symbolic processing instead of numerical processing and is often used to symbolically solve problems in calculus, robotics, and artificial reasoning. SQL is a database language for manipulating large quantities of data without regard for whether it is numeric or symbolic. C++ is based on the **object-oriented paradigm**, a model of the world that is particularly powerful for engineering, scientific, and business problem solving.

None of these modern languages bear much resemblance to the machines they run on. The idea of a mechanical lever has been pushed aside by the more powerful idea of language as world builder. The kinds of worlds that can be constructed, manipulated, and studied are limited only by the HLL designer's formulation of the world as a paradigm.

In this section we answer some fundamental questions about HLLs: What are they? What do we mean by "high level"? What constitutes a paradigm? What are the advantages and disadvantages of HLLs? Who uses HLLs? What problems can be solved with these languages?

What Is a HLL?

At a rudimentary level, all languages, high and low, must obey a finite set of rules that specify both their syntax and semantics. **Syntax** specifies legal combinations of symbols that make up statements in the language. **Semantics** specifies the meanings attached to a syntactically correct statement in the language. To illustrate the difference between these two fundamental traits of all languages consider the statement, "The corners of the round table were sharp." This is syntactically correct according to the rules of English grammar, but what does it mean? Round tables do not have sharp corners, so this is a meaningless statement. We say it is semantically incorrect.

Statements of a language can be both syntactically and semantically correct and still be unsuitable for computer languages. For example, the phrase ". . . time flies . . ." has two meanings: one as an expression of clock speed, and the other as a reference to a species of insects. Therefore, we add one other requirement for computer languages: there must be only one meaning attached to each syntactically correct statement of the language. That is, the language must be *unambiguous*.

This definition of a computer language does not separate a HLL from all other computer languages. To understand the features of HLLs that make them different from other computer languages, we must understand the concepts of mechanical translation and abstraction. Furthermore, to understand the differences among HLLs, we must know how abstractions are used to change the computing paradigm. But first, what is a HLL in terms of translation and abstraction?

Defining the syntax of a HLL is easy. We simply write rules that define all legal combinations of the symbols used by the language. Thus, in FORTRAN, we know that arithmetic statements obey the rules of algebra, with some concessions to accommodate keyboards. A **metalanguage** is sometimes used as a kind of shorthand for defining the syntax of other languages, thus reducing the number of cases to be listed.

Defining the semantics of a language is more difficult because there is no universally accepted metalanguage for expressing semantics. Instead, semantics is usually defined by another program that translates from the HLL into some machine-level language. In a way, the semantics of a certain HLL is defined by writing a program that unambiguously maps each statement of the HLL into an equivalent sequence of machine-level statements. For example, the FORTRAN statement below is converted into an equivalent machine-level sequence of statements as shown to the right:

```
X = (B**2 – 4*A*C)      PUSH B
                        PUSH #2
                        POWER       //B**2
                        PUSH #4
                        PUSH A
                        PUSH C
                        MULT        //A*C
                        MULT        //4*(A*C)
                        SUB         //(B**2)–(4*(A*C))
                        POP   X     //X=
```

In this example, we assume the presence of a **pushdown stack** (see Fig. 87.10). The PUSH and POP operations are machine-level instructions for loading/storing the top element of the stack. The POWER, MULT, and SUB instructions take their arguments from the top of the stack and return the results of exponentiation, multiplication, and subtraction to the top of the stack. The symbolic expression of calculation in fortran becomes a sequence of low-level machine instructions which often bear little resemblance to the HLL program.

The foregoing example illustrates the mechanical advantage provided by FORTRAN because one FORTRAN statement is implemented by many

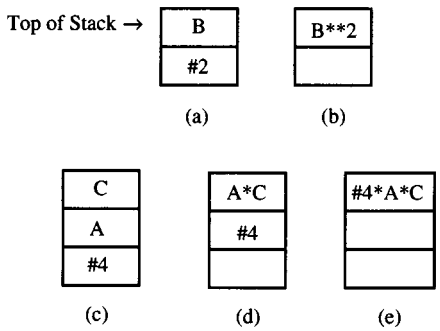

FIGURE 87.10 (a) The stack after PUSH #4 and PUSH B; (b) the stack after POWER; (c) the stack after PUSH #4, PUSH A, and PUSH C; (d) the stack after MULT; and (e) the stack after MULT a second time.

machine-level statements. Furthermore, it is much easier for a human programmer to read and write FORTRAN than to read and write machine-level instructions. One major advantage of a HLL is the obvious improvement in program creation and, later on, its maintenance. As the size of the program increases, this advantage becomes larger as we consider the total cost to design, code, test, and enhance an application program.

The FORTRAN program containing the example statement is treated like input data by the translating program which produces a machine-level sequence as output. In general, the input data is called the **source program**, and the resulting translated output is called the **object program**. There are two ways to obtain an object program from a source program: compiling and interpreting.

In most cases, FORTRAN is translated by a compiler program. The idea behind a **compiler** is that the translator converts the source program in its entirety before any part of the resulting object program is actually run on the computer. That is, compiling is a two-step process. In some HLLs, however, it is impossible to entirely convert a source program into an object program until the program executes.

Suppose the storage for A, B, and C in the previous example is not known at the time the program is compiled. We might want to allocate storage on-the-fly while the program is running, because we do not know in advance that the storage is needed. This is an example of **delayed binding** of a variable to its storage location in memory.

Powerful languages such as Pascal and C permit a limited amount of delayed binding, as illustrated in the following example written in Pascal. This example also illustrates a limited amount of abstraction introduced by the HLL.

```
type    rnumber = real;                 {template}
        rptr = ^rnumber;                {pointer}
var     Aptr, Bptr, Cptr : rptr;        {instance}
...
{later in the program...}
new(Aptr); read( Aptr^);                {binding}
new(Bptr); read( Bptr^);
new(Cptr); read( Cptr^);
X := (Bptr^) * (Bptr^) – 4 * (Aptr^) * (Cptr^);
```

The **type** statement is an abstraction that defines a template and access mechanism for the variables A, B, and C that are to be created on-the-fly. The **var** statement is similar to the DIMENSION statement in that it tells the translator to allocate space for three pointers: Aptr, Bptr, and Cptr. Each of these allocations will point to the actual values of A, B, and C according to the previous **type** statement.

The actual allocation of storage is not known until the program executes the sequence of new() functions in the body of the program. Each new() function allocates space according to the **type** statement and returns a pointer to that space. To access the actual values in these storage spaces, the up arrow, ^, is written following the variable name. Thus, the read() function gets a number from the keyboard and puts it in the space pointed to by the pointer variable. Similarly, the value of X is computed by indirect reference to each value stored at the newly allocated memory location.

The purpose of this example is to illustrate the use of delayed binding in a HLL. Languages such as LISP and C++ require even greater degrees of delayed binding because of the abstractions they support. When the amount of delayed binding becomes so great that very little of the program can be compiled, we say that the HLL is an *interpreted language*, and the translator becomes an **interpreter** rather than a compiler. This crossover is often obscure, so some HLLs are translated by both a compiler and an interpreter. BASIC is a classic example of a HLL that is both interpreted and compiled.

The purpose of delayed binding is to increase the level of a HLL by introducing abstraction. Abstraction is the major differentiating feature between HLLs and other computer languages. Without abstraction and delayed binding, most HLLs would be no more powerful than a macro **assembler** language. However, with abstraction, HLLs permit a programmer to express ideas that transcend the boundaries of the physical machine.

We can now define HLL based on the concept of abstraction. *A HLL is a set of symbols which obey unambiguous syntactic and semantic rules: the syntactic rules specify legal combinations of symbols, and the semantic rules specify legal meanings of syntactically correct statements relative to a collection of abstractions.*

The notion of abstraction is very important to understanding what a HLL is. The example above illustrates a simple abstraction, e.g., that of data structure abstraction, but other HLLs employ much more powerful abstraction mechanisms. In fact, the *level of abstraction* of a HLL defines how high a HLL is. But, how do we measure the level of a HLL? What constitutes a HLL's height?

How High Is a HLL?

There have been many attempts to quantify the level of a programming language. The major obstacle has been to find a suitable measure of level. This is further complicated by the fact that nearly all computer languages contain some use of abstraction, and therefore nearly all languages have a "level." Perhaps the most interesting approach comes from information theory.

Suppose a certain HLL program uses P operators and Q operands to express a solution to some problem. For example, a four-function pocket calculator uses $P = 4$ operators for addition, subtraction, multiplication, and division. The same calculator might permit $Q = 2$ operands by saving one number in a temporary memory and the other in the display register. In a HLL the number of operators and operands might number in the hundreds or thousands.

We can think of the set of P operators as a grab bag of symbols that a working programmer selects one at a time and places in a program. Suppose each symbol is selected with probability $1/P$, so the information content of the entire set is

$$-\sum_{1}^{P} \frac{1}{P} \log\left(\frac{1}{P}\right) = \log(P)$$

Assuming the set is not depleted, the programmer repeats this process P times, until all of the operators have been selected and placed in the program. The information content contributed by the operators is $P \log(P)$, and if we repeat the process for selecting and placing all Q operands, we get $Q \log(Q)$ steps again. The sum of these two processes yields $P \log(P) + Q \log(Q)$ symbols. This is known as Halstead's **metric** for *program length* [Halstead, 1977].

Similar arguments can be made to derive the volume of a program, V, level of program abstraction, L, and level of the HLL, l, as follows.

P = Number of distinct operators appearing in the program
p = Total number of operators appearing in the program
Q = Number of distinct operands appearing in the program
q = Total number of operands appearing in the program
N = Number of operators and operands appearing in the program
V = Volume = $N \log_2(P + Q)$
L = Level of abstraction used to write the program $\approx (2/P)^*(Q/q)$
l = Level of the HLL used to write the program = L^2V
E = Mental effort to create the program = V/L

Halstead's theory has been applied to English (*Moby Dick*) and a number of programs written in both HLL and machine-level languages. A few results based on the values reported in Halstead [1977] are given in Table 87.4. This theory quantifies the level of a programming language: *PL/I* is higher level than Algol-58, but lower level than English.

In terms of the mental effort required to write the same program in different languages, Table 87.4 suggests that a HLL is about twice as high level as assembler language. That is, the level of abstraction of *PL/I* is more than double that of assembler. This abstraction is used to reduce mental effort and solve the problem faster.

TABLE 87.4 Comparison of Languages in Terms of Level, l, and Programming Effort, E

Language	Level, l	Effort, E
English	2.16	1.00
PL/I	1.53	2.00
Algol-58	1.21	3.19
FORTRAN	1.14	3.59
Assembler	0.88	6.02

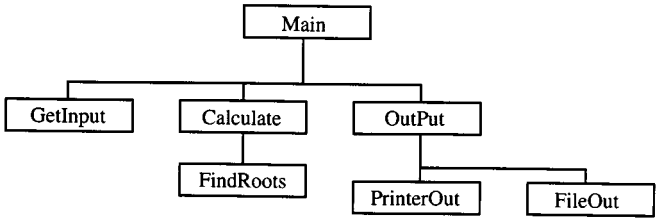

FIGURE 87.11 Hierarchical decomposition of procedural program.

HLLs and Paradigms

A programming **paradigm** is a way of viewing the world, e.g., an idealized model. HLLs depend on paradigms to guide their design and use. In fact, one might call HLL designers *paradigm engineers* because a good HLL starts with a strong model. Without such a model, the abstraction of a HLL is meaningless. In this section we examine the variety of paradigms embodied in a number of HLLs.

The **procedural paradigm** was the earliest programming paradigm. It is the basis of COBOL, FORTRAN, Pascal, C, BASIC, and most early languages. In this paradigm the world is modeled by an algorithm. Thus, an electrical circuit's behavior is modeled as a system of equations. The equations are solved for voltage, current, and so forth by writing an algorithmic procedure to numerically compute these quantities.

In the procedural paradigm a large system is composed of modules which encapsulate procedures which in turn implement algorithms. Hierarchical decomposition of a large problem into a collection of subordinate problems results in a hierarchical program structure. Hence, a large FORTRAN or C program is typically composed of a collection of procedures (subroutines in FORTRAN and functions in C) organized in layers, forming a tree structure, much like the organization chart of a large corporation (see Fig. 87.11).

Hierarchy is used in the procedural paradigm to encapsulate low-level algorithms, thus abstracting them away. That is, algorithm abstraction is the major contributor to leveling in a procedural HLL. Figure 87.11 illustrates this layering as a tree where each box is a procedure and subordinate boxes represent procedures called by parent boxes, the top-most box is the most abstract, and the lowest boxes in the tree are the most concrete.

Intellectual leverage is limited to control flow encapsulation in most procedural languages. Only the execution paths through the program are hidden in lower levels. While this is an improvement over machine-level languages, it does not permit much flexibility. For example, algorithmic abstraction is not powerful enough to easily express non-numerical ideas. Thus, a C program is not able to easily model an electronic circuit as a diagram or object that can be reasoned about, symbolically.

One of the reasons procedural HLLs fail to fully hide all details of an abstraction is that they typically have weak models of data. Data is allowed to flow across many boundaries, which leads to problems with encapsulation. In FORTRAN, BASIC, Pascal, and C, for example, access to any data is given freely through globals, parameter passing, and files. This is called **coupling** and can have disastrous implications if not carefully controlled.

One way to reduce coupling in a procedural language is to eliminate side-effects caused by unruly access to data. Indeed, if procedures were prohibited from directly passing and accessing data altogether, many of the problems of procedural languages would go away. An alternative to the procedural paradigm is the **functional paradigm**. In this model of the world, everything is a function that returns a value. Data is totally abstracted away so that algorithms are totally encapsulated as a hierarchical collection of functions. LISP is the most popular example of a functional HLL [Winston and Horn, 1989].

A LISP statement that limits data access usually consists of a series of function calls; each function returns a single value which is used as an argument by another function and so on until the calculation is finished. For example, the FORTRAN statement X = (B**2 – 4*A*C) given earlier is written in functional form as follows:

```
ASSIGN( X, MINUS(SQUARE(B), TIMES( 4, TIMES(A,C))))
```

This statement means to multiply A times C, then multiply the result returned by TIMES by 4, then subtract this from the result returned by SQUARE, and so forth. The final result is assigned to X.

One of the most difficult concepts to adjust to when using the procedural paradigm is the idea that all things are functions. The most significant implication of this kind of thinking is the replacement of loops with **recursion** and branches with guards. Recall that everything is a function that must return a value—even control structures. To illustrate, consider the functional (non-LISP) equivalent of the summation loop in FORTRAN, below.

```
S=0
DO 20 I=1,10          SUM( XList, N):
S=S+X(I)              N>0 |
20 CONTINUE                   N is N–1,
                              SUM is Head( XList ) + SUM (TAIL(Xlist), N)
```

The functional form will seem strange to a procedural programmer because it is higher level, e.g., more abstract. It hides more details and uses functional operators HEAD (for returning the first element of XList), TAIL (for returning the N–1 tail elements of XList), and **is** for binding a value to a name. Also, notice the disappearance of the loop. Recursion on SUM is used to run through the entire list, one element at a time. Finally, the guard N>0 prevents further recursion when N reaches zero.

In the functional program, N is decremented each time SUM is recursively called. Suppose N = 10, initially; then SUM is called 10 times. When N > 0 is false, the SUM routine does nothing, thus terminating the recursion. Interestingly, the additions are not performed until the final attempt to recurse fails. That is, when N = 0, the following sums are collected as the nested calls unwind:

```
SUM     : XList(10)
        : SUM+Xlist(9)
 …      …
        : SUM+XList(1)
```

Functional HLLs are higher level than procedural languages because they reduce the number of symbols needed to encode a solution as a program. The problem with functional programs, however, is their high execution overhead caused by the delayed binding of their interpreters. This makes LISP and PROLOG, for example, excellent **prototyping** languages but expensive production languages. LISP has been confined to predominantly research use; few commercial products based on LISP have been successfully delivered without first rewriting them in a lower-level language such as C. Other functional languages such as PROLOG and STRAND88 have had only limited success as commercial languages.

Another alternative is the **declarative paradigm.** Declarative languages such as Prolog and STRAND88 are both functional and declarative. In the declarative paradigm, solutions are obtained as a byproduct of meeting limitations imposed by constraints. Think of the solution to a problem as the only (first) solution that satisfies all constraints declared by the program.

An example of the declarative paradigm is given by the simplified PROLOG program below for declaring an electrical circuit as a list of constraints. All of the constraints must be true for the circuit() constraint to be true. Thus, this program eliminates all possible R, L, C, V circuits from consideration, except the one displayed in Fig. 87.12. The declarations literally assert that Circuit(R, L, C, V) is a thing with "R connected to L, L connected to C, L connected to R, C connected to V, and V connected to R." This eliminates "V connected to L," for example, and leaves only the solution shown in Fig. 87.12.

```
Circuit(R, L, C, V) :
        Connected(R, L)
        Connected(L, C)
        Connected(L, R)
        Connected(C, V)
        Connected(V, R)
```

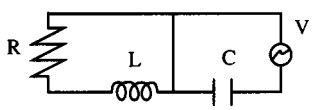

FIGURE 87.12 Solution to declaration for Circuit(R, L, C, V).

One interesting feature of declarative languages is their ability to represent infinite calculations. A declaration might constrain a solution to be in an infinite series of numbers, but the series may not need to be fully computed to arrive at an answer.

Another feature of such languages is their ability to compute an answer when in fact there may be many answers that meet all of the constraints. In many engineering problems, the first answer is as good as any other answer.

The declarative paradigm is a very useful abstraction for unbounded problems. Adding abstraction to the functional paradigm elevates declarative languages even higher. Solutions in these languages are arrived at in the most abstract manner, leading to comparatively short, powerful programs.

Perhaps the most common use of declarative languages is for construction of expert systems [Smith, 1988]. These kinds of applications are typically diagnostic. That is, they derive a conclusion based on assertions of fact. An electrical circuit board might be diagnosed with an expert system that takes symptoms of the ailing board as its input and derives a conclusion based on rules of electronic circuits—human rules of thumb given it by an experienced technician—and declarative reasoning. In this example, the rules are constraints expressed as declarations. The expert system program may derive more than one solution to the problem because many solutions may fit the constraints.

Declarative languages have the same inefficiencies as functional languages. For this reason, expert system applications are usually developed in a specialized declarative system called an *expert system shell*. A shell extracts the declarative or constraint-based capability from functional languages such LISP and PROLOG to improve efficiency. Often it is possible to simplify the shell so that early binding is achieved, thus leading to compiling translators rather than interpreters. Very large and efficient expert systems have been developed for commercial use using this approach.

Yet another paradigm used as the basis of modern languages such as C++ and Object Pascal is the *object-oriented programming (OOP) paradigm* [Budd, 1991]. OOP merges data and procedural abstractions into a single concept. In OOP, an object has both storage capacity and algorithmic functionality. These two abstractions are encapsulated in a construct called a **class**. One or more objects can be created by cloning the class. Thus, an **object** is defined as an instance of a class [Lewis, 1991].

OOP actually represents a culmination of ideas of procedural programming that have evolved over the past three to four decades. It is a gross oversimplification to say that OOP is procedural programming, because it is not, but consider the following evolution.

Procedure = Algorithm + Data Structures
Abstract Data Structure = Implementation Part + Interface Part
Class = Abstract Data Structure + Functions
Object = Class + Inheritance

The first "equation" states that a procedure treats algorithms and data separately, but the programmer must understand both the data structure and the algorithms for manipulating the data structures of an application. This separation between algorithms and data is a key feature of the procedural paradigm. During the 1970s structured programming was introduced to control the complexity of the procedural paradigm. While only partially successful, structured programming limited procedures to less powerful control structures by eliminating the GOTO and programs with labels. However, structured programming did not go far enough.

The next improvement in procedural programming came in the form of increased abstraction, called **ADT** (abstract data structures). An ADT separates the interface part of a procedure from its implementation part. Modula II and Ada™ were designed to support ADTs in the form of modules and packages. The interface part is an abstraction that hides the details of the algorithm. Programming in this form of the procedural paradigm reduces complexity by elevating a programmer's thoughts to a higher level of abstraction, but it still does not remove the problem of how procedures are related to one another.

Classes group data together into clusters that contain all of the functions that are allowed to access and manipulate the data. The class concept is a powerful structuring concept because it isolates the data portion of a program, thus reducing coupling and change propagation.

The class construct invented by the designers of Simula67 enforced the separation of interface and implementation parts of a module, and in addition introduced a new concept. Inheritance is the ability to do what another module can do. Thus, inheritance relates modules by passing on the algorithmic portion of a module

TABLE 87.5 Procedural versus Object-Oriented Thinking

Procedural	Object-Oriented
Instructions and data are separated.	Objects consist of both data and instructions.
Software design is linear, e.g., it progresses from design through coding and testing. This means change is difficult to accommodate.	Software design is interactive with coding and testing. This means change is easier to accommodate.
Programs are top-down decompositions of procedures, e.g., trees.	Programs are networks of objects that send messages to one another without concern for tree structure.
Program components are the real world, thus making programming more of a magic art.	Program components have abstractions of corres-pondence with the real world, thus making programming more of a discipline.
New programs are mostly custom built with little reuse from earlier programs. This leads to high construction costs and errors.	New programs are mostly specializations of earlier programs through reuse of their components. This leads to low construction costs and higher quality.

to other modules. Inheritance in a programming language like SmallTalk, Object Pascal, and C++ means even greater abstraction because code can be reused without being understood.

An object is an instance of a class. New objects inherit all of the functions defined on all of the classes used to define the parent of the object. This simple idea, copied from genetics, has a profound impact on both design and programming. It changes the way software is designed and constructed, i.e., it is a new paradigm.

Object-oriented thinking greatly differs from procedural thinking (see Table 87.5). In OOP a problem is decomposed into objects which mimic the real world. For example, the objects in Fig. 87.12 are resistor, inductor, capacitor, and voltage source. These objects have real-world features (state) such as resistance, inductance, capacitance, and voltage. They also have behaviors defined by sinusoidal curves or phase shifts. In short, the real-world objects have both state and function. The state is represented in a program by storage and the function is represented by an algorithm. A resistor is a program module containing a variable to store the resistance and a function to model the behavior of the resistor when it is subjected to an input signal.

The objects in an object-oriented world use inheritance to relate to one another. That is, objects of the same class all inherit the same functions. These functions are called **methods** in SmallTalk and **member functions** in C++[Ellis and Stroustrup, 1990]. However, the state or storage attributes of objects cloned from the same class differ. The storage components of an object are called **instance variables** in SmallTalk and **member fields** in C++.

The wholism of combining data with instructions is known as *ADTs*; the concept of sending messages instead of calling procedures is the *message-passing paradigm*; the concept of interactive, nonlinear, and iterative development of a program is a consequence of an object's **interface specification** being separated from its **implementation part**; the notion of modeling the real world as a network of interacting objects is called *OOD* (object-oriented design); the concept of specialization and **reuse** is known as *inheritance;* and OOP is the act of writing a program in an object-oriented language while adhering to an object-oriented view of the world.

Perhaps an analogy will add a touch of concreteness to these vague concepts. Suppose automobiles were constructed using both technologies. Table 87.6 repeats the comparison of Table 87.5 using an automobile design and manufacturing analogy.

We illustrate these ideas with a simple C++ example. The following code declares a class and two subclasses which inherit some properties of the class. The code also shows how interface and implementation parts are separated and how to override unwanted methods. Figure 87.13 depicts the inheritance and class hierarchy for this example.

```
class Node{
   public:                          //The interface part...
        Node() {}                   //Constructor function
        virtual ~Node() {}          //Destructor function
        virtual int eval() { error(); return 0;}    //Override this function
}
```

TABLE 87.6 Analogy with an Automobile Manufacturer

Procedural	Object-Oriented
Vendors and Assemblers work from their own plans. There is little coordination between the two.	Vendors and Assemblers follow the same blueprints; thus the resulting parts are guaranteed to fit together.
Manufacturing and design are sequential processes. A change in the design causes everyone to wait while the change propagates from designers to workers on the production line.	Design interacts with production. Prototypes are made and discarded. Production workers are asked to give suggestions for improvement or on how to reduce costs.
Changes on the manufacturing floor are not easily reflected as improvements to the design on the drafting board.	Changes in implementation rarely affect the design as interfaces are separated from implementation. Thus, the materials may change, but not the need for the parts themselves.
New cars are designed and constructed from the ground up, much like the first car ever produced.	New cars are evolutionary improvement to existing base technology, plus specializations that improve over last year's model.

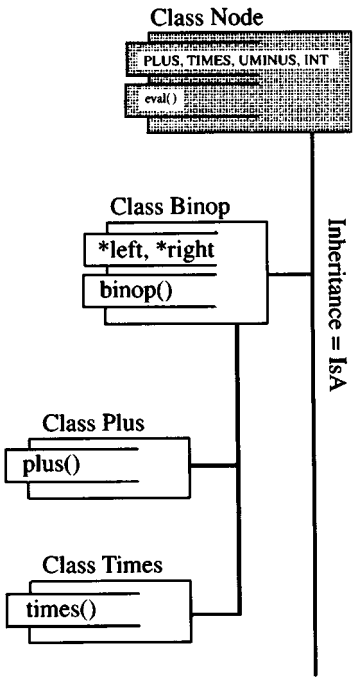

FIGURE 87.13 Partial class hierarchy for a C++ program that simulates a pocket calculator. The shaded Node class is an abstract class that all other classes use as a template.

The Node class consists of public functions that are to be overridden by descendants of the class. We know this because the functions are virtual, which in C++ means we expect to replace them later. Therefore we call this an **abstract class**. Also, Node() is the name of both the constructor and destructor member functions. A constructor is executed when a new object is created from the class, and the destructor is executed when the object is destroyed. These two functions take care of initialization and garbage collection which must be performed before and after dynamic binding of objects to memory space. Figure 87.13 shows this Node as an abstract class from which all other subclasses of this application are derived.

Now, we create a subclass that inherits the properties (interface) of Node() and adds a new property, e.g., Binop. Binop is an abstraction of the binary operators of a pocket calculator, which is the real-world object being simulated by this example program. The expression to be calculated is stored in a binary tree, and Binop sprouts a new left and right subtree when it is created and deletes this subtree when it is disposed.

```
class Binop : public Node {          //Derive Binop from Node
  public:
      Node *left, *right;            //Pointers to left and right subtrees
      ~Binop() { delete left; delete right;} //Collect garbage
      Binop( Node *lptr, Node *rptr) {left = lptr; right=rptr;}
}
```

Next, we define further specializations of Binop: one for addition of two numbers, Plus(), and the other for multiplication, Times(). The reader can see how to extend this to other operators.

```
class Plus: public Binop {
  public:                            //Add member functions to Binop
      Plus( Node *lptr, Node *rptr) : Binop( lptr, rptr) {} //Use Binop
      int eval() { return left->eval()+right->eval();}        //Do Addition
};
class Times: public Binop {
  public:                            //Add member functions to Binop
      Times( Node *lptr, Node *rptr) : Binop( lptr, rptr) {}  //Use Binop
      int eval() { return left->eval()*right->eval();}            //Do Multiply
};
```

In each case, the special-purpose operations defined in Plus() and Times() reuse Binop's code to perform the pointer operations. Then they add a member function eval() to carry out the operation. This illustrates reuse and the value of inheritance.

At this point, we have a collection of abstractions in the form of C++ classes. An object, however, is an instance of a class. Where are the objects in this example? We must dynamically create the required objects using the new function of C++.

```
Node *ptr = new Plus ( lptr, rptr );      //Create an object and point to it
int result = ptr->eval();                 //Add
delete ptr;
```

The foregoing code instantiates an object that ptr points to, sends a message to the object telling it to perform the eval() function, and then disposes of the object. This example assumes that lptr and rptr have already been defined elsewhere.

Clearly, the level of abstraction is greatly raised by OOP. Once a class hierarchy is established, the actual data processing is hidden or abstracted away. This is the power of the OOP paradigm.

The pure object-oriented languages such as SmallTalk80 and CLOS have achieved only modest success due to their unique syntax and heavy demands on computing power. Hybrid HLLs such as Object Pascal and C++ have become widely accepted because they retain the familiar syntax of procedural languages, and they place fewer demands on hardware.

Although OOP is an old technology (circa 1970), it began to gain widespread acceptance in the 1990s because of the growing power of workstations, the increased use of graphical user interfaces, and the invention of hybrid object-oriented languages such as C++. Typically, C++ adds 15–20% overhead to an application program due to delayed binding of objects to their methods. Given that the power of the hardware increases more than 20% per annum, this is an acceptable performance penalty. In addition, OOP is much more suitable for the design of graphical user-interface-intensive applications because the display objects correspond with programming objects, thus simplifying design and coding. Finally, if you know C, it is a small step to learn C++.

Summary and Conclusions

HLLs: What are they? What do we mean by "high level"? What constitutes a paradigm? What are the advantages and disadvantages of HLLs? Who uses HLLs? What problems can be solved with these languages?

HLLs are human inventions that allow humans to control and communicate with machines. They obey rules of syntax and unambiguous semantics which are combined to express abstract ideas. HLLs are called "high level" because they express abstractions.

We have chosen to define the level of a HLL in terms of the information content of its syntax and semantics. The Halstead measure of language level essentially says that the higher a HLL is, the fewer symbols are needed to express an idea. Thus, if language A is higher than language B, a certain program can be expressed more succinctly in A than B. This is clearly the case when comparing HLLs with various machine-level languages, where a single statement in the HLL requires many statements in the machine-level language.

HLLs differ from one another in the abstractions they support. Abstract views of the world are called paradigms, and the guiding principle of any HLL is its programming paradigm.

We have compared the following programming paradigms: procedural, functional, declarative, and object-oriented. Procedural programming has the longest history because the first HLLs were based on low-level abstractions that are procedural. FORTRAN, COBOL, C, and Pascal are classical examples of the procedural languages.

Functional and declarative languages employ higher levels of abstraction by restricting the world view to simple mechanisms: mathematical functions and constraints. It may seem odd that such restrictions increase the level of abstraction, but languages like LISP and PROLOG hide much of the detail found to be necessary in the procedural paradigm. This increases the measure of level defined in this section.

Object-oriented programming embraces a novel abstraction that seems to fit the world of computing: objects. In this paradigm, the world is modeled as a collection of objects that communicate by sending messages to one another. The objects are related to each other through an inheritance mechanism that passes on the algorithmic behavior from one class of objects to another class. Inheritance permits reuse and thus raises the programming abstraction to a level above previous paradigms.

The future of HLLs is uncertain and unpredictable. It is unlikely that anyone in 1970 would have predicted the acceptance of functional, declarative, or object-oriented paradigms in the 1990s. Therefore, it is unlikely that the following predictions bear much relationship to computing in the year 2000. However, it is instructive to project a few scenarios and explain their power.

Functional and declarative programming result in software that can be mathematically analyzed, thus leading to greater assurances that the software actually works. Currently these paradigms consume too much memory and machine cycles. However, in the year 2000, very high-speed machines will be commonplace. What will we use these powerful machines for? One answer is that we will no longer be concerned with the execution efficiency of a HLL. The drawbacks of functional and declarative languages will fade, to be replaced by concern for the correctness and expressiveness of the HLL. If this occurs, functional and declarative languages will be the preferred HLLs because of the elevated abstractions supported by the functional and declarative paradigms. Applications constructed from these HLLs will exhibit more sophisticated logic, communicate in non-numeric languages such as speech and graphics, and solve problems that are beyond the reach of current HLLs.

Object-orientation is an appealing idea whose time has come. OOP will be to the 1990s what structured programming was to the 1970s. Computer hardware is becoming increasingly distributed and remote. Networks of workstations routinely solve problems in concert rather than as stand-alone systems. This places greater demands on flexibility and functionality of applications. Consider the next step beyond objects—servers:

$$\text{Server} = \text{Object} + \text{Process}$$

A server is an object that is instantiated as an operating system process or task. The server sends messages to other servers to get work done. The servers "live" on any processor located anywhere on the network. Software is distributed and so is the work. OOP offers the greatest hope for distributing applications in this fashion without loss of control. Should this scenario come true, the OOP paradigm will not only be appropriate, but contribute to greater HLL leverage through reusable objects, distributed servers, and delayed binding of methods to these servers.

Object-oriented languages, databases, and operating systems are on the immediate horizon. Graphical user-interface servers such as X-Windows already exist, lending credibility to this scenario. At least for the near future, HLLs are most likely to become identical with the object-oriented paradigm.

Defining Terms

Abstract class: A class consisting of only an interface specification. The implementation part is unspecified, because the purpose of an abstract class is to establish an interface.

Abstraction: Abstraction in computer languages is a measure of the amount of separation between the hardware and an expression of a programming idea. The level of abstraction of a high-level language defines the level of that language.

ADT: An abstract data type (ADT) is a software module that encapsulates data and functions allowed to be performed on that data. ADTs also separate the interface specification of a module from the implementation part to minimize coupling among modules.

Assembler: A computer program for translating symbolic machine instructions into numerical machine instructions. Assemblers are considered low-level languages for programming a computer.

Class: A specification for one or more objects that defines state (data) and functions (algorithms) that all objects may inherit when created from the class. A class is a template for implementing objects.

Compiler: A computer program that translates the source program statements of a high-level language into lower-leveled object program statements. Compilers differ from interpreters in that they do not immediately perform the operations specified in the source program. Instead, a compiler produces an object program that in turn performs the intended operations when it is run.

Coupling: A measure of the amount of interaction between modules in a computer program. High coupling means that a change in one module is likely to affect another module. Low coupling means there is little impact on other modules whenever a change is made in one module.

Declarative paradigm: A programming paradigm in which the world is modeled as a collection of rules and constraints.

Delayed binding: The process of postponing the meaning of a programming object until the object is manipulated by the computer. Delayed binding is used by interpreters and compilers, but more often it is employed by interpreters.

Functional paradigm: A programming paradigm in which the world is modeled as a collection of mathematical functions.

HLL (also **HOL**)**:** A HLL is a set of symbols which obey unambiguous syntactic and semantic rules: the syntactic rules specify legal combinations of symbols, and the semantic rules specify legal meanings of syntactically correct statements relative to a collection of abstractions.

Implementation part: The definition or algorithm for a programming module which gives the details of how the module works.

Instance variables: Data encapsulated by an object.

Interface specification: The definition of a programming module without any indication of how the module works.

Interpreter: A computer program that translates and performs the intended operations of the source statements of a high-level language program. Interpreters differ from compilers in that they immediately perform the intended operations specified in the source program, and they do not produce an object program.

Member fields: Instance variables of a C++ object.

Member functions: Methods defined on a C++ object.

Metalanguage: A formal language for defining other languages. A metalanguage is typically used to define the syntax of a high-level language.

Methods: Functions allowed to be performed on the data of an object.

Metric: A measure of a computer program's complexity, clarity, length, difficulty, etc.

Object: An instance of a class. Objects have state (data) and function (algorithms) that are allowed to manipulate the data.

Object-oriented paradigm: A programming paradigm in which the world is modeled as a collection of self-contained objects that interact by sending messages. Objects are modules that contain data and all functions that are allowed to be performed on the encapsulated data. In addition, objects are related to one another through an inheritance hierarchy.

Object program: Machine form of a computer program, which is the output from a translator.

Paradigm: An idealized model, typically used as a conceptual basis for software design. Programming paradigms dictate the approach taken by a programmer to organize, and then write, a computer program.

Procedural paradigm: A programming paradigm in which the world is modeled as a collection of procedures which in turn encapsulate algorithms.

Prototyping: A simplified version of a software system is a prototype. Prototyping is the process of designing a computer program through a series of versions; each version becomes a closer approximation to the final one.

Pushdown stack: A data structure containing a list of elements which are restricted to insertions and deletions at one end of the list, only. Insertion is called a push operation and deletion is called a pull operation.

Recursion: A procedure is called recursive if it calls itself.

Reuse: Programming modules are reused when they are copied from one application program and used in another. Reusability is a property of module design that permits reuse.

Semantics: The part of a formal definition of a language that specifies the meanings attached to a syntactically correct statement in the language.

Source program: Symbolic form of a computer program, which is the input to a translator.

Syntax : The part of a formal definition of a language that specifies legal combinations of symbols that make up statements in the language.

87.3 Data Types and Data Structures

Johannes J. Martin

The study of *data types* and *data structures* is a part of the discipline of computer programming. The terms refer to the two aspects of data objects: their usage and their implementation, respectively. The study of data *types* deals with the *identification* of (abstract) data objects in the context of a programming project and with methods of their more or less formal *specification*; the study of data *structures*, on the other hand, is concerned with the *implementation* of such objects using already existing data objects as raw material.

Concretely, the area addresses a basic problem of programming: the reduction of complex objects, such as vectors, tensors, text, graphic images, sound, functions, directories, maps, corporate organizations, models of ecosystems or machinery, or anything else that a program may have to deal with, to the only native objects of digital computers: arrays of binary digits (bits). The fundamental problem of this reduction is managing program complexity. Two organizational tools are essential to its solution: abstraction and hierarchical structuring. Abstraction refers to the separation of *what* computational objects are used for from *how* they are reduced to (i.e., implemented by means of) simpler ones. Hierarchical structuring refers to breaking this reduction up into small manageable steps. Through several steps of abstraction more and more complex objects are constructed, each one reduced to the previous, simpler generation of objects. This process ends when the desired objects have been composed.

Abstract Data Types

An **abstract data type** is one or more *sets* of computational objects together with some basic operations on those objects. One of these sets is defined by the type either by enumeration or by generating operations and

is called the *carrier set* of the type. Customarily it is given the same name as the type. All other sets are called auxiliary sets of the type. In exceptional cases a type may have more than one carrier set.

The heart of the specification of an abstract data type is the definition of its functions, their syntax and semantics. Their syntax is specified by their **functionalities** and their semantics by algebraic axioms. [For more details see, e.g., Martin, 1986].

With sets A and B, the expression $A \rightarrow B$ denotes the set of all functions that have the domain A and the codomain B. Functions $f \in A \rightarrow B$ (traditionally denoted by $f: A \rightarrow B$) are said to have the functionality $A \rightarrow B$.

The collection of basic operations does not need to be minimal. It should, however, be rich enough so that all other operations that one might wish to perform on the objects of the carrier set can be expressed exclusively by these basic operations. The type *Boolean*, for example, consists of the set of Boolean values, Boolean = {true, false}, with, e.g., the operations *not*, *and*, and *or*.

In general, things are not quite this simple. To be useful for programming purposes, even the type Boolean requires at least one additional function. This function, called a *conditional expression*, provides a choice of one of two given values depending on a given Boolean value. It has the form:

f: Boolean 3 SomeType 3 SomeType → SomeType

and, with a, b ∈ SomeType, is defined by:

f (true, a, b) = a and
f (false, a, b) = b

The syntactical form of conditional expressions varies for different programming languages that provide this construct. For example, in the language C it has the form:

```
Boolean ? SomeType : SomeType.        /* with the result type of SomeType */
```

The set SomeType is an auxiliary set of the type Boolean.

Fundamental Data Types

The fundamental types listed next are supported by almost all modern high-level programming languages (reference books on Pascal, Modula II, C, and Ada are listed among the references at the end of this section):

Integer, Real (sometimes called Float), Character, and Boolean

Since their carrier sets are ordered (one of the operations of these types is ≤), these types are also called scalar types. All provide operations for comparing values; in addition, Integer and Real come equipped with the usual arithmetic operations (+, –, *, /) and Boolean with the basic logical operations (not, and, or). Most computers support these operations by hardware instructions. Thus, while bit arrays are the original native objects of a digital computer, the fundamental scalar types may be viewed as the given elementary building blocks for the construction of all other types.

Type Constructors

Enumerated Types

Beginning with Pascal, modern languages provide a rather useful constructor for scalar types, called enumerated types. Enumerated types have finite (small) carrier sets that the programmer defines by enumerating the constants of the type (specified as identifiers). For example, if the type Boolean were not available in Pascal, its carrier set could simply be defined by:

type Boolean = (false, true)

In Pascal, enumerated types are automatically equipped with operations for comparison as well as with the functions succ and pred, i.e., successor and predecessor. In the above example, succ(false) = true, pred(true) = false; succ(true) and pred(false) are not allowed.

Records

Values of scalar types can be arranged into tuples by a construct called a *record* (also called a *structure* in some languages). Into programming languages, records introduce the equivalent of the Cartesian product. Tuples can be viewed as abstract data types. Consider pairs as an example:

The type *Pairs:*

Carrier set:	*Pairs*,
Auxiliary sets:	*A, B*;
Operations:	pair $\in$ *A* 3 *B* $\rightarrow$ *Pairs*;
	first $\in$ *Pairs* $\rightarrow$ *A*;
	scnd $\in$ *Pairs* $\rightarrow$ *B*;

where $\forall$ a $\in$ *A*, b $\in$ *B*

first (pair (a, b)) = a; scnd (pair(a, b)) = b;

Using Pascal notation this type is defined by:

type Pairs = **record** first: A; scnd: B **end**

By providing the so-called field names, first and scnd, the programmer implicitly chooses the names for the selector functions. Pascal does not provide the function "pair." Instead, it permits the declaration of variables of type Pairs whose component values may be set (by assignment) and retrieved:

p: Pairs;	{declaration of p as a variable of type Pairs}
p.first := a; p.scnd := b;	{p now has the value of "pair(a,b)" above}
if p.first = x then . . . else . . .	{p.first is Pascals notation for "first(p)" }

The sets A and B can be of any type including records. Furthermore, since there is no restriction on the number of fields records may have, they can represent arbitrary tuples.

Arrays

Arrays permit the construction of simple function spaces, I $\rightarrow$ A. The domain I, a scalar type—in some languages restricted to a subset {0, 1, ..., *n*} of the integers—is called the index set of the array; A is an arbitrary type. In Pascal, the mathematical notation f $\in$ I $\rightarrow$ A assumes the form:

f**: array**[I] **of** A

I has to be a finite scalar type (e.g., 0 .. 40). The function f can now be defined by associating values of type A with the values of the domain I using the assignment operation:

f[i] := a; where i $\in$ I and a $\in$ A

Application of f to a value j $\in$ I is expressed by f[j]. This expression has a value of type A and can be used as such.

As with records, Pascal allows the naming of the function space I $\rightarrow$ A by the definition:

type myFunctions = **array**[I] **of** A

and the subsequent declaration of a specific function (array) by:

f : myFunctions

Functions of several arguments are represented by so-called multidimensional arrays:

f $\in$ I_1 3 . . . 3 I_n $\rightarrow$ A

is defined by

f : **array**[I_1, . . ., I_n] **of** A

Variant Records

Variant records model *disjoint* (also called *tagged*) *unions*. In contrast to an ordinary union C = A ∪ B, a disjoint union D = A + B is formed by tagging the elements of A and B before forming D such that elements of D can be recognized as elements of A or of B. In programming, this amounts to creating variables that can be used to house values of both type A and type B. A tag field, (usually) part of the variable, is used to keep track of the type of the value currently stored in the variable. In Pascal, D = A + B is expressed by:

```
type    tagType = (inA, inB) {an enumerated type};
        D       = record
                  case kind: tagType of
                    inA: (aValue: A);
                    inB: (bValue:B);
                  end.
```

Variables of type D are now used as follows:

```
            mix:    D;              {mix is declared to be of type D}
mix.kind            :=      inA;
mix.aValue          :=      a;
. . .
if mix.kind = inA
   then {do something with mix.aValue, which is of type A}
   else {do something with mix.bValue, which is of type B}
```

Conceptually, only one of the two fields, mix.aValue or mix.bValue, exists at any one time. The proper use of the tag is policed in some languages (e.g., Ada) and left to the programmer in others (e.g., Pascal).

An Example of a User-Defined Abstract Data Type

Most carrier sets are assumed to contain a distinguished value: *error*. *Error* is not a proper computational object: a function is considered to compute *error* if it does not return to the point of its invocation due to some error condition. Functions are called **strict** if they compute the value *error* whenever one or more of their arguments have the value *error*.

The following example models a cafeteria tray stack with the following operations:

1. create a new stack with n trays;
2. remove a tray from a stack;
3. add a tray to the stack;
4. check if the stack is empty;

Specification:

```
Cts (cafeteria tray stacks)          is the carrier set of the type;
Boolean and Integer                  are auxiliary sets;
newStack, remove, add, isEmpty       are the operations of the type
where
        newStack        ∈ Integer    → Cts; {create a stack of n trays}
        remove, add     ∈ Cts        → Cts;
        isEmpty         ∈ Cts        → Boolean;
```

Axioms (logical expressions that describe the semantics of the operations): All functions are strict and, for all non-negative values of n,

1. remove (newStack(n)) = if n = 0 then *error* else newStack(n − 1);
2. add(newStack(n)) = newStack(n + 1);
3. isEmpty (newStack(n)) = (n = 0).

These axioms suffice to describe the desired behavior of Cts exactly, i.e., using these axioms, arbitrary expressions built with the above operations can be reduced to *error* or newStack(m) for some m.

Implementation:
For the representation of Cts (i.e. its data structure) we will choose the type Integer.

```
type      Cts = integer;

function newStack(n: Integer):Integer;
    begin if n < 0     then error ('n must be >= 0')     else newStack := n end;

function remove (s: Cts):Cts;
    begin if s = 0     then error ('stack empty')        else remove := s - 1 end;

function add (s: Cts):Cts;                    begin add := s + 1 end;

function isEmpty (s: Cts):Boolean;            begin isEmpty := (s = 0) end;
```

Above, "error" is a function that prints an error message and stops the program.

Dynamic Types

The carrier sets of dynamic types contain objects of vastly different size. For these types, variables (memory space) must be allocated dynamically, i.e., at run time, when the actual sizes of objects are known. Examples for dynamic types are character strings, lists, tree structures, sets, and graphs. A classical example of a dynamic type is a special type of a list: a queue. As the name suggests, a queue object is a sequence of other objects with the particular restrictive property that objects are inspected at and removed from its front and added to its rear.

Specification of Queues

Carrier set: *Queues*
Auxiliary sets: *Boolean*, *A* (*A* contains the items to be queued)
Operations: newQueue, isEmpty, queue, pop, front

1. newQueue	$\in$ *Queues*;		{a new, empty queue}
2. isEmpty	$\in$ *Queues*	$\rightarrow$ *Boolean*;	{check if a queue is empty}
3. queue	$\in A \times$ *Queues*	$\rightarrow$ *Queues*;	{add an object to the rear of a queue}
4. front	$\in$ *Queues*	$\rightarrow A$;	{return front element for inspection}
5. pop	$\in$ *Queues*	$\rightarrow$ *Queues*;	{remove front element from a queue}

Axioms: All functions are strict and, for a $\in$ A and s $\in$ Queues,

```
      isEmpty (newQueue);       (i.e. isEmpty (newQueue)    is true)
not   isEmpty (queue(a, s));    (i.e. isEmpty (queue(a, s))  is false)
      pop (newQueue)        =   error;
      pop (queue(a, s))     =   if s = newQueue
                                      then newQueue else queue(a, pop(s));
      front(newQueue)       =   error;
      front(queue(a, s))    =   if s = newQueue
                                      then a else front(s).
```

Implementation of Queues

The following implementation represents queues of the form queue(a, s) by the ordered pair (a, s) and a new, empty queue by the null pair *nil*. For the moment we assume that a data type, *Pairs*, which provides pairs on demand at run time, already exists and is defined as follows:

Specification of Pairs

Carrier Set: *Pairs*
Auxiliary sets: *Boolean*, *A*

Operations: nil, isNil, pair, first, scnd

1. nil	∈ Pairs,		{a distinguished pair, the null pair}
2. isNil	∈ Pairs	→ Boolean,	{test for the null pair}
3. pair	∈ A 3 Pairs	→ Pairs,	{combine an item and a pair to a new pair}
4. first	∈ Pairs	→ A,	{the first component, i.e., the item}
5. scnd	∈ Pairs	→ Pairs,	{the second component, i.e., the pair}

Axioms: All functions are strict and, for a ∈ A and p ∈ Pairs,

	isNil(nil);	(i.e. isNil(nil)	is true)
not	isNil(pair(a,p));	(i.e. isNil(pair(a,p))	is false)
	first (nil) = error;		
	first(pair(a,p)) = a;		
	scnd (nil) = error;		
	scnd(pair(a,p)) = p;		

With pairs, queues may now be implemented as follows:

```
type   Queues = Pairs;
function newQueue    : Queues;                  begin  newQueue  := nil          end;
function isEmpty (s : Queues)    : Boolean;     begin  isEmpty   := (s = nil)    end;
function queue (x : A; s : Queues)   : Queues;  begin  queue    := pair(x, s)   end;
function pop (s : Queues) : Queues;
begin
  if isNil(s)
       then error ('cannot pop empty queue')
       else if scnd(s) = nil
            then pop := nil
            else pop := pair (first(s), pop (scnd(s)))
  end;
function front (s : Queues) : A;
begin
  if isNil(s)
       then error ('an empty queue does not have a front')
       else if scnd(s) = nil
            then front := first(s)
            else front := front(scnd(s))
  end;
```

The logic of these programs echoes the axioms. Such implementations are sometimes not very efficient but useful for prototype programs, since the probability of their correctness is very high. The queues behave as *values*, i.e., the functions queue(a,s) and pop(s) do not modify the queues s but compute new queues; after the execution of, e.g., s1 := pop(s) there are two independent queue values, s and s1. This is exactly the behavior postulated by the axioms. However, practical applications frequently deal with *mutable objects*, objects that can be modified. With mutable objects memory may often be used more efficiently, since it is easier to decide when a memory cell, used, e.g., for storing an ordered pair, is no longer needed and thus may be recycled. If queues are viewed as mutable objects, the operations *queue* and *pop* are implemented as procedures that modify a queue. In order to apply the style of axioms introduced above for the description of mutable objects, these objects are best viewed as containers of values. The *procedure* queue(a, qobj), for example, takes the queue value, e.g., s, out of the container qobj, applies the *function* queue(a, s) (described by the axioms), and puts the result back into qobj.

If more than one place in a program needs to maintain a reference to such an object, the object must be implemented using a *head cell:* a storage location that represents the object and that is not released. The following

implementation uses a head cell with two fields, one pointing to the front and one to the rear of the queue. We assume that the type *Pairs* has two additional functions:

```
6. pairH ∈ Pairs 3 Pairs   → Pairs;   {create a pair with 2 pair fields}
7. firstH ∈ Pairs          → Pairs;   {retrieve the first field of such a 2-pair cell}
```

and three procedures:

```
8. setfirstH ( p: Pairs; q: Pairs);     {change the firstH field of q to p}
9. setscnd ( p: Pairs; q: Pairs);       {change the scnd field of q to p}
10. delete (s: Pairs)                   {free the storage space occupied by s}
```

```
type    Queues = Pairs;
procedure newQueue(var q : Queues);      begin q          := pairH(nil, nil)    end;
function isEmpty (s : Queues) : Boolean; begin isEmpty    := (firstH(s) = nil)  end;
procedure queue (x : A; s : Queues);
   var temp: Pairs;
   begin temp := pair(x, nil);
      if isNil(firstH(s)) then setfirstH(temp, s) else setscnd(temp, scnd(s));
      setscnd (temp, s);
      end;
function pop (s : Queues) : Queues;
   var temp : Pairs;
   begin
      if isNil(firstH(s))
         then error ('cannot pop empty queue')
         else begin temp := firstH(s); setfirstH(scnd(temp), s); delete(temp) end
      end;
function front (s : Queues) : A;
   begin
      if isNil(firstH(s))
         then error ('an empty queue does not have a front')
         else front := first(firstH(s))
      end;
```

Compared to the value implementation given earlier, this implementation improves the performance of *front* and *pop* from O(n) to O(1).

An algorithm has O(f(n)) (pronounced: order f(n) or proportional to f(n)) time performance if there exists a constant c, such that, for arbitrary values of the input size n, the time that the algorithm needs for its computation is $t \leq c \cdot f(n)$.

Most modern programming languages support the implementation of the type *pairs* (*n-tuples*) whose instances can be created dynamically. It requires two operations, called *new* and *dispose* in Pascal, that dynamically allocate and deallocate variables, respectively. These operations depend on the concept of a *reference* (or *pointer*), which serves as a name for a variable. References always occupy the same storage space independently of the type of variable they refer to. The following implementation of *Pairs* explains the concept.

```
type CellKind  = (headCell, bodyCell);
     Pairs     = ^PairCell; {Pairs are references to PairCells}
     PairCell  = record     tail: Pairs;
                   case  kind: CellKind of
                         headCell: (frnt: Pairs);
                         bodyCell: (val: A)
                   end;
function pair(item: A; next:Pairs):Pairs;
  var p: Pairs;
```

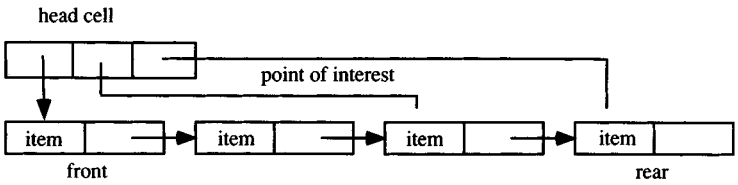

FIGURE 87.14 A list implementation with a point of interest and access to front and rear.

```
    begin
      new(p, bodyCell); {a new "bodyCell" is created and accessible through p}
      p^.kind := bodyCell; p^.val := item; p^.tail := next; pair := p
      end;
  function first(p: Pairs):A;
    begin
      if p = nil then error('...')
          else if p^.kind = bodyCell then first := p^.val else error('...')
      end;
  procedure setfirstH(p, q:Pairs);
    begin
      if q = nil then error('...')
          else if q^.kind = headCell then q^.frnt := p else error('...')
      end;
```

(Note: The Pascal constant **nil** denotes the null pointer, a reference to nothing.)

```
  function isNil(p: Pairs): Boolean; begin isNil := (p = nil) end;
```

The reader should have no difficulty filling in the rest of the implementation of Pairs. Most of the algorithms on dynamic data structures have been developed in the 1960s; still, an excellent reference is Knuth [1973].

More Dynamic Data Types

Stacks and Lists with a Point of Interest

A queue is the type of (linear) list used to realize first-come-first-served behavior. In contrast, another linear type, the *stack*, realizes last-come-first-served behavior. Sometimes it is necessary to scan a list object without dismantling it. This is accomplished by giving the list a point of interest (see Fig. 87.14). This requires four additional operations:

```
restart(l: List);                 {moves point of interest to beginning of list l}
current(l:List):A;                {returns object at point of interest}
advance(l:List);                  {advances point of interest by one toward end of list l}
endOfList(l : List): Boolean;     {true, if end of list has been reached}
```

The type can be extended further by allowing insertions and deletions at the point of interest.

N-ary, Binary, and General Trees

An **n-ary tree** is the smallest set containing the *empty tree* and all ordered n+1-tuples $t = (a, t_1, ..., t_n)$ where a is member of some auxiliary set and the t_i are n-ary trees. The element a is called the *root element* or simply the root of t and the t_i are called *subtrees* of t.

Note that in this sense, a list is a unary tree. Binary trees used as searchtrees access finite ordered sets.

A **binary searchtree** is a tree that accesses a set. A tree t *accesses* a set s if the root of t is some element a of s, and s_1, called the left subtree of t, accesses the subset $\{x | x \in s \text{ and } x < a\}$ and s_2, *called the right subtree of t, accesses the subset* $\{x | x \in s \text{ and } x > a\}$.

If the left and right subtrees of the above definition are of similar size, then the time for finding an element in the set is proportional to log(n) where n is the cardinality of the set.

Quaternary trees (usually called quad trees) and octonary trees (called oct trees) are used to access two-dimensionally and three-dimensionally organized data, respectively. As with lists, the implementation of n-ary trees is based on n+1-tuples. A minimal set of operations for binary trees includes:

nilTree	∈ Trees;		{the empty tree, represented by nil}
isNil	∈ Trees	→ Boolean;	{test if tree is empty}
tree	∈ A 3 Trees 3 Trees	→ Trees;	{build tree from an item and subtrees}
root	∈ Trees	→ A;	{retrieve root item of tree}
left	∈ Trees	→ Trees;	{retrieve left subtree}
right	∈ Trees	→ Trees;	{retrieve right subtree}

A **general tree** is the smallest set containing all order pairs $t = (a,s)$ where a is a member of some auxiliary set and s is a possibly empty list of general trees. The element a is called the root element or simply the root of t and the trees in s are called subtrees of t.

Note that there is no empty general tree; the simplest tree has a root and an empty list of subtrees. General trees are useful for the representation of hierarchical organizations such as the table of contents of a book or the organization of a corporation.

Functions, Sets, Relations, Graphs

Functions with reasonably small domains can be represented by arrays, as described earlier. Similarly, sets formed from a reasonably small universal set, relations on small domains, and graphs with not too many vertices can be represented by their characteristic functions implemented as bit arrays. In fact, Pascal provides a type constructor for sets that are derived from small universal sets.

Frequently domains are far too large for this approach. For example, the symbol table that a compiler of a programming language maintains is a function from the set of valid identifiers to some set of attributes. The set of valid identifiers is infinite, or, if some length limitation is imposed, finite but exceedingly large (there are nearly 300 billion identifiers of eight characters or less). For most of its domain a symbol table returns the default value *new* or *not found*. It is therefore economical to store the mapping only for those domain values that map to a value different from the default value. A function of this sort is usually specified as follows:

Specification of Functions:

Carrier Set:	*Functions*	
Auxiliary sets:	*Dom*, *Cod*	(domain and codomain)
Operations:	newFun, apply, update	

1. newFun	∈ Functions,	(returns default everywhere)	
2. apply	∈ Functions 3 Dom		→ Cod,
3. update	∈ Functions 3 Dom 3 Cod		→ Functions;

Axioms: All functions are strict and, for x,z ∈ Dom, y ∈ Cod and f ∈ Functions,

apply(newFun, x)	= default;
apply (update(f,x,y), z)	= if x = z then y else apply (f, z);

An implementation based on these axioms amounts to representing a function as a list of those of its individual mappings that differ from *default* and leads to an O(1) performance for *update* and an **O(n) performance** of *apply*. Better is an implementation by binary searchtrees with a performance of O(log(n)) for both *apply* and *update*.

Hashing

The fastest method for the implementation of functions is *hash coding* or *hashing*. By means of a *hash function,* h ∈ Dom → 0 .. k–1, the domain of the function is partitioned into k sections and each section is associated with an index. For each partition a simple list implementation is used and the lists are stored in an array A:

array[1 .. k–1]. In order to compute apply(f,x) or update(f,x,y), the list at A[hash(x)] is searched or updated. If the hash function has been properly chosen and if k and the number of function values different from default are of similar size, then the individual lists can be expected to be very short and independent of the number of nondefault entries of the function; thus performance for apply and update is O(1).

The above discussion applies also to sets, relations, and graphs, since these objects can be represented by their characteristic functions.

Object-Oriented Programming

In languages that support object-oriented programming, *classes* (i.e., types) of objects are defined by specifying (1) the variables that each object will own as *instance variables* and (2) operations, called *methods,* applicable to the objects of the class. As a difference in style, these methods are not invoked like functions or procedures, but are *sent* to an object as a *message.* The expression [*window moveTo* : *x* : *y*] is an example of a message in the programming language *Objective C*, a dialect of C. Here the object *window*, which may represent a window on the screen, is instructed to apply to itself the method *moveTo* using the parameters *x* and *y.*

New objects of a class are created—usually dynamically—by *factory methods* addressed to the class itself. These methods allocate the equivalent of a record whose fields are the instance variables of the object and return a reference to this record, which represents the new object. After its creation an object can receive messages from other objects.

To data abstraction, object-oriented programming adds the concept of inheritance: from an existing class new (sub)classes can be derived by adding additional instance variables and/or methods. Each subclass inherits the instance variables and methods of its superclass. This encourages the use of existing code for new purposes. As an example, consider a class of a *list* objects. Each object has two instance variables pointing to the front and the rear of the list. In Objective C, the specification of the interface for this list class, i.e., the declaration of the instance variables and headers (functionalities) of the methods, has the following form:

```
@interface MyLists : Object     /* Object is the universal (system) class from which
                                   all classes are derived directly or indirectly */
{                               /* declaration of the instance variables;
   listRef front;                  listRef is the type of a pointer to a list assumed
   listRef rear;                   to be defined elsewhere */
}
– initList;                     /* initializes instance variables with null pointers */
– (BOOL) isEmpty;               /* test for empty list; note: parameter list is implied */
– add : (item) theThing;        /* item is the type of things on the list */
– pop;
– (item) front;
@end
```

As a companion of the *interface* file there is also an *implementation* file that contains the executable code for the methods of the class. A list with a point of interest can be defined as a subclass of MyList as follows:

```
@interface   ScanList : MyList   /* ScanList is made a subclass of MyList */

{   listRef pointOfInterest; }

– restart;
– (BOOL)endOfList;
– advance;
– (Item)current;
@end
```

If we also need a list that can add and delete at the point of interest, we define:

```
@interface      InsertionList : ScanList
{ }                             /* there are no new instance variables */
```

```
– insert : (item) theThing;
– shrink;                    /* removes item at the point of interest */
@end
```

If a subclass defines a method already defined in the superclass, the new definition overrides the old one. Suppose we need a list where items are kept in ascending order:

```
@interface  SortedList : MyList
{ }
– add : (item) theThing;     /* this version of add inserts theThing at the proper
                                place to keep the list sorted */
@end
```

Defining Terms

Abstract data type: One or more sets of computational objects together with some basic operations on those objects. One of these sets is defined by the type either by enumeration or by generating operations and is called the *carrier set* of the type. Customarily it is given the same name as the type. All other sets are called auxiliary sets of the type. In exceptional cases a type may have more than one carrier set.

Binary searchtree: A tree that accesses a set. A tree t accesses a set s if the root of t is some element a of s, and s_1, called the left subtree of t, accesses the subset $\{x \mid x \in s \text{ and } x < a\}$, *and* s_2, *called the right subtree of t, accesses the subset* $\{x \mid x \in s \text{ and } x > a\}$.

Functionality: With sets A and B, the expression $A \rightarrow B$ denotes the set of all functions that have the domain A and the codomain B. Functions $f \in A \rightarrow B$ (traditionally denoted by $f: A \rightarrow B$) are said to have the functionality $A \rightarrow B$.

General tree: The smallest set containing all ordered pairs $t = (a, s)$ where a is member of some auxiliary set and s is a possibly empty list of general trees. The element a is called the root element or simply the root of t and the trees in s are called subtrees of t.

n-ary tree: The smallest set containing the *empty tree* and all ordered n+1-tuples $t = (a, t_1, \ldots, t_n)$ where a is member of some auxiliary set and the t_i are n-ary trees. The element a is called the root element or simply the root of t and the t_i are called subtrees of t.

O(f(n)) performance: An algorithm has O(f(n)) (pronounced: order f(n) or proportional to f(n)) time performance if there exists a constant c, such that, for arbitrary values of the input size n, the time that the algorithm needs for its computation is $t \leq c \cdot f(n)$.

Strictness: Most carrier sets are assumed to contain a distinguished value: *error*. *Error* is not a proper computational object: a function is considered to compute *error* if it does not return to the point of its invocation due to some error condition. Functions are called *strict* if they compute the value *error* whenever one or more of their arguments have the value *error*.

88.1 Introduction

A *memory system* serves as a repository of information (data) in a computer system. The processor [also called the central processing unit (CPU)] accesses (reads or loads) data from the memory system, performs computations on them, and stores (writes) them back to memory. The memory system is a collection of storage locations. Each storage location, or *memory word*, has a numerical *address*. A collection of storage locations forms an *address space*. Figure 88.1 shows the essentials of how a processor is connected to a memory system via address, data, and control lines.

When a processor attempts to load the contents of a memory location, the request is very urgent. In virtually all computers, the work soon comes to a halt (in other words, the processor *stalls*) if the memory request does not return quickly. Modern computers are generally able to continue briefly by overlapping memory requests, but even the most sophisticated computers will frequently exhaust their ability to process data and stall momentarily in the face of long memory delays. Thus, a key performance parameter in the design of any computer, fast or slow, is the effective speed of its memory.

Ideally, the memory system must be both infinitely large so that it can contain an arbitrarily large amount of information and infinitely fast so that it does not limit the processing unit. Practically, however, this is not possible. There are three properties of memory that are inherently in conflict: speed, capacity, and cost. In general, technology tradeoffs can be employed to optimize any two of the three factors at the expense of the third. Thus it is possible to have memories that are (1) large and cheap, but not fast; (2) cheap and fast, but small; or (3) large and fast, but expensive. The last of the three is further limited by physical constraints. A large-capacity memory that is very fast is also physically large, and speed-of-light delays place a limit on the speed of such a memory system.

The **latency** (L) of the memory is the delay from when the processor first requests a word from memory until that word arrives and is available for use by the processor. The latency of a memory system is one attribute of performance. The other is **bandwidth** (BW), which is the rate at which information can be transferred from the memory system. The bandwidth and the latency are related. If R is the number of requests that the memory can service simultaneously, then:

$$BW = \frac{R}{L} \tag{88.1}$$

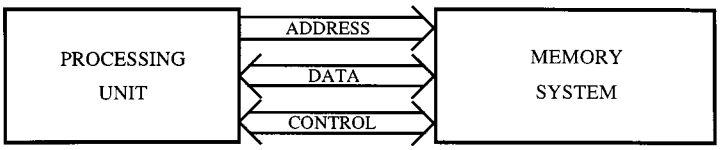

FIGURE 88.1 The memory interface.

From Eq. (88.1) we see that a decrease in the latency will result in an increase in bandwidth, and vice versa, if R is unchanged. We can also see that the bandwidth can be increased by increasing R, if L does not increase proportionately. For example, we can build a memory system that takes 20 ns to service the access of a single 32-bit word. Its latency is 20 ns per 32-bit word, and its bandwidth is

$$\frac{32}{20 \times 10^{-9}} \frac{\text{bits}}{\text{sec}}$$

or 200 Mbytes/s. If the memory system is modified to accept a new (still 20 ns) request for a 32-bit word every 5 ns by overlapping results, then its bandwidth is

$$\frac{32}{5 \times 10^{-9}} \frac{\text{bits}}{\text{sec}}$$

or 800 Mbytes/s. This memory system must be able to handle four requests at a given time.

Building an ideal memory system (infinite capacity, zero latency and infinite bandwidth, with affordable cost) is not feasible. The challenge is, given a set of cost and technology constraints, to engineer a memory system whose abilities match the abilities that the processor demands of it. That is, engineering a memory system that performs as close to an ideal memory system (for the given processing unit) as is possible. For a processor that stalls when it makes a memory request (some current microprocessors are in this category), it is important to engineer a memory system with the lowest possible latency. For those processors that can handle multiple outstanding memory requests (vector processors and high-end CPUs), it is important not only to reduce latency, but also to increase bandwidth (over what is possible by latency reduction alone) by designing a memory system that is capable of servicing multiple requests simultaneously.

Memory hierarchies provide decreased average latency and reduced bandwidth requirements, whereas parallel or **interleaved** memories provide higher bandwidth.

88.2 Memory Hierarchies

Technology does not permit memories that are cheap, large, and fast. By recognizing the nonrandom nature of memory requests, and emphasizing the *average* rather than worst case latency, it is possible to implement a hierarchical memory system that performs well. A small amount of very fast memory, placed in front of a large, slow memory, can be designed to satisfy most requests at the speed of the small memory. This, in fact, is the primary motivation for the use of registers in the CPU: in this case, the programmer or compiler makes sure that the most commonly accessed variables are allocated to registers.

A variety of techniques, employing either hardware, software, or a combination of the two, can be employed to assure that most memory references are satisfied by the faster memory. The foremost of these techniques is the exploitation of the *locality of reference* principle. This principle captures the fact that some memory locations are referenced much more frequently than others. *Spatial locality* is the property that an access to a given memory location greatly increases the probability that neighboring locations will soon be accessed. This is largely, but not exclusively, a result of the tendency to access memory locations sequentially. *Temporal locality* is the property that an access to a given memory location greatly increases the probability that the same location

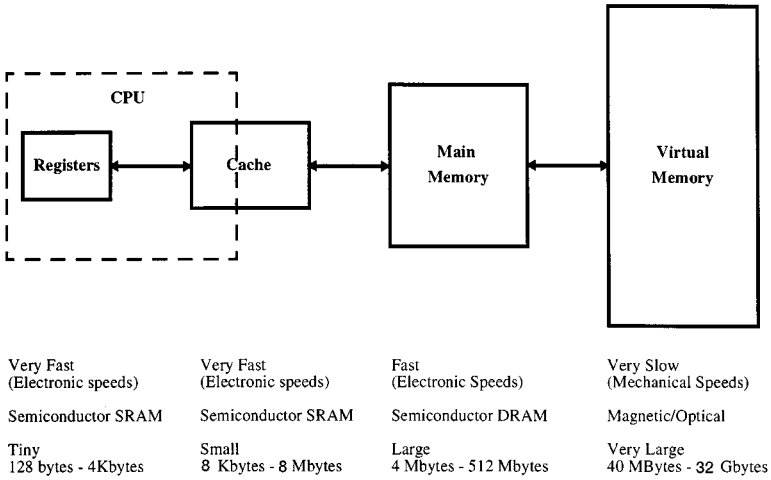

FIGURE 88.2 A memory hierarchy.

will be accessed again soon. This is largely, but not exclusively, a result of the frequency of looping behavior of programs. Particularly for temporal locality, a good predictor of the future is the past: the longer a variable has gone unreferenced, the less likely it is to be accessed soon.

Figure 88.2 depicts a common construction of a memory hierarchy. At the top of the hierarchy are the CPU registers, which are small and extremely fast. The next level down in the hierarchy is a special, high-speed semiconductor memory known as a **cache memory**. The cache can actually be divided into multiple distinct levels; most current systems have between one and three levels of cache. Some of the levels of cache may be on the CPU chip itself, they may be on the same module as the CPU, or they all may be entirely distinct. Below the cache is the conventional memory, referred to as *main memory,* or *backing storage.* Like a cache, main memory is semiconductor memory, but it is slower, cheaper, and denser than a cache. Below the main memory is the virtual memory, which is generally stored on magnetic or optical disk. Accessing the virtual memory can be tens of thousands times slower than accessing the main memory because it involves moving mechanical parts.

As requests go deeper into the memory hierarchy, they encounter levels that are larger (in terms of capacity) and slower than the higher levels (moving left to right in Fig. 88.2). In addition to size and speed, the bandwidth in-between adjacent levels in the memory hierarchy is smaller for the lower levels. The bandwidth in-between the registers and top cache level, for example, is higher than that between cache and main memory or main memory and virtual memory. Since each level presumably intercepts a fraction of the requests, the bandwidth to the level below need not be as great as that to the intercepting level.

A useful performance parameter is the *effective latency.* If the needed word is found in a level of the hierarchy, it is a *hit;* if a request must be sent to the next lower level, the request is said to *miss.* If the latency L_{HIT} is known in the case of a hit and the latency in the case of a miss is L_{MISS}, the effective latency for that level in the hierarchy can be determined from the *hit ratio* (H), the fraction of memory accesses that are hits:

$$L_{\text{average}} = L_{\text{HIT}} \cdot H + L_{\text{MISS}} \cdot (1 - H) \tag{88.2}$$

The portion of memory accesses that miss is called the *miss ratio* ($M = 1 - H$). The hit ratio is strongly influenced by the program being executed, but is largely independent of the ratio of cache size to memory size. It is not uncommon for a cache with a capacity a few thousand bytes to exhibit a hit ratio greater than 90%.

88.3 Cache Memories

The basic unit of construction of a semiconductor memory system is a *module* or *bank.* A memory bank, constructed from several memory chips, can service a single request at a time. The time that a bank is busy servicing a request is called the *bank busy time.* The bank busy time limits the bandwidth of a memory bank.

Both caches and main memories are constructed in this fashion, although caches have significantly shorter bank busy times than do main memory banks.

The hardware can dynamically allocate parts of the cache memory for addresses deemed most likely to be accessed soon. The cache contains only redundant copies of the address space. The cache memory is *associative,* or *content-addressable.* In an associative memory, the address of a memory location is stored, along with its content. Rather than reading data directly from a memory location, the cache is given an address and responds by providing data which may or may not be the data requested. When a cache miss occurs, the memory access is then performed with respect to the backing storage, and the cache is updated to include the new data.

The cache is intended to hold the most active portions of the memory, and the hardware dynamically selects portions of main memory to store in the cache. When the cache is full, bringing in new data must be matched by deleting old data. Thus a strategy for cache management is necessary. Cache management strategies exploit the principle of locality. Spatial locality is exploited by the choice of what is brought into the cache. Temporal locality is exploited in the choice of which block is removed. When a cache miss occurs, hardware copies a large, contiguous block of memory into the cache, which includes the word requested. This fixed-size region of memory, known as a cache *line* or *block*, may be as small as a single word, or up to several hundred bytes. A block is a set of contiguous memory locations, the number of which is usually a power of two. A block is said to be *aligned* if the lowest address in the block is exactly divisible by the block size. That is to say, for a block of size B beginning at location A, the block is aligned if

$$A \ modulo \ B = 0 \tag{88.3}$$

Conventional caches require that all blocks be aligned.

When a block is brought into the cache, it is likely that another block must be evicted. The selection of the evicted block is based on some attempt to capture temporal locality. Since prescience is so difficult to achieve, other methods are generally used to predict future memory accesses. A least-recently-used (LRU) policy is often the basis for the choice. Other replacement policies are sometimes used, particularly because true LRU replacement requires extensive logic and bookkeeping.

The cache often comprises two conventional memories: the data memory and the tag memory, shown in Fig. 88.3. The address of each cache line contained in the data memory is stored in the tag memory, as well as other information (*state* information), particularly the fact that a valid cache line is present. The state also keeps track of which cache lines the processor has modified. Each line contained in the data memory is allocated a corresponding entry in the tag memory to indicate the full address of the cache line.

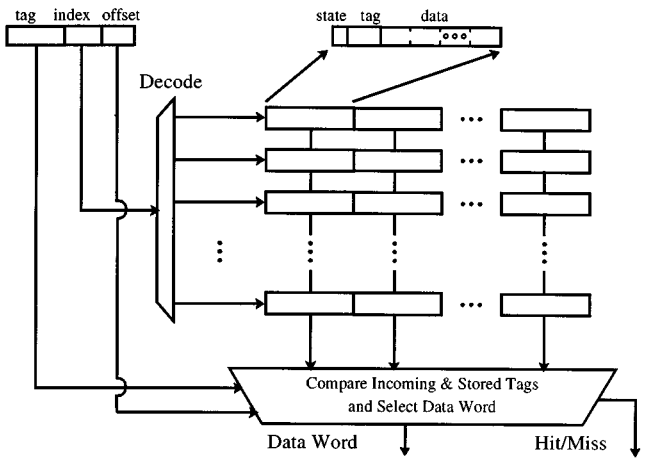

FIGURE 88.3 Components of a cache memory. (*Source:* Adapted from M. D. Hill, "A case for direct-mapped caches," *IEEE Computer,* 21(12), 27, 1988.)

The requirement that the cache memory be associative (content-addressable) complicates the design. Addressing data by content is inherently more complicated than by its address. All the tags must be compared concurrently, of course, because the whole point of the cache is to achieve low latency. The cache can be made simpler, however, by introducing a mapping of memory locations to cache cells. This mapping limits the number of possible cells in which a particular line may reside. The extreme case is known as *direct mapping*, in which each memory location is mapped to a single location in the cache. Direct mapping makes many aspects of the design simpler, since there is no choice of where the line might reside, and no choice as to which line must be replaced. However, direct mapping can result in poor utilization of the cache when two memory locations are alternately accessed and must share a single cache cell.

A hashing algorithm is used to determine the cache address from the memory address. The conventional mapping algorithm consists of a function of the form

$$A_{\text{cache}} = \frac{A_{\text{memory}} \bmod cache\_size}{cache\_line\_size} \tag{88.4}$$

where A_{cache} is the address within the cache for main memory location A_{memory}, *cache_size* is the capacity of the cache in addressable units (usually bytes), and *cache_line_size* is the size of the cache line in addressable units. Since the hashing function is simple bit selection, the tag memory need only contain the part of the address not implied by the hashing function. That is,

$$A_{\text{tag}} = A_{\text{memory}} \text{ div } size\_of\_cache \tag{88.5}$$

where A_{tag} is stored in the tag memory and *div* is the integer divide operation. In testing for a match, the complete address of a line stored in the cache can be inferred from the tag and its storage location within the cache.

A *two-way set-associative* cache maps each memory location into either of two locations in the cache and can be constructed essentially as two identical direct-mapped caches. However, both caches must be searched at each memory access and the appropriate data selected and multiplexed on a tag match (hit). On a miss, a choice must be made between the two possible cache lines as to which is to be replaced. A single LRU bit can be saved for each such pair of lines to remember which line has been accessed more recently. This bit must be toggled to the current state each time either of the cache lines is accessed.

In the same way, an *M-way associative* cache maps each memory location into any of *M* memory locations in the cache and can be constructed from *M* identical direct-mapped caches. The problem of maintaining the LRU ordering of *M* cache lines quickly becomes hard, however, since there are *M*! possible orderings, and therefore it takes at least

$$\lceil \log_2 (M!) \rceil \tag{88.6}$$

bits to store the ordering. In practice, this requirement limits true LRU replacement to 3- or 4-way set associativity.

Figure 88.4 shows how a cache is organized into sets, blocks, and words. The cache shown is a 2-Kbyte, 4-way set-associative cache, with 16 sets. Each set consists of four blocks. The cache block size in this example is 32 bytes, so each block contains eight 4-byte words. Also depicted at the bottom of Fig. 88.4 is a 4-way interleaved main memory system (see the next section for details). Each successive word in the cache block maps into a different main memory bank. Because of the cache's mapping restrictions, each cache block obtained from main memory will be loaded into its corresponding set, but may appear anywhere within that set.

Write operations require special handling in the cache. If the main memory copy is updated with each write operation—a technique known as *write-through* or *store-through*—the writes may force operations to stall while the write operations are completing. This can happen after a series of write operations even if the processor is allowed to proceed before the write to the memory has completed. If the main memory copy is not updated

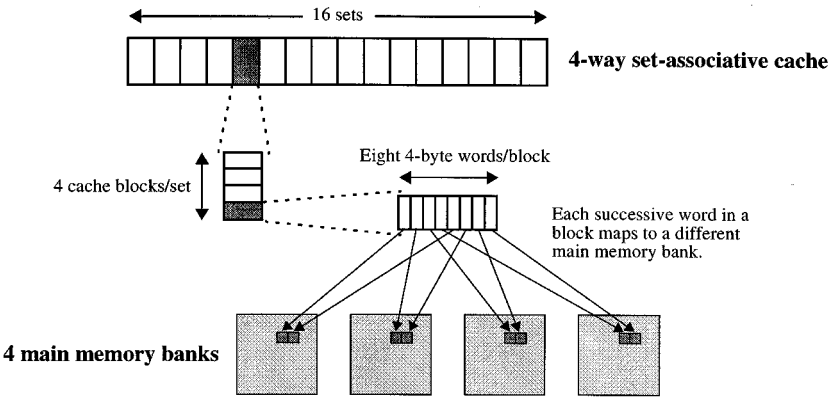

FIGURE 88.4 Organization of a cache.

with each write operation—a technique known as *write-back* or *copy-back* or *deferred writes*—the main memory locations become stale, that is, memory no longer contains the correct values and must not be relied upon to provide data. This is generally permissible, but care must be exercised to make sure that it is always updated before the line is purged from the cache and that the cache is never bypassed. Such a bypass could occur with DMA (*direct memory access*), in which the I/O system writes directly into main memory without the involvement of the processor.

Even for a system that implements write-through, care must be exercised if memory requests bypass the cache. While the main memory is never stale, a write that bypasses the cache, such as from I/O, could have the effect of making the cached copy stale. A later access by the CPU could then provide an incorrect value. This can only be avoided by making sure that cached entries are invalidated even if the cache is bypassed. The problem is relatively easy to solve for a single processor with I/O, but becomes very difficult to solve for multiple processors, particularly so if multiple caches are involved as well. This is known in general as the cache *coherence* or *consistency* problem.

The cache exploits spatial locality by loading an entire cache line after a miss. This tends to result in bursty traffic to the main memory, since most accesses are filtered out by the cache. After a miss, however, the memory system must provide an entire line at once. Cache memory nicely complements an interleaved, high-bandwidth main memory (described in the next section), since a cache line can be interleaved across many banks in a regular manner, thus avoiding memory conflicts, and thus can be loaded rapidly into the cache. The example main memory shown in Fig. 88.3 can provide an entire cache line with two parallel memory accesses.

Conventional caches traditionally could not accept requests while they were servicing a miss request. In other words, they *locked up* or *blocked* when servicing a miss. The growing penalty for cache misses has made it necessary for high-end commodity memory systems to continue to accept (and service) requests from the processor while a miss is being serviced. Some systems are able to service multiple miss requests simultaneously. To allow this mode of operation, the cache design is *lockup-free* or *non-blocking* [Kroft, 1981]. Lockup-free caches have one structure for each simultaneous outstanding miss that they can service. This structure holds the information necessary to correctly return the loaded data to the processor, even if the misses come back in a different order than that in which they were sent.

Two factors drive the existence of multiple levels of cache memory in the memory hierarchy: access times and a limited number of transistors on the CPU chip. Larger banks with greater capacity are slower than smaller banks. If the time needed to access the cache limits the clock frequency of the CPU, then the first-level cache size may need to be constrained. Much of the benefit of a large cache may be obtained by placing a small first-level cache above a larger second-level cache; the first is accessed quickly and the second holds more data close to the processor. Since many modern CPUs have caches on the CPU chip itself, the size of the cache is limited by the CPU silicon real-estate. Some CPU designers have assumed that system designers will add large off-chip caches to the one or two levels of caches on the processor chip. The complexity of this part of the memory hierarchy may continue to grow as main memory access penalties continue to increase.

Caches that appear on the CPU chip are manufactured by the CPU vendor. Off-chip caches, however, are a commodity part sold in large volume. An incomplete list of major cache manufacturers is Hitachi, IBM Micro, Micron, Motorola, NEC, Samsung, SGS-Thomson, Sony, and Toshiba. Although most personal computers and all major workstations now contain caches, very high-end machines (such as multi-million dollar supercomputers) do not usually have caches. These ultra-expensive computers can afford to implement their main memory in a comparatively fast semiconductor technology such as static RAM (SRAM), and can afford so many banks that cacheless bandwidth out of the main memory system is sufficient. Massively parallel processors (MPPs), however, are often constructed out of workstation-like nodes to reduce cost. MPPs therefore contain cache hierarchies similar to those found in the workstations on which the nodes of the MPPs are based.

Cache sizes have been steadily increasing on personal computers and workstations. Intel Pentium-based personal computers come with 8 Kbyte each of instruction and data caches. Two of the Pentium chip sets, manufactured by Intel and OPTi, allow level-two caches ranging from 256 to 512 Kbyte and 64 Kbyte to 2 Mbyte, respectively. The newer Pentium Pro systems also have 8 Kbyte, first-level instruction and data caches, but they also have either a 256 Kbyte or a 512 Kbyte second-level cache on the same module as the processor chip. Higher-end workstations—such as DEC Alpha 21164-based systems—are configured with substantially more cache. The 21164 also has 8 Kbyte, first-level instruction and data caches. Its second-level cache is entirely on-chip, and is 96 Kbyte. The third-level cache is off-chip, and can have a size ranging from 1 to 64 Mbyte.

For all desktop machines, cache sizes are likely to continue to grow—although the rate of growth compared to processor speed increases and main memory size increases is unclear.

88.4 Parallel and Interleaved Memories

Main memories are comprised of a series of semiconductor memory chips. A number of these chips, like caches, form a *bank*. Multiple memory banks can be connected together to form an **interleaved** (or parallel) memory system. Since each bank can service a request, an interleaved memory system with K banks can service K requests simultaneously, increasing the peak bandwidth of the memory system to K times the bandwidth of a single bank. In most interleaved memory systems, the number of banks is a power of two, that is, $K = 2^k$. An n-bit memory word address is broken into two parts: a k-bit bank number and an m-bit address of a word within a bank. Though the k bits used to select a bank number could be any k bits of the n-bit word address, typical interleaved memory systems use the low-order k address bits to select the bank number; the higher order $m = n - k$ bits of the word address are used to access a word in the selected bank. The reason for using the low-order k bits will be discussed shortly. An interleaved memory system which uses the low-order k bits to select the bank is referred to as a *low-order* or a *standard* interleaved memory.

There are two ways of connecting multiple memory banks: *simple interleaving* and *complex interleaving*. Sometimes simple interleaving is also referred to as *interleaving*, and complex interleaving as *banking*.

Figure 88.5 shows the structure of a simple interleaved memory system. m address bits are simultaneously supplied to every memory bank. All banks are also connected to the same read/write control line (not shown in Fig. 88.5). For a read operation, the banks start the read operation and deposit the data in their latches. Data can then be read from the latches, one by one, by setting the switch appropriately. Meanwhile, the banks could be accessed again, to carry out another read or write operation. For a write operation, the latches are loaded, one by one. When all the latches have been written, their contents can be written into the memory banks by supplying m bits of address (they will be written into the same word in each of the different banks). In a simple interleaved memory, all banks are cycled at the same time; each bank starts and completes its individual operations at the same time as every other bank; a new memory cycle can start (for all banks) once the previous cycle is complete. Timing details of the accesses can be found in *The Architecture of Pipelined Computers*, [Kogge, 1981].

One use of a simple interleaved memory system is to back up a cache memory. To do so, the memory must be able to read blocks of contiguous words (a cache block) and supply them to the cache. If the low-order k bits of the address are used to select the bank number, then consecutive words of the block reside in different banks, and they can all be read in parallel, and supplied to the cache one by one. If some other address bits are used for bank selection, then multiple words from the block might fall in the same memory bank, requiring multiple accesses to the same bank to fetch the block.

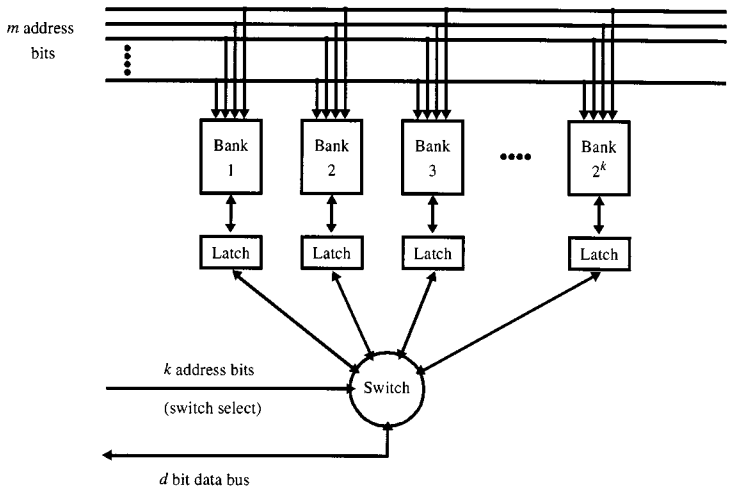

FIGURE 88.5 A simple interleaved memory system. (*Source:* Adapted from P. M. Kogge, *The Architecture of Pipelined Computers,* 1st ed., New York: McGraw-Hill, 1981, p. 41.)

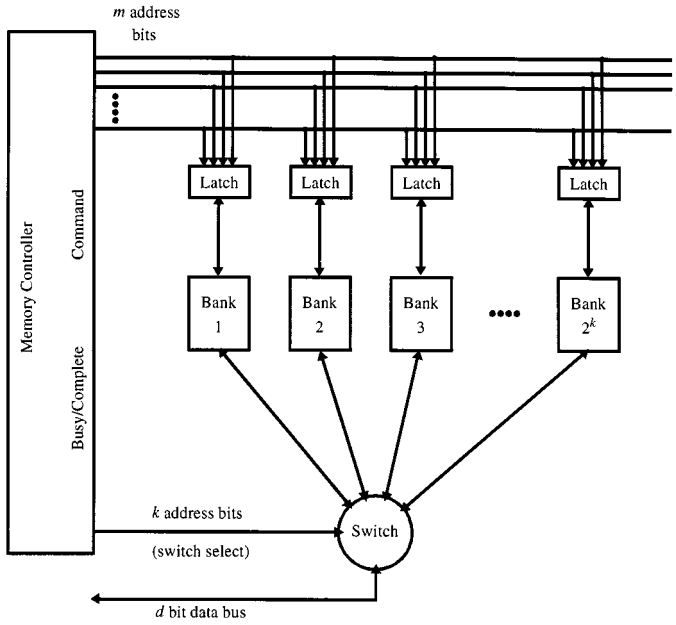

FIGURE 88.6 A complex interleaved memory system. (*Source:* Adapted from P. M. Kogge, *The Architecture of Pipelined Computers,* 1st ed., New York: McGraw-Hill, 1981, p. 42.)

Figure 88.6 shows the structure of a complex interleaved memory system. In such a system, each bank is set up to operate on its own, independent of the operation of the other banks. For example, bank 1 could carry out a read operation on a particular memory address, and bank 2 carries out a write operation on a completely unrelated memory address. (Contrast this with the operation in a simple interleaved memory where all banks are carrying out the same operation, read or write, and the locations accessed within each bank represent a contiguous block of memory.) Complex interleaving is accomplished by providing an address latch and a read/write command line for each bank. The *memory controller* handles the overall operation of the interleaved memory. The processing unit submits the memory request to the memory controller, which determines which bank needs to be accessed. The controller then determines if the bank is busy (by monitoring a busy line for

each bank). The controller holds the request if the bank is busy, submitting it later when the bank is available to accept the request. When the bank responds to a read request, the switch is set by the controller to accept the request from the bank and forward it to the processing unit. Details of the timing of accesses can be found in *The Architecture of Pipelined Computers* [Kogge, 1981].

A typical use of a complex interleaved memory system is in a *vector processor*. In a vector processor, the processing units operate on a vector, for example a portion of a row or a column of a matrix. If consecutive elements of a vector are present in different memory banks, then the memory system can sustain a bandwidth of one element per clock cycle. By arranging the data suitably in memory and using standard interleaving (for example, storing the matrix in row-major order will place consecutive elements in consecutive memory banks), the vector can be accessed at the rate of one element per clock cycle as long as the number of banks is greater than the bank busy time.

Memory systems that are built for current machines vary widely, the price and purpose of the machine being the main determinant of the memory system design. The actual memory chips, which are the components of the memory systems, are generally commodity parts built by a number of manufacturers. The major commodity DRAM manufacturers include (but certainly are not limited to) Hitachi, Fujitsu, LG Semicon, NEC, Oki, Samsung, Texas Instruments, and Toshiba.

The low-end of the price/performance spectrum is the personal computer, presently typified by Intel Pentium systems. Three of the manufacturers of Pentium-compatible chip sets (which include the memory controllers) are Intel, OPTi, and VLSI Technologies. Their controllers provide for memory systems that are simply interleaved, all with minimum bank depths of 256 Kbyte, and maximum system sizes of 192 Mbyte, 128 Mbyte, and 1 Gbyte, respectively.

Both higher-end personal computers and workstations tend to have more main memory than the lower-end systems, although they usually have similar upper limits. Two examples of such systems are workstations built with the DEC Alpha 21164, and servers built with the Intel Pentium Pro. The Alpha systems, using the 21171 chip set, are limited to 128 Mbyte of main memory using 16 Mbit DRAMs, although they will be expandable to 512 Mbyte when 64-Mbit DRAMs are available. Their memory systems are 8-way simply interleaved, providing 128 bits per DRAM access. The Pentium Pro systems support slightly different features. The 82450KX and 82450GX chip sets include memory controllers that allow reads to bypass writes (performing writes when the memory banks are idle). These controllers can also buffer eight outstanding requests simultaneously. The 82450KX controller permits 1- or 2-way interleaving, and up to 256 Mbyte of memory when 16-Mbit DRAMs are used. The 82450GX chip set is more aggressive, allowing up to four separate (complex-interleaved) memory controllers, each of which can be up to 4-way interleaved and have up to 1 Gbyte of memory (again with 16 Mbit DRAMs).

Interleaved memory systems found in high-end *vector supercomputers* are slight variants on the basic complex interleaved memory system of Fig. 88.6. Such memory systems may have hundreds of banks, with multiple memory controllers that allow multiple independent memory requests to be made every clock cycle. Two examples of modern vector supercomputers are the Cray T-90 series and the NEC SX series. The Cray T-90 models come with varying numbers of processors—up to 32 in the largest configuration. Each of these processors is coupled with 256 Mbyte of memory, split into 16 banks of 16 Mbyte each. The T-90 has complex interleaving among banks. the largest configuration (the T-932) has 32 processors, for a total of 512 banks and 8 Gbyte of main memory. The T-932 can provide a peak of 800 Gbyte/s bandwidth out of its memory system. NEC's SX-4 product line, their most recent vector supercomputer series, has numerous models. Their largest single-node model (with one processor per node) contains 32 processors, with a maximum of 8 Gbyte of memory, and a peak bandwidth of 512 Gbyte/s out of main memory. Although the sizes of the memory systems are vastly different between workstations and vector machines, the techniques that both use to increase total bandwidth and minimize bank conflicts are similar.

88.5 Virtual Memory

Cache memory contains portions of the main memory in dynamically allocated cache lines. Since the data portion of the cache memory is itself a conventional memory, each line present in the cache has two addresses associated with it: its main memory address and its cache address. Thus, the main memory address of a word

can be divorced from a particular storage location and abstractly thought of as an element in the address space. The use of a two-level hierarchy—consisting of main memory and a slower, larger disk storage device—evolved by making a clear distinction between the address space and the locations in memory. An address generated during the execution of a program is known as a *virtual address*, which must be translated to a *physical address* before it can be accessed in main memory. The total address space is simply an abstraction.

A **virtual memory** address is mapped to a physical address, which indicates the location in main memory where the data actually reside [Denning, 1970]. The mapping is maintained through a structure called the *page table*, which is maintained in software by the operating system. Like the tag memory of a cache memory, the page table is accessed through a virtual address to determine the physical (main memory) address of the entry. Unlike the tag memory, however, the table is usually sorted by virtual addresses, making the translation process a simple matter of an extra memory access to determine the real physical address of the desired item. A system maintaining the page table in the way analogous to a cache tag memory is said to have *inverted page tables*. In addition to the real address mapped to a virtual page, and an indication of whether the page is present at all, a page table entry often contains other information. For example, the page table may contain the location on the disk where each block of data is stored when not present in main memory.

The virtual memory can be thought of as a collection of blocks. These blocks are often aligned and of fixed size, in which case they are known as *pages*. Pages are the unit of transfer between the disk and main memory, and are generally larger than a cache line—usually thousands of bytes. A typical page size for machines in 1997 is 4 Kbyte. A page's virtual address can be broken into two parts, a virtual page number and an offset. The page number specifies the page to be accessed, and the page offset indicates the distance from the beginning of the page to the indicated address.

A physical address can also be broken into two parts, a physical page number (also called a *page frame* number) and an offset. This mapping is done at the level of pages, so the page table can be indexed by means of the virtual page number. The page frame number is contained in the page table and is read out during the translation, along with other information about the page. In most implementations the page offset is the same for a virtual address and the physical address to which it is mapped.

The virtual memory hierarchy is different than the cache/main memory hierarchy in a number of respects, resulting primarily from the fact that there is a much greater difference in latency between accesses to the disk and the main memory. While a typical latency ratio for cache and main memory is one order of magnitude (main memory has a latency ten times larger than the cache), the latency ratio between disk and main memory is often four orders of magnitude or more. This large ratio exists because the disk is a mechanical device—with a latency partially determined by velocity and inertia—whereas main memory is limited only by electronic and energy constraints. Because of the much larger penalty for a page miss, many design decisions are affected by the need to minimize the frequency of misses. When a miss does occur, the processor could be idle for a period during which it could execute tens of thousands of instructions. Rather than stall during this time, as may occur upon a cache miss, the processor invokes the operating system and may switch to a different task. Because the operating system is being invoked anyway, it is convenient to rely on the operating system to set up and maintain the page table, unlike cache memory, where it is done entirely in hardware. The fact that this accounting occurs in the operating system enables the system to use virtual memory to enforce protection on the memory. This ensures that no program can corrupt the data in memory that belong to any other program.

Hardware support provided for a virtual memory system generally includes the ability to translate the virtual addresses provided by the processor into the physical addresses needed to access main memory. Thus, only on a virtual address miss is the operating system invoked. An important aspect of a computer implementing virtual memory, however, is the necessity of freezing the processor at the point where a miss occurs, servicing the page table fault, and later returning to continue the execution as if no page fault had occurred. This requirement means either that it must be possible to halt execution at any point—including possibly in the middle of a complex instruction—or it must be possible to guarantee that all memory accesses will be to pages resident in main memory.

As described above, virtual memory requires two memory accesses to fetch a single entry from memory, one into the page table to map the virtual address into the physical address, and the second to fetch the actual data. This process can be sped up in a variety of ways. First, a special-purpose cache memory to store the active portion of the page table can be used to speed up the first access. This special-purpose cache is usually called

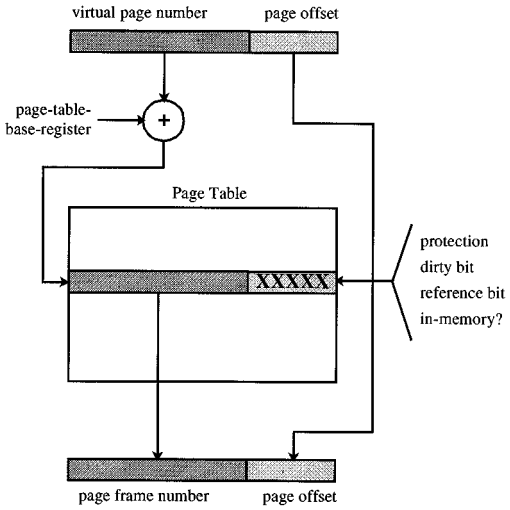

FIGURE 88.7 Virtual-to-real address translation.

a *translation lookaside buffer* (TLB). Second, if the system also employs a cache memory, it may be possible to overlap the access of the cache memory with the access to the TLB, ideally allowing the requested item to be accessed in a single cache access time. The two accesses can be fully overlapped if the virtual address supplies sufficient information to fetch the data from the cache before the virtual-to-physical address translation has been accomplished. This is true for an M-way set-associative cache of capacity C if the following relationship holds:

$$Page\_size \geq \frac{C}{M} \tag{88.7}$$

For such a cache, the index into the cache can be determined strictly from the page offset. Since the virtual page offset is identical to the physical page offset, no translation is necessary, and the cache can be accessed concurrently with the TLB. The physical address must be obtained before the tag can be compared.

An alternative method applicable to a system containing both virtual memory and a cache is to store the virtual address in the tag memory instead of the physical address. This technique introduces consistency problems in virtual memory systems that permit more than a single address space or allow a single physical page to be mapped to more than a single virtual page. This problem is known as the *aliasing* problem.

88.6 Research Issues

Research is occurring on all levels of the memory hierarchy. At the register level, researchers are exploring techniques to provide more registers than are architecturally visible to the compiler. A large volume of work exists (and is occurring) for cache optimizations and alternate cache organizations. For instance, modern processors now commonly split the top level of the cache into separate physical caches, one for instructions (code) and one for program data. Due to the increasing cost of cache misses (in terms of processor cycles), some research trades-off increase the complexity of the cache for reducing the miss rate. Two examples of cache research from opposite ends of the hardware/software spectrum are *blocking* [Lam, 1901] and *skewed-associative caches* [Seznec, 1993]. Blocking is a software technique in which the programmer or compiler reorganizes algorithms to work on subsets of data that are smaller than the cache, instead of streaming entire large data structures repeatedly through the cache. This reorganization greatly improves temporal locality. The skewed-associative cache is one example of a host of hardware techniques that map blocks into the cache differently, with the goal of reducing misses from conflicts within a set. In skewed-associative caches, either one of two

hashing functions may determine where a block should be placed in the cache, as opposed to just the one hashing function (low-order index bits) that traditional caches use. An important cache-related research topic is *prefetching* [Mowry, 1992], in which the processor issues requests for data well before the data are actually needed. Speculative prefetching is also a current research topic. In speculative prefetching, prefetches are issued based on guesses as to which data will be needed soon. Other cache-related research examines placing special structures in parallel with the cache, trying to optimize for workloads that do not lend themselves well to caches. Stream buffers [Jouppi, 1990] are one such example. A stream buffer automatically detects when a linear access through a data structure is occurring. The stream buffer issues multiple sequential prefetches upon detection of a linear array access.

Much of the ongoing research on main memory involves improving the bandwidth from the memory system without greatly increasing the number of banks. Multiple banks are expensive, particularly with the large and growing capacity of modern DRAM chips. Rambus [Rambus Inc., 1992] and Ramlink [IEEE Computer Society, 1993] are two such examples.

Research issues associated with improving the performance of the virtual memory system fall under the domain of operating system research. One proposed strategy for reducing page faults allows each running program to specify its own page replacement algorithm, enabling each program to optimize the choice of page replacements based on its reference pattern [Engler et al., 1995]. Other recent research focuses on improving the performance of the TLB. Two techniques for doing this are the use of a two-level TLB (the motivation is similar to that for a two-level cache), and the use of superpages [Talluri, 1994]. With superpages, each TLB entry may represent a mapping for more than one consecutive page, thus increasing the total address range that a fixed number of TLB entries may cover.

Summary

A computer's memory system is the repository for all the information that the CPU uses and produces. A perfect memory system is one that can immediately supply any datum that the CPU requests. This ideal memory is not implementable, however, as the three factors of memory capacity, speed, and cost are directly in opposition.

By staging smaller, faster memories in front of larger, slower, and cheaper memories, the performance of the memory system may approach that of a perfect memory system—at a reasonable cost. The memory hierarchies of modern general-purpose computers generally contain registers at the top, followed by one or more levels of cache memory, main memory, and virtual memory on a magnetic or optical disk.

Performance of a memory system is measured in terms of latency and bandwidth. The latency of a memory request is how long it takes the memory system to produce the result of the request. The bandwidth of a memory system is the rate at which the memory system can accept requests and produce results. The memory hierarchy improves average latency by quickly returning results that are found in the higher levels of the hierarchy. The memory hierarchy generally reduces bandwidth requirements by intercepting a fraction of the memory requests at higher levels of the hierarchy. Some machines—such as high-performance vector machines—may have fewer levels in the hierarchy, increasing memory cost for better predictability and performance. Some of these machines contain no caches at all, relying on large arrays of main memory banks to supply very high bandwidth, with pipelined accesses to operands that mitigate the adverse performance impact of long latencies.

Cache memories are a general solution for improving the performance of a memory system. Although caches are smaller than typical main memory sizes, they ideally contain the most frequently accessed portions of main memory. By keeping the most heavily used data near the CPU, caches can service a large fraction of the requests without accessing main memory (the fraction serviced is called the hit rate). Caches assume locality of reference to work well transparently—they assume that accessed memory words will be accessed again quickly (temporal locality), and that memory words adjacent to an accessed word will be accessed soon after the access in question (spatial locality). When the CPU issues a request for a datum not in the cache (a cache miss), the cache loads that datum and some number of adjacent data (a cache block) into itself from main memory.

To reduce cache misses, some caches are associative—a cache may place a given block in one of several places, collectively called a set. This set is content-addressable; a block may or may not be accessed based on an address tag, one of which is coupled with each block. When a new block is brought into a set and the set is full, the cache's replacement policy dictates which of the old blocks should be removed from the cache to make room

for the new block. Most caches use an approximation of least-recently-used (LRU) replacement, in which the block last accessed farthest in the past is the one that the cache replaces.

Main memory, or backing store, consists of banks of dense semiconductor memory. Since each memory chip has a small off-chip bandwidth, rows of these chips are placed together to form a bank, and multiple banks are used to increase the total bandwidth from main memory. When a bank is accessed, it remains busy for a period of time, during which the processor may make no other accesses to that bank. By increasing the number of interleaved (parallel) banks, the chance that the processor issues two conflicting requests to the same bank is reduced.

Systems generally require a greater number of memory locations than are available in the main memory (i.e., a larger address space). The entire address space that the CPU uses is kept on large magnetic or optical disks; this is called the virtual address space, or virtual memory. The most frequently used sections of the virtual memory are kept in main memory (physical memory), and are moved back and forth in units called pages. The place at which a virtual address lies in main memory is called its physical address. Since a much larger address space (virtual memory) is mapped onto a much smaller one (physical memory), the CPU must translate the memory addresses issued by a program (virtual addresses) into their corresponding locations in physical memory (physical addresses). This mapping is maintained in a memory structure called the page table. When the CPU attempts to access a virtual address that does not have a corresponding entry in physical memory, a page fault occurs. Since a page fault requires an access to a slow mechanical storage device (such as a disk), the CPU usually switches to a different task while the needed page is read from the disk.

Every memory request issued by the CPU requires an address translation, which in turn requires an access to the page table stored in memory. A translation lookaside buffer (TLB) is used to reduce the number of page table lookups. The most frequent virtual-to-physical mappings are kept in the TLB, which is a small associative memory tightly coupled with the CPU. If the needed mapping is found in the TLB, the translation is performed quickly and no access to the page table needs to be made. Virtual memory allows systems to run larger or more programs than are able to fit in main memory, enhancing the capabilities of the system.

Defining Terms

Bandwidth: The rate at which the memory system can service requests.

Cache memory: A small, fast, redundant memory used to store the most frequently accessed parts of the main memory.

Interleaving: Technique for connecting multiple memory modules together in order to improve the bandwidth of the memory system.

Latency: The time between the initiation of a memory request and its completion.

Memory hierarchy: Successive levels of different types of memory, which attempt to approximate a single large, fast, and cheap memory structure.

Virtual memory: A memory space implemented by storing the most frequently accessed parts in main memory and less frequently accessed parts on disk.

89.1 Input Devices[1]

Solomon Sherr

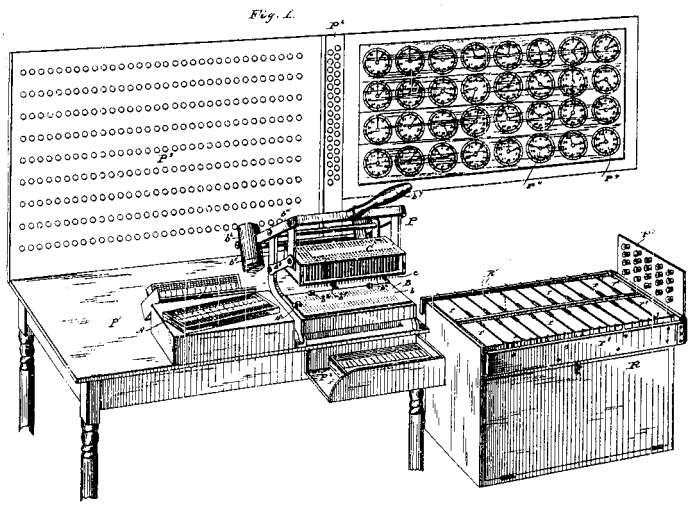
Input devices are those portions of computer, data processing, and information systems that perform the essential function of providing some means for entering commands and data into the system. Therefore, input devices are found in all such systems, but are treated here as a separate equipment group, independent of the total system configuration. However, the place of input devices in a representative computer system may be clarified by reference to Fig. 89.1(a), which shows the interface of the main input device categories in relation to the portions of the generalized system that accept the inputs. The categories and the devices listed in Table 89.1 are the subject of this section.

Keyboards

Keyboards are essentially electromechanical devices, and are still ubiquitous, in spite of the inroads of other input devices. The primary type of keyboard in use as an input device is the alphanumeric (A/N) form, well known in its typewriter application, but with various additions and expansions consisting of numeric and special function keys. This type of keyboard is shown in Fig. 89.1(b) with a standard QWERTY format, so named because of the layout of the top left alpha keys, for the A/N portion, a separate numeric set to the right, and a group of function keys at the top. Other layouts for the A/N portion have been proposed and at least one (Dvorak) accepted by the American National Standards Institute (ANSI), but it has not received much use in spite of its advantages in increased efficiency. At present, the overwhelming majority of system keyboards still use the QWERTY layout, and it is the only one considered here.

As illustrated in Fig. 89.1, a keyboard consists of a number of keyswitches whose exact structure is of prime importance in keyboard design. The relevant characteristics of keyswitch operation are life, actuation force, travel distance, and feedback. Accepted values are shown in Table 89.2 for different keyswitch designs. The elastomer type is preferred to a limited extent over the other two when the electronic audio feedback is included. This indicates that some type of audio feedback is desirable. One form of keyswitch design using an elastomer

[1]The material contained in this section is a shortened version of that which appears in *Electronic Displays,* 2nd ed., by Sol Sherr, Chapter 6, Section 6.1, 1993, published by John Wiley & Sons, Inc., and is reprinted here by permission.



Art of Compiling Statistics

Herman Hollerith
Patented January 8, 1889
#395,781

An excerpt from Herman Hollerith's patent application:

Having thus described my invention, what I claim as new is (1) The improvement in the art of compiling statistics, which consists in first preparing a series of separate record-cards, each card representing an individual or subject; second, applying to each card at predetermined intervals circuit-controlling index points arranged according to a fixed plan of distribution, to represent each item or characteristic of the individual or subject, and third, applying said separate record-cards successively to circuit-controlling devices acted upon by the index-points to designate each statistical item represented by one or more of said index-points, substantially as described.

This patent, along with two others, describes a system for tabulating statistical items represented by holes punched in cards. The 1890 U.S. census was completed $5 million under budget and two years ahead of schedule because of Hollerith's system. The punch card system with encoded holes (the code for representing alphanumeric characters with holes was named after Hollerith) was widely used for sorting, counting, and tabulating even into the 1980s. Hollerith's original Tabulating Machine Company was the forerunner to the computer giant, IBM.

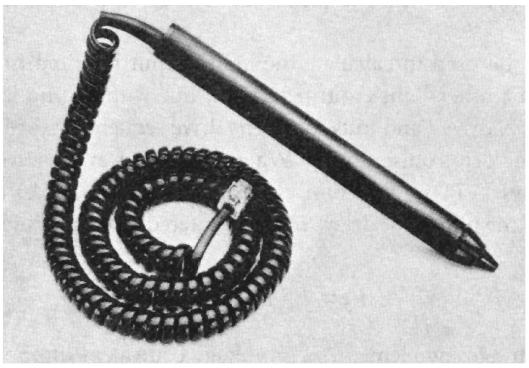
or "molded boot" is shown in Fig. 89.2(a), in which the boot consists of two collapsible domes. In this design, the internal movement of the keyswitch is completely silent so that some source of sound must be added to achieve the desired audible feedback. The snap switch design shown in Fig. 89.2(b) has built-in sound and achieves a small reduction in insertion errors over the elastomer design with audio feedback.

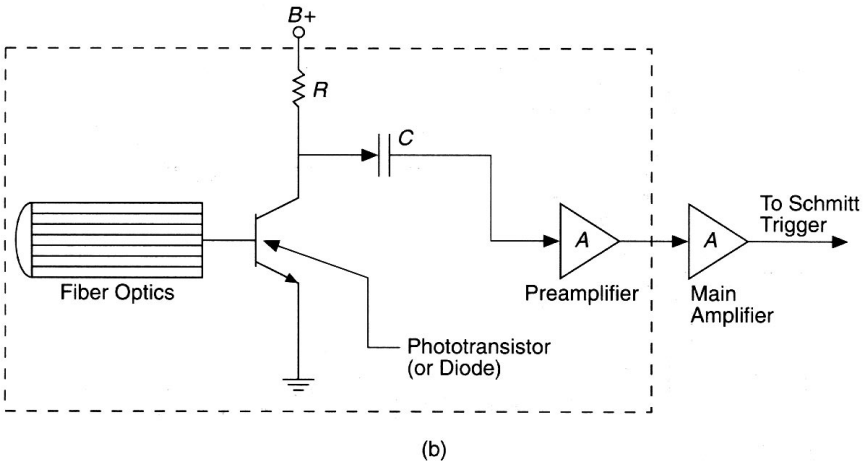
The life requirement is estimated on the basis of workstation users operating at approximately half the accepted rate of 20 million actuations per key used for electronic typewriters. The actual layout and content of the keyboard may vary greatly, ranging from the standard typewriter arrangement, through different combinations of alphanumerics and symbols, to the special-function keyboards that contain legends and symbols specific to the particular application. However, the outputs of each type are the same in that they must contain coded signals that relate the action to be performed by the information system to that defined by the key being operated, in terms of the input code of the system. Thus, many of the keyboards output the ASCII code, and the system is usually designed so that it can accept this type of standard code. Incidentally, ASCII, the acronym for American Standard Code for Information Interchange, is the standard means for encoding alphanumerics and a group of selected symbols for transmission to a display system, among others. It is the standard code used in the United States and most other English-speaking countries and corresponds to the ISO seven-bit code. The seven-bit ASCII is usually used, and it should be noted that for serial data transmission an eighth bit is added for parity. Various keyboard arrangements are possible, and many variants are found in particular applications. The means for coding the key operation may be through magnetic reed relays, solid-state circuits, or more exotic devices such as Hall effect sensors. These device characteristics are only incidental to the operation and beyond the scope of this chapter. Similarly, we do not discuss the human-factors aspects of keyboard design, not because they are not important, but because, apart from the visual considerations, the other factors have to do with tactile and physical features best left to others.

Light Pen

The light pen initially was a very popular means for accomplishing manual input to the random deflection information display systems, but fell out of favor when raster systems became more popular due to its being



(a)



(b)

FIGURE 89.3 (a) Light pen. (Courtesy of FTG Data Systems.) (b) Light pen schematic. (*Source:* After S. Sherr, *Electronic Displays*, New York: John Wiley & Sons, 1979, p. 388. With permission.)

somewhat difficult to use with raster systems. This device goes by a misleading name, as it does not emit light and is not a pen other than being somewhat similar to one in its physical appearance, as shown in Fig. 89.3(a). However, when we consider its functional characteristics, the validity of the term becomes apparent, as it is used to cause the electron beam to "write" patterns on the cathode ray tube (CRT) that are defined by the motion of the light pen on the CRT faceplate.

The light pen operates by sensing the existence or nonexistence of a pulse of light at the point on the screen of the CRT or surface of any other light-emitting device where the point of the pen is placed. This is accomplished by means of the circuit shown in Fig. 89.3(b), where the light pulse is collected and transmitted through the fiber optics to a light-sensitive device that converts the light pulse into an electrical pulse which is shaped by some form of electronics (of which a Schmitt trigger is one example). We need not concern ourselves with the exact form of the electronics except to note that this pulse is then sent to the computer, as shown in Fig. 89.4, and provides a complete, closed-loop system. As the electronic pulse occurs at the time when the light pulse passes under the light pen, the computer is informed of the location at which the designated operation is to be performed and may proceed accordingly. Thus, the light pen is a pointing device that designates a point on the display screen and can be used as an input device. Various light pen programs have been written to expand the capabilities of the original one, and it should be noted that the light pen is coming back into favor as improvements in accuracy, ease of operation, and reliability occur.

There are two characteristics of light pen operation that affect the capabilities of this input device. The first is the sensitivity, given by

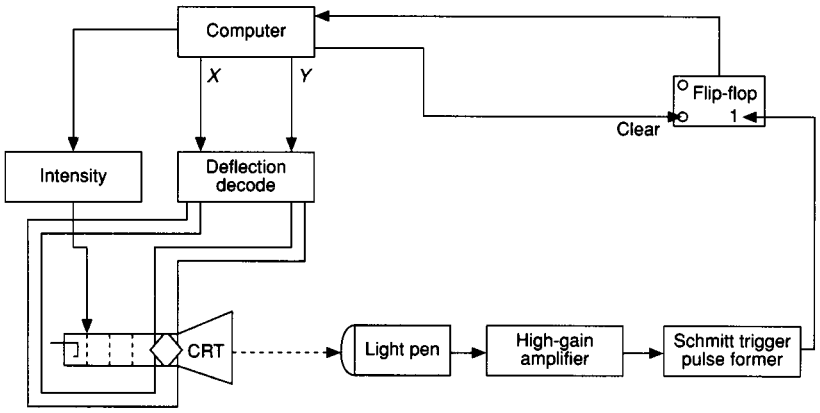


FIGURE 89.4 Block diagram of light pen computer system. (*Source:* S. Sherr, *Electronic Displays*, New York: John Wiley & Sons, 1979, p. 389. With permission.)

$$S = E_L \mu_p A_p A_m \mu_s \mu_f t_L \tag{89.1}$$

where E_L = illuminance at photodetector, μ_p = photodetector sensitivity, A_p = preamplifier gain, A_m = main amplifier gain, μ_s = Schmitt trigger sensitivity, μ_f = flip-flop sensitivity, and t_L = optical loss.

Equation (89.1) may be used to calculate the light output required from the display surface, which may be a CRT or other light-emitting device, but with the limitation that most of the flat panel units are matrix driven and must track the drive sequence in order to know the location of the light pen from the drive pulse timing. When phosphors are involved as for the CRT, vacuum fluorescent displays (VFDs), thin-film electroluminescent (TFEL) units, and color liquid crystal displays (LCDs), the phosphor delays must be entered into the timing, and the total delay is given by

$$E_o = E_i(1 - e - t/\tau) \tag{89.2}$$

where E_o = voltage at triggering element, E_i = voltage equivalent of phosphor light output, t = time, and τ = sum of all delays.

These delays set limits to the positional accuracy, as the computer tracking the signal will be in error by this amount. Other inaccuracies are due to the dimensions of the optical pickup surface, all of which somewhat negate the simplicity of operation. The result is the parameter values shown in Table 89.3.

TABLE 89.3 Light Pen Data

Field of View	Response Time	Sensitivity
0.02–0.08 in.	120–150 ns	0.02–0.04 ft.L

Data Tablet (Graphics, Digitizer)

A very convenient means for data entry, retaining some of the ease of operation of the light pen but with much better accuracy, are the various forms of data tablets available. These tablets differ from the light pen in another significant way in that they do not require a moving spot of light to detect the location of the beam or direct it to a new location. This need for a moving light spot made the light pen difficult to use with the data tablets initially designed to overcome this limitation while still using a device with a pen-like input. The first successful example was the Rand tablet, a digital device that used an *X*–*Y* assembly from which a wand placed above some point on the *X*–*Y* wire matrix could pick up pulse generator output that fed *X* and *Y* electrical pulses into the matrix. By determining the number of pulses in a time period, the location of the wand is established. Another similar device used magnetostrictive rather than electrical signals to accomplish the same result, and this location is converted into display coordinates used to position a cursor on the CRT screen. The cursor may then be

used as a visual feedback element so that the operator can correct the position of the wand until the cursor is properly placed. At this time the information from the tablet may also be transferred to either the host computer or the resident desktop or portable computer, as desired. Since the cursor is not used to signal its position to a pickup device, as is the case with the light pen, it may be used with any type of display system, including the non-light-emitting flat panel displays. Another advantage of the tablet is that it may be used to position cursors in the blank areas of the display, where no light pulses are available unless they are specially generated by the light pen.

There have been numerous improvements and new developments using a variety of technologies that include magnetostrictive, electromagnetic, electrostatic or capacitive, scanned *X–Y* grid, resistive, and sonic. Of these, electromagnetic tablets dominate the digitizer market, and sonic is of interest because it does not require a tablet, but most of the other technologies are essentially restricted to touch input devices covered later. As noted previously, electromagnetic is the most popular technology for high-performance digitizer tablets. Operation is based on transformer principles, whereby a conductor carrying ac creates a magnetic field around it that induces a current in a second conductor. The digitizer tablet uses the amplitude and phase of the induced current to determine digitizing data. The tablet contains an *X–Y* pattern of conductors beneath its surface, in a manner similar to the Rand Tablet, but instead of counting pulses in a time period a circular conductor is used as the pick-up element for the induced current. This coil is placed on the tablet surface, and its position is determined by measuring the phase and amplitude of the current in the coil. Its center is interpolated by sweeping through the *X–Y* grid lines and demodulating the signal in the coil to determine the phase reversal point, or by calculating this point using digitized data fed into a microprocessor. The *X–Y* coordinates may be resolved to better than 0.025 mm using either of these two techniques. Figure 89.5(a) is a photograph of a representative digitizer tablet.

Another digitizer technology is the one that uses the measurement of the time required for sound waves to travel from a source to movable microphone pickups.This sonic technology has the advantage that no special digitizing board is required, and either a stylus or a cursor can be used as the digitizer. Two sonic sources are contained in an *L* frame so that both *X* and *Y* coordinates can be determined by calculating the time it takes for the sound wave to reach the microphones contained in the pickup device. This calculation is made on the basis of sound traveling at 345 m/s at 20°C, and the accuracy is dependent on stable ambient conditions. This tends to limit the resolution to about 300 lpi, and the accuracy to ±0.1%. The device may also be implemented with a single sonic source as the digitizing means and a pair of microphones located outside the digitizing area. In this case the location of the transducer is calculated by triangulation and converted into Cartesian coordinates.

Digitizers are used primarily for inputting accurate coordinate data from maps and engineering drawings. Their high accuracy requirements have led to relatively high prices. Alternative means for inputting data are the data and graphics tablets that meet most input requirements at a lower cost and accuracy. The main technology is still electromagnetic, and the units are essentially the same as the digitizers, but with lower accuracies. However, several of the other technologies have also been used to achieve lower costs. Most successful among them are the capacitive and resistive versions, which may also be used as digitizers. The capacitive units, also termed electrostatic, use capacitive coupling where the coupling between the tablet and the cursor or stylus is determined by the capacitance made up of the tablet surface as one plate and the pickup element as the other. In this case, the capacitance is given by

$$C = f(™A/d) \tag{89.3}$$

where C = capacitance, ™ = permittivity of dielectric, A = relative area of two plates, d = distance between plates, and f = proportionality factor.

A scanned grid approach is used to determine the location of the cursor. As in the electromagnetic tablet, an *X–Y* grid of conductors is embedded in the tablet, with semiconductor switches on each line providing contact on a scanned basis. The charge flowing from each capacitance is summed through a summing amplifier as shown in Fig. 89.5(b). The resultant voltage peaks twice, once for the *X* and once for the *Y* lines, as they are scanned. The peak positions are digitized by means of a counter that starts at the beginning of the scan, and runs at some multiple of the scan rate. The digital values represent the coordinates of the cursor location.

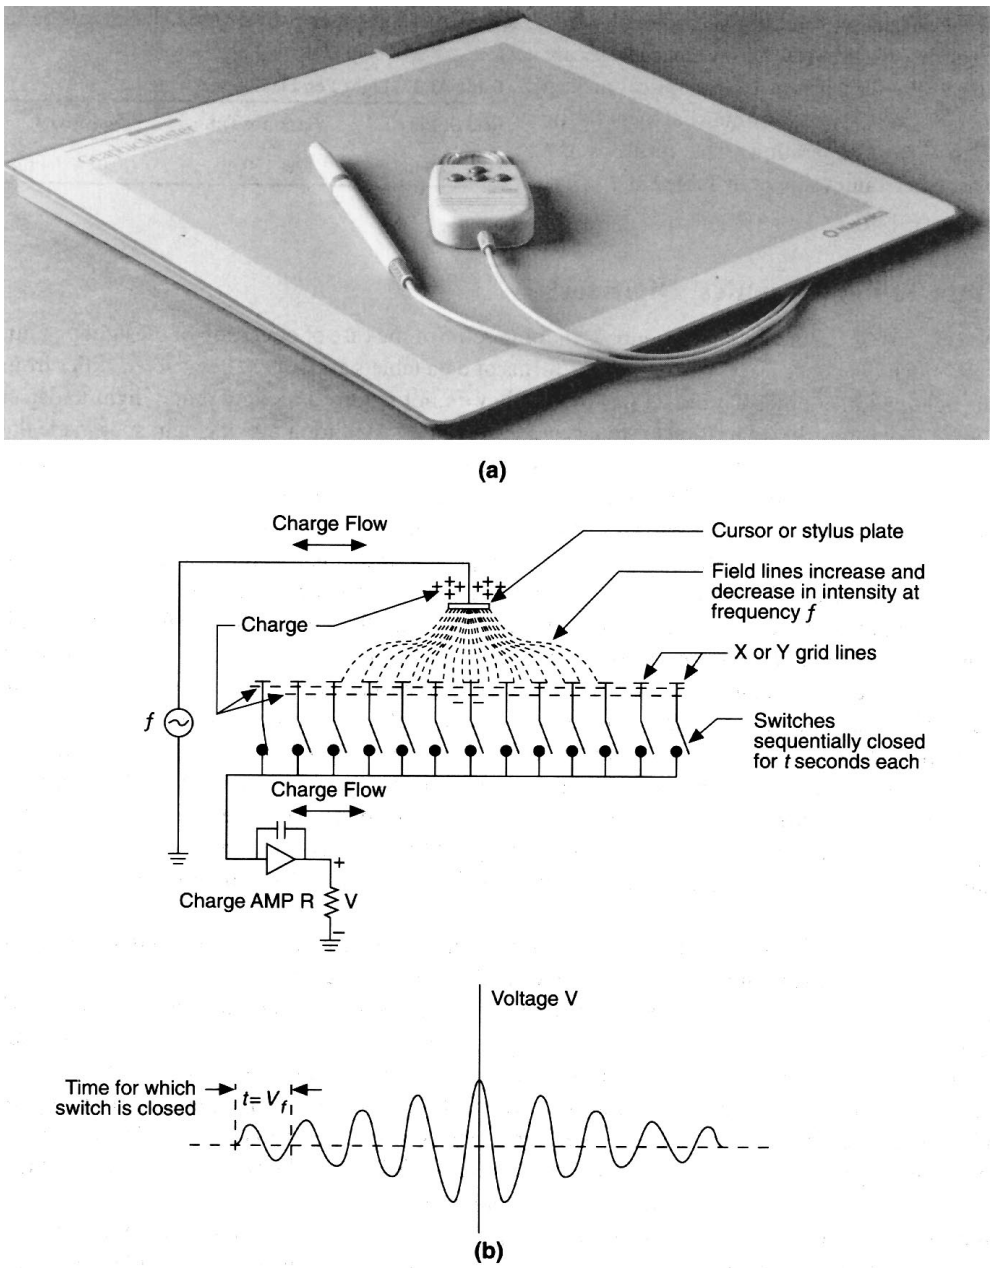

FIGURE 89.5 (a) Digitizer tablet. (Courtesy of Numonics.) (b) Capacitive technology. (*Source:* After T. E. Davies et al., "Digitizers and input tablets," in *Input Devices*, S. Sherr, Ed., New York: Academic Press, 1988, p. 186. With permission.)

Mouse

The mouse has gone a long way from its original invention by Engelbart in 1965, through its redesign at Xerox and introduction by Apple as a main input device, and its general acceptance by computer users as an important addition to the group of input devices. It should be noted, in passing, that the mouse is essentially an upside-down trackball, although the latter is now being referred to as an upside-down mouse. However, the trackball came first and is described further in the next section.

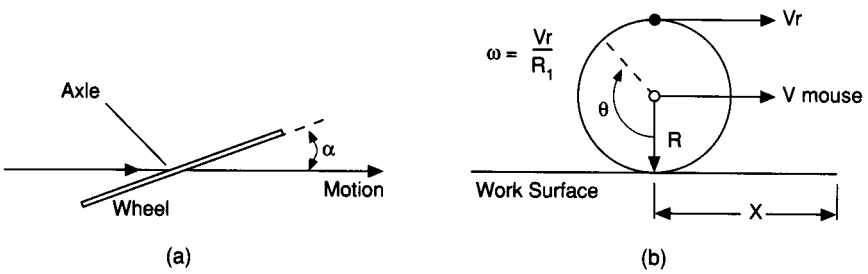

FIGURE 89.6 Wheel showing velocities and slip angle. (*Source:* After C. Goy, "Mice," in *Input Devices*, S. Sherr, Ed., New York: Academic Press, 1988, p. 225. With permission.)

Mice contain motion-sensing elements and are operated by moving mechanical or optical elements. One form uses wheels and shafts to drive the sensing elements, as shown schematically in Fig. 89.6. The angular velocity (ω) of the wheel and shaft is given by

$$\omega = V_r/R \quad \text{rad/s} \tag{89.4}$$

where V_r = velocity of wheel and R = wheel radius.

The rotation angle (θ) is given by

$$(\theta) = X/R \quad \text{rad} \tag{89.5}$$

where X = distance moved.

This type of mouse has two sets of wheels and shafts, one for horizontal and the other for vertical motion.

A more popular type of mechanical mouse is the one that uses a ball for the motion sensing device, as shown in Fig. 89.7. Again, the velocity of the ball circumference equals the velocity of the mouse, and the angular velocity is given by

$$\omega = V/R_1 \text{ rad/s} \tag{89.6}$$

where R_1 = shaft radius.

The smaller the shaft the more rapid its rotation for a given mouse velocity. Another form of the ball-and-shaft mouse is the one that uses an optical interrupter, as shown in Fig. 89.8. In this form, the light from the light-emitting diodes (LEDs) is interrupted by the coded disks that are rotated by the shafts, and is then picked up by the phototransistors and converted into the digital signal that represents the disk rotation. An optical interrupter is also used for the optomechanical mouse, and here the interrupter contains a set of slots; as the interrupter rotates quadrature signals are created that correspond to the shaft rotation.

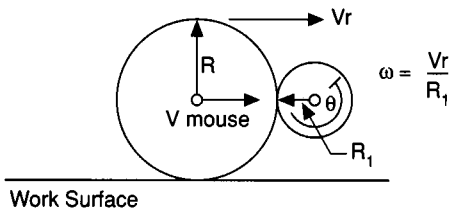

FIGURE 89.7 Ball and shaft. (*Source:* C. Goy, "Mice," in *Input Devices*, S. Sherr, Ed., New York: Academic Press, 1988. With permission.)

In addition to the shaft and optomechanical mice, an early form of mouse used multiturn potentiometers connected to the wheels, and the output voltage that represented the motion varied in direct proportion to the mouse motion. The voltage was then converted by means of an analog-to-digital converter into digital form for input to the computer.

Finally, there are the true optical mice that use a special surface that is printed with a set of geometric shapes, usually a grid of lines or dots, that are illuminated and focused on a light detector. The most common form uses a grid made up of orthogonal lines, with the vertical and horizontal lines printed in different colors. These colors absorb light at different frequencies so that the optical detectors can differentiate between horizontal

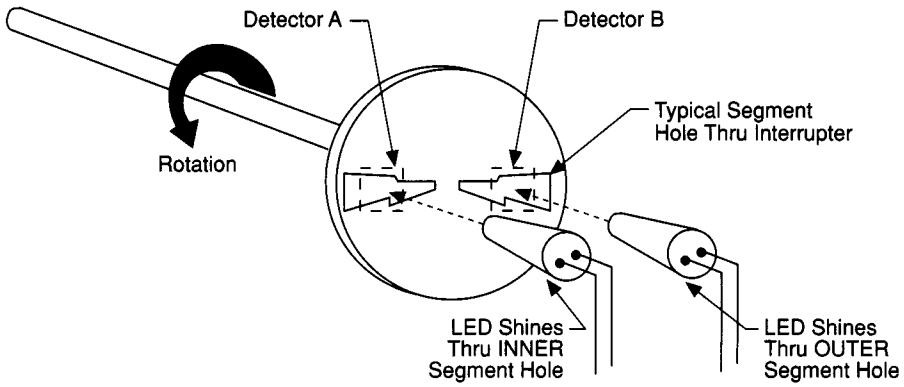

FIGURE 89.8 Optical interrupter. (*Source:* C. Goy, "Mice," in *Input Devices*, S. Sherr, Ed., New York: Academic Press, 1988, p. 229. With permission.)

and vertical movement of the mouse. If such a structure is used as the mouse, then the photodetector will pick up a series of light-dark impulses consisting of the reflections from the mirror surface and the grid lines and convert them into square waves. A second LED and photodetector that is mounted orthogonally to the first is used to detect motion in the orthogonal direction, and the combination of the two inks avoids confusion between the two directions of motion. The system then counts the number of impulses created by the mouse motion and converts the result into motion information for the cursor. This type of mouse has the advantage that no mechanical elements are required.

Trackball

As noted previously, the trackball uses technology similar to the mouse, but preceded it as an input device. Thus, the comment that it is an upside-down mouse should be reversed. The movable element is housed in an assembly as is shown in Fig. 89.9, and the assembly remains stationary so that much less desk space is required than for the mouse. In addition, the trackball may be mounted on a keyboard so that very little additional desk space is needed. The movable element can be the same as used in the mouse, and the output can be a set of bits corresponding to the coordinates to which the cursor should be driven, or where the command should be carried out. The output format is essentially equivalent to that used for the mouse, and the same protocols are used.

The typical trackball has an *X* and *Y* optical encoder that generates a pulse for each 0.76 mm of incremental motion of the ball. This means that the pulse train may range from 10 to 2500 pulses per second (pps), depending on how fast the ball is rotated. This is much more rapid than required for satisfactory updates, which need not be greater than about 100 times per second. This can easily be accomodated by the RS-232 protocol using an eight-bit word. Thus, the trackball is an excellent alternative for the mouse, and is rapidly returning to a preferred position as an input device.

Joystick

The joystick has not achieved much acceptance as an input device for electronic display systems, except for video games, although it has been the preferred control for many types of aircraft. However, it can be used to some extent in display systems other than those used in video games, and therefore warrants inclusion in this section. There are two basic types of joysticks, termed "displacement" and "force-operated". A typical displacement joystick is shown in Fig. 89.10, and may have two or three degrees of freedom. The activating means may vary from as few as four switches mounted 90 degrees apart, to full potentiometers for analog output, and optical encoders for digital output. A third axis may be added by allowing the handle to rotate and drive a third potentiometer. Spring forces of 5 to 10 lbs. are usual for the other two axes, and displacements go from 6 to 30 degrees.

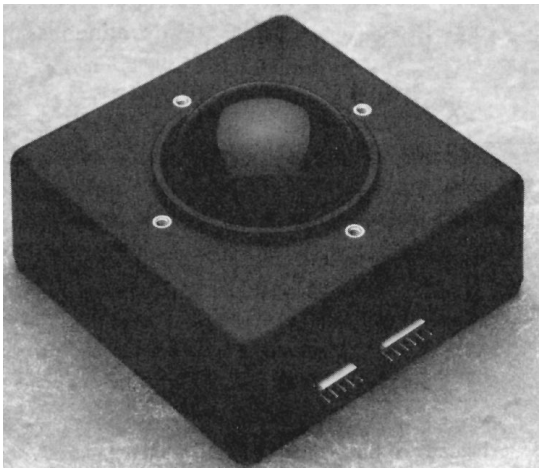

FIGURE 89.9 Trackball. (Courtesy of CH Products,Vista, Calif.)

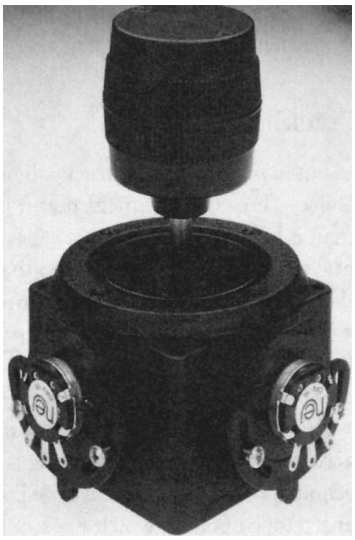

FIGURE 89.10 Three-axis displacement joystick. (Courtesy of CH Products, Vista, Calif.)

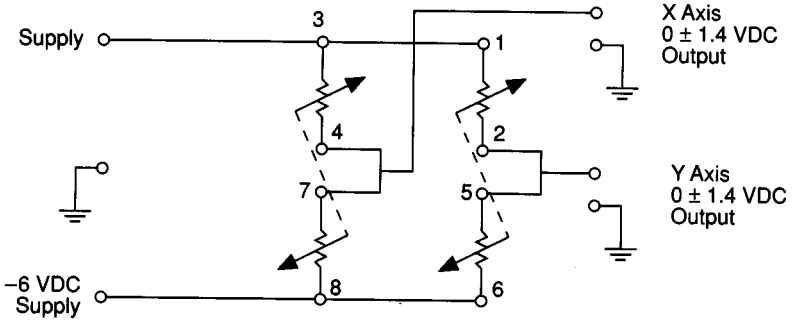

FIGURE 89.11 Schematic connections in a force joystick. (*Source:* After D. Doran, "Trackballs and joysticks," in *Input Devices*, S. Sherr, Ed., New York: Academic Press, 1988, p. 260. With permission.)

The force joystick operates by responding to pressure on the handle to generate the *X*–*Y* coordinates. It may be either a two- or three-dimensional version, with the same types of handles as for the displacement joysticks. However, it is difficult to use a rotating handle for the third dimension because some force is usually transmitted to the other dimensions causing crosstalk. Therefore, a separate lever is preferred. The force is detected by means of piezoelectric sensors that are bonded to the handle rod, and a voltage source is applied across the network, as shown in Fig. 89.11. The output is taken from the strain gauge and the analog voltage will be proportional to the amount of force. The same type of protocol and output circuitry may be used as for the displacement unit, and both can generate either position or rate data. An exponential curve with a dead zone threshhold is preferred for pulse rates in order to avoid starting pulse rate uncertainties, with the first pulse starting as soon as the threshhold is exceeded.

Touch Input

Touch input devices come in two basic forms, either placed directly on the display surface, or as a separate panel attached to the computer system. In its second form it is essentially a data tablet differing mainly in that it acts as another display unit with some form of a touch-sensitive surface. In this implementation it is the

same as the *Touchscreen* input device, and this discussion concentrates on the technologies used for Touchscreens. There are five different technologies used for touch input devices, which are capacitive or resistive overlays, piezoelectric, light beam interruption, and surface acoustic wave. The system may be divided into the sensor unit, which senses the location of the pointing element, and the controller that interfaces with the sensor and communicates the location information to the system computer. Since the controller is an electronic device that does not use technology different from the computer it is not covered here. The main differences among the different touch input devices are due to the choice of sensor technology, and the discussion concentrates on these technologies.

Capacitive. Capacitive overlay technology is illustrated in Fig. 89.12 where a transparent metallic coating is placed over the display screen and the finger or stylus capacitance is sensed to determine the touch location. The overlay may consist of a group of separate sections etched into the surface with each separate section connected to the controller, or a continuous surface connected at the four corners. The first form is termed discrete capacitive, and touch location is determined by having each section sequentially connected to an oscillator circuit where the frequency of oscillations is affected by the pointing device. The oscillation frequency is measured and compared to a stored reference frequency. If the frequency difference is large enough then it is recognized as a touch at that location. It is a simple system, but suffers from low resolution and slow response so that it is only practical for menu selection.

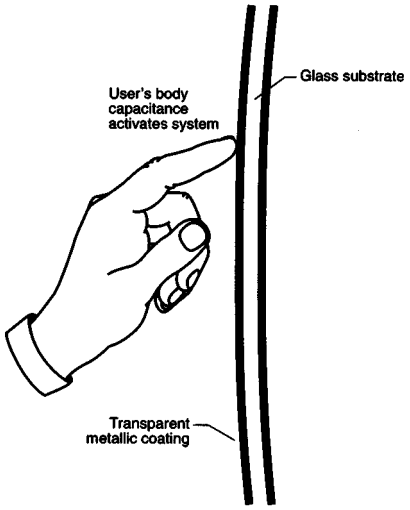

FIGURE 89.12 Capacitive overlay technology. (*Source:* After A. B. Carrell and J. Carstedt, "Touch input technology," *SID Sem. Lecture Notes*, p. 15.30, 1987. With permission. Courtesy Society for Information Display.)

The analog capacitive system uses the same metallic overlay, but the metallic surface is continuous rather than etched. The connections at the four ends are each connected to a separate oscillator, and the frequency of each is measured and stored. Then when the overlay is touched the change in capacitance will have a different effect on the frequency of each oscillator. These are measured and the differences are used to determine the coordinates of the touch by means of an algorithm. This technique is capable of much higher resolution (250×250) than the digital approach and is preferred for graphics or other high-density displays.

Resistive. Resistive overlay technology requires a more complex assembly consisting of two layers, as illustrated in Fig. 89.13. The layers both contain transparent metallic surfaces and are separated by spacers so that an air gap exists between the layers in the absence of any pressure on the touch panel. The metallic layers face each other and when the outer panel is pressed the metallic layers make contact and form a conductive path at the point of contact. When a voltage is applied between the top of the outer layer and the bottom of the inner layer, the two layers act as a voltage divider, and the voltage at the point of contact may be measured in the X and Y directions by applying the voltage in first one and then the other direction. The measured voltages are then transmitted to the controller where they are converted into coordinates which are then sent to the computer.

The panel may be discrete, in which the conductive coating on the top layer is etched in one direction and that on the bottom layer in the other direction, or analog, where the conductive coatings in both layers are continuous. In the discrete case, the panel then acts as an X–Y matrix, and the resolution is determined by the number of etched lines. The analog configuration requires the addition of linearization networks on each edge of the panel so that a large-area resistor is created with a voltage drop in one direction. Other linearization techniques are also possible, but only the four-element system is described here as shown in Fig. 89.14. In this arrangement, one of the layers acts as the large-area resistor and the other as a voltage probe where either can function in either role. For the Y coordinate value the top layer is the voltage probe, and the voltage is applied by the controller to the bottom layer. Similarly, the X coordinate is found by connecting the voltage to the top layer and making the bottom layer into the voltage probe. In either type of system, the resolution can be very high, but the transmissivity is reduced to under 80% due to the multiple layers.

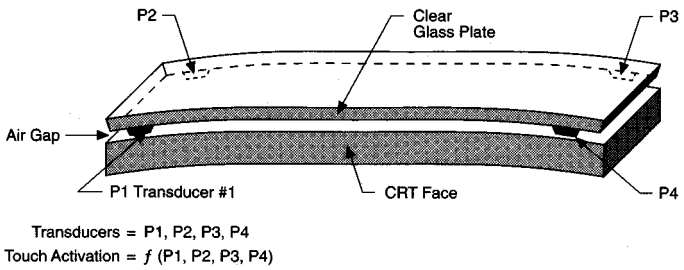

FIGURE 89.15 Piezoelectric technology. (*Source:* A. B. Carrell and J. Carstedt, "Touch input technology," *SID Sem. Lecture Notes*, p. 15.34, 1987. With permission. Courtesy Society for Information Display.)

Piezoelectric. The piezoelectric technology uses pressure-sensitive transducers as the means for determining the location of the touch, as shown in Fig. 89.15. The sensor is a glass plate with transducers connected to the four corners. Pressure on the plate causes readings to occur at each of the transducers, which depend on the location of the pressure. Thus, the controller can measure the readings and obtain the coordinates by means of a proper algorithm. This technique allows a high-transmissivity plate to be used that can be curved to follow the CRT face plate curvature, but it allows only a limited number of touch points to be used.

Light Beam Interruption. This is a fairly straightforward technology that requires a matrix of light sources and detectors facing each other in the *X* and *Y* directions. When the beams from the *X* and *Y* light sources are interrupted, this is sensed by the facing light detectors and the signals are sent to the controller. The light beams

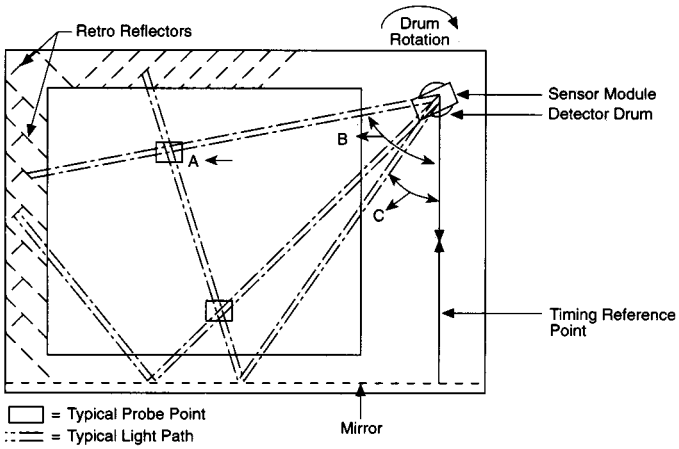

FIGURE 89.16 Rotating infrared beam technology. (*Source:* A. B. Carrell and J. Carstedt, "Touch input technology," *SID Sem. Lecture Notes*, p. 15.34, 1987. With permission. Courtesy Society for Information Display.)

are turned on sequentially by pulsing the LEDs and thus create a full matrix of light beams without requiring each of them to be on continuously. This system does not reduce the screen transmissivity as there is no obstruction of the screen output, but it is limited in resolution to the number of LED detector pairs that can be placed on the periphery of the screen.

Another approach to light interruption is to use a rotating beam of light, which has the advantage that only one light source and detector pair is required. This technology is depicted in Fig. 89.16 and consists of a LED and a light detector placed inside a rotating drum which has a slit that allows light to be transmitted outside the drum. The light is swept across the surface and strikes the retroreflectors that sends it back directly to the detector. The beam scan is sampled 256 times on each scan, and Fig. 89.16 shows how two angles of interruption are created, angle B by direct interruption, and angle C by mirror reflection interruption. The result is that the location of the interruption can be calculated by comparing the two angles. Again, there is no obstruction of the screen but a moving element must be added, and parallax errors may occur.

Pen-Based Computing. This is an application for touch input devices that is growing at a rapid rate. The input device comes in several forms, each of which can recognize hand printing with the special operating system and software recognizing this type of input. The pen-based input device comes in several forms, of which the one termed TouchPen™ can function both as a digitizer with a touch tablet, and as the touch input device with a touch input pen-based computer system. A second one is that developed by Wacom, Inc., primarily for the GO Systems computer, but used by other pen-based systems as well. Finally, a third unit is that made by Scriptel Corp. and used by Wang Laboratories in its system.

TouchPen™ was developed by Microtouch Systems, Inc., initially for use in GridPad made by the Grid Systems Corp. It is essentially a high-resolution digitizer consisting of an all-glass tablet that can be used with a number of stylus input operating systems to digitize handwriting. It is basically a touch input device using resistive techniques to digitize the handwriting appearing on the display surface of pen-based computer systems. The glass tablet is placed on the display surface and the system pen is used to transmit the digitized data to the computer. As noted previously, the tablet may also be used as a standard touch input device.

The second form of pen-based input device is one that uses electromagnetic technology and consists of a grid of wires that transmit radio waves that are picked up by a tuned circuit in the stylus. This circuit resonates at its own frequency and transmits that signal back to the wires at the grid location it is touching. The pen also transmits its signal to the computer, which turns off the grid transmission, and locates the position of the pen by determining which of the grid wires pick up the pen signal. The pen does not need to actually touch the display surface and does not require any power, which is an advantage somewhat counteracted by the higher cost.

Finally, the Scriptel unit is similar to that made by Microtouch, but differs in that it uses electrostatic technology and is also similar to the capacitive touch panel.

Surface Acoustic Wave (SAW). This technology is more recent than the others and has not received wide acceptance as yet. It is based on the transmission through the glass of SAWs generated by transducers mounted on the glass overlay. These waves are detected by receivers also mounted on the glass, and the time of arrival of the waves at the receivers is known because the wave velocity is known. The placing of a finger on the glass weakens the signal and the location of the finger can be determined by the difference in its effect on the SAW.

There are two types of SAW systems in use, namely those using reflective techniques and those using attenuation as the source of position information. The reflective systems are similar to sonar where the time from the source to the pointing finger and then from the finger to the receiver is measured to arrive at finger location. The attenuation technology is illustrated in Fig. 89.17 and consists of two transducers, two receivers, and four reflector strips, all mounted on a glass substrate. One transducer-receiver pair is used for *X* and the other for *Y* location. Figure 89.17 shows the *X* axis pair, and the transducer transmits a burst of acoustic energy in a horizontal wave. The wave is partially reflected by the top reflector strips and travels down to the bottom strip where the reflectors are at an angle such that it is reflected to the lower left corner receiver. The wave now has a long rectangular shape, and each point in time corresponds to a specific vertical path across the substrate. The *Y* axis is scanned in the same fashion after the *X* wave dies out. Then, when the finger touches the substrate, its water content absorbs some of the energy in the wave, and the wave is attenuated. The dip in the wave amplitude corresponds to the amount of absorbed energy, and the time of the lowest point can be determined, allowing the location of the finger to be calculated. Finally, in addition to the *X* and *Y* coordinates, a *Z* coordinate can be determined, depending on how hard the user presses. This depends on surface contact, which affects the amount of attenuation. The advantages of this system are high resolution, speed of transmission, and the availability of a *Z* axis component. Its main disadvantages are the variation in moisture content in fingers and sensitivity to local moisture on the substrate. However, it is being used in developmental units and should be considered as another input device technology.

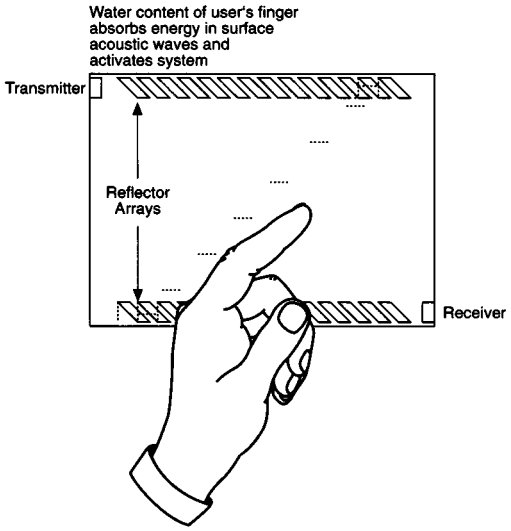

FIGURE 89.17 Attenuation SAW technology. (*Source:* A. B. Carrell and J. Carstedt, "Touch input technology," *SID Sem. Lecture Notes*, p. 15.35, 1987. With permission. Courtesy Society for Information Display.)

Scanners

Scanners are a means for inputting text and/or images directly into the computer system, thus avoiding the need for retyping and redrawing information contained in other sources. It is a relatively convenient way to avoid repetition if the data to be entered already exist in readable form. This is done by special image-recognition software that accompanies the scanning hardware, and can transfer an entire image containing both text and illustrations, but without the capability to modify the image. However, the addition of optical character recognition (OCR) software allows the entered text to be modified as if it were entered by typewriter. This can greatly simplify entering and editing text from some preexistent source and has resulted in a proliferation of devices that can perform this function.

These devices come in two main forms, *hand-held* and *page* scanners, with or without OCR software in addition to the standard image-recognition software. A typical hand-held scanner is shown in Fig. 89.18 and it consists of a light source, a light-sensitive device such as a charge-coupled device (CCD) array, and the electronics to actuate the elements of the array sequentially under software control. The scanner window is placed over the page, and is moved down or across the page so that the window covers as much of the page as falls within the capability of the software. The light source is reflected from the page to the CCD and the charge in the CCD is modified by the reflectivity of the printed material.

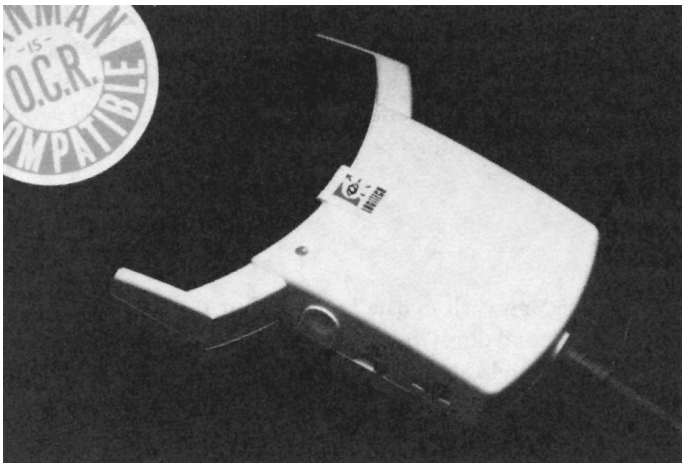

FIGURE 89.18 Hand-held scanner. (Courtesy of Logitech, Freemont, Calif.)

The window area ranges from 4 to 5 in. in width by 0.5 in. in height and may be moved through 14 to 20 in., so that a fairly large area may be covered in a single manual scan. Images wider than the maximum window may be scanned in two passes, and the OCR software can stitch the two scans together into a single image, although this procedure requires considerable care in scanning so that the scans line up properly. Therefore, when images wider than the window of the hand-held scanner are to be scanned, it is advisable to use a *flatbed scanner* of the type shown in Fig. 89.19 which can handle a full 8.5 in. by 11 in. page, or some of the larger scanners than can accept large drawings and input them into the computer system. Resolutions of 400 dpi and higher, with up to 250 levels of gray and 24 bits of color resolution are available. Thus, scanners offer a wide variety of choice and performance capabilities, and are powerful input devices when prepared data in visual form is to be entered into the computer system.

Voice

Voice input is an intriguing approach to data input, with particular attractiveness to managers who want a simple and direct means for inputting data and commands. For many years, this technology tended to promise more than it could achieve, but recent developments have brought it to the point where it can be considered as a viable input means. This has been due to new developments in software that make it possible to minimize the amount of training required and increase the success rate to close to 100%.

One basic approach to speech recognition is represented by the block diagram shown in Fig. 89.20. This is a system that is built around a special chip developed by Texas Instruments. This system uses templates and special algorithms for recognizing the input speech patterns. The system is speaker dependent, with the capability of storing up to 32 word templates and user-defined phrases. The output portion may be superfluous when the system is used only for inputting data and commands, but can be a useful adjunct to the visual response. Other techniques such as speaker-independent and phoneme-recognition systems are also available. Vocabularies range from 50 to 5000 active words, and both isolated and connected words can be recognized, although the larger numbers tend to be associated with isolated word systems. In general, it seems feasible that a combination of speech input and pen-based computing may find a viable market.

TABLE 89.4 Input Device Functional Evaluation

		Function		
Input Device	Control	Data/Text	Data/Graphics	Total
Keyboard	E	E	P	9
Light Pen	G	G	E	10
Tablet	E	G	E	11
Mouse	E	F	E	11
Trackball	E	G	E	11
Joystick	F	F	G	5
Touchscreen	G	F	G	8
Scanner	F	E	G	9
Voice	G	F	P	6
Total	29	23	28	80

E = Excellent = 5; G = Good = 4; F = Fair = 3; P = Poor = 2

Summary

The multiplicity of input devices that are available makes it difficult to determine which is most suitable for any specific set of requirements. However, the limited functional comparison of the input devices covered in this section shown in Table 89.4 may be of some use, and in any event is a starting point in this evaluation. It should be noted that what appears best at one time may become unpopular or obsolete at a later time, as occurred for light pens and trackballs, both of which have come back into favor.

In addition to the generalized evaluation shown in Table 89.4, it is also of interest to examine representative performance parameters. These are shown in Table 89.5 and while representative do not necessarily cover the range of performance parameters offered. More data may be obtained from the vendors of these devices.

Advantages and Disadvantages

Input devices make up one of the functional groups of the display systems, and their technical characteristics are covered in some detail at the beginning of this chapter, with performance information provided in Table 89.5 containing characteristic parameter values for each type, as available. The following material expands somewhat on that information by placing these devices in the context of a full graphics display system and evaluating the functions that the various types of input devices perform in that type of system in terms of their advantages and disadvantages. It is of some interest to compare the advantages and disadvantages of each type at this point, as listed in Table 89.6. This is an imposing list and may be used to aid in choosing the best input devices for specific applications. It also concludes this section on input devices.

TABLE 89.5 Representative Performance Parameters

Input Device	Parameter	Value
Light pen	Response time	150–500 ns
	Spectral response	4200–9500 A
	Luminous sensitivity	0.03–0.7 nts
	Field of view	0.02–0.1 in.
	Ambient rejection	350 nts
Data tablet (digitizers)	Resolution (l/in.)	100–2000
	Accuracy (in.)	0.0005–0.02
	Active area (in.)	12 × 12–60 × 120
	Active height (in.)	0.02–2.5
	Digitizing rate (pps)	100–350
	Transducers	Stylus, puck, cursor
Mouse	Resolution	10–1000 dpi
	Speed	1–20 in./s
	Accuracy	25–1000 dpi
Trackball	Resolution	100–1000 cpi
	Speed	1200–9600 BPS
	Accuracy	100–1000 dpi
	Ball diameter	1.5–2.5 in.
Joystick	Travel	25–30°
	Accuracy	5–10%
	Repeatability	1%
Touchscreen	Resolution	256 × 256–4096 × 4096
	Transmissivity	60–100%
	Viewing area (in.)	3 × 4.5–15 × 20
	Speed	80–200 touch pts./s
Scanner	Resolution (dpi)	75–1600
	Scan rate (in./s)	0.5–2.0
	Scanning width (in.)	4.1–36 gray shades 32–256
	Scan time (s/page)	1–30
Voice	Active vocabulary	13–5000 words

Defining Terms

Data tablet/digitizer: A device consisting of a surface, usually flat, and incorporating means for selecting a specific location on the surface of the device and transmitting the coordinates of this location to a computer or other data processing unit that can use this information for moving a cursor on the screen of the display unit.

Joystick: An input device somewhat in the form of the navigation control device found in early aircraft and operating in a somewhat similar manner by generating series of pulses whose frequency or number depend on how far, with what force, and in what direction the control stick is moved from the central position.

Keyboards: Electromechanical devices consisting of sets of keys labeled with alphanumeric, numeric, and functional designations that enable the user to describe and define the operation to be performed.

Light pen: Neither a pen or a light source but rather an input device in the shape of a pen that operates by sensing the existence or nonexistence of light pulses at specific locations on the surface of a display device and uses this information to signal the computer as to the location of the pen.

Mouse: An input device based on a much older type known as a trackball and fancifully named because it bears only a casual resemblance to a mouse. It consists of a roller ball that is moved on a flat surface and causes orthogonal potentiometers or other types of *X*–*Y*-position signal generators to move and produce electrical signals defining the desired coordinates of the cursor on the screen so that the cursor can be moved to that position.

TABLE 89.6 Input Devices—Advantages and Disadvantages

Device	Advantages	Disadvantages
Keyboard	Simple operation	Requires many keys
	Well known	Requires training
	Standard interface	No graphics
Light pen	Eye-hand coordination	Arm fatigue
	Low cost models	Limited resolution
	No desk space required	May block display
Graphic tablet	Natural hand movements	Eye-hand conflict
	Screen not blocked	Requires desk space
	No parallax	Breakable stylus
	Good for graphics	Poor for A/N entry
Mouse	Small space needed	Some space needed
	Low cost	Slow transmission
	Screen viewing	Low resolution
	Any surface may be used	Grid for optical
	(Optical) noiseless	Mechanical noise
Trackball	High resolution	Poor for A/N input
	Fixed desk space	Slow transmission
	Screen viewing	Mechanical noise
	Tactile feedback	3-D difficult
Joystick	Fixed desk space	Low accuracy
	Low fatigue	Low resolution
	Low cost	No A/N input
Touchscreen	Eye-hand coordination	Arm fatigue
	Minimal training	May block display
	Minimum input errors	Varied resolution
	User acceptance	Parallax
	No special commands	Slow data entry
Scanner	Full A/N page input	Hand scanner width
	Color scan input	High cost for color
	High resolution	Slow input
	OCR software	Compatibility
Voice	Ease of use	Limited words
	Minimal training	Machine training
	No special devices	Graphics difficult

Scanners: Means for converting hard copy into electrical signals that can be entered into a computer or data processing system. The usual means for accomplishing such conversion is to move a light beam over the surface containing the data either by hand or automatically and using arrays of light-sensitive devices to convert the reflected light into electrical pulses.

Touch input: A means for selecting a location on the surface of the display unit using a variety of technologies that can respond to the placing of a finger or other pointing device on the surface. These are essentially data panels placed either on the display surface or between the user and the display surface.

Trackball: The earliest version of an input device using a roller ball, differing from the mouse in that the ball is contained in a unit that can remain in a fixed position while the ball is rotated. It is sometimes referred to as an upside-down mouse, but the reverse is more appropriate as the trackball came first.

Voice: Means for enabling a computer or data processing system to recognize spoken commands and input data and convert them into electrical signals that can be used to cause the system to carry out these commands or accept the data. Various types of algorithms and stored templates are used to achieve this recognition.

Further Information

Electronic Displays, 2nd ed., by Sol Sherr and published by John Wiley & Sons, Inc., contains an extensive and detailed discussion of other aspects of display systems and technology, as well as a somewhat expanded version of this section. In addition, *Input Devices,* edited by Sol Sherr, and *Output Hardcopy Devices,* edited by Robert C. Durbeck and Sol Sherr, both published by Academic Press, include extensive discussions of a wide variety of devices.

The Society for Information Display (SID) sponsors a yearly symposium at which a large amount of information on new developments in information display as well as tutorials and seminars on basic information display topics are presented and made available in published form. In addition, it publishes two journals, namely, *Proceedings of the Society for Information Display* and *Information Display.* Other relevant meetings and publications are those sponsored by the Computer Society and Electron Devices groups of the IEEE, the SIGGRAPH group of the Association for Computing Machines (ACM), and the National Computer Graphics Association (NCGA).

89.2 Computer Output Printer Technologies

Robert C. Durbeck

Electronic printers for computer output represent a very important part of the computer industry. They range from small, inexpensive printers for personal computers and workstations to very large and fast page printers used for bulk printing output for large-scale computer systems. The technologies employed for this wide scope of printing requirements are diverse: some based on "impact" methods to transfer ink from a sheet or ribbon to paper, others based on more sophisticated "nonimpact" methods. Today, there is no single technology which completely dominates. A wide range of user needs has led to the present proliferation of printer technologies. The most prevalent are discussed in the following.

Classification of Printer Technologies

Table 89.7 illustrates the two main classifications of printer technologies and also the wide range of extant technologies. Those technologies listed under **line impact** and **page printing** are used for large computer system printing; by far the most popular are *fully formed character* and *electrophotographic* (so-called laser printers). The most common printing technologies used for personal/workstation computer systems are *electrophotographic, ink jet,* and *serial wire matrix.* Emphasis in the following is directed to these favored technologies, with brief descriptions of the others included.

Page Printer Technologies

By far the most important page printer technology is electrophotography (EP). EP, as well as the much less employed ionographic and magnetographic technologies, uses "powder toning" development of an intermediate

TABLE 89.7 Types of Printer Technologies

Impact	Nonimpact
Line impact	Page printing
Fully formed character	Electrophotographic
Dot band matrix	Ionographic
Shuttle hammer matrix	Magnetographic
	Electrostatic
	Thermal
Serial impact	Serial nonimpact
Fully formed character	Ink-jet
Serial wire matrix	Continuous
	Piezoelectric/impulse
	Thermal/bubble-jet
	Thermal
	Direct (thermal paper)
	Thermal transfer
	Resistive ribbon

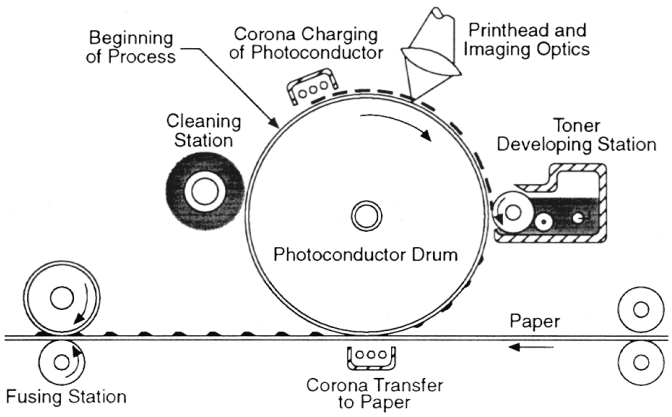

Figure 89.21 The six basic electrophotographic printer process steps: charge, image, develop, transfer, fuse, and clean.

"image" created in the process. Liquid toners are also used to develop electrostatic images. Thermal page printers employ a full-page-width linear array of thin-film heater elements to melt and transfer ink from a ribbon to the paper or to mark special thermal-sensitive paper.

Electrophotographic Printing

EP printers use essentially the same technology found in most "plain paper" copiers, the major exception being the printhead. Instead of using page- or line-imaging optics as in a copier, the printhead utilizes a solid-state laser (usually GaAlAs) or gas laser (typically HeNe) to scan across and expose a photoconductor drum or belt to create a "latent image" (see below). A few EP printers use stitched arrays of light-emitting $GaAs_{1-x}P_x$ diodes (LEDs) with Selfoc™ glass fiber optics or an array of liquid crystal shutters, the latter to modulate light from a bright line light source. Other possibilities are electroluminescent, magnetooptic or electrooptic arrays, but these have not been commercialized to any extent.

There are basically six major steps employed in the EP printing process (see Fig. 89.21): (1) uniform charging of the photoconductor (PC) electrostatically; (2) exposing the PC to the image light pattern, which results in selective discharge of the area charge created in Step 1, creating an electrostatic image; (3) developing the PC by bringing electrostatically charged toner particles (black or colored) to the surface of the PC where they selectively adhere to appropriately charged regions; (4) electrostatically transferring the toned image from the PC to the final medium (usually paper); (5) thermal fusing of the toner to the paper; and (6) cleaning residual toner from the surface of the PC to allow reinitiation of the six step cycle.

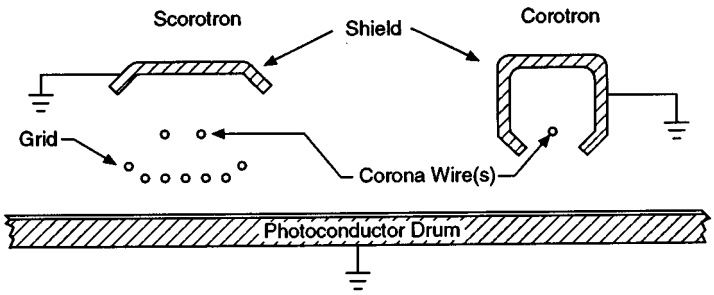

Figure 89.22 Two types of coronas for charging the photoconductor: the scorotron and the corotron.

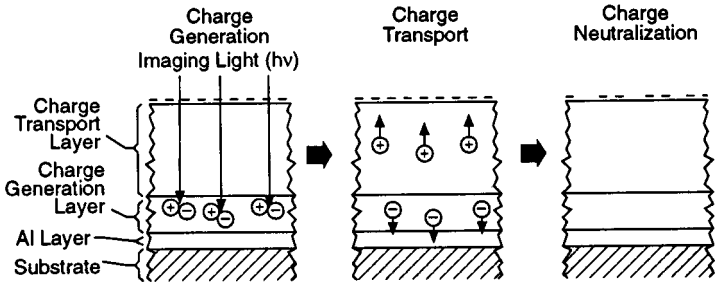

Figure 89.23 Light is used to selectively discharge the photoconductor. Electron-hole pairs are photogenerated in the charge-generation layer, followed by charge transport under a dc bias field and then selective neutralization of the surface charges, thereby creating an electrostatic image.

Step 1—Charging the PC. The most common approach used is corona charging. One or more thin corona wires (typically tungsten) are supported directly above the PC and are energized to 5–8 kV. The resultant high electric field surrounding the wire causes electrons in the immediate region to be accelerated to energies sufficient to ionize local air molecules. Either positive or negative ions are then attracted to the outer surface of the PC (which, when unexposed to light, acts for a short period of time as an insulator) depending on the sign of the potential difference. At the same time, a counter-image charge is formed on the inner side of the PC. The two corona structures most commonly used are the corotron and the scorotron (see Fig. 89.22). The grid on the scorotron is used to more precisely control the resultant voltage charge level on the PC (approximates the grid voltage). Both dc and ac designs are used; the latter usually include a glass sleeve around the corona wire to reduce localized high-emission spots on the wire due to contaminants. To save on cost for very low-cost EP printers and to reduce corona by-products (e.g., ozone), a lower-voltage conductive elastomer charge roll in direct contact with the PC has also been used in place of the corona wire.

Step 2—Exposing the PC. The wavelength of the exposing light source must match the spectral sensitivity of the PC. If the PC is discharged in areas that will be printed white, the overall process is termed charge area development (CAD); if the discharged area will be printed black (or color), the process is called discharge area development (DAD). Both CAD and DAD processes are used in EP printers but CAD is the only common process used in copiers.

Selective discharge of the PC involves two steps: (1) photogeneration of electron-hole pairs and (2) transport of the electrons and holes in opposite directions under the influence of a high-dc bias field, locally dissipating the surface charges created in Step 1 (see Fig. 89.23).

Both organic and inorganic PC materials are used (see Fig. 89.24). A variety of charge-generation and charge-transport material systems have been developed for organic PCs; most use separate layers for charge generation and charge transport. Examples of efficient organic charge-generation materials sensitive at both GaAlAs (7800 Å) and HeNe (6328 Å) wavelengths include squarylium and thiopyridium dyes in an appropriate binder layer (≈0.5 μm thick). The charge-transport layer (CTL) consists of a thicker layer (20–30 μm) of a charge-transport

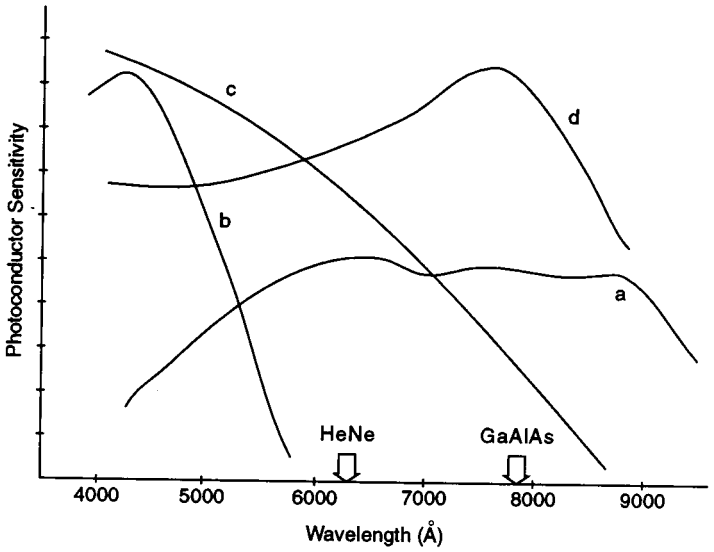

Figure 89.24 Spectral absorption characteristics of several photoconductor materials: (a) squarylium dye, (b) SeTe, (c) As_2Se_3, and (d) a-Si.

molecule dispersed in an inert binder, or simply a good charge-transporting polymer (e.g., polyvinylcarbazole). Since most polymer transport materials are essentially hole-transport materials, this requires that the PC surface charge produced in Step 1 be negative. The CTL must be transparent at the imaging wavelength.

Examples of inorganic PC materials include amorphous chalcogenide alloys such as a-Se, a-As_2Se_3 and Te-doped Se. Most do not have a high sensitivity at GaAlAs wavelength, but a-Si does. a-Si also offers other desirable properties (e.g., durability and lack of fatigue), but is quite expensive to produce.

The laser beam is scanned linearly over the PC in a direction orthogonal to the PC motion; the combined motions covering a "page". The most common gas laser scanning technique employs a high-speed rotating polygon mirror along with beam-expanding optics, an acoustic-optic modulator (not required for solid-state lasers) and an f-θ imaging lens. To produce a quality image, the multifaceted scanning mirror system must be essentially free of facet defects, up-and-down wobble, variations in polygon rotational velocity and lack of synchronization with the **pixel** clock. Some nonplanarity of the facet surfaces can be corrected with anamorphic optics. LED arrays and liquid crystal shutter systems do not have these same technical challenges but, so far, they are more expensive to produce.

Step 3—Developing the PC. There are basically three development techniques: dual component, monocomponent and liquid development. The first two use powder toner. Until the advent of EP printers for personal and workstation computers, the most common method of development was dual component, where polymer-coated magnetic carrier beads are mixed with the toner particles and development is done with a "magnetic brush." This technique is still prevalent in high-end printers. With this approach, the 5–20 μm toner particles (consisting mainly of resin plus carbon particles or colorant) are triboelectrically charged by repeated contacts during mixing with the much larger (60–250 μm) magnetic carrier beads. The toner particles then electrostatically adhere to the opposite-sign charged carrier beads. Charge control agents (e.g., complex organometallic salts) are often included in the toner composition to control the charge level, rate of charging, and consistency of charge. The mix is mechanically directed to a nonmagnetic rotating shell which has fixed magnets located within its core, adjacent to the gap between the PC and the shell (see Fig. 89.25). The gap is typically 0.5 to 6 mm, depending on the specific system. As the shell rotates, the mixture is carried to the gap, and chains of carrier beads (coated with toner—the "magnetic brush"!) form along the local magnetic field lines. These field lines are approximately perpendicular to the shell at the smallest gap. In addition, a development voltage (200–500 V) is applied between the PC and shell. This provides a high field in the gap whose local value is determined by the applied voltage, gap dimension and the electrical properties of the material mix in the gap.

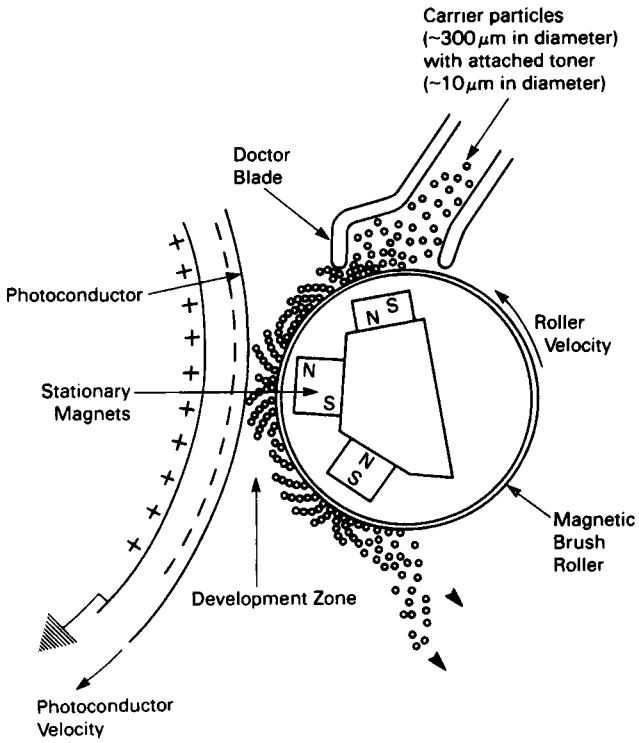

Figure 89.25 Dual-component magnetic brush developer. Toner particles, adhering electrostatically to much larger magnetic carrier beads, are transported into the photoconductor-developer gap to tone the electrostatic image. (*Source:* R. C. Durbeck and S. Sherr, Eds., *Output Hardcopy Devices,* San Diego, Calif.: Academic Press, 1988, p. 242. With permission.)

The electric field at the end of the last carrier bead (next to the PC) in a chain may be up to 50 times the nominal unfilled gap field, the value being greatest with uncoated carrier beads. It can be shown that for coated carrier beads, the mass of toner per unit area developed on the PC is approximately

$$\frac{m}{A} = \frac{\pi \epsilon_0 V}{2 L_g C_m} \left\{ r_c \, / [(r_t / \kappa) + \delta_c] \right\} \cdot \left| v_r / v_p \right| \tag{89.7}$$

where v_r/v_p is the surface speed ratio between the developer roll (shell) and the PC surface, V the voltage across the gap L_g, C_m the toner charge-to-mass ratio, ™$_0$ the permittivity of free space, r_c the carrier bead radius, r_t the toner radius, κ the dielectric constant of the bulk toner, and δ_c the thickness of the carrier polymer coating.

Monocomponent development is used almost exclusively for low-end printers because this process does not require carrier beads, toner concentration sensors or toner replenishment hardware, resulting in much lower manufacturing costs. This approach has also allowed the use of replaceable toner/developer cartridges which, although more costly on a supplies cost-per-page basis, adds greatly to the user-perceived reliability of the system (if it fails—just replace the cartridge!). A rotating donor/development roll with appropriate charging properties is employed to charge the toner by touch-and-rubbing contacts (see Fig. 89.26). The toner electrostatically adheres to the donor roll and is transported to contact the PC at the nip. Here, in the presence of a development bias field, the toner is selectively transferred to those areas on the PC with opposite sign charge.

Liquid development employs a high-resistivity hydrocarbon dispersion of very fine toner particles (<1 μm) that are charged naturally in the solvate. Mechanical means are used to bring the liquid into contact with the PC, and the toner is then electrophoretically transferred to the latent image areas on the PC.

Color can be accomplished by using multiple development stations, one each for the subtractive colors (cyan, yellow and magenta) plus black. Toners are colored by either dyes or pigments. The four-colored images may

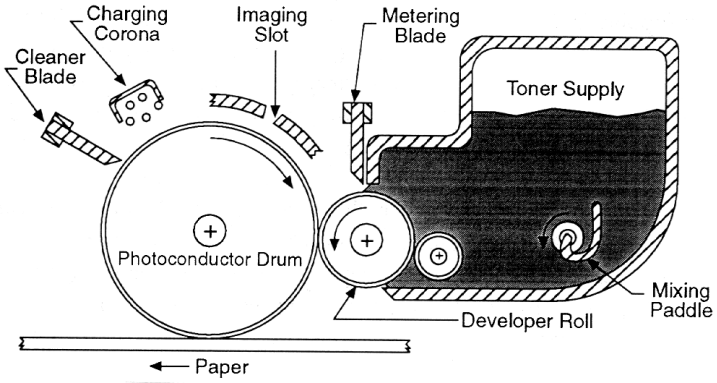

Figure 89.26 Monocomponent developer system.

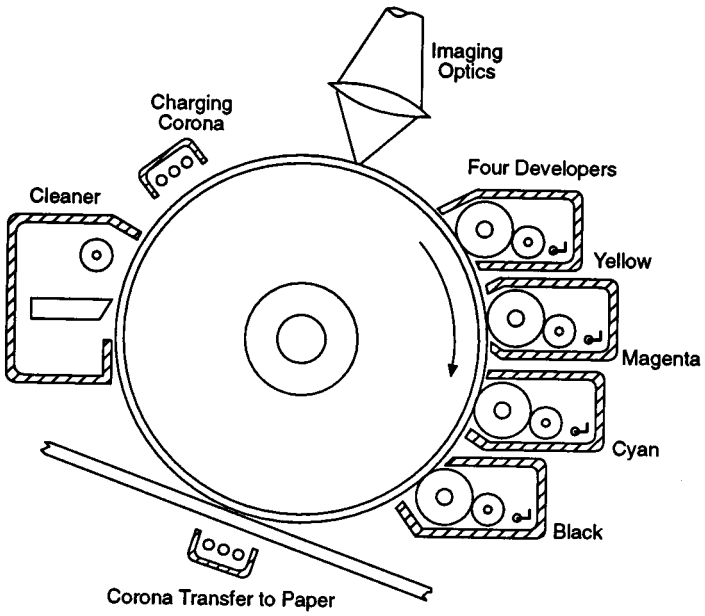

Figure 89.27 Four developers are used to produce color plus black. Four photoconductor drum rotations are needed to accumulate the four-color toner images.

be accumulated on the PC (see Fig. 89.27) or alternatively on an intermediate belt or drum, or even on the paper itself. A wide range of colors and the visual illusion of gray scale can be achieved by the use of laser pulse-width modulation and the use of "super-pixels" consisting of $N \div M$ arrays of binary pixels to provide digital half-toning.

Step 4—Transfer of Toner to Paper. Here a corona is used to charge the back side of the paper and the toner is transferred from the PC to the paper. Typically, some small fraction of the toner usually has a charge of the wrong sign. It is at this step where most of this wrong-sign toner is removed, minimizing "background" on the page, since primarily only toner with the correct sign gets transferred.

Step 5—Fusing Toner on the Paper. After transfer the toner is only loosely held (electrostatically) onto the paper; it must be fixed by fusing. There are several fusing techniques: (1) hot-roll using hot fuser rolls under pressure, (2) cold-roll, (3) solvent vapor, (4) flash lamp, and (5) radiant heating. Hot-roll fusing is predominantly used but all five techniques have been commercialized. The most efficient approach is hot-roll but all

of the thermal approaches require 0.5–2.0 J/cm^2 energy at the paper surface. The energy required is determined by the contact duration (related to the nip compliance and roll speed), pressure, paper water content, and the melt-flow rheological characteristics of the toner. Flash fusing has only been used in mid-range to high-end printers because expensive power supplies and capacitor banks are needed. A xenon flash lamp is typically pulsed for a few milliseconds to provide the required energy. Thermal efficiency improves with very short pulses, but undesired toner degradation volatiles increase with the higher temperatures produced. Care must be taken with radiant fusing to insure that excessive paper overheating does not occur if the paper is stopped under the incandescent lamp.

Step 6—Cleaning the PC. To restart the overall EP process, the PC must be cleaned of residual toner and contaminants. Fiber brushes, scraper blades, and "magnetic-brush" cleaners are used. For low-end printers, scraper blades suffice and are replaced (in some systems) with each new cartridge. Rotating soft-fiber brushes with air flow collection are used commonly in mid-range to high-end printers. Magnetic-brush cleaning is very similar to magnetic-brush development (see above).

Ionographic Printing

Ionographic printer devices also use powder toner technology and the overall technology is very similar to EP. One major difference, however, is the creation of the electrostatic image for subsequent toner development. The ionographic process uses an ion source (high-voltage drive electrode) and a page-wide array of control and screen electrodes to gate ions directed toward a drum coated with a thin-film dielectric material (e.g., Al_2O_3), thus creating a charged image on the drum. In present commercial ionographic printers, the transfer and fuse steps of EP are also replaced with a "transfix" process where the paper sheet is squeezed between the toner-developed dielectric drum and a compliant cold pressure roll. The ionographic technology has two fewer process steps (vis-à-vis EP) but the ion printhead represents significant technical challenges (cost and lifetime).

Magnetographic Printing

Magnetographic printing is also similar to EP but employs magnetic powder toner and a magnetic printhead. The magnetic head is an array of individually addressable magnetic write gaps, each representing a pixel location on a line across the page. The head writes a magnetic "image" on a belt or drum coated with a magnetic material such as γ-Fe_2O_3, Co:P or Co:Cr. Toner is attracted to those areas on the drum where flux reversals (and, hence, magnetic fields external to the the magnetic media) are present. The other process steps are essentially the same as used with EP but toner charge levels must be kept under control to ensure that electrostatic forces do not dominate over magnetic forces.

Electrostatic Printing

There are two basic approaches that have been developed: (1) one using a special dielectric paper, and (2) the other using plain paper. In the first approach, a page-wide linear array of electrode discharge pins are independently pulsed to charge the surface of a moving, conductive-base, dielectric-coated paper. Both powder and liquid toners may be used to develop the image; thermal fusing of the image is required for powder toner. With the plain paper version, either a precharged or uncharged dielectric drum or belt can be used depending on whether the array of electrode pins are used to charge or discharge the media surface. The other process steps are essentially the same as with the nominal EP printing process. Cost savings can be realized by multiplexing the electrode driver lines because there is a process threshold of hundreds of volts. This requires, however, that segmented counter electrodes be positioned behind the receiving surface (drum, belt, or paper).

Thermal Page Printing

Thermal transfer page printing is accomplished by using a stationary page-wide linear array of thermal heating elements coupled with a page-wide transfer ribbon roll (see Serial Thermal Printing below for discussion of thermal printhead technologies). The ribbon is positioned between the printhead and the receiving paper. The ribbon typically consists of a polycarbonate or polyester film substrate (10–20 μm) coated with a waxy ink layer. Heat from the thermal printhead elements must penetrate through the substrate to heat (melt) the dye/wax coating. The melted ink layer is pressed into the paper surface by printhead pressure, and after the paper and ribbon move together away from the printhead, the partially cooled ink layer adheres better to the paper than

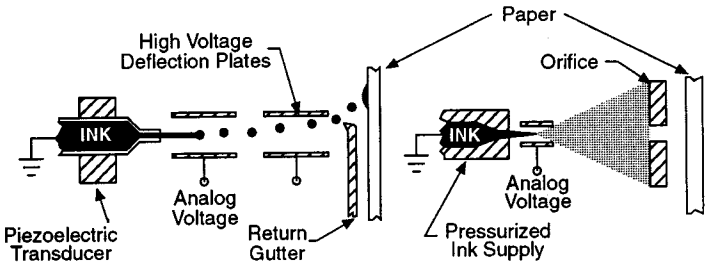

Figure 89.28 (a) Continuous drop ink-jet, and (b) continuous spray ink-jet technologies.

to the ribbon substrate. The ribbon is then peeled away from the paper, leaving the desired image on the paper. Considerable energy must be applied to melt the ink layer (e.g., 2–4 J/cm^2) which does restrict speed. Also, comparably smooth paper (≤50–100 ml/min Sheffield roughness) is required for quality printing with minimal gaps or voids. Print resolution of better than 8 pixels/mm can be achieved with smooth paper.

Sublimable transfer dyes have been used for high-quality colored images since the amount of dye transferred can be controlled somewhat by the energy supplied to the head heater elements. Also, since the sublimable dyes tend to penetrate into the paper sizing and fibers, a less smooth paper can be used than with waxy materials. The energy required for dye transfer is similar to that required for waxy ribbons.

Serial Nonimpact Printer Technologies

Ink-jet and thermal printers represent the two major classes of serial nonimpact technologies used for personal and workstation computer printer output. As shown in Table 89.7, the ink-jet technologies can be subclassified as continuous, piezoelectric, and thermal/bubble-jet. The thermal technologies can be subdivided into direct thermal, thermal transfer, and resistive ribbon.

Serial Ink-Jet Printing

Ink-jet technologies have evolved over the last two decades with continuous ink-jet being the first to be developed, followed by piezoelectric and then thermal or bubble-jet technologies. All three have been commercialized, although bubble-jet is by far the most popular today and continuous ink-jet is used primarily for speciality page printer or high-quality color graphics and image applications. Both piezoelectric and bubble-jet are "drop-on-demand" or "impulse" technologies, i.e., a drop is ejected from the printhead only when desired. With continuous ink-jet, a continuous stream of droplets is generated by the printhead and undesired drops are deflected electrostatically away from the paper (or vice versa). Ink requirements for these technologies are very demanding and the development of appropriate inks is as important (and difficult) as the development of the printer and printhead hardware. Demands on the ink are both extensive and conflicting, and include the requirements of nonclogging in the nozzle but fast dry time on the paper, water-based but water-resistant after drying on the paper, and quality printing on a wide range of papers (requires minimal feathering and controlled spot size). Nonaqueous solid inks have also been used; the ink is solid at room temperature but is liquid at an elevated head temperature.

Continuous Ink-Jet Printing. With this technology, ink is continuously jetted from a small-diameter nozzle under pressure (see Fig. 89.28). Although the resultant jet stream will naturally break into small drops, this phenomenon is assisted and stabilized by the inclusion of a piezoelectric perturbation transducer, driven at the desired drop rate. Lord Rayleigh was the first to determine that the *dimensionless instability factor*

$$\frac{g_r}{(\sigma/\rho d^3)^{1/2}} \tag{89.8}$$

(where g_r is the growth rate of jet instability, σ the surface tension, ρ the fluid density, and d the jet diameter) is maximized for $\lambda/d = 4.51$, where λ is the perturbation wavelength. Operation at this design point produces

very consistent drop breakoff and diameter. Operation at frequencies in excess of 100 kHz is possible with drop velocities of typically 25 m/s with a 50-μm nozzle diameter. Because the drops must be electrostatically charged at the breakoff point, conductive ink must be used. The ink source is typically grounded and a controllable voltage electrode is placed at the breakoff point (usually surrounding the jet stream). The charge level on each drop is then proportional to the applied voltage. Each charged drop can then be deflected by parallel downstream deflection plates with a field of typically 10 kV/cm. This deflection (assuming parallel plates and a uniform electric field between the plates) can be approximated by:

$$d_l = \frac{l_p}{2}\left(\frac{qE}{mv^2}\right)\cdot(2l_z - l_p) \tag{89.9}$$

where d_l is the deflection length, q the drop charge, m the drop mass, E the electric field, v the drop velocity, l_p the deflection plate length, and l_z the distance from the upstream end of the deflection plates to the paper. Drop deflection can be either binary or analog. With the former, the drop either reaches the paper or is directed into a collection gutter. With analog deflection, the drop may be deflected linear (e.g., any position over the height of a printed character).

Smaller satellite drops may be also produced between the primary drops. To eliminate their effect, the excitation system is designed to produce forward-merging satellites as these charge simultaneous with the preceding drop; thus the forward-merging (through "drafting") and subsequent drop coalescence will not alter the charge-to-mass ratio of the augmented drop.

Compensation must be provided for both aerodynamic and electrostatic interactions. Two primary examples are that (1) the first drop in a sequence of drops encounters much greater aerodynamic drag than subsequent drops, and (2) the charge on a drop is influenced by the charge on the previous few drops. One approach to greatly reduce electrostatic drop interaction and to stabilize merging effects is to include noncharged drops between charged drops. This obviously reduces the effective drop rate by a factor of two and requires a design configuration where only charged drops reach the paper. Charging electrode voltage adjustment algorithms based on voltages applied to prior drops are also used to reduce the electrostatic interaction.

An alternate approach is the *continuous spray* design where a smaller nozzle (10–20 μm) is used. Much smaller drops are produced at higher velocities (≈40 m/s). It is often called the Hertz method [see Fig. 89.28(b)]. As with the *continuous drop* approach, a controlled voltage electrode is positioned around the breakoff point of the jet stream, a conductive ink is used, and the smaller droplets are charged proportionally to the applied voltage. The stream of droplets is directed to the paper when no voltage is applied. When a voltage is applied, the resulting electrostatic charge on the droplets produces strong mutual repulsion forces and the stream transforms into a spray, the cone angle of which is determined by the applied voltage. The spray is intercepted by a collecting surface surrounding the collection orifice which allows only uncharged or low-charged droplets through to the paper. With analog voltage control, the amount of spray that passes through the orifice can be varied, thus providing gray-scale capability. This approach (with multiple orifices) has been commercialized for very high-quality color image and graphics applications.

Piezoelectric Ink-Jet Printing. Piezoelectric ceramic transducers are employed with this technology. These materials (e.g., lead zirconate titanate and barium titanate), when polarized, change their physical dimensions when subject to an electric field—usually applied through surface electrodes. Deflections of several angstroms per volt are typical. When the transducer is pulsed with a voltage, the deflection generates a pressure wave in an adjacent ink chamber, resulting in the ejection of a single drop—hence the descriptors, "impulse" or "drop-on demand". Four implementations are shown in Fig. 89.29. Often arrays of these devices are integrated into a serial printhead which allows the printing of a one-character-high-per-head pass across the paper. Color printing can be accomplished by assigning one or more nozzles per color.

Only a very small (100–1000 Å) deflection of the piezoelectric transducer is needed to create the ink chamber pressure wave if the displacement is very rapid (10–100 μs). Hence, these devices are very efficient; only a few microjoules per drop are required for robust operation. Drop ejection rates of over 20 kHz have been demonstrated in the laboratory but commercial devices are typically designed for the 5–10 kHz range. Drops that produce a

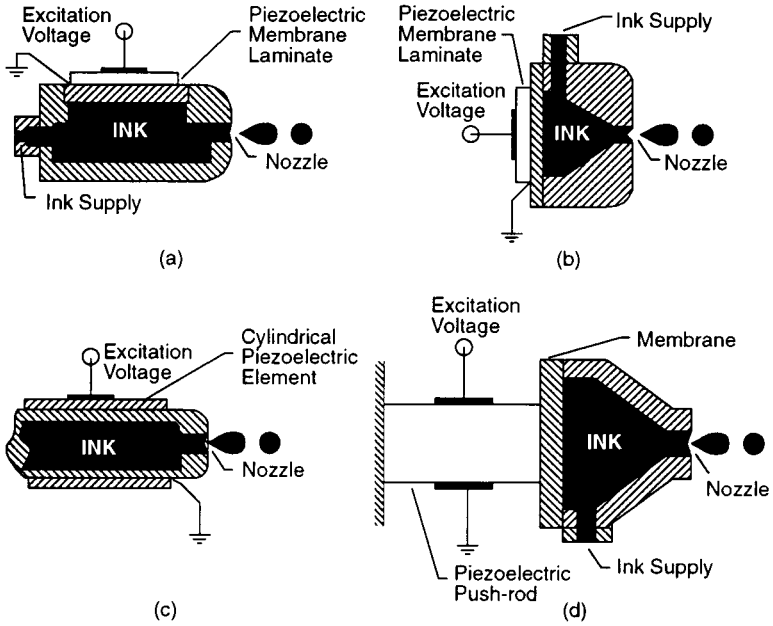

Figure 89.29 Four approaches to piezoelectric drop-on-demand ink-jet technology: (a) piezoelectric/membrane laminate design, (b) "oil-can" version of (a), (c) piezoelectric squeeze-tube approach, and (d) piezoelectric push-rod method.

spot size of 150–200 μm on paper can be achieved with an orifice diameter of about 50 μm. Even greater device efficiency can be obtained by synchronizing the arrival of a direct wave and a reflected wave at the nozzle (e.g., a negatively reflected wave caused by an initial expansion pulse plus the direct wave from a following compression pulse). These two waves can be made to reinforce one another at the time and place of drop ejection.

Figure 89.29(a) shows a piezoelectric/membrane laminate design with a disk-shaped piezoelectric transducer which, upon being pulsed, deforms (assumes a finite radius of curvature) and thus creates a pressure wave in the ink chamber. Figure 89.29(b) illustrates an "oil-can" version of the laminate approach. In Figure 89.29(c), a tubular transducer is used to squeeze the ink chamber. Figure 89.29(d) represents a push-rod or piston design where the piezoelectric material is used in the extensional mode. Attempts have also been made to use modern semiconductor planar/etching processing techniques to create low-cost arrays of devices.

Bubble-Jet Printing. This technology has also been called thermal-jet. With this approach, very small thermal resistors on the ink chamber wall are electrically pulsed. Joule heating of the resistor causes the temperature of the ink adjacent to the heater to rise to 350–400°C (see Fig. 89.30). Because the ink becomes locally superheated, nucleation of tiny bubbles takes place on the surface over the heater. These bubbles coalesce and very rapidly form a single expanding bubble which, by displacement (like a piston), propels a single drop of ink out at the orifice. The electrical pulse must be short (typically 3–6 μs) to insure low conductive heat losses; however, the power density is extremely high (~500 MW/m^2). The energy applied per drop is 30–50 μJ but only a small fraction (a few percent) represents the kinetic energy of the drop. The remaining energy is thermally dissipated in the ink and device structure.

When the thermal energy in the superheated layer is depleted, the bubble begins to collapse. The total cycle (nucleation plus bubble growth and collapse) is normally complete in about 20 μs. Drop rate, however, is typically limited to less than 10 kHz, mainly because of the limits of thermal dissipation. Cavitation damage can occur to the heater structure if the bubble collapse is too violent. Proper design of the ink chamber geometry can provide the necessary damping and minimize this problem. Heater element materials used for this technology include HfB_2, ZrB_2, Ta_2Al and TaN. Passivation over-layers (e.g., SiC, SiO_2, Si_3N_4, plus certain metals such as tantalum) are deposited on top of the thin-film heaters to provide protection from chemical and mechanically enhanced corrosion. Materials, structures and thin-film deposition processes must be carefully

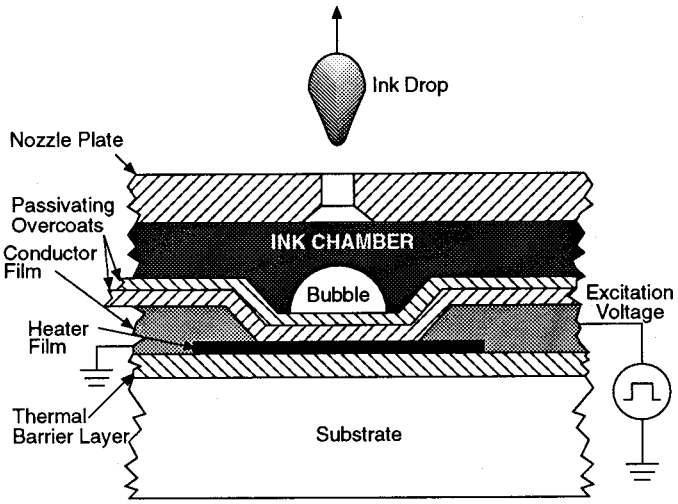

Figure 89.30 Thermal-jet device showing one heater-nozzle package. Joule heating of the thin-film heater causes nucleate boiling in the ink adjacent to the heater. A bubble forms and pushes a drop of ink out of the nozzle.

designed to allow billions of heater pulse cycles without failure at a local power density of 500 MW/m^2. Also, very special ink must be used so that very minimal chemistry occurs at the hot interface layer, e.g., so that the chemicals in the ink do not break down and form a thick carbonaceous film over the heater. These carbonaceous films, when more than a few hundred angstroms thick, destroy the device velocity and thermal efficiency characteristics. The ink must also not etch the overcoats.

Very low-cost, compact, low-power printers have been developed based on this technology because energy requirements are very low and the printhead can be made inexpensively using semiconductor-like planar processing techniques. A proliferation of these printer products (many with color) have appeared in the market over the past five years.

Serial Thermal Printing

Thermal technologies have been used in many low-cost serial printer applications. There are three basic approaches: (1) use of a heat-sensitive special paper, (2) thermal transfer of ink from a ribbon to paper, and (3) a variant on (2) with a special ribbon structure and printhead that improve thermal efficiency and allow printing on a wide range of standard papers (including the relatively rough office bond papers).

Direct Thermal Printing. The key aspects to this technology are the thin-film resistive serial printhead and the special paper required. A typical array structure (see Fig. 89.31) consists of photolithographically defined and deposited heater material (e.g., Ta_2N or TaAl) on a contoured insulating substrate. One or more protective layers (e.g., SiO_2, Ta_2O_5 or SiC) are deposited on top of the heater layer for abrasion resistance and electrical insulation. Contours (raised areas or bumps) on the surface under the heater areas are constructed by a raised glass "glaze" of about 40 μm and provide both improved contact with the paper and short time constant thermal insulation to the substrate. This structure is often called the *thin-film head structure.* Alternates include (1) the *silicon mesa technology,* where a two-dimensional array of silicon mesas is fabricated from monolithic silicon, and (2) the *thick-film technology.* With the former, each mesa contains its own resistor-transistor/diode on the base of the silicon chip. Joule heating occurs when voltage is applied to the resistor via the transistor/diode. With the thick-film approach, a resistor

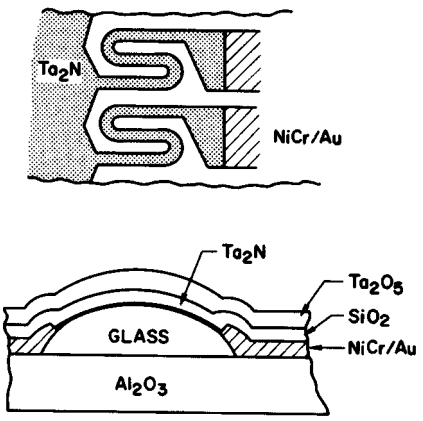

Figure 89.31 Thin-film thermal head structure. (*Source:* R.C. Durbeck and S. Sherr, Eds., *Output Hardcopy Devices*, San Diego, Calif.: Academic Press, 1988, p. 282. With permission.)

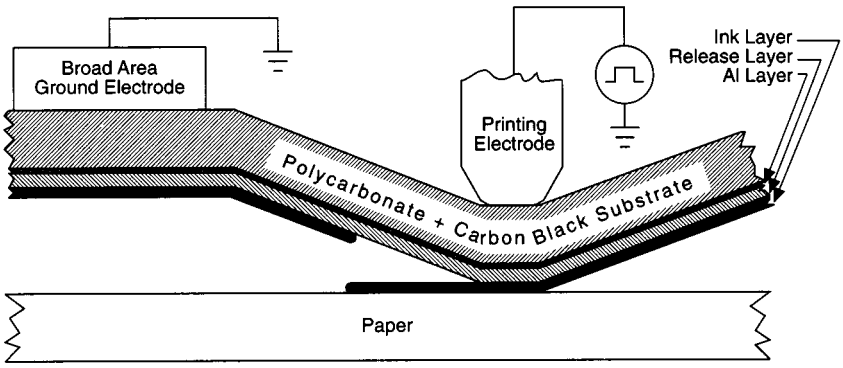

Figure 89.32 Resistive ribbon head and ribbon system.

paste is typically screened onto a ceramic substrate. Materials for the resistor paste include borosilicate glass and lanthanum glass-ruthenium oxide. The elements are typically 25 μm thick and slowly wear down by contact with the paper. Since, with each approach, the resistive elements must be allowed to cool before the head is ready to "write" the next pixel position on the paper, the heating and cooling time constants of the head primarily determine the attainable print speed.

Special thermal paper typically has a coating with a leuco dye plus a phenol developer in a polymer binder which react at the elevated temperature provided by the printhead to form a colored species. The resulting optical density is a function of the temperature reached so that some gray-scale capability is possible. Energy density requirements are in the range of 2–6 J/cm^2.

Thermal Transfer Printing. The desire to eliminate costly special thermal papers even for low-cost serial printers led to the development of the thermal transfer printing technology where a separate transfer ribbon is interposed between the thermal printhead and the paper (see Thermal Page Printing above for discussion of ribbon technology).

Resistive Ribbon Printing. This technology grew from the need to provide quality thermal printing at higher speeds and on a wide range of papers, including standard office bonds. With this technology, the heating function is repositioned from within the printhead into the ribbon itself. The ribbon (see Fig. 89.32) includes an additional aluminum conductive and heating thin-film layer, sandwiched between the "standard" thermoplastic ink layer and the ribbon substrate. The substrate is made conductive (350–900 Ω/□) by the incorporation of sufficient (20–30%) carbon black in the polycarbonate film. Joule heating occurs as current flows from the addressable head pixel-size electrodes through the aluminum layer to the large single-ground return electrode. Current density is maximum directly beneath the addressable electrodes so that temperatures there (but not elsewhere) are sufficient to cause ink layer melt and transfer. In addition, a thin release layer can be added between the ink layer and the aluminum heating layer to provide enhanced and smooth-edged pixels; this provides sharp character edges and allows more detail in images.

This technology allows (1) 2–3 speed increase (vis-à-vis conventional thermal transfer printing) because printhead thermal time constants are much less of a factor, (2) very high-resolution printing (up to 40 pixels/mm), and (3) printing on office-quality bond papers. Also, already deposited ink can be selectively lifted off the paper by reducing the printhead power and using a fresh ribbon area. Offsetting these advantages is the fact that the ribbon is more complex and costly than conventional transfer ribbons.

Impact Printer Technologies

The earliest electronic printing technologies were impact devices employed on the early plug-board programmable accounting machines that used punched-card input. Before that there were typewriters and teleprinters. *Line impact* printers are used on mid-range to high-end computer systems; their continuing appeal is based first on the ability to print multipart forms, and secondly on lower cost of printing and greater reliability (as compared with electrophotographic printers). *Serial impact* printers historically represent the greatest sales

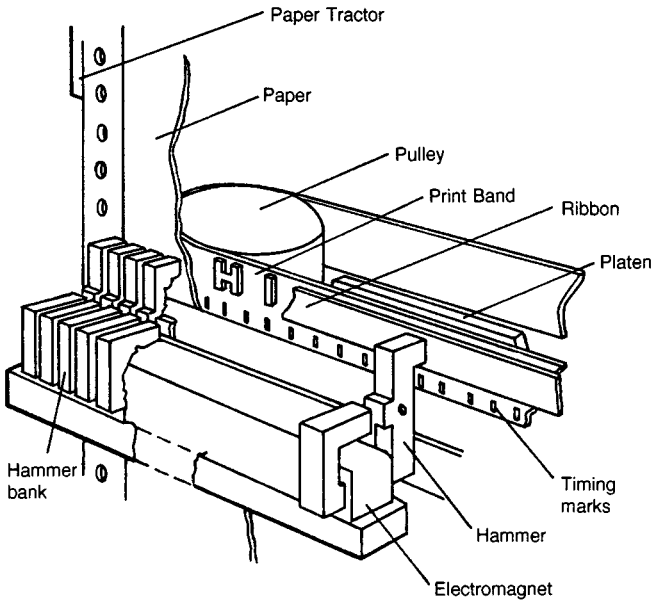

Figure 89.33 Line impact printer mechanism. (*Source:* R.C. Durbeck and S. Sherr, Eds., *Output Hardcopy Devices*, San Diego, Calif.: Academic Press, 1988, p. 130. With permission.)

volume for all computer printer technologies by a wide margin. By far the largest volume has been for personal computer output applications. Their appeal stems from products offering very low cost (device and supplies), high reliability and, again, multipart forms. More recently, however, thermal ink-jet and low-end EP printers have largely supplanted these impact products.

Line Impact Printer Technologies

As shown in Table 89.7, there are three distinct technology approaches for line impact printers: (1) *fully formed character*, (2) *dot band matrix*, and (3) *shuttle hammer matrix*. The first method dominates in high-end computer applications. The other two approaches are primarily used with mid-range computer systems.

Fully Formed Character Printing. Various line printer technologies have evolved over the past but the most popular extant technology makes use of a band of etched engraved characters (plus timing and position marks) in a continuously moving loop configuration (see Fig. 89.33). This band is positioned between a page-wide bank (typically 132) of hammers-actuators and the paper/ribbon set. With timing and position marks, the location of the characters (replicated several times on the band loop) can be easily tracked and the appropriate hammers can be asynchronously fired to provide a full line of print in tens of milliseconds. A limit to the throughput P_r (lines per minute [lpm]) of such a printer may be approximated by:

$$P_r = \frac{V_b}{V_b T_i + P_c N_c} \tag{89.10}$$

where V_b is the band velocity (in./min), T_i the time to increment the paper to the next print line position (min), P_c the character pitch (in.), and N_c the number of characters in the character string. This relation assumes that the hammer settle-out time is less than the paper advance time, the latter normally not the limiting speed factor. The usual limiting speed factor is related to print quality, i.e., well-registered, sharp-edged, high-optical-density characters. In addition, because not all lines on a page are usually printed, with line skipping the actual throughput may be significantly faster than indicated above.

Several factors are important to achieve high-quality print characters. First, the hammer-actuator must provide enough impact force and energy to produce optically dense print. Second, it must impact the ribbon/paper set at

just the right instant to provide good character registration. Third, it must have a short impact time. The impact force and energy are determined by the kinetic energy transferred by the hammer; this is the main factor in determining the amount of ink transfer to the paper. The hammer energy is typically 4–8 mJ. The total time from electronic print impulse to impact with the ribbon/paper set must be closely controlled to achieve good character registration, increasing in importance with band loop speed. The flight time variance must not be more than 1.7 μs to yield a print registration error of no greater than 0.05 mm with a loop speed of 30 m/s. This can best be done by automatically and periodically measuring the time to impact (using a piezoelectric impact bar) and then making microcode/electronic impulse delay adjustments. To minimize "slur" (i.e., the blurring of a character caused by lateral relative motion between the engraved character and the ribbon/paper set during impact), short impact time is important. It may be shown that this impact time is inversely proportional to the square root of the hammer mass (for given hammer kinetic energy), and inversely proportional to the hammer velocity (for given ribbon/paper set thickness and compliance). For a given amount of acceptable slur, the hammer velocity must increase proportional to the band loop velocity, and the hammer mass (for fixed kinetic energy) must decrease—inversely proportional to the square of the band loop velocity.

Hammer-actuator systems have been designed with one, two and even three moving piece components. With the one-piece design, the mass impacting the paper is largest, limiting this design to slower printers (≤650 lpm). To have less mass in the hammer impacting the ribbon/paper set, separate parts are used for the armature and the impacting hammer (two-piece design). In this case, most of the kinetic energy from the pivoting armature is transferred to the hammer without the large mass handicap of the ferromagnetic armature. Of course, the residual energy in the armature must be absorbed and dissipated within the printhead. Further design improvements are possible by interposing a push rod between the the armature and the hammer pieces (see Fig. 89.34). Since the lengths of adjacent push rods can be made alternately short and long, close packing of these actuator assemblies having a single pivot axis is possible. With the most efficient designs, printing speeds of over 5000 lpm are possible.

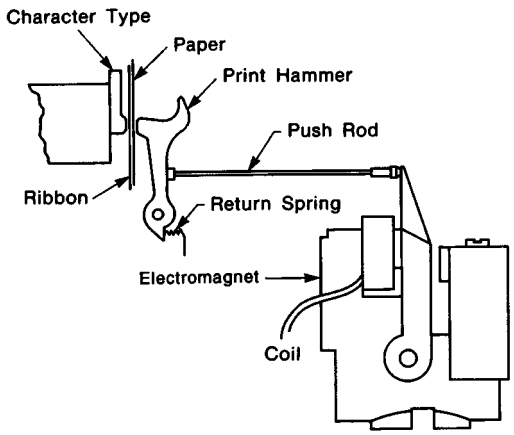

Figure 89.34 Three-piece hammer-actuator design. (*Source:* R.C. Durbeck and S. Sherr, Eds., *Output Hardcop Devices*, San Diego, Calif.: Academic Press, 1988, p. 143. With permission.)

Both moving-coil and stored-energy actuators are used, the latter using a "bucking" coil and a stored-energy flexible spring. The bucking coil, when energized, cancels the magnetic flux from a permanent magnet, holding the actuator in the "cocked" position, and thus converts the stored spring energy to kinetic energy.

Dot Band Matrix Printing. This technology has been employed on some printers used for mid-range computer systems, and, in a sense, is a hybrid technology combining attributes of high-end line band printers with features found in serial wire matrix printers (see below). Present designs also use a moving metal band but incorporate pixel-size raised bumps instead of etched characters. These bumps (typically 120 on a band) are positioned at the apex of chevron-shaped springs etched into the band (see Fig. 89.35). Also, timing/position slots are etched into the band above the spring slots. Instead of one full line of characters being printed in one cycle, one full line of dots is printed with this technology. Also, each hammer covers typically three character positions across the page; thus, 45 hammers can cover a page-width of 135 character positions. Hammer cycle time is typically 1.2 ms and the band speed can be 0.28 m/s or higher. After a line of dots is printed, the paper is advanced *N* times until a full character height is achieved.

This technology is much less expensive than typical engraved band technology, and allows the use of a faster draft mode using fewer dots per character; however, normal throughput (lpm) is generally much less.

Shuttle Hammer Matrix Printing. Transverse shuttling a reduced number of horizontally spaced hammers to cover a full print line is another way to implement matrix line printing. Here, a pixel-size raised bump is

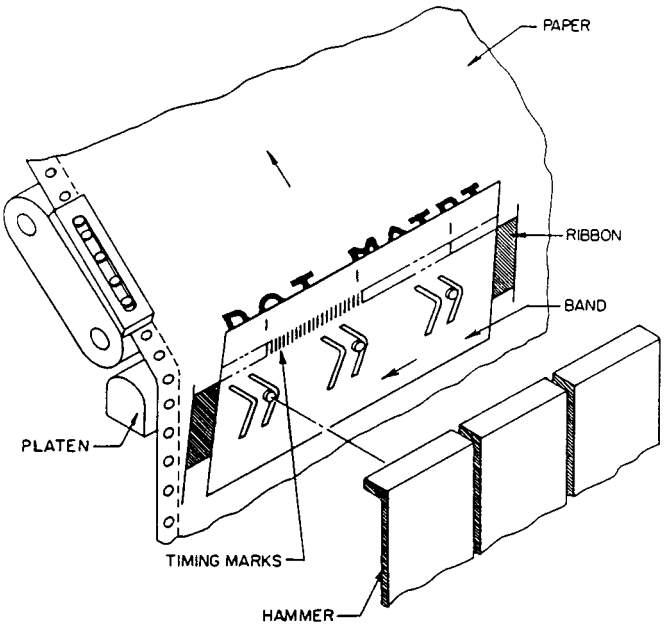

Figure 89.35 Dot band printer technology. (*Source:* R.C. Durbeck and S. Sherr, Eds., *Output Hardcopy Devices*, San Diego, Calif.: Academic Press, 1988, p. 198. With permission.)

incorporated into the strike surface of each hammer. One design includes 33 hammers (each spaced 1 cm from its neighbor) covering 132 character positions. With an oscillatory shuttle motion of 1 cm, all line dot positions are covered, and the shuttle return time can be used for paper advance. Moderate printing speeds (600–900 lpm) can be accomplished with $^1/_4$-cm hammer spacing; 300 lpm is possible with 1-cm spacing. Opposite moving counterweights have been employed to reduce shuttle vibration.

Serial Impact Printing

There are two classes of technologies presently employed for serial impact printing: fully formed character and wire matrix. The former category includes both daisywheel and typeball technologies, the latter now in little use for computer output except for a few dedicated word processing applications. Daisywheel technology is used in many dedicated word processing systems and for some personal computer systems. With these two technologies, font change can be implemented by simply changing a wheel or ball, but all-points-addressable printing for image and graphics is basically not possible. Serial wire matrix technology has for years been the most popular output device for personal computers, but has now lost most of its market share to low-end laser printers and thermal ink-jet.

Daisywheel Printing. This technology makes use of a "petal-like" rotating print wheel with typically 96 spring-like fingers or "petals" radiating outward from a central core. An engraved raised character is present at the end of each petal. The wheel is rotated by a dc servomotor to the desired character. A single hammer-actuator then impacts the back side of the petal, forcing the raised character into the ribbon/paper set. The simplest designs have a constant carriage speed and a fixed time delay to allow for up to 180° rotation of the wheel between strokes. These systems are typically limited to about 30 characters per second (cps). More modern designs have incorporated microcode logic which slow down the carriage motor when the next character position is more than, for example, 30° away. This can increase the net average speed to as high as 60 cps.

Variants on this design use thimble- and cup-like rotary devices with petals bent parallel to the axis of rotation. This lowers the rotational inertia and allows for more petals (and hence more characters—up to 128).

Typeball Printing. Typeball technology was first developed for typewriters in the 1950s, but has also been used for low-speed, correspondence-quality printers. The golf ball-size sphere, rotated and tilted to reach the

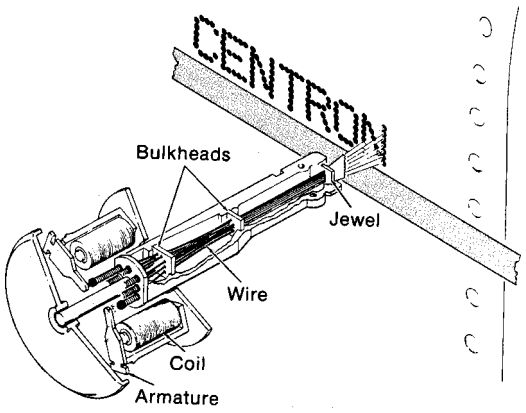

Figure 89.36 Wire matrix serial printhead. (*Source:* R.C. Durbeck and S. Sherr, Eds., *Output Hardcopy Devices*, San Diego, Calif.: Academic Press, 1988, p. 187. With permission.)

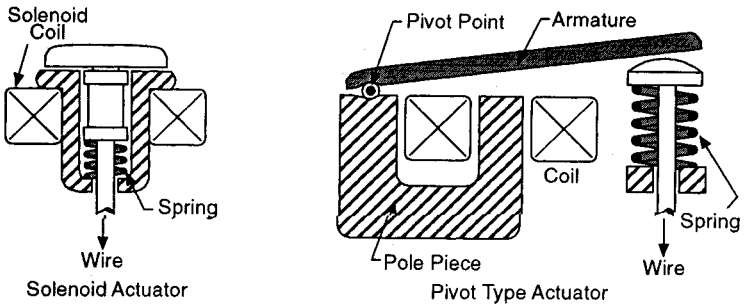

Figure 89.37 Solenoid and pivot-type actuators for serial wire matrix printing.

desired character position, has four rows of 11 characters, repeated on both hemispheres, making a total of 88 character positions. The usual operating speed is 10 cps but up to 15 cps has been achieved.

Serial Wire Matrix Printing. This technology employs an array of guided wires (often tungsten) that are individually driven into the ribbon/paper set (see Fig. 89.36). The array may form a single-row configuration at the plane of ribbon impact, may have two in-line rows, or may have two staggered rows. Nine wire designs became very popular in the 1980s for low-cost personal computer systems, but the demand for higher print quality has moved the "standard" design point to 24 wires. Early technology limited wire cycle repetition rates to about 500 Hz. More advanced designs can perform at 2500 Hz, but most available products operate in the 1000–1500 Hz range.

Actuators to drive these wires are quite robust and can print through many layers (up to 6) of a multipart form. The kinetic energy needed to print through 4–6 layers is normally about 0.5 mJ for 200-μm diameter wires, 1.0 mJ for 300-μm wires. For 2-layer forms, these energies drop to about 0.3 mJ and 0.45 mJ, respectively. There are two common approaches to driving the guided wires. One is a pivot-type actuator and the other is a direct solenoid design (see Fig. 89.37). The magnetic circuit in all cases must be designed to maximize either (1) the moving wire kinetic energy in the case of a free flight wire configuration or (2) the kinetic energy of the combined armature and moving wire in the case where these two components are either permanently connected or remain in contact during the drive cycle.

Other actuator designs use a stored energy approach where a preloaded leaf spring is held by a permanent magnet until released by a "bucking coil" to counteract the static flux. Also, experimental stacked piezoelectric transducers have been investigated using high lever ratios (e.g., 30:1) which have operated at 3 kHz and above. Synthetic ruby or ceramic wire guide holes are sometimes used to combat wear. Several hundred million cycles lifetime operation for each wire is typically required for today's devices.

Higher draft-quality speed (e.g., 200 cps) can be achieved without decreasing wire cycle time by simply increasing the carriage speed. Higher than normal print quality can be accomplished by both slowing down the carriage and interlacing horizontal rows of dots. This near letter-quality printing is usually at greatly reduced speed (e.g., 48 cps). Most printers also print during the carriage return. Color can be produced by shifting four-color ribbons.

Defining Terms

Line printing: A printer prints one full line width of characters or dots at a time. The paper is then moved into the next print line position, ready for the next line of characters or dots. The printer may pause or stop between lines. Printing speed is often given in units of lines per minute (lpm).

Page printing: The information to be printed on a page is electronically composed and stored before shipping to the printer. The printer then prints the full page nonstop. Printing speed is usually given in units of pages per minute (ppm).

Pixel: The nominal printed spot area or "picture element" addressed by a particular printing device. It is sometimes called "pel."

Serial printing: Printing is done one character at a time. The print head must move across the entire page to print a line of characters. The printer may pause or stop between characters. Printing speed is usually given in units of characters per second (cps).

89.3 Smart Cards

Witold Suryn and Michel Veillette

The smallest laptop in the world.

That is the frequently used expression describing intelligent chip cards. The word "intelligent" plays an important role, as there are also other, very popular chip cards that can hardly be named that way — memory cards containing defined amounts of available memory and some access control logic. One can find them today as the most consumed commodity articles: prepaid services cards. A good example would be a telephone card, preloaded with some electronic "money" when manufactured, debited each time one makes a phone call and, finally, thrown out when emptied. Even if interesting as technology solution this type of card won't be a subject of next chapters as this article is rather dedicated to intelligent members of chip card's family — Smart Cards.

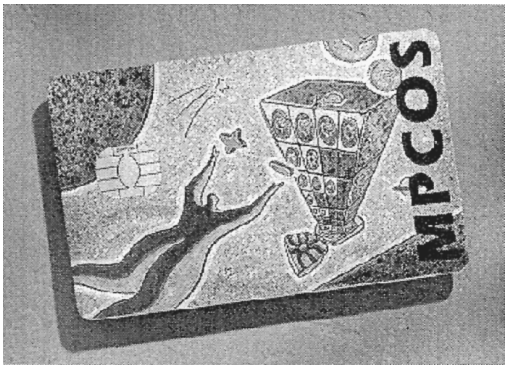

FIGURE 89.38 Pocket computer — Smart Card (courtesy of Gemplus Corporation).

The history of this device is long with plenty of defeats. Invented in 1974 by Roland Moreno in France (there were also earlier announcements: in 1968 in Germany and 1970 in Japan), it was refused any right of recognition as a "usable invention." These years the world was dominated successfully by a still-new fashion — plastic cards with a magnetic stripe.

The very important questions are: did such a status quo change? Where? And why?

Depending on the region of the world, smart cards replaced magnetic-stripe cards more or less successfully. In Europe, you could hardly find a single magnetic stripe card in use, while in America, intelligent chip cards (ICC) still experience their childhood. The reason for such a worldly footprint of ICC technology is due to the market's demand for security measures as well as for diverse functionality. Last, but not least, the costs of on-line telecommunication services should be mentioned. Magnetic stripe offers about 140 bytes of available memory, almost nonexistent security, and in most cases, requires costly on-line service while ICC may be used in both on- and off-line environments, grants a very high, sophisticated level of secure operation and, finally, allows multifunctionality.

Could it be explained more vividly? Yes, if you make comparison between a piece of magnetic tape and a computer. Because *a smart card is a computer.*

In following chapters, we will attempt to present to the reader a complete overview of the world of smart cards. Beginning with internal hardware architecture through card software applications and ending by complete system solutions, we hope to prove the exceptionality of ICC technology both from technical and applicability points of view.

Hardware Architecture

Year 1998 state of the art recognizes two main hardware architectures of the ICC: 8-bit and 32-bit microcontrollers. Why not 16-bit? Because silicon chip technology goes faster than "bits-and-bytes" maturity fights of smart card software developers. 16-bit did not catch its historical moment, however, from time to time there are successful attempts to re-use this technology. This statement may sound strange for nowadays' software programmers used to easy "consumption" of megabytes of memory but for those who began their developer careers in early 1980s, the mastership of putting every required functionality in magic "64k" number of bytes must sound familiar.

8-bit Microcontroller Based ICC

The architecture presented in Fig. 89.39 is one of the most obvious schemas known in computer science. Things become less obvious when put in ICC context. What are the roles of blocks forming ICC when compared to "full-blooded" computer?

- Microprocessor is a typical CISC (Complete Instruction Set Computer) 8-bit unit driven by an external clock of 3.57 MHz frequency you might find in early standalone systems.
- I/O — typical input/output serial communication device.
- RAM — the same memory you find today in any type of a machine.

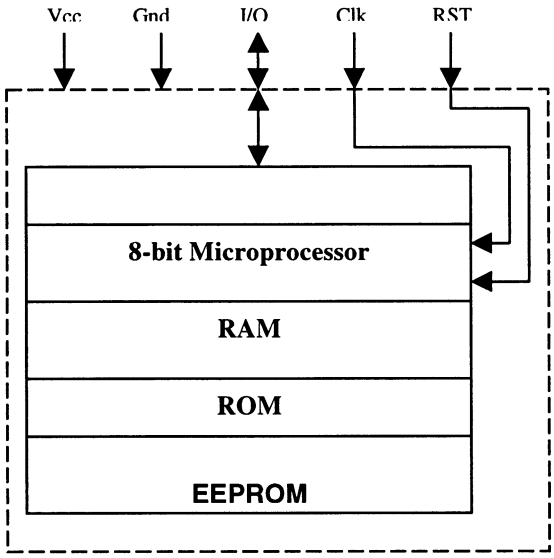

FIGURE 89.39 The general hardware architecture of 8-bit ICC, where:
Vcc — +5V power supply line
Gnd — 0V (ground) line
I/O — bi-directional communication line
Clk — external clock line
RST — external reset signal line
RAM — random access memory
ROM — read only memory
EEPROM — electrically erasable programmable ROM

- ROM — system kernel in ICC, BIOS in PC (observe the difference).
- EEPROM — ICC's hard disk.

It may happen that some readers now feel a bit surprised, but the surprise will become bigger when we look at "numbers."

By default, 8-bit processor maximum memory space is 64 kilobytes (2^{16}), but in most manufactured ICCs that space is not fully used. Why so, if even 64k seems to be today less than nothing? The answer is simple: price. The device being sold yearly in hundreds of millions must be cheap, but memory forms a considerable part of the overall cost of the chip. So, as much software as possible is needed in as little memory as a developer can possibly accept.

Let's then come back to numbers: ROM — average 8k, RAM — 256 to 1024 bytes (no, we did not forget "kilo"), EEPROM — 4 to 32k (we can imagine the ironical smile of the reader — 32 kb of hard disk).

And that's the whole wealth that the developer has for his needs. Now, dear reader you can understand why developers fight for every bit. Sometimes even for a half of it. And why the ICC software world is so specific, closed and exacting.

The last important feature of chips being used is the voltage of power supply (Vcc). The most commonly used voltages are 5V and 3V, however, lower (1V, 0.5V) voltages are being strongly considered.

Let's have a quick look at the industry. Most of manufactured ICCs are based on one of two industrial patterns: Intel's I8051 microcontroller and Motorola's 6805 one. These patterns were broadly accommodated by the world's biggest hardware manufacturers like Siemens, Hitachi, SGS Thomson, Texas Instruments and of course — Motorola. These five names are the leaders of the smart card industry.

32-bit Microcontroller Based ICC

Thirty-two bit microcontrollers are the discovery of the past year. Still new and fresh, they attract card manufacturers' attention by its potential processing power and much larger memory space.

The internal structure of the chip is very similar to this shown in the Fig. 89.39, however, some differences may be observed:

- Microprocessor is 32-bit RISC (Reduced Instruction Set Computer) type.
- EEPROM may be replaced by faster and easier to re-program Flash ROM.
- Two I/O lines.
- In newest releases, ordinary RAM is being replaced by FeRAM (20 times quicker if used in 8-bit chip, several hundred times in 32-bit chip).
- Clock rate is 33MHz (for Vcc = 5V).
- Memory is split into Banks (pages).

Now again numbers: ROM — average 56kb, RAM — 2kb, EEPROM — up to 64kb. The first impression we might have is that such a machine should give the output several tens of times better than its 8-bit sister. Surprise! The recent benchmarking based on Java Card applications (Java Card will be discussed later) have shown that the performances of both cards may be comparable, but not the price, as the 32-bit card is several times more expensive. So why go in this direction?

There are many reasons among which some are crucial. Although the 8-bit solution has almost reached its top performance, that does not mean that it'll vanish overnight. As in the world of cars, there are fans of Rolls Royce, Cadillac, and Geo Metro which exactly reflect the future of 8-bit cards. Many existing and incoming applications will still be satisfied by an 8-bit solution, offering to card issuers and clients something fulfilling their needs and at the same time remaining affordable. The second crucial reason is 32-bit technology maturity being on its learning curve. In certain, software developers as well as chip manufacturers will reach the level of expertise high enough to push prices from the "Cadillac" level to the "Geo Metro" level. The 8-bit card shall survive even if in the "bicycle" position. The market continuously creates a third important factor: multi-application requirement. Today most of us have his/her wallet filled up with dozens of credit and/or debit cards, ID cards, healthcare cards, loyalty program cards, etc. Card issuers try to attract their customers by a vision of merged functionalities installed on one card, requiring a need for more sophisticated technology. The perception today of such a solution directs issuers' as well as card manufacturers' interest toward 32-bit technology. There is still a future for now since there are few 32-bit chip manufacturers known: NEC, Philips, Siemens, and Hitachi, however, the rest of world's biggest players are close to launching their modern products.

Contact ICC, Contactless ICC

The distinction of contact and contactless cards brings us on the next level of smart card technology. "Contact" or "contactless" define the method in which the card communicates with the external world. There are cards combining both methods sometimes called "combi" cards.

Contact ICC (Fig. 89.38) is equipped with a small field of ohmic contacts to which all necessary signals are being applied. To operate such a card, a reader would have to possess the ability of physical touch.

Contacless ICC uses "untouchable" media such as microwave transmission, optical transmission, capacitive coupling and inductive coupling, but — due to physical constraints — the latter one is most commonly accommodated.

Before we proceed further, two facts should be strongly expressed: there is no power supply on board the card and the transmission is unidirectional (terminal to card). In such a case, four problems arise:

- How to power up the card.
- How to transmit clock.
- How to transmit data to the card.
- How to transmit data from the card.

From a purely electrical point of view, the solution seems to be simple: both card and terminal are equipped with coupling loops (electrical coils) allowing transmission of energy similar to a coreless transformer (Fig. 89.40). The card's loop is embedded in a plastic body to avoid getting destroyed or touched.

The main carrier is a sinusoidal magnetic field (f = 4.9152MHz) that transmits the power supply to the card. To transmit the data/clock to the card, the terminal uses frequency modulation of the main carrier, being easily

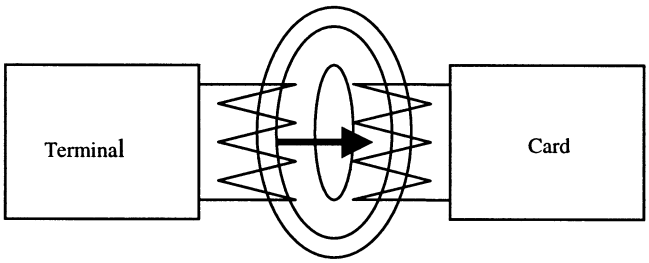

FIGURE 89.40 Card-terminal communication principle.

filtered and decoded by the card's I/O device. Transmission of the data from the card to the terminal is based on the passive amplitude modulation of the main carrier, which is executed by changing the card's I/O circuit impedance differently for "0" and "1." To read the information, a reader must be able to detect a potential drop in the impedance in its internal AC generator.

Inside the contactless type of cards there are two sub-groups recognized: close coupling cards and remote coupling cards. The distinction between the two is based on the distance terminal-card and the power that may be transmitted to the card.

Regardless of which communication carrier is used, the transmission speed between the card and the terminal is, in most cases, one of the following: 9600 bit/s, 19,200 bit/s, or 115 kbit/s.

Operating Systems

Operating system (OS) is the next layer of technology that makes the microprocessor card a *smart* card. The term *operating system* applied to a smart card is in some sense misleading as in many cases even highly experienced programmer/analysts would not be able to find a clear borderline between "system" and "applicative" layers. Due to continuous memory constraints smart card software designers chose the formula of "nested functionalities" that finally resulted in placing real functionality inside OS services (or the opposite, depending on your point of view). Each card manufacturer has its own family of operating systems offering different dedicated functionalities to the user that are characteristic of the specific manufacturer. That type of OS forms a vast group of software products called proprietary OS.

In the mid-1990s, another approach to smart card OS emerged: open OS. By its definition the open OS is quite similar to familiar DOS with the exception of being placed in the card's ROM instead of the computer's hard disk.

For either of them some principles apply:

- The stable part of software application is placed in ROM during the **masking** (chip manufacturing) process. For proprietary OS, it makes all the functions regardless of whether "system" or "applicative" form the basic dedicated platform. For open OS, in most cases ROM keeps, at a minimum, basic OS.
- The changeable part of software application is always loaded to EEPROM. In both cases, EEPROM keeps "add-ins" stored in ROM. For proprietary OS, this is the **"filter"** consisting of either additional functionalities or corrective patches. For open OS, real functional software is stored. EEPROM contents may be loaded to the card during **personalization process** (when a real, customer-dedicated card is manufactured) or in any moment of a card's life cycle.
- RAM is used to store only temporary data during transaction time. No application code is allowed to be loaded to RAM for a card may be withdrawn from the terminal at any moment causing a permanent loss of important code.
- Communication with the external world is processed by means of specific interpreted code structures called **APDU** (Application Protocol Data Unit) and data exchange (for further details see [1–3]).
- The way in which a card performs required functions is based on strictly-defined rules concerning memory file structure, data structure and format, file management, data management, access rights (read/write/execute control), execution control, and atomic (backup) methods (for further details see [1–3]).

- Of the pair, the terminal-card card is always a "slave." Such a situation results from the simple fact that it's the terminal that "wakes up" a card by applying power and reset signals to the card. In response, the card sends back **ATR** (Answer To Reset) **APDU** which identifies itself to a terminal. From this moment on the real session starts. The session may be terminated either by a card or by a terminal.

In the following two sections, we will try to present both types of OS and discuss their pros and cons.

Proprietary Operating Systems

Proprietary OS is always targeted to fulfill a defined scope of dedicated functionalities. The general, however specific, structure of the proprietary OS is shown on the Fig. 89.41.

Such a structure may give the impression that proprietary OS is created in a "fuzzy" manner. This is incorrect. All the memory is perfectly structured, with areas storing data, application code, and basic OS functions as well as native functions (procedures performing most basic functions as I/O protocol, **DES algorithm**, basic math, atomic functions, etc.). What are not that well-structured are *functionalities* performed by the card. Let's take the example of an electronic purse. From the user's point of view, the card should perform at minimum the following functions:

- User authenticate (user proves to the card that he/she is the owner of the card).
- Credit the card within pre-defined limit.
- Debit the card within pre-defined limits.
- Disable any attempt to break into the contents of the card.

In "nested" OS, none of the above functions are standalone. All of them are, in great part or even totally, performed by OS. In most cases, the reader may find in an application area "script(s)" performing needed function(s) by calling necessary subroutines within OS, but rather rarely a standalone block of software performing an independently new function.

What are the pros and cons of such a structure? Let's investigate:

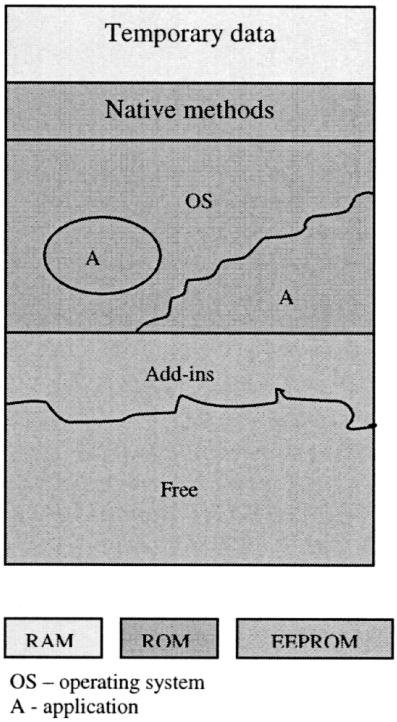

FIGURE 89.41 Proprietary OS structure.

PROS

- High "density" of the software or, in other words, good functionality/memory consumption ratio,
- Good functionality/price ratio,
- Good functionality/performance (speed) ratio,
- Good way to build a stable relationship between the card issuer and card manufacturer (watch the interpretation of this point in *CONS*).

CONS

- Applications are not portable, sometimes even within the same family of operating systems.
- Debugging process requires tremendous efforts as, in the worst case, the entire card software has to be verified.
- There are only two ways to correct found bugs: add the **"filter"** in EEPROM (not always possible, but always temporary) or remask the chip. Specifically, the second possibility in some cases may be called the *disaster* as when the bug is found in the card that has been deployed into the market in 100 million volume.
- Good relationship created by a chain Card Manufacturer → Functionality → Card Issuer is more and more often perceived as a master-slave relationship. Card issuers prefer to be supplier independent.

The conclusion drawn is somewhat obvious: proprietary OS is a handicapped solution, but there are hundreds of millions of such cards issued each year that imply the message: more flexible technologies are still to come.

Open Operating Systems

Smart Card open operating systems (OOS) are being developed continuously since the early 1990s reaching the position today of emerging technology. The basic assumptions for OOS development are:

- Portability of applications.
- Application load/delete function.
- Multi-application ability.
- Upward/downward compatibility of OOS within the family.
- Development environment similar to or being a subset of "full-blooded" computer software development environment.
- High-level programming language.
- High level of security, both inside the application and outside (firewalls).
- Shorter development time (time to market).

The general structure of OOS smart card is presented on Fig. 89.42.

How much clearer is such a structure when compared to proprietary OS? The OOS forms a well-defined group of layers over which the real applications reside. Bottom-up direction shows higher and higher levels of abstraction of consecutive layers:

- Native functions and system resources — all the basic functions that are time critical (I/O subroutines, basic cryptographic functions, atomicity, basic file management) developed in assembly language.
- Virtual Machine — on-card interpreter of bytecodes.
- **API** — application programming interface — set of generic libraries.
- Specific API — nonmandatory API dedicated to specific card functionalities.
- Card Executive — file and application manager (loading/removing applications).
- Applications — developed in high-level languages, stored on the card in bytecode format.

Applications developed for such a type of the card are commonly called applets or, better, cardlets. Usually, the cardlet is developed on the PC using one of several higher-level languages in a not necessarily dedicated development environment. Dedicated environment comes on the stage in the moment of the first compilation

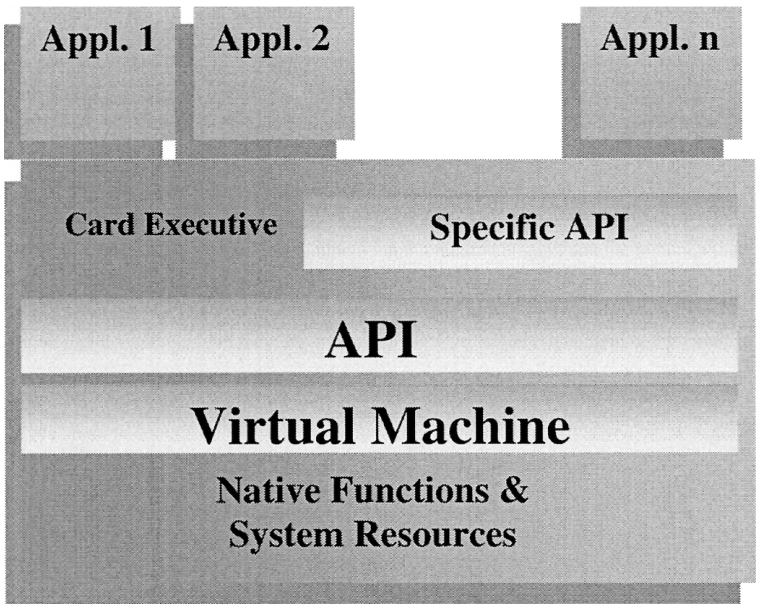

FIGURE 89.42 General structure of OOP Smart Card, where:
Appl1,2,..n — card applications,
API — application programming interface

and debugging. What is important to observe as the difference between PC-dedicated compilation and card-dedicated compilation is the result: for PC you may obtain the executable file (*.exe), for card it's always bytecode (*.cap) as the card *interprets* application code by code. Debugging of the cardlet may be done in a simulated, PC-based environment as well as in a natural card environment.

Ideally, during card life cycle, cardlets may be downloaded, added, or removed changing the profile of the card. All three possibilities generate immediate problems of a different nature:

- Co-existence of two or more cardlets requires high security measures to firewall cardlets against cross-corruption in any form as well as raises the needs of re-usability of common objects.
- Any type of manipulation of the cardlets creates responsibility/legal issues to be solved in the near future such as Who's got the right to manipulate cardlets? Card issuer (bank?), card manufacturer, or card user? How to maintain cardlets and their life cycle, etc.

There are more issues of both a technical and legal nature, to be answered, so those interested in smart card technology may get closer to it by observing the works of international standard bodies (e.g., ISO), industry associations (e.g., SCIA) or international forums (best known is Smart Card Forum).

PROS

- Any developer knowing higher-level programming languages may develop an application. No "bits-and-bytes" fighter knowledge necessary.
- Development environment is PC-like or purely PC.
- Debugging may be off-card as well as on-card.
- Development time is incomparably shorter than this for proprietary OS.
- As applications are loaded by default to EEPROM, any in-the-field bug may be fixed by simply reloading the cardlet.
- Time to market dramatically shorter.
- Portability of applications.
- The customer is supplier independent.

CONS

- Technology still not mastered, both in hardware and software domains.
- Development/debugging tools in a childhood phase.
- Performance still low (due to interpretation mode of operation and slow hardware).
- Due to evolution phase of standards, portability of cardlets merely applicable.
- High cost of cards.

The conclusion might be: first steps are always the heaviest, but to explode, OOS technology needs more maturity rather than technical improvements. Next five years are forecasted as the real startup for OOS smart cards.

Standards

Smart card is one of the best standard-guarded pieces of equipment. The set of ISO 7816 regulations defines all the aspects of smart card technology and life cycle. Most of them are stable, however, due to continuous software and hardware technological improvements all of them are being amended. The complete list of applicable standards is presented below:

- ISO 7816-1 — Identification cards — Integrated circuit(s) cards with contacts — Part 1: Physical characteristics. *Defines physical characteristics of cards as well as tests to be applied.*
- ISO 7816-2 — Identification cards — Integrated circuit(s) cards with contacts — Part 2: Dimensions and location of the contacts. *Defines dimensions and locations of contacts and magnetic stripe as well as tests to be applied.*
- ISO 7816-3 — Identification cards — Integrated circuit(s) cards with contacts — Part 3: Electronic signals and transmission protocols. *Defines basic electronic characteristics of ICCs, power supply, data elements in* ***ATR*** *and transmission protocol T = 0.*

- ISO 7816-4 — Identification cards — Integrated circuit(s) cards with contacts — Part 4: Interindustry command for interchange. *Defines internal software structure of ICCs, security requirements, formats of APDUs, communication codes.*
- ISO 7816-5 — Identification cards — Integrated circuit(s) cards with contacts — Part 5: Numbering system and registration procedure for application identifiers. *Defines system for clear identification of national and international applications in ICC.*
- ISO 7816-6 — Identification cards — Integrated circuit(s) cards with contacts — Part 6: Interindustry data elements. *Defines data elements and structures used in retrieval of data from ICC.*
- ISO 7816-7 — Identification cards — Integrated circuit(s) cards with contacts — Part 7: Enhanced interindustry commands. *Defines additional commands added to Part 4 for SQL access, encryption, secure messaging.*
- ISO 7816-8 — Identification cards — Integrated circuit(s) cards with contacts — Part 8: Interindustry security architecture. *Defines security architecture of ICCs.*
- ISO 7816-9 — Identification cards — Integrated circuit(s) cards with contacts — Part 9: Additional interindustry commands and security attributes. *Describes coding of the life cycle of the cards and related objects, coding of security attributes of card related objects; functions and syntax of interindustry commands not defined in other parts of ISO/IEC 7816; data elements associated with these commands; and a mechanism for initiating card-initiated messages.*
- ISO 7816-10 — Identification cards — Integrated circuit(s) cards with contacts — Part 10: Electronic signals and Answer To Reset for synchronous cards. *Defines basic electronic characteristics, power supply, data elements in **ATR** for synchronous cards.*
- ISO 7816-11 — Identification cards — Integrated circuit(s) cards with contacts — Part 11: Card structure and enhanced functions for multi-application use. *Defines an enhanced logical structure for multi-application cards to support security with applications loaded after issuance, prerequisites for loading of an application after issuance, a mechanism to support an application life cycle independent of the card life cycle, interapplication security issues, including storage partitioning.*

For more details you may refer either directly to International Standards Organization or to ISO Web site: www.iso.org.

Applications

The purpose of this chapter is mostly descriptive, aiming to show the wealth and diversity of existing and upcoming applications deployed all over the world.

The smart card industry is formed by a few big manufacturers covering practically all of the world's needs (Gemplus, Schlumberger, Motorola, Orga, De La Rue, Gisecke&Devrient, and Oberthur). Each of them offers either applications, platforms, or both. The short overview of possible applications will be more persuasive if done by market sectors:

- Banking: credit/debit card, electronic purse, loyalty programs, individual financial programs.
- Retail: loyalty programs, retailers' credit cards.
- Healthcare: personal medical treatment databases (medical files).
- Wireless communication: SIM (Subscriber Identity Module) card, OTA (Over The Air) services, e-mail services.
- IT (Information Technology): security access to IT systems, encrypting/decrypting files, securing e-mail, Internet transactions (e-wallet, e-commerce).
- Universities: multi-functional ID cards (credit, electronic purse).
- Government and agencies: ID cards, internal electronic purse, time control.
- Physical access: ID cards, zone access control.
- Manufacturing: electronic tags.
- Transportation: ticketing, air-miles programs, driving licenses.

Most of the above-mentioned applications are based on a proprietary OS, however, OOS early birds are also observed. The first steps on the way to commercial OOS have been recently done by some of the industry

leaders. The joint efforts of Sun Microsystems, Gemplus, and VISA-created Java-based Visa Open Platform (VOP), Schlumberger has created its Java-based Open Platform — Cyberflex, Gemplus has its Java-based GemXpresso and its own OOS — Nucleos, and last but not least, MULTOS — OOS created by consortium MAOSCO/Mondex. Though still not matured, all of these OOSs have already provoked the chain reaction: creating cardlets' development industry.

Readers

A smart card is of no use if you cannot communicate with it and the reader is the element that will give life to this hand-held device. The market offers several kinds of readers. Readers are categorized in three classes: standalone, peripheral, and contactless.

Standalone Readers

Standalone readers are modules that offer a complete interface to operate and communicate with the smart card. That kind of reader can be a part of a complex machine such as an automatic teller machine or presented as a hand-held device. For an application such as an automated bank teller, the smart card reader is then a programmable device integrated into a larger system with several peripherals such as display, keyboard, real-time clock, and printers. In many cases, the complete system also includes several security mechanisms from protected housings to sensors for detecting attacks and security modules. A security module is a smart card that holds the terminal secret keys, which are used to create card-specific keys. A standalone reader usually has a communication link to operate as a peripheral of a larger transaction server that will verify the user identification and take charge of the information transmission, reconciliation of transactions, etc.

Other applications require a reader that will participate in a secure information exchange transaction between participants. Thus, desktop systems are smaller and have their use in business application to provide secured services. Along with security modules, some readers will accept several cards to authenticate, for instance, the owner and the receiver of a confidential information. In healthcare application, the patient will authorize access to his files while the doctor will provide the proof that he has the right to access this kind of information. Several security modules will ensure security and protection for different applications executed through the same reader, treated separately one from another. Other suitable applications for those readers are payment transactions, electronic purses, and loyalty programs. The integration of the keyboard and the display to the security of the process ensures that the user's PIN and exchanged information are not tapped by another software.

Hand-held systems offer the flexibility of mobile systems. Integrated with telecommunication devices and hand-held computer technology, these systems can present touchscreen interfaces and provide facilities such as gaming, fax, e-mail, telephone, e-purse, loyalty, healthcare or driver's license programs, security, authentication, identification, electronic payment, secure access to networks, secure data transfer over those networks, etc. GSM is gaining more popularity by using the cell phone as a mobile reader to personalize your phone and provide the user with facilities such as e-mail and prepaid services.

Peripheral Readers

A peripheral reader provides a communication interface between a larger system and a smart card. Using standard interfaces, the reader is usually coupled to a control system that will send commands to the reader. A peripheral reader can be integrated into a larger peripheral, such as payphones, a vending machine, or a card personalization device.

Peripheral readers are often attached to a computer to add functionality for card-aware applications. The market offers several types of connections for peripheral devices. Serial connections are suitable for most desktop computers and are standard and affordable. PC Card connections (pcmcia) are mainly for laptop computers. Although slow, keyboard readers, using the PS/2 connection, provide better security, mainly for the PIN management. When entering a pin, the reader intercepts the characters from the keyboard and replaces them with a neutral character that is sent to the system. This way no resident software can intercept the PIN. A keyboard reader can be integrated to the keyboard itself or added to the PS2 connector of the keyboard. **USB** readers are now coming into the market and will compensate for any deficiency of the serial reader. Some

attempts are also done to integrate a reader into a mouse or floppy disk. This last solution offers the user the possibility to use a smart card without adding new hardware to his machine.

Finally, one can find specialized peripheral readers combining the functionality of other device types. For instance, a smart card reader and modem were combined to secure network access in Internet communication, electronic commerce, and home banking. Also, a smart card reader and a television signal processing module were combined for conditional access, electronic program guides, interactive applications, home shopping, and payment systems.

The use of peripheral readers is an emerging market with the recent deployment of application for the electronic commerce, home banking, online gaming, health care, network security on the Internet, and telecommunications. Readers with biometrics interfaces have begun their introduction on the markets. Fingerprints are used instead of a PIN to authenticate the user.

Contactless Reader

A contactless reader (also called proximity reader) needs no physical contact between the card and the reader to exchange data. The card goes immediately into action when it is within a few inches of the reader. Transmission details were described earlier.

Using a hard-wired algorithm and random number generation, it is possible to provide high-level security. The reader and the card use a mutual authentication and a stream ciphering. Such system must also provide anticollision management to operate with multiple cards in the communication field.

Contactless smart card readers are perfectly suited for physical access control and smart tracking applications. The use of Smart Labels (or tags) injected or embedded into a product allows the identification and tracking of product for either authentication or automated manipulation. Since data can also be written into a contactless card, payment functions can be implemented for fare collection in public transportation, for instance. When the distance between communications is a concern, systems using intelligent transponders enable the payment of tolls from equipped vehicles travelling on motorways at normal speed.

Card-to-System Solutions

Naturally, communication with a smart card would be impossible without several software layers that transform the request of the user into a sequence of bits transmitted to the device. At the lowest level, the drivers provide the basic functionality by transferring a sequence of bytes to the reader. Then layers of software are built over the driver to form application program interfaces (APIs). **API** offers to the application developer functions that combine basic operations to hide specificity of a particular device and to ease the development.

Drivers

To communicate with a reader, the basic transmission is handled by three protocol layers: the physical layer, the transport layer, and the command layer. The physical layer is related to the data transmission itself through the physical port (serial, pcmcia, usb, etc.). The transport layer specifies the transmission type, the message addressing, and handles the message validation. It defines how each byte transmitted by the physical layer is interpreted and ensures that it forms a consistent and valid message. Finally, the command layer specifies commands that are transmitted to the reader to execute a set of functions. These functions will allow the communication with a smart card and the management of events such as insertion and removal of the card.

In the communication process, the driver is a piece of software that hides the treatment related to the physical and the transport layers. With documented interfaces, the user can use the command layer to send commands to the reader and to communicate with the card. Usually, the operating system integrates drivers that take charge of the physical layer. The device vendor will then write a **filter driver** that is placed over the other one to wrap up the transport layer, transmitting commands into well-defined packages. The driver will allow basic commands to the reader: setting parameters of the readers (communication speed, voltage levels, card type used), setting communication parameters between reader and card (protocol, speed), power on, power off, transmitting bytes to the card. Moreover, the driver must manage the events coming from the system and control the states of the device. For instance, the insertion or the removal of the reader involves some processes of initialization of the communication and registration of the connection. The driver must also allow the sharing

of the resource by multiple applications or threads. Security issues regarding those accesses must be considered. One must preserve access to the information on the card from the application that was not allowed.

With only the driver, the development of an application requires the knowledge of the command format to send to the card and of the mapping of the smart card. To ease and speed up his development, a programmer needs tools that hide specificity of cards and readers. **API** and middleware are coming to his rescue.

APIs and Middleware

Application program interfaces (API, also called middleware) usually take the form of libraries that provide the user with high-level functions to ease the development and to hide disparities between different technologies. Basic APIs try to hide the command layer to the user and regroup under common interfaces the communication with different readers. At a higher lever, an API hides the smart card operating system particularities, providing the user with card services and with abstract concepts that ease the use of the information on the card. Thus, card services will allow the user to select a file, to read, write, and erase objects on the card, and to authenticate the user. API can also regroup specialized functions such as cryptographic functions, purse functions, etc.

Usually, APIs are proposed by smart card vendors to offer an easy-to-use environment for the development of applications on their products. It offers a wide variety of commands and responses. However, it makes the developer dependent of a product and of the support of these API. Efforts were made to standardize some API. PKCS#11[5] is an example of cryptographic libraries. This standard API is defined by RSA (RSA Data Security, Inc.) and permits the use of data objects in the form of tag-length-value.

Standardizing Approach

With the lack of interoperability between operating systems, API, readers, and smart cards, some efforts were made to offer more compatibility and harmonization. **PC/SC** and the OpenCard Framework are the main stream.

PC/SC

PC/SC[4] is an effort to provide interoperability of the smart card technology in the personal computer environment. The aims of PC/SC is to simplify the development of application by defining high-level programming interfaces that reduce the dependency of application on proprietary implementation. To achieve its goals, PC/SC distinguishes three layers between the hardware device and the application level: The IFDHandler Layer, the resource manager layer, and the service provider layer.

The IFDHandler allows access to the smart card reader. It is the driver level and the hardware manufacturer that will normally provide it. PC/SC defines the interfaces that the IFDHandler must expose to take place in the structure. The IFDHandler is the implementation of the functionality required by the exposed functions to transmit commands to the reader and/or the card. The IFDHandler maps the native capabilities of the smart card reader to the IFDHandler interface. All distinctions between smart cards based on ISO protocol handling, whether synchronous or asynchronous, are hidden. Once installed, the IFDhandler registers itself to the Resource Manager.

The Resource Manager is a key component of the PC/SC architecture. It is responsible for managing the other resources (such as service providers) within the system and for controlling access to the smart card readers and to the card itself. The Resource Manager is provided by the operating system vendor. Thus, the Resource Manager is responsible for identification and tracking of resources. This includes the tracking of the readers, of the smart cards, of the service providers, of the supported interfaces and of the smart card insertion and removal events. Thus, the Resource Manager can list the available resources to each application.

The Resource Manager is also responsible for controlling the allocation of readers and across multiple applications with shared or exclusive modes of operations. Finally, it supports transaction primitives to allow multiple commands to be executed without interruption, ensuring that intermediate state information is not corrupted.

The Service Provider regroups a set of functions exposed by a specific smart card and makes it accessible through high-level programming interfaces. The common functionalities are related to file access, authentication, and cryptographic services. However, these interfaces may be extended to meet the needs of specific domains.

PC/SC divides the Service Provider into two independent components: the Smart Card Service Provider (SCSP) and the Cryptographic Service Provider (CSP). The CSP regroups cryptographic functionality through high-level programming interfaces. This distinction was brought to deal with security issues and with international laws regarding cryptographic devices.

The Answer To Reset (**ATR**) string is used to perform the binding between a card and an interface. Thus, when a service provider is installed on a system, it registers itself to the Resource Manager with the ATR of cards it can serve. An application can define at run-time which Service Provider will be used since the Resource Manager enumerates the list of the available interfaces when the card is inserted.

Although PC/SC is platform neutral, to date, Microsoft did the only implementation of this standard on Windows platform (even now the implementation still lacks of some features: "plug and play" and power management). Card services are exposed to an application through Component Objet Model (COM) interface.

PS/SC v.1.0 supports only T = 0 and T = 1 cards and optionally T = 14 (protocols of communication between a card and a reader. For details see [1–3]). Next release of this standard will consider memory card and multiple interfaces readers such as keyboard, display, multiple cards, and SAM modules.

OpenCard Framework

OpenCard Framework (OCF) [6] objective is to offer to the programmer a transparency with regard to smart card operating systems, card terminals, and card issuers. To achieve this, OCF has defined a provision of functions to support installation, removal, enumeration, selection of applications on the card and of functions to perform name resolution for data files on the card. Several mechanisms allow a user to develop an application without knowing where the card issuer placed his applications. OpenCard Framework based its architecture on two main parts: the CardTerminal layer and the CardService layer.

The CardTerminal layer plays the role of the driver and the reader manufacturer should provide it. It offers an interface that enables the seamless integration of the reader in the OCF environment. With OCF-compliant interfaces, a specific card terminal gives access to the reader and the smart card. A CardTerminal can also act as a bridge to provide a transparent access to a reader through the PCSC interface to take advantage of the existing components.

The CardService layer is defined as a high-level application programming interface that hides the characteristics of a particular provider's components (specific to a type of smart card and/or smart card reader) from the application and service developers. Card services are standard **APIs** regrouping functions to access resources of a card operating system. Thus, a card issuer will provide the users with a card services allowing access to the files (FileAccessCardService), to the signature functions (SignatureCardService), to PKCS#11 functions, to the ISO7816 file system, and to purse functions.

Between those two layers, a specific card service, the application management card service, manages the card resident applications. The application management component lists the applications that a card can support, locates them or even installs or removes them from the card. It is a special card service, also provided by the card issuer, that can manage multiple applications on the same smart card.

OCF essentially was created for the Java programming environment and the world of network computing. Because of this, it claims all the advantages that the Java language provides. Basically, any platform that is capable of running JAVA can exploit OCF right away. Moreover, OCF offers mechanisms to allow one to download from the network missing components for a particular card at hand and plug them into the framework. As it is for Java, OCF targets embedded systems such as automatic teller machines, point-of-sales terminals, and hand-held devices (phone, electronic agenda).

Applications

Developing an application is made easier and more flexible when based over standard API and middleware products. The challenge remains, however, to respond to the new needs of the industry. Applications must integrate security schemes to avoid holes and prevent piracy of a system. To secure their system, applications developers must be aware of the complete structure of the operating system they are using. For instance, the market proposes new software to protect access to a computer and to encrypt files on computers. Such a system requires low level control of the resources of a computer to block unexpected entry. Also, sensitive information must not be exposed. Encryption keys are never kept clearly in memory to prevent software attack.

Applications are also confronted with the Internet challenge. Security systems are facing new offensives and new security schemes that must be put in place. The Internet not only broadcasts the information at the speed of light; it represents to hackers a tremendous power for parallel computing. Competitions are organized on the net to break encryption keys: each participant downloads the required software and adds its contribution to the computing effort. Key size is lengthened, consequently. Secure transactions over the net also bring new problems. Applications are distributed, client-server schemes become more important, the number of transactions are growing and, consequentially, we do not know who is on the other side. For an electronic wallet application, this is crucial because nobody wants to give his credit card number without some credentials. Third party certificates are there to authenticate your invisible partner and mechanisms are set to establish a confidence path between all involved parties of a transaction.

Trends

Trends in smart card industry may, but rather should not be, seen only from an ICC perspective. The reason is amazingly simple: the most powerful, super fast and multi-functional card is nothing more than a piece of plastic and silicon if there is no IT system able to use it. That's why the trends will be discussed in two groups: card technology and complete solutions.

The general challenges driving card technology trends may be defined by four simple words: faster, cheaper, more, easier. Technical solutions to come should allow multi-application (more), flexible functional profile i.e., easy changeable dedicated applications (easier), shorter, nonspecific technology-tied development cycle (faster), shorter time to market (more, cheaper), higher security level (easier). All of the above points to a generally named card open OS solution.

How serious this trend is depends upon industry reactions. Hardware manufacturers design more powerful chips dedicated to operate with higher clock speeds, offering larger memory space, in some cases injecting specific commands into the processor's command list (Siemens's picoJava concept encapsulating specific JavaCard commands in processor design), and adding specialized coprocessors (cryptographic functions). Card manufacturers improve their OOSs to meet multi-application requirements by adding new features up to recently imminent to pure IT (multi-thread, COM, firewalls, add/load/delete), system integrators adapt their solutions to absorb specific card management systems (CMS) allowing control over the live cycle of applications (and cards), card issuers design multi-applicative programs for their customers, and finally, software development companies begin to create competitive, cutting edge competence in smart card OOS-dedicated applications development. The recent entry into the industry includes the software giant — Microsoft with its Smart Card for Windows (SCW). This entry establishes the seriousness of the smart card trend.

To penetrate new markets, the smart card industry must now develop value-added solutions by enhancing the functionality of the conventional card. To be attractive to customers, the same card should be used for access control, securing transactions on the net, and for payment. This trend implies the coexistence of multiple applications on the same card. It also means the customization of the user card. The Java Card and, more recently, the Smart Card for Windows are supporting this stream where developers can download their own application into the card.

Defining Terms

APDU: Application Protocol Data Unit is a set of bytes forming a unitary "container" used to send to or receive data from a card. There are two types of APDUs: command APDU (sent to a card) and response APDU (sent by a card). Formats of both APDUs are different, however, no mismatch is possible as the communication between a card and the reader is ruled by a sequence: command (reader)-response (card).

API: Application Programming Interface. In general terms, API is a set of functionalities (library) loadable or preloaded available for a programmer developing the application. In smart card technology, APIs are found on board the card (e.g., Java Card) as well as on the system side (reader APIs). The goal of creating API is to free the developer from card-related specific knowledge allowing him/her to develop on the higher level of abstraction.

ATR: Answer To Reset is a set of maximum 33 bytes returned by a card to a reader after RESET signal was applied. ATR consists of information necessary to authenticate a card to the system and the reader as well as to negotiate all communication parameters as protocol, transmission speed, etc.

DES algorithm: Data Encryption Standard algorithm is the most popular encryption/decryption mathematical engine. DES is being broadly applied in the security domain for encryption/decryption purposes, secure messaging, and authentication. Best known is 56-bit encryption/decryption key version. For more sophisticated security applications, 3DES (triple DES) is being applied. 3DES is a method using DES three consecutive times with a different encryption key used each time.

Filter: Filter, in smart card technology, defines an additional block of code loaded to the card's EEPROM whose function is to either enhance the existing card's functionality or patch found bugs. In the first case, you can see it as the development "pilot" that allows the manufacturer to check new releases before its industrial launch. In the second case, a "filter" is the easiest way to debug and fix existing application or OS. When checked, verified, and approved, the "filter" is moved to ROM and remasked.

Masking process: The masking process is the essential process of manufacturing the chip to be later embedded onto a card. The masked chip contains all the hardware components as well as all of the software stored in ROM. The remaining EEPROM and RAM are empty and not structured.

Personalizing process: The personalizing process is performed by a card manufacturer. The goal is to make a masked chip card that the customer can use. The process covers loading onto the card all specific customer info (name, primary security keys, serial number) as well as building the internal memory structure (directories, file structures, file types).

PC/SC: Personal Computer/Smart Card (PC/SC) is the "de facto" or industry standard introduced by Microsoft Corporation. The standard defines structure, functionality, and communication entries for smart card readers' drivers being installed on all existing Windows platforms (95, 98, NT4, 2000).

USB: Universal Serial Bus is the newest PC technology applied to serial communication solutions. The technology allows connecting to a PC several serial devices in a chain at the same time. The communication protocol between PC and external serial devices is similar to this used in networking. USB becomes more and more in demand in PC-Smart Card solutions.

90.1 Tools and Techniques[1]

Carl A. Argila

The last decade has seen a revolution in software engineering tools and techniques. This revolution has been fueled by the ever-increasing complexity of the software component of delivered systems. Although the software component of delivered systems may not be the most expensive component, it is usually, however, "in series" with the hardware component; if the software doesn't work, the hardware is useless.

Traditionally, software engineering has focused primarily on computer programming with ad hoc analysis and design techniques. Each software system was a unique piece of intellectual work; little emphasis was placed on architecture, interchangeability of parts, reusability, etc. These ad hoc software engineering methods resulted in the production of software systems which did not meet user requirements, were usually delivered over budget and beyond schedule, and were extraordinarily difficult to maintain and enhance.

In an attempt to find some solutions to the "software crisis," large governmental and private organizations motivated the development of so-called "waterfall" methods. These methods defined formal requirement definition and analysis phases, which had to be completed before commencing a formal design stage, which in turn had to be completed before beginning a formal implementation phase, etc. Although waterfall methods were usually superior to ad hoc methods, large and complex software systems were still being delivered over budget and beyond schedule, which did not meet user requirements. There were several reasons for this. First, waterfall methods focus on the generation of *work products* rather than "engineering." Simply put, writing documents is not the same as doing good engineering. Second, the waterfall methods do not support the *evolution* of system requirements throughout the development life cycle. Also, the prose English specifications produced within the waterfall methods are not well suited to describing the complex behaviors of software systems.

[1]The material in this article was originally published by CRC Press in *The Electrical Engineering Handbook,* Richard C. Dorf, Editor, 1993.

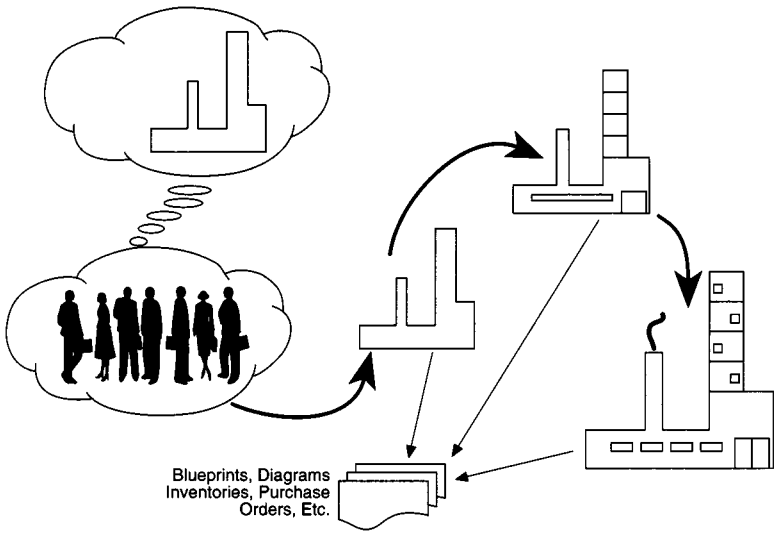

FIGURE 90.1 Model-based software engineering.

The basic, underlying philosophy of how software systems should be developed changed dramatically in 1978 when Tom DeMarco published his truly seminal book, *Structured Analysis and System Specification* [DeMarco, 1979]. DeMarco proposed that software systems should be developed like any large, complex engineering systems—by first building scale models of proposed systems so as to investigate their behavior. This *model-based software engineering* approach is analogous to that used by architects to specify and design large complex buildings (see Fig. 90.1). We build scale models of software systems for the same reason that architects build scale models of houses, so that users can visualize living with the systems of the future. These models serve as vehicles for communication and negotiation between users, developers, sponsors, builders, etc. Model-based software engineering holds considerable promise for enabling large, complex software systems to be developed on budget, within schedule, while meeting user requirements [see Harel, 1992].

As shown in Fig. 90.2, a number of specific software development models may be built as part of the software development process. These models may be built by different communities of users, developers, customers, etc. Most importantly, however, these models are built in an *iterative* fashion. Although work products (documents, milestone reviews, code releases, etc.) may be delivered chronologically, models are built iteratively throughout the software system's development life cycle.

In Fig. 90.3 we illustrate the distinction between *methodology*, *tool*, and *work product*. A number of differing software development methods have evolved, all based on the underlying model-based philosophy. Different methods may in fact be used for the requirements and analysis phases of project development than for design and implementation. These differing methods may or may not integrate well. Tools such as **CASE** may support all, or only a part, of a given method. Work products, such as document production or code generation, may be generated manually or by means of CASE tools.

This article will present a synopsis of various practical software engineering techniques which can be used to construct software development models; these techniques are illustrated within the context of a simple case study system.

Approach

One of the most widely accepted approaches in the software engineering industry is to build two software development models. An **essential model** captures the behavior of a proposed software system, independent of implementation specifics. An essential model of a software system is analogous to the scale model of a house built by an architect; this model is used to negotiate the *essential* requirements of a system between customers and developers. A second model, an **implementation model**, of a software system describes the technical aspects of a proposed system within a particular implementation environment. This model is analogous to the detailed

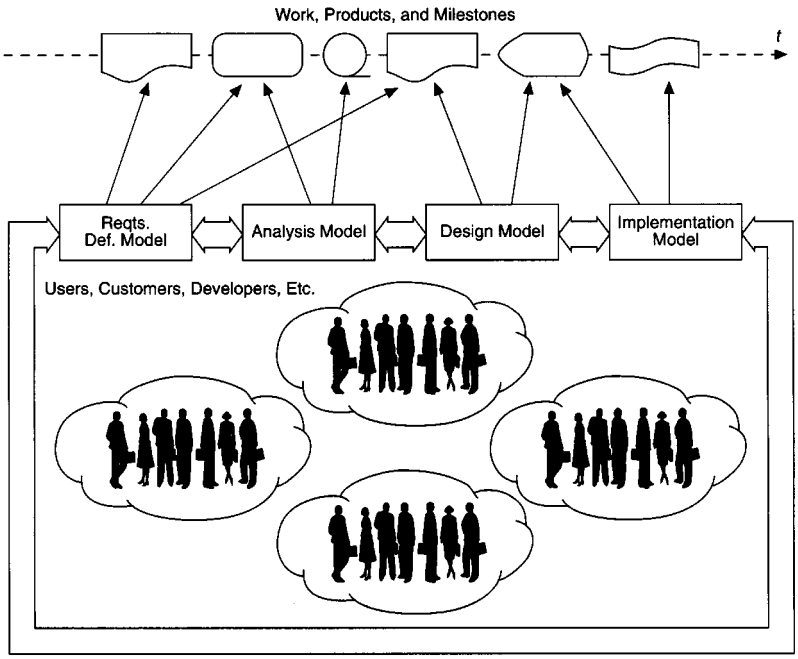

FIGURE 90.2 Modeling life cycle.

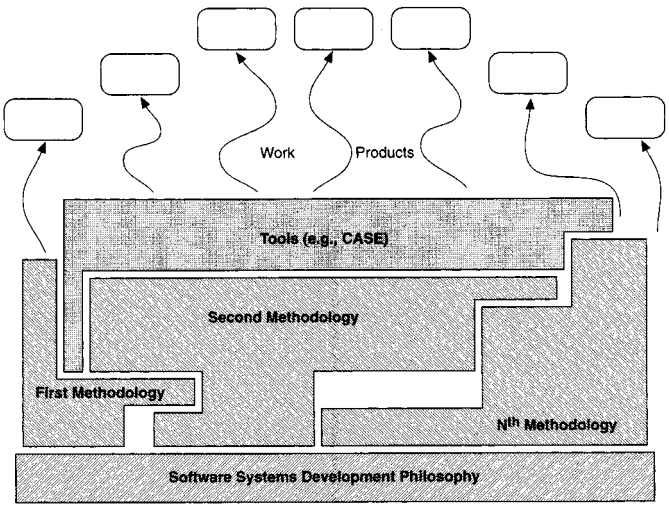

FIGURE 90.3 Methods, tools and work products.

blueprints created by an architect; it specifies the *implementation* aspects of a system to those who will do the construction. These models [described in Argila, 1992] are shown in Fig. 90.4. The essential and implementation models of a proposed software system are built in an iterative fashion.

Methods

The techniques used to build the essential and implementation models of a proposed software system are illustrated by means of a simple case study. The Radio Button System (RBS) is a component of a fully automated, digital automobile sound system. The RBS monitors a set of front-panel *station selection buttons* and performs station selection functions.

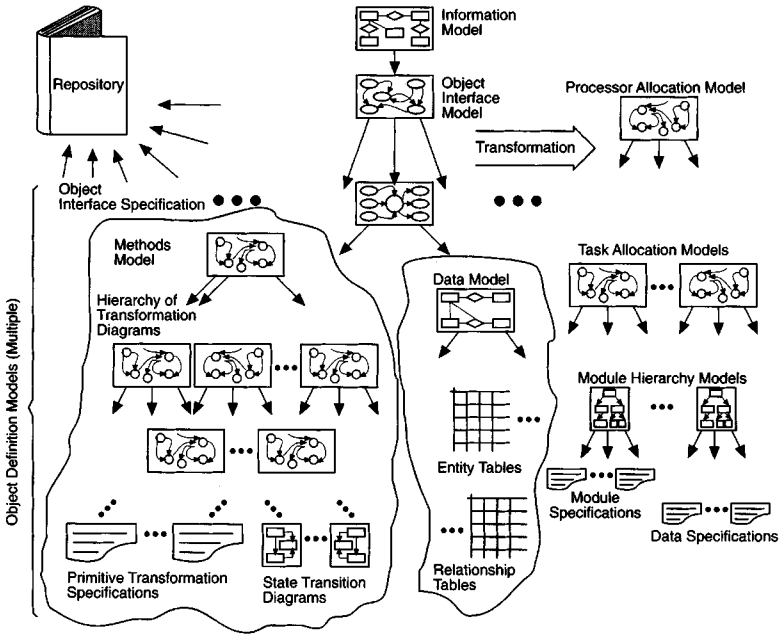

FIGURE 90.4 Software engineering methods overview.

When a station selection button is momentarily depressed, the RBS causes a new station to be selected. This selection is made on the basis of station-setting information stored within the RBS. The RBS can "memorize" new station selections in the following manner: When a given station selection button is depressed longer than "momentarily" (say, for more than 2 seconds), the currently selected station will be "memorized." Future momentary depressions of this button will result in this "memorized" station being selected.

The RBS also performs a muting function. While a station is being selected, the RBS will cause the *audio system* to mute the audio output signal. The RBS will also cause the audio output signal to be muted until a new station selection has been successfully memorized.

The RBS interfaces with the front-panel station selection buttons by "reading" a single-byte memory location. Each bit position of this memory location is associated with a particular front-panel station selection button. The value of 0 in a given bit position indicates that the corresponding button is *not* depressed. The value of 1 in that bit position indicates that the corresponding button *is* depressed. (For example, 0000 0000 indicates no station selection buttons are currently depressed; 0000 0010 indicates that the second button is currently depressed, etc.)

The RBS interfaces with the *tuning system* by means of a common memory location. This single-byte memory location contains a non-negative integer value which represents a station selection. (For example, 0000 0000 might represent 87.9 MHz, 0000 0001 might represent 88.1 MHz, etc.) The RBS may "read" this memory location to "memorize" a current station selection. The RBS may also "write" to this memory location to cause the tuning system to select another station.

Finally, the RBS interfaces with the audio system by sending two signals. The RBS may send a MUTE-ON signal to the audio system causing the audio system to disable the audio output. A MUTE-OFF signal would cause the audio system to enable the audio output.

Information Modeling

The construction of an **information model** is fundamental to so-called object-oriented approaches. An information model captures a "view" of an application domain within which a software system will be built. Information models are based on entity-relationship diagrams and underlying textual information. A sample

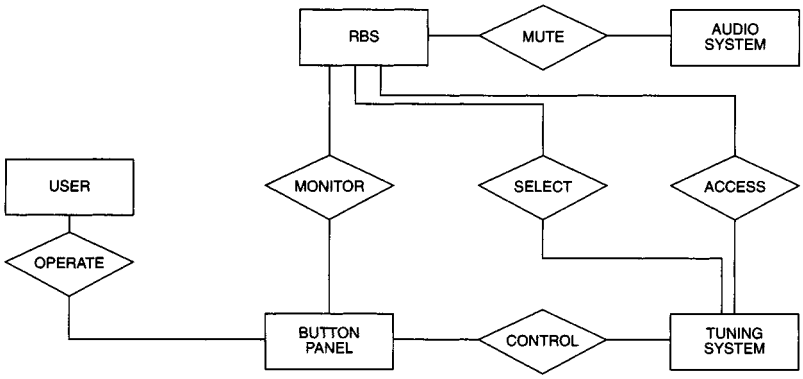

FIGURE 90.5 RBS information model.

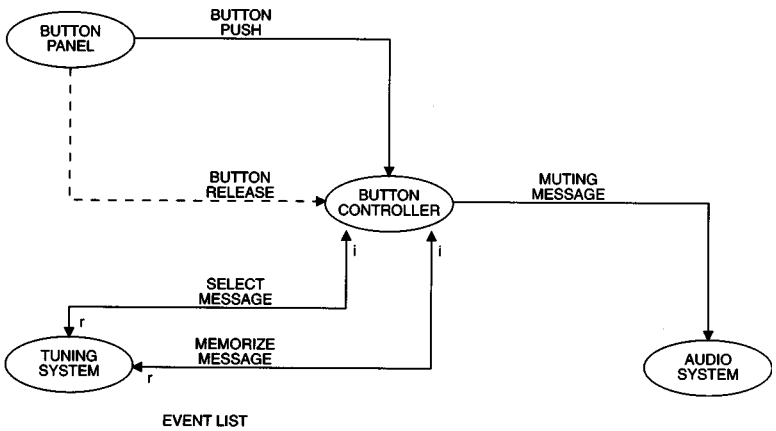
information model for the RBS is shown in Fig. 90.5. Entities (shown as rectangles) represent "things" or "**objects**" in the application domain. Entities may be established by considering principal nouns or noun phrases in the application domain. Entities have *attributes* associated with them which express the qualities of the entity. Entities participate in *relationships;* these are shown as diamonds in the entity-relationship diagram. Relationships may be determined by considering principal verbs or verb phrases in the application domain. Relationships have *cardinality* associated with them and entities may participate *conditionally* in relationships. Finally, there are special kinds of relationships which show *hierarchical relationships* between objects.

Essential Modeling

The essential model consists of a number of graphical components with integrated textual information. Figure 90.6 shows the **object collaboration model** for the RBS. This model depicts how a collection of objects or entities can communicate (by exchanging messages) to perform the proposed system functions. An *event list* is part of this model; it shows what responses must be produced for a given external stimulus.



EVENT LIST

EVENT	RESPONSE
1. Selection button depressed.	1. Mute audio system.
2. Button released within two seconds after it was depressed.	2. Select a memorized station. Un-mute audio system.
3. Two seconds elapses after button was depressed while button remained depressed.	3. Memorize current station. Un-mute audio system.

FIGURE 90.6 RBS object collaboration model.

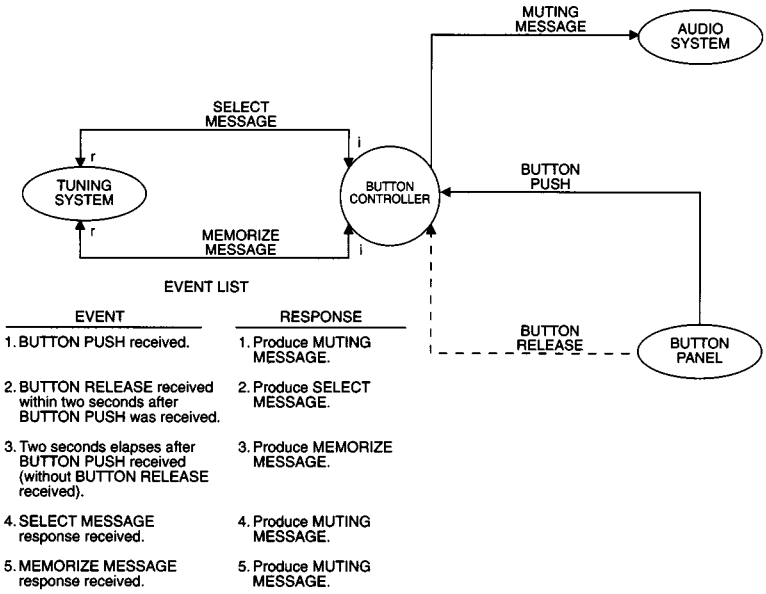


FIGURE 90.7 RBS object interface specification.

For each object there is an **object interface specification** (as shown in Fig. 90.7) which shows the public and private interfaces to an object. An event list is also associated with this specification; it shows how the object will respond to external stimuli. A hierarchy of **transformation diagrams** is associated with each object specification (as shown in Fig. 90.8 for the RBS). This diagram defines all of the functions or "methods" which the object performs. Some behavior may be expressed by means of a **state transition diagram** (Fig. 90.9).

Implementation Modeling

Two principal activities must be accomplished in transitioning from the essential to the implementation model. First, all of the methods and data encapsulated by each object must be mapped to the implementation environment. This process is illustrated in Fig. 90.10. Second, all of the details which were ignored in the essential model (such as user interfaces, communication protocols, hardware limitations, etc.) must now be accounted for.

Each component of the essential model must be allocated to hardware processors. Within each hardware processor, allocation must be continued to the *task* level. Within each task, the computer program controlling that task must be described. This latter description is accomplished by means of a **module structure chart.** As illustrated in Fig. 90.11 for one component of the RBS, the module structure chart is a formal description of each of the computer program units and their interfaces.

CASE Tools

The term *computer-aided software engineering* (CASE) is used to describe a collection of tools which automate all or some of various of the software engineering life cycle phases. These tools may facilitate the capturing, tracking and tracing of requirements, the construction and verification of essential and implementation models and the automatic generation of computer programs. Most CASE tools have an underlying *project repository* which stores project-related information, both textual and graphical, and uses this information for producing reports and work products.

CASE tool features may include:

- Requirements capture, tracing, and tracking
- Maintenance of all project-related information
- Model verification
- Facilitation of model validation

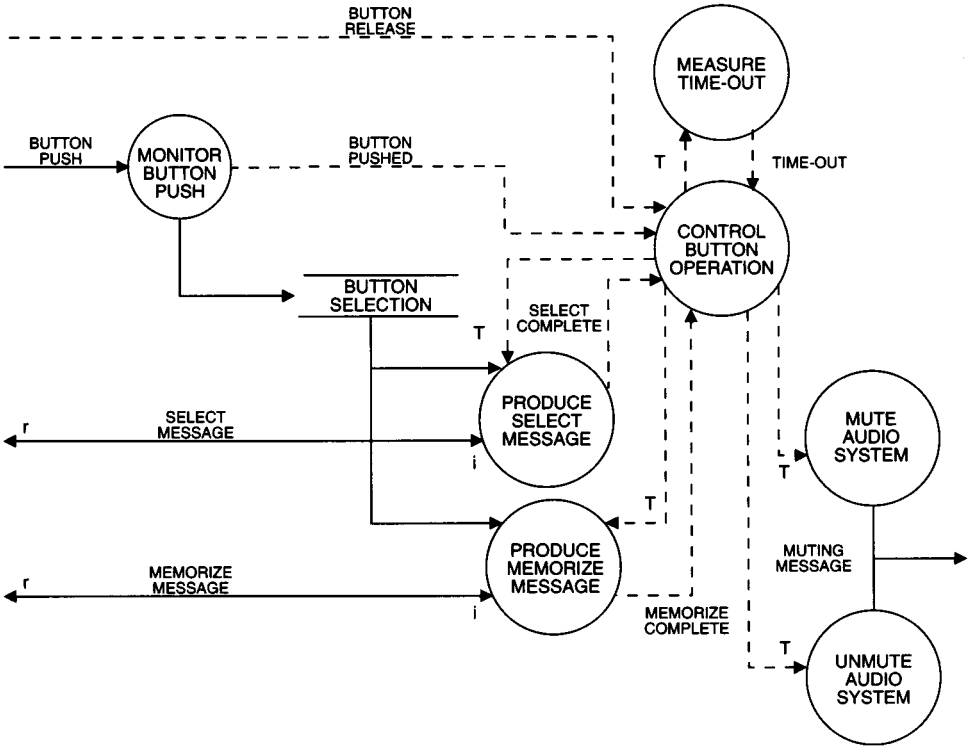

FIGURE 90.8 RBS transformation diagram.

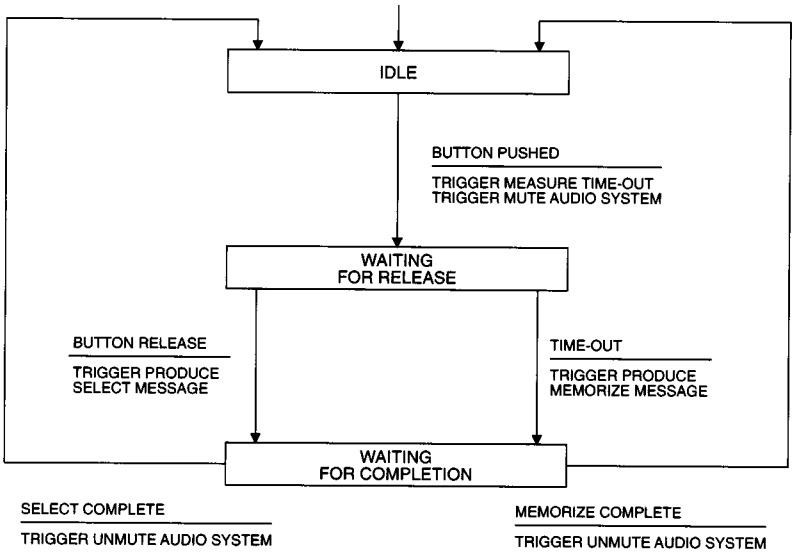

FIGURE 90.9 RBS state transition diagram.

- Document production
- Configuration management
- Collection and reporting of project management data
- CASE data exchange

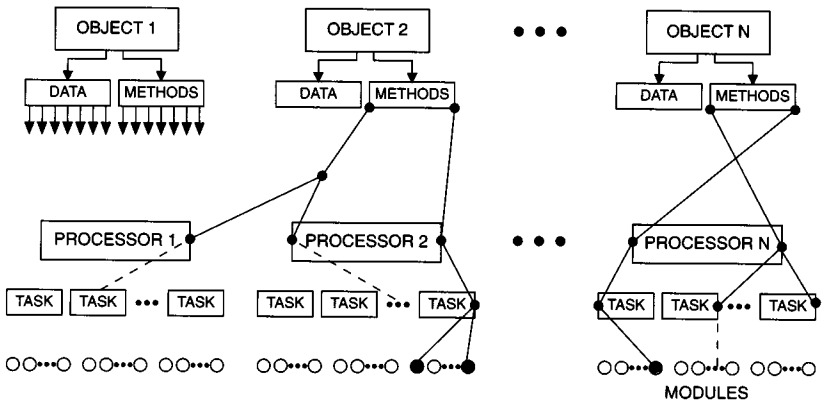

FIGURE 90.10 Implementation modeling.

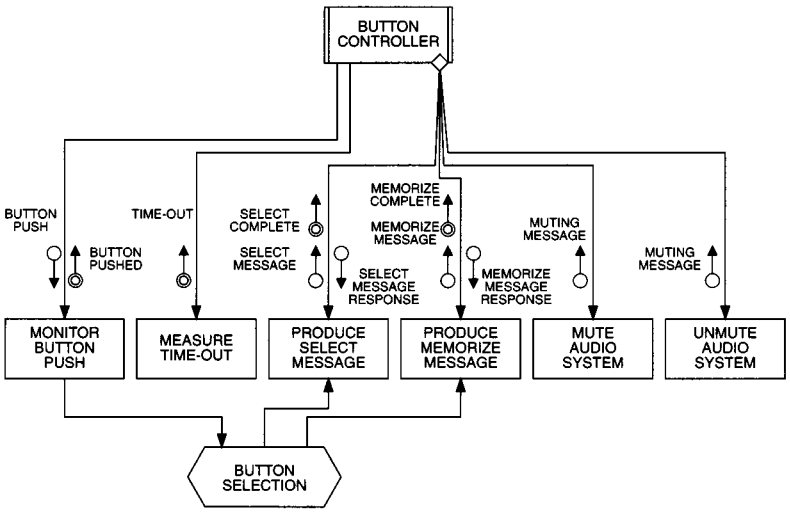

FIGURE 90.11 RBS module structure chart.

Defining Terms

CASE: Computer-aided software engineering. A general term for tools which automate various of the software engineering life cycle phases.

Essential model: A software engineering model which describes the behavior of a proposed software system independent of implementation aspects.

Implementation model: A software engineering model which describes the technical aspects of a proposed system within a particular implementation environment.

Information model: A software engineering model which describes an application domain as a collection of objects and relationships between those objects.

Module structure chart: A component of the implementation model; it describes the architecture of a single computer program.

Object: An "entity" or "thing" within the application domain of a proposed software system.

Object collaboration model: A component of the essential model; it describes how objects exchange messages in order to perform the work specified for a proposed system.

Object interface specification: A component of the essential model; it describes all of the public and private interfaces to an object.
State transition diagram: A component of the essential model; it describes event-response behaviors.
Transformation diagram: A component of the essential model; it describes system functions or "methods."

Further Information

A video course presenting the software engineering techniques described here is available [see Argila, 1992]. The author may be contacted for additional information and comments at (800) 347-6903.

90.2 Testing, Debugging, and Verification

Capers Jones

Achieving acceptable levels of software quality has been one of the most troublesome areas of software engineering since the industry began. It has been so difficult to achieve error-free software that, historically, the cost of finding and fixing **"bugs"** has been the most time-consuming and expensive aspect of large-scale software development.

Software quality control is difficult to achieve, but the results of the careful application of **defect prevention** and **defect removal** techniques are quite good. The software producers who are most effective in quality control discover several derivative benefits as well: software with the highest quality levels also tends to be the least expensive to produce, tends to have minimum schedules during development, and also tends to have the highest levels of post-release user satisfaction.

The topic of defect prevention is outside the primary scope of this article. However, it is important to note that the set of technologies associated with defect prevention must be utilized concurrently with the technologies of defect removal in order to achieve high levels of final quality. The technologies which prevent defects are those concerned with optimizing both clarity and structure and with minimizing ambiguity. Joint application design (JAD) for preventing requirements defects; prototyping; reuse of certified material; clean-room development; any of the standard structured analysis, design, and coding techniques; and quality function deployment (QFD) for evaluating end-user quality demands are examples of the technologies associated with defect prevention. Many aspects of total quality management (TQM) programs are also associated with defect prevention.

TABLE 90.1 Origins and Causes of Software Defects

	Defect Causes		
Defect Origins	Errors of Omission	Errors of Commission	Errors of Clarity or Ambiguity
Requirements defects	Frequent	Seldom	Frequent
Design defects	Frequent	Frequent	Frequent
Coding defects	Frequent	Frequent	Frequent
Document defects	Frequent	Seldom	Frequent
Bad fix defects	Seldom	Frequent	Seldom

The Origins and Causes of Software Defects

Before software defects can be prevented or removed effectively, it is necessary to know where defects originate and what causes them. There are five primary origin points for software defects and three primary causes. The five primary origin points are (1) requirements, (2) design, (3) code, (4) user documentation, and (5) bad fixes, or secondary defects that occur while attempting to repair a primary defect. The three primary causes of software defects are (1) errors of omission, (2) errors of commission, and (3) errors of clarity or ambiguity. Table 90.1 shows the interaction of software defect origins and defect types.

The phrase *errors of omission* refers to problems caused by a failure to include vital information. Such errors are frequently encountered in requirements, specifications, source code, and user documents. An example of such an error became highly visible on February 29, 1992, when it was discovered that the calendar routine for a particular application omitted leap year calculations, thus shutting down the system at midnight on the 28th. From 15% to more than 30% of the post-deployment problems encountered in software can be traced to errors of omission. The probability and frequency of such errors rises with the size of the system.

The phrase *errors of commission* refers to problems caused by an action that is not correct, such as looping through a counter routine one time too often or including conditions in a specification that are mutually contradictory. Such errors are frequently encountered in design, code, and in "bad fixes" or secondary defects created as a by-product of repairing prior defects. From 40 to 65% of the post-deployment problems encountered in software can be traced to errors of commission, thus making it the most common source of software problems.

The phrase *errors of clarity or ambiguity* refers to problems caused by two or more interpretations of the same information. For example, a requirement may contain a phrase that an application should provide "rapid response time" without actually defining what "rapid" means. To the client, sub-second response time may have been intended, but to the development team one-minute response time may have been their interpretation. Such errors are frequently encountered in all software deliverables based on natural language such as English. They are also frequently encountered in source code itself, especially so if the code were not well structured. Also, certain languages such as APL and those using nested parentheses are notorious for being ambiguous. From less than 5% to more than 10% of the post-deployment problems encountered in software can be traced to errors of clarity or ambiguity.

When considering the origins of software defects, it is significant that the requirements and specifications themselves may be the source of as many as 40% of the defects later encountered after deployment. This fact implies that some forms of verification and validation, which assume the requirements and specifications are complete and correct, have hidden logical flaws.

The distribution of defects among the common origin points varies with the size and complexity of the application. Table 90.2 shows the probable defect distributions for four size ranges of software projects, using the language C as the nominal coding language.

The sum of the five defect categories is termed the *defect potential* of a software program or system [Jones, 1986]. The defect potential constitutes the universe of all errors and bugs that might cause an application to either fail to operate or to produce erratic and unacceptable results while operating.

The defect potential of software tends to be alarmingly high. When expressed with the traditional metric "KLOC" (where K stands for 1000 and LOC stands for lines of code) the observed defect potentials have ranged from about 10 bugs per KLOC to more than 100 bugs per KLOC, assuming procedural languages such as C,

TABLE 90.2 Software Defect Origins and Project Size

	Software Project Size (Statements in C Language)			
	1000	10,000	100,000	1,000,000
Requirements	5%	7%	10%	15%
Design	10%	15%	20%	25%
Code	70%	60%	50%	40%
Documents	5%	8%	10%	10%
Bad fixes	10%	10%	10%	10%
Total	100%	100%	100%	100%

Fortran, or Jovial. When expressed with the newer Function Point metric, the range of software defect potentials is from less than 2 to more than 10 bugs per Function Point.

When historical defect data is analyzed, it can easily be seen why defect prevention and defect removal are complementary and synergistic technologies. The defect prevention approaches are used to lower defect potentials, and the defect removal technologies are then used to eliminate residual defects.

Another dimension of concern is the *severity level* of software defects. The severity level scheme used by IBM, and widely adopted by other software producers, is based on a four-point scale. Severity 1 defects are those which stop the software completely or prevent it from being used at all. Severity 2 defects are those where major functions are disabled or unusable. Severity 3 defects are those that can be bypassed or which have a minor impact. Severity 4 defects are very minor problems which do not affect the operation of the software, for example, a spelling error in a text message.

Software **debugging,** testing, and verification methods should be effective against the entire defect potential of software, and not just against coding defects. Defect removal methods should approach 100% in efficiency against severity 1 and severity 2 defects. Further, defect removal methods should deal with errors of omission as well as errors of commission. Software operates at extremely high speed, so defect removal operations must deal with timing and performance problems as well as with structural and logical problems. Finally, and most difficult, defect removal methods should deal with errors of clarity or ambiguity. These are challenging tasks.

The Taxonomy and Efficiency of Software Defect Removal

There is no standard taxonomy that encompasses all of the many forms of defect removal that can be applied to software [Dunn, 1984]. For convenience, we will divide defect removal operations into three broad categories: pre-test defect removal, testing, and post-release defect removal.

Since the goal of defect removal is the elimination of bugs or defects, the primary figure of merit for a defect removal operation is its *efficiency* [Jones, 1991]. **Defect removal efficiency** is defined as the percent of latent defects which a given removal operation will detect. Cumulative defect removal efficiency is the overall efficiency of a complete series of pre-test removal activities combined with all test stages.

Calculating the efficiency of a defect removal operation, or a series, is necessarily a long-range operation. All defects encountered prior to release are enumerated and running totals are kept. After the first year of production, the client-reported defects and the pre-release defects are aggregated as a set, and the efficiencies of pre-release operations are then calibrated. Thus for large systems with multi-year development cycles, it may take up to five years before defect removal efficiency rates are fully known.

Major computer companies, telecommunications manufacturers, defense contractors, and some software vendors have been measuring defect removal efficiencies for more than 20 years. The body of empirical data is large enough to make general observations about the efficiencies of many different kinds of defect removal operation.

Empirical observations and long-range studies of commercial software have demonstrated that most forms of testing are less than 30% efficient. That is, any given stage of testing such as system testing or acceptance testing is likely to find less than 30% of the latent defects that are actually present. However, a carefully planned series of defect removal operations can achieve very respectable levels of cumulative defect removal efficiency. Computer manufacturers, commercial software producers, and defense software producers may utilize as many as 9 to 20 consecutive defect removal operations, and sometimes achieve cumulative defect removal efficiencies that approach the six sigma quality level, i.e., defect removal efficiency rates approaching 99.999999%.

Pre-Test Defect Removal

The set of defect removal activities for software carried out prior to the commencement of testing can be further subdivided into *manual defect removal* and *automated defect removal.*

A fundamental form of manual defect removal is termed *desk checking*, or the private review of a specification, code document, or document by the author. The efficiency of desk checking varies widely in response to both individual talents and to the clarity and structure of the materials being analyzed. However, most humans are not particularly efficient in finding their own mistakes, so the overall efficiency of desk checking is normally less than 35%.

The most widely utilized forms of manual defect removal are reviews, inspections, and walkthroughs. Unfortunately common usage blurs the distinction among these three forms of defect removal. All three are group activities where software deliverables such as the requirements, preliminary or detailed design, or a source code listing are discussed and evaluated by technical team members.

Casual reviews or informal walkthroughs seldom keep adequate records, and so their defect removal efficiencies are not precisely known. A few controlled studies carried out by large companies such as IBM indicate that informal reviews or walkthroughs may average less than 45% in defect removal efficiency.

The term *inspection* is often used to define a very rigorous form of manual analysis [Fagan, 1976]. Ideally, the inspection team will have received formal training before participating in their first inspection. Also, the inspection team will follow formal protocols in terms of preparation, execution, recording of defects encountered, and follow-up of the inspection session. The normal complement for a formal inspection includes a moderator, a recorder, a reader to paraphrase the material being inspected, the developer whose work is undergoing inspection, and often one or more additional inspectors.

Formal inspections of the kind just discussed have the highest measured efficiency of any kind of defect removal operation yet observed. For inspections of plans, specifications, and documents the defect removal efficiency of formal inspections can exceed 65%. Formal inspections of source code listings can exceed 60%.

Formal inspections are rather expensive, but extremely valuable and cost-effective. Not only do inspections achieve high rates of defect removal efficiency, but they are also effective against both errors of omission and errors of clarity or ambiguity, which are extremely difficult to find via testing. Formal inspections also operate as a defect prevention mechanism. Those who participate in the inspection process obviously learn a great deal about the kinds of defects encountered. These observations are kept in memory and usually lead to spontaneous reductions in potential defects within a few months of the adoption of formal inspections.

Military software projects in the United States are governed by various military standards such as DOD 2167A and DOD 1614. These standards call for an extensive series of reviews or inspections that are given the generic name of *verification and validation.* The word *verification* is generally defined as ensuring that each stage in the software process follows the logical intent of its predecessor. The term *validation* is generally defined as ensuring that each delivered feature or function can be traced back to a formal requirement.

U.S. military verification and validation has developed its own argot, and those interested in the full set of U.S. military verification and validation steps should refer to the military standards themselves or to some of the specialized books that deal with this topic. Examples of the forms of verification and validation used on U.S. military projects, and the three-letter abbreviations by which they are commonly known, include system requirements review (SRR), system design review (SDR), preliminary design review (PDR), critical design review (CDR).

The defect removal efficiencies of the various forms of military review have not been published, but there is no reason to doubt that they are equivalent or even superior to similar reviews in the civilian domain. The cumulative defect removal efficiency of the full series of U.S. military defect removal operations is rather good: from about 94% to well over 99% for critical weapons systems.

Large military software projects use a special kind of external review, termed *independent verification and validation* (IV&V). The IV&V activities are often performed by contracting organizations which specialize in this kind of work. The efficiency ranges of IV&V reviews have not been published, but there is no reason to doubt that they would achieve levels similar to those of civilian reviews and inspections, i.e., in the 40 to 60% range.

The most elaborate and formal type of manual defect removal methodology is that of *correctness proofs.* The technique of correctness proofs calls for using various mathematical and logical procedures to validate the assertions of software algorithms. Large-scale studies and data on the efficiency of correctness proofs have not

been published, and anecdotal results indicate efficiency levels of less than 30%. To date there is no empirical evidence that software where correctness proofs were used actually achieves lower defect rates in the field than software not using such proofs. Also, the number of correctness proofs which are themselves in error appears to constitute an alarming percentage, perhaps more than half, of all proofs attempted.

Among commercial and military software producers, a very wide spectrum of manual defect removal activities are performed by *software quality assurance* (SQA) teams [Dunn and Ullman, 1982]. The full set of activities associated with formal software quality assurance is outside the primary scope of this article. However, defect prediction, defect measurement, moderating and participating in formal inspections, test planning, test case execution, and providing training in quality-related topics are all aspects of software quality assurance. Organizations that have formal software quality assurance teams will typically average 10 to 15% higher in cumulative defect removal efficiency than organizations which lack such teams.

The suite of automated pre-test tools that facilitate software defect removal has improved significantly in recent years, but still has a number of gaps that may be filled in the future.

For requirements, specifications, user documents, and other software deliverables based on natural language, the use of word processors and their built-in spelling checkers has minimized the presence of minor spelling errors. Also available, although not used as widely as spelling checkers, are a variety of automated grammar and syntax checkers and even textual complexity analyzers. Errors of clarity and ambiguity, long a bane of software, can be reduced significantly by judicious usage of such tools.

Several categories of specialized tools have recently become available for software projects. Many CASE (computer-aided software engineering) tool suites have integral support for both producing and verifying structural descriptions of software applications. There are also tools that can automatically generate test cases from specifications and tools that can trace test cases back to the original requirements. While such tools do not fully eliminate errors of commission, they do provide welcome assistance.

Errors of omission in requirements, specifications, and user documents are the most resistant to automatic detection and elimination. Studies carried out on operating systems and large switching systems have revealed that in spite of the enormous volume of software specifications (sometimes more than 100 English words per source statement, with many diagrams and tables also occurring) more than 50% of the functionality in the source code could not be found described in the specifications or requirements. Indeed, one of the unsolved challenges of software engineering is to determine if it is even theoretically possible to fully specify large and complex software systems. Assuming that full specification is possible, several practical issues are also unknown: (1) What combination of text, graphics, and other symbols is optimal for software specifications? (2) What is the optimum volume or size of the specifications for an application of any given size? (3) What will be the impact of multi-media software extensions on specifications, debugging, and testing?

The number and utility of debugging tools for programming and programmers have made enormous strides over the past few years, and continued progress can be expected indefinitely. Software development in the 1990s often takes place with the aid of what is termed a *programming environment*. The environment constitutes the set of tools and aids which support various programming activities. For debugging purposes, software syntax checkers, trace routines, trap routines, static analyzers, complexity analyzers, cross-reference analyzers, comparators, and various data recording capabilities are fairly standard. Not every language and not every vendor provides the same level of debugging support, but the best are very good indeed.

Testing Software

There is no standard taxonomy for discussing testing. For convenience, it is useful to consider test planning, test case construction, test case execution, test coverage analysis, and test library control as the major topics encompassing software testing.

For such a mainstream activity as test planning, both the literature and tool suites are surprisingly sparse. The standard reference is Myers [1979]. The basic aspects of test planning are to consider which of the many varieties of testing will be carried out and to specify the number and kind of test cases that will be performed at each step. U.S. military specifications are fairly thorough in defining the contents of test plans. There are also commercial books and courses available, but on the whole the topic of test planning is underreported in the software literature.

A new method for estimating the number of test cases required for software was developed in 1991 and is starting to produce excellent results. A metric termed *Function Points* was invented by A. J. Albrecht of IBM and placed in the public domain in 1978 [Albrecht, 1979]. This metric is derived from the weighted sums of five parameters: the numbers of inputs, outputs, inquiries, logical files, and interfaces that constitute a software application [Garmus, 1991]. The Function Point total of an application can be enumerated during the requirements and design phases.

It is obvious that testing must be carried out for each of the factors utilized by the Function Point metric. Empirical observations indicate that from two to four test cases per Function Point are the normal quantities created by commercial software vendors and computer manufacturers. Thus for an application of 1000 Function Points in size, from 2000 to 4000 test cases may be required to test the user-defined functionality of the application.

Testing can be approached from several directions. Testing which attempts to validate user requirements or the functionality of software, without regard for its inner structure of the application, is termed *black-box* testing.

Black-box test case construction for software has long been a largely manual operation that is both labor-intensive and unreliable. (Empirical observations of operating system test libraries revealed more errors in the test cases than in the product being tested.) Test case generators have been used experimentally since the 1970s and are starting to appear as both stand-alone products and as parts of CASE tool suites. However, in order for test case generation to work effectively, the specifications or written description of the software must be fairly complete, rigorous, and valid in its own right. It is to no purpose to generate automatic test cases for incorrect specifications.

Testing which attempts to exercise the structure, branching, and control flows of software is termed *white-box* or sometimes *glass-box* testing. In this domain, a fairly rich variety of tools has come into existence since 1985 that can analyze the structure and complexity of software. For certain languages such as COBOL and C, tools are available that not only analyze complexity but can restructure or simplify it. In addition, there are tools that can either create or aid in the creation of test cases. Quite a number of tools are available that can monitor the execution of test cases and identify portions of code which have or have not been reached by any given test run.

Although not full test case generators, many supplemental testing tools are available that provide services such as creating matrices of how test cases interact with functions and modules. Also widely used are *record and playback* tools which capture all events during testing. One of the more widely used testing tool classes is that of *test coverage analyzers*. Test coverage analyzers dynamically monitor the code that is being executed while test cases are being run, and then report on any code or paths that may have been missed. Test coverage is not the same as removal efficiency: it is possible to execute 100% of the instructions in a software application without finding 100% of the bugs. However, for areas of code that are not executed at all, the removal efficiency may be zero. Software *defect tracking systems* are exceptionally useful.

Once created, effective test cases will have residual value long after the first release of a software product. Therefore, formal test case libraries are highly desirable, to ensure that future changes to software do not cause regression or damage to existing functionality. Test library tools occur in several CASE tool suites, are available as stand-alone products, and are also often constructed as custom in-house tools by the larger software vendors and computer manufacturers.

Test case execution can be carried out either singly for individual test cases or for entire sets of related test cases using *test scripts*. It is obvious that manually running one test case at a time is too expensive for large software projects. Tools for multi-test execution support, sometimes called a *test harness*, are available in either stand-alone form or as part of several CASE tool suites.

There are no rigorous definitions or standard naming conventions for the kinds and varieties of testing that occur for software. Some of the more common forms of testing include the following.

The testing of an individual module or program by the programmer who created it is normally called *unit test*. Unit testing can include both black-box and white-box test cases. The efficiency of unit test varies with the skill of the programmer and the size and complexity of the unit being tested. However, the observed defect removal efficiency of unit testing seldom exceeds 50% and the average efficiency hovers around 25%. For small projects developed by a single programmer, unit test may be the only test step performed.

For large software projects involving multiple programmers, modules, or components a number of test stages will normally occur that deal with testing multiple facets of the application.

The phrase *new function test* is used to define the testing of capabilities being created or added to an evolving software project. New function testing may consist of testing the aggregated work of several programmers. New function testing may be carried out by the developers themselves, or it may be carried out by a team of testing specialists. The observed efficiency of new function testing is in the 30% range when carried out by developers and in the 35% range when carried out by testing specialists.

The phrase *regression test* is used to define the testing of an evolving software product to ensure that existing capabilities have not been damaged or degraded as a by-product of adding new capabilities. Regression testing is normally carried out using test cases created for earlier releases, or at least created earlier in the development cycle of the current release. The observed removal efficiency of regression testing against the specific class of errors that it targets may exceed 50% when carried out by sophisticated organizations such as computer manufacturers or defense contractors. However, efficiencies in the 20 to 25% range are more common.

The phrase *stress test* is used to define a special kind of testing often carried out for real-time or embedded software. With stress testing, the software is executed at maximum load and under maximum performance levels, to ensure that it can meet critical timing requirements. The observed removal efficiency of stress testing often exceeds 50% against timing and performance-related problems. Stress testing is normally carried out by testing and performance specialists who are supported by fairly sophisticated test tool suites.

The phrase *integration test* is used to define a recurring series of tests that occur when components or modules of an evolving software product are added to the fundamental system. The purpose of integration testing is to ensure that the newer portions of the product can interact and operate safely with the existing portions. The observed removal efficiency of integration testing is normally in the 20 to 35% range. When performed by commercial software producers, integration test is normally carried out by testing specialists supported by fairly powerful tools.

The phrase *system test* is used to define the final, internal testing stage of a complete product before it is released to customers. The test suites that are executed during system test will include both special tests created for system test and also regression tests drawn from the product's test library. The observed removal efficiency of system testing is in the 25 to 35% range when such testing is done by the developers themselves. When system testing is carried out by testing specialists for commercial software, its defect removal efficiency may achieve levels approaching 50%. However, high defect removal efficiency this late in a development cycle often leads to alarming schedule slippages.

The phrase *independent test* is used to define a form of testing by an independent testing contractor or an outside organization. Independent testing is standard for U.S. military software and sometimes used for commercial software as well. Defect removal efficiency of independent test may approach 50%.

The phrase *field test* is used to define testing by early customers of a software product, often under a special agreement with the software vendor. Field testing often uses live data and actual customer usage as the vehicle for finding bugs, although prepared test cases may also occur. The defect removal efficiency of field test fluctuates wildly from customer to customer and product to product, but seldom exceeds 30%.

The phrase *acceptance test* is used to define testing by a specific client, as a precursor to determining whether to accept a software product or not. Acceptance testing may be covered by an actual contract, and if so is a major business factor. The defect removal efficiency of acceptance testing fluctuates from client to client and product to product, but seldom exceeds 30%.

Sometimes the phrases *alpha test* and *beta test* are used as a linked pair of related terms. Alpha testing defines the set of tests run by a development organization prior to release to early customers. Beta testing defines the set of tests and actual usage experiences of a small group of early customers. Unfortunately the term alpha test is so ambiguous that it is not possible to assign a defect removal efficiency rating. Beta testing is better understood, and the observed removal efficiency is usually in the 25% range.

Selecting an Optimal Series of Defect Prevention and Removal Operations

Since most forms of defect removal are less than 60% efficient, it is obvious that more than a single defect removal activity will be necessary for any software project. For mission-critical software systems where it is imperative to achieve a cumulative defect removal efficiency higher than 99%, then at least 10 discrete defect removal activities should be utilized, and careful defect prevention activities should also be planned (i.e., prototyping, use of structured techniques, etc.).

An effective series of defect removal operations utilized by computer manufacturers, telecommunication manufacturers, and defense contractors who wish to approach the six-sigma quality level (99.999999% efficiency) will include from 16 to 20 steps and resemble the following, although there are variances from company to company and project to project:

Pre-Test Defect Removal Activities

1. Requirements inspection
2. Functional design inspection
3. Logical design inspection
4. Test plan inspection
5. User documentation inspection
6. Desk checking and debugging by developers
7. Code inspection
8. Software quality assurance review
9. Independent verification and validation (military projects)

Testing Activities

10. Unit testing by developers
11. New function testing
12. Regression testing
13. Integration testing
14. Stress testing
15. Independent testing (military projects)
16. System testing
17. Field testing
18. Acceptance testing

Post-Release Defect Removal Activities

19. Incoming defect report analysis
20. Defect removal efficiency calibration (after one year of deployment)

The series of defect removal operations just illustrated can achieve cumulative defect removal efficiencies well in excess of 99%. However, these levels of efficiency are normally encountered only for large mission-critical or important commercial-grade software systems, such as operating systems, defense systems, and telecommunication systems.

A rough rule of thumb can predict that number of defect removal operations that are normally carried out for software projects. Using the Function Point total of the application as the starting point, calculate the 0.3rd power, and express the result as an integer. Thus an application of 100 Function Points in size would normally employ a series of 4 defect removal operations. An application of 1000 Function Points in size would normally employ a series of 8 defect removal operations. An application of 10,000 Function Points in size would normally employ 16 defect removal operations.

Post-Release Defect Removal

Defect removal operations do not cease when a software project is released. Indeed, one of the embarrassing facts about software is that post-deployment defect removal must sometimes continue indefinitely.

One of the critical tasks of post-release defect removal is the retroactive calculation of defect removal efficiency levels after software has been in use for one year. For a software project of some nominal size, such as 1000 Function Points, assume that 2000 bugs or defects were found via inspections and tests prior to release. The first year total of user-reported defects might be 50. Dividing the pre-release defect total (2000) by the sum of all defects (2050) indicates a provisional defect removal efficiency of 97.56%.

The defect potential of the application can be retroactively calculated at the same time, and in this case is 2.05 defects per Function Point. The annual rate of incoming user-reported defects for the first year is 0.05 defects per Function Point per year.

In addition to calculating defect removal efficiency, it is also useful to trace each incoming user-reported defect back to its origin, i.e., whether the defect originated in requirements, design, code, documentation, or as a result of a "bad fix." Defect origin analysis also requires a sophisticated tracking system, and full configuration control and traceability tools are useful adjuncts.

Note that the use of Function Points rather than the traditional KLOC metric is preferred for both defect potential and for defect origin analysis. KLOC metrics produce invalid and paradoxical results when applied to requirements, specification, and documentation error classes. Since defects outside the code itself often constitute more than 50% of the total bugs discovered, KLOC metrics are harmful to the long-range understanding of software quality.

If additional bugs are reported during the second or subsequent years, then defect removal efficiency levels should be recalculated as necessary. Removal efficiency analysis should also be performed for each specific review, inspection, and test step utilized on the project.

Calculating post-release defect removal efficiency requires an accurate quality measurement system throughout the life cycle. In addition, rules for counting post-release defects must be established. For example, if the same bug is reported more than once by different users, it should still count as only a single bug. If upon investigation user bug reports should turn out to be usage errors, hardware errors, or errors against some other software package, such bug reports should not be considered in calculating defect removal efficiency rates. If bugs are found by project personnel, rather than users, after release to customers, those bugs should still be considered to be in the post-release category.

The leading computer manufacturers, telecommunication companies, defense contractors, and software vendors utilize powerful defect tracking systems for monitoring both pre-release and post-release software defects. These systems record all incoming defects and the symptoms which were present when the defect was discovered. They offer a variety of supplemental facilities as well. Obviously statistical analysis on defect quantities and severities is a by-product of defect tracking systems. Less obvious, but quite important, is support for routing defects to the appropriate repair center and for notifying users of anticipated repair schedules. The most powerful defect tracking systems can show defect trends by product, by development laboratory, by time period, by country, by state, by city, by industry, and even by specific customer.

Recent Industry Trends in Software Quality Control

Since the previous edition of this handbook, a number of changes have occurred which affect software quality control approaches. Three factors, in particular, are beginning to exert a major influence on the way software is built, inspected, and tested:

1. The explosion of software viruses
2. The on-rushing approach of the Year 2000 problem
3. The marked increase in lawsuits where poor quality is alleged

These three new and emerging topics are likely to stay important software considerations well into the 21st century.

The Explosion of Software Viruses

Over the past 10 years, software viruses have grown from becoming a rare and minor annoyance to becoming major risks for software projects. The rampant increase in the number of viruses and the ever increasing sophistication of viruses has triggered a new subindustry of viral protection tools and software.

For the purpose of this handbook, viruses have also introduced new and "standard" testing phases aimed at eliminating all possibilities of viral contamination from the final delivered versions of software. As of 1996, every major software vendor in the world now includes viral protection screening as a standard activity, and many include multiple kinds of viral protection tools and approaches. This is a serious problem and it is not showing any sign of becoming less serious.

The On-Rushing Year 2000 Software Problem

Another very significant change in recent years has been the sudden recognition that at the end of the century when the calendar changes from 1999 to 2000 AD, many of the world's software applications may stop completely

or begin to put out incorrect data. The reason for the Year 2000 problem (as it has come to be called) is because of the historical practice of storing all dates in two-digit form. Thus, calendar year "1997" would be stored as "97". The obvious failing of the two-digit approach will occur when "99" becomes "00". This will throw off normal collating sequences and cause major errors. This problem is an interesting one because, although obvious for more than 20 years, the problem was never found during testing. The reason for this situation is because the two-digit form of storing dates originated as a requirement and was also included in software designs. Therefore, test cases tended to conform to erroneous requirements rather than actually find the problem. The Year 2000 problem provides a strong lesson to the software community that "quality means conformance to user requirements" may sometimes be dangerous. The Year 2000 problem is going to be the most expensive software problem in history, and it was caused primarily by conforming to a requirement that was dangerous and flawed. Now that the end of the century is rapidly approaching, every corporation and government agency in the world is frantically racing to make software repairs before the problem surfaces at the end of 1999. Some hidden and obscure instances of this problem will almost certainly slip through, causing major errors and probable litigation.

The Emergence of Software Quality as a Litigation Issue

On the topic of software litigation, another major change since the previous edition of this handbook is the increase in lawsuits and litigation involving allegations of poor quality. From observations on half a dozen such lawsuits, Table 90.3 shows the sequence of defect removal operations that are common when clients sue vendors for poor quality. It is an interesting observation that for outsource, military, and systems software that ends up in court for litigation which involves assertions of unacceptable or inadequate quality, the number of testing stages is much smaller, while formal design and code inspections were not utilized at all. Table 90.3 shows the typical patterns of defect removal activities for software projects larger than 1000 function points in size where the client sued the developing organization for producing software with inadequate quality levels. The table simply compares the pattern of defect removal operations observed for reliable software packages with high quality levels to the pattern noted during lawsuits where poor quality and low reliability was part of the litigation. It is interesting and ironic that the "reliable" projects actually had shorter development schedules than the projects that ended up in court with charges of poor quality. The reason for this is because finding and fixing software bugs late in the development cycle is the major cause for slipping delivery dates. High quality and short schedules usually are closely coupled, although few software project managers know this.

It is interesting that during the depositions and testimony of the litigation, the vendor often counter-charges that the short-cuts were made at the direct request of the client. Sometimes the vendors assert that the client

TABLE 90.3 Defect Removal and Testing Stages Noted During Litigation for Poor Quality

	Reliable Software	Software Involved in Litigation for Poor Quality
Formal design inspections	Used	Not used
Formal code inspections	Used	Not used
Subroutine testing	Used	Used
Unit testing	Used	Used
New function testing	Used	Rushed or omitted
Regression testing	Used	Rushed or omitted
Integration testing	Used	Used
System testing	Used	Rushed or omitted
Performance testing	Used	Rushed or omitted
Capacity testing	Used	Rushed or omitted

Note: The phrase "rushed or omitted" indicates that the vendor departed from best standard practices by eliminating a stage of defect removal or by rushing it in order to meet an arbitrary finish date or commitment to the client.

ordered the short-cuts even in the face of warnings that the results might be hazardous. As can be seen, software developed under contractual obligations is at some peril if quality control and testing approaches are not carefully performed.

Summary and Conclusions

Software has been prone to such a wide variety of error conditions that much of the cost and time associated with developing software projects is devoted to defect removal. In spite of the high expense levels and long schedules historically associated with defect removal, deployed software is often unstable and requires continuous maintenance.

Synergistic combinations of defect prevention and defect removal operations, accompanied by careful measurements and the long-range calibration of inspection and test efficiencies, can give software-producing organizations the ability to consistently create stable and reliable software packages. As the state of the art advances, both six-sigma quality levels or even zero-defect quality levels may be achievable. Achieving high quality levels also reduces development schedules and lowers development costs.

Defining Terms

Bug: The generic term for a defect or error in a software program. The term originated with Admiral Grace Hopper in the 1950s, who discovered an actual insect that was blocking a contact in an electromechanical device.

Debugging: The generic term for the process of eliminating bugs, i.e., errors, from software programs. The phrase is often used in a somewhat narrow sense to refer to the defect removal activities of individual programmers prior to the commencement of formal testing.

Defect prevention: The set of technologies which simplify complexity and reduce the probability of making errors when constructing software. Examples of defect prevention technologies include prototypes, structured methods, and reuse of certified components.

Defect removal: The set of activities concerned with finding and eliminating errors in software deliverables. This is a broad term which encompasses both manual and automated activities and which covers errors associated with requirement, design, documentation, code, and bad fixes or secondary defects created as a by-product of eliminating prior bugs.

Defect removal efficiency: The ratio of defects discovered and eliminated to defects present. Removal efficiency is normally expressed as a percent and is calculated based on all defects discovered prior to release and for the first year of deployment.

90.3 Programming Methodology

Johannes J. Martin

Programming methodology is concerned with the problem of producing and managing large software projects. It relates to programming as the theory of style relates to writing prose. Abiding by its rules does not, in itself, guarantee success, but ignoring them usually creates chaos. Many useful books have been written on the subject and there is a wealth of primary literature. Some of these books, that themselves contain numerous pointers to the primary literature, are listed at the end of this section.

The rules and recommendations of programming methodology are rather independent of particular programming languages; however, significant progress in the understanding of programming methods has always led to the design of new languages or the enhancement of existing ones. Because of the necessity of upward compatibility, enhanced old languages are, in comparison to new designs, less likely to realize progressive programming concepts satisfactorily. Consequently, the year of its design usually determines how well a language supports state-of-the-art programming methods.

Programming methodology promotes program correctness, maintainability, portability, and efficiency.

Program Correctness. For some relatively simple programs specifications and even verifications can be formalized. Unfortunately, however, formal specification methods are not available or not sufficiently developed for most programs of practical interest, and the specifications, given as narratives, are most likely less than complete. For the situations not explicitly covered by the specifications, the resulting program may exhibit bizarre behavior or simply terminate. Furthermore, informal methods of demonstrating correctness may also miss points that were, indeed, addressed by the specifications. The costs of these problems may range from time wasted in the workplace to injuries and loss of lives.

Short of formal methods for proving **program correctness,** simplicity of design gives informal methods a chance to succeed.

Maintainability. Since the programmer who will do the **program maintenance** is usually not the one who also did the original coding (or if he did he cannot be expected to remember the details), proper documentation and straightforward design and implementation of the pertinent algorithms is mandatory.

Portability. A program is called (easily) portable if it can be adapted to a different computer system without much change. One step toward **program portability** is using a high-level language common to both computer systems. The second step is avoiding the use of idiosyncratic features of a system if at all possible or, if such a

feature must be used, to isolate its use to small, well-designed program segments that can easily be rewritten for the new system.

Efficiency. The costs of running a computer program are determined (1) by the time needed to compute the desired result and (2) by the amount of storage space the program requires to run. As the costs of computer hardware have declined dramatically over the past decade, the importance of program efficiency has similarly declined. Yet, there are different dimensions to efficiency. Choosing the right algorithm is still crucial, while local optimization should not be pursued, if it increases the complexity and decreases the clarity of a program and thereby jeopardizes its correctness and maintainability.

Analysis of Algorithms

The solution of a problem as a sequence of computational steps, each taking finite time, is called an algorithm. As an example consider the algorithm that finds the greatest element in a random list of n elements:

1. Give the name A to the first element of the list.
2. For each element x of the list beginning with the second and proceeding to the last, if $x > A$ then give the name A to x.
3. The element named A is the greatest element in the list.

Assume that examining the "next" element, comparing it with A and possibly reassigning the name A to the new element takes a fixed amount of time that does not depend on the number of elements in the list. Then the total time for finding the maximum increases proportional to the length n of the list. We say the *time complexity* of the algorithm is of *order n*, denoted by $O(n)$.

While there are not many algorithms for finding the maximum (or minimum) in an unordered list, other tasks may have many different solutions with distinctly different performances. The task of putting a list in ascending or descending order (sorting), for example, has many different solutions, with time complexities of $O(n^2)$ and $O(n \cdot \log(n))$. Compared with the $O(n \cdot \log(n))$ algorithms, the $O(n^2)$ algorithms are simpler and their individual steps take less time, so that they are the appropriate choice, if n, the number of items to be sorted, is relatively small. However, as n grows, the balance tips decidedly toward the $O(n \cdot \log(n))$ algorithms. In order to compute the break-even point suppose that the individual steps of an $O(n \cdot \log(n))$ and an $O(n^2)$ algorithm take $k \cdot t$ and t units of time, respectively. Thus, for the break-even point we have

$$t \cdot n^2 = k \cdot t \cdot n \cdot \log(n)$$

hence

$$k = n/\log(n)$$

With $k = 5$, for example, the break-even point is $n = 13$. The difference in performance of the two algorithms for large numbers of n is quite dramatic. Again with $k = 5$, the $O(n \cdot \log(n))$ algorithm is 217 times faster if $n =$ 10,000, and it is 14,476 times faster if $n =$ 1,000,000. If the faster algorithm would need, e.g., 10 minutes to sort a million items, the slower one would require about 100 days.

Consequently, while efficiency is no longer a predominant concern, analyzing algorithms and choosing the proper one is still a most important step in the process of program development.

Flow of Control

The term *flow of control* refers to the order in which individual instructions of a program are performed. For the specification of the flow of control, assembly (machine) languages (and older high-level languages) provide conditional and unconditional branch instructions. Programmers discovered that the indiscriminate use of these instructions frequently leads to flow structures too complex to be analyzed at reasonable costs. On the other hand, keeping the flow of control reasonably simple is, indeed, possible since three elementary control

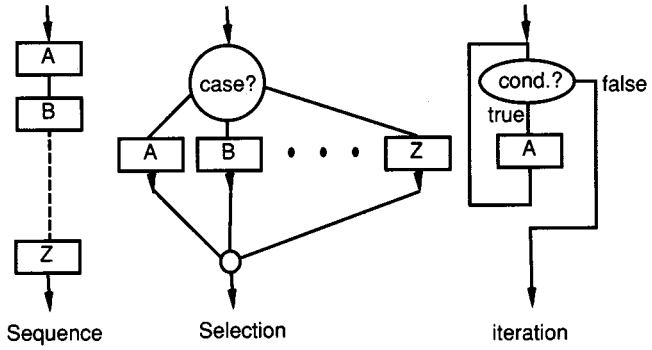

FIGURE 90.12 Basic control constructors.

constructors are sufficient to express arbitrary algorithms. Using only these constructors contributes in an essential way to the manageability of programs. The basic rules are as follows:

1. A proper computational unit has exactly one entry point and one exit.
2. New computational units are formed from existing units A, B, . . . by a.sequencing (perform A, then B, and so forth) b.selection (perform A or B or . . ., depending on some condition) c.iteration (while some condition prevails, repeat A).

Figure 90.12 shows diagrams that illustrate these rules.

High-level languages support these three constructors by (1) juxtaposition for sequencing, (2) if-then-else and case (switch) constructs for selection, and (3) while-do and for loops for iteration. The somewhat rigid restriction on loops sometimes requires the duplication of code. Some languages ease this problem by providing a *break* or *leave* statement that permits leaving a loop prematurely (Fig. 90.13). A typical example for a program that profits from this mechanism is a loop that reads and processes records and terminates when a record with some given property is found. In Fig. 90.13 block B reads and block A processes a record. With a strict while-loop the code of B must be duplicated.

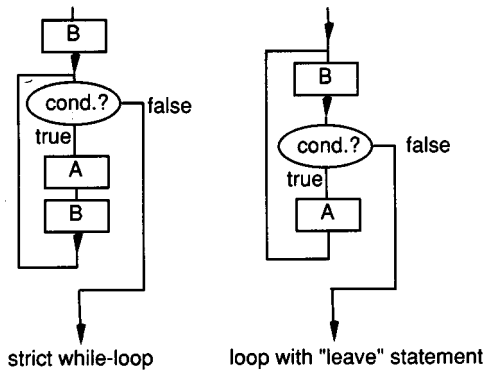

FIGURE 90.13 The use of a leave statement.

Abstraction

In programming, abstraction refers to the separation of what needs to be done from the details of how to do it. As it facilitates the separation of unrelated issues, it is a most powerful tool for making complex structures comprehensible. There are two varieties: *functional (procedural) abstraction* and *data abstraction.*

Almost all programming languages support *functional abstraction* by providing facilities for the definition of *subprograms.* The definition of a subprogram (procedure or function) associates a possibly complex sequence of instructions with an identifier and (usually) a list of parameters. The instruction sequence may then be performed by referring to its associated identifier and providing the required parameters. We could, for example, define a procedure *findRecord* that searches a given list of records for a record with a given key, e.g., an identification number. We could then use the statement

```
findRecord(theRecord, id_number, list);
```

instead of the instruction sequence that actually searches the list for the record. If this operation is needed more than once, then the obvious advantage is saving the replication of instructions. Much more important is a second advantage: When we study the text of a program that *uses findRecord*, we most likely wish to understand how this program processes and updates records or uses the information they contain. As this in itself may be

quite complex, we do not wish to be burdened simultaneously with the details of how to *find* a record, since this second problem has absolutely nothing to do with the process that we are trying to understand. Functional abstraction allows us to separate these different concerns and, thus, make each comprehensible.

The essential property of a data object is not its representation (is it an array, a record or something else?) but the operations that can be applied to it. The separation of these (abstract) operations from the subprograms that implement them, as well as from the representation of the object, is called *data abstraction*. This separation is possible because only the implementations of the operations need to know about the actual representation of the object. A system of data objects and operations defined by data abstraction is called an *abstract data type*. See Chapter 81.3 on *data types and data structures* for more details.

Modularity

With the tool of abstraction programs are made modular, that is, they are broken into fairly small, manageable parts. Each part, called a module, consists of one or more procedures or functions and addresses a particular detail of a project. A module may consist of a sorting program, a package for matrix or time and date calculations, a team of programs that preprocess input or format output, and the like.

A program should be broken up into smaller parts for one of two reasons: (1) if it addresses more than one problem and (2) if it is physically too large.

First, a procedure (function) should address a single problem. If more than one problem is addressed by the same procedure, a reader of the program text experiences a distracting shift in subject, which makes the comprehension of the text unnecessarily difficult. For example, a program involved in interest calculations should not also solve calendar problems (such as how many days are between March 15 and June 27) but use a calendar module that provides the abstract data type *Date* to obtain the desired results. Similarly, a sorting procedure should not be burdened with the details of comparing records. Instead, a different function should be written that contains the details of the comparison, and this function should then be invoked by the sorting program. The program fragments in Example 1, written in the programming language C, illustrate the separation of these levels of concern.

Considering Example 2, the advantage of separating levels of concern may appear to be subtle. The reason is the small size of the original sort program. A quote by B. Stroustrup [1991] emphasizes this point, "You can make a small program (less than 1000 lines) work through brute force even when breaking every rule of good style. For a larger program, this is simply not so. . . ." Advantages that do not seem very significant for small programs become invaluable for large ones. Writing large programs is an inherently difficult activity that demands a high level of concentration, helped by separating and hindered by mixing unrelated levels of concern.

Second, as a rule of thumb, the text of a procedure should fit onto one page (or into a window). A single page of text can be studied exclusively by eye movement and, thus, comprehended more easily than text that spans over several pages. That is not to say that longer procedures are necessarily an indication of poor programming methods, but there should be compelling reasons if the limit of one page is to be exceeded.

Simple Hierarchical Structuring

The relation among modules should be hierarchical, i.e., modules should be the vertices of a directed acyclic graph whose edges describe how modules refer to other modules. In such a structure, called a top-down design, each module can be understood in terms of the modules to which it refers directly. Yet, hierarchical structuring by itself does not yield simple and comprehensible programs. In addition, interfaces between modules must be kept narrow, that is, (1) the use of nonlocal variables must be avoided and (2) the number of parameters passed to a subprogram should be held to a minimum.

First, the scope rules of many programming languages permit subprograms to access entities of the program in which they are defined (static scoping) or of the calling program (dynamic scoping). These entities are called nonlocal in contrast to those defined within the subprogram itself. *Nonvariable* entities can and should be broadcast by means of nonlocal, preferably global definitions (i.e., definitions available to all modules and subprograms within an entire project). For these entities—types, procedures, and constant values—global definitions are very beneficial, since changes that may become necessary need to be made only at the place of

Example 1. A program that addresses more than one problem:

```
void sort (recType *table, int size) /* recType is a structure with fields
                                        suitable for a personnel record */
{
   int i, j, result;
   recType temp;
  for (i = 0; i < size-1; i++)
    for (j = i+1; j<size; j++){
        if ((result = strcmp(table[i].last, table[j].last)) == 0)
           if ((result = strcmp(table[i].f irst, table[j].f irst)) == 0)
              if ((result = strcmp(table[i].midl, table[j].midl)) == 0)
                 if ((result = datecmp(table[i].birthdate, table[j].birthdate)) == 0)
                     result = addresscmp(table[i].address, table[j].address);
        if (result > 0){
             temp = table[i];
             table[i] = table[j];
             table[j] = temp;
         }
   }
}
```

Example 2. Programs tackling one problem at a time:

```
BOOL isGreater (recType a, recType b);
void swap (recType *a, recType *b);

void sort (recType *table, int size)
{
   int i, j;
  for (i = 0; i < size-1; i++)
    for (j = i+1; j<size; j++)
        if (isGreater(table[i], table[j])) swap(&table[i], &table[j]);
}

BOOL isGreater (recType a, recType b)
{
   int result;
  if ((result = strcmp(a.last, b.last)) == 0)
     if ((result = strcmp(a.f irst, b.f irst)) == 0)
       if ((result = strcmp(a.midl, b.midl)) == 0)
          if ((result = datecmp(a.birthdate, b.birthdate)) == 0)
              result = addresscmp(a.address, b.address);
  return result > 0;
}

void swap (recType *a, recType *b)
{
   recType temp;
  temp = * a;
  *a = *b;
  *b = temp;
}
```

definition, not at every place of usage. Moreover, global definitions that replace numeric or alphanumeric constants by descriptive identifiers improve the readability of a program. Nonlocal *variables,* on the other hand, are to be avoided. For reasons of simplicity and clarity, the task performed by a subprogram should be determined *exclusively* by the subprogram itself and the values of its parameters. As a result, all information needed to understand why a subprogram may behave differently for different invocations is provided at each point of invocation. This rule, related to the concept of *referential transparency,* is clearly violated if a subprogram

uses nonlocal variables: in order to understand the behavior of the subprogram, information contained in the nonlocal variables must be consulted. These variables may appear nowhere near the point of invocation.

Similarly, because their return values are clearly identified, functions that do not change their parameters are preferred over those that do and over procedures. As functions are not always appropriate, a programmer choosing to use a procedure should aid the reader's comprehension by adopting some documented standard of consistently changing either the procedure's first or last parameter(s).

Second, the number of parameters should be kept to a minimum. If more than four or five parameters seem to be required, programmers should seriously consider packaging some of them into a record or an array. Of course, only values that in some logical sense belong together should be packaged, while parameters that serve different functions should be kept separate. For example, suppose the operation *updateRecord* is to find a personnel record with a given identification number in a file or a list and then change certain fields such as the job title, rate of pay, etc. A programmer may be tempted to define

```
updateRecord (Rectype myRecord);
```

yet the form

```
updateRecord (Idtype idNumber, Packtype attributes)
```

is better, since it suggests that the record with the key *idNumber* is the one to be updated by modifying the *attributes*.

The term *top-down design* (also called step-wise refinement) is frequently misunderstood as exclusively describing the *method* of design rather than the *structure* of the *finished product*. However, the creative process of designing software (or anything else) frequently proceeds in a rather erratic fashion, and there is no fault in this as long as the final product through analyses and reorganizations has a simple hierarchical structure. This is not to say that the process of design should not be guided by a top-down analysis; however, neither should a programmer's creativity be hampered by the straightjacket of a formalistic design principle, nor can a poorly designed program be defended with reference to the superior (top-down design) method used for its creation.

Object-Oriented Programming

In languages that support object-oriented programming, *classes* (i.e., data types) of objects are defined by specifying (1) the variables that each object will own as *instance variables* and (2) operations, called *methods*, applicable to the objects of the class. As a difference in style, these methods are not invoked like functions or procedures, but are *sent* to an object as a *message*. The expression [*window moveTo* : *x* : *y*], for example, is a message in the programming language *Objective C*, a dialect of C. Here the object *window*, which may represent a window on the screen, is instructed to apply to itself the method *moveTo* using the parameters *x* and *y*.

New objects of a class are created—usually dynamically—by *factory methods* addressed to the *class* itself. These methods allocate the equivalent of a record whose fields are the instance variables of the object and return a reference to this record, which represents the new object. After its creation, an object can receive messages from other objects.

To data abstraction, object-oriented programming adds the concept of inheritance: From an existing class new (sub)classes can be derived by adding additional instance variables and/or methods. Each subclass inherits the instance variables and methods of its superclass. This encourages the use of existing code for new purposes.

With object-oriented programming, classes become the modules of a project. For the most part, the rules of hierarchical structuring apply, interfaces should be kept narrow, and nonlocal variables ought to be restricted to the instance variables of an object. There are, however, at least two situations, both occurring with modern graphical user interfaces, where the strict hierarchical structure is replaced by a structure of mutual referencing.

Objects—instances of classes—frequently represent visible objects on the screen such as windows, panels, menus, or parts thereof. It may now happen that actions (such as mouse clicks) applied to one object influence another object and vice versa. For example, the selection of an object, such as a button or a text field, may launch or modify an inspector panel that, in turn, allows the modification of the appearance or function of the button or the text field (mutual referencing).

In conventional programming, library routines are, with rare exceptions, at the bottom of the hierarchy, i.e., they are called by subprograms written by the user of the library (later referred to as the "user") but they do not call subprograms that the user has written.

With object-oriented systems, library programs may have user-written *delegates* whose methods are used by the library object. For example, a window—a library object—may send the message "windowWillClose" (written by the user) to its delegate in response to the operators clicking of the window's close button. In response, the delegate may now interrogate the window in order to determine whether its contents have been changed and possibly require saving (mutual referencing).

Furthermore, buttons, menus, and the like are library objects. Yet, when operated, they usually activate user methods. Again, the user program may then interrogate the button about its state or request that the button highlight itself, etc. (mutual referencing).

While in the cases discussed, mutual referencing seems to be natural and appropriate, it should, in general, be used very sparingly.

Program Testing

Aside from keeping the structure of a program as simple as possible, a top-down design can be tested in a divide-and-conquer fashion. There are basically two possible strategies: bottom-up testing and top-down testing.

Bottom-up testing proceeds by first testing all those modules that do not depend on other modules (except library modules). One then proceeds always testing those modules that use only modules already tested earlier. Testing of each (sub)program must exercise all statements of the program, and it must ensure that the program handles all exceptional responses from supporting subprograms correctly. For each module a driver program must be written that invokes the module's functions and procedures in an appropriate way. If a program is developed in a top-down fashion, this method cannot be used until a substantial part of the project is completed. Thus design flaws may not be detected until corrections have become difficult and costly.

Top-down testing begins with the modules that are not used by any other module. Since the supporting modules have not been tested yet (or do not even exist yet), simple stand-in programs must be written that simulate the actual programs. This can be done by replacing the computation of the actual program with the programmer, who enters the required results from the keyboard in response to the parameter values displayed on the screen. This method is nontrivial, especially if the supporting program deals with complex objects.

In practice both methods are being used. Frequently, developing the procedure for top-down testing by itself leads to the discovery of errors and can prevent major design flaws.

Defining Terms

Program correctness: A program's conformation with its specifications.
Program maintenance: Modifications and (late) corrections of programs already released for use.
Program portability: A program is called (easily) portable if it can be adapted to a different computer system without much change.

91.1 Introduction

The term **computer graphics** refers to the generation, representation, manipulation, processing, and display of data by a computer. Computer-generated images may be real or imagined, animated or still, two-dimensional (2-D) or three-dimensional (3-D). Today most computers, particularly those in the PC, Macintosh, or workstation categories, have graphics capability. Their central components are a graphical display device, usually a cathode ray tube (CRT), and one or more input devices (e.g., keyboard, mouse, digitizer, data glove). Output devices include laser printers or video or such other displays as goggles or "eyephones" as in the case of some **virtual reality** systems.

Computer graphics encompasses a wide variety of applications. It has expanded its scope from the mundane business/presentation graphics to placing desktop publishing at everyone's fingertips. Highly interactive real-time systems are used in flight simulators where the display represents changes in the scene or landscape. In engineering, computer-aided design (CAD) systems allow users to create, store, manipulate, and test objects and designs. Fully integrated systems allow standard component parts libraries to be incorporated into a product. Product design and drafting information is fed into manufacturing operations via numerical control interfaces. Other engineering applications that make extensive use of graphics include very large scale integration (VLSI) and solid modeling.

Graphics has emerged as the vehicle for visualizing physical phenomena and the volume visualization of complex datasets [Purgathofer and Schonhut, 1989; Vince, 1990; Kaufmen et al., 1996]. Some examples include the medical modeling of the anatomy and MRIs [Kaufmen et al., 1996]. One application simulates laboratory testing of a new friction material for disc brakes and visualizes temperature distribution of the brakes' ability to conduct or absorb heat [Purgathofer and Schonhut, 1989]. In mathematics, B. B. Mandelbrot defined the geometry of **fractals**. Fractals, geometrical self-similar objects with fractional dimension, form a powerful tool for generating objects that resemble natural phenomena such as mountains, trees, and coastlines [de Ruiter, 1988; Mandelbrot, 1982].

In the world of animation, the computer has taken the drudgery out of transforming and redrawing objects. It has enhanced cell animation as well as produced glitzy Hollywood special effects such as morphing, a process of letting the computer transform one image to another by generating all the in-between images.

One of the most spectacular uses of graphics is in the area of virtual reality (VR). This technology, which uses high-resolution graphics terminals and head-mounted displays (HMD) or eyephones, provides the user

with a stereo view of a virtual world and an ability to navigate through it. These systems have a tracking device to determine the position of the user and devices, such as data gloves, for inputting commands [Thomas and Stuart, 1992]. Applications include simulation and architecture.

Research in the area of computer graphics has centered on all aspects of hardware, software, and algorithm development. Some of these areas are

1. Object-oriented environments: Design of programming languages, tools, databases, user interfaces, and animation [Purgathofer and Schonhut, 1989; Cunningham et al., 1992; de Ruiter, 1988].
2. Virtual reality: The design of system architecture, the creation and integration of component hardwares, the creation of software, the building of virtual environments, the development of real-world applications, and the study of philosophical and human perceptual issues [Stuart, 1992].
3. **Scientific visualization:** Graphics software solutions, practical implementations, user interfaces, high-resolution hard copy, data representation and metafiles [Purgathofer and Schonhut, 1989].
4. Algorithmic design: Ray tracing [Straber, 1987].
5. Hardware design: Workstation architectures, support for geometric modeling [Straber, 1987].
6. Color models and manipulation [Purgathofer and Schonhut, 1989].
7. Page description languages (PDLs): PostScript interpreters [Purgathofer and Schonhut, 1989].
8. CAD and solid modeling: VLSI, data exchange, geometric modeling [de Ruiter, 1988; Purgathofer and Schonhut, 1989].

91.2 Graphics Hardware

Computer graphics systems comprise several different output components in which to display computer-generated images. These components are classified into two groups: (1) hard copy technologies and (2) display technologies.

Hard Copy Technologies

Hard copy technologies include printers, pen plotters, electrostatic plotters, laser printers, ink-jet plotters, thermal transfer plotters, and film recorders [Foley et al., 1996]. These devices use either a raster or vector style of drawing. The raster style uses discrete dots, and the vector style uses a continuous drawing motion. Each display device is distinguished by its dot size and the number of dots per inch, known as *addressability*. The closer the dots, the smoother the image. The smaller the dot, the finer the detail. *Resolution* is related to dot size and is the number of distinguishable lines per inch. This may vary in the horizontal and vertical directions. High-resolution devices have fine detail, smooth lines, and crisp images.

Color may be achieved in several ways, depending on the device. Some devices use multicolored ribbons with single print heads, multiple print heads with different ribbons, or overstriking to combine colors. Other devices use color pens, spray (e.g., ink jet), toner (e.g., laser printer, electrostatic plotters), or pigment from colored wax paper (e.g., thermal transfer).

The hard copy devices vary in color and intensity levels, addressability, dot size, cost, image quality, and speed. The laser printer is becoming the most common, high-quality output device in this category [Foley et al., 1996].

Display Technologies

Displays are, for the most part, characterized by their responsiveness to a changing image. As with the hard copy technologies, display technologies vary greatly with respect to performance and cost. Guidelines for comparisons are based on the following characteristics: power consumption, screen size, depth, weight, ruggedness, brightness, addressability, contrast, intensity levels per dot, viewing angle, color capability, and relative cost.

Standard CRT

The most common component of graphics displays has been the CRT, which is used in televisions. The CRT is composed of five parts: (1) the electron gun, which when heated emits electrons at an appropriate rate; (2) the control grid, which regulates the flow of electrons; (3) the focusing system, which concentrates the beam

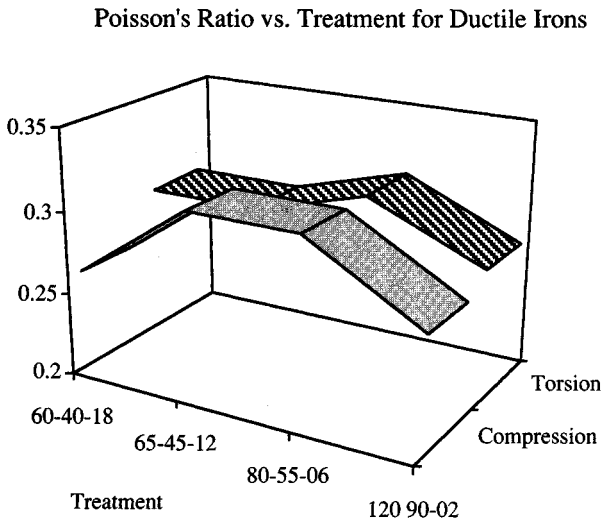

FIGURE 91.1 An example of a figure generated on the Macintosh with Microsoft Excel 3.0, showing the effect of four different treatments on two different measured variables. Although this information could be presented in two dimensions, the 3-D illustration can be more intuitive and interesting.

into a fine point; (4) the deflection system, which directs the beam to the appropriate location; and (5) the phosphor screen, which glows when bombarded with the electron beam. The *persistence* of the phosphor is defined as the time from the removal of excitation to when the phosphorescence has decayed to 10% of the initial light output [Foley et al., 1996]. Depending on the persistence of the phosphor used, the screen will need to be continually *refreshed*, or redrawn. Color is produced by laying triads of red-green-blue (RGB) phosphors on the screen and using three electron guns, one for each color, to excite the corresponding phosphor.

The raster CRT scans the image, one row at a time, from a matrix whose elements correspond to a *pixel,* or point on the screen. This matrix is referred to as the *frame buffer* and allows for a constant refresh rate, usually 60 times per second. Systems may also have more than one frame buffer (double buffer) to facilitate faster image generation. These displays include high resolution (1024×11280), SVGA (768×1024), NTSC ($\sim 350 \times 480$) and HDTV (720×1280 and 1080×1920) [Baily et al., 1996]. In vector CRT displays, the picture is generated in a continuous sweep, much like tracing an image on paper. The refresh rate on the vector displays is a function of the complexity of the image. The result may be a noticeable flicker on the screen.

Other Display Technologies

1. Direct view storage tubes (DVST): These devices were the primary displays used in earlier systems. These vector drawing devices stored their images on a grid, which was continually bombarded with electrons in order to transfer the image to the screen. The advantage was that once the image was drawn, the refresh process took place independently of the complexity of the image, thereby producing a constant image on the screen. The disadvantage of these systems was that no part of the image could be selectively erased without erasing the entire grid and resending the modified image to the display.
2. Liquid crystal display (LCD): This device uses matrix addressing and refreshes the display one row at a time. Appropriate voltages are applied to the crystals, causing them to line up. They remain polarized, not allowing light to pass through; light is absorbed, causing dark spots on the display. These devices are light in weight, rugged, and have a low power consumption, fair intensity, and low cost.
3. Plasma panels: These devices have an array of neon bulbs between glass plates, which may be turned on or off. While color is possible, it has not been commercially available. These devices excel in screen size, weight, ruggedness, and brightness characteristics but are generally high in cost.
4. Electroluminescent displays: These devices also use a grid-like structure for addressing elements. The light-emitting material, a zinc sulfide doped with manganese, is available in color. These devices have excellent brightness characteristics but are high in cost.

91.3 Graphics Software

Software for scientific and engineering applications has changed dramatically in the past several years. In the 1970s and early 1980s, there were few graphics software tools available. Most of the engineering packages were in the CAD area. Many specific engineering applications required users to develop and implement programs to solve their problems. These programs were written in the Fortran or C programming languages using low-level graphical commands or calls to some standard or quasi-standard (e.g., the CORE package) graphical routines. Most of these systems were developed for a mainframe computer environment. A trend begun in the late 1980s resulted in a change in computing hardware environments as well as in software approaches. Predominantly, the hardware platforms are PCs, microcomputers, and powerful Unix workstations, with most of these machines having excellent graphics capabilities. Software moved from code generation to customized stand-alone scientific and engineering software tools. Software development uses standard languages and graphical user interfaces for CH, C, Fortran, and Pascal, as well as more sophisticated languages such as JAVA, HyperText, Unix X.11, Microsoft's Windows, and PostScript. The technical community is relying more and more on the increased power of computers to easily support software packages that manipulate complex data and represent them in a visual manner.

Engineering Software Packages

Several commercial scientific and engineering software packages have graphics functionality. It is difficult to distinguish graphics or visualization capabilities without discussing some of these packages. An excellent reference is found in the *IEEE Spectrum Focus Report: Software*.

These graphical application software packages fall into five categories:

1. Logic simulation for application-specific integrated circuits (ASICs). Software in this area might display a schematic of a multigate ASIC from large functional building blocks. These blocks could represent a finite-state machine with several states and gates. Representative packages are Mentor Graphics' Auto-Logic, Cadence Design Systems' HDL Synthesizer and Optimizer, and Teradyne's Frenchip. HDL is a hardware description language.
2. Electromagnetic design and simulation. Software in this area might simulate a printed-circuit board for a 32-bit-wide, 8-bit-byte reversal network. Multilayers of a board are displayed, with colors indicating current densities in lines. Representative systems are Hewlett-Packard's High Frequency Structure Simulator (HFSS), a finite-element-based product having animation of field plots and conductor loss and 3-D full-wave solution and S-parameter output; Sonnet Software's "em" package with animation of conductor currents; and Compact Software's Microwave Explorer with X-Windows and OSF Motif graphical interfaces.
3. Data acquisition, analysis, display, and technical reporting. Systems in this area have compute-intensive analysis routines and enhanced visualization of data which capitalize on sharper display resolutions. These packages could produce plots and graphs based on acquired data that are displayed in several windows at once; changes to one window could result in recalculation and updating of corresponding windows. Packages in this area frequently have support for standard languages and graphical user interfaces for C and Fortran as well as the Unix X.11 interface or Microsoft's Windows. Representative packages are HP's VEE-Test; Design Science's MathType; DSP Development's DADiSP; National Instruments' LabWindows; Speakeasy Computing's Speakeasy Zeta, which features user-tailored graphical user interface and PostScript output; and Mihalisin Associates' Temple-Graph, which produces a color PostScript output link to *Mathematica*.
4. Mathematical calculations and graphics for visualization. Applications for these packages would be curve fitting, evaluation of integrals, statistical analysis, signal processing, and numerical analysis. Features include programmability in languages such as C, Fortran, and Pascal and 2-D and 3-D representations. The leading package in this area is *Mathematica* by Wolfram Research, which is a general system and programming language for numerical, symbolic, and graphical computations in engineering, research, science, financial analysis, and education [Wolfram, 1991]. Other packages are Amtec Engineering's Tecplot, Integrated Systems' Xmath, MathWorks' Mathlab, Jandel Scientific's SigmaPlot, and NAG's Axiom.

Computer artist: (top) Joel Rosen, (bottom) Alex Dao, M.F.A. in Computer Graphics Design program students, Rochester Institute of Technology.

5. Digital signal processors for embedded systems. The tools available in this area let the engineer focus on the application rather than the programming details. The Audio Frequency Fourier Analyzer by National Instruments is a combination of graphical programming with development software for the Macintosh environment. Signals can be analyzed, manipulated, and displayed using custom graphics software. Some packages allow for programming in C and user interfaces. Representative packages include

General Purpose Libraries and Packages

Traditionally, graphical software systems are developed as a result of programming in high-level languages with interfaces to standard or quasi-standard software packages. These packages attempt to address the issues of device independence and application program portability by allowing systems to drive a wide variety of display devices as well as isolating the programmer from machine-specific graphics commands. Portability of programs is enhanced by allowing the user to move an application from one system to another. The primary programming languages include C, Fortran, and Pascal.

The quasi-standard graphical package is ACM/SIGGRAPH's Core system developed in 1977 and revised in 1979. While it was not a formally recognized standard, it did fulfill a role as a baseline specification for graphical systems [Foley et al., 1996]. The two official standards are GKS-3D, the 3-D Graphical Kernel System; and

PHIGS and PHIGS+, the Programmer's Hierarchical Interactive Graphics System. Both systems support graphics primitives, such as lines, polygons, and character strings, and their attributes. The GKS system allows for groupings into segments with no nesting capabilities. PHIGS supports geometrical transformations (i.e., scaling, translating, and rotating) and a database structure that allows for selective editing and manipulation of the picture. PHIGS runs best when there is hardware support for the transformation, clipping, and **rendering** features. Other software include the cross-platform OpenGL, which is a low-level graphics rendering and imaging library, and Inventor, which is object-oriented and built on top of Open GL [Reynolds and Danielson, 1996].

In traditional graphical systems development, image data are stored either as Cartesian coordinates or as vectors. These data are manipulated through the geometrical transformations of scaling, translating, and rotating in a reference system known as the *world coordinate system* (WCS). The units of the WCS system might be inches, millimeters, or miles. Physical devices use their own coordinate systems known as *screen coordinate systems* (SCS). In order to ready the image for display, a *viewing transformation* takes place, which changes the image data in the WCS to its corresponding device-specific screen coordinates in SCS. A *window* or portion of the world picture is chosen to be shown in an area of the display known as the *viewport*. Because some of the data in the world could be outside the window, a *clipping* operation is necessary. Clipping will eliminate any data points outside the window. These values are then converted to an intermediate coordinate system known as the *normalized device coordinate system* (NDC). Values in this system are in the range of 0 to 1. Because a viewport may be any portion of the display area and the image could be displayed on more than one device, the NDC values are easily adjusted to screen coordinates. In 3-D, the clipping volume uses the viewing transformation which must take into account the *view reference point* (i.e., the position from which an object is to be viewed) and the *perspective* or *parallel projection* (i.e., the conversion from the object's 3-D coordinates to the screen's 2-D coordinates).

Solid Modeling Packages

Feature-based systems such as solid or geometric modeling rather than mathematical-based systems form the basis of some CAD systems. **Solid modeling** (SM) systems use constructive solid geometry to build complicated objects. These systems have a descriptive language which uses a database of 3-D primitive objects such as block, cylinder, sphere, wedge, cone, and torus. These solids are combined to form other solids using the set operators of union, intersection, and difference. The resultant object can then be named, saved, and positioned into a picture or drawing. Attributes stored with the objects allow them to be displayed in wire-frame format or as a completely rendered image. Representative SM systems are MAGI (Mathematical Applications Group, Inc.), Synthavision, PADL-2 (Production Automation Project), GM Solid (a proprietary package of General Motors), and McDonnell Douglas's UNISOLID [Teicholz, 1985].

Object-Oriented Programming

Object-oriented programming is the paradigm for designing and implementing software and is particularly important in computer graphics. An engineering approach, these languages allow software to be constructed from reusable, interchangeable, and extensible parts [Cunningham et al., 1992]. *Class* libraries of graphical objects are being developed. Classes of objects are defined in terms of what an object can do (i.e., what actions and reactions it might produce) and communicate via messages. Subclasses *inherit* actions or characteristics of the superclass. For example, a robot could be constructed from instances of such classes as legs, arms, and head. Each class would have actions defined for it (e.g., a head would be able to nod up and down or shake from side to side). An instance of a head in the object robot would preserve these characteristics. Representative object-oriented languages are Smalltalk, C++, Objective-C, Actor, and Object Pascal.

Plotting and Page Description Languages

Plotting packages, such as ISSCO's DISSPLA and Precision Visuals' DI-3000, consist of routines that are callable from a high-level program. These packages handle 2-D and 3-D images and generally display them in a wire-frame format.

Page description languages are desktop publishing formats that produce graphical output on a printer, display, or other output device. They are used in application programs such as composition systems and illustrators where text, graphical shapes, and sampled images are to be combined into a single document. The dominant language in this category is PostScript, which is a simple interpretive programming language with powerful graphics capabilities. It communicates the description of a document to a printing system in a high level, device-independent manner. PostScript features construction of arbitrary shapes, which may self-intersect, be painted, transformed, cropped, or rendered. The commands are embedded in a general purpose programming language. PostScript programs can be created, transmitted, and interpreted in the form of ASCII source text. The resultant representations will allow for document interchange [Adobe, 1990].

Interaction

The power of computer graphics is to be able to input commands or data in a manner that is appropriate for an application and to have the program react in a timely fashion. These interactions may involve typing words or labels, pointing to items or commands, specifying values or directions for movement, or choosing picture parts displayed on the screen.

Some of the input devices that are available include mouse, special purpose keyboards using buttons or dials, data gloves and other VR devices, touch panels and screens, light pens, graphics tablets, joysticks, 3-D digitizers, trackballs, and voice systems. Each of these devices is capable of sending appropriate values to the graphics program for action [Hearn and Baker, 1997].

Graphics software packages categorize input devices as one of the following logical devices:

1. Locator: a device for specifying a coordinate position (x,y) or orientation (e.g., tablet)
2. Valuator: a device for specifying scalar values (e.g., dials)
3. Keyboard: a device for specifying text input
4. Pick: a device for selecting displayed entities (e.g., mouse)
5. Choice/button: a device for selecting among alternatives (e.g., function keys)

In some systems, an input device might be used for more than one operation. For example, in the Macintosh computer, the mouse is used as a locator, valuator, and pick device [Foley et al., 1996].

91.4 Conclusion

The field of computer graphics has changed dramatically over the past decade. Scientific and engineering applications have expanded from the CAD systems to scientific visualization of complex systems, enhanced solid modeling systems, real-time animated simulations, and now to another dimension, virtual reality.

On the hardware side, we have seen a movement from large, costly systems to putting the power and speed of computers with advanced graphics capabilities on a desktop. PCs, microcomputers, and professional workstations have provided cost-effective platforms that are within the reach of every engineer.

Interaction with a system has been simplified. In most cases, the user has been relieved of the task of keying in and remembering commands. By merely pointing to menu items, the user is led through a system.

Advances in hardware have driven the software development side. Gone are the days of tediously programming and interfacing with low-level graphics commands. Off-the-shelf and vendor-supplied applications packages that incorporate sophisticated graphics abound. These systems are characterized by user-friendly interfaces and high-quality output capabilities.

When programming is necessary, high-level picture constructs through object-oriented environments make manipulation of graphical images more natural. Other support allows for high-level interfaces to X-Windows, Windows, and PostScript by providing the programmer with more graphical development tools.

Overall, scientists and engineers will find the visual dimension for their applications an integral and common component of their tool kit.

Defining Terms

Computer graphics: The generation, representation, manipulation, processing, and display of data by a computer.
Fractals: Geometrical self-similar objects with fractional dimension.
Object-oriented programming: An engineering approach that uses software constructs that are reusable, interchangeable, and extensible.
Rendering: The preparation of the representation of an image to include illumination, shading, depth cueing, coloring, texture, and reflection.
Scientific visualization: The use of computer graphics techniques to represent complex physical phenomena and multidimensional data in order to aid in its understanding and interpretation.
Solid modeling: The use of constructive geometry to build complicated 3-D objects.
Virtual reality (VR): Three or more dimensionality of computer-generated images, which give the user a sense of presence (i.e., a first-person experience) in the scene.
Volume visualization: A method of extracting information from datasets with interactive graphics and imaging; it is concerned with the representation, manipulation, and rendering of volumetric data [Kaufmen et al., 1996].

92.1 Introduction

Computer networks are geographically distributed collections of communication links and switching processors, the purpose of which is to transport data between computers, workstations, and terminals. In general the elements of a computer network must follow compatible rules of operation together to function effectively. These rules of operation are known as protocols.

There are three broad categories of computer networks, distinguished by geographical extent. Local **area networks** (LANs) connect computer equipment in a single building or floor of a building. Metropolitan area networks (MANs) interconnect network users over a campus or metropolitan-sized region. Finally, wide area networks (WANs) interconnect users on a national or an international scale. In the following, key features of these types of networks will be outlined.

92.2 Local Area Networks

There are six main types of local network architectures that have been commercially produced to date: carrier sense multiple-access buses with collision detection, token rings, token buses, wireless LANs, ATM LANs, and private branch exchanges. The first four have been standardized in the IEEE 802 series standards.

Carrier Sense Buses

The **IEEE 802.3 standard** deals with a network architecture and protocol first constructed at Xerox in the 1970s and termed *Ethernet*. All stations in an Ethernet can be connected, through interfaces, to a **coaxial cable** that is usually run through the ceiling near each user's computer equipment.

The coaxial cable essentially acts as a private radio channel for the users. An interesting protocol called carrier sense multiple-access with collision detection (CSMA/CD) is used in such a network. Each station constantly monitors the cable and can detect when it is idle (no user transmitting), when one user is transmitting (successfully), or when more than one user is simultaneously transmitting (resulting in an unsuccessful collision on the channel). The cable basically acts as a broadcast bus. Any station can transmit on the cable if the station detects it to be idle. Once a station transmits, other stations will not interrupt the transmission. As there is no central control in the network, occasionally two or more stations may attempt to transmit at about the same

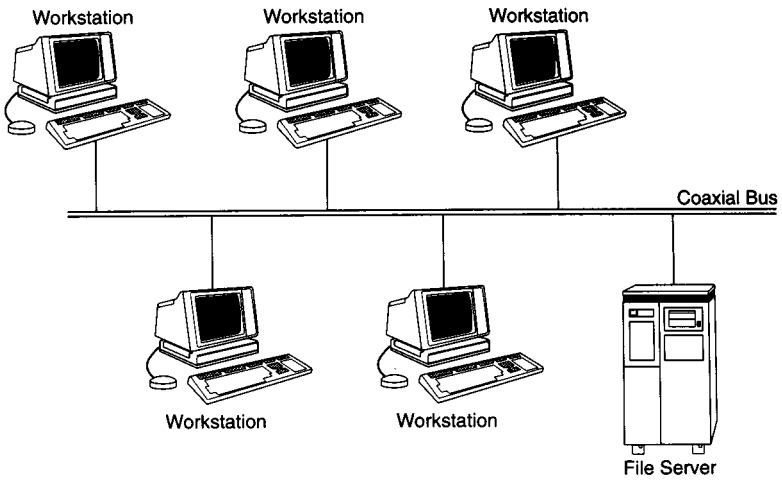

FIGURE 92.1 Bus-type local area network.

time. The transmissions will overlap and be unintelligible (collision). The transmitting stations will detect such a situation and each will retransmit at a randomly chosen later time.

Ethernet and 802.3 networks have raw speeds of up to 10 million bits per second (Mbps). Idle time and collisions, however, can reduce the useful information throughput significantly. The maximum length of these networks is limited by signal propagation delay. An 802.3 coaxial bus differs from an internal computer bus in size and in the lack of a bus controller. Ethernet connections can also be made over unshielded twisted pair or, for long runs, over fiber optics.

Since the introduction of ethernet more than a dozen years ago, desktop computer capabilities and networking requirements have increased significantly. To meet these demands a 100-Mb/s (fast) ethernet has been developed by a consortium of companies. This will be standardized within IEEE 802.3. Media options for the 100-Mb/s ethernet include shielded or unshielded twisted pair as well as fiber optics. Wiring distances of up to 100 m between an end system and wiring closet can be supported. Adapters as well as repeaters that can operate at either 10 or 100 Mb/s will be available. In 1994 there were 50 million ethernet nodes with 15 million new nodes being added each year.

Token Ring

Token ring LANs were developed by IBM in the early 1980s. Topologically, stations are arranged in a circle with point-to-point links between neighbors. Transmissions flow in only one direction (clockwise or counterclockwise). A message transmitted is relayed over the point-to-point links to the receiving station and then forwarded around the rest of the ring and back to the sender to serve as an acknowledgment.

Only a station possessing a special digital code word known as a *token* may transmit. When a station is finished transmitting, it passes the token to its downstream neighbor. Thus, there are no collisions in a token ring, and utilization can approach 100% under heavy loads.

Because of the use of point-to-point links, token rings can use various transmission media such as twisted-pair wire or fiber-optic cables. The transmission speed of a token ring can range from 1 to 16 Mbps, depending on the type of point-to-point links used. Token rings are often wired in star configurations for ease of installation. Token rings are covered by the **IEEE 802.5 standard**. In 1994 there were 10 million token ring nodes with 3–4 million new nodes being added each year.

Token Bus

A token bus uses a coaxial cable along with the token concept to produce a LAN with improved throughput compared to the 802.3 protocol. That is, stations pass a token from one to another to determine which station currently has permission to transmit. Also, in a token bus (and in a token ring), response times can be

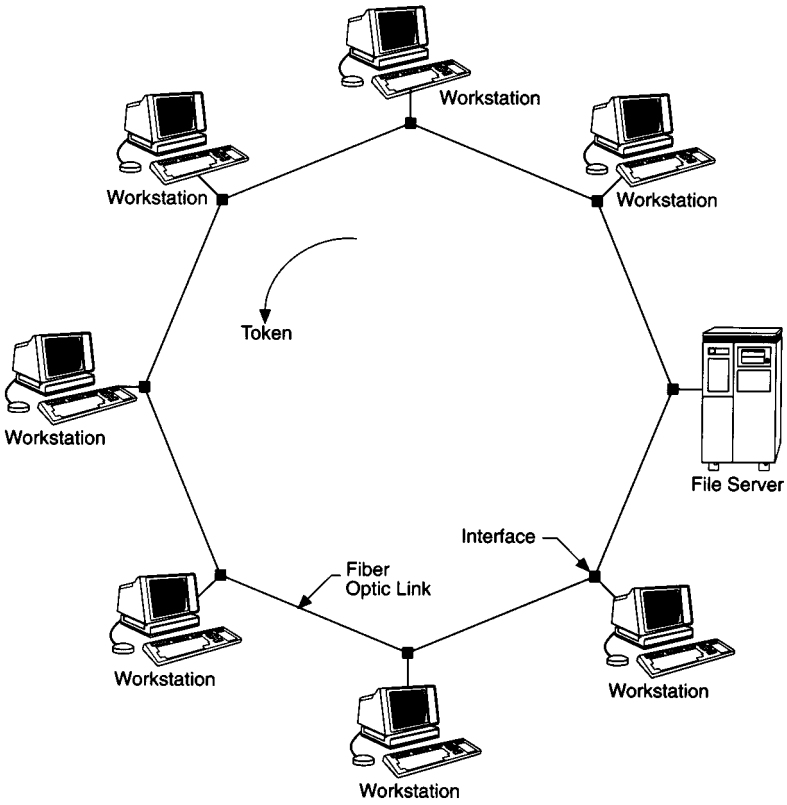

FIGURE 92.2 Token ring local area network.

deterministically bounded. This is important in factory automation, where commands to machines must be received by set times. By way of comparison, response times in an Ethernet-like network can only be probabilistically defined. For this reason, General Motors' Manufacturing Automation Protocol makes use of the token bus. Token buses can operate at 1, 5 and 10 Mbps. Token bus operation is standardized in the **IEEE 802.4 standard**.

Wireless Lans[1]

Wireless LANs use a common radio channel to provide LAN connectivity without any physical wiring. Protocols for wireless LANs are currently being standardized as the IEEE 802.11 standard. Although, one might consider the use of a CSMA/CD protocol in this environment, stations using radio technology are unable to listen to the same channel on which they are transmitting. Thus, it is not possible to implement the collision detection (CD) part of CSMA/CD in a radio environment. Therefore, a modified protocol known as carrier sense multiple access with collision avoidance (CSMA/CA) can be used.

In this variant on CSMA contention for the channel at the end of a successful transmission is mitigated by computing a stochastic idle time for each station during which a station puts off its transmission to see if the channel remains free. A second method of channel access in the form of polling from a master station can be provided for traffic with time delay constraints.

Wireless LANs have aggregate capacities from several hundred kilobit per second to the low megabit per second range. The future of wireless LANs is unclear since it is possible that this capacity will not be sufficient to meet new demands for services.

[1]This material was previously published in *The Mobile Communications Handbook*, J. D. Gibson, Ed., Boca Raton, Fla.: CRC Press, 1996.

One possible way around the problem of the limited spectrum available for wireless LANs is to use infrared light as the transmission medium. There are both direct infrared systems (range: 1–3 mi) and nondirect systems (bounced off walls or ceilings). For small areas data rates are consistent with those of existing ethernet and token ring networks with 100-Mb/s systems on the horizon.

Asyncronous Transfer Mode (ATM) LANs[2]

ATM LANs are relatively new to the LAN marketplace. This is a packet switching technology utilizing relatively short, fixed length packets to provide networking services. ATM was originally seen as a way to develop the next generation wide area telephone network using packet switching, rather than the more conventional circuit switching technology. It was envisioned as a way to transport video, voice, and data in an integrated network. A short packet size was chosen to meet several requirements including minimizing real-time queueing delay.

While progress on the original goal of using ATM technology in wide area telephone networks proceeded slowly because of the complexity of the challenge and the large investments involved, a number of smaller companies introduced ATM local area network products using much the same technology.

An ATM LAN consists of a switch into which are wired end users in a star-type topology. There are several possibilities for the internal architecture of the switch. A low-cost switch may essentially be a computer bus in a box. More sophisticated switches may use switching fabrics. These are very large-scale integrated (VLSI) implementations of patterned networks of simple switching elements, sometimes referred to as space division switching. A great deal of effort has gone into producing cost-effective ATM switches over the past 12 years. It should be pointed out that many of the issues that are not yet resolved for wide area network ATM (i.e., traffic policing, billing) are more tractable in the private ATM LAN environment.

ATM LANs can support a relatively small number of users at high data access rates (low megabit per second). Although ATM is good at handling mixed media traffic at high speeds, it remains to be seen if enough applications are developed requiring its high-bandwidth capability to make it a success. The cost effectiveness of ATM technology is another issue awaiting resolution.

Private Branch Exchange

Historically, private branch exchanges (PBXs) were privately owned telephone switching computers that would be placed in the basement of a building and serve to interconnect phones in the building and provide access to outside lines provided by common carriers. However, PBXs are now available that offer both telephone and data service. In a typical system a phone may have a data socket for terminals or workstations. PBXs are wired in a star topology with the PBX at the center of the star and each user wired directly to it.

92.3 Metropolitan Area Networks

While several network architectures have been proposed for use as MANs, the two that are closest to widespread commercial implementation are fiber-distributed data interface (FDDI) and distributed queue dual bus (DQDB) interface. A key feature of a MAN is the ability to interconnect LANs. This is a problem because of the high data rates at which LANs operate.

FDDI

The FDDI is similar to a token ring LAN except that two rings, instead of one, may be used. Stations needing high-reliability communication are connected to both rings. In the case of a break in the rings the network can be automatically reconfigured. FDDI rings operate at 100 Mbps with a maximum of 500 nodes and a maximum fiber length of 200 km. In fact, most actual FDDI installations have only a small number of nodes (such as routers). There is an American National Standards Institute (ANSI) standard for FDDI.

[2]This material was previously published in *The Mobile Communications Handbook,* J. D. Gibson, Ed., Boca Raton, Fla.: CRC Press, 1996.

DQDB

The DQDB forms the basis of the **IEEE 802.6 standard** for MANs. DQDB is descended from the earlier QPSX, which was developed at the University of Western Australia and Telecom Australia. DQDB uses two unidirectional linear fiber-optic buses. Stations are connected to both buses. Through the clever use of counters the DQDB protocol provides approximate first in, first out (FIFO) service to arriving packets. There are no collisions in DQDB, so utilization can approach 100%. Bus speeds of 150 Mbps are possible.

92.4 Wide Area Networks

Data are generally transmitted over long distances by wide area packet networks. These networks generally lease telephone lines from telecommunications carriers that are used to carry data exclusively. Packet switching technology was first used on a large scale in the ARPANET beginning in the 1960s. The Internet (which replaced the earlier ARPANET) serves to connect universities, industrial and government research centers, and private users.

One problem area unique to wide area packet networks is that of routing. Unlike the previously mentioned networks, there are usually multiple routes available between sources and destinations. Distributed routing algorithms have been developed that route based on current traffic conditions.

92.5 The Future

The future is likely to see an increase in data rates as fiber-optic cables are widely deployed. This will spur the development of faster switching nodes through the use of parallel processing and VLSI implementation. Protocols will have to be simplified to increase processor throughput. New forms of traffic such as video and graphics will become more important. Computer networks will proliferate throughout the world, making possible the ubiquitous transport of data between any two points. These networks are likely to consist of both private networks and new service offerings from telecommunications companies.

Defining Terms

Area networks: LAN, within single building; MAN, metropolitan-sized region; WAN, national/international region.

Coaxial cable: A shielded cable that conducts electrical signals and is used in bus-type local area networks.

Fiber-optic cable: A glass fiber cable that conducts light signals and can be used in token ring local area networks and metropolitan area networks. Fiber optics can provide higher data rates than coaxial cable. They are also immune to electrical interference.

IEEE standards: 802.3, CSMA/CD bus; 802.4, token bus; 802.5, token ring; 802.6, DQDB MAN.

93.1 Introduction

Fault tolerance is the ability of a system to continue correct performance of its tasks after the occurrence of hardware or software faults. A **fault** is simply any physical defect, imperfection, or flaw that occurs in hardware or software. Applications of fault-tolerant computing can be categorized broadly into four primary areas: long-life, critical computations, maintenance postponement, and high availability. The most common examples of long-life applications are unmanned space flight and satellites. Examples of critical-computation applications include aircraft flight control systems, military systems, and certain types of industrial controllers. Maintenance postponement applications appear most frequently when maintenance operations are extremely costly, inconvenient, or difficult to perform. Remote processing stations and certain space applications are good examples. Banking and other time-shared systems are good examples of high-availability applications. Fault tolerance can be achieved in systems by incorporating various forms of redundancy, including hardware, information, time, and software redundancy [Johnson, 1989].

93.2 Hardware Redundancy

The physical replication of hardware is perhaps the most common form of fault tolerance used in systems. As semiconductor components have become smaller and less expensive, the concept of hardware redundancy has become more common and more practical. There are three basic forms of hardware redundancy. First, *passive* techniques use the concept of fault masking to hide the occurrence of faults and prevent the faults from resulting in **errors**. Passive approaches are designed to achieve fault tolerance without requiring any action on the part of the system or an operator. Passive techniques, in their most basic form, do not provide for the detection of faults but simply mask the faults. An example of a passive approach is triple modular redundancy (TMR), which is illustrated in Fig. 93.1. In the TMR system three identical units perform identical functions, and a majority vote is performed on the output.

The second form of hardware redundancy is the *active* approach, which is sometimes called the *dynamic* method. Active methods achieve fault tolerance by detecting the existence of faults and performing some action to remove the faulty hardware from the system. In other words, active techniques require that the system perform reconfiguration to tolerate faults. Active hardware redundancy uses fault detection, fault location, and fault recovery in an attempt to achieve fault tolerance. An example of an active approach to hardware redundancy is standby sparing, which is illustrated in Fig. 93.2. In standby sparing one or more units operate as spares and replace the primary unit when it fails.

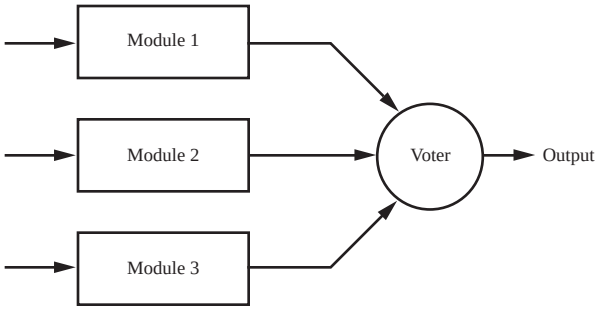

FIGURE 93.1 Fault masking using triple modular redundancy (TMR).

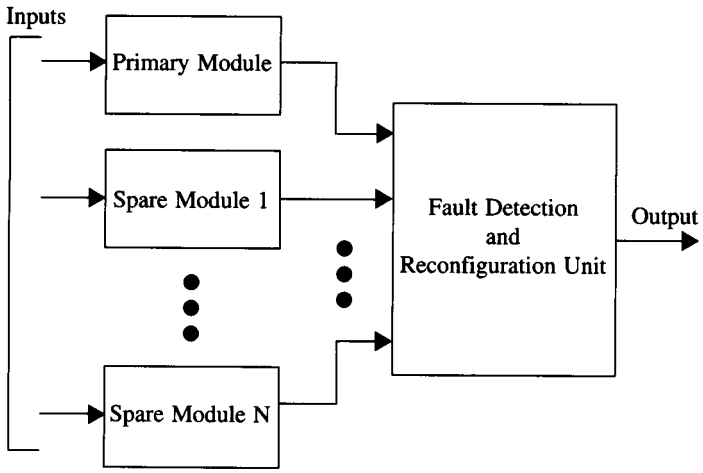

FIGURE 93.2 General concept of standby sparing.

The final form of hardware redundancy is the *hybrid* approach. Hybrid techniques combine the attractive features of both the passive and active approaches. Fault masking is used in hybrid systems to prevent erroneous results from being generated. Fault detection, fault location, and fault recovery are also used in the hybrid approaches to improve fault tolerance by removing faulty hardware and replacing it with spares. Providing spares is one form of providing redundancy in a system. Hybrid methods are most often used in the critical-computation applications where fault masking is required to prevent momentary errors, and high reliability must be achieved. The basic concept of the hybrid approach is illustrated in Fig. 93.3.

93.3 Information Redundancy

Another approach to fault tolerance is to employ redundancy of information. Information redundancy is simply the addition of redundant information to data to allow fault detection, fault masking, or possibly fault tolerance. Good examples of information redundancy are error detecting and error correcting codes, formed by the addition of redundant information to data words or by the mapping of data words into new representations containing redundant information [Lin and Costello, 1983].

In general, a *code* is a means of representing information, or data, using a well-defined set of rules. A *code word* is a collection of symbols, often called digits if the symbols are numbers, used to represent a particular piece of data based upon a specified code. A *binary code* is one in which the symbols forming each code word consist of only the digits 0 and 1. A code word is said to be *valid* if the code word adheres to all of the rules that define the code; otherwise, the code word is said to be *invalid.*

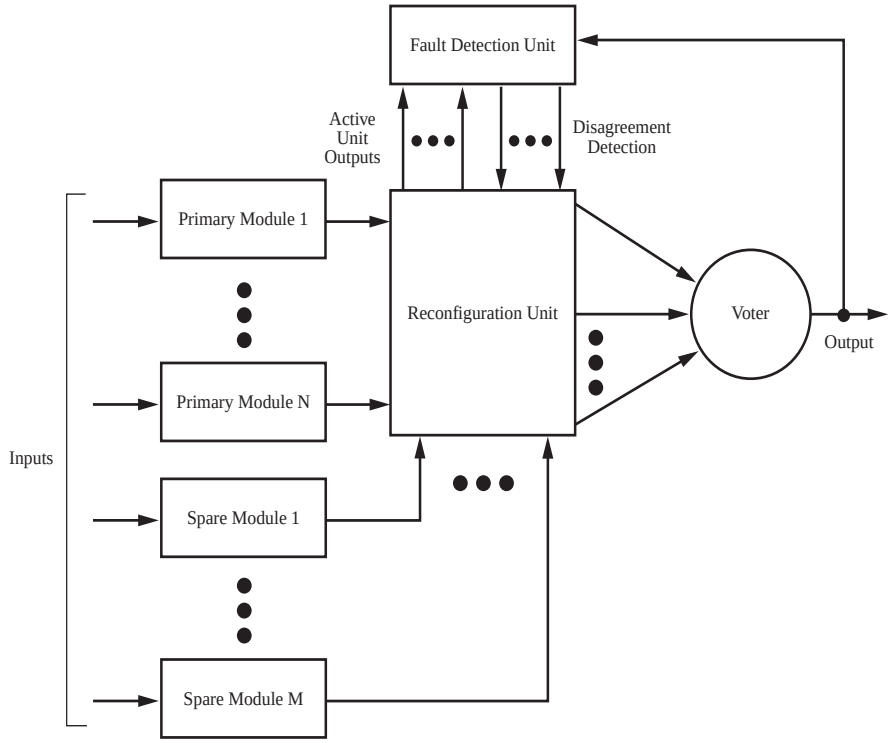

FIGURE 93.3 Hybrid redundancy approach.

The *encoding operation* is the process of determining the corresponding code word for a particular data item. In other words, the encoding process takes an original data item and represents it as a code word using the rules of the code. The *decoding operation* is the process of recovering the original data from the code word. In other words, the decoding process takes a code word and determines the data that it represents.

It is possible to create a binary code for which the valid code words are a subset of the total number of possible combinations of 1s and 0s. If the code words are formed correctly, errors introduced into a code word will force it to lie in the range of illegal, or invalid, code words, and the error can be detected. This is the basic concept of the *error detecting codes.* The basic concept of the *error correcting code* is that the code word is structured such that it is possible to determine the correct code word from the corrupted, or erroneous, code word.

A fundamental concept in the characterization of codes is the *Hamming distance* [Hamming, 1950]. The *Hamming distance* between any two binary words is the number of bit positions in which the two words differ. For example, the binary words 0000 and 0001 differ in only one position and therefore have a Hamming distance of 1. The binary words 0000 and 0101, however, differ in two positions; consequently, their Hamming distance is 2. Clearly, if two words have a Hamming distance of 1, it is possible to change one word into the other simply by modifying one bit in one of the words. If, however, two words differ in two bit positions, it is impossible to transform one word into the other by changing one bit in one of the words.

The Hamming distance gives insight into the requirements of error detecting codes and error correcting codes. We define the *distance* of a code as the minimum Hamming distance between any two valid code words. If a binary code has a distance of two, then any single-bit error introduced into a code word will result in the erroneous word being an invalid code word because all valid code words differ in at least two bit positions. If a code has a distance of 3, then any single-bit error or any double-bit error will result in the erroneous word being an invalid code word because all valid code words differ in at least three positions. However, a code distance of 3 allows any single-bit error to be corrected, if it is desired to do so, because the erroneous word with a single-bit error will be a Hamming distance of 1 from the correct code word and at least a Hamming

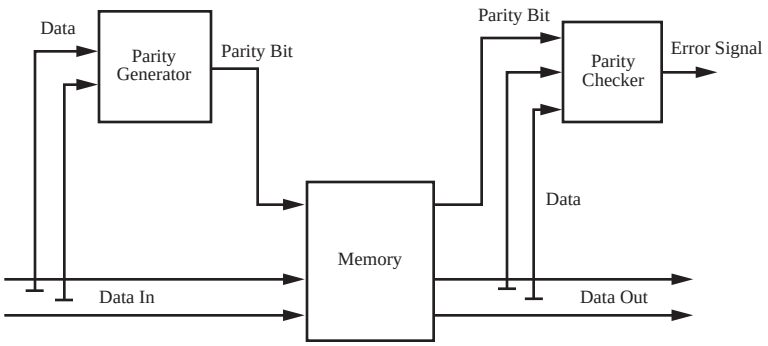

FIGURE 93.4 Use of parity coding in a memory application.

distance of 2 from all others. Consequently, the correct code word can be identified from the corrupted code word.

In general, a binary code can correct up to c bit errors and detect an additional d bit errors if and only if

$$2c - d - 1 \leq H_d$$

where H_d is the distance of the code [Nelson and Carroll, 1986]. For example, a code with a distance of 2 cannot provide any error correction but can detect single-bit errors. Similarly, a code with a distance of 3 can correct single-bit errors or detect a double-bit error.

A second fundamental concept of codes is *separability.* A *separable code* is one in which the original information is appended with new information to form the code word, thus allowing the decoding process to consist of simply removing the additional information and keeping the original data. In other words, the original data is obtained from the code word by stripping away extra bits, called the code bits or check bits, and retaining only those associated with the original information. A *nonseparable code* does not possess the property of separability and, consequently, requires more complicated decoding procedures.

Perhaps the simplest form of a code is the parity code. The basic concept of parity is very straightforward, but there are variations on the fundamental idea. Single-bit parity codes require the addition of an extra bit to a binary word such that the resulting code word has either an even number of 1s or an odd number of 1s. If the extra bit results in the total number of 1s in the code word being odd, the code is referred to as *odd parity.* If the resulting number of 1s in the code word is even, the code is called *even parity.* If a code word with odd parity experiences a change in one of its bits, the parity will become even. Likewise, if a code word with even parity encounters a single-bit change, the parity will become odd. Consequently, a single-bit error can be detected by checking the number of ls in the code words. The single-bit parity code (either odd or even) has a distance of 2, therefore allowing any single-bit error to be detected but not corrected. Figure 93.4 illustrates the use of parity coding in a simple memory application.

Arithmetic codes are very useful when it is desired to check arithmetic operations such as addition, multiplication, and division [Avizienis, 1971]. The basic concept is the same as all coding techniques. The data presented to the arithmetic operation is encoded before the operations are performed. After completing the arithmetic operations, the resulting code words are checked to make sure that they are valid code words. If the resulting code words are not valid, an error condition is signaled. An arithmetic code must be invariant to a set of arithmetic operations. An arithmetic code, A, has the property that $A(b^*c) = A(b)^*A(c)$, where b and c are operands, * is some arithmetic operation, and $A(b)$ and $A(c)$ are the arithmetic code words for the operands b and c, respectively. Stated verbally, the performance of the arithmetic operation on two arithmetic code words will produce the arithmetic code word of the result of the arithmetic operation. To completely define an arithmetic code, the method of encoding and the arithmetic operations for which the code is invariant must be specified. The most common examples of arithmetic codes are the *AN* codes, residue codes, and the inverse residue codes.

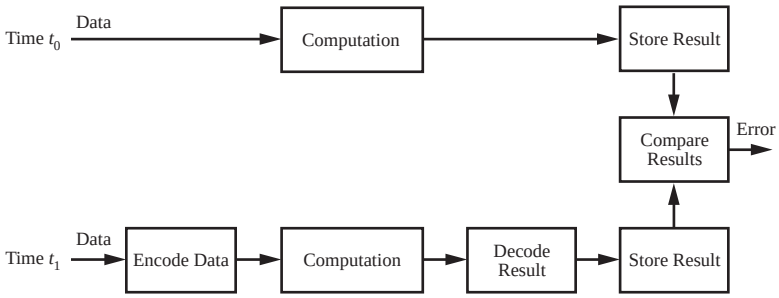

FIGURE 93.5 Time redundancy concept.

93.4 Time Redundancy

Time redundancy methods attempt to reduce the amount of extra hardware at the expense of using additional time. In many applications, the time is of much less importance than the hardware because hardware is a physical entity that impacts weight, size, power consumption, and cost. Time, on the other hand, may be readily available in some applications. The basic concept of time redundancy is the repetition of computations in ways that allow faults to be detected. Time redundancy can function in a system in several ways. The fundamental concept is to perform the same computation two or more times and compare the results to determine if a discrepancy exists. If an error is detected, the computations can be performed again to see if the disagreement remains or disappears. Such approaches are often good for detecting errors resulting from transient faults but cannot provide protection against errors resulting from permanent faults.

The main problem with many time redundancy techniques is assuring that the system has the same data to manipulate each time it redundantly performs a computation. If a transient fault has occurred, a system's data may be completely corrupted, making it difficult to repeat a given computation. Time redundancy has been used primarily to detect transients in systems. One of the biggest potentials of time redundancy, however, now appears to be the ability to detect permanent faults while using a minimum of extra hardware. The fundamental concept is illustrated in Fig. 93.5. During the first computation or transmission, the operands are used as presented and the results are stored in a register. Prior to the second computation or transmission, the operands are encoded in some fashion using an encoding function. After the operations have been performed on the encoded data, the results are then decoded and compared to those obtained during the first operation. The selection of the encoding function is made so as to allow faults in the hardware to be detected. Example encoding functions might include the complementation operator and an arithmetic shift.

93.5 Software Redundancy

Software faults are unusual entities. Software does not break as hardware does, but instead software faults are the result of incorrect software designs or coding mistakes. Therefore, any technique that detects faults in software must detect design flaws. A simple duplication and comparison procedure will not detect software faults if the duplicated software modules are identical, because the design mistakes will appear in both modules.

The concept of N self-checking programming is to first write N unique versions of the program and to develop a set of acceptance tests for each version. The acceptance tests are essentially checks performed on the results produced by the program and may be created using consistency checks and capability checks, for example. Selection logic, which may be a program itself, chooses the results from one of the programs that passes the acceptance tests. This approach is analogous to the hardware technique known as hot standby sparing. Since each program is running simultaneously, the reconfiguration process can be very fast. Provided that the software faults in each version of the program are independent and the faults are detected as they occur by the acceptance tests, then this approach can tolerate $N - 1$ faults. It is important to note that the assumptions of fault independence and perfect fault coverage are very big assumptions to make in almost all applications.

The concept of *N*-version programming was developed to allow certain design flaws in software modules to be tolerated [Chen and Avizienis, 1978]. The basic concept of *N*-version programming is to design and code the software module *N* times and to vote on the *N* results produced by these modules. Each of the *N* modules is designed and coded by a separate group of programmers. Each group designs the software from the same set of specifications such that each of the *N* modules performs the same function. However, it is hoped that by performing the *N* designs independently, the same mistakes will not be made by the different groups. Therefore, when a fault occurs, the fault will either not occur in all modules or it will occur differently in each module, so that the results generated by the modules will differ. Assuming that the faults are independent the approach can tolerate $(N-1)/2$ faults where N is odd.

The recovery block approach to software fault tolerance is analogous to the active approaches to hardware fault tolerance, specifically the cold standby sparing approach. *N* versions of a program are provided, and a single set of acceptance tests is used. One version of the program is designated as the primary version, and the remaining $N-1$ versions are designated as spares, or secondary versions. The primary version of the software is always used unless it fails to pass the acceptance tests. If the acceptance tests are failed by the primary version, then the first secondary version is tried. This process continues until one version passes the acceptance tests or the system fails because none of the versions can pass the tests.

93.6 Dependability Evaluation

Dependability is defined as the quality of service provided by a system [Laprie, 1985]. Perhaps the most important measures of dependability are reliability and availability. Fundamental to reliability calculations is the concept of failure rate. Intuitively, the *failure rate is* the expected number of **failures** of a type of device or system per a given time period [Shooman, 1968]. The failure rate is typically denoted as λ when it is assumed to have a constant value. To more clearly understand the mathematical basis for the concept of a failure rate, first consider the definition of the reliability function. The **reliability** $R(t)$ of a component, or a system, is the conditional probability that the component operates correctly throughout the interval $[t_0, t]$ given that it was operating correctly at the time t_0.

There are a number of different ways in which the failure rate function can be expressed. For example, the failure rate function $z(t)$ can be written strictly in terms of the reliability function $R(t)$ as

$$z(t) = \left(-\frac{dR(t)/dt}{R(t)} \right)$$

Similarly, $z(t)$ can be written in terms of the unreliability $Q(t)$ as

$$z(t) = -\frac{dR(t)/dt}{R(t)} = \frac{dQ(t)/dt}{1-Q(t)}$$

where $Q(t) = 1 - R(t)$. The derivative of the unreliability, $dQ(t)/dt$, is called the *failure density function.*

The failure rate function is clearly dependent upon time; however, experience has shown that the failure rate function for electronic components does have a period where the value of $z(t)$ is approximately constant. The commonly accepted relationship between the failure rate function and time for electronic components is called the bathtub curve and is illustrated in Fig. 93.6. The bathtub curve assumes that during the early life of systems, failures occur frequently due to substandard or weak components. The decreasing part of the bathtub curve is called the early-life or infant mortality region. At the opposite end of the curve is the wear-out region where systems have been functional for a long period of time and are beginning to experience failures due to the physical wearing of electronic or mechanical components. During the intermediate region, the failure rate function is assumed to be a constant. The constant portion of the bathtub curve is called the useful-life phase

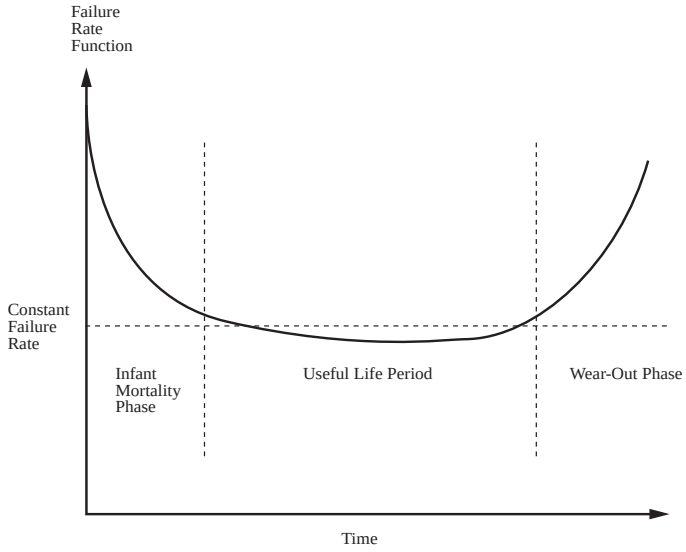

FIGURE 93.6 Bathtub curve relationship between the failure rate function and time.

of the system, and the failure rate function is assumed to have a value of λ during that period. λ is referred to as the failure rate and is normally expressed in units of failures per hour.

The reliability can be expressed in terms of the failure rate function as a differential equation of the form

$$\frac{dR(t)}{dt} = -z(t)R(t)$$

The general solution of this differential equation is given by

$$R(t) = e^{-\int z(t)dt}$$

If we assume that the system is in the useful-life stage where the failure rate function has a constant value of λ, the solution to the differential equation is an exponential function of the parameter λ given by

$$R(t) = e^{-\lambda t}$$

where λ is the constant failure rate. The exponential relationship between the reliability and time is known as the *exponential failure law,* which states that for a constant failure rate function, the reliability varies exponentially as a function of time.

In addition to the failure rate, the mean time to failure (MTTF) is a useful parameter to specify the quality of a system. The MTTF is the expected time that a system will operate before the first failure occurs. The MTTF can be calculated by finding the expected value of the time of failure.

From probability theory, we know that the expected value of a random variable, X, is

$$E[X] = \int_{-\infty}^{\infty} x f(x) dx$$

where $f(x)$ is the probability density function. In reliability analysis we are interested in the expected value of the time of failure (MTTF), so

$$\text{MTTF} = \int_0^\infty t f(t) dt$$

where $f(t)$ is the failure density function, and the integral runs from 0 to ∞ because the failure density function is undefined for times less than 0. We know, however, that the failure density function is

$$f(t) = \frac{dQ(t)}{dt}$$

so, the MTTF can be written as

$$\text{MTTF} = \int_0^\infty t \frac{dQ(t)}{dt} dt$$

Using integration by parts and the fact that $dQ(t)/dt = -dR(t)/dt$ we can show that

$$\text{MTTF} = \int_0^\infty t \frac{dQ(t)}{dt} dt = -\int_0^\infty t \frac{dR(t)}{dt} dt = \left[-tR(t) + \int R(t) dt\right]\Big|_0^\infty = \int_0^\infty R(t) dt$$

Consequently, the MTTF is defined in terms of the reliability function as

$$\text{MTTF} = \int_0^\infty R(t) dt$$

which is valid for any reliability function that satisfies $R(\infty) = 0$.

The mean time to repair (MTTR) is simply the average time required to repair a system. The MTTR is extremely difficult to estimate and is often determined experimentally by injecting a set of faults, one at a time, into a system and measuring the time required to repair the system in each case. The MTTR is normally specified in terms of a repair rate, μ, which is the average number of repairs that occur per time period. The units of the repair rate are normally number of repairs per hour. The MTTR and the rate, μ, are related by

$$\text{MTTR} = \frac{1}{\mu}$$

It is very important to understand the difference between the MTTF and the mean time between failure (MTBF). Unfortunately, these two terms are often used interchangeably. While the numerical difference is small in many cases, the conceptual difference is very important. The MTTF is the average time until the first failure of a system, while the MTBF is the average time between failures of a system. If we assume that all repairs to a system make the system perfect once again just as it was when it was new, the relationship between the MTTF and the MTBF can be determined easily. Once successfully placed into operation, a system will operate, on the average, a time corresponding to the MTTF before encountering the first failure. The system will then require

some time, MTTR, to repair the system and place it back into operation once again. The system will then be perfect once again and will operate for a time corresponding to the MTTF before encountering its next failure. The time between the two failures is the sum of the MTTF and the MTTR and is the MTBF. Thus, the difference between the MTTF and the MTBF is the MTTR. Specifically, the MTBF is given by

$$\text{MTBF} = \text{MTTF} + \text{MTTR}$$

In most practical applications the MTTR is a small fraction of the MTTF, so the approximation that the MTBF and MTTF are equal is often quite good. Conceptually, however, it is crucial to understand the difference between the MTBF and the MTTF.

An extremely important parameter in the design and analysis of fault-tolerant systems is fault coverage. The fault coverage available in a system can have a tremendous impact on the reliability, safety, and other attributes of the system. Fault coverage is mathematically defined as the conditional probability that, given the existence of a fault, the system recovers [Bouricius et al., 1969]. The fundamental problem with fault coverage is that it is extremely difficult to calculate. Probably the most common approach to estimating fault coverage is to develop a list all of the faults that can occur in a system and to form, from that list, a list of faults from which the system can recover. The fault coverage factor is then calculated appropriately.

Reliability is perhaps one of the most important attributes of systems. The reliability of a system is generally derived in terms of the reliabilities of the individual components of the system. The two models of systems that are most common in practice are the series and the parallel. In a series system, each element of the system is required to operate correctly for the system to operate correctly. In a parallel system, on the other hand, only one of several elements must be operational for the system to perform its functions correctly.

The series system is best thought of as a system that contains no redundancy; that is, each element of the system is needed to make the system function correctly. In general, a system may contain N elements, and in a series system each of the N elements is required for the system to function correctly. The reliability of the series system can be calculated as the probability that none of the elements will fail. Another way to look at this is that the reliability of the series system is the probability that all of the elements are working properly. The reliability of a series system is given by

$$R_{\text{series}}(t) = R_1(t)R_2(t) \ldots R_N(t)$$

or

$$R_{\text{series}}(t) = \prod_{i=1}^{N} R_i(t)$$

An interesting relationship exists in a series system if each individual component satisfies the exponential failure law. Suppose that we have a series system made up of N components, and each component, i, has a constant failure rate of λ_i. Also assume that each component satisfies the exponential failure law. The reliability of the series system is given by

$$R_{\text{series}}(t) = e^{-\lambda_1 t} e^{-\lambda_2 t} \ldots e^{-\lambda_N t}$$

$$R_{\text{series}}(t) = e^{-\sum_{i=1}^{N} \lambda_i t}$$

The distinguishing feature of the basic parallel system is that only one of N identical elements is required for the system to function. The reliability of the parallel system can be written as

$$R_{\text{parallel}}(t) = 1.0 - Q_{\text{parallel}}(t) = 1.0 - \prod_{i=1}^{N} Q_i(t) = 1.0 - \prod_{i=1}^{N} (1.0 - R_i(t))$$

It should be noted that the equations for the parallel system assume that the failures of the individual elements that make up the parallel system are independent.

M-of-*N* systems are a generalization of the ideal parallel system. In the ideal parallel system, only one of *N* modules is required to work for the system to work. In the *M*-of-*N* system, however, *M* of the total of *N* identical modules are required to function for the system to function. A good example is the TMR configuration where two of the three modules must work for the majority voting mechanism to function properly. Therefore, the TMR system is a 2-of-3 system.

In general, if there are *N* identical modules and *M* of those are required for the system to function properly, then the system can tolerate $N - M$ module failures. The expression for the reliability of an *M*-of-*N* system can be written as

$$R_{M\text{-of-}N}(t) = \sum_{i=0}^{N-M} \binom{N}{i} R^{N-i}(t)(1.0 - R(t))^i$$

where

$$\binom{N}{i} = \frac{N!}{(N-i)!\,i!}$$

The **availability**, $A(t)$, of a system is defined as the probability that a system will be available to perform its tasks at the instant of time *t*. Intuitively, we can see that the availability can be approximated as the total time that a system has been operational divided by the total time elapsed since the system was initially placed into operation. In other words, the availability is the percentage of time that the system is available to perform its expected tasks. Suppose that we place a system into operation at time $t = 0$. As time moves along, the system will perform its functions, perhaps fail, and hopefully be repaired. At some time $t = t_{\text{current}}$, suppose that the system has operated correctly for a total of t_{op} hours and has been in the process of repair or waiting for repair to begin for a total of t_{repair} hours. The time t_{current} is then the sum of t_{op} and t_{repair}. The availability can be determined as

$$A(t_{\text{current}}) = \frac{t_{\text{op}}}{t_{\text{op}} + t_{\text{repair}}}$$

where $A(t_{\text{current}})$ is the availability at time t_{current}.

If the average system experiences *N* failures during its lifetime, the total time that the system will be operational is *N*(MTTF) hours. Likewise, the total time that the system is down for repairs is *N*(MTTR) hours. In other words, the operational time, t_{op}, is *N*(MTTF) hours and the downtime, t_{repair}, is *N*(MTTR) hours. The average, or steady-state, availability is

$$A_{SS} = \frac{N(\text{MTTF})}{N(\text{MTTF}) + N(\text{MTTR})}$$

We know, however, that the MTTF and the MTTR are related to the failure rate and the repair rate, respectively, for simplex systems, as

$$\text{MTTF} = \frac{1}{\lambda}$$

$$\text{MTTR} = \frac{1}{\mu}$$

Therefore, the steady-state availability is given by

$$A_{SS} = \frac{1/\lambda}{1/\lambda + 1/\mu} = \frac{1}{1 + \lambda/\mu}$$

Defining Terms

Availability, $A(t)$: The probability that a system is operating correctly and is available to perform its functions at the instant of time t.

Dependability: The quality of service provided by a particular system.

Error: The occurrence of an incorrect value in some unit of information within a system.

Failure: A deviation in the expected performance of a system.

Fault: A physical defect, imperfection, or flaw that occurs in hardware or software.

Fault avoidance: A technique that attempts to prevent the occurrence of faults.

Fault tolerance: The ability to continue the correct performance of functions in the presence of faults.

Maintainability, $M(t)$: The probability that an inoperable system will be restored to an operational state within the time t.

Performability, $P(L,t)$: The probability that a system is performing at or above some level of performance, L, at the instant of time t.

Reliability, $R(t)$: The conditional probability that a system has functioned correctly throughout an interval of time, $[t_0,t]$, given that the system was performing correctly at time t_0.

Safety, $S(t)$: The probability that a system will either perform its functions correctly or will discontinue its functions in a well-defined, safe manner.

94.1 Databases

M. Abdelguerfi and R. Eskicioglu

In the past, file processing techniques were used to design information systems. These systems usually consist of a set of files and a collection of application programs. Permanent records are stored in the files, and application programs are used to update and query the files. The application programs were in general developed individually to meet the needs of different groups of users. In many cases, this approach leads to a duplication of data among the files of different users. Also, the lack of coordination between files belonging to different users often leads to a lack of data consistency. In addition, changes to the underlying data requirements usually necessitate major changes to existing application programs. Among other major problems that arise with the use of file processing techniques are lack of data sharing, reduced programming productivity, and increased program maintenance. Because of their inherent difficulties and lack of flexibility, file processing techniques have lost a great deal of their popularity and are being replaced by **database management systems (DBMS).**

A DBMS is designed to efficiently manage a shared pool of interrelated data (**database**). This includes the existence of features such as a *data definition language* for the definition of the logical structure of the database (*database schema*), a *data manipulation language* to query and update the database, a *concurrency control* mechanism to keep the database consistent when shared by several users, a *crash recovery* strategy to avoid any loss of information after a system crash, and *safety* mechanisms against any unauthorized access.

Database Abstraction

A DBMS is expected to provide for *data independence*, i.e., user requests are made at a *logical level* without any need for the knowledge of how the data is stored in actual files. This implies that the internal file structure could be modified without any change to the user's perception of the database. To achieve data independence, the Standards Planning and Requirements Committee (SPARC) of the American National Standards Institute (ANSI) in its 1977 report recommended three levels of database abstraction (see Fig. 94.1). The lowest level in the abstraction is the internal level. Here, the database is viewed as a collection of files organized according to one of several possible internal data organizations (e.g., B^+-tree data organization). In the conceptual level, the database is viewed at an abstract level. The user at this level is shielded from the internal storage details. At the external level, each group of users has their own perception or *view* of the database. Each view is derived from

the conceptual database and is designed to meet the needs of a particular group of users. Such a group can only have access to the data specified by its particular view. This, of course, ensures both privacy and security.

The mapping between the three levels of abstraction is the task of the DBMS. When changes to the internal level (such as a change in file organization) do not affect the conceptual and external levels, the system is said to provide for *physical data independence*. *Logical data independence* prevents changes to the conceptual level to affect users' views. Both types of data independence are desired features in a database system.

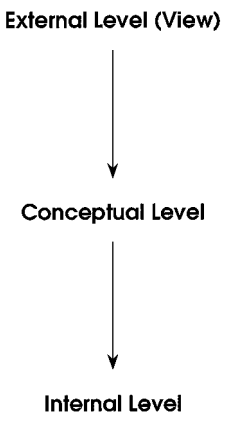

FIGURE 94.1 Data abstraction.

Data Models

A **data model** refers to an integrated set of tools used to describe the data and its structure, data relationships, and data constraints. Some data models provide a set of operators that is used to update and query the database. Data models can be classified in two main categories: *record-based* and *object-based*. Both classes are used to describe the database at the conceptual and external levels. With object-based data models, constraints on the data can be specified more explicitly.

There are three main record-based data models: the *relational*, *network*, and *hierarchical* models. In the relational model, data at the conceptual level is represented as a collection of interrelated tables. These tables are *normalized* so as to minimize data redundancy and update anomalies. In this model, data relationships are implicit and are derived by matching columns in tables. In the hierarchical and network models, the data is represented as a collection of records and data relationships are explicit and are represented by *links*. The difference between the last two models is that in the hierarchical model, data is represented as a tree structure, while it is represented as a generalized graph in the network model.

In hierarchical and network models, the existence of physical pointers (links) to link related records allows an application program to retrieve a single record at a time by following the pointer's chain. The process of following the pointer's chain and selecting one record at a time is referred to as *navigation*. In nonnavigational models such as the relational model, records are not related through pointer's chains, but relationships are established by matching columns in different tables.

The hierarchical and network models require the application programmer to be aware of the internal structure of the database. The relational model, on the other hand, allows for a high degree of physical and logical data independence. Earlier DBMSs were for the most part navigational systems. Because of its simplicity and strong theoretical foundations, the relational model has since received wide acceptance. Today, most DBMSs are based on the relational model.

Other data models include a popular high level conceptual data model, known as the *Entity-Relationship* (ER) model. The ER model is mainly used for the conceptual design of databases and their applications. The ER model describes data as entities, attributes, and relationships.

An *entity* is an "object" in the real world with an independent existence. Each entity has a set of properties, called *attributes,* that describes it. A *relationship* is an association between entities. For example, a professor entity may be described by its name, age, and salary and can be associated with a department entity by the relationship "works for".

With the advent of advanced database applications, the ER modeling concepts became insufficient. This has led to the enhancement of the ER model with additional concepts, such as generalization, categories, and inheritance, leading to the *Enhanced-ER* or *EER* model.

Relational Databases

The relational model was introduced by E. F. Codd [1970]. Since the theoretical underpinnings of the relational model have been well defined, it has become the focus of most commercial DBMSs.

In the relational model, the data is represented as a collection of relations. To a large extent, each relation can be thought of as a table. The example of Fig. 94.2 shows part of a university database composed of two

FIGURE 94.2 An example of two relations: FAC_INFO and DEP_CHAIR.

relations. FAC_INFO gives personal information (last name, social security, street and city of residence, and department) of a faculty. DEP_CHAIR gives the last name of the chairman of each department. A faculty is not allowed to belong to two departments. Each row in a relation is referred to as a *tuple*. A column name is called an *attribute name*. The data type of each attribute name is known as its *domain*. A *relation scheme* is a set of attribute names. For instance, the relation scheme (or scheme for short) of the relation FAC_INFO is (lname, social_sec#, street, city, dept). A *key* is a set of attribute names whose composite value is distinct for all tuples. In addition, no proper subset of the key is allowed to have this property. It is not unusual for a scheme to have several possible keys. In FAC_INFO, both lname and social_sec# are possible keys. In this case, each possible key is known as a *candidate key,* and the one selected to act as the relation's key, say, lname, is referred to as the *primary key.* A *superkey* is a key with the exception that there is no requirement for minimality. In a relation, an attribute name (or a set of attribute names) is referred to as a *foreign key,* if it is the primary key of another relation. In FAC_INFO, the attribute name dept is a foreign key, since the same attribute is a key in DEP_CHAIR. Because of updates to the database, the content of a relation is dynamic. For this reason, the data in a relation at a given time instant is called an *instance* of the relation.

There are three integrity constraints that are usually imposed on each instance of a relation: primary key integrity, entity integrity, and referential integrity. The key integrity constraint requires that no two tuples of a relation have the same key value. The entity integrity constraint specifies that the key value of each tuple should have a known value (i.e., no *null* values are allowed for primary keys). The referential integrity constraint specifies that if a relation r_1 contains a foreign key that matches the primary key of a relation r_2, then each value of the foreign key in r_1 must either match a value of the primary key in r_2 or must be null. For the database of Fig. 94.2 to be consistent, each value of dept in FAC_INFO must match a value of dept in DEP_CHAIR.

Relational Database Design

The relational database design [Maier, 1983] refers to the process of generating a set of relation schemes that minimizes data redundancy and removes update anomalies. One of the most popular approaches is the use of the *normalization theory*. The normalization theory is based on the notion of *functional dependencies*.

Functional dependencies are constraints imposed on a database. The notion of superkey, introduced in the previous section, can be formulated as follows: A subset of a relation scheme is a superkey if, in any instance of the relation, no two distinct tuples have the same superkey value. If $r(R)$ is used to denote a relation r on a schema R, $K \subseteq R$ a superkey, and $t(k)$ the K-value of tuple t, then no two tuples t_1 and t_2 in $r(R)$ are such that $t_1(K) = t_2(K)$.

The notion of a functional dependency can be seen as a generalization of the notion of superkey. Let X and Y be two subsets of R; the functional dependency $X \rightarrow Y$ exists in $r(R)$ if whenever two tuples in $r(R)$ have the same X-value, their Y-value is also the same. That is, if $t_1(X) = t_2(X)$, then $t_1(Y) = t_2(Y)$. Using functional dependencies, one can define the notion of a key more precisely. A key k of a relation $r(R)$ is such that $k \rightarrow R$ and no proper subset of k has this property. Note that if the schema R is composed of attribute names $\{A_1, A_2, \ldots, A_n\}$, then each attribute name A_i is functionally determined by the key k, i.e., $k \rightarrow A_i$, $i = 1, \ldots, n$. An

attribute name that is part of a key is referred to as a *prime attribute*. In the example of Fig. 94.2, both attribute names street and city are nonprime attributes.

The normalization process can be thought of as the process of decomposing a scheme with update anomalies and data redundancy into smaller schemes in which these undesirable properties are to a large extent eliminated. Depending on the severity of these undesirable properties, schemes are classified into *normal forms*. Originally, Codd defined three normal forms: *first normal form* (1NF), *second normal form* (2NF), and *third normal form* (3NF). Thereafter, a stronger version of the 3NF, known as Boyce-Codd normal form (BCNF), was suggested. These four normal forms are based on the concept of functional dependencies.

The 1NF requires that attribute name values be *atomic*. That is, composite values for attribute names are not allowed. A 2NF scheme is a 1NF scheme in which all nonprime attributes are fully dependent on the key. Consider the relation of Fig. 94.3. Each tuple in PRODUCT gives the name of a supplier, a product name, its price, and the supplier's location. The scheme (supplier_name, product_name, price, quantity) is in 1NF since each attribute name is atomic. It is assumed that many products can be supplied by a single supplier, that a given product can be supplied by more than one supplier, and that a supplier has only one location. So, (supplier_name, product_name) is the relation's key and the functional dependency supplier_name $\rightarrow$ location should hold for any instance of PRODUCT.

The structure of the relation of Fig. 94.3 does not allow a supplier to appear in the relation unless it offers at least one product. Even the use of null values is not of much help in this case as product_name is part of a key and therefore cannot be assigned a null value. Another anomaly can be encountered during the deletion process. For instance, deleting the last tuple in the relation results in the loss of the information that Rudd is a supplier located in Metairie. It is seen that the relation PRODUCT suffers from insertion and deletion anomalies.

Modifications can also be a problem in the relation PRODUCT. Suppose that the location of the supplier Martin is moved from Kenner to Slidell. In order not to violate the functional dependency supplier_name $\rightarrow$ location, the location attribute name of all tuples where the supplier is Martin needs to be changed from Kenner to Slidell. This modification anomaly has a negative effect on performance.

In addition, the relation PRODUCT suffers from data redundancy. For example, although Martin has only one location "Kenner", such a location appears in all three tuples where the supplier_name is Martin.

The update anomalies and data redundancy encountered in PRODUCT are all due to the functional dependency supplier_name $\rightarrow$ location. The right-hand side of this dependency "location" is a nonprime attribute, and the left-hand side represents part of the key. Therefore, we have a nonprime attribute that is only partially dependent on the key (supplier_name, product_name). As a consequence, the schema (supplier_name, product_name, price, location) is not in 2NF. The removal of the partial dependency supplier_name $\rightarrow$ location will eliminate all the above anomalies. The removal of the partial dependency is achieved by decomposing the scheme (supplier_name, product_name, price, quantity) into two 2NF schemes: (supplier_name, product_name, price), and (supplier_name, location). This decomposition results in relations PRO_INFO and SUP_LOC shown in Fig. 94.4. The keys of PRO_INFO and SUP_LOC are (supplier_name, product_name), and supplier_name, respectively.

Normalizing schemes into 2NF removes all update anomalies due to nonprime attributes being partially dependent on keys. Anomalies of a different nature, however, are still possible.

Update anomalies and data redundancy can originate from *transitive dependencies*. A nonprime attribute A_i is said to be transitively dependent on a key k via attribute name A_j, if $k \rightarrow A_j$, $A_j \rightarrow A_i$, and A_j does not functionally determine A_k. A 3NF is a 1NF where no nonprime attribute is transitively dependent on a key.

FIGURE 94.6 Decomposition of SUPPLIES into SUP_CLI and SUP_LOC.

The relation of Fig. 94.5, which is in 2NF, highlights update anomalies and data redundancy due to the transitive dependency of a nonprime attribute on a key. The relation gives the name of a client (client_name), the corresponding supplier (supplier_name), and the supplier's location. Each client is assumed to have one supplier. The relation's key is client_name, and each supplier has only one location. A supplier and his location cannot be inserted in SUPPLIES unless the supplier has at least one client. In addition, the relation has a deletion anomaly since if Tillis is no longer a client of Rudd, the information about Rudd as a supplier and his location is lost. A change to a supplier's location may require updating the location attribute name of several tuples in the relation. Also, although each supplier has only one location, such a location is sometimes repeated several time unnecessarily, leading to data redundancy.

The relation exhibits the following transitive dependency: client_name $\rightarrow$ supplier_name, supplier_name $\rightarrow$ location (but not the inverse). The relation CLIENT is clearly in 2NF, but because of the transitive dependency of the nonprime attribute location on the key, it is not in 3NF. This is the cause of the anomalies mentioned above. Eliminating this transitive dependency by splitting the schema into two components will remove these anomalies. Clearly, the resulting two relations SUP_CLI and SUP_LOC are in 3NF (see Fig. 94.6).

Each partial dependency of a nonprime attribute on a key can be expressed as a transitive dependency of a nonprime attribute on a key. Therefore, a scheme in 3NF is also in 2NF.

BCNF is a stricter form of 3NF, where a relation r on a schema R is in BCNF if whenever a functional dependency $X \rightarrow Y$ exists in $r(R)$, then X is a superkey of R. The condition of 3NF, which allows Y to be prime if X is not a superkey, does not exist in BCNF. Thus, every scheme in BCNF is also in 3NF, but the opposite is not always true.

A detailed discussion of higher level normalizations, such as 4NF and 5NF, which are based on other forms of dependencies, can be found in [Elmasri and Navathe, 1994].

Data Definition and Manipulation in Relational Databases

Upon completion of the relational database design, a descriptive language, usually referred to as Data Definition Language (DDL), is used to define the designed schemes and their relationships. The DDL can be used to create new schemes or modify existing ones, but it cannot be used to query the database. Once DDL statements are compiled, they are stored in the *data dictionary*. A data dictionary is a repository where information about database schemas, such as attribute names, indexes, and integrity constraints are stored. Data dictionaries also contain other information about databases, such as design decisions, usage standards, application program descriptions, and user information. During the processing of a query, the DBMS usually checks the data dictionary. The data dictionary can be seen as a relational database of its own. As a result, data manipulation languages that are used to manipulate databases can also be used to query the data dictionary.

An important function of a DBMS is to provide a Data Manipulation Language (DML) with which a user can retrieve, change, insert, and delete data from the database. DMLs are classified into two types: *procedural* and *nonprocedural*. The main difference between the two types is that in procedural DMLs, a user has to specify the desired data and how to obtain it, while in nonprocedural DMLs, a user has only to describe the desired data. Because they impose less burden on the user, nonprocedural DMLs are normally easier to learn and use.

The component of a DML that deals with data retrieval is referred to as *query language*. A query language can be used interactively in a stand-alone manner, or it can be embedded in a general-purpose programming language such as C and Cobol.

One of the most popular query languages is SQL (Structured Query Language). SQL is a query language based to a large extent on Codd's *relational algebra*. SQL has additional features for data definition and update. Therefore, SQL is a comprehensive relational database language that includes both a DDL and DML.

SQL includes the following commands for data definition: CREATE TABLE, DROP TABLE, and ALTER TABLE. The CREATE TABLE is used to create and describe a new relation. The two relations of Fig. 94.4 can be created in the following manner:

```
CREATE TABLE PRO_INFO   (supplier_name   VARCHAR(12)     NOT NULL,
                         product_name    VARCHAR(8)      NOT NULL,
                         price           DECIMAL(6,2));
CREATE TABLE SUP_LOC    (supplier_name   VARCHAR(12)     NOT NULL,
                         location        VARCHAR(10));
```

The CREATE TABLE command specifies all the attribute names of a relation and their data types (e.g., INTEGER, DECIMAL, fixed length character "CHAR", variable length character "VARCHAR", DATE). The constraint NOT NULL is usually specified for those attributes that cannot have null values. The primary key of each relation in the database is usually required to have a nonnull value.

If a relation is created incorrectly, it can be deleted using the DROP TABLE command. The command is DROP TABLE followed by the name of the relation to be deleted. A variation of DROP command, DROP SCHEMA, is used if the whole schema is no longer needed.

The ALTER TABLE is used to add new attribute names to an existing relation, as follows:

```
ALTER TABLE SUP_LOC ADD zip_code CHAR(5);
```

The SUP_LOC relation now contains an extra attribute name, zip_code. In most DBMSs, the zip_code value of existing tuples will automatically be assigned a null value. Other DBMSs allow for the assignment of an initial value to a newly added attribute name. Also, definitions of attributes can be changed and new constraints can be added, or current constraints can be dropped.

The DML component of SQL has one basic query statement, sometimes called a mapping, that has the following structure:

```
SELECT    <attribute_name list>
FROM      <relation_list>
WHERE     <restriction>
```

PROFESSOR *(faculty,*	*department,*	*salary)*
Smith	Electrical Eng.	$39,000
Joe	Mechanical Eng.	$35,000
Susan	Computer Sci.	$36,000
Erick	Electrical Eng.	$38,000
Paul	Electrical Eng.	$37,000
Johannes	Computer Sci.	$65,000
Rick	Computer Sci.	$32,000
Gerard	Computer Sci.	$43,000
Kenneth	Mechanical Eng.	$40,000

FIGURE 94.7 Instance of the relation PROFESSOR.

In the above statement, the SELECT clause specifies the attribute names that are to be retrieved, FROM gives the list of the relations involved, and WHERE is a Boolean predicate that completely specifies the tuples to be retrieved.

Consider the database of Fig. 94.4, and suppose that we want the name of all suppliers that supply either beds or desks. In SQL, this query can be expressed as:

```
SELECT    supplier_name
FROM      PRO_INFO
WHERE     product_name = "bed" OR product_name = "sofa"
```

The result of an SQL command may contain duplicate values and is therefore not always a true relation. In fact, the result of the above query, shown below, has duplicate entries.

```
supplier_name
Martin
Martin
Rudd
```

The entry Martin appears twice in the result, because the supplier Martin supplies both beds and sofas. Removal of duplicates is usually a computationally intensive operation. As a result, duplicate entries are not automatically removed by SQL. To ensure uniqueness, the command DISTINCT should be used. In the above query, if we want the supplier names to be listed only once, the above query should be modified as follows:

```
SELECT DISTINCT   supplier_name
FROM              PRO_INFO
WHERE             product_name = "bed" OR product_name = "sofa"
```

In SQL, a query can involve more than one relation. Suppose that we want the list of all suppliers from Metairie who supply beds. Such a query, shown below, involves both PRO_INFO and SUP_LOC.

```
SELECT    supplier_name
FROM      PRO_INFO, SUP_LOC
WHERE     PRO_INFO.supplier_name = SUP_LOC.supplier_name
                                AND product_name = "bed"
```

When an SQL expression, such as the one above, involves more than one relation, it is sometimes necessary to qualify attribute names, that is, to precede an attribute name by the relation (a period is placed between the two) it belongs to. Such a qualification removes possible ambiguities.

In SQL, it is possible to have several levels of query nesting; this is done by including a SELECT query statement within the WHERE clause.

The output data can be presented in sorted order by using the SQL ORDER BY clause followed by the attribute name(s) according to which the output is to be sorted.

In database management applications it is often desirable to categorize the tuples of a relation by the values of a set of attributes and extract an aggregated characteristic of each category. Such database management tasks are referred to as *aggregation functions*. For instance, SQL includes the following built-in aggregation functions: SUM, COUNT, AVERAGE, MIN, MAX. The attribute names used for the categorization are referred to as

GROUP BY columns. Consider the relation PROFESSOR of Fig. 94.7. Each tuple of the above relation gives the name of a faculty and his department and academic year salary.

Suppose that we want to know the number of faculty in each department and the result to be ordered by department. This query requests for each department a count of the number of faculty. Faculty are therefore categorized according to the attribute name department. As a result, department is referred to as a GROUP BY attribute. In SQL, the above query is formulated as follows:

```
SELECT      department, COUNT (faculty)
FROM        PROFESSOR
GROUP BY    department
ORDER BY    department
```

The result of applying the COUNT aggregation function is a new relation with two attribute names. They are a GROUP BY attribute (department in this case) and a new attribute called COUNT. The tuples are ordered lexicographically in ascending order according to the ORDER BY attribute, which is department in this case:

```
department          COUNT (faculty)
Computer Sc.          4
Electrical Eng.       3
Mechanical Eng.       2
```

The relations created through the CREATE TABLE command are known as *base relations*. A base relation exists physically and is stored as a file by the DBMS. SQL can be used to create views using the CREATE VIEW command. In contrast to base relations, the creation of a view results in a *virtual relation*, that is, one that does not necessarily correspond to a physical file. Consider the database of Fig. 94.4, and suppose that we want to create a view giving the name of all suppliers located in Metairie, the products each one provides, and the corresponding prices. Such a view, called METAIRIE_SUPPLIER, can be created as follows:

```
CREATE VIEW     METAIRIE_SUPPLIER
AS SELECT       PRO_INFO.supplier_name, product_name, price
FROM            PRO_INFO, SUP_LOC
WHERE           PRO_INFO.supplier_name = SUP_LOC.supplier_name
                                  AND location = "Metairie"
```

Because a view is a virtual relation that can be constructed from one or more relations, updating a view may lead to ambiguities. As a result, when a view is generated from more than one relation, there are, in general, restrictions on updating such a view.

Hierarchical Databases

The hierarchical data model [Elmasri and Navathe, 1994] uses a tree data structure to conceptualize associations between different record types. In this model, record types are represented as nodes and associations as links. Each record type, except the root, has only one parent; that is, only parent-child (or one-to-many) relationships are allowed. This restriction gives hierarchical databases their simplicity. Since links are only one way, from a parent to a child, the design of hierarchical database management systems is made simpler, and only a small set of data manipulation commands are needed.

Because only parent-child relationships are allowed, the hierarchical model cannot efficiently represent two main types of relationships: many-to-many relationships and the case where a record type is a child in more than one *hierarchical schema*. These two restrictions can be handled by allowing redundant *record instances*. However, such a duplication requires that all the copies of the same record should be kept consistent at all times.

The example of Fig. 94.8 shows a hierarchical schema. The schema gives the relationship between a DEPARTMENT, its employees (D_EMPLOYEE), the projects (D_PROJECT) handled by the different departments, and how employees are assigned to these projects. It is assumed that an employee belongs to only one department, a project is handled by only one department, and an employee can be assigned to several projects. Notice that since a project has several employees assigned to it, and an employee can be assigned to more than one project, the relationship between D_PROJECT and D_EMPLOYEE is many-to-many. To model this relationship multiple instances of the same record type D-EMPLOYEE may appear under different projects.

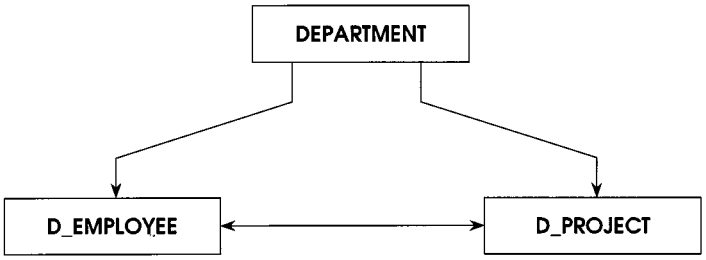

FIGURE 94.8 A hierarchical schema.

Such redundancies can be reduced to a large extent through the use of *logical links*. A logical link associates a *virtual record* from a hierarchical schema with an actual record from either the same schema or another schema. The redundant copy of the actual record is therefore replaced by a virtual record, which is nothing more than a pointer to the actual one.

Hierarchical DLLs are used by a designer to declare the different hierarchical schemas, record types, and logical links. Furthermore, a root node must be declared for each hierarchical schema, and each record type declaration must also specify the parent record type.

Unlike relational DMLs, hierarchical DMLs such as DL/1 are record at-a-time languages. DL/1 is used by IBM's IMS hierarchical DBMS. In DL/1 a tree traversal is based on a preorder algorithm, and within each tree, the last record accessed through a DL/1 command can be located through a *currency indicator*.

Retrieval commands are of three types:

GET UNIQUE <record type> **WHERE** <restrictions>
Such a command retrieves the leftmost record that meets the imposed restrictions. The search always starts at the root of the tree pointed to by the currency indicator.

GET NEXT [<record type> **WHERE** <restrictions>]
Starting from the current position, this command uses the preodrer algorithm to retrieve the next record that satisfies the restrictions. The clause enclosed between brackets is optional. GET NEXT is used to retrieve the next (preorder) record from the current position.

GET NEXT WITHIN PARENT [<record type> **WHERE** <restrictions>]
It retrieves all records that have the same parent and that satisfy the restrictions. The parent is assumed to have been selected through a previous GET command.
Four commands are used for record updates:

INSERT
Stores a new record and links it to a parent. The parent has been already selected through a GET command.

REPLACE
The current record (selected through a previous GET command) is modified.

DELETE
The current record and all its descendants are deleted.

GET HOLD
Locks the current record while it is being modified.

The DL/1 commands are usually embedded in a general-purpose (host) language. In this case, a record accessed through a DL/1 command is assigned to a program variable.

Network Databases

In the network model [Elmasri and Navathe, 1994] associations between record types are less restrictive than with the hierarchy model. Here, associations among record types are represented as graphs.

One-to-one and one-to-many relationships are described using the notion of *set type*. Each set type has an *owner* record type and a *member* record type. In the example of Fig. 94.8, the relationship between DEPARTMENT and

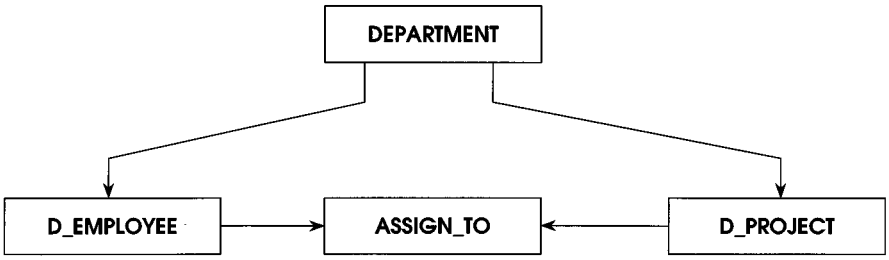

FIGURE 94.9 Representing many-to-many relationships in the network model.

employee (D_EMPLOYEE) is one-to-many. This relationship defines a set type where the owner record type is DEPARTMENT and the member record type is D_EMPLOYEE. Each instance of an owner record type along with all the corresponding member records represents a set instance of the underlying set type. In practice, a set is commonly implemented using a circular-linked list which allows an owner record to be linked to all its member records. The pointer associated with the owner record is known as the FIRST pointer, and the one associated with a member record is known as a NEXT pointer.

In general, a record type cannot be both the owner and a member of the same set type. Also, a record cannot exist in more than one instance of a specific set type. The latter requirement implies that many-to-many relationships are not directly implemented in the network data model.

The relationship between D_PROJECT and D-EMPLOYEE is many-to-many. In the network model, this relationship is represented by two set types and an intermediate record type. The new record type could be named ASSIGNED_TO (see Fig. 94.9). One set has D_EMPLOYEE as owner and ASSIGNED_TO as member record type, and the other has D_PROJECT as owner and ASSIGNED_TO as member record type.

Standards for the network model's DDL and DML were originally proposed by the CODASYL (Conference On Data SYstems Languages) committee in 1971. Several revisions to the original proposal were made later.

In a network DDL, such as that of the IDMS database management system, a set declaration specifies the name of the set, its owner record type, and its member record type. The insertion mode for the set members needs to be specified using combinations of the following four commands:

AUTOMATIC
An inserted record is automatically connected to the appropriate set instance.

MANUAL
In this case, records are inserted into the appropriate set instance by an application program.

OPTIONAL
A member record does not have to be a member of a set instance. The member record can be connected to or disconnected from a set instance using DML commands.

MANDATORY
A member record needs to be connected to a set instance. A member record can be moved to another set instance using the network's DML.

FIXED
A member record needs to be connected to a set instance. A member record cannot be moved to another set instance.

The network's DDL allows member records to be ordered in several ways. Member records can be sorted in ascending or descending order according to one or more fields. Alternatively, a new member record can be inserted next (prior) to the current record (pointed to by the currency indicator) in the set instance. A newly inserted member record can also be placed first (or last) in the set instance. This will lead to a chronological (or reverse chronological) order among member records.

As with the hierarchy model, network DMLs are record-at-a-time languages, and currency indicators are necessary for navigation through the network database. For example, the IDMS main data manipulation commands can be summarized as follows:

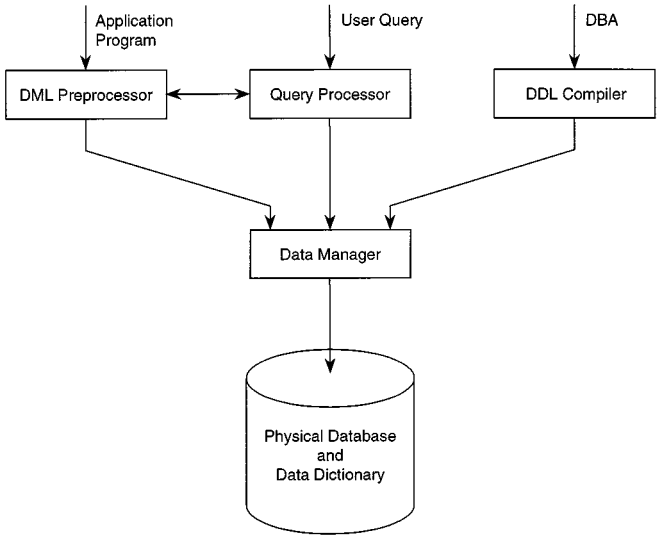

FIGURE 94.10 Simplified architecture of a DBMS.

`CONNECT`
Connects a member record to the specified set instance.

`DISCONNECT`
A member record is disconnected from a set instance (set membership must be manual in this case).

`STORE, MODIFY,` and **`DELETE`**
These commands are used for data storage, modification, and deletion.

`FIND`
Retrieval command based on set membership.

`GET`
Retrieval command based on key values.

Architecture of a DBMS

A DBMS is a complicated software structure that includes several components (see Fig. 94.10). The DBMS has to interact with the operating system for secondary storage access. The *data manager* is usually the interface between the DBMS and the operating system. The *DDL compiler* converts schema definitions, expressed using DDL statements, into a collection of metadata tables that are stored in the data dictionary. The design of the schemas is the function of the *database administrator* (DBA). The DBA is also responsible for specifying the data storage structure and access methodology and granting and revoking access authorizations. The *query processor* converts high-level DML statements into low-level instructions that the database manager can interpret. The *DML preprocessor* separates embedded DML statements from the rest of an application program. The resulting DML commands are processed by a DML compiler, and the rest of the application program is compiled by a host compiler. The object codes of the two components are then linked.

Data Integrity and Security

Data Integrity

In general, during the design of a database schema several integrity constraints are identified. These constraints may include the uniqueness of a key value, restrictions on the domain of an attribute name, and the ability of an attribute to have a null value. A DBMS includes mechanisms with which integrity constraints can be specified. Constraints such as key uniqueness and the admissibility of null values can be specified during schema definition. Also, more elaborate integrity constraints can be specified. For example, constraints can be imposed

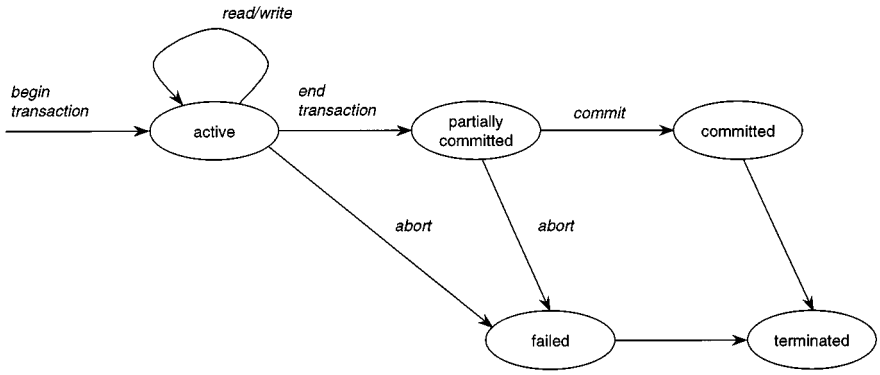

FIGURE 94.11 State transition diagram for transaction execution.

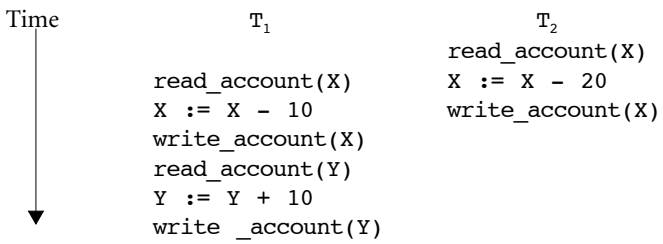
on the domain of an attribute name, and any transaction that violates the imposed constraints is aborted. In some cases, it is useful to specify that the system take some actions, rather than just have the transaction responsible for the constraint violation being aborted. A mechanism called *trigger* can be used for that purpose. A trigger specifies a condition and an action to be taken when the condition is met.

Transactions and Data Integrity

In a multiuser DBMS, the database is a shared resource that can be accessed concurrently by many users. A *transaction* usually refers to the execution of a retrieval or an update program. A transaction performs a single logical operation in a database application. Therefore, it is an *atomic* unit of processing. That is, a transaction is either performed in its entirety or is not performed at all. Basically, a transaction may be in one of the following states (Fig. 94.11):

- active — where read and write operations are performed.
- partially committed — when the transaction ends and various checks are made to ensure that the transaction did not interfere with other transactions.
- failed — when one of the checks failed or the transaction is aborted during the active state.
- committed — when the execution was successfully completed.
- terminated — when the transaction leaves the system.

Transactions originating from different users may be aimed at the same database records. This situation, if not carefully monitored, may cause the database to become *inconsistent*. Starting from a database in a consistent state, it is obvious that if all transactions are executed one after the other, then the database will remain in a consistent state. In a multiuser DBMS, serial execution of transactions is wasteful of system resources. In this case, the solution is to interleave the execution of the transactions. However, the interleaving of transactions has to be performed in a way that prevents the database from becoming inconsistent. Suppose that two transactions T_1 and T_2 proceed in the following way:



The first transaction transfers $10 from bank account X to bank account Y. The second transaction withdraws $20 from bank account X. Assume that initially there was $200 in X and $100 in Y. When the two transactions are performed serially, the final amounts in X and Y are $170 and $110, respectively. However, if the two transactions are interleaved as shown, then after the completion of both transactions, there will be $190 in X and $110 in Y. The database is now in an inconsistent state.

It is therefore important to ensure that the interleaving of the execution of transactions leaves the database in a consistent state. One way of preserving data consistency is to ensure that the interleaved execution of transactions is equivalent to their serial execution. This is referred to as *serializable* execution. Therefore, an interleaved execution of transactions is said to be serializable if it is equivalent to a serial execution.

Locking is one of the most popular approachs to achieving serializability. Locking is the process of ensuring that some actions are not performed on a data item. Therefore, a transaction may request a lock on a data item to prevent it from being either accessed or modified by other transactions. There are two basic types of locks. A *shared lock* allows other transactions to read but not write to the data item. An *exclusive lock* allows only a single transaction to read and write a data item. To achieve a high degree of concurrency, the locked data item size must be as small as possible. A data item can range from the whole database to a particular field in a record. Large data items limit concurrency, while small data items result in a large storage overhead and a greater number of lock and unlock operations that the system will have to handle.

Transactions scheduling based on locking achieves serializability in two phases. This is known as *two-phase locking*. During the first phase, the growing phase, a transaction can only lock new data items, but it cannot release any locked ones. During the second phase, the shrinking phase, existing locks can be released, but no new data item can be locked. The two-phase locking scheme guarantees the serializability of a schedule.

Because of its simplicity, the above scheduling method is very practical. However, it may lead to a *deadlock*. A deadlock occurs when two transactions are waiting for each other to release locks and both cannot proceed. A deadlock prevention (or detection) strategy is needed to handle the situation. For example, this can be achieved by requiring that a transactions locks all data items it needs for its execution before it can proceed; when the transaction finds that a needed data item is already locked, then it releases all locks.

If a transaction fails for whatever reason after (partially committed) or (active) while updating the database, it may be necessary to bring the database to its previous (original) state by undoing the transaction. This operation is called *roll-back*. A roll-back operation requires some information about the changes made on the data items during a transaction. Such information is usually kept outside the database in a system log. Generally, roll-back operations are part of the techniques used to recover from transaction failures.

Database Security

A database needs to be protected against unauthorized access. It is the responsibility of the DBA to create account numbers and passwords for legitimate users. The DBA can also specify the type of privileges a particular account has. In relational databases, this includes the privilege to create base relations, create views, alter relations by adding or dropping a column, and delete relations. The DBA can also revoke privileges that were granted previously. In SQL, the command GRANT is used to grant privileges and the REVOKE command to revoke privileges that have been granted.

The concept of views can serve as a convenient security mechanism. Consider a relation EMPLOYEE that gives the name of an employee, date of birth, the department worked for, address, phone number, and salary. A database user who is not allowed to have access to the salary of employees from his own department can have this portion of the database hidden from him. This can be achieved by limiting his access to a view obtained from the relation EMPLOYEE by selecting only those tuples where the department attribute is different from his.

Database security can be enhanced by using *data encryption*. The idea here is to encrypt the data using some coding technique. An unauthorized user will have difficulty deciphering the encrypted data. Only authorized users are provided with keys to decipher the encoded data.

Emerging Trends

Object-Oriented Databases

Object-oriented database systems (OODBMSs) [Brown, 1991] are one of the latest trends in database technology. The emergence of OODBMS is in response to the requirements of advanced applications. In general, traditional commercial and administrative applications can be effectively modeled using one of the three record-based data models. These applications are characterized by simple data types. Furthermore, for such applications, access and relationships are based on data values. Advanced database applications such as those found in engineering CAD/CAM require complex data structures. When these applications are modeled using the relational model, they require an excessive number of relations. In addition, a large number of complex

operations are usually needed to produce an answer. This leads, in most cases, to unacceptable performance levels.

The notion of "object" is central to OODBMS. An object can be seen as being an entity consisting of its own *private memory* and *external interface* (or protocol). The private memory is used to store the state of the object, and the external interface consists of a set of operations that can be performed on the object. An object communicates with other objects through messages sent to its external interface. When an object receives a message, it responds by using its own procedures, known as *methods*. The methods are responsible for processing the data in the object's private memory and sending messages to other objects to perform specific tasks and possibly send back appropriate results.

The object-oriented approach provides for a high level of *abstraction*. In addition, this model has constructs that can be used to define new data types and specialized operators that can be applied to them. This feature is known as *encapsulation*.

An object is usually a member of a class. The class specifies the internal structure and the external interface of an object. New object classes can be defined as a *specialization* of existing ones. For example, in a university environment, the object type "faculty" can be seen as a specialization of the object type "employee." Since a faculty is a university employee, it has all the properties of a university employee plus some of its own. For example, some of the general operations that can be performed on an employee could be "raise_salary," "fire_employee," "transfer_employee." For a faculty, specialized operations such as "faculty_tenure" could be defined. Faculty can be viewed as a subclass of employee. As a result, faculty (the subclass) will respond to the same messages as employee (the superclass) in addition to those defined specifically for faculty. This technique is known as *inheritance*. A subclass is said to inherit the behavior of its superclass.

Opponents to the object-oriented paradigm point to the fact that while this model has greater modeling capability, it lacks the simplicity and the strong theoretical foundations of the relational model. Also, the reappearance of the navigational approach is seen by many as a step backward.

Supporters of the object-oriented approach believe that a navigational approach is a necessity in several applications. They point to the rich modeling capability of the model, its high level of abstraction, and its suitability for modular design.

Distributed Databases

A **distributed database** [Ozsu and Valdurez, 1991] is a collection of interrelated databases spread over the nodes of a computer network. The management of the distributed database is the responsibility of a software system usually known as distributed DBMS (DDBMS). One of the tasks of the DDBMS is to make the distributed nature of the database transparent to the user. A distributed database usually reflects the distributed nature of some applications. For example, a bank may have branches in different cities. A database used by such an organization is usually distributed over all these sites. The different sites are connected by a computer network. A user may access data stored locally or access data stored at other sites through the network.

Distributed databases have several advantages. In distributed databases, the effect of a site failure or data loss at a particular node can be minimized through data replication. However, data replication reduces security and makes the process of keeping the database consistent more complicated.

In distributed databases, data is decomposed into fragments that are allocated to the different sites. A fragment is allocated to a site in a way that maximizes local use. This allocation scheme, which is known as *data localization*, reduces the frequency of remote access. In addition, since each site deals with only a portion of the database, local query processing is expected to exhibit increased performance.

A distributed database is inherently well suited for parallel processing at both interquery and intraquery levels. Parallel processing at the interquery level is the ability to have multiple queries executed concurrently. Parallelism at the intraquery level results from the possibility of a single query being simultaneously handled by many sites, each site acting on a different portion of the database.

The data distribution increases the complexity of DDBMS over a centralized DBMS. In fact, in distributed databases, several research issues in distributed query processing, distributed database design, and distributed transaction processing remain to be solved. It is only then that the potential of distributed databases can be fully appreciated.

Parallel Database Systems

There has been a continuing increase in the amount of data handled by database management systems (DBMSs) in recent years. Indeed, it is no longer unusual for a DBMS to manage databases ranging in sizes from hundreds of gigabytes to terabytes. This massive increase in database sizes is coupled with a growing need for DBMSs to exhibit more sophisticated functionality such as the support of object-oriented, deductive, and multimedia applications. In many cases, these new requirements have rendered existing DBMSs unable to provide the necessary system performance, especially given that many mainframe DBMSs already have difficulty meeting the I/O and CPU performance requirements of traditional information systems that service large numbers of concurrent users and/or handle massive amounts of data [DeWitt and Gray, 1992].

To achieve the required performance levels, database systems have been increasingly required to make use of parallelism. Two approaches were suggested to provide parallelism in database systems [Abdelguerfi and Lavington, 1995]. The first approach uses massively parallel general-purpose hardware platforms. Commercial systems, such as Intel's nCube and IBM's SP2 follow this approach and support Oracle's Parallel Server. The second approach makes use of arrays of off-the-shelf components to form custom massively parallel systems. Usually, these hardware systems are based on MIMD parallel architectures. The NCR 3700 and the Super Database Computer II (SDC-II) are two such systems. The NCR 3700 now supports parallel version of Sybase relational DBMS.

The number of general purpose or dedicated parallel database computers is increasing each year. It is not unrealistic to envisage that most high performance database management systems in the year 2000 will support parallel processing. The high potential of parallel databases in the future urges both the database vendors and practitioners to understand the concept of parallel database system in depth.

It is noteworthy that in recent years, popularity of the client/server architecture has increased. This architecture is practically a derivative of shared-nothing case. In this model, clients' nodes access data through one or more servers. This approach derives its strength from an attractive price/performance ratio, a high level of scalability, and the ease with which additional remote hosts can be integrated into the system. Another driving force of the client/server approach is the current trend toward corporate downsizing.

Multimedia

Yet another new generation database application is multimedia, where non-text forms of data, such as voice, video, and image, are accessed via some form of a user interface. Hypermedia interfaces are becoming the primary delivery system for the multimedia applications. These interfaces, such as Mosaic, allow users to browse through an information base consisting of many different types of data. The basis of hypermedia is the hypertext, where some text based information is accessed in a non-sequential manner. Hypermedia is an extension of hypertext paradigm into multimedia.

Defining Terms

Database: A shared pool of interrelated data.

Database computer: A special hardware and software configuration aimed primarily at handling large databases and answering complex queries.

Database management system (DBMS): A software system that allows for the definition, construction, and manipulation of a database.

Data model: An integrated set of tools to describe the data and its structure, data relationships, and data constraints.

Distributed database: A collection of multiple, logically interrelated databases distributed over a computer network.

94.2 Rule-Based Expert Systems

Jay Liebowitz

Expert systems is probably the most practical application of artificial intelligence (AI). Artificial intelligence, as a field, has two major thrusts: (1) to supplement human brain power with intelligent computer power and (2) to better understand how we think, learn, and reason. Expert systems are one application of AI, and they are being developed and used throughout the world [Feigenbaum et al., 1988; Liebowitz, 1990]. Other major applications of AI are robotics, speech understanding, natural-language understanding, computer vision, and neural networks.

Expert systems are computer programs that emulate the behavior of a human expert in a well-bounded domain of knowledge [Liebowitz, 1988]. They have been used in a number of tasks, ranging from sheep reproduction management in Australia, hurricane damage assessment in the Caribbean, boiler plant operation in Japan, computer configuration in the United States, to strategic management consulting in Europe [Liebowitz, 1991b]. Expert systems technology has been around since the late 1950s, but it has been only since 1980–1981 that the commercialization of expert systems has emerged [Turban, 1992].

An expert system typically has three major components: the dialog structure, inference engine, and knowledge base [Liebowitz and DeSalvo, 1989]. The dialog structure is the user interface that allows the user to interact with the expert system. Most expert systems are able to explain their reasoning, in the same manner that one would want human experts to explain their decisions. The inference engine is the control structure within the expert system that houses the search strategies to allow the expert system to arrive at various conclusions. The third component is the **knowledge base,** which is the set of facts and heuristics (rules of thumb) about the specific domain task. The knowledge principle says that the power of the expert system lies in its knowledge base. Expert system shells have been developed and are widely used on various platforms to help one build an expert system and concentrate on the knowledge base construction. Most operational expert systems are integrated with existing databases, spreadsheets, optimization modules, or information systems [Mockler and Dologite, 1992].

The most successful type of expert system is the rule-based, or production, system. This type of expert system is chiefly composed of IF-THEN (condition-action) rules. For example, the infamous MYCIN expert system, developed at Stanford University for diagnosing bacterial infections in the blood (meningitis), is rule-based, consisting of 450–500 rules. XCON, the expert system at Digital Equipment Corporation used for configuring VAX computer systems, is probably the largest rule-based expert system, consisting of over 11,000 rules. There are other types of expert systems that represent knowledge in ways other than rules or in conjunction with rules. Frames, scripts, and semantic networks are popular knowledge representation methods that could be used in expert systems.

The development of rule-based systems is typically called **knowledge engineering.** The knowledge engineer is the individual involved in the development and deployment of the expert system. Knowledge engineering, in rule-based systems, refers primarily to the construction of the knowledge base. As such, there are six major steps in this process, namely (1) problem selection, (2) knowledge acquisition, (3) knowledge representation, (4) knowledge encoding, (5) knowledge testing and evaluation, and (6) implementation and maintenance. The knowledge engineering process typically uses a rapid prototyping approach (build a little, test a little). Each of the six steps in the knowledge engineering process will be briefly discussed in turn.

Problem Selection

In selecting an appropriate application for expert systems technology, there are a few guidelines to follow:

- Pick a problem that is causing a large number of people a fair amount of grief.
- Select a "doable," well-bounded problem (i.e., task takes a few minutes to a few hours to solve)—this is especially important for the first expert system project for winning management's support of the technology.
- Select a task that is performed frequently.
- Choose an application where there is a consensus on the solution of the problem.
- Pick a task that utilizes primarily symbolic knowledge.
- Choose an application where an expert exists and is willing to cooperate in the expert systems development.
- Make sure the expert is articulate and available and a backup expert exists.
- Have the financial and moral support from management.

The problem selection and scoping are critical to the success of the expert systems project. As with any information systems project, the systems analysis stage is an essential and crucial part of the development process. With expert systems technology, if the problem domain is not carefully selected, then difficulties will ensue later in the development process.

Knowledge Acquisition

After the problem is carefully selected and scoped, the next step is knowledge acquisition. Knowledge acquisition involves eliciting knowledge from an expert or multiple experts and also using available documentation, regulations, manuals, and other written reports to facilitate the knowledge acquisition process. The biggest bottleneck in expert systems development has, thus far, been in the ability to acquire knowledge. Various automated knowledge acquisition tools, such as Boeing Computer Services' AQUINAS, have been developed to assist in this process, but there are very few knowledge acquisition tools on the market. The most commonly used approaches for acquiring/eliciting knowledge include: interviewing (structured and unstructured), protocol analysis, questionnaires (structured and open-ended), observation, learning by example/analogy, and other various techniques (Delphi technique, statistical methods).

To aid the knowledge acquisition process, some helpful guidelines are:

- Before interviewing the expert, make sure that you (as the knowledge engineer) are familiar/ comfortable with the domain.
- The first session with the expert should be an introductory lecture on the task at hand.
- The knowledge engineer should have a systematic approach to acquiring knowledge.
- Incorporate the input and feedback from the expert (and users) into the system—get the expert and users enthusiastic about the project.
- Pick up manuals and documentation on the subject material.
- Tape the knowledge acquisition sessions, if allowed.

Knowledge Representation

After acquiring the knowledge, the next step is to represent the knowledge. In a rule-based expert system, the IF-THEN (condition-action) rules are used. Rules are typically used to represent knowledge if the preexisting knowledge can best be naturally represented as rules, if the knowledge is procedural, if the knowledge is mostly context-independent, and if the knowledge is mostly categorical ("yes-no" type of answers). Frames, scripts, and semantic networks are used as knowledge representation schemes for more descriptive, declarative knowledge. In selecting an appropriate knowledge representation scheme, try to use the representation method which most closely resembles the way the expert is thinking and expressing his/her knowledge.

Knowledge Encoding

Once the knowledge is represented, the next step is to encode the knowledge. Many knowledge engineers use expert system shells to help develop the expert system prototypes. Other developers may build the expert system from scratch, using such languages as Lisp, Prolog, C, and others. The following general guidelines may be useful in encoding the knowledge:

- Remember that for every shell there is a perfect task, but for every task there is NOT a perfect shell.
- Consider using an expert system shell for prototyping/proof-of-concept purposes—remember to first determine the requirements of the task, instead of force-fitting a shell to a task.
- Try to develop the knowledge base in a modular format for ease of updating.
- Concentrate on the user interface and human factors features, as well as the knowledge base.
- Use an incremental, iterative approach.
- Consider whether uncertainty should play a part in the expert system.
- Consider if the expert reasons in a data-driven manner (forward chaining) or a goal-directed manner (backward chaining), or both.

Knowledge Testing and Evaluation

Once the knowledge is encoded in the system, testing and evaluation need to be conducted. Verification and validation refers to checking for the consistency of the knowledge/logic and checking the quality/accuracy of advice reached by the expert system. Various approaches to testing can be used, such as: performing "backcasting" by running the expert system (using a representative set of test cases) against documented cases and comparing the expert system-generated results with the historical results, using blind verification tests (modified Turing test), having the expert and other experts test the system, using statistical methods for testing, and others. In evaluating the expert system, the users should evaluate the design of the human factors in the system (i.e., instructions, free-text comments, ease of updating, exiting capabilities, response time, display and presentation of conclusions, ability to restart, ability for user to offer degree of certainty, graphics, utility of the system, etc.).

Implementation and Maintenance

Once the system is ready to be deployed within the organization, the knowledge engineer must be cognizant of various institutionalization factors [Liebowitz, 1991a; Turban and Liebowitz, 1992]. Institutionalization refers to implementing and transitioning the expert system into the organization. Frequently, the technology is not the limiting factor—the *management* of the technology is often the culprit. An expert system may be accurate and a technical success, but without careful attention to management and institutionalization considerations, the expert system may be a technology transfer failure. There are several useful guidelines for proper institutionalization of expert systems:

- Know the corporate culture in which the expert system is deployed.
- Planning for the institutionalization process must be thought out well in advance, as early as the requirements analysis stage.

- Through user training, help desks, good documentation, hotlines, etc., the manager can provide mechanisms to reduce "resistance to change."
- Solicit and incorporate users' comments during the analysis, design, development, and implementation stages of the expert system.
- Make sure there is a team/individual empowered to maintain the expert system.
- Be cognizant of possible legal problems resulting from the use and misuse of the expert system.
- During the planning stages, determine how the expert system will be distributed.
- Keep the company's awareness of expert systems at a high level throughout the system's development and implementation, and even after its institutionalization.

Defining Terms

Expert systems: A computer program that emulates a human expert in a well-bounded domain of knowledge.
Knowledge base: The set of facts and rules of thumb (heuristics) on the domain task.
Knowledge engineering: The process of developing an expert system.

95.1 Introduction

A computer usually consists of four major components: the arithmetic-logic unit (ALU), the main memory unit (MU), the input/output unit (I/O), and the control unit (CU). Such a computer is known as a uniprocessor since the processing is achieved by operating on one word or word pair at a time. In order to increase the computer performance, we may improve the device technology to reduce the switching (gate delay) time. Indeed, for the past half century we have seen switching speeds improve from 200 to 300 ms for relays to present-day subnanosecond very large scale integration (VLSI) circuits. As the switching speeds of computer devices approach a limit, however, any further significant improvement in performance is more likely to be in increasing the number of words or word pairs that can be processed simultaneously. For example, we may use one ALU to compute N sets of additions N times in a uniprocessor, or we may design a computer system with N ALUs to add all N sets once. Conceptually, such a computer system may still consist of the four major components mentioned previously except that there are N ALUs. An organization with multiple ALUs under the control of a single CU is called a **parallel processor.** To make a parallel processor more efficient and cost-effective, a fifth major component, called **interconnection networks,** is usually required to facilitate the interprocessor and processor-memory communications. In addition, each ALU requires not only its own registers but also network interfaces; the expanded ALU is then called a **processing element** (PE). Figure 95.1 shows a block diagram of a parallel processor.

95.2 Classifications

Flynn has classified computer systems according to the multiplicity of instruction and data streams, where computers are partitioned into four groups [Flynn, 1966]:

1. Single instruction stream, single data stream (SISD): The conventional, word-sequential architecture including pipelined computers (usually with parallel ALU)
2. Single instruction stream, multiple data stream (SIMD): The multiple ALU-type architectures (e.g., parallel/array processor). The ALU may be either bit-serial or bit-parallel.
3. Multiple instruction stream, single data stream (MISD): Not as practical as the other classes.
4. Multiple instruction stream, multiple data stream (MIMD): The multiprocessor system.

As a general rule, one could conclude that SISD and SIMD machines are single CU systems, whereas MIMD machines are multiple CU systems. Flynn's classification does not address the interactions among the processing

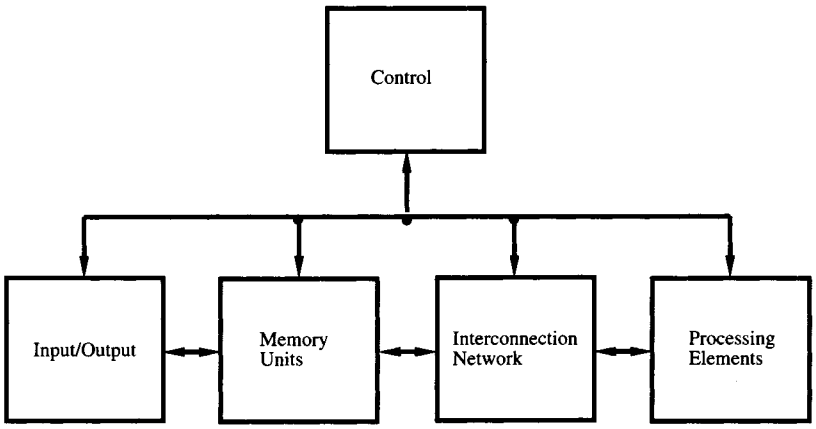

FIGURE 95.1 A basic parallel processor organization.

modules and the methods by which processing modules in concurrent system are controlled. As a result, one can classify both uniprocessors and pipelined computers as SISD machines, because both instructions and data are provided sequentially.

We may also classify computer systems according to the number of bits or bit pairs a computer executes at any instant [Feng, 1972]. For example, a computer may perform operations on one bit or bit pair at a time through the use of a simple serial ALU. For an M-bit word or operand, the operation repeats M times (Point A in Fig. 95.2). To speed up the processing, a parallel ALU is usually used so that all bits of a word can be operated on simultaneously. This is how a conventional word-sequential computer executes on its operands (Point B in Fig. 95.2). In a parallel processor, it may execute either (a) all the ith bits of N operands or operand pairs (i.e., bit slice or bis) or (b) all N M-bit operands or operand pairs simultaneously (Points C and D in Fig. 95.2, respectively). Figure 95.2 also shows some of the systems in this classification. It is seen from this classification that the performance of a computer is proportional to the total number of bits or bit pairs it can execute simultaneously.

Feng's classification [Hwang and Briggs, 1984] was originally intended for parallel processors, and as a result, the number of CUs in a computer system was not specified. Händler extended Feng's classification by adding a third dimension, namely, the number of CUs. Pipelined systems are also included in this classification through additional parameters [Händler, 1977].

95.3 Types of Parallel Processors

Ensemble Processors

An ensemble system is an extension of the conventional uniprocessor systems. It is a collection of N PEs (a PE here consists of an ALU, a set of local registers, and limited local control capability) and N MUs, under the control of a single CU. Thus, the organization of an **ensemble processor** is similar to that shown in Fig. 95.1 except that there are no direct interprocessor and processor-memory communications, i.e., no interconnection networks. When the need for communication arises, it is done through the CU. This slows down the system for applications requiring extensive interprocessor and processor-memory communications. For example, the sum of two matrices A and B can be executed in one step, if R^2 PEs are available in an ensemble processor, where R is the rank of the matrices. On the other hand, the product of the same two matrices requires extensive data alignment between the elements of A and B. As a result, it is ineffective for performing matrix multiplications with an ensemble processor. Therefore, while the ensemble processors are capable of executing up to N identical jobs simultaneously, they have very limited applications. Parallel element processing ensemble (PEPE) [Evensen and Troy, 1973] is an example of such parallel processors.

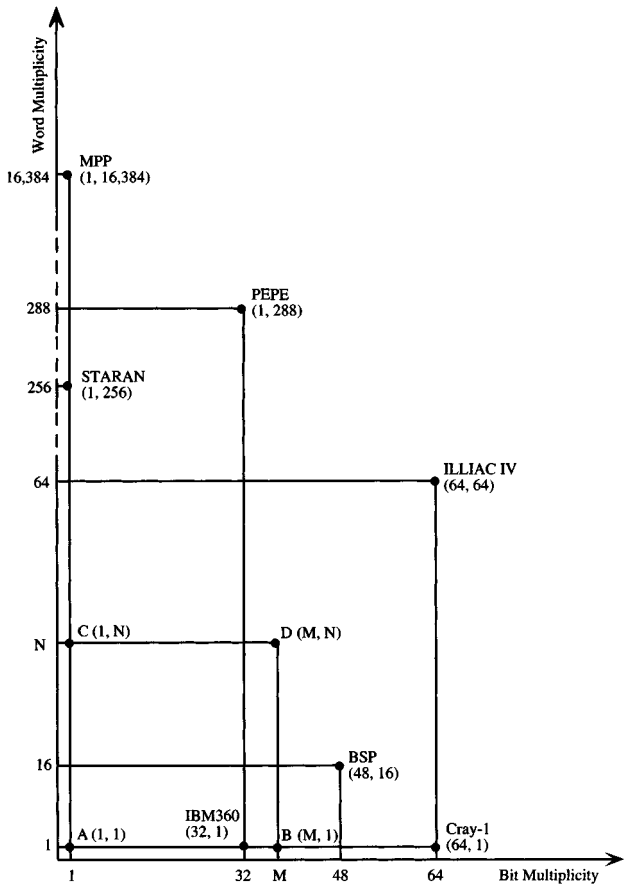

FIGURE 95.2 Feng's classification.

Array Processors

Because of the need for interprocessor and processor-memory communication for most applications, a parallel processor usually has one or more circuits (known as interconnection networks) to support various applications for efficient processing. In general, an **array processor** may consist of N identical PEs under the control of a single CU and a number of MUs. Within each PE there are circuits for network interface as well as its own local memories. The PEs and MUs communicate with each other through an interconnection network. A typical array processor organization is shown in Fig. 95.3. Depending on the design, each PE may perform serial-by-bit (as in MPP) or parallel-by-bit (as in ILLIAC IV) operations.

As can be seen from Fig. 95.3, the interconnection networks play a very important role in parallel processors. The network usually provides a uniform interconnection among PEs on one hand and PEs and MUs on the other. Different array processor organizations might use different interconnection networks. In general, the interconnection networks can be classified into two categories: static and dynamic, as shown in Fig. 95.4.

ILLIAC IV [Barnes et al., 1968] and MPP [Batcher, 1979] are examples of parallel processors using static interconnections, while STARAN [Batcher, 1973] and BSP [Kuck and Stokes, 1982] are examples using dynamic interconnections.

The CU usually has its own high-speed registers, local memory, and arithmetic unit. Thus, in many cases, it is a conventional computer and the instructions are stored in a main memory, together with data. However, in some machines such as ILLIAC IV, programs are distributed among the local memories of the PEs. Hence, the instructions are fetched from the processors' local memories into an instruction buffer in the CU. Each

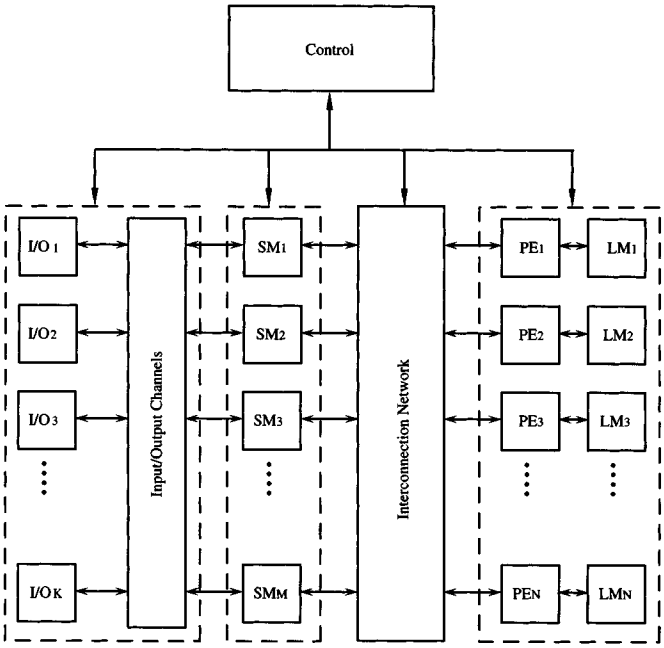

FIGURE 95.3 An array processor organization. I/O, input/output devices; LM, local memory; PE, processing element; SM, shared memory.

instruction is either a local type instruction, where it is executed entirely within the CU, or it is a parallel instruction and is executed in the processing array. The primary function of the CU is to examine each instruction as it is to be executed and to determine where the execution should take place.

Associative Processor

Associative memories, also known as content-addressable memories, retrieve information on the basis of data content rather than addresses. An associative memory performs comparison (i.e., exclusive-OR or equivalence) operations at its bit level. The results of the comparison on a group of bits in a word for all words in the memory are transmitted to a register called a response register or flag. In addition, there are circuits such as multiple match resolver, enable/disable register, a number of temporary registers, as well as appropriate logic gates for resolving multiple responses and information retrieval. For **associative processors,** arithmetic capabilities are added to this unit. The unit can be viewed as consisting of a number of bit-serial PEs. Furthermore, the bit-level logic is moved out of the memory so that the memory part of the processor consists of a number of random-access memories called word modules. A typical associative processor is shown in Fig. 95.5. STARAN and MPP (Fig. 95.2) are representative of this bit-serial, word-parallel SIMD organization. In Fig. 95.5 the common register is where the common operand is stored and the mask register defines the bit positions requiring operation. The enable/disable register provides local control of individual PEs. Because of its simplicity in design the per-PE cost of an associative processor is much lower, but the bit-serial operations slow down the system drastically. To compensate for this, these systems are useful only for applications requiring a large number of PEs.

95.4 System Utilization

As discussed previously, for any computer there is a maximum number of bits or bit pairs that can be processed concurrently, whether it is under single-instruction or multiple-instruction control [Feng, 1972, 1973]. This maximum degree of concurrency, or maximum concurrency (C_m), is an indication of the computer-processing capability. The actual utilization of this capability is indicated by the average concurrency defined to be

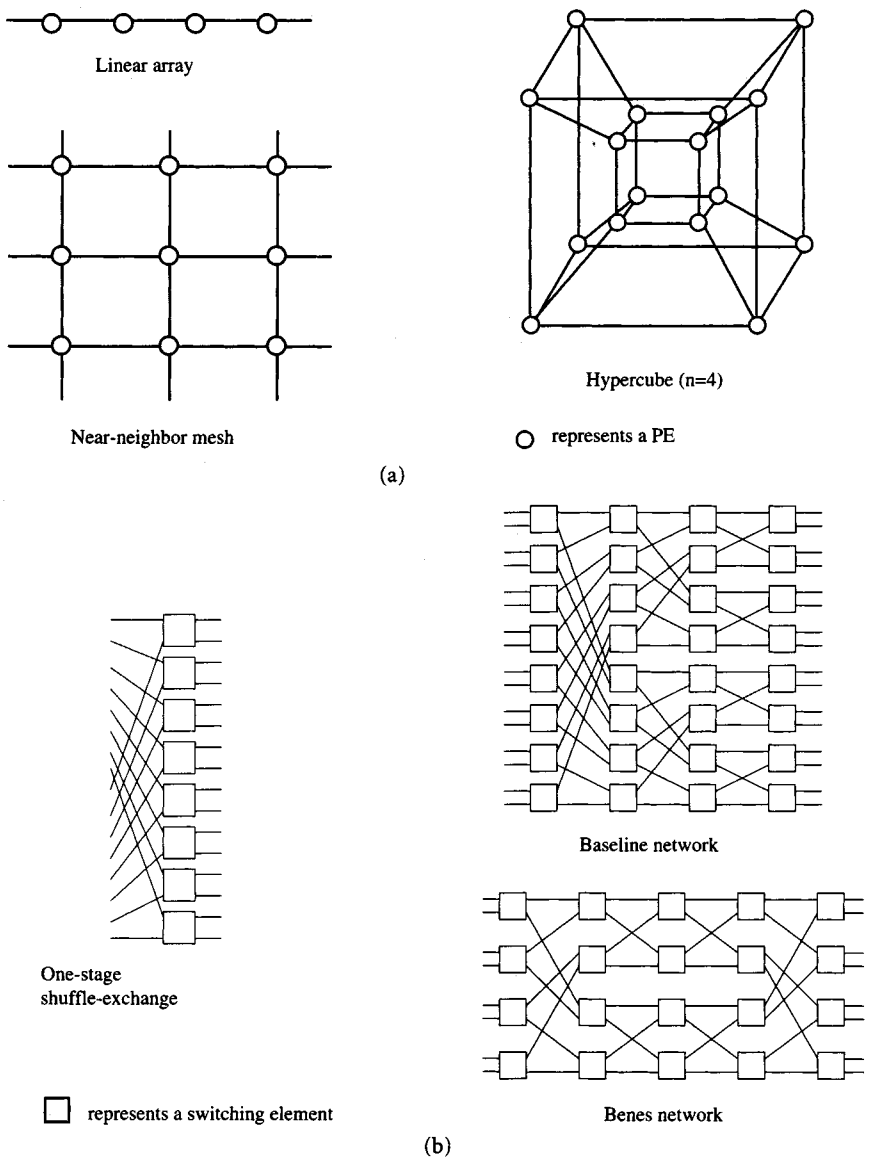

FIGURE 95.4 Some examples of static (a) and dynamic (b) interconnection networks.

$$C_a = \frac{\Sigma c_i \Delta t_i}{\Sigma \Delta t_i}$$

where c_i is the concurrency at Δt_i. If Δt_i is set to one time unit, then the average concurrency over a period of T time units is

$$C_a = \frac{\sum_{i=1}^{T} c_i}{T}$$

The average hardware utilization is then

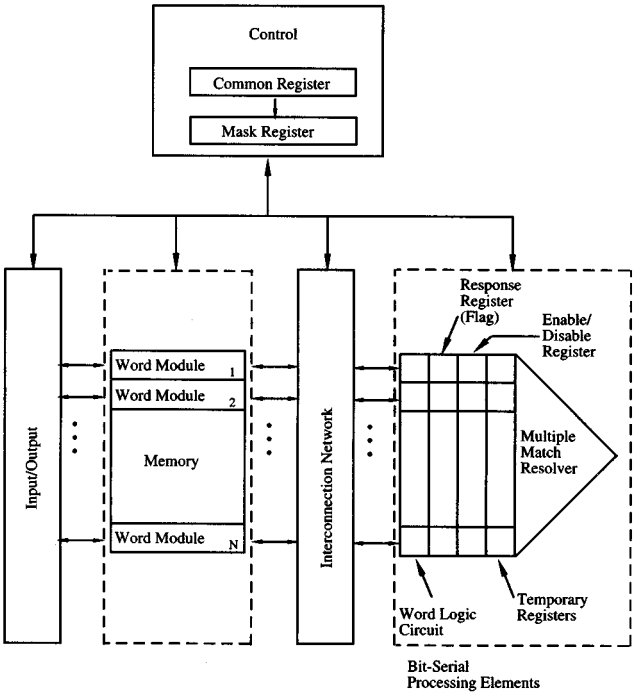

FIGURE 95.5 An associative processor organization.

$$\mu = \frac{C_a}{C_m} = \frac{\sum_{i=1}^{T} c_i}{TC_m} = \frac{1}{T}\sum_{i=1}^{T} \sigma_i$$

where σ_i is the hardware utilization at time *i*. Whereas C_m is determined by the hardware design, C_a or μ is highly dependent on the software and applications. A general-purpose computer should achieve a high μ for as many applications as possible, whereas a special-purpose computer would yield a high μ for at least the intended applications. In either case, maximizing the value of μ for a computer design is important. This equation can also be used to evaluate the relative effectiveness of machine designs.

For a parallel processor, the degree of concurrency is called the degree of parallelism. A similar discussion can be used to define the average hardware utilization of a parallel processor. The maximum parallelism is then P_m, and the average parallelism is

$$P_a = \frac{\Sigma p_i \Delta t_i}{\Sigma \Delta t_i}$$

or

$$P_a = \frac{\sum_{i=1}^{T} p_i}{T}$$

for T time units. The average hardware utilization becomes

$$\upsilon = \frac{P_a}{P_m} = \frac{\sum_{i=1}^{T} p_i}{TP_m} = \frac{1}{T}\sum_{i=1}^{T} \rho_i$$

where ρ_i is the hardware utilization for parallel processors at time i. With appropriate instrumentation, the average hardware utilization of a system can be determined.

In practice, however, it is not always true that every bit or bit pair that is being processed would be productive. Some of the bits produce only repetitious (superfluous) or even meaningless results. This happens more often and more severely in a parallel processor than in a word-sequential processor. Consider, for example, performing a maximum search operation in a mesh-connected parallel processor (such as ILLIAC IV). For N operands, it takes $(N/2)\log_2 N$ comparisons ($N/2$ comparisons for each of $\log_2 N$ iterations) instead of the usual $N-1$ comparisons in word-sequential machines. Thus, in effect there are

$$\left(\frac{N}{2}\log_2 N\right) - (N-1) = \frac{N}{2}(\log_2 N - 2) + 1$$

comparisons that are nonproductive. If we let $\hat{P}_a$ be the effective parallelism over a period of T time units and $\hat{\upsilon}$, $\hat{p}_i$, and $\hat{\rho}_i$ be the corresponding effective values, the effective hardware utilization is then

$$\hat{\upsilon} = \frac{\hat{P}_a}{P_m} = \frac{\sum_{i=1}^{T} \hat{p}_i}{TP_m} = \frac{1}{T}\sum_{i=1}^{T} \hat{\rho}_i$$

A successful parallel processor design should yield a high $\hat{\upsilon}$, as well as the required throughput for, at least, the intended applications. This not only involves a proper hardware and software design but also the development of efficient parallel algorithms for these applications.

Suppose T_u is the execution time of an application program using a conventional word-sequential machine, and T_c is the execution time of the same program using a concurrent system; the speed-up ratio is then defined as

$$S = \frac{T_u}{T_c}$$

Naturally, for a specific parallel organization, the speed-up ratio determines how well an application program can utilize the hardware resources. Supporting software has a direct effect on the speed-up ratio.

Defining Terms

Array processor: A parallel processor consisting of a number of processing elements, memory modules, and input/output devices as well as interconnection networks under a single control unit.

Associative processor: A parallel processor consisting of a number of processing elements, memory modules, and input/output devices under a single control unit. The capability of the processing elements is usually limited to the bit-serial operations.

Ensemble processor: A parallel processor consisting of a number of processing elements, memory modules, and input/output devices under a single control unit. It has no interconnection network to provide interprocessor or processor-memory communications.

Interconnection network: A network of interconnections providing interprocessor and processor-memory communications. It may be static or dynamic, distributed, or centralized.

Parallel processor: A computing system consisting of a number of processors, memory modules, input/output devices, and other components under the control of a single control unit. It is known to be a single-instruction-stream, multiple-data-stream (SIMD) machine.

Processing element: A basic processor consisting of an arithmetic-logic unit, a number of registers, network interfaces, and some local control facilities.

96.1 Introduction

An operating system is just another program running on a computer. It is unlike any other program, however. An operating system's primary function is the management of all hardware and software resources. It manages processors, memory, I/O devices, and networks. It enforces policies such as *protection* of one program from another and *fairness* to ensure that users have equal access to system resources. It is privileged in that it is the only program that can perform specialized hardware operations. The operating system is the primary program upon which all other programs rely.

To understand modern operating systems we must begin with some history [Boykin and LoVerso, 1990]. The modern digital computer is only about 40 years old. The first machines were giant monoliths housed in special rooms, and access to them was carefully controlled. To program one of these systems the user scheduled access time well in advance, for in those days the user had sole access to the machine. The program such a user ran was the *only* program running on the machine.

It did not take long to recognize the need for better control over computer resources. This began in the mid-1950s with the dawn of batch processing and early operating systems that did little more than load programs and manage I/O devices.

In the 1960s we saw more general-purpose systems. New operating systems that provided time-sharing and **real-time computing** were developed. This was the time when the foundation for all modern operating systems was laid.

Today's operating systems are sophisticated pieces of software. They may contain millions of lines of code and provide such services as distributed file access, security, **fault tolerance**, and **real-time** scheduling. In this chapter we examine many of these features of modern operating systems and their use to the practicing engineer.

96.2 Types of Operating Systems

Different operating systems (OS) provide a wide range of functionality. Some are designed as single-user systems and some for multiple users. The operating system, with appropriate hardware support, can protect one executing program from malicious or inadvertent attempts of another to modify or examine its memory. When connected to a storage device such as a disk drive, the OS implements a **file system** to permit storage of files.

The file system often includes security features to protect against file access by unauthorized users. The system may be connected to other computers via a *network* and thus provide access to remote system resources.

Operating systems are often categorized by the major functionality they provide. This functionality includes **distributed computing,** *fault tolerance,* **parallel processing,** *real-time,* and *security.* While no operating system incorporates all of these capabilities, many have characteristics from each category.

An operating system does not need to contain every modern feature to be useful. For example, MS-DOS[1] is a single-user system with few of the features now common in other systems. Indeed, this system is little more than a program loader reminiscent of operating systems from the early 1960s. Unlike those vintage systems, there are numerous applications that run under MS-DOS. It is the abundance of programs that solve problems from word processing to spreadsheets to graphics that has made MS-DOS popular. The simplicity of these systems is exactly what makes them popular for the average person.

Systems capable of supporting multiple users are termed *time-sharing* systems; the system is shared among all users, with each user having the view that he or she has all system resources available. Multiuser operating systems provide protection for both the file system and the contents of main memory. The operating system must also mediate access to peripheral devices. For example, only one user may have access to a tape drive at a time.

Fault-tolerant systems rely on both hardware and software to ensure that the failure of any single hardware component, or even multiple components, does not cause the system to cease operation. To build such a system requires that each critical hardware component be replicated at least once. The operating system must be able to dynamically determine which resources are available and, if a resource fails, move a running program to an operational unit.

Security has become more important during recent years. Theft of data and unauthorized access to data are prevented in secure systems. Within the United States, levels of security are defined by a government-produced document known as the *Orange Book.* This document defines seven levels of security, denoted from lowest to highest as *D, C1, C2, B1, B2, B3,* and *A1.* Many operating systems provide no security and are labeled D. Most time-sharing systems are secure enough that they could be classified at the C1 level. The C2 and B1 levels are similar, and this is where most secure operating systems are currently classified. During the 1990s B2 and B3 systems will become readily available from vendors. The A1 level is extremely difficult to achieve, although several such systems are being worked on.

In the next several sections we expand upon the topics of distributed computing, fault-tolerant systems, parallel processing, and real-time systems.

96.3 Distributed Computing Systems

The ability to connect multiple computers through a communications network has existed for many years. Initially, computer-to-computer communication consisted of a small number of systems performing bulk file transfers. The 1980s brought the invention of high-speed *local area networks,* or LANs. A LAN allows hundreds of machines to be connected together. New capabilities began to emerge, such as *virtual terminals* that allowed a user to log on to a computer without being physically connected to that system. Networks were used to provide remote access to printers, disks, and other peripherals. The drawback to these systems was the software; it was not sophisticated enough to provide a totally integrated environment. Only small, well-defined interactions among machines were permitted.

Distributed systems provide the view that *all* resources from every computer on the network are available to the user. What's more, access to resources on a remote computer is viewed in the same way as access to resources on the local computer. For example, a file system that implements a directory hierarchy, such as UNIX,[2] may have some directories on a local disk while one or more directories are on a remote system. Figure 96.1 illustrates how much of the directory hierarchy would be on the local system, while user directories (shaded directories) could be on a remote system.

[1]MS-DOS is a trademark of Microsoft, Inc.

[2]UNIX is a trademark of UNIX Software Laboratories (USL).

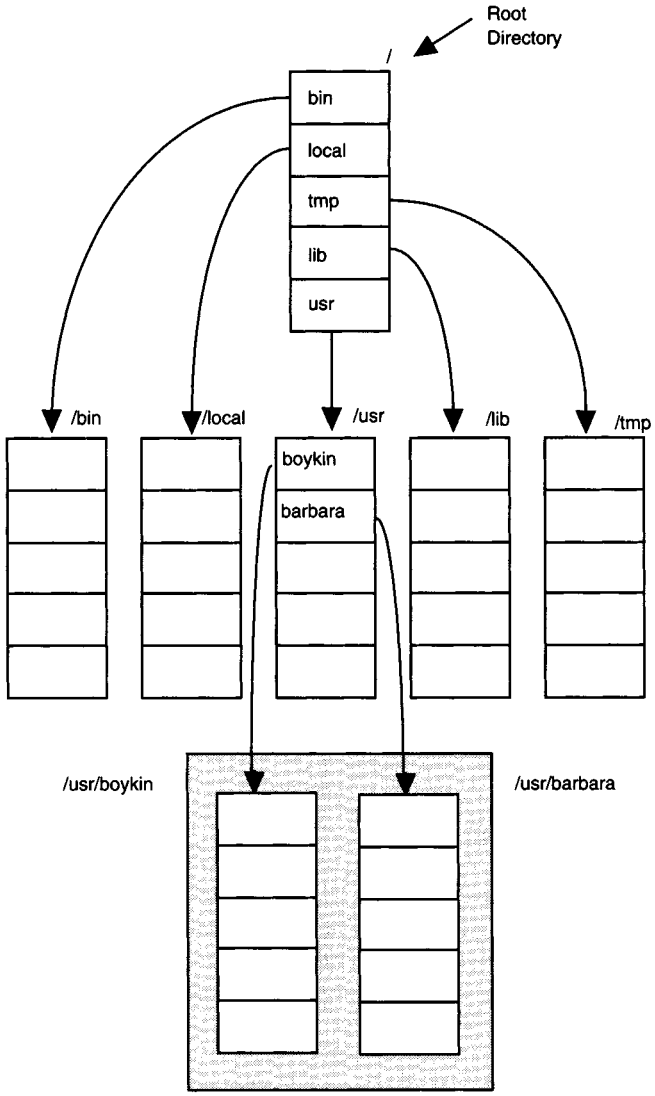

FIGURE 96.1 UNIX file system hierarchy in a distributed environment.

There are many advantages of distributed systems. Advantages over centralized systems include [Tanenbaum, 1992]:

- *Economics:* Microprocessors offer a better price/performance than mainframes.
- *Speed:* A distributed system may have more total computing power than a mainframe.
- *Reliability:* If one machine crashes, the system as a whole can still survive.
- *Incremental growth:* Computing power can be added in small increments.

Advantages over nonnetworked personal computers include [Tanenbaum, 1992]:

- *Data sharing:* Allow many users access to a common database.
- *Device sharing:* Allow many users to share expensive peripherals like color printers.
- *Communication:* Make human-to-human communication easier, for example, by electronic mail.
- *Flexibility:* Spread the workload over the available machines in the most cost effective way.

While there are many advantages to distributed systems, there are also several disadvantages. The primary difficulty is that software for implementing distributed systems is large and complex. Small personal computers could not effectively run modern distributed applications. Software development tools for this environment are not well advanced. Thus, application developers are having a difficult time working in this environment.

An additional problem is network speed. Most office networks are currently based on IEEE standard 802.3 [IEEE, 1985], commonly (although erroneously) called Ethernet, which operates at 10 Mb/s (ten million bits per second). With this limited bandwidth, it is easy to saturate the network. While higher-speed networks such as FDDI[1] and ATM[2] networks do exist, they are not yet in common use. While distributed computing has many advantages, we must also understand that without appropriate safeguards, our data may not be secure.

Security is a difficult problem in a distributed environment. Whom do you trust when there are potentially thousands of users with access to your local system? A network is subject to security attack by a number of mechanisms. It is possible to monitor all packets going across the network; hence, unencrypted data are easily obtained by an unauthorized user. A malicious user may cause a *denial-of-service* attack by flooding the network with packets, making all systems inaccessible to legitimate users.

Finally, we must deal with the problem of scale. To connect a few dozen or even a few hundred computers together may not cause a problem with current software. However, global networks of computers are now being installed. Scaling our current software to work with tens of thousands of computers running across large geographic boundaries with many different types of networks is a challenge that has not yet been met.

96.4 Fault-Tolerant Systems

Most computers simply stop running when they break. We take this as a given. There are many environments, however, where it is not acceptable for the computer to stop working. The space shuttle is a good example. There are other environments where you would simply prefer if the system continued to operate. A business using a computer for order entry can continue to operate if the computer breaks, but the cost and inconvenience may be high. Fault-tolerant systems are composed of specially designed hardware and software that are capable of continuous operation.

To build a fault-tolerant system requires both hardware and software modifications. Let's take a look at an example of a small problem that illustrates the type of changes that must be made. Remember, the goal of such a system is to achieve continuous operation. That means we can never purposely shut the computer off. How then do we repair the system if we cannot shut it off? First, the hardware must be capable of having circuit boards plugged and unplugged while the system is running; this is not possible on most computers. Second, removing a board must be detected by the hardware and reported to the operating system. The operating system, the manager of resources, must then discontinue use of that resource.

Each component of the computer system, both hardware and software, must be specially built to handle failures. It should also be obvious that a fault-tolerant system must have redundant hardware. If, for example, a disk controller should fail, there must be another controller communicating with the disks that can take over.

One problem with implementing a fault-tolerant system is knowing when something has failed. If a circuit board totally ceases operation, we can determine the failure by its lack of response to commands. Another failure mode exists where the failing component appears to work but is operating incorrectly. A common approach to detect this problem is a *voting* mechanism. By implementing three hardware replicas the system can detect when any one has failed by its producing output inconsistent with the other two. In that case, the output of the two components in agreement is used.

The operating system must be capable of restarting a program from a known point when a component on which the program was running has failed. The system can use *checkpoints* for this purpose. When an application program reaches a known state, such as when it completes a transaction, it stores the current state of the

[1]Fiber distributed data interface. The FDDI standard specifies an optical fiber ring with a data rate of 100 Mb/s.

[2]Asynchronous transfer mode. A packet-oriented transfer mode moving data in fixed-size packets called *cells*. There is no fixed speed for ATM. Typical speed is currently 155 Mb/s, although there are implementations running at 2 Gb/s.

program and all I/O operations; this is known as a checkpoint. Should a component on which this program is running fail, the operating system can restart the program from the most recent checkpoint.

While the advantage of fault-tolerant systems is obvious, they come at a price. Redundant hardware is expensive, and software capable of recovering from faults runs more slowly. As with many other systems, the price may be more than offset by the advantage of continuous computing.

96.5 Parallel Processing

No matter how fast computers become, it seems they are never fast enough. Manufacturers make faster computers by decreasing the amount of time it takes to do each operation. An alternative is to build a computer that performs several operations simultaneously. A parallel computer, also called a multiprocessor, is one that contains more than one CPU.[1]

The advantage of a parallel computer is that it can run more than one program simultaneously. In a general-purpose time-sharing environment, parallel computers can greatly enhance overall system throughput. A program shares a CPU with fewer programs. This approach is similar to having several computers connected on a network but has the advantage that all resources are more easily shared.

To take full advantage of a parallel computer will require changes to the operating system [Boykin and Langerman, 1990] and application programs. Most programs are easily divided into pieces that can each run at the same time. If each of these pieces is a separate thread of control, they could run simultaneously on a parallel computer. By so dividing the application, the program may run in less time than it would on a single-processor (uniprocessor) computer.

Within the application program, each thread runs as if it were the only thread of control. It may call functions, manipulate memory, perform I/O operations, etc. If the threads do not interact with each other, then, to the application programmer, there is little change other than determining how to subdivide the program. However, it would be unusual for these threads not to interact. It is this interaction that makes parallel programming more complex.

In principle, the solution is rather simple. Whenever a thread will manipulate memory or perform an I/O operation, it must ensure that it is the *only* thread that will modify that memory location or do I/O to that file until it has completed the operation. To do so, the programmer uses a *lock*. A lock is a mechanism that allows only a single thread to execute a given code segment at a time. Consider an application with several threads of control. Each thread performs an action and writes the result to a file—the same file. Within each thread we might have code that looks as follows:

```
thread()
{
        dowork();
        writeresult();
}
writeresult()
{
        lock();
        write(logfid, result, 512);
        unlock();
}
```

In this example the **writeresult** function calls the **lock** function before it writes the result and calls **unlock** afterward. Other threads simultaneously calling **writeresult** will wait at the call to **lock** until the thread that currently holds the lock calls the **unlock** function.

While this approach is simple in principle, in practice it is more difficult. It takes experience to determine how a program may be divided. Even with appropriate experience, it is more difficult to debug a multithreaded

[1]Central processing unit, the hardware component that does all arithmetic and logical operations.

application. With several threads of control operating simultaneously, it is not simply a matter of stepping through the program line by line to find a mistake. Most often, it is the interaction between threads that is the problem.

Multithreading a program may not be a trivial matter. As with most types of programming, however, experience makes the process easier. The benefit is significantly enhanced performance.

96.6 Real-Time Systems

Real-time systems are those that guarantee that the system will respond in a predetermined amount of time. We use real-time systems when, for example, computers control an assembly line or run a flight simulator. In such an environment we define an action that must occur and a deadline by which we wish that action to take place. On an assembly line an event may occur, such as a part arriving at a station, and an action, such as painting that part. The deadline we impose will be based on the speed of the assembly line. Obviously, we must paint the part before it passes to the next station. This is called a *hard* real-time system because the system must meet a strict deadline.

Another class of system is termed *soft* real-time. These are environments in which response time is important, but the consequences are not as serious as, for example, on an assembly line. Airline reservation systems are in this category. Rapid response time to an event, such as an agent attempting to book a ticket, is important and must be considered when the system performs other activities.

One way of distinguishing hard and soft real-time systems is by examining the *value* of a response over time. For example, if a computer was controlling a nuclear reactor and the reactor began to overheat, the command to open the cooling valves has extremely high value until a deadline, when the reactor explodes. After that deadline, there is no value in opening the valves (see Fig. 96.2).

Relatively few events require that type of responsiveness. Most events have a deadline, but there continues to be value in responding to that event even past the deadline. In our airline reservation example, the airline may wish to respond to a customer request within, say, 10 seconds. However, if the response comes in 11 seconds, there is still value in the response. The value is lessened because the customer has become upset. As time increases, the customer becomes more and more upset and the value of responding decreases. We illustrate this in Fig. 96.3.

96.7 Operating System Structure

Operating systems are large, complex pieces of software. They must handle asynchronous events such as interrupts from I/O devices, control hardware memory management units (MMUs) to implement virtual memory, support multiple simultaneous users, implement complex network protocols, and much more. As with any software of this magnitude, an operating system is logically divided into smaller pieces. The structure of a typical modern operating system is depicted in Fig. 96.4.

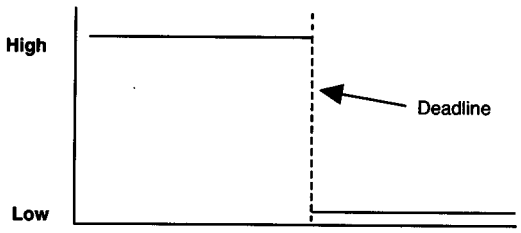

FIGURE 96.2 Relative value of a response over time in a critical situation.

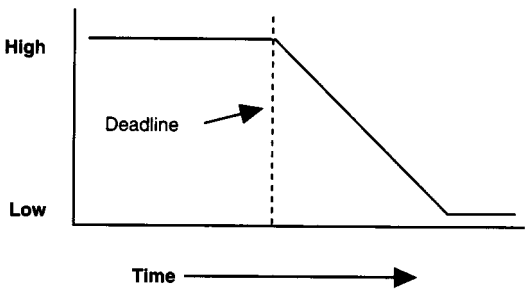

FIGURE 96.3 Relative value of a response over time in a noncritical situation.

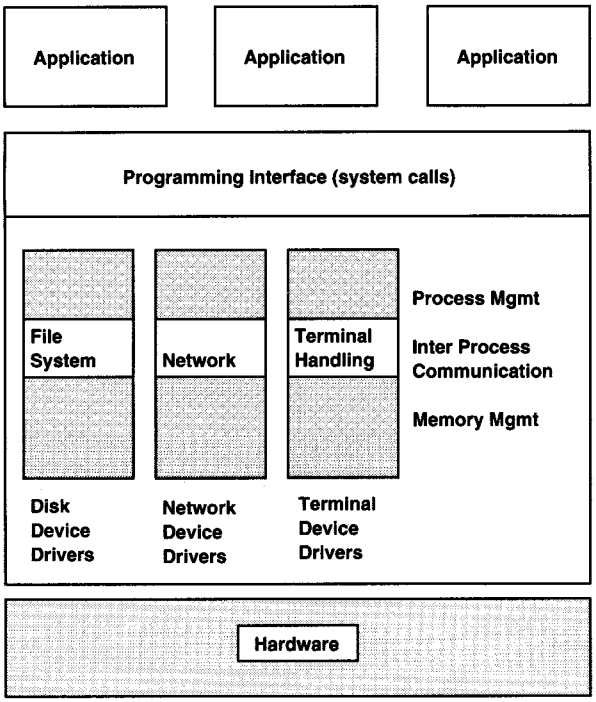

FIGURE 96.4 The structure of a modern operating system.

From the user's standpoint, the operating system is a collection of system calls—the *programmers' interface.* Sometimes this is termed an *application program interface,* or API. System calls provide the mechanism for an application program to obtain services from the system. System calls exist to perform file operations such as *create, open, close, read,* and *write.* For terminals, system calls would perform such functions as changing the baud rate and number of parity bits. Network connections may be established or network protocol options, such as the size of network buffers, are also controlled through system calls.

While every operating system provides a system call interface, there is little uniformity to the appearance of that interface. Some systems provide an interface that appears as a simple function call. For example, to open a file under the UNIX operating system, we use the following system call:

```
open("/home/boykin/crc-press/oschapter", O_RDONLY);
```

Other operating systems require a user to fill in complex data structures for various operations. For example, the following code fragment illustrates how to send an IPC message using the Mach operating system's **interprocess communication** (IPC) facility [Boykin et al., 1993]:

```
msg_header_t header;

header.msg_simple = TRUE;
header.msg_size = sizeof(header);
header.msg_type = MSG_TYPE_NORMAL;
header.msg_local_port = PORT_NULL;
header.msg_remote_port = remote_port;
header.msg_id = 100;
```

Regardless of the interface format, a programmer should become familiar with the parameters, options, and return codes from each system call to use the system proficiently.

Beneath the programming interface lies the heart of the operating system. We can divide the system into two major sections. The first section directly implements the system calls. This includes the file system, terminal

handling, etc. The second section provides basic capabilities upon which the rest of the system is built. Interprocess communication, memory management, and **process** management are all examples of these basic capabilities. A brief explanation of each of these sections will be given shortly.

The lowest level of the operating system interfaces directly with the computer hardware. For each physical device, such as a disk, tape, or serial line, a device driver must exist to communicate with the hardware. Device drivers accept requests to read or write data or determine the status of the device. They may do polled I/O or be interrupt driven, although polled I/O is usually only done on small personal computers. Writing a device driver requires a thorough knowledge of the hardware as well as the interface to the operating system.

In addition to I/O devices, the system must also manipulate such hardware as counters, timers and memory management units. Timers are used to satisfy user requests such as terminating an operation after a specified length of time. MMUs provide the ability to protect memory. Each time a program is run, the operating system programs the MMU with the physical memory addresses the program may access. Any attempt to access other memory is not allowed by the MMU.

An MMU is also required to implement *virtual memory*. Virtual memory allows a program to use more memory than is physically present on the machine. The operating system implements virtual memory by using an external device, typically a disk, to store portions of the program that are not currently in use. When a program attempts to access memory temporarily stored on disk, the MMU traps[1] to the operating system, which reads the memory from disk and restarts the program.

In recent years the structure depicted here has been changing. A new concept, called the *microkernel*, has begun to emerge. The idea behind a micro-kernel is to dramatically reduce the size of the operating system by placing most OS subsystems in the application layer. A micro-kernel would not be a usable system by itself. A number of programs would be run on top of the micro-kernel to provide such services as a file system and network protocols.

In the micro-kernel architecture shown in Fig. 96.5, notice that subsystems traditionally within the operating system are now at the same level as an application program. An application program wishing to, for example, open a file makes its request to the file system program, rather than the micro-kernel. The file system may call upon other OS subsystems or on the micro-kernel to perform an operation.

From the user standpoint, there is no programming difference between a micro-kernel structure and the traditional structure. There are two advantages of the micro-kernel approach. The first is that programming

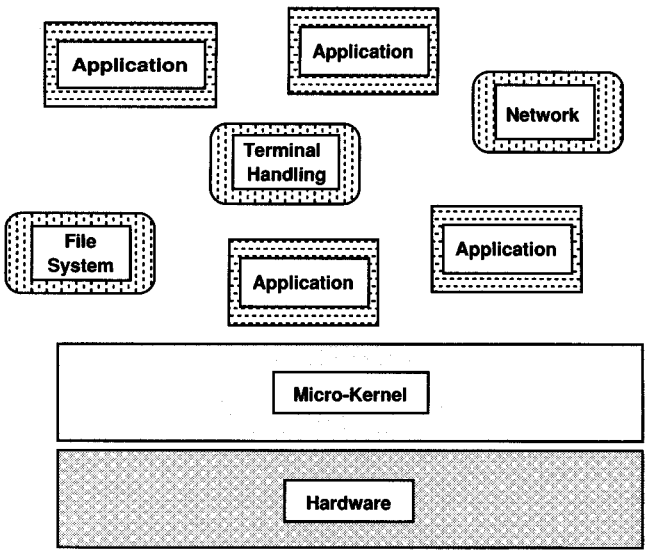

FIGURE 96.5 Micro-kernel structure.

[1]A *trap* is a hardware signal that is received by the operating system. It is very similar to an interrupt from an I/O device

and debugging at the application layer is inherently simpler than programming at the OS layer. The benefit here is to the OS designer and implementors who can now write and debug OS code faster and easier than before. This benefits the user by having an operating system that is more reliable.

The second advantage stems from the ability to incorporate several different OS environments on top of the same micro-kernel. In this way, the computer acts as though it is running several operating systems. For example, if both MS-DOS and UNIX coexisted on the same micro-kernel, the user could choose to run an MS-DOS spreadsheet or word processor and communicate using UNIX network commands. The user has gained increased flexibility.

96.8 Industry Standards

As computer technologies come into widespread use, users begin to desire standardization. Standardization allows a user to know that a program written to a standard will work without concern for which vendor supplies the programming environment. Operating systems are no exception to this general rule, and there are several standards, both industry standards and *de facto* standards, that apply. Porting software from one system to another, often an expensive proposition, becomes a trivial task.

Perhaps the most notable OS standard is POSIX, standard number 1003 [IEEE, 1990], sponsored by the IEEE Computer Society's Technical Committee on Operating Systems. POSIX is a family of standards based on the UNIX operating system that includes the system call interface, user-level commands, real-time extensions, and networking extensions. The POSIX system call interface, 1003.1, was adopted by the U.S. government verbatim as a Federal Information Processing Standard, FIPS 151. Many vendors conform to POSIX; thus, a program that conforms to this standard can be ported to many system platforms without change.

An example of a *de facto* standard is the X/Open Portability Guide (XPG) [X/Open, 1989]. X/Open is not a standards-setting body but is a joint initiative by members of the business community to adopt and adapt existing standards into a consistent environment. The X/Open system interface and headers are based on POSIX 1003.1 but also include extensions to POSIX-defined interfaces as well as additional interfaces.

The importance of such standards is evidenced by the strong support of such organizations as the Open Software Foundation. OSF's OSF/1 operating system conforms to various POSIX standards. Where not superseded by POSIX, it also conforms to XPG and AT&T's System V Interface Definition (SVID) [AT&T, 1985]. Conforming to these standards is considered critical for the success of OSF/1.

Some might consider an operating system such as MS-DOS to be a *de facto* standard. While MS-DOS is in common use, however, it is proprietary software subject to change without notice. Defining a standard implies an open system on which vendors and users agree.

96.9 Conclusions

I have been hearing for the past 15 years about the demise of the operating system. It has been said over and over that the role of the OS will go away. So far, the only change has been to *expand* on the role the operating system plays. One must remember that the operating system is not the user interface it portrays or the applications that run on it. It is, as it always has been, the manager of all resources on a computer system.

While the interface to computers has changed and the use to which we apply computer technology has changed, there will always be the need for an operating system. Without question, the OS will change as well. We have already seen micro-kernel architectures begin to emerge from the research labs into commercial operating systems. Distributed computing will become more widespread and force additional changes to the operating system. Regardless of the changes that come, it will always be the operating system on which all other programs rely.

Defining Terms

Distributed computing: An environment in which multiple computers are networked together and the resources from more than one computer are available to a user. Those resources are accessed in a manner identical to accessing resources on a local computer system.

Fault-tolerant systems: A computer system with both hardware and software that are capable of continuous operation even in the event hardware components fail.

File system: The logical organization of files on a storage device, typically a disk drive. The file system may support a hierarchical structure with directories and subdirectories (sometimes called folders).

Interprocess communication: The transfer of information between two cooperating programs. Communication may take the form of a *signal* (the arrival of an event) or the transfer of data.

Parallel processing: A parallel computer is one that contains more than one CPU. Parallel processing is when a program is divided into multiple threads of control, each of which is capable of running simultaneously. On a parallel computer, multiple threads could be running at the same time, thus resulting in better performance than on a uniprocessor system.

Process: A single executable program. A process is the context in which an operating system places a running program. It contains the program itself as well as allocated memory, open files, network connections, etc.

Real-time computing: Support for environments in which response time to an event must occur within a predetermined amount of time. Real-time systems may be categorized into *hard* and *soft* real-time.

Further Information

Many textbooks describe operating system concepts. The three cited in the reference section [Dietel, 1990; Silberschatz et al., 1991; and Tanenbaum, 1992] are excellent. The IEEE Computer Society has a number of tutorials on operating system related topics such as fault tolerance, real-time, local area networks and distributed processing. Readers should contact the Computer Society Press office at 10662 Los Vaqueros Circle, Los Alamitos, Calif. 90720. Phone: 714-821-8380.

For those interested in learning more about the implementation of specific operating systems, M.J. Bach, *The Design of the UNIX Operating System*, Prentice-Hall, 1986, describes the implementation of AT&T System V. The 4.3BSD operating system is described in Leffler et al., *The Design and Implementation of the 4.3BSD UNIX Operating System,* Addison-Wesley, 1990.

notion of breaking it. Specifically, the attacker is allowed to obtain signatures to any message of his choice. One may argue that in many applications, such a general attack is not possible (as messages to be signed must have a specific format). Yet, our view is that it is impossible to define a general (i.e., application-independent) notion of admissible messages, and thus a general/robust definition of an attack seems to have to be formulated, as suggested here. (Note that, at worst, our approach is overly cautious.) Likewise, the adversary is said to be successful if he can produce a valid signature to any message for which he has not asked for a signature during his attack. Again, this refers to the ability to form signatures to possibly "nonsensical" messages as a breaking of the scheme. Yet, again, we see no way to have a general (i.e., application-independent) notion of "meaningful" messages (so that only forging signatures to them will be consider a breaking of the scheme).

A *chosen message attack* is a process that, on input, a verification key can obtain signatures (relative to the corresponding signing key) to messages of its choice. Such an attack is said to *succeed* (in existential forgery) if it outputs a valid signature to a message for which it has *not* requested a signature during the attack. A signature scheme is *secure* (or unforgeable) if every *feasible* chosen message attack succeeds with, at most, negligible probability.

We stress that *plain* RSA (similar to plain versions of Rabin's [1979] scheme and DSS) is not secure under the above definition. However, it may be secure if the message is "randomized" before RSA (or the other schemes) is applied. Thus, the randomization paradigm seems pivotal here too.

Message Authentication Schemes

Message authentication is a task related to the setting considered for encryption schemes; that is, communication over an insecure channel. This time, we consider an active adversary that is monitoring the channel and may alter the messages sent on it. The parties communicating through this insecure channel wish to authenticate the messages they send so that their counterpart can tell an original message (sent by the sender) from a modified one (i.e., modified by the adversary). Loosely speaking, a *scheme for message authentication* requires that:

- Each of the communicating parties can *efficiently produce an authentication tag* to any message of his choice.
- Each of the communicating parties can *efficiently verify* whether a given string is an authentication tag of a given message.
- But, *it is infeasible for an external adversary* (i.e., a party other than the communicating parties) to *produce authentication tags* to messages not sent by the communicating parties.

Note that in contrast to the specification of signature schemes, we do not require universal verification. That is, only the receiver is required to be able to verify the authentication tags; and the fact that the receiver can also produce such tags is of no concern. Thus, schemes for message authentication can be viewed as a private-key version of signature schemes. The difference between the two is that, in the setting of message authentication, the ability to verify tags can be linked to the ability to authenticate messages; whereas in the setting of signature schemes, these abilities are separated (i.e., everybody can verify signatures but only the holder of the signing key can produce valid signatures). Hence, digital signatures provide a solution to the message authentication problem, but message authentication schemes do not necessarily constitute digital signature schemes.

Constructions

Message authentication schemes can be constructed using pseudorandom functions. However, as noted by Bellare, Canetti, and Krawczyk [1996], *extensive* usage of pseudorandom functions seems an overkill for achieving message authentication, and more efficient schemes can be obtained based on other cryptographic primitives.

Three central paradigms in the construction of *signature schemes* are the "refreshing" of the "effective" signing-key, the usage of an "authentication tree," and the "hashing paradigm." The first paradigm is aimed at limiting the potential dangers of a chosen message attack by signing the given message using a newly generated (random) instance of the signature scheme, and authenticating this random instance relative to the fixed public key. A natural way of carrying on the authentication of the many newly generated keys is by using an authentication tree [Merkle, 1980]. Finally, the hashing paradigm refers to the common practice of signing real documents

via a two-stage process: first, the document is hashed into a (relatively) short bit string, and then the basic signature scheme is applied to the resulting string. This practice, as well as other usages of the paradigm, is sound provided the hashing function belongs to a family of *Universal One-Way Hash Functions* (cf., [Naor and Yung, 1989]).

Cryptographic Protocols

A general framework for casting n-party cryptographic problems consists of specifying a random process that maps n inputs to n outputs. The inputs to the process are to be thought of as local inputs of n parties, and the n outputs are their corresponding local outputs. The random process describes the desired functionality. That is, if the n parties were to trust each other (or trust some outside party), then they could each send their local input to the trusted party, who would compute the outcome of the process and send each party the corresponding output. The question addressed in this section is: to what extent can such a trusted party be "emulated" by the mutually distrustful parties themselves? We consider two general settings: two-party protocols and multi-party protocols in which the majority of the players are honest. We start with the latter case.

Multi-Party Protocols with Honest Majority

Consider any multi-party protocol. We first observe that each party can change its local input before even entering the execution of the protocol. However, this is also unavoidable when the parties utilize a trusted party. In general, the basic paradigm underlying the definitions of *secure multi-party computations* amounts to saying that situations that can occur in the real protocol, can be simulated in an ideal model (where the parties can employ a trusted party). Thus, the effective malfunctioning of parties in secure protocols is restricted to what is postulated in the corresponding ideal model.

Here, we consider an ideal model in which any minority group (of the parties) may collude as follows. First, this minority shares its original inputs and decides together on replaced inputs to be sent to the trusted party. (The other parties send their respective original inputs to the trusted party.) When the trusted party returns the output, each majority player outputs it locally, whereas the colluding minority can compute outputs based on all they know. A *secure multi-party computation with honest majority* is required to simulate this ideal model. That is, the effect of any feasible adversary that controls a minority of the players in the actual protocol, can be essentially simulated by a (different) feasible adversary that controls the corresponding players in the ideal model. This means that in a secure protocol, the effect of each minority group is "essentially restricted" to replacing its own local inputs (independently of the local inputs of the majority players) before the protocol starts, and replacing its own local outputs (depending only on its local inputs and outputs) after the protocol terminates. (We stress that in the real execution, the minority players do obtain additional pieces of information; yet in a secure protocol, they gain nothing from these additional pieces of information, as they can actually reproduce those by themselves.)

It turns out that efficient and secure multi-party computation of any functionality is possible, provided that a majority of the parties are honest and that trapdoor permutations do exist (e.g., factoring is intractable) [Goldreich, Micali, and Wigderson, 1987].

Two-Party Protocols

Secure multi-party protocols with honest majority can even tolerate a situation in which a minority of the parties abort the execution. This cannot be expected to happen when there is no honest majority (e.g., in a two-party computation). In light of this fact, we consider an ideal model in which each of the two parties can "shut down" the trusted (third) party at any point in time. In particular, this can happen after the trusted party has supplied the outcome of the computation to one party, but before it has supplied it to the second. A *secure two-party computation allowing abort* is required to simulate this ideal model. That is, each party's "effective malfunctioning" in a secure protocol is restricted to supplying an initial input of its choice and aborting the computation at any point in time. We stress that, as above, the choice of the initial input of each party may *not* depend on the input of the other party. Again, it turns out that efficient and secure two-party computation (allowing abort) of any functionality is possible, provided that trapdoor permutations do exist [Yao, 1986].

Defining Terms

Message authentication scheme: A scheme to generate keys so that signing messages and authenticating the validity of signatures can be executed efficiently when knowing the key; but without the key, it is infeasible to falsely authenticate a new message even when given authentication tags to messages of one's choice.

NP-sets: The set S is in NP if there exists a polynomial-time recognizable binary relation R_S and a polynomial ℓ so that $x \in S$ if and only if there exists y so that $|y| \leq \ell(|x|)$ and $(x, y) \in R_S$. Such a y is called an *NP-witness* to $x \in S$.

One-way functions: Functions that are easy to evaluate but difficult (on average) to invert.

Private-key encryption scheme: A scheme to generate keys so that encryption and decryption of messages can be executed efficiently when knowing the key, but it is infeasible to gain any information of the message given only the encrypted message (but not the key).

Pseudorandom functions: Efficient deterministic programs that, given a random seed, present an input-output behavior that is indistinguishable from the one of a truly random function.

Pseudorandom generators: Efficient deterministic programs that stretch short random seeds into longer sequences that are computationally indistinguishable from truly random sequences.

Public-key encryption scheme: A scheme to generate pairs of encryption-decryption keys to that encryption and decryption of messages can be executed efficiently when knowing the corresponding key, but it is infeasible to gain any information of the message given only the encrypted message and the encryption key (but not the decryption key).

Signature scheme: A scheme to generate pairs of signing-verifying keys so that signing messages and verifying the validity of signatures can be executed efficiently when knowing the corresponding key; but without the signing key, it is infeasible to forge a signature to a new message even when given signatures to messages of one's choice.

Zero-knowledge proofs: Two-party protocols by which one party can convince the other party of the validity to an assertion without yielding anything else. That is, when executing such a protocol, the verifier is essentially in the same situation as he would have been if he was granted by a trusted party that the assertion is valid.

98.1 Introduction

This chapter outlines the knowledge needed to estimate the **reliability** of any electronic system or subsystem within a computer. The word *estimate* was used in the first sentence to emphasize that the following calculations, even if carried out perfectly correctly, can provide no guarantee that a particular example of a piece of electronic equipment will work for any length of time. However, they can provide a reasonable guide to the probability that something will function as expected over a given time period. The first step in estimating the reliability of a computer system is to determine the likelihood of failure of each of the individual components, such as resistors, capacitors, integrated circuits, and connectors, that make up the system. This information can then be used in a full system analysis.

98.2 Definitions of Failure, Fault, and Error

A *failure* occurs when a system or component does not perform as expected. Examples of failures at the component level could be a base-emitter short in a transistor somewhere within a large integrated circuit or a solder joint going open circuit because of vibrations. If a component experiences a failure, it may cause a fault, leading to an error, which may lead to a system failure.

A *fault* may be either the outward manifestation of a component failure or a design fault. Component failure may be caused by internal physical phenomena or by external environmental effects such as electromagnetic fields or power supply variations. *Design faults* may be divided into two classes. The first class of design fault is caused by using components outside their rated specification. It should be possible to eliminate this class of faults by careful design checking. The second class, which is characteristic of large digital circuits such as those found in computer systems, is caused by the designer not taking into account every logical condition that could occur during system operation. All computer systems have a software component as an integral part of their operation, and software is especially prone to this kind of design fault.

A fault may be permanent or transitory. Examples of *permanent faults* are short or open circuits within a component caused by physical failures. *Transitory faults* can be subdivided further into two classes. The first, usually called *transient faults,* are caused by such things as alpha-particle radiation or power supply variations. Large random access memory circuits are particularly prone to this kind of fault. By definition, a transient fault is not caused by physical damage to the hardware. The second class is usually called *intermittent faults.* These faults are temporary but reoccur in an unpredictable manner. They are caused by loose physical connections between components or by components used at the limits of their specification. Intermittent faults often become permanent faults after a period of time. A fault may be *active* or *inactive.* For example, if a fault causes the output of a digital component to be stuck at logic 1, and the desired output is logic 1, then this would be classed as an inactive fault. Once the desired output becomes logic 0, then the fault becomes active.

The consequence for the system operation of a fault is an error. As the error may be caused by a permanent or by a transitory fault, it may be classed as a *hard error* or a *soft error.* An error in an individual subsystem may be due to a fault in that subsystem or to the propagation of an error from another part of the overall system.

The terms *fault* and *error* are sometimes interchanged. The term *failure* is often used to mean anything covered by these definitions. The definitions given here are those in most common usage.

Physical faults within a component can be characterized by their external electrical effects. These effects are commonly classified into *fault models.* The intention of any fault model is to take into account every possible failure mechanism, so that the effects on the system can be worked out. The manifestation of faults in a system can be classified according to the likely effects, producing an *error model.* The purpose of error models is to try to establish what kinds of corrective action need be taken in order to effect repairs.

98.3 Failure Rate and Reliability

An individual component may fail after a random time, so it is impossible to predict any pattern of failure from one example. It is possible, however, to estimate the rate at which members of a group of identical components will fail. This rate can be determined by experimental means using accelerated life tests. In a normal operating environment, the time for a statistically significant number of failures to have occurred in a group of modern digital components could be tens or even hundreds of years. Consequently, the manufacturers must make the environment for the tests extremely unfavorable in order to produce failures in a few hours or days and then extrapolate back to produce the likely number of failures in a normal environment. The **failure rate** is then defined as the number of failures per unit time, in a given environment, compared with the number of surviving components. It is usually expressed as a number of failures per million hours.

If $f(t)$ is the number of components that have failed up to time t, and $s(t)$ is the number of components that have survived, then $z(t)$, the *failure rate* or *hazard rate,* is defined as

$$z(t) = \frac{1}{s(t)} \cdot \frac{df(t)}{d(t)} \tag{98.1}$$

Most electronic components will exhibit a variation of failure rate with time. Many studies have shown that this variation can often be approximated to the pattern shown in Fig. 98.1. For obvious reasons this is known as a *bathtub* curve. The first phase, where the failure rate starts high but is decreasing with time, is where the components are suffering infant mortality; in other words, those that had manufacturing defects are failing. This is often called the *burn-in* phase. The second part, where the failure rate is roughly constant, is the useful life period of operation for the component. The final part, where the failure rate is increasing with time, is where the components are starting to wear out.

Using the same nomenclature as before, if:

$$s(t) + f(t) = N \tag{98.2}$$

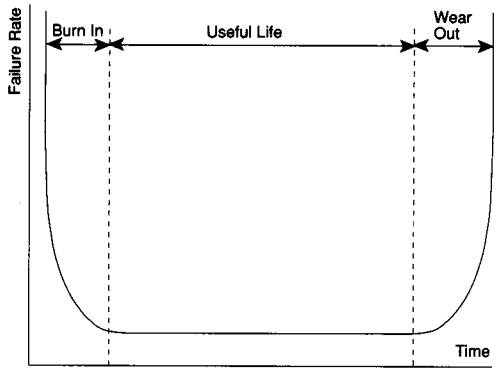

FIGURE 98.1 Variation of failure rate with time.

i.e., N is the total number of components in the test, then the *reliability* $r(t)$ is defined as

$$r(t) = \frac{s(t)}{N} \tag{98.3}$$

or in words, and using the definition from the *IEEE Standard Dictionary of Electrical and Electronic Terms,* reliability is the probability that a device will function without failure over a specified time period or amount of usage, under stated conditions.

98.4 Relationship Between Reliability and Failure Rate

Using Eqs. (98.1), (98.2), and (98.3) then

$$z(t) = -\frac{N}{s(t)} \cdot \frac{dr(t)}{d(t)} \tag{98.4}$$

λ is commonly used as the symbol for the failure rate $z(t)$ in the period where it is a constant, i.e., the useful life of the component. Consequently, we may write Eq. (98.4) as

$$\lambda = -\frac{1}{r(t)} \cdot \frac{dr(t)}{d(t)} \tag{98.5}$$

Rewriting, integrating, and using the limits of integration as $r(t) = 1$ at t=0 and $r(t) = 0$ at $t = \infty$ gives the result:

$$r(t) = e^{-\lambda t} \tag{98.6}$$

This result is true only for the period of operation where the failure rate is a constant. For most common components, real failure rates can be obtained from such handbooks as the American military MIL-HDBK-217E, as explained in Section 98.12.

It must also be borne in mind that the calculated reliability is a probability function based on lifetime tests. There can be no guarantee that any batch of components will exhibit the same failure rate and hence reliability as those predicted because of variations in manufacturing conditions. Even if the components were made at

the same factory as those tested, the process used might have been slightly different and the equipment will be older. Quality assurance standards are imposed on companies to try to guarantee that they meet minimum manufacturing standards, but some cases in the United States have shown that even the largest plants can fall short of these standards.

98.5 Mean Time to Failure

A figure that is commonly quoted because it gives a readier feel for the system performance is the **mean time to failure** or MTTF. This is defined as

$$\text{MTTF} = \int_0^\infty r(t)\, dt \tag{98.7}$$

Hence, for the period where the failure rate is constant:

$$\text{MTTF} = \frac{1}{\lambda} \tag{98.8}$$

98.6 Mean Time to Repair

For many computer systems it is possible to define a **mean time to repair** (MTTR). This will be a function of a number of things, including the time taken to detect the failure, the time taken to isolate and replace the faulty component, and the time taken to verify that the system is operating correctly again. While the MTTF is a function of the system design and the operating environment, the MTTR is often a function of unpredictable human factors and, hence, is difficult to quantify. Figures used for MTTR for a given system in a fixed situation could be predictions based on the experience of the reliability engineers or could be simply the maximum response time given in the maintenance contract for a computer. In either case, MTTR predictions may be subject to some fluctuations. To take an extreme example, if the service engineer has a flat tire while on the way to effect the repair, then the repair time may be many times the predicted MTTR. For some systems no MTTR can be predicted, as they are in situations that make repair impossible or uneconomic. Computers in satellites are a good example. In these cases and all others where no errors in the output can be allowed, fault tolerant approaches must be used in order to extend the MTTF beyond the desired system operational lifetime.

98.7 Mean Time Between Failures

For systems where repair is possible, a figure for the expected time between failures can be defined as

$$\text{MTBF} = \text{MTTF} + \text{MTTR} \tag{98.9}$$

The definitions given for MTTF and MTBF are the most commonly accepted ones. In some texts, MTBF is wrongly used as mean time before failure, confusing it with MTTF. In many real systems, MTTF is very much greater than MTTR, so the values of MTTF and MTBF will be almost identical, in any case.

98.8 Availability

Availability is defined as the probability that the system will be functioning at a given time during its normal working period.

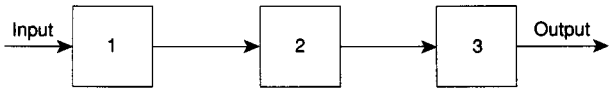

FIGURE 98.2 Series model.

$$\text{Av} = \frac{\text{total working time}}{\text{total time}} \tag{98.10}$$

This can also be written as

$$\text{Av} = \frac{\text{MTTF}}{\text{MTTF} + \text{MTTR}} \tag{98.11}$$

Some systems are designed for extremely high availability. For example, the computers used by AT&T to control its telephone exchanges are designed for an availability of 0.9999999, which corresponds to an unplanned downtime of 2 min in 40 years. In order to achieve this level of availability, fault tolerant techniques have to be used from the design stage, accompanied by a high level of monitoring and maintenance.

98.9 Calculation of Computer System Reliability

For systems that have not been designed to be fault tolerant it is common to assume that the failure of any component implies the failure of the system. Thus, the system failure rate can be determined by the so-called parts count method. If the system contains m types of component, each with a failure rate λ_m, then the system failure rate λ_s can be defined as

$$\lambda_s = \sum_1^m N_m \cdot \lambda_m \tag{98.12}$$

where N_m is the number of each type of component.

The system reliability will be

$$r_s(t) = \prod_1^m N_m \cdot r_m \tag{98.13}$$

If the system design is such that the failure of an individual component does not necessarily cause system failure, then the calculations of MTTF and $r_s(t)$ become more complicated.

Consider two situations where a computer system is made up of several subsystems. These may be individual components or groups of components, e.g., circuit boards. The first is where failure of an individual subsystem implies system failure. This is known as the series model and is shown in Fig. 98.2. This is the same case as considered previously, and the parts count method, Eqs. (98.12) and (98.13), can be used. The second case is where failure of an individual subsystem does not imply system failure. This is shown in Fig. 98.3. Only the failure of every subsystem means that the system has failed, and the system reliability can be evaluated by the following method. If $r(t)$ is the reliability (or probability of not failing) of each subsystem, then $q(t) = 1 - r(t)$ is the probability of an individual subsystem failing. Hence, the probability of them all failing is

$$q_s(t) = [1 - r(t)]^n \tag{98.14}$$

for n subsystems.

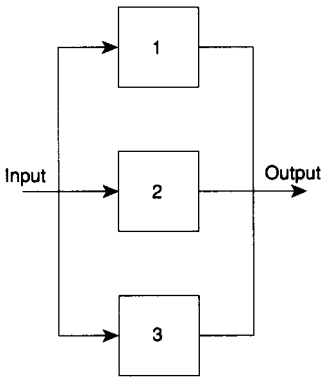

FIGURE 98.3 Parallel model.

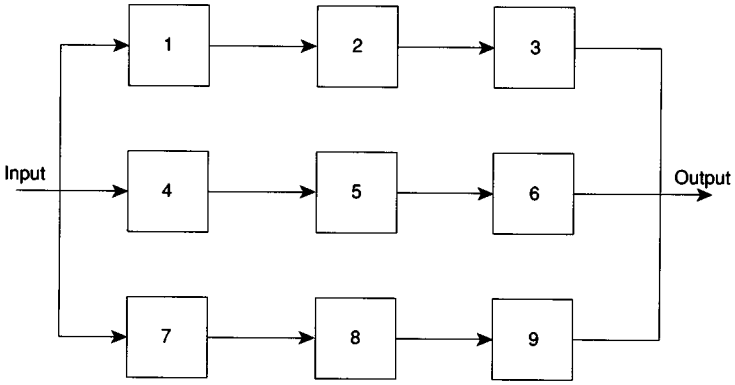

FIGURE 98.4 Parallel series model.

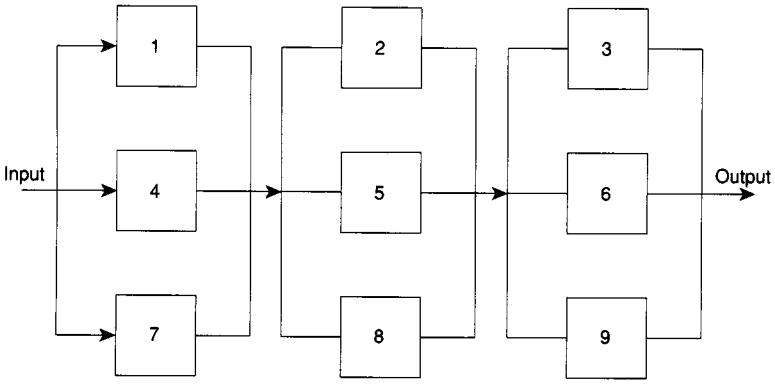

FIGURE 98.5 Series-parallel model.

Hence the system reliability will be:

$$r_s(t) = 1 - [1 - r(t)]^n \tag{98.15}$$

In practice, systems will be made up of differing combinations of parallel and series networks; the simplest examples are shown in Figs. 98.4 and 98.5.

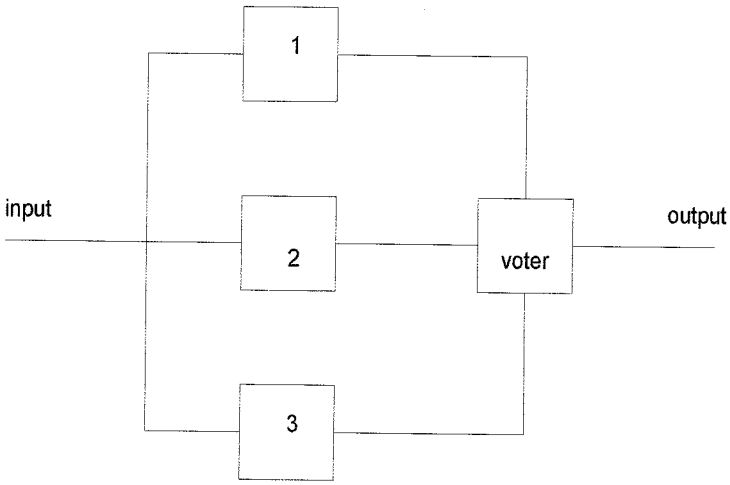

FIGURE 98.6 Triple-modular-redundant system.

Parallel-Series System

Assuming that the reliability of each subsystem is identical, then the overall reliability can be calculated thus. The reliability of one unit is *r;* hence the reliability of the series path is r^n. The probability of failure of each path is then $q = 1 - r^n$. Hence, the probability of failure of all m paths is $(1 - r^n)^m$, and the reliability of the complete system is

$$r_{ps} = 1 - (1 - r^n)^m \tag{98.16}$$

Series-Parallel System

Making similar assumptions, and using a similar method, the reliability can be written as

$$r_{sp} = [1 - (1 - r)^n]^m \tag{98.17}$$

It is straightforward to extend these results to systems with subsystems having different reliabilities and in different combinations. It can be seen that these simple models could be used as the basis for a fault tolerant system, i.e., one that is able to carry on performing its designated function even while some of its parts have failed.

Practical Systems Using Parallel Sub-Systems

A computer system that uses parallel sub-systems to improve reliability must incorporate some kind of arbitrator to determine which output to use at any given time. A common method of arbitration involves adding a voter to a system with N parallel modules, where N is an odd number. For example, if $N = 3$, a single incorrect output can be masked by the two correct outputs outvoting it. Hence, the system output will be correct, even though an error has occurred in one of the sub-systems. This system would be known as Triple-Modular-Redundant (TMR) (Fig. 98.6).

The reliability of a TMR system is the probability that any two out of the three units will be working. This can be expressed as

$$r_{tmr} = r_1 r_2 r_3 + r_1 r_2 (1 - r_3) + r_1 (1 - r_2) r_3 + (1 - r_1) r_2 r_3$$

where r_n $(n = 1, 2, 3)$ is the reliability of each subsystem. If $r_1 = r_2 = r_3 = r$ this reduces to

$$r_{tmr} = 3r^2 - 2r^3$$

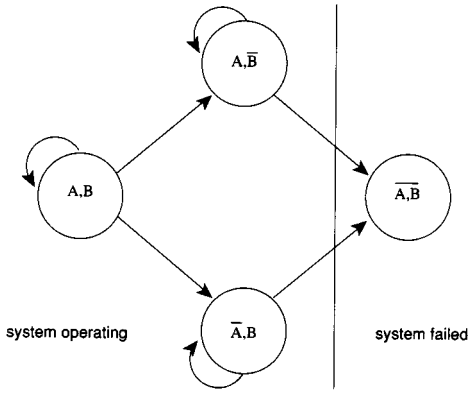

FIGURE 98.7 State diagram for two-unit parallel system.

The reliability of the voter must be included when calculating the overall reliability of such a system. As the voter appears in every path from input to output, it can be included as a series element in a series-parallel model. This leads to

$$r_{tmr} = r_v\left[3r^2 - 2r^3\right] \tag{98.18}$$

where r_v is the reliability of the voter.

More information on methods of using redundancy to improve system reliability can be found in Chapter 93.

98.10 Markov Modeling

Another approach to determining the probability of system failure is to use a Markov model of the system, rather than the combinatorial methods outlined previously. Markov models involve the defining of *system states* and *state transitions*. The mathematics of Markov modeling are well beyond the scope of this brief introduction, but most engineering mathematics textbooks will cover the technique.

To model the reliability of any system it is necessary to define the various fault-free and faulty states that could exist. For example, a system consisting of two identical units (A and B), either of which has to work for the system to work, would have four possible states. They would be (1) A and B working; (2) A working, B failed; (3) B working, A failed; and (4) A and B failed. The system designer must assign to each state a series of probabilities that determine whether it will remain in the same state or change to another after a given time period. This is usually shown in a state diagram, as in Fig. 98.7. This model does not allow for the possibility of repair, but this could easily be added.

98.11 Software Reliability

One of the major components in any computer system is its software. Although software is unlikely to wear out in a physical sense, it is still impossible to prove that anything other than the simplest of programs is totally free from bugs. Hence, any piece of software will follow the first and second parts of the normal bathtub curve (Fig. 98.1). The burn-in phase for hardware corresponds to the early release of a complex program, where bugs are commonly found and have to be fixed. The useful life phase for hardware corresponds to the time when the software can be described as stable, even though bugs may still be found. In this phase, where the failure rate can be characterized as constant (even if it is very low), the hardware performance criteria, such as MTTF and MTTR can be estimated. They must be included in any estimation of the overall availability for the computer system as a whole. Just as with hardware, techniques using redundancy can be used to improve the availability through fault tolerance.

98.12 Reliability Calculations for Real Systems

The most common source of basic reliability data for electronic components and circuits is the military handbook *Reliability Prediction of Electronic Equipment,* published by the U.S. Department of Defense. It has the designation MIL-HDBK-217E in its most recent version. This handbook provides both the basic reliability data and the formulae to modify those data for the application of interest. For example, the formula for predicting the failure rate, λ_p, of a bipolar or MOS microprocessor is given as

$$\lambda_p = \pi_Q(C_1\pi_T\pi_V + C_2\pi_E)\pi_L \text{ failures per } 10^6 \text{ hours}$$

where π_Q is the part quality factor, with several categories, ranging from a full mil-spec part to a commercial part; π_T is the temperature acceleration factor, related to both the technology in use and the actual operating temperature; π_V is the voltage stress derating factor, which is higher for devices operating at higher voltages; π_E is the application environment factor (the handbook gives figures for many categories of environment, ranging from laboratory conditions up to the conditions found in the nose cone of a missile in flight); π_L is the device learning factor, related to how mature the technology is and how long the production of the part has been going on; C_1 is the circuit complexity factor, dependent on the number of transistors on the chip; and C_2 is the package complexity, related to the number of pins and the type of package.

The following figures are given for a 16-bit microprocessor, operating on the ground in a laboratory environment, with a junction temperature of 51°C. The device is assumed to be packaged in a plastic, 64-pin dual in-line package and to have been manufactured using the same technology for several years:

$$\begin{array}{llll} \pi_Q = 20 & \pi_T = 0.89 & \pi_V = 1 & \pi_E = 0.38 \\ \pi_L = 1 & C_1 = 0.06 & C_2 = 0.033 & \end{array}$$

Hence, the failure rate λ_p for this device, operating in the specified environment, is estimated to be 1.32 failures per 10^6 hours. To calculate the predicted failure rate for a system based around this microprocessor would involve similar calculations for all the parts, including the passive components, the PCB, and connectors, and multiplying all the resultant failure rates together. The resulting figure could then be inverted to give a predicted MTTF. This kind of calculation is repetitive, tedious, and therefore prone to errors, so many companies now provide software to perform the calculations. The official Department of Defense program for automating the calculation of reliability figures is called ORACLE. It is regularly updated to include all the changes since MIL-HDBK-217E was released. Versions for VAX/VMS and the IBM PC are available from the Rome Air Defense Center, RBET, Griffiss Air Force Base, NY 13441-5700. Other software to perform the same function is advertised in the publications listed under Further Information.

Defining Terms

Availability: This figure gives a prediction for the proportion of time that a given part or system will be in full working order. It can be calculated from

$$\text{Av} = \frac{\text{MTTF}}{\text{MTTF} + \text{MTTR}}$$

Failure rate: The failure rate, λ, is the (predicted or measured) number of failures per unit time for a specified part or system operating in a given environment. It is usually assumed to be constant during the working life of a component or system.

Mean time to failure: This figure is used to give an expected working lifetime for a given part, in a given environment. It is defined by the equation

$$\text{MTTF} = \int_0^\infty r(t)\,dt$$

If the failure rate λ is constant, then

$$\text{MTTF} = \frac{1}{\lambda}$$

Mean time to repair: The MTTR figure gives a prediction for the amount of time taken to repair a given part or system.

Reliability: Reliability $r(t)$ is the probability that a component or system will function without failure over a specified time period, under stated conditions.

99.1 Introduction

The creation of the computer rivals any invention in our history. The wide use of computers and their resultant affect on all communication is tied directly to their ability to contact and interface with each other. This ability to link computers together is the basis for all global success of computer usage. It is the key to sharing knowledge, data, conversation, and discovery on a global scale.

The Internet is the adolescent offspring developed from the creation of a backbone connecting computers and computer networks. These **Local Area Networks (LANs)** within internal locations can now be linked to other networks worldwide. The Internet, not really a place but a concept, is intended to connect global information resources. The value of the Internet is more than its ability to link computers and networks, its real value is in bringing information to any who need it.

This chapter will attempt to give a broad overview of the Internet, condensing the major points of interest into one short chapter. There are, of course, hundreds of books on the subject. At the end of the chapter there is a list of just a few publications the reader may wish to check for more in-depth information.

The rapid advances in technology and innovations in operating software make any published account of the Internet obsolete before they arrive in the reader's hands. As we look at the Internet as it exists today, we also try to take a glimpse at the future of this creation. There are, however, as many visions of the future as there are dreamers. So, with due respect to those who envision the developments and uses of the Internet in the years to come, here is a basic introduction.

99.2 History

Early in the development of the mainframe computer, the creators realized these machines would have to be able to talk to each other for the technology to be of real meaning. They began by connecting one computer to another through direct cable hook-up, then to printers, and eventually they sought a means of connection outside their own building. The telephone system seemed like a logical choice. It was virtually everywhere. It was flexible, inexpensive, and one could simply dial up the location one wanted to reach. The **modem** was invented to send computer information over telephone lines instead of a direct wire connection. It provided the **modulated** (**Mo**) computer signal from one location and the **demodulated** (**dem**) to the other end of the connection. Protocols were developed that would translate the computer signal to telephone tones. Modems

are limited by the speed at which they can make this translation. Later in the chapter, modem speeds and types will be discussed at greater length.

Computers can speak with each other in various methods over telephone lines. **Circuit switching** is when one computer directly dials up another. As phone lines in and out of locations began to become "busy" at times, the **multiplexing** idea was born. This allows an electronic cue system where computers may line up to access the next available line when one computer is done. Various forms of multiplexing have been developed to hold the data to be transmitted until an outgoing line is available, then delivering it. This eliminates the need for the entire computer waiting for a path. Other tasks can be undertaken while the outgoing data is in the hold position.

This same early system is still the main access to the Internet for businesses and personal use. It allows anyone access to the Internet anywhere in the world that telephone service is available. This now includes cellular applications and even direct satellite transmission for extremely remote locations. The system works very well and is expanding on a local access basis.

As the Cold War continued, the government began the search for a system that would be less vulnerable to damage or sabotage. The **U.S. Advanced Research Projects Agency (ARPA)** began to explore an alternate path for government, business, and research locations to interconnect. This national network would allow different operating systems the ability to talk to each other and to route this path in a multitude of connects. Thus, if one path was damaged, the system would seek another path to its destination. The packet system of transmitting, which divides the information into streams of small packets of information, each with an I.D. number for final assembly, was developed. This new network would allow scientists from around the country to connect to one another to further computer technology. The system would be able to share equipment, transfer data files, and use long distance login capabilities. However, according to one of its early developers, Vint Cerf, vice-president of the Corporation for National Research Initiatives, "...we didn't know that e-mail was important...we weren't even sure what it was at the time" [Dern, 1994]. This new network would be called **ARPAnet**.

Soon researchers at private companies and institutions of higher learning were cranking out new software protocols to allow computers access to this new highway. In 1969, the first three ARPAnet participants were linked between Stanford University in Palo Alto, California, and the University of California at Los Angeles and the University of California at Santa Barbara. The system grew slowly for the first decade, a bit faster over the next 10 years, and exploded in the 1990s as protocols, access, and individual desk top computers increased.

During these years many operating systems, high speed (including fiber optic) transmission lines, access providers, and language protocols were developed. The Defense Advanced Research Projects Agency developed a protocol for network interconnection called **Transmission Control Protocol/Internetworking Protocol (TCP/IP)**. In 1983 this protocol was adopted as the standard for what would later be called *Internet*.

99.3 The Internet Today

Today the Internet is a conglomeration of a huge number of interconnected LANs around the world. These are a series of linked IPs, functioning on their own, but able to instantly connect with any other LAN likewise connected to the Internet. It also covers the thousands of personal computers at home or in the office. The Internet can also connect to a wide range of other networks, including privately operated ones like America On Line, Prodigy, and Compuserve, plus hundreds of other special networks now in use throughout the world. All you need is their IP, email account, or Web site address. As more and more users access the Internet problems of speed, capacity, and reliability begin to crop up. These will be discussed later in the chapter.

The operating system most used by computers on the Internet is **Unix**. This system was developed by AT&T Bell Labs. This system uses characters on a menu or command message to access files. For more detailed information on Unix see [Dern, 1994].

The Internet has four major services: (1) **electronic mail** (email), (2) **telnet**, (3) **file transfer protocol (FTP)**, and (4) **client/server connections**. Discussion on each service follows.

1. Email—Probably the most used process on the Internet, email is a text transfer of messages from one point to another. Email addresses will route a message anywhere in the world in seconds. Several email programs are in use, from free shared systems such as Elm, **Pine**, **Mailx**, and **Eudora**. Recently some

advanced features have been added to mail programs and many have been released at low cost. **Eudora Pro** is an example. Email is a low-cost instant information carrier. It can be used internally or on the Internet and will continue to expand in usage.

2. Telnet—This program allows the user to log onto other computers in distant locations and to operate those computers from their own terminal, running systems or downloading data. This defines how computers speak to each other for login applications. Of course, most computers require a **password** to be able to access their information. The use of telnet to open other computers has spawned a rash of **hacking**, which attempts to forge passwords for unauthorized access. These can be criminal acts and are the very situations seen on occasional newscasts! Telnet is available on a public domain basis and can operate with almost all computer hardware.
3. FTP—This allows you to transfer files from one computer to another or from one remote site to another remote site. The user has the ability to download files from shareware servers or from private files using a password for entry. FTP can download small files and huge databases. It is the primary method for those doing research or fact finding to acquire massive amounts of information in a very short time. As was mentioned previously, the time it takes to download files is directly related to the speed of your modem, or direct connection. This can take a very long time in the case of large files.
4. Client/server—Much of the current use of the Internet is to share information. This can happen when one computer accesses another that operates separately and serves information to the client who has logged in. You request another computer to send files to you, the client. In the early days of the Internet, most of these were text files only. One such text-based browse is **Lynx**, developed at the University of Kansas for exploration of the documents on the Internet and the **World Wide Web (www)** Web, for short. WWW is a system for finding and accessing Internet resources. The Web's most innovative feature is the ability to "point and click" on a text word or graphic to **hypertext link** you to another Web site holding the information you request. This process allows you to move from one computer to the next hop-scotching across the globe to find the information you seek. By using hypertext-based protocol, the world is at your fingertips in an instant. The Lynx program is only text-based, but later developments brought graphics to the Web search vehicles. In order to search the vast reserves of information, **browsers** were developed. An early public domain browser, developed by the National Center for Supercomputing Applications, is **Mosaic**. Mosaic is all you need for Web site access. Later, **Netscape Navigator** was commercially developed with lots of bells and whistles for quick and easy access. There is a cost for Netscape.

Send/Receive Capacity

Computers function using binary numbers. This series of 0 or 1 format exists at the smallest level as a bit. This digital system is transmitted over modems or direct connections in a series of 8-bit packets called bytes. The number of bits per second that can be transmitted or received equates to the speed at which you can send or receive information over the Internet. This **bandwidth** of the transmission line is expressed in bits per second, normally in metric form.

Early computer connects were made at 56 bits per second (56 bps). As the speed of machine and systems improved, rates of transmission have increased to kilobits (kbs), megabits (mps), gigabits (gbs), and so on. Early modems operated at 14.4 kbs (14,000 bps), more modern modems function at 28.8 kbs (28,800 bps). Higher capacity "pipelines" include **Integrated Services Digital Network (ISDN)** lines that can now be installed at home or business that operate at 56 kbs, direct **Ethernet** connections (a technology that can connect computers at a 10 Mbps). Higher capacity lines such as **T-1** (1.54 Mbs) and multiples of those, **T-2**, and **T-3** lines are now being used for extremely high capacity systems. The T-1 and higher lines are very expensive to install and maintain but offer extremely quick Internet work speed.

Login

In order to begin the process of logging in, you will need an account of some kind. This is established through your service provider, which could be your own company or a commercial service such as Compuserve, America

on Line, etc. If you are operating your own system, you'll first need a TCP/IP plus a serial communications protocol such as a **Serial Line Internet Protocol (SLIP)**, **Point to Point Protocol (PPP)**, or the like. If you access one of these from your desktop computer you may start an email program, such as Eudora, without logging in to your multiuser account. Your mail will be downloaded to your desktop, where you can read it, print it, save it, or compose a new message. When you copy files from public acccess sites, your desktop system can bring them directly to it. You can also use the full desktop visual capabilities of your system when attaching to a Web site. If you are using a modem connection to another server/host, you'll need to check the speed. From Internet providers and accounts available you can select:

- full network sites
- dial in IP accounts
- telnet (long distance telephone service)
- public access accounts (terminal servers)
- commercial servers

Email and Web sites are identified by an address. On the Internet, address always refers to an electronic address. The form is **Userid**, the name selected by the user, followed by the @ character, followed by the **computer's name** (all computers on the Internet have a specific name).

Example: ghawke@ukans.edu In this case "ukans" refers to the University of Kansas computer center. No spaces are used in the address. The information after the "@" refers to a **domain**. There can be any number of user names alike but each and every domain will have their own unique name.

After the userid –@– and domain name, there can be one or more sub-domains. In the example above, the sub-domain is "edu" for educational institution. The sub-domains are listed with the most general information about the domain computer being further to the right or end of the address and the most specific name being to the immediate right of the domain name. Domains and their meanings are listed in Table 99.1.

Password

At this point of your login, you'll be asked to create a password. This password is the key to your account and the tighter you guard it, the more secure your system will be. Common passwords are a combination of letter and number characters, usually eight or so in number. Obviously, these can be the subject of unauthorized usage. The more creative the password, the more secure it will be.

The World Wide Web (WWW, Web)

The WWW has more Internet locations than any other resource. It serves as a huge reference book for the world, with the added feature of hypertext links . Hypertext allows one to follow a topic line or reference idea

TABLE 99.1 Organizational Top-Level Domains

Domain	Meaning
art	Cultural and entertainment entities
com	Commercial organization
edu	Educational institution
firm	Businesses or firms
gov	Government
info	Information services
int	International organization
mil	U.S. military
net	Networking organization
nom	Individual or personal nomenclature
org	Non-profit organization
rec	Recreational activity organizations
store	Businesses offering goods to purchase
web	WWW related activity organizations

from one site to another, just by a point and "click" of a mouse. This link can take you to another page of the site you initially addressed or it can automatically link you around the world to another computer with a totally different Web site full of additional information. This is done through a computer program titled **HyperText Markup Language (HTML)**. This program will allow you to create your own Web site, or **home page** as they are sometimes called, or connect your site to any others you wish to link.

With the millions of Web sites out there, the browsers we previously mentioned are invaluable in locating the site you want. You may access these by topic name, individual name, address, or randomly. A list of **searching tools** is provided in the Defining Terms section.

99.4 The Future

Obviously, the future of the Internet is as wide open as imagination itself. The author, therefore, can only propose one person's opinion. Those who have the vision and talent for the future needs of information and services on the Internet will be the millionaires and experts in the years to come. There are a few areas that current trends indicate will be open for expansion.

Advertising and Marketing

It seems clear that what is driving the expanse of the Internet's development is directly linked to advertising and marketing. When *Netscape* and *Yahoo* went public, the company founders became instant millionaires and the value of those and other companies soared. Although theses two companies now charge for their software, these search vehicles will create the majority of their income for advertising on their search pages and by the sale of marketing research they can develop from the chronicling of data received from their visitors. Every time one of these is accessed, computers can archive the visitor's name and address, the sites they visited, the time spent on each page, the links made to other sites and any purchases ordered. Advertisers can focus on the exact customer profile they want in purchasing this information database or to advertise directly on the page. There are huge dollars waiting to be spent on this form of advertising. The user of the Internet may feel they are an independent wanderer through the garden of knowledge, with no forced direction and no guided path. They should know, however, that the most popular search vehicles, most exciting Web site pages, and most creative browsers will be paid for by advertising dollars. Their use of these sites will contribute to databases designed to exploit these visitors.

One of the major reasons the Internet and, more specifically, the World Wide Web will increase in use is its ability for *interactive* use by the public. This takes the form of game playing, research responses, banking, entertainment, and purchases. Recent trade shows have unveiled incredible interactive games designed for all ages that can be played over the Internet from *Scrabble* to *Super Mario*. The Web already contains hundreds of sites that allow you to respond directly to research questions, interest levels and personal inquiry. There are many sites that already involve banking and the ordering of goods and services. Obviously, the popularity of these services is directly related to the public's confidence in their security. Just as with Automated Teller Machines, I believe this aspect of technology will be mastered on the Internet, although any code or security system designed by one can be broken by another.

The entertainment side will grow rapidly. Movies on demand, archival information from existing print media and traditional radio and TV will be available. In December of 1994, *KJHK*, the student FM radio station at the University of Kansas, was the first station to provide a real time, live and continuous programming source to the Internet. The on-air programming of the station can be heard anywhere in the world by attaching to their Web site. There are many radio stations now "broadcasting" over the Internet and several commercial software companies around to facilitate that use. On January 2, 1996, the University of Kansas provided a live television signal to the Internet that could be viewed by computers connected to the Internet with 28.8 modems or higher. These real time audio and video services will be used in all kinds of applications in the future. They not only provide good quality and diverse choice, but can be delivered at very low costs since most long distance telephone charges are not present.

The huge growth in the use of the Internet is even more amazing when one considers that the ownership of personal computers is still rather low when compared with the entire population, although 1995 was the first

year that the purchase of computers outpaced the purchase of television sets! The use of the Internet for email will continue to increase. This will also take the form of video conferencing. The speed and low cost of both of these systems make contact between family and student or between corporations and their clients a very desirable advantage of the Internet.

No discussion about the Internet's future would be complete without a quick look at the legal aspects. We have already seen an attempt by the government to censor content on the Internet. The recent Telecommunications Act called for criminal penalties for certain obscene material provided to the Internet. This was struck down by the Supreme Court, but look for more attempts to regulate this new media. In addition, the concerns about intellectual property and copyright infringement are already being addressed. Many Internet users "use" material on their Web sites without permission from their creators. This applies to music licenses for entertainment, reprints of news stories and books, cartoons, artists creations, and copyrighted research. Be careful in this area. The larger the pockets of the user, the more apt they are to be sued for copyright infringement. As the years go by, you will see many new regulations and judicial decisions in favor of the creators of this material.

Finally, the anonymity for Internet users, the personal soap box it offers, and the ability to gather even the most obscure interest groups together in the privacy of their very own home means a huge use of the Internet for personal expression. This new technology will be as great, if not greater, an influence on world society than television has been. Your predictions on its future are as good as mine.

Defining Terms

The following list of terms is based in large part from the published list compiled by *Academic Computing Services, University of Kansas*, and is reprinted with their permission.

Anonymous FTP: Used to log into public access file sites and download files by logging in the user name "anonymous"

Archie: A search system for locating publicly available files by anonymous FTP.

ARPA: The United States Advanced Research Projects Agency was the original source for the development of a network to inter-connect computers.

ARPAnet: The original inter-connecting network that was the basis for the Internet.

ASCII: American Standard Code for Information Interchange. An industry-wide computer standard for the encoding of numeric characters.

ASCII file: American Standard Code for Information Interchange. A file type where characters are stored as a series of eight binary digits (A=01000001).

Buad rate: The primary signaling rate of a carrier. A 9600 "baud" modem transfers data at 2400 baud, but the signal rate is 4 bits per cycle allowing for a transfer rate of 9600 bps. Baud and bps are used synonymously but they not the same.

BBS: Bulletin board system. An electronic multi-user system that often includes a message database people can login to and leave messages for a particular group.

binary file: A file in which all 8 bits of a byte are used to encode information. Binary is also a file transfer type used for .zip and executable files in ftp.

BITNET: An academically oriented international network using a different protocol than the Internet, although email may be exchanged via gateways. A typical BITNET address might look like *joe@ukanvm.*

bps: Bits per second.

Bridge: A connection using software or hardware to connect two segments of a network not necessarily using the same protocol.

Browser: any program that reads hypertext. *Mosaic, Lynx,* and *Netscape Navigator* are browser clients used to access World Wide Web sites.

Client: A software application that exists to extract some service from a remote server somewhere on the network. (Think of your telephone as the client and the telephone company as the server).

Compression: A utility used on many platforms to make files smaller for transport. On a Mac common compression formats are *.sit* (use *Stuffit* to uncompress) or *.cpx* (use *Compact Pro t*o uncompress). On a PC, *.zip* is common (use *pkunzip* to uncompress).

Domain name server: A distribution database system for translating mnemonic computer addresses (like *kuhub.cc.ukans.edu* into numeric addresses (like *129.237.32.1*) and vice versa.

Domain name: The exclusive name assigned to a site on the Internet.

Email: Electronic mail. The exchange of messages between people on an electronic network.

Ethernet: A computer communications technology designed to connect computer systems together to form local area networks (*LANs*). Ethernet transmits information at 10 million bits per second over different physical media ranging from twisted pair wires to fiber optic cable.

Fetch: An easy to use public domain *ftp* program for the Macintosh.

FTP: File Transfer Protocol. The process of moving a file from one computer to another. The application program that moves files using the file transfer protocol.

Gateway: Device that converts messages from one protocol to another allowing two different networks to communicate.

Gopher: A menu-based system for exploring the Internet.

HTML: HyperText Markup Language. Used to define the various components of a World Wide Web document. HTML tells Web browsers like *Netscape* how to display text.

Hypertext: Documents that contain links to other documents or other areas of the same document. Selecting a link in a hypertext document automatically displays the second location.

IP: Internet Protocol. Allows a packet to transverse multiple networks to find a destination.

LAN: Local area network. A hardware/software combination that allows a group of computers in a limited area to share resources.

Lynx: A cursor-based hypertext browser for exploring the Web. Developed at the University of Kansas by members of the Distributed Computing Group of User Services.

Modem: A piece of equipment that connects a computer to a data transmission line (usually a telephone line).

Mosaic: An Internet navigating tool for exploring the Web.

Multiplexing: As it relates to the modem connection of computer, the ability to process on command while waiting for another to "cue up" and wait for a connection to another site.

Netscape Navigator: An Internet navigating tool for exploring the Web, sometimes called *Netscape*.

NIC: Network Information Center. As close as the Internet gets to a central office.

Packet: A bundle of data. Data on the Internet is broken up into small chunks called packets. When packets arrive at an addressed location, they are reassembled into the original data stream.

PPP: Point to point protocol. A format that allows a computer to use Internet protocols over a serial dial-in connection.

Protocol: A definition of a formal process. For example, a communications protocol allows computers from different manufacturers to talk to each other.

Public domain: A file is said to be in the public domain if it can be downloaded free without restrictions such as shareware fees.

Router: A combined hardware/software system to transfer data between two networks that use the same protocol.

Searching tools: Programs that aide you in finding the many Internet sites you wish to connect to, searchable by name, subject, or category. Some of these are:

- **Archie:** A toll for locating files on publicly accessible sites. The results of an Archie search are the names and directories of files on *anonymous ftp* sites. Access Archie at: *http://www.lerc.nasa.gov/Doc/archieplezhttpd.html*
- **Finger:** Designed to give information about a person with an account on a particular system. From the system prompt enter the command: *talk address*
- **Gopher:** A menu-based system for exploring Internet resources. Accessed files may be on an *anonymous ftp*, library, or database that is accessible only with Gopher. To access Gopher: *http://www.cc.ukans.edu/cwis/ reference/gopher_ resources.html*
- **WAIS:** Access at: *http://www.w3.org/hypertext/DataSources/WAIS/ByHost.html*
- **Whois:** Access from your multiuser account by entering the command: *whois name*

Server: A computer that provides files and other facilities to anyone with proper access and authorization.

Shareware: Software that is distributed for use by the public. If found to be useful, a fee is expected by the developer.

SLIP: Serial Line Internet Protocol. A protocol that allows a computer to use Internet protocols over a serial dial-in connection.

TCP/IP: The Transmission Control Protocol/Internet Protocol. One of the protocols on which the Internet is based.

Telnet: A terminal emulation protocol that allows someone to sign-on to a remote system on the Internet and an application that implements the telnet protocol.

Terminal server: Provides dial-in access to basic services (i.e., telnet) for file transfer and Internet service via PPP of SLIP.

UNIX: A popular operating system developed by AT&T/Bell labs. This is the major system by which Internet servers are programmed. The most common user interfaces on the Internet are character-based menu-choice or command-line interfaces to Unix systems.

vt100: A type of terminal made by Digital Equipment Corp. Many terminal emulation programs provide vt100 emulation.

WAIS: Wide Area Information Services. A system for searching databases across the Internet.

Whois: An application used to access a directory of domain names and addresses using the *Network Information Center* database. To access whois from a multiuser account enter the command: *whois name.* The name may be a registered person, Internet host name, or an organization.

Web (WWW): World Wide Web. A hypertext-based system for finding and accessing Internet resources.

The following are Internet program locaters.

Archie for Macintosh: Via anonymous ftp from *sumex-aim.stanford.edu* in the directory *info-mac/comm.*

Eudora: Commercial version email *eudora-info@qulcomm.com.* No charge version available via anonymous ftp from *sumex-aim.stanford.edu* in the directory *info-mac/comm* or from *ftp.qualcomm.com* in the mac/eudora directory.

PC Eudora: Available via anonymous ftp from *ftp.qualcomm.com.*

Fetch: Via anonymous ftp from *sumex-aim.stanford.edu* in the directory *info-mac* or *dartmouth.edu* in the *pub/mac* directory.

Gopher Book for Widows: *gophbook.zip* is available via anonymous ftp from *sunsite.unc.edu.* Directory *pub/micro/pc-stuff/ms-windows/winsock/apps.*

PC Gopher for DOS: From *sunsite.unc.edu pub/package/gopher/PC_client.*

HGopher for Windows: Available via anonymous ftp from *lister.cc.ic.ac.uk* in the directory *pub/wingopher.*

TurboGopher: Via anonymous ftp from *sumex-aim.stanford.edu* in the directory *info-mac/comm.*

Mosaic: Via anonymous ftp from *ftp.ncsa.uiuc.edu* in the *Mosaic/mosaic-binaries* directory.

NCSA Telnet: Via anonymous ftp from *sumex-sim.stanford.edu* in the directory *info-mac/comm* or from *ftp.nsca.uiuc.edu* in Mac directory.

MacPPP: *pub/pp* directory at *merit.edu.* Combine this with MacTCP to get your Mac directly on the Internet.

PC/TCP Plus for DOS: *info@ftp.com.*

MacTCP: Contact *apda@applelink.apple.com.*

InterSLIP: *pub/sales* directory at *ftp.intercon.com.*

MacSLIP: For information, e-mail *infor@hdepark.com.*

Super-TCP//NFS for Windows: *tcp@frontiertech.com.*

Talk for the Macintosh: Via anonymous ftp from *mac.archive.umich.edu* in the directory *mac/util/comm.*

WAIS-for-Mac: Via anonymous ftp from *ftp/wais.com.* Go to the file *wais-for-mac-1.2-alpha.sea.hqx* from the directory *pub/freeware/mac.*

WinWAIS for Windows: *wnwais21.zip* is available via anonymous ftp from *ridgisd.er.usgs.gov* in the directory *software/wais.*

WWW Browser for Macintosh: In the directory *pub/www/bin/mac* via anonymous ftp from *infor.cern.ch.*

WorldWideWeb Browser: Via anonymous ftp from *info.cern.ch* in the directory *pub.www.bin.next.*

This small robotic rover has been sent to Mars inside the Mars Pathfinder lander which was launched from Kennedy Space Center on December 4, 1996. Known as Sojourner, this compact, semi-autonomous six-wheeler will become the first vehicle to traverse the Martian surface.

The rover weighs just 22 lb (10 kg) and when fully deployed is 11 in. (280 mm) high, 25 in. (630 mm) long, and 19 in. (480 mm) wide. It is equipped with three cameras and an alpha proton x-ray spectrometer which must be in contact with rocks or soil to measure elemental composition. A sensor detects alpha particle scattering and proton and x-ray emissions. Sojourner runs on a solar array, sufficient to power the rover for several hours per day, even in the worst dust storms.

The rover control system features operator designation of targets and autonomous control to reach targets and perform tasks. The instructions will be sent to the rover from a controller on earth. The onboard control system is built around an Intel 80C85 processor, which is an 8-bit processor and runs at about 100,000 instructions per second.

Landers and rovers of the future will share the heritage of Mars Pathfinder designs and technologies first tested during this mission. (Photo courtesy of National Aeronautics and Space Administration.)

FUNDAMENTAL IDEAS, CONCEPTS, AND TOOLS developed in system theory have contributed significantly to the breakthroughs in aerospace, manufacturing, and medicine, to name a few. In 1990, the National Academy of Engineering identified ten outstanding engineering achievements of the preceding 25 years. These feats included five accomplishments made possible by utilizing modern system theory: Apollo lunar landings, satellites, computer-based manufacturing, computer axial tomography, and the jumbo jet. At present, these ideas are being extended to increase the productivity of the manufacturing sector, improve highway safety, increase fuel efficiency of automobiles, and design and produce environmentally friendly products.

This section discusses conceptual approaches and tools of modern system theory and their applications. The key concepts for the analysis and design of linear and non-linear control systems: modeling, dynamic response, frequency response, root locus, compensation, digital control, describing functions, and phase plane are discussed in Chapter 100. Application of these concepts to a variety of systems is discussed in the following chapters. These systems draw their name from their application, for example, vehicular systems. The topic discussed in Chapter 101 is robotics. A robot is a computer-based mechanical manipulator which can be programmed to perform a variety of tasks. The authors review modeling, control, and application of robots. Chapter 102 describes aerospace systems in avionics and their use in communication satellite systems. The next chapter reviews the command, control, and communication systems used to monitor and control military aerospace systems. Chapter 104 describes two key industrial systems: welding and bonding, and large drives. The authors describe modeling, sensor requirements, control system requirements, and implementation for these systems. Chapter 105 discusses man-machine systems and models used to analyze them. The next two chapters review the key characteristics and electronic controls for vehicular systems, and industrial illumination systems. Chapter 108 describes instruments, which are systems consisting of sensors and electronic circuits, usually for measurement applications. Modern approaches to navigation on the land, sea, or in the air are discussed in Chapter 109. Important topics such as reliability (Chapter 110) and environment (Chapter 111) are included to emphasize their improtance in the design of modern products and processes. With the advent of computer technology, system theory tools are widely available on the computer and the use of this is widespread and thus deserves special attention. Chapter 112 discusses this software.

100.1 Models

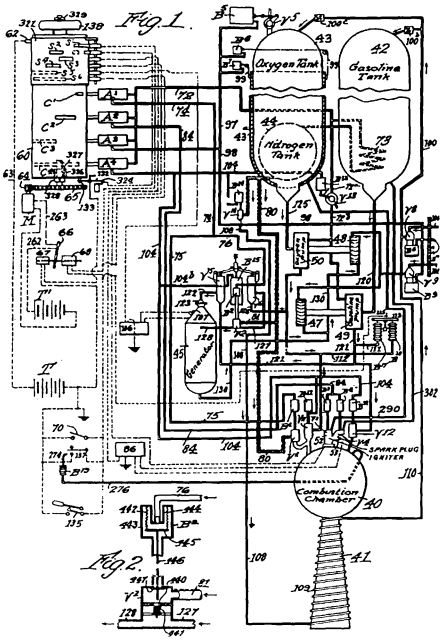
William L. Brogan

A naive trial-and-error approach to the design of a control system might consist of constructing a controller, installing it into the system to be controlled, performing tests, and then modifying the controller until satisfactory performance is achieved. This approach could be dangerous and uneconomical, if not impossible. A more rational approach to control system design uses mathematical models. A *model* is a mathematical description of system behavior, as influenced by input variables or initial conditions. The model is a stand-in for the actual system during the control system design stage. It is used to predict performance; to carry out stability, sensitivity, and trade-off



Control Mechanism for Rocket Apparatus

Robert H. Goddard
Patented April 2, 1946
#2,397,657

An excerpt from Robert Goddard's patent application:

This invention relates to rockets and rocket craft which are propelled by combustion apparatus using liquid fuel and a liquid to support combustion, such as liquid oxygen. Such combustion apparatus is disclosed in my prior application Serial No. 327,257 filed April 1, 1940.

It is the general object of my present invention to provide control mechanism by which the necessary operative steps and adjustments for such mechanism will be affected automatically and in predetermined and orderly sequence.

To the attainment of this object, I provide control mechanism which will automatically discontinue flight in a safe and orderly manner.

Dr. Goddard was instrumental in developing rocket propulsion in this country, both solid-fuel rocket engines and later liquid-fuel rocket motors used in missile and spaceflight applications. Goddard died in 1945, before this pivotal patent (filed June 23, 1941) on automatic control of liquid-fuel rockets was granted. He assigned half the rights to the Guggenheim Foundation in New York.

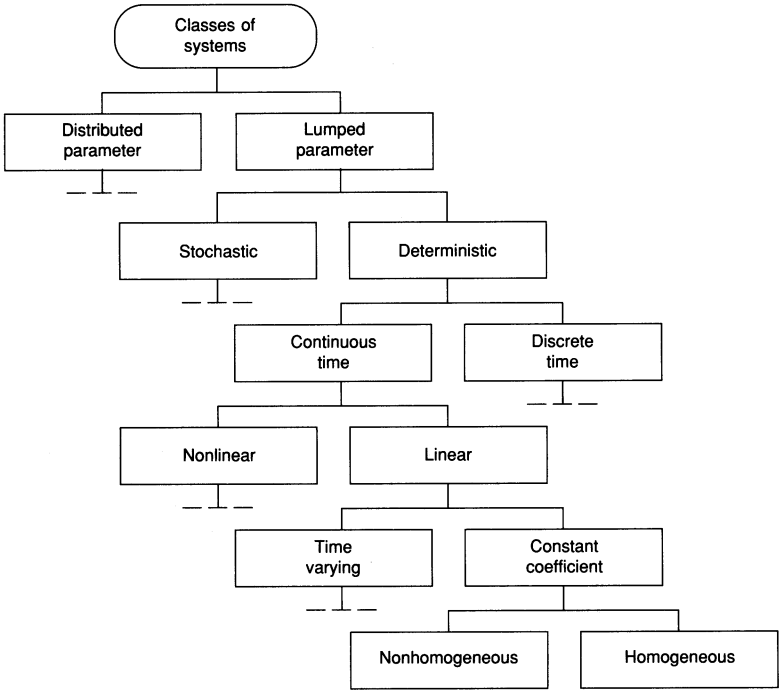


FIGURE 100.1 Major classes of system equations. (*Source:* W.L. Brogan, *Modern Control Theory,* 3rd ed., Englewood Cliffs, N.J.: Prentice-Hall, 1991, p. 13. With permission.)

studies; and answer various "what-if" questions in a safe and efficient manner. Of course, the validation of the model, and all conclusions derived from it, must ultimately be based upon test results with the physical hardware.

The final form of the mathematical model depends upon the type of physical system, the method used to develop the model, and mathematical manipulations applied to it. These issues are discussed next.

Classes of Systems to Be Modeled

Most control problems are multidisciplinary. The system may consist of electrical, mechanical, thermal, optical, fluidic, or other physical components, as well as economic, biological, or ecological systems. Analogies exist between these various disciplines, based upon the similarity of the equations that describe the phenomena. The discussion of models in this section will be given in mathematical terms and therefore will apply to several disciplines.

Figure 100.1 [Brogan, 1991] shows the classes of systems that might be encountered in control systems modeling. Several branches of this tree diagram are terminated with a dashed line indicating that additional branches have been omitted, similar to those at the same level on other paths.

Distributed parameter systems have variables that are functions of both space and time (such as the voltage along a transmission line or the deflection of a point on an elastic structure). They are described by partial differential equations. These are often approximately modeled as a set of *lumped parameter* systems (described by ordinary differential or difference equations) by using modal expansions, finite element methods, or other approximations [Brogan, 1968]. The lumped parameter continuous-time and discrete-time families are stressed here.

Two Major Approaches to Modeling

In principle, models of a given physical system can be developed by two distinct approaches. Figure 100.2 shows the steps involved in *analytical modeling.* The real-world system is represented by an interconnection of idealized elements. Table 100.1 [Dorf, 1989] shows model elements from several disciplines and their elemental equations. An electrical circuit diagram is a typical result of this physical modeling step (box 3 of Fig. 100.2). Application of the appropriate physical laws (Kirchhoff, Newton, etc.) to the idealized physical model (consisting of point masses, ideal springs, lumped resistors, etc.) leads to a set of mathematical equations. For a circuit these will

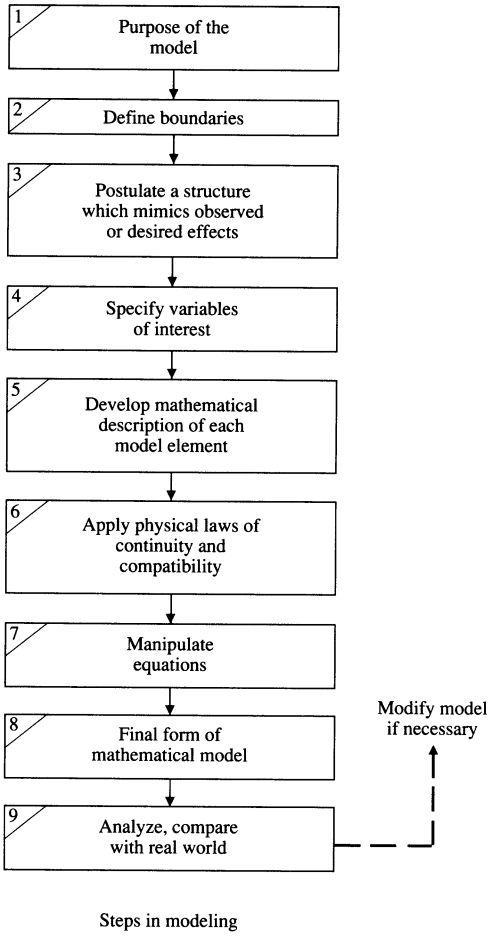

FIGURE 100.2 Modeling considerations. (*Source:* W.L. Brogan, *Modern Control Theory,* 3rd ed., Englewood Cliffs, N.J.: Prentice-Hall, 1991, p. 5. With permission.)

be mesh or node equations in terms of elemental currents and voltages. Box 6 of Fig. 100.2 suggests a generalization to other disciplines, in terms of continuity and compatibility laws, using through variables (generalization of current that flows through an element) and across variables (generalization of voltage, which has a differential value across an element) [Shearer et al., 1967; Dorf, 1989].

Experimental or *empirical* modeling typically assumes an *a priori* form for the model equations and then uses available measurements to estimate the coefficient values that cause the assumed form to best fit the data. The assumed form could be based upon physical knowledge or it could be just a credible assumption. Time-series models include autoregressive (AR) models, moving average (MA) models, and the combination, called ARMA models. All are difference equations relating the input variables to the output variables at the discrete measurement times, of the form

$$y(k+1) = a_0 y(k) + a_1 y(k-1) + a_2 y(k-2) + \ldots + a_n y(k-n) + b_0 u(k+1) + b_1 u(k) + \ldots + b_p u(k+1-p) + v(k) \quad (100.1)$$

where $v(k)$ is a random noise term. The z-transform transfer function relating u to y is

$$\frac{y(z)}{u(z)} = \frac{b_0 + b_1 z^{-1} + \cdots + b_p z^{-p}}{1 - (a_0 z^{-1} + \cdots + a_{n-1} z^{-n})} = H(z) \quad (100.2)$$

TABLE 100.1 Summary of Describing Differential Equations for Ideal Elements

Type of Element	Physical Element	Describing Equation	Energy E or Power $\mathcal{P}$	Symbol
Inductive storage	Electrical inductance	$v_{21} = L\,\frac{di}{dt}$	$E = \frac{1}{2}\,Li^2$		Translational spring	$v_{21} = \frac{1}{K}\,\frac{dF}{dt}$	$E = \frac{1}{2}\,\frac{F^2}{K}$		Rotational spring	$\omega_{21} = \frac{1}{K}\,\frac{dT}{dt}$	$E = \frac{1}{2}\,\frac{T^2}{K}$		Fluid inertia	$P_{21} = I\,\frac{dQ}{dt}$	$E = \frac{1}{2}\,IQ^2$	Capacitive storage	Electrical capacitance	$i = C\,\frac{dv_{21}}{dt}$	$E = \frac{1}{2}\,Cv_{21}^2$		Translational mass	$F = M\,\frac{dv_2}{dt}$	$E = \frac{1}{2}\,Mv_2^2$		Rotational mass	$T = J\,\frac{d\omega_2}{dt}$	$E = \frac{1}{2}\,J\omega_2^2$		Fluid capacitance	$Q = C_f\,\frac{dP_{21}}{dt}$	$E = \frac{1}{2}\,C_fP_{21}^2$		Thermal capacitance	$q = C_t\,\frac{d\tau_2}{dt}$	$E = C_t\tau_2$	Energy dissipators	Electrical resistance	$i = \frac{1}{R}\,v_{21}$	$\mathcal{P} = \frac{1}{R}\,v_{21}^2$		Translational damper	$F = fv_{21}$	$\mathcal{P} = fv_{21}^2$		Rotational damper	$T = f\omega_{21}$	$\mathcal{P} = f\omega_{21}^2$		Fluid resistance	$Q = \frac{1}{R_f}\,P_{21}$	$\mathcal{P} = \frac{1}{R_f}\,P_{21}^2$		Thermal resistance	$q = \frac{1}{R_t}\,\tau_{21}$	$\mathcal{P} = \frac{1}{R_t}\,\tau_{21}$	
In the MA model all $a_i = 0$. This is alternatively called an all-zero model or a finite impulse response (FIR) model. In the AR model all b_j terms are zero except b_0. This is called an all-pole model or an infinite impulse response (IIR) model. The ARMA model has both poles and zeros and also is an IIR model [Makhoul, 1975].

Adaptive and learning control systems have an experimental modeling aspect. The data fitting is carried out on-line, in real time, as part of the system operation. The modeling described above is normally done off-line [Astrom and Wittenmark, 1989].

Forms of the Model

Regardless of whether a model is developed from knowledge of the physics of the process or from empirical data fitting, it can be further manipulated into several different but equivalent forms. This manipulation is box 7 in Fig. 100.2. The class that is most widely used in control studies is the deterministic lumped-parameter continuous-time constant-coefficient system. A simple example has one input u and one output y. This might be a circuit composed of one ideal source and an interconnection of ideal resistors, capacitors, and inductors.

The equations for this system might consist of a set of mesh or node equations. These could be reduced to a single nth-order linear ordinary differential equation by eliminating extraneous variables.

$$\frac{d^n y}{dt^n} + a_{n-1}\frac{d^{n-1} y}{dt^{n-1}} + \cdots + a_1\frac{dy}{dt} + a_0 y = b_0 u + b_1\frac{du}{dt} + \cdots + b_m\frac{d^m u}{dt^m} \tag{100.3}$$

This nth-order equation can be replaced by an input-output transfer function

$$\frac{Y(s)}{U(s)} = H(s) = \frac{b_m s^m + b_{m-1}s^{m-1} + \cdots + b_1 s + b_0}{s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0} \tag{100.4}$$

The inverse Laplace transform $\mathcal{L}^{-1}\{H(s)\} = h(t)$ is the system impulse response function. Alternatively, by selecting a set of n internal **state variables,** Eq.(100.3) can be written as a coupled set of first-order differential equations plus an algebraic equation relating the states to the original output y. These equations are called state equations, and one possible choice for this example is, assuming $m = n$,

$$\dot{\mathbf{x}}(t) = \begin{bmatrix} -a_{n-1} & 1 & 0 & 0 & \cdots & 0 \\ -a_{n-2} & 0 & 1 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ -a_1 & 0 & 0 & 0 & \cdots & 1 \\ -a_0 & 0 & 0 & 0 & \cdots & 0 \end{bmatrix}\mathbf{x}(t) + \begin{bmatrix} b_{n-1} - a_{n-1}b_n \\ b_{n-2} - a_{n-2}b_n \\ \vdots \\ b_1 - a_1 b_n \\ b_0 - a_0 b_n \end{bmatrix} u(t)$$

and

$$y(t) = [1 \;\; 0 \;\; 0 \;\; \ldots \;\; 0]\mathbf{x}(t) + b_n u(t) \tag{100.5}$$

In matrix notation these are written more succinctly as

$$\dot{\mathbf{x}} = A\mathbf{x} + Bu \quad \text{and} \quad y = C\mathbf{x} + Du \tag{100.6}$$

Any one of these six possible model forms, or others, might constitute the result of box 8 in Fig. 100.2. Discrete-time system models have similar choices of form, including an nth-order difference equation as given in Eq. (100.1) or a z-transform input-output transfer function as given in Eq. (100.2). A set of n first-order difference equations (state equations) analogous to Eq. (100.5) or (100.6) also can be written.

Extensions to systems with r inputs and m outputs lead to a set of m coupled equations similar to Eq. (100.3), one for each output y_i. These higher-order equations can be reduced to n first-order state differential equations and m algebraic output equations as in Eq. (100.5) or (100.6). The **A** matrix is again of dimension $n \times n$, but **B** is now $n \times r$, **C** is $m \times n$, and **D** is $m \times r$. In all previous discussions, the number of state variables, n, is the order of the model. In transfer function form, an $m \times r$ matrix $H(s)$ of transfer functions will describe the input-output behavior

$$Y(s) = H(s)U(s) \tag{100.7}$$

Other transfer function forms are also applicable, including the left and right forms of the matrix fraction description (MFD) of the transfer functions [Kailath, 1980]

$$H(s) = P(s)^{-1}N(s) \quad \text{or} \quad H(s) = N(s)P(s)^{-1} \tag{100.8}$$

Both **P** and **N** are matrices whose elements are polynomials in s. Very similar model forms apply to continuous-time and discrete-time systems, with the major difference being whether Laplace transform or z-transform transfer functions are involved.

When time-variable systems are encountered, the option of using high-order differential or difference equations versus sets of first-order state equations is still open. The system coefficients $a_i(t)$, $b_j(t)$ and/or the matrices $\mathbf{A}(t)$, $\mathbf{B}(t)$, $\mathbf{C}(t)$, and $\mathbf{D}(t)$ will now be time-varying. Transfer function approaches lose most of their utility in time-varying cases and are seldom used. With nonlinear systems all the options relating to the order and number of differential or difference equation still apply.

The form of the nonlinear state equations is

$$\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u}, \mathbf{t})$$

$$y = h(\mathbf{x}, \mathbf{u}, \mathbf{t}) \tag{100.9}$$

where the nonlinear vector-valued functions $f(\mathbf{x}, \mathbf{u}, \mathbf{t})$ and $h(\mathbf{x}, \mathbf{u}, \mathbf{t})$ replace the right-hand sides of Eq. (100.6). The transfer function forms are of no value in nonlinear cases.

Stochastic systems [Maybeck, 1979] are modeled in similar forms, except the coefficients of the model and/or the inputs are described in probabilistic terms.

Nonuniqueness

There is not a unique correct model of a given system for several reasons. The selection of idealized elements to represent the system requires judgment based upon the intended purpose. For example, a satellite might be modeled as a point mass in a study of its gross motion through space. A detailed flexible structure model might be required if the goal is to control vibration of a crucial on-board sensor. In empirical modeling, the assumed starting form, Eq. (100.1), can vary.

There is a trade-off between the complexity of the model form and the fidelity with which it will match the data set. For example, a pth-degree polynomial can exactly fit to $p + 1$ data points, but a straight line might be a better model of the underlying physics. Deviations from the line might be caused by extraneous measurement noise. Issues such as these are addressed in Astrom [1980].

The preceding paragraph addresses nonuniqueness in determining an input-output system description. In addition, state models developed from input-output descriptions are not unique. Suppose the transfer function of a single-input, single-output linear system is known exactly. The state variable model of this system is not unique for at least two reasons. An arbitrarily high-order state variable model can be found that will have this same transfer function. There is, however, a unique minimal or irreducible order $n_{\min}$ from among all state models that have the specified transfer function. A state model of this order will have the desirable properties of **controllability** and **observability.** It is interesting to point out that the minimal order may be less than the actual order of the physical system.

The second aspect of the nonuniqueness issue relates not to order, i.e., the *number* of state variables, but to *choice* of internal variables (state variables). Mathematical and physical methods of selecting state variables are available [Brogan, 1991]. An infinite number of choices exist, and each leads to a different set $\{A, B, C, D\}$, called a realization. Some state variable model forms are more convenient for revealing key system properties such as stability, controllability, observability, **stabilizability,** and **detectability.** Common forms include the controllable canonical form, the observable canonical form, the Jordan canonical form, and the Kalman canonical form.

The reverse process is unique in that every valid realization leads to the same model transfer function

$$H(s) = C\{sI - A\}^{-1}B + D \tag{100.10}$$

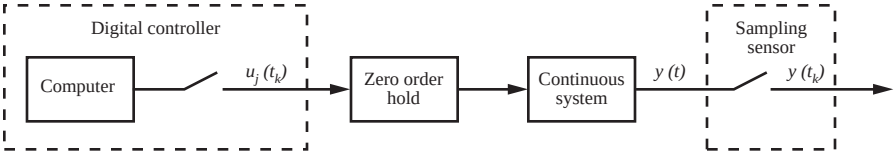

FIGURE 100.3 Digital output provided by modern sensor.

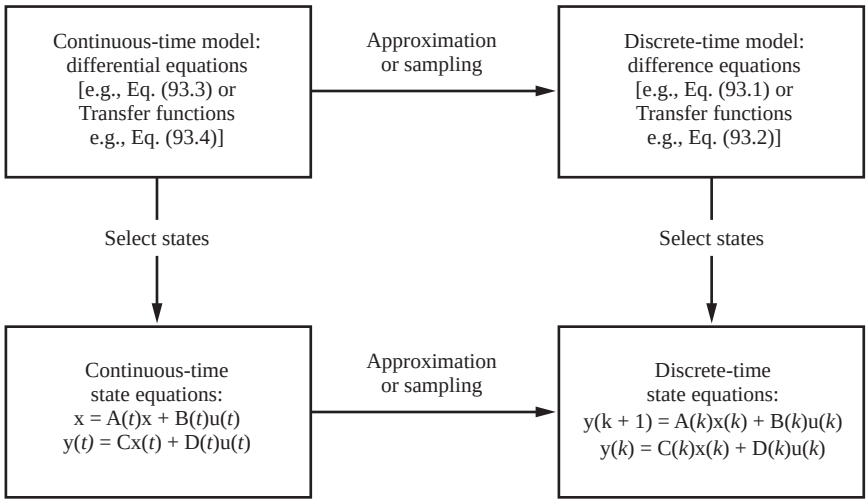

FIGURE 100.4 State variable modeling paradigm.

Approximation of Continuous Systems by Discrete Models

Modern control systems often are implemented digitally, and many modern sensors provide digital output, as shown in Fig. 100.3. In designing or analyzing such systems discrete-time approximate models of continuous-time systems are frequently needed. There are several general ways of proceeding, as shown in Fig. 100.4. Many choices exist for each path on the figure. Alternative choices of states or of approximation methods, such as forward or backward differences, lead to an infinite number of valid models.

Defining Terms

Controllability: A property that in the linear system case depends upon the **A,B** matrix pair which ensures the existence of some control input that will drive any arbitrary initial state to zero in finite time.

Detectability: A system is detectable if all its unstable modes are observable.

Observability: A property that in the linear system case depends upon the **A,C** matrix pair which ensures the ability to determine the initial values of all states by observing the system outputs for some finite time interval.

Stabilizable: A system is stabilizable if all its unstable modes are controllable.

State variables: A set of variables that completely summarize the system's status in the following sense. If all states x_i are known at time t_0, then the values of all states and outputs can be determined uniquely for any time $t_1 > t_0$, provided the inputs are known from t_0 onward. State variables are components in the state vector. State space is a vector space containing the state vectors.

Further Information

The monthly *IEEE Control Systems Magazine* frequently contains application articles involving models of interesting physical systems.

The monthly *IEEE Transactions on Automatic Control* is concerned with theoretical aspects of systems. Models as discussed here are often the starting point for these investigations.

Automatica is the source of many related articles. In particular an extended survey on system identification is given by Astrom and Eykhoff in vol. 7, pp. 123–162, 1971.

Early developments of the state variable approach are given by R. E. Kalman in "Mathematical description of linear dynamical systems," *SIAM J. Control Ser.,* vol. A1, no. 2, pp. 152–192, 1963.

100.2 Dynamic Response

Gordon K. F. Lee

Computing the Dynamic System Response

Consider a linear time-invariant dynamic system represented by a differential equation form

$$\frac{d^n y(t)}{dt^n} + a_{n-1}\frac{d^{n-1} y(t)}{dt^{n-1}} + \cdots + a_1\frac{dy(t)}{dt} + a_0 y(t) = b_m\frac{d^m f(t)}{dt^m} + \cdots + b_1\frac{df(t)}{dt} + b_0 f(t) \tag{100.11}$$

where $y(t)$ and $f(t)$ represent the output and input, respectively, of the system.

Let $p^k(\cdot) \triangleq (d^k/dt^k)(\cdot)$ define the differential operator so that (100.11) becomes

$$(p^n + a_{n-1}p^{n-1} + \ldots + a_1 p + a_0)y(t) = (b_m p^m + \ldots + b_1 p + b_0)f(t) \tag{100.12}$$

The solution to (100.11) is given by

$$y(t) = y_S(t) + y_I(t) \tag{100.13}$$

where $y_S(t)$ is the **zero-input response,** or that part of the response due to the initial conditions (or states) only, and $y_I(t)$ is the **zero-state response,** or that part of the response due to the input $f(t)$ only.

Zero-Input Response: $y_S(t)$

Here $f(t) = 0$, and thus (100.11) becomes

$$(p^n + a_{n-1}p^{n-1} + \ldots + a_1 p + a_0)y(t) = 0 \tag{100.14}$$

That is,

$$D(p)y(t) = 0$$

The roots of $D(p) = 0$ can be categorized as either distinct or multiple. That is, in general,

$$D(p) = \prod_{i=1}^{q} (p - \lambda_i)^{k_i} \prod_{i=1}^{r} (p - \lambda_{q+i})$$

where there are r distinct roots and q sets of multiple roots (each set has multiplicity k_i). Note that $r + \sigma = n$, where $\sigma \triangleq \sum_{i=1}^{q} k_i$. Each distinct root contributes a term to $y_S(t)$ of the form $c_i e^{\lambda_i t}$, where c_i is a constant, while each set of multiple roots contributes a set of terms to $y_S(t)$ of the form $\sum_{j=0}^{k_i-1} c_{i,j} t^j e^{\lambda_i t}$, where $c_{i,j}$ is some constant. Thus, the zero-input response is given by

$$y_S(t) = \sum_{i=1}^{q} \sum_{j=0}^{k_i-1} c_{i,j} t^j e^{\lambda_i t} + \sum_{i=1}^{r} c_{\sigma+i} e^{\lambda_{\sigma+i} t} \tag{100.15}$$

The coefficients $c_{i,j}$ and $c_{\sigma+i}$ are selected to satisfy the initial conditions.

Special Case

If all the roots of $D(p) = 0$ are distinct and the initial conditions for (100.11) are given by

$$\left\{ y(0), \frac{dy(0)}{dt}, \ldots, \frac{d^{n-1}y(0)}{dt^{n-1}} \right\}$$

then the coefficients of (100.15) are given by the solution of

$$\begin{bmatrix} y(0) \\ \dfrac{dy(0)}{dt} \\ \vdots \\ \dfrac{d^{n-1}y(0)}{dt^{n-1}} \end{bmatrix} = \begin{bmatrix} 1 & 1 & \cdots & 1 \\ \lambda_1 & \lambda_2 & \cdots & \lambda_n \\ \vdots & \vdots & \vdots & \vdots \\ \lambda_1^{(n-1)} & \lambda_2^{(n-1)} & \cdots & \lambda_n^{(n-1)} \end{bmatrix} \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_n \end{bmatrix} \tag{100.16}$$

Zero-State Response: $y_I(t)$

Here the initial conditions are made identically zero. Observing (100.11), let

$$H(p) = \frac{b_m p^m + \cdots + b_1 p + b_0}{p^n + a_{n-1}p^{n-1} + \cdots + a_1 p + a_0}$$

denote a rational function in the p operator. Consider using partial-fraction expansion on $H(p)$ as

$$H(p) = \sum_{i=1}^{q} \sum_{j=1}^{k_i} \frac{g_{i,j}}{(p - \lambda_i)^j} + \sum_{i=1}^{r} \frac{g_{\sigma+i}}{p - \lambda_{q+i}} \tag{100.17}$$

when the first term corresponds to the sets of multiple roots and the second term corresponds to the distinct roots.

Note the constant residuals are computed as

$$g_{\sigma+i} = [(p - \lambda_{q+i})H(p)]_{p = \lambda q+i}$$

and

$$g_{i,j} = \frac{1}{(k_i - j)!} \frac{d^{(k_i-j)}}{dp^{(k_i-j)}} \left\{(p - \lambda_i)^{k_i} H(p)\right\} \Big|_{p=\lambda_i}$$

Then

$$h(t) = \sum_{i=1}^{q} \sum_{j=1}^{k_i} \frac{g_{i,j}}{(j-1)!} t^{j-1} e^{\lambda_i t} + \sum_{i=1}^{r} g_{\sigma+i} e^{\lambda_{\sigma+i} t} \tag{100.18}$$

is the **impulse response** of the system (100.11). Then the zero-state response is given by

$$y_I(t) = \int_0^t f(\tau) h(t - \tau)\, d\tau \tag{100.19}$$

that is, $y_I(t)$ is the time convolution between input $f(t)$ and impulse response $h(t)$. In some instances, it may be easier to find $y_s(t)$ and $y_I(t)$ using Laplace Transform methods.

Measures of the Dynamic System Response

Several measures may be employed to investigate dynamic response performance. These include:

1. Speed of the response—how quickly does the system reach its final value
2. Accuracy—how close is the final response to the desired response
3. Relative stability—how stable is the system or how close is the system to instability
4. Sensitivity—what happens to the system response if the system parameters change

Objectives 3 and 4 may be analyzed by frequency domain methods (Section 100.3). Time-domain measures classically analyze the dynamic response by partitioning the total response into its steady-state (objective 2) and transient (objective 1) components. The **steady-state response** is that part of the response which remains as time approaches infinity; the **transient response** is that part of the response which vanishes as time approaches infinity.

Measures of the Steady-State Response

In the steady state, the accuracy of the time response is an indication of how well the dynamic response follows a desired time trajectory. Usually a test signal (reference signal) is selected to measure accuracy. Consider Fig. 100.5. In this configuration, the objective is to force $y(t)$ to track a reference signal $r(t)$ as close as possible.

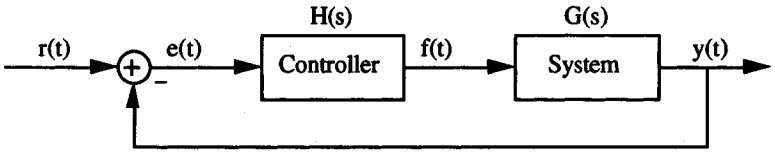

FIGURE 100.5 A tracking controller configuration.

TABLE 100.2 Steady-State Error Constants

$r(t)$ Test Signal	$eSS(t)$	Error Constant
$Ru(t)$: step function	$\frac{R}{1+K_p}$	$K_p = \lim_{s\to 0} G(s)H(s)$
$Rtu(t)$: ramp function	$\frac{R}{K_v}$	$K_v = \lim_{s\to 0} sG(s)H(s)$
$\frac{R}{2}t^2u(t)$: parabolic function	$\frac{R}{K_a}$	$K_a = \lim_{s\to 0} s^2G(s)H(s)$

The **steady-state error** is a measure of the accuracy of the output $y(t)$ in tracking the reference input $r(t)$. Other configurations with different performance measures would result in other definitions of the steady-state error between two signals.

From Fig. 100.5, the error $e(t)$ is

$$e(t) = r(t) - y(t) \tag{100.20}$$

and the steady-state error is

$$e_{SS}(t) = \lim_{t\to\infty} e(t) = \lim_{s\to\infty} sE(s) \tag{100.21}$$

assuming the limits exists, where $E(s)$ is the Laplace transform of $e(t)$, and s is the Laplacian operator. With $G(s)$ the transfer function of the system and $H(s)$ the transfer function of the controller, the transfer function between $y(t)$ and $r(t)$ is found to be

$$T(s) = \frac{G(s)H(s)}{1 + G(s)H(s)} \tag{100.22}$$

with

$$E(s) = \frac{R(s)}{1 + G(s)H(s)} \tag{100.23}$$

Direct application of the steady-state error for various inputs yields Table 100.2. Note $u(t)$ is the unit step function. This table can be extended to an mth-order input in a straightforward manner. Note that for $e_{SS}(t)$ to go to zero with a reference signal $Ct^m u(t)$, the term $G(s)H(s)$ must have at least m poles at the origin (a type m system).

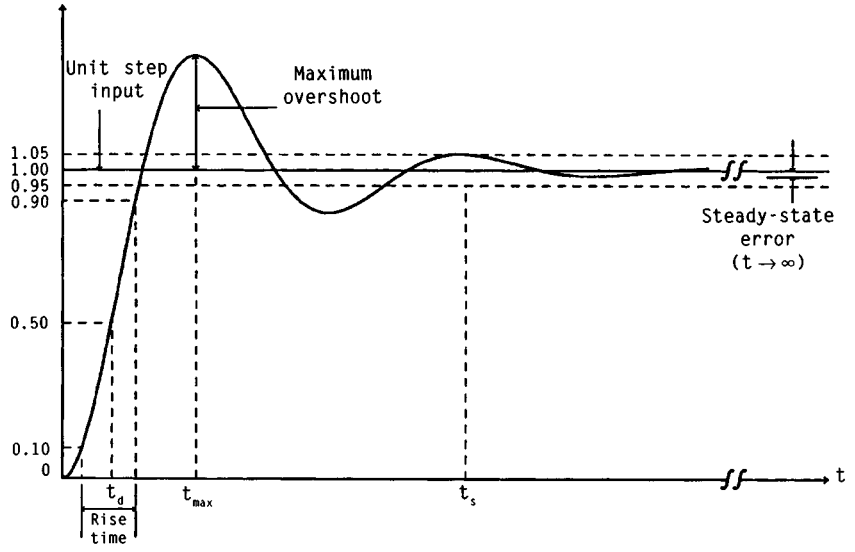

FIGURE 100.6 Step response.

Measures of the Transient Response

In general, analysis of the transient response of a dynamic system to a reference input is difficult. Hence formulating a standard measure of performance becomes complicated. In many cases, the response is dominated by a pair of poles and thus acts like a second-order system.

Consider a reference unit step input to a dynamic system (Fig. 100.6). Critical parameters that measure transient response include:

1. *M:* maximum overshoot
2. % overshoot = $M/A \times 100\%$, where A is the final value of the time response
3. t_d: delay time—the time required to reach 50% of A
4. t_r: rise time—the time required to go from 10% of A to 90% of A
5. t_s: settling time—the time required for the response to reach and stay within 5% of A

To calculate these measures, consider a second-order system

$$T(s) = \frac{\omega_n^2}{s^2 + 2\xi\omega_n s + \omega_n^2} \tag{100.24}$$

where ξ is the damping coefficient and ω_n is the natural frequency of oscillation.

For the range $0 < \xi < 1$, the system response is *underdamped,* resulting in a damped oscillatory output. For a unit step input, the response is given by

$$y(t) = 1 + \frac{e^{-\xi\omega_n t}}{\sqrt{1-\xi^2}} \sin\left(\omega_n\sqrt{1-\xi^2}\,t - \tan^{-1}\frac{\sqrt{1-\xi^2}}{-\xi}\right) \quad (0 < \xi < 1) \tag{100.25}$$

The eigenvalues (poles) of the system [roots of the denominator of $T(s)$] provide some measure of the time constants of the system. For the system under study, the eigenvalues are at

$$-\xi\omega_n \pm j\omega_n\sqrt{1-\xi^2} \qquad \text{where} \qquad j \triangleq \sqrt{-1}$$

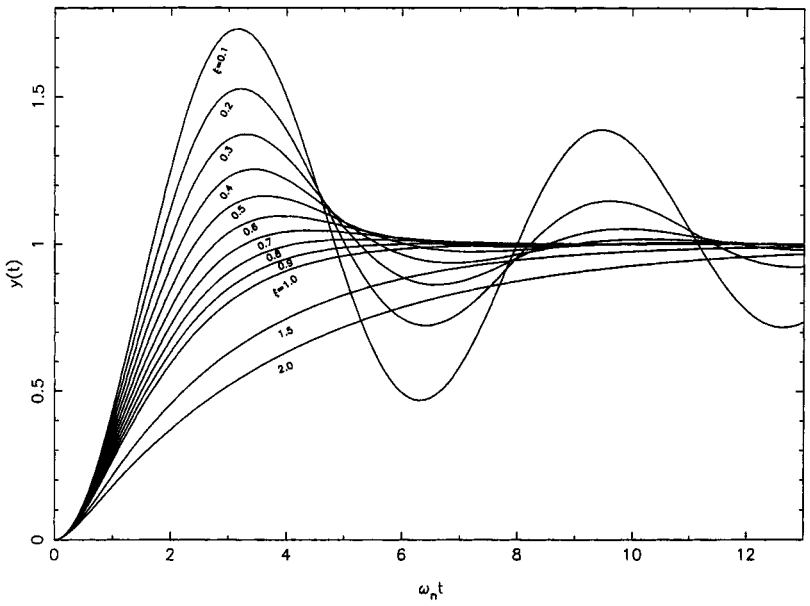

FIGURE 100.7 Effect of the damping coefficient on the dynamic response.

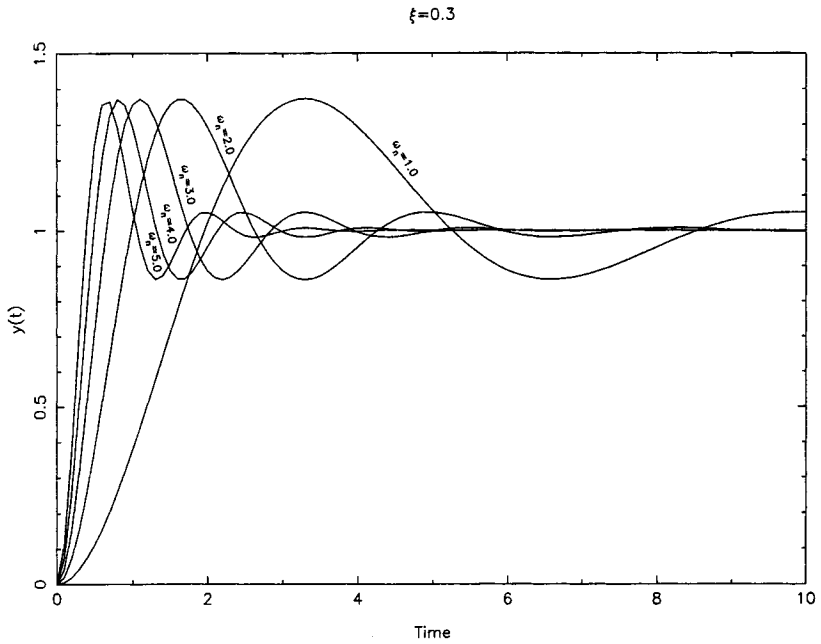

FIGURE 100.8 Effect of the natural frequency of oscillation on the dynamic response.

From the expression of $y(t)$, one sees that the term $\xi\omega_n$ affects the rise time and exponential decay time.

The effects of the damping coefficient on the transient response are seen in Fig. 100.7.

The effects of the natural frequency of oscillation ω_n of the transient response can be seen in Fig. 100.8. As ω_n increases, the frequency of oscillation increases.

For the case when $0 < \xi < 1$, the underdamped case, one can analyze the critical transient response parameters.

To measure the peaks of Fig. 100.6, one finds

$$y_{\text{peak}}(t) = 1 + (-1)^{n-1} \exp \frac{-n\pi\xi}{\sqrt{1-\xi^2}} \qquad n = 0, 1, \ldots \tag{100.26}$$

occurring at

$$t = \frac{n\,\pi}{\omega_n\sqrt{1-\xi^2}} \qquad \begin{matrix} n\text{: odd (overshoot)} \\ n\text{: even (undershoot)} \end{matrix} \tag{100.27}$$

Hence

$$y_{\max} = 1 + \exp \frac{-\pi\xi}{\sqrt{1-\xi^2}} \tag{100.28}$$

occurring at

$$t_{\max} = \frac{\pi}{\omega_n\sqrt{1-\xi^2}} \tag{100.29}$$

With these parameters, one finds

$$t_d \approx \frac{1 + 0.7\xi}{\omega_n}$$

$$t_r \approx \frac{1 + 1.1\xi + 1.4\xi^2}{\omega_n}$$

and

$$t_s \approx \frac{3}{\xi\omega_n}$$

Note that increasing ξ decreases the % overshoot and decreases the settling time but increases t_d and t_r.

When $\xi = 1$, the system has a double pole at $-\omega_n$, resulting in a *critically damped* response. This is the point when the response just changes from oscillatory to exponential in form. For a unit step input, the response is given by

$$y(t) = 1 - e^{-\omega nt}(1 + \omega_n t) \quad (\xi = 1) \tag{100.30}$$

For the range $\xi > 1$, the system is overdamped due to two real system poles. For a unit step input, the response is given by

$$y(t) = 1 + \frac{1}{c_1 - c_2}\left(\frac{1}{c_1}\, e^{c_1\omega_n t} - \frac{1}{c_2}\, e^{c_2\omega_n t}\right) \quad (\xi > 1)$$

$$c_1 = -\xi + \sqrt{\xi^2 - 1} \qquad c_2 = -\xi - \sqrt{\xi^2 - 1} \tag{100.31}$$

Finally, when $\xi = 0$, the response is purely sinusoidal. For a unit step, the response is given by

$$y(t) = 1 - \cos \omega_n t \quad (\xi = 0) \tag{100.32}$$

Defining Terms

Impulse response: The response of a system when the input is an impulse function.
Steady-state error: The difference between the desired reference signal and the actual signal in steady-state, i.e., when time approaches infinity.
Steady-state response: That part of the response which remains as time approaches infinity.
Transient response: That part of the response which vanishes as time approaches infinity.
Zero-input response: That part of the response due to the initial condition only.
Zero-state response: That part of the response due to the input only.

100.3 Frequency Response Methods: Bode Diagram Approach

Andrew P. Sage

Our efforts in this section are concerned with analysis and design of linear control systems by frequency response methods. Design generally involves trial-and-error repetition of analysis until a set of design **specifications** has been met. Thus, analysis methods are most useful in the design process, which is one phase of the **systems engineering** life cycle [Sage, 1992]. We will discuss one design method based on **Bode diagrams.** We will discuss the use of both simple **series equalizers** and composite equalizers as well as the use of minor-loop feedback in systems design.

Figure 100.9 presents a flowchart of the frequency response method design process and indicates the key role of analysis in linear systems control design. The flowchart of Fig. 100.9 is applicable to control system design methods in general. There are several iterative loops, generally calling for trial-and-error efforts, that comprise the suggested design process. An experienced designer will often be able, primarily due to successful prior experience, to select a system structure and generic components such that the design specifications can be met with no or perhaps a very few iterations through the iterative loop involving adjustment of equalizer or compensation parameters to best meet specifications.

If the parameter optimization, or parameter refinement such as to lead to maximum phase margin, approach shows the specifications cannot be met, we are then assured that no **equalizer** of the specific form selected will meet specifications. The next design step, if needed, would consist of modification of the equalizer form or

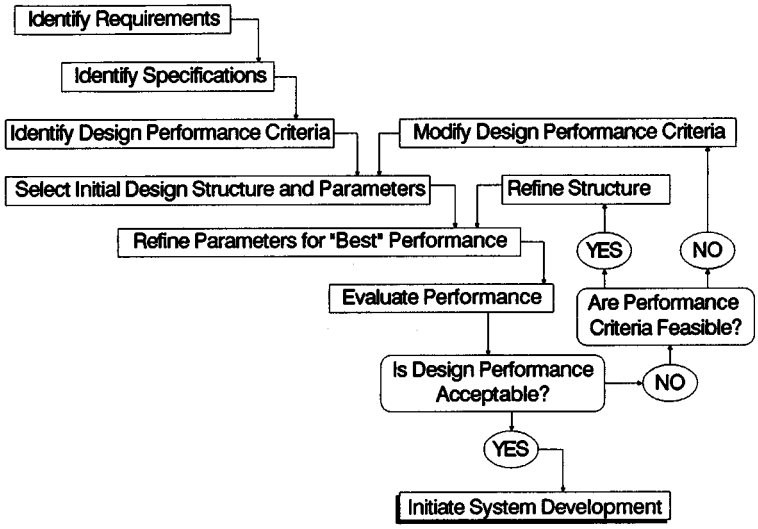

FIGURE 100.9 System design life cycle for frequency-response-based design.

structure and repetition of the analysis process to determine equalizer parameter values to best meet specifications. If specifications still cannot be met, we will usually next modify generic fixed components used in the system. This iterative design and analysis process is again repeated. If no reasonable fixed components can be obtained to meet specifications, then structural changes in the proposed system are next contemplated. If no structure can be found that allows satisfaction of specifications, either the client must be requested to relax the frequency response specifications or the project may be rejected as infeasible using present technology. As we might suspect, economics will play a dominant role in this design process. Changes made due to iteration in the inner loops of Fig. 100.9 normally involve little additional costs, whereas those made due to iterations in the outer loops will often involve major cost changes.

Frequency Response Analysis Using the Bode Diagram

The steady-state response of a stable linear constant-coefficient system has particular significance, as we know from an elementary study of electrical networks and circuits and of dynamics. We consider a stable linear system with input-output transfer function

$$H(s) = \frac{Z(s)}{U(s)}$$

We assume a sinusoidal input $u(t) = \cos \omega t$ so that we have for the Laplace transform of the system output

$$Z(s) = \frac{sH(s)}{s^2 + \omega^2}$$

We expand this ratio of polynomials using the partial-fraction approach and obtain

$$Z(s) = F(s) + \frac{a_1}{s + j\omega} + \frac{a_2}{s - j\omega}$$

In this expression, $F(s)$ contains all the poles of $H(s)$. All of these lie in the left half plane since the system, represented by $H(s)$, is assumed to be stable. The coefficients a_1 and a_2 are easily determined as

$$a_1 = \frac{H(-j\omega)}{2}$$

$$a_2 = \frac{H(j\omega)}{2}$$

We can represent the complex transfer function $H(j\omega)$ in either of two forms,

$$H(j\omega) = B(\omega) + jC(\omega)$$

$$H(-j\omega) = B(\omega) - jC(\omega)$$

The inverse Laplace transform of the system transfer function will result in a transient term due to the inverse transform of $F(s)$, which will decay to zero as time progresses. A steady-state component will remain, and this is, from the inverse transform of the system equation, given by

$$z(t) = a_1 e^{-j\omega t} + a_2 e^{j\omega t}$$

We combine several of these relations and obtain the result

$$z(t) = B(\omega)\left(\frac{e^{j\omega t} + e^{-j\omega t}}{2}\right) - C(\omega)\left(\frac{e^{j\omega t} - e^{-j\omega t}}{2j}\right)$$

This result becomes, using the Euler identity,[1]

$$\begin{aligned} z(t) &= B(\omega)\cos\omega t - C(\omega)\sin\omega t \\ &= [B^2(\omega) + C^2(\omega)]^{1/2}\cos(\omega + \beta) \\ &= |H(j\omega)|\cos(\omega t + \beta) \end{aligned}$$

where $\tan\beta(\omega) = C(\omega)/B(\omega)$.

As we see from this last result, there is a very direct relationship between the transfer function of a linear constant-coefficient system, the time response of a system to any known input, and the sinusoidal steady-state response of the system. We can always determine any of these if we are given any one of them. This is a very important result. This important conclusion justifies a design procedure for linear systems that is based only on sinusoidal steady-state response, as it is possible to determine transient responses, or responses to any given system input, from a knowledge of steady-state sinusoidal responses, at least in theory. In practice, this might be rather difficult computationally without some form of automated assistance.

Bode Diagram Design-Series Equalizers

In this subsection we consider three types of series equalization:

1. Gain adjustment, normally attenuation by a constant at all frequencies
2. Increasing the phase lead, or reducing the phase lag, at the **crossover frequency** by use of a phase **lead network**
3. Attenuation of the gain at middle and high frequencies such that the crossover frequency will be decreased to a lower value where the phase lag is less, by use of a **lag network**

[1]The Euler identity is $e^{j\omega t} = \cos\omega t + j\sin\omega t$.

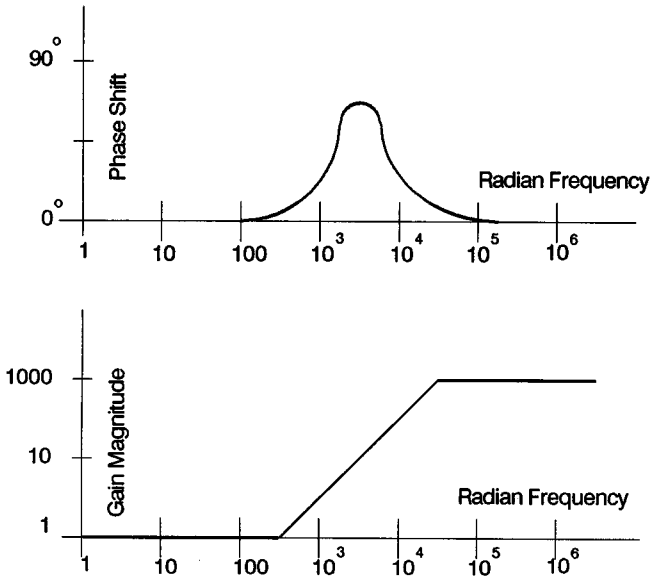

FIGURE 100.10 Phase shift and gain curves for a simple lead network.

In the subsection that follows this, we will first consider use of a composite or **lag-lead network** near crossover to attenuate gain only to reduce the crossover frequency to a value where the phase lag is less. Then we will consider more complex composite equalizers and state some general guidelines for Bode diagram design. Here, we will use Bode diagram frequency domain design techniques to develop a design procedure for each of three elementary types of series equalization.

Gain Reduction

Many linear control systems can be made sufficiently stable merely by reduction of the open-loop system gain to a sufficiently low value. This approach ignores all performance specifications, however, except that of phase margin (PM) and is, therefore, usually not a satisfactory approach. It is a very simple one, however, and serves to illustrate the approach to be taken in more complex cases.

The following steps constitute an appropriate Bode diagram design procedure for compensation by gain adjustment:

1. Determine the required PM and the corresponding phase shift $\beta_c = -\pi + \text{PM}$.
2. Determine the frequency ω_c at which the phase shift is such as to yield the phase shift at crossover required to give the desired PM.
3. Adjust the gain such that the actual crossover frequency occurs at the value computed in step 2.

Phase-Lead Compensation

In compensation using a phase-lead network, we increase the phase lead at the crossover frequency such that we meet a performance specification concerning phase shift. A phase-lead-compensating network transfer function is

$$G_c(s) = \left(1 + \frac{s}{\omega_1}\right) \Big/ \left(1 + \frac{s}{\omega_2}\right) \qquad \omega_1 < \omega_2$$

Figure 100.10 illustrates the gain versus frequency and phase versus frequency curves for a simple lead network with the transfer function of the foregoing equation. The maximum phase lead obtainable from a phase-lead network depends upon the ratio ω_2/ω_1 that is used in designing the network. From the expression for the phase shift of the transfer function for this system, which is given by

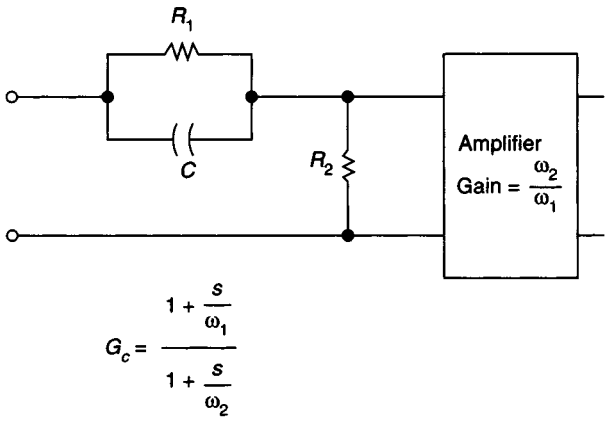

FIGURE 100.11 A simple electrical lead network.

$$\beta = \tan^{-1}\frac{\omega}{\omega_1} - \tan^{-1}\frac{\omega}{\omega_2}$$

we see that the maximum amount of phase lead occurs at the point where the first derivative with respect to frequency is zero, or

$$\left.\frac{d\beta}{d\omega}\right|_{\omega=\omega_m} = 0$$

or at the frequency where

$$\omega_m = (\omega_1\omega_2)^{0.5}$$

This frequency is easily seen to be at the center of the two break frequencies for the lead network on a Bode log asymptotic gain plot. It is interesting to note that this is exactly the same frequency that we would obtain using an arctangent approximation[2] with the assumption that $\omega_1 < \omega < \omega_2$.

There are many ways of realizing a simple phase-lead network. All methods require the use of an active element since the gain of the lead network at high frequencies is greater than 1. A simple electrical network realization is shown in Fig. 100.11.

We now consider a simple design example. Suppose that we have an open-loop system with transfer function

$$G_f(s) = \frac{10^4}{s^2}$$

It turns out that this is often called a type-two system due to the presence of the double integration. This system will have a steady-state error of zero for a constant acceleration input. The crossover frequency, that is to say

[2]The arctangent approximation is $\tan^{-1}(\omega/\alpha) = \omega/\alpha$ for $\omega < \alpha$ and $\tan^{-1}(\omega/\alpha) = \pi/2 - \alpha/\omega$ for $\omega > \alpha$. This approximation is rather easily obtained through use of a Taylor series approximation.

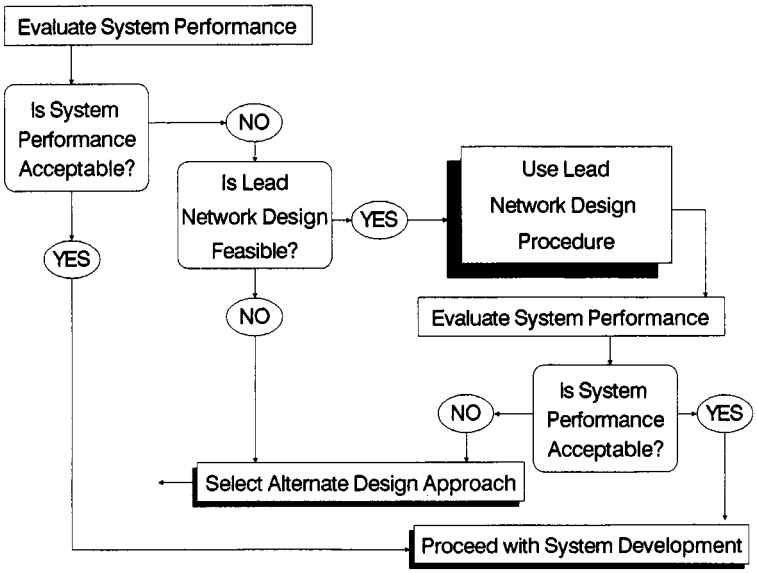

FIGURE 100.12 Life cycle of frequency domain design incorporating lead network compensation.

the frequency where the magnitude of the open-loop gain is 1, is 100 rad/s. The PM for the system without equalization is zero. We will design a simple lead network compensation for this zero PM system. If uncompensated, the closed-loop transfer function will be such that the system is unstable and any disturbance at all will result in a sinusoidally oscillating output.

The asymptotic gain diagram for this example is easily obtained from the open-loop transfer function

$$G_f(s)G_c(s) = \frac{K(1 + s/\omega_1)}{(1 + s/\omega_2)s^2}$$

and we wish to select the break frequencies ω_1 and ω_2 such that the phase shift at crossover is maximum. Further, we want this maximum phase shift to be such that we obtain the specified PM. We use the procedure suggested in Fig. 100.12.

Since the crossover frequency is such that $\omega_1 < \omega_c < \omega_2$, we have for the arctangent approximation to the phase shift in the vicinity of the crossover frequency

$$\beta(\omega) = -\pi + \tan^{-1}\frac{\omega}{\omega_1} - \tan^{-1}\frac{\omega}{\omega_2}$$

$$\approx \frac{-\pi}{2} - \frac{\omega_1}{\omega} - \frac{\omega}{\omega_2}$$

In order to maximize the phase shift at crossover, we set

$$\left.\frac{d\beta}{d\omega}\right|_{\omega=\omega_m} = 0$$

and obtain as a result

$$\omega_m = (\omega_1\ \omega_2)^{0.5}$$

We see that the crossover frequency obtained is halfway between the two break frequencies ω_1 and ω_2 on a logarithmic frequency coordinate. The phase shift at this optimum value of crossover frequency becomes

$$\beta_c = \beta(\omega_c) = \frac{-\pi}{2} - 2\left(\frac{\omega_1}{\omega_2}\right)^{0.5}$$

For a PM of $-3\pi/4$, for example, we have $-3\pi/4 = -\pi/2 - 2(\omega_1/\omega_2)^{0.5}$, and we obtain $\omega_1/\omega_2 = 0.1542$ as the ratio of frequencies. We see that we have need for a lead network with a gain of $\omega_1/\omega_2 = 6.485$. The gain at the crossover frequency is 1, and from the asymptotic gain approximation that is valid for $\omega_1 < \omega < \omega_2$, we have the expressions $|G(j\omega)| = K/\omega\omega_1$ and $|G(j\omega_c)| = 1 = K/\omega_c\omega_1$ which for a known K can be solved for ω_c and ω_1.

Now that we have illustrated the design computation with a very simple example, we are in a position to state some general results. In the direct approach to design for a specified PM we assume a single lead network equalizer such that the open-loop system to transfer function results. This approach to design results in the following steps that are applicable for Bode diagram design to achieve maximum PM within an experientially determined control system structure that comprises a fixed plant and a compensation network with adjustable parameters:

1. We find an equation for the gain at the crossover frequency in terms of the compensated open-loop system break frequency.
2. We find an equation of the phase shift at crossover.
3. We find the relationship between equalizer parameters and crossover frequency such that the phase shift at crossover is the maximum possible and a minimum of additional gain is needed.
4. We determine all parameter specifications to meet the PM specifications.
5. We check to see that all design specifications have been met. If they have not, we iterate the design process.

Figure 100.12 illustrates the steps involved in implementing this frequency domain design approach.

Phase-Lag Compensation

In the phase-lag-compensation frequency domain design approach, we reduce the gain at low frequencies such that crossover, the frequency where the gain magnitude is 1, occurs before the phase lag has had a chance to become intolerably large. A simple single-stage phase-lag-compensating network transfer function is

$$G_c(s) = \frac{1 + s/\omega_2}{1 + s/\omega_1} \qquad \omega_1 < \omega_2$$

Figure 100.13 illustrates the gain and phase versus frequency curves for a simple lag network with this transfer function. The maximum phase lag obtainable from a phase-lag network depends upon the ratio ω_2/ω_1 that is used in designing the network. From the expression for the phase shift of this transfer function,

$$\beta = \tan^{-1}\frac{\omega}{\omega_2} - \tan^{-1}\frac{\omega}{\omega_1}$$

we see that maximum phase lag occurs at that frequency ω_c where $d\beta/d\omega = 0$. We obtain for this value

$$\omega_m = (\omega_1\omega_2)^{0.5}$$

which is at the center of the two break frequencies for the lag network when the frequency response diagram is illustrated on a Bode diagram log-log asymptotic gain plot.

The maximum value of the phase lag obtained at $\omega = \omega_m$ is

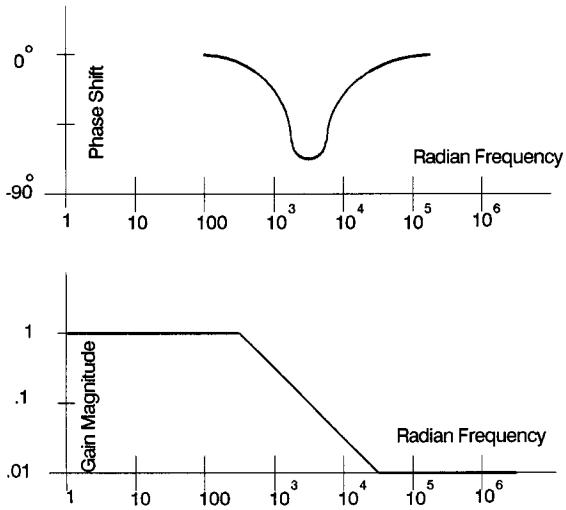

FIGURE 100.13 Phase shift and gain curves for a simple lag network.

$$\beta_m(\omega_m) = \frac{\pi}{2} - 2\tan^{-1}\left(\frac{\omega_2}{\omega_1}\right)^{0.5}$$
$$= \frac{\pi}{2} - 2\tan^{-1}\left(\frac{\omega_1}{\omega_2}\right)^{0.5}$$

which can be approximated in a more usable form, using the arctangent approximation, as

$$\beta_m(\omega_m) \approx \frac{\pi}{2}\sqrt{\frac{\omega_2}{\omega_1}}$$

The attenuation of the lag network at the frequency of minimum phase shift, or maximum phase lag, is obtained from the asymptotic approximation as

$$|G_c(\omega_m)| = \left(\frac{\omega_1}{\omega_2}\right)^{0.5}$$

Figure 100.13 presents a curve of attenuation magnitude obtainable at the frequency of maximum phase lag and the amount of the phase lag for various ratios ω_2/ω_1 for this simple lag network.

There are many ways to physically realize a lag network transfer function. Since the network only attenuates at some frequencies, as it never has a gain greater than 1 at any frequency, it can be realized with passive components only. Figure 100.14 presents an electrical realization of the simple lag network. Figure 100.15 presents a flowchart illustrating the design procedure envisioned here for lag network design. This is conceptually very similar to that for a lead network and makes use of the five-step parameter optimization procedure suggested earlier.

The object of lag network design is to reduce the gain at frequencies lower than the original crossover frequency in order to reduce the open-loop gain to unity before the phase shift becomes so excessive that the system PM is too small. A disadvantage of lag network compensation is that the attenuation introduced reduces

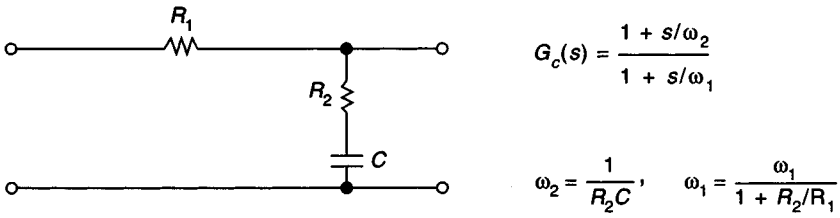

FIGURE 100.14 A simple electrical lag network.

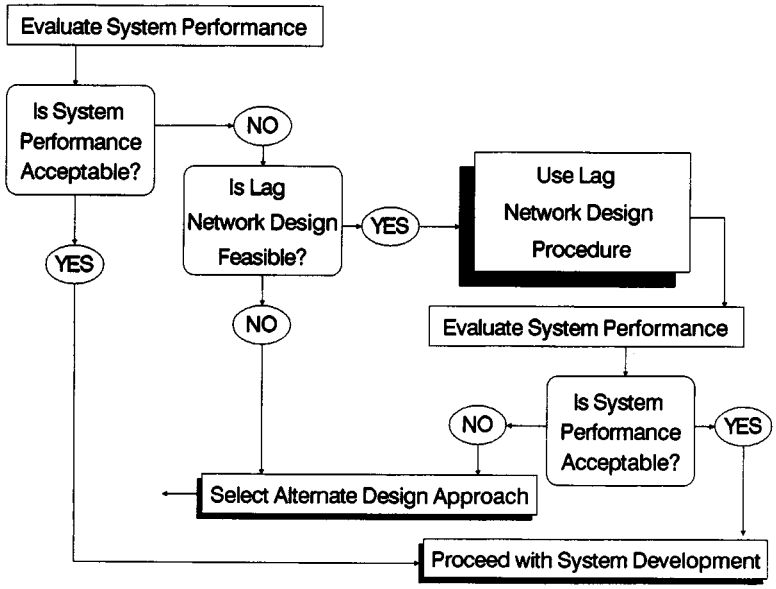

FIGURE 100.15 Life cycle of frequency domain design incorporating lag network compensation.

the crossover frequency and makes the system slower in terms of its transient response. Of course, this would be advantageous if high-frequency noise is present and we wish to reduce its effect. The lag network is an entirely passive device and thus is more economical to instrument than the lead network.

In lead network compensation we actually insert phase lead in the vicinity of the crossover frequency to increase the PM. Thus we realize a specified PM without lowering the medium-frequency system gain. We see that the disadvantages of the lag network are the advantages of the lead network and the advantages of the lag network are the disadvantages of the lead network.

We can attempt to combine the lag network with the lead network into an all-passive structure called a lag-lead network. Generally we obtain better results than we can achieve using either a lead or a lag network. We will consider design using lag-lead networks in our next subsection as well as more complex composite equalization networks.

Composite Equalizers

In the previous subsection we examined the simplest forms of series equalization: gain adjustment, lead network compensation, and lag network compensation. In this subsection we will consider more complex design examples in which composite equalizers will be used for series compensation. The same design principles used earlier in this section will be used here as well.

Lag-Lead Network Design

The prime purpose of a lead network is to add phase lead near the crossover frequency to increase the PM. Accompanied with this phase lead is a gain increase that will increase the crossover frequency. This will sometimes cause difficulties if there is much phase lag in the uncompensated system at high frequencies. There may be situations where use of a phase-lead network to achieve a given PM is not possible due to too many high-frequency poles.

The basic idea behind lag network design is to reduce the gain at "middle" frequencies such as to reduce the crossover frequency to a lower value than for the uncompensated system. If the phase lag is less at this lower frequency, then the PM will be increased by use of the lag network. We have seen that is not possible to use a lag network in situations in which there is not a frequency where an acceptable PM would exist if this frequency were the crossover frequency. Even if use of a lag network is possible, the significantly reduced crossover frequency resulting from its use may make the system so slow and sluggish in response to an input that system performance is unacceptable even though the relative stability of the system is acceptable.

Examination of these characteristics or attributes of lead network and lag network compensation suggests that it might be possible to combine the two approaches to achieve the desirable features of each approach. Thus we will attempt to provide attenuation below the crossover frequency to decrease the phase lag at crossover and phase lead closer to the crossover frequency in order to increase the phase lead of the uncompensated system at the crossover frequency.

The transfer function of the basic lag-lead network is

$$G_c(s) = \frac{(1 + s/\omega_2)(1 + s/\omega_3)}{(1 + s/\omega_1)(1 + s/\omega_4)}$$

where $\omega_4 > \omega_3 > \omega_2 > \omega_1$. Often it is desirable that $\omega_2\omega_3 = \omega_1\omega_4$ such that the high-frequency gain of the equalizer is unity. It is generally not desirable that $\omega_1\omega_4 > \omega_2\omega_3$ as this indicates a high-frequency gain greater than 1, and this will require an active network, or gain, and a passive equalizer. It is a fact that we should always be able to realize a linear minimum phase network using passive components only if the network has a rational transfer function with a gain magnitude that is no greater than 1 at any real frequency.

Figure 100.16 illustrates the gain magnitude and phase shift curves for a single-stage lag-lead network equalizer or compensator transfer function. Figure 100.17 illustrates an electrical network realization of a passive lag-lead network equalizer. Parameter matching can be used to determine the electrical network parameters that yield a specified transfer function. Because the relationships between the break frequencies and the equalizer component values are complex, it may be desirable, particularly in preliminary instrumentation of the control system, to use analog or digital computer programming techniques to construct the equalizer. Traditionally, there has been much analog computer simulation of control systems. The more contemporary approach suggests use of digital computer approaches that require numerical approximation of continuous-time physical systems.

Figure 100.18 presents a flowchart that we may use for lag-lead network design. We see that this flowchart has much in common with the charts and design procedures for lead network and lag network design and that each of these approaches first involves determining or obtaining a set of desired specifications for the control system. Next, the form of a trial compensating network and the number of break frequencies in the network are selected. We must then obtain a number of equations, equal to the number of network break frequencies plus 1. One of these equations shows that the gain magnitude is 1 at the crossover frequency. The second equation will be an equation for the phase shift at crossover. It is generally desirable that there be at least two unspecified compensating network break frequencies such that we may use a third equation, the optimality of the phase shift at crossover equation, in which we set $d\beta/d\omega|_{\omega=\omega c} = 0$. If other equations are needed to represent the design situation, we obtain these from the design specifications themselves.

General Bode Diagram Design

Figure 100.19 presents a flowchart of a general design procedure for Bode diagram design. As we will see in the next subsection, a minor modification of this flowchart can be used to accomplish design using minor-loop feedback

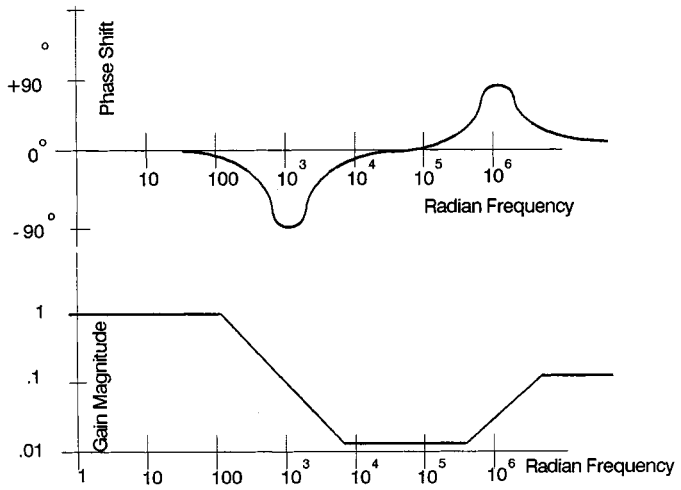

FIGURE 100.16 Phase shift and gain curves for a simple lag-lead network.

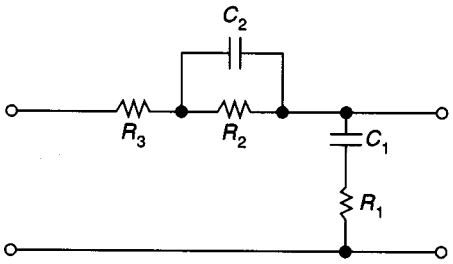

$$G_c(s) = \frac{(1 + s/\omega_2)(1 + s/\omega_3)}{(1 + s/\omega_1)(1 + s/\omega_4)}$$

$$= \frac{(1 + R_1C_1s)(1 + R_2C_2s)}{1 + (R_1C_1 + R_2C_1 + R_3C_1 + R_2C_2)s + (R_1R_2C_1C_2 + R_2R_3C_1C_2)s^2}$$

Special case: $R_3 = 0$

$$\omega_2 = \frac{1}{R_1C_1}, \quad \omega_3 = \frac{1}{R_2C_2}, \quad \omega_1\omega_4 = \omega_2\omega_3, \quad \omega_1 + \omega_4 = \omega_2 + \omega_3 + \frac{1}{R_1C_2}$$

FIGURE 100.17 Simple electrical lag-lead network.

or a combination of minor-loop and series equations. These detailed flowcharts for Bode diagram design are, of course, part of the overall design procedure of Fig. 100.9.

Much experience leads to the conclusion that satisfactory linear systems control design using frequency response approaches is such that the crossover frequency occurs on a gain magnitude curve which has a –1 slope at the crossover frequency. In the vicinity of crossover we may approximate any minimum phase transfer function, with crossover on a –1 slope, by

$$G(s) = G_f(s)G_c(s) = \frac{\omega_c\omega_1^{n-1}(1 + s/\omega_1)^{n-1}}{s^n(1 + s/\omega_2)^{m-1}} \qquad \text{for } \omega_1 > \omega_c > \omega_2$$

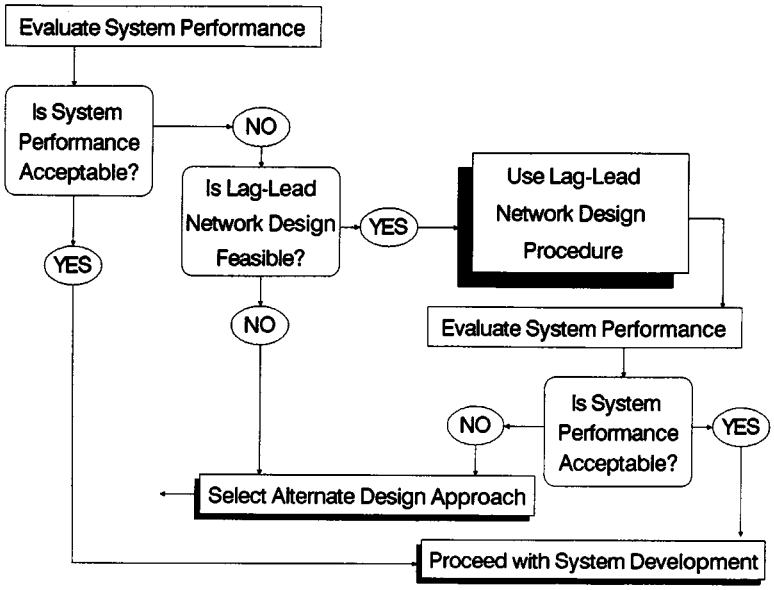

FIGURE 100.18 Life cycle of frequency domain design incorporating lag-lead network compensation.

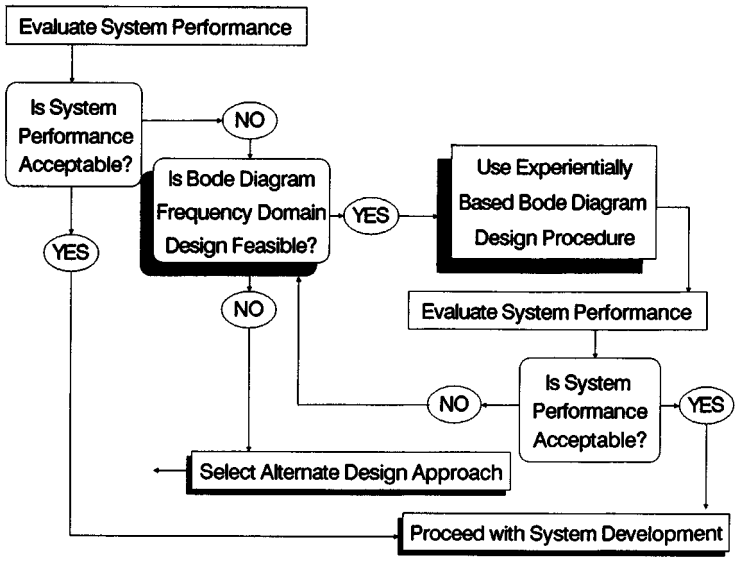

FIGURE 100.19 Life cycle of frequency domain design incorporating general Bode diagram compensation procedure.

Here ω_1 is the break frequency just prior to crossover and ω_2 is the break frequency just after crossover. It is easy to verify that we have $|G(j\omega_c)| = 1$ if $\omega_1 > \omega_c > \omega_2$. Figure 100.20 illustrates this rather general approximation to a compensated system Bode diagram in the vicinity of the crossover frequency. We will conclude this subsection by determining some general design requirements for a system with this transfer function and the associated Bode asymptotic gain magnitude diagram of Fig. 100.20.

There are three unknown frequencies in the foregoing equation. Thus we need three requirements or equations to determine design parameters. We will use the same three requirements used thus far in all our efforts in this section, namely:

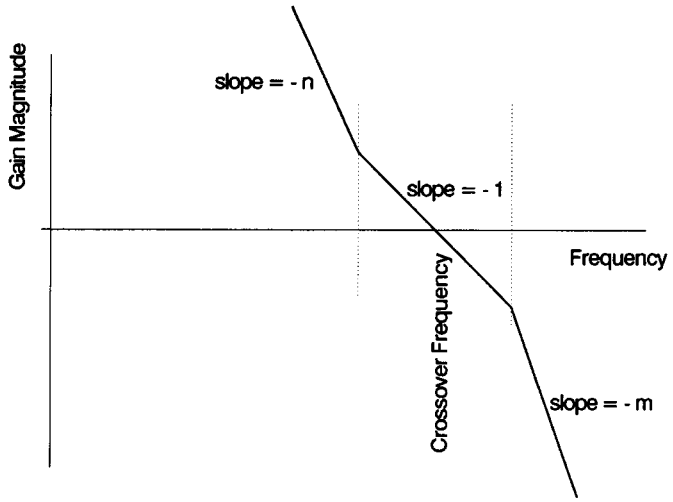

FIGURE 100.20 Illustration of generic gain magnitude in the vicinity of crossover.

1. The gain at crossover is 1.
2. The PM is some specified value.
3. The PM at crossover is the maximum possible for a given ω_2/ω_1 ratio.

We see that the first requirement, that the gain is 1 at the crossover frequency, is satisfied by the foregoing equation if the crossover frequency occurs on the –1 slope portion of the gain curve as assumed in Fig. 100.20. We use the arctangent approximation to obtain the phase shift in the vicinity of crossover as

$$\beta(\omega) = -\frac{n\pi}{2} + (n-1)\left(\frac{\pi}{2} - \frac{\omega_1}{\omega}\right) - (m-1)\frac{\omega}{\omega_2}$$

To satisfy requirement 3 we set

$$\left.\frac{d\beta(\omega)}{d\omega}\right|_{\omega=\omega_c} = 0 = \frac{(n-1)\omega_1}{\omega_c^2} - \frac{m-1}{\omega_2}$$

and obtain

$$\omega_c^2 = \frac{n-1}{m-1}\omega_1\omega_2$$

as the optimum setting for the crossover frequency. Substitution of the "optimum" frequency given by the foregoing into the phase shift equation results in

$$\beta(\omega_c) = \frac{-\pi}{2} - 2\sqrt{(m-1)(n-1)}\sqrt{\frac{\omega_1}{\omega_2}}$$

We desire a specific PM here, and so the equalizer break frequency locations are specified. There is a single parameter here that is unspecified, and an additional equation must be found in any specific application. Alternately, we could simply assume a nominal crossover frequency of unity or simply normalize frequencies ω_1 and ω_2 in terms of the crossover frequency by use of the normalized frequencies $\omega_1 = W_1\omega_c$ and $\omega_2 = W_2\omega_c$.

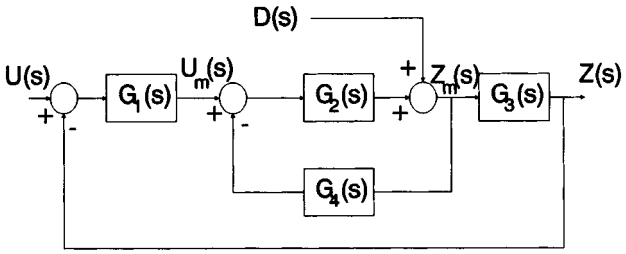

FIGURE 100.21 Feedback control system with a single minor loop and output disturbance.

It is a relatively simple matter to show that for a specified PM expressed in radians, we obtain for the normalized break frequencies

$$W_1 = \frac{\omega_1}{\omega_c} = \frac{\text{PM}}{2(n-1)}$$

$$W_2 = \frac{\omega_2}{\omega_c} = \frac{2(m-1)}{\text{PM}}$$

It is relatively easy to implement this suggested Bode diagram design procedure which is based upon considering only these break frequencies immediately above and below crossover and which approximate all others. Break frequencies far below crossover are approximated by integrations or differentiations, that is, poles or zeros at $s = 0$, and break frequencies far above the crossover frequency are ignored.

Minor-Loop Design

In our efforts thus far in this section we have assumed that compensating networks would be placed in series with the fixed plant and then a unity feedback ratio loop closed around these elements to yield the closed-loop system. In many applications it may be physically convenient, perhaps due to instrumentation considerations, to use one or more minor loops to obtain a desired compensation of a fixed plant transfer function.

For a single-input–single-output linear system there are no theoretical advantages whatever to any minor-loop compensation to series compensation as the same closed-loop transfer function can be realized by all procedures. However, when there are multiple inputs or outputs, then there may be considerable advantages to minor-loop design as contrasted to series compensation design. Multiple inputs often occur when there is a single-signal input and one or more noise or disturbance inputs present and a task of the system is to pass the signal inputs and reject the noise inputs. Also there may be saturation-type nonlinearities present, and we may be concerned not only with the primary system output but also with keeping the output at the saturation point within bounds such that the system remains linear. Thus there are reasons why minor-loop design may be preferable to series equalization.

We have discussed block diagrams elsewhere in this handbook. It is desirable here to review some concepts that will be of value for our discussion of minor-loop design. Figure 100.21 illustrates a relatively general linear control system with a single minor loop. This block diagram could represent many simple control systems. $G_1(s)$ could represent a discriminator and series compensation and $G_2(s)$ could represent an amplifier and that part of a motor transfer function excluding the final integration to convert velocity to position. $G_3(s)$ might then represent an integrator. $G_4(s)$ would then represent a minor-loop compensation transfer function, such as that of a tachometer.

The closed-loop transfer function for this system is given by

$$\frac{Z(s)}{U(s)} = H(s) = \frac{G_1(s)G_2(s)G_3(s)}{1 + G_2(s)G_4(s) + G_1(s)G_2(s)G_3(s)}$$

It is convenient to define several other transfer functions that are based on the block diagram in Fig. 100.21. First there is the minor-loop gain

$$G_m(s) = G_2(s)G_4(s)$$

which is just the loop gain of the minor loop only. The minor loop has the transfer function

$$\frac{Z_m(s)}{U_m(s)} = H_m(s) = \frac{G_2(s)}{1 + G_2(s)G_4(s)} = \frac{G_2(s)}{1 + G_m(s)}$$

There will usually be a range or ranges of frequency for which the minor-loop gain magnitude is much less than 1, and we then have

$$\frac{Z_m(s)}{U_m(s)} = H_m(s) \approx G_2(s) \qquad \left|G_m(\omega)\right| << 1$$

There will also generally be ranges of frequency for which the minor-loop gain magnitude is much greater than 1, and we then have

$$\frac{Z_m(s)}{U_m(s)} = H_m(s) \approx \frac{1}{G_4(s)} \qquad \left|G_m(\omega)\right| >> 1$$

We may use these two relations to considerably simplify our approach to the minor-loop design problem. For illustrative purposes, we will use two major-loop gain functions. First we will consider the major-loop gain with the minor-loop-compensating network removed such that $G_4(s) = 0$. This represents the standard situation we have examined in the last subsection. This uncompensated major-loop transfer function is

$$G_{Mu}(s) = G_1(s)G_2(s)G_3(s)$$

With the minor-loop compensation inserted, the major-loop gain, the input-output transfer function with the unity ratio feedback open, is

$$G_{Mc}(s) = \frac{G_1(s)G_2(s)G_3(s)}{1 + G_m(s)}$$

We may express the complete closed-loop transfer function in the form

$$\frac{Z(s)}{U(s)} = H(s) = \frac{G_{Mc}(s)}{1 + G_{Mc}(s)}$$

A particularly useful relationship may be obtained by combining the last three equations into one equation of the form

$$G_{Mc}(s) = \frac{G_{Mu}(s)}{1 + G_m(s)}$$

We may give this latter equation a particularly simple interpretation. For frequencies where the minor-loop gain $G_m(s)$ is low, the minor-loop–closed major-loop transfer function $G_{Mc}(s)$ is approximately that of the minor-loop–open major-loop transfer function G_{Mu} in that

$$G_{Mc}(s) \approx G_{Mu}(s) \qquad |G_m(\omega)| << 1$$

For frequencies where the minor-loop gain $G_m(s)$ is high, the minor-loop–closed major-loop transfer function is just

$$G_{Mc}(s) \approx \frac{G_{Mu}(s)}{G_m(s)} \qquad |G_m(\omega)| >> 1$$

This has an especially simple interpretation on the logarithmic frequency plots we use for Bode diagrams for we may simply subtract the minor-loop gain $G_m(s)$ from the minor-loop–open major-loop gain $G_{Mu}(s)$ to obtain the compensated system gain as the transfer function $G_{Mc}(s)$.

The last several equations are the key relations for minor-loop design using this frequency response approach. These relations indicate that some forms of series compensation yield a given major-loop transfer function $G_{Mc}(s)$ which will not be appropriate for realization by minor-loop compensation. In particular, a lead network series compensation cannot be realized by means of equivalent minor-loop compensation. The gain of the fixed plant $G_{Mu}(s)$ is raised at high frequencies due to the use of a lead network compensation. Also, we see that $G_{Mc}(s)$ can only be lowered by use of a minor-loop gain $G_m(s)$.

A lag network used for series compensation will result in a reduction in the fixed plant gain $|G_{Mu}(\omega)|$ at all high frequencies. This can only be achieved if the minor-loop transfer gain $G_m(s)$ is constant for high frequencies. In some cases this may be achievable but often will not be. It is possible to realize the equivalent of lag network series equalization by means of a minor-loop equalization for systems where the low- and high-frequency behavior of $G_{Mu}(s)$, or $G_f(s)$, and $G_{Mc}(s)$ are the same and where the gain magnitude of the compensated system $|G_{Mc}(s)|$ is at no frequency any greater than is the gain magnitude of the fixed plant $|G_f(s)|$ or the minor-loop–open major-loop transfer function $|G_{Mu}(s)|$. Thus we see that lag-lead network series equalization is an ideal type of equalization to realize by means of equivalent minor-loop equalization. Figures 100.9 and 100.19 represent flowcharts of a suggested general design procedure for minor-loop compensator design as well as for the series equalization approaches we examined previously.

In our work thus far we have assumed that parameters were constant and known. Such is seldom the case, and we must naturally be concerned with the effects of parameter variations, disturbances, and nonlinearities upon system performance. Suppose, for example, that we design a system with a certain gain assumed as K_1. If the system operates open loop and the gain K_1 is in cascade or series with the other input-output components, then the overall transfer function changes by precisely the same factor as K_1 changes. If we have an amplifier with unity ratio feedback around a gain K_1, the situation is much different. The closed-loop gain would nominally be $K_1/(1 + K_1)$, and a change to $2K_1$ would give a closed-loop gain $2K_1/(1 + 2K_1)$. If K_1 is large, say 10_3, then the new gain is 0.99950025, which is a percentage change of less than 0.05% for a change in gain of 100%.

Another advantage of minor-loop feedback occurs when there are output disturbances such as those due to wind gusts on an antenna. We consider the system illustrated in Fig. 100.21. The response due to $D(s)$ alone is

$$\frac{Z(s)}{D(s)} = \frac{1}{1 + G_2(s)\,G_4(s) + G_1(s)\,G_2(s)}$$

When we use the relation for the minor-loop gain

$$G_m(s) = G_2(s)G_4(s)$$

and the major-loop gain

$$G_{Mc}(s) = \frac{G_1(s)G_2(s)}{1 + G_2(s)G_4(s)}$$

we can rewrite the response due to $D(s)$ as

$$\frac{Z(s)}{D(s)} = \frac{1}{[1 + G_m(s)]G_{Mc}(s)}$$

Over the range of frequency where $|G_{Mc}(j\omega)| >> 1$, such that the corrected loop gain is large, the attenuation of a load disturbance is proportional to the uncorrected loop gain. This is generally larger over a wider frequency range than the corrected loop gain magnitude $|G_{Mc}(j\omega)|$, which is what the attenuation would be if series compensation were used.

Over the range of frequencies where the minor-loop gain is large but where the corrected loop gain is small, that is, where $|G_m(j\omega)| > 1$ and $|G_{Mc}(j\omega)| < 1$, we obtain for the approximate response due to the disturbance

$$\frac{Z(s)}{D(s)} \approx G_m(s)$$

and the output disturbance is therefore seen to be attenuated by the minor-loop gain rather than unattenuated as would be the case if series compensation had been used. This is, of course, highly desirable.

At frequencies where both the minor-loop gain transfer and the major-loop gain are small we have $Z(s)/D(s) \approx 1$, and over this range of frequencies neither minor-loop compensation nor series equalization is useful in reducing the effect of a load disturbance. Thus, we have shown here that there are quite a number of advantages to minor-loop compensation as compared to series equalization. Of course, there are limitations as well.

Summary

In this section, we have examined the subject of linear system compensation by means of the frequency response method of Bode diagrams. Our approach has been entirely in the frequency domain. We have discussed a variety of compensation networks, including:

1. Gain attenuation
2. Lead networks
3. Lag networks
4. Lag-lead networks and composite equalizers
5. Minor-loop feedback

Despite its age, the frequency domain design approach represents a most useful approach for the design of linear control systems. It has been tested and proven in a great many practical design situations.

Defining Terms

Bode diagram: A graph of the gain magnitude and frequency response of a linear circuit or system, generally plotted on log-log coordinates. A major advantage of Bode diagrams is that the gain magnitude plot will look like straight lines or be asymptotic to straight lines. H.W. Bode, a well-known Bell Telephone Laboratories researcher, published *Network Analysis and Feedback Amplifier Design* in 1945. The approach, first described there, has been refined by a number of other workers over the past half-century.

Crossover frequency: The frequency where the magnitude of the open-loop gain is 1.

Equalizer: A network inserted into a system that has a transfer function or frequency response designed to compensate for undesired amplitude, phase, and frequency characteristics of the initial system. Filter and equalizer are generally synonymous terms.

Lag network: In a simple phase-lag network, the phase angle associated with the input-output transfer function is always negative, or lagging. Figures 100.13 and 100.14 illustrate the essential characteristics of a lag network.

Lag-lead network: The phase shift versus frequency curve in a phase lag-lead network is negative, or lagging, for low frequencies and positive, or leading, for high frequencies. The phase angle associated with the input-output transfer function is always positive, or leading. Figures 100.16 and 100.17 illustrate the essential characteristics of a lag-lead network, or composite equalizer.

Lead network: In a simple phase-lead network, the phase angle associated with the input-output transfer function is always positive, or leading. Figures 100.10 and 100.11 illustrate the essential characteristics of a lead network.

Series equalizer: In a single-loop feedback system, a series equalizer is placed in the single loop, generally at a point along the forward path from input to output where the equalizer itself consumes only a small amount of energy. In Fig. 100.21, $G_1(s)$ could represent a series equalizer. $G_1(s)$ could also be a series equalizer if $G_4(s) = 0$.

Specification: A statement of the design or development requirements to be satisfied by a system or product.

Systems engineering: An approach to the overall life cycle evolution of a product or system. Generally, the systems engineering process comprises a number of phases. There are three essential phases in any systems engineering life cycle: formulation of requirements and specifications, design and development of the system or product, and deployment of the system. Each of these three basic phases may be further expanded into a larger number. For example, deployment generally comprises operational test and evaluation, maintenance over an extended operational life of the system, and modification and retrofit (or replacement) to meet new and evolving user needs.

Further Information

Many of the practical design situations used to test the frequency domain design approach are described in the excellent classic text by Bower and Schultheiss [1958]. A rather detailed discussion of the approach may also be found in Sage [1978] on which this discussion is, in part, based. A great variety of control systems design approaches, including frequency domain design approaches, are discussed in a recent definitive control systems encyclopedia [Singh, 1987], and there are a plethora of new introductory control systems textbooks that discuss it as well. As noted earlier, frequency domain design, in particular, and control systems design, in general, constitute one facet of systems engineering effort, such as described in Sage [1992].

100.4 Root Locus

Benjamin C. Kuo

Root locus represents a trajectory of the roots of an algebraic equation with constant coefficients when a parameter varies. The technique is used extensively for the analysis and design of linear time-invariant control

systems. For linear time-invariant control systems the roots of the characteristic equation determine the stability of the system. For a stable continuous-data system the roots must all lie in the left half of the s plane. For a digital control system to be stable, the roots of the characteristic equation must all lie inside the unit circle $|z| = 1$ in the z plane. Thus, in the s plane, the imaginary axis is the stability boundary, whereas in the z plane the stability boundary is the unit circle. The location of the characteristic equation roots with respect to the stability boundary also determine the relative stability, i.e., the degree of stability, of the system.

For a linear time-invariant system with continuous data, the characteristic equation can be written as

$$F(s) = P(s) + KQ(s) = 0 \tag{100.33}$$

where $P(s)$ is an Nth-order polynomial of s,

$$P(s) = s^N + a_1 s^{N-1} + \ldots + a_{N-1}s + a_N \tag{100.34}$$

and $Q(s)$ is the Mth-order polynomial of s,

$$Q(s) = s^M + b_1 s^{M-1} + \ldots + b_{M-1}s + b_M \tag{100.35}$$

where N and M are positive integers. The real constant K can vary from $-\infty$ to $+\infty$. The coefficients $a_1, a_2, \ldots, a_N, b_1, b_2, \ldots, b_M$ are real. As K is varied from $-\infty$ to $+\infty$, the roots of Eq. (100.33) trace out continuous trajectories in the s plane called the *root loci.*

The above development can be extended to digital control systems by replacing s with z in Eqs. (100.33) through (100.35).

Root Locus Properties

The root locus problem can be formulated from Eq. (100.33) by dividing both sides of the equation by the terms that do not contain the variable parameter K. The result is

$$1 + \frac{KQ(s)}{P(s)} = 0 \tag{100.36}$$

For a closed-loop control system with the loop transfer function $KG(s)H(s)$, where the gain factor K has been factored out, the characteristic equation is known to be the zeros of the rational function

$$1 + KG(s)H(s) = 0 \tag{100.37}$$

Since Eqs. (100.36) and (100.37) have the same form, the general root locus problem can be formulated using Eq. (100.36).

Equation (100.37) is written

$$G(s)H(s) = -\frac{1}{K} \tag{100.38}$$

To satisfy the last equation, the following conditions must be met simultaneously:

$$\text{Condition on magnitude:} \quad |G(s)H(s)| = \frac{1}{|K|} \tag{100.39}$$

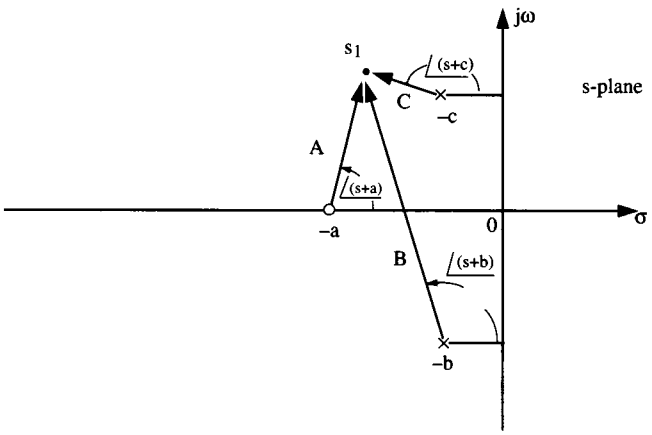

FIGURE 100.22 Graphical interpretation of magnitude and angle conditions of root loci.

where K varies between $-\infty$ and $+\infty$.

$$\text{Conditions on angles: } \angle G(s)H(s) = (2k+1)\pi \quad K \geq 0$$

$$= \text{odd multiples of } \pi \text{ rad} \tag{100.40}$$

$$\angle G(s)H(s) = 2k\pi \quad K \leq 0$$

$$= \text{even multiples of } \pi \text{ rad} \tag{100.41}$$

where $k = 0, \pm 1, \pm 2, \ldots, \pm$ any integer.

In general, the conditions on angles in Eqs. (100.40) and (100.41) are used for the construction of the root loci, whereas the condition on magnitude in Eq. (100.39) is used to find the value of K on the loci once the loci are drawn. Let $KG(s)H(s)$ be of the form

$$KG(s)H(s) = \frac{K(s+a)}{(s+b)(s+c)} \tag{100.42}$$

Applying Eqs. (100.40) and (100.41) to the last equation, the angles conditions are

$$K \geq 0: \quad \angle G(s)H(s) = \angle(s+a) - \angle(s+b) - \angle(s+c)$$

$$= (2k+1)\pi \tag{100.43}$$

$$K \leq 0: \quad \angle G(s)H(s) = \angle(s+a) - \angle(s+b) - \angle(s+c)$$

$$= 2k\pi \tag{100.44}$$

where $k = 0, \pm 1, \pm 2, \ldots$. The graphical interpretation of the last two equations is shown in Fig. 100.22. For the point s_1 to be a point on the root locus, the angles of the phasors drawn from the poles and zeros of $G(s)H(s)$ to s_1 must satisfy Eq. (100.43) or (100.44) depending on the sign of K. Applying the magnitude condition of Eq. (100.39) to (100.42), the magnitude of K is expressed as

$$|K| = \frac{|s+b|\,|s+c|}{|s+a|} = \frac{B \cdot C}{A} \tag{100.45}$$

where A, B, and C are the lengths of the phasors drawn from the poles and zeros of $G(s)H(s)$ to the point s_1.

The following properties of the root loci are useful for sketching the root loci based on the pole-zero configuration of $G(s)H(s)$. Many computer programs, such as the ROOTLOCI in the ACSP software package [Kuo, 1991b], are available for computing and plotting the root loci. The proofs and derivations of these properties can be carried out from Eqs. (100.39), (100.40), and (100.41) [Kuo, 1991a].

Starting Points (K 5 0 Points). The points at which $K = 0$ on the root loci are at the poles of $G(s)H(s)$.

Ending Points (K 56` Points). The points at which $K = \pm\infty$ on the root loci are at the zeros of $G(s)H(s)$. The poles and zeros referred to above include those at s = ∞.

Number of Root Loci. The total number of root loci of Eq. (100.37) equals the higher of the number of poles and zeros of $G(s)H(s)$.

Symmetry of Root Loci. The root loci are symmetrical with respect to the axes of symmetry of the pole-zero configuration of $G(s)H(s)$. In general, the root loci are symmetrical at least to the real axis of the complex s plane.

Asymptotes of the Root Loci. Asymptotes of the root loci refer to the behavior of the root loci at $|s| = \infty$ when the number of poles and zeros of $G(s)H(s)$ is not equal. Let N denote the number of finite poles of $G(s)H(s)$ and M be the number of finite zeros of $G(s)H(s)$. In general, $2|N - M|$ of the loci will approach infinity in the s plane. The properties of the root loci at $|s| = \infty$ are described by the angles and the intersects of the asymptotes. When $N \neq M$, the angles of the asymptotes are given by

$$\phi_k = \begin{cases} \dfrac{(2k + 1)\pi}{|N - M|} & K \geq 0 \quad (100.46) \\ \dfrac{2k\,\pi}{|N - M|} & K \leq 0 \quad (100.47) \end{cases}$$

where $k = 0, 1, 2, \ldots, |N - M| - 1$.

The asymptotes intersect on the real axis at

$$\sigma = \frac{\sum \text{finite poles of } G(s)H(s) - \sum \text{finite zeros of } G(s)H(s)}{N - M} \quad (100.48)$$

Root Loci on the Real Axis. The entire real axis of the s plane is occupied by the root loci. When $K > 0$, root loci are found in sections of the real axis to the right of which the total number of poles and zeros of $G(s)H(s)$ is *odd*. When $K < 0$, root loci are found in sections to the right of which the total number of poles and zeros of $G(s)H(s)$ is *even*.

As a summary of the root locus properties discussed above, the properties of the root loci of the following equation are displayed in Fig. 100.23.

$$s^3 + 2s^2 + 2s + K(s + 3) = 0 \quad (100.49)$$

Dividing both sides of the last equation by the terms that do not contain K we get

$$1 + KG(s)H(s) = 1 + \frac{K(s + 3)}{s(s^2 + 2s + 2)} \quad (100.50)$$

Thus, the poles of $G(s)H(s)$ are at $s = 0$, $s = -1 + j$, and $s = -1 - j$. The zero of $G(s)H(s)$ is at $z = -3$.

As shown in Fig. 100.23, the $K = 0$ points on the root loci are at the poles of $G(s)H(s)$, and the $K = \pm\infty$ points are at the zeros of $G(s)H(s)$. Since $G(s)H(s)$ has two zeros at $s = \infty$, two of the three root loci approach

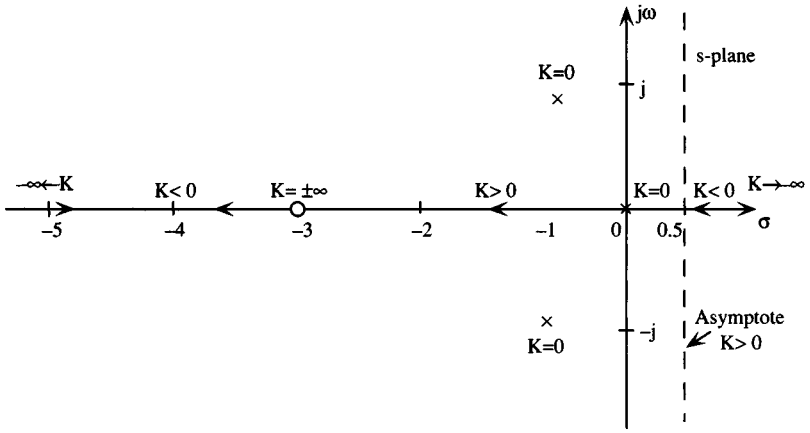

FIGURE 100.23 Some properties of the root loci of $G(s)H(s) = K(s + 3)/[s(s^2 + 2s + 2)]$.

infinity in the s plane. The root loci are symmetrical to the real axis of the s plane, since the pole-zero configuration of $G(s)H(s)$ is symmetrical to the axis. The asymptotes of the two root loci that approach infinity are characterized by Eqs. (100.46) through (100.48). The angles of the asymptotes are:

$$K \geq 0: \quad \phi_k = \frac{(2k + 1)\pi}{3 - 1} \qquad k = 0, 1 \tag{100.51}$$

$$K \leq 0: \quad \phi_k = \frac{2k\pi}{3 - 1} \qquad k = 0, 1 \tag{100.52}$$

Thus, for $K \geq 0$, the angles of the asymptotes are $\phi_0 = 90°$ and $\phi_1 = 270°$. For $K \leq 0$, $\phi_0 = 0°$ and $\phi_1 = 180°$.

The intersect of the asymptotes is at

$$\sigma = \frac{-1 + j - 1 - j - (-3)}{3 - 1} = \frac{1}{2} \tag{100.53}$$

The root loci on the real axis are as indicated in Fig. 100.23.

Angles of Departure and Arrival. The slope of the root locus in the vicinity of a pole of $G(s)H(s)$ is measured at the *angle of departure* and that in the vicinity of a zero of $G(s)H(s)$ is measured at the *angle of arrival.*

The angle of departure (arrival) of a root locus at a pole (zero) of $G(s)H(s)$ is determined by assigning a point s_1 to the root locus that is very close to the pole (zero) and applying the angle conditions of Eqs. (100.40) or (100.41). Figure 100.24 illustrates the calculation of the angles of arrival and departure of the root locus at the pole $s = -1 + j$. We assign a point s_1 that is on the locus for $K > 0$ near the pole and draw phasors from *all* the poles and the zero of $G(s)H(s)$ to this point. The angles made by the phasors with respect to the real axis must satisfy the angle condition in Eq. (100.46). Let the angle of the phasor drawn from $-1 + j$ to s_1 be designated as θ, which is the angle of departure; the angles drawn from the other poles and zero can be approximated by regarding s_1 as being very close to $-1 + j$. Thus, Eq. (100.46) leads to

$$\angle G(s_1)H(s_1) = -\theta - 135° - 90° + 26.6° = -180° \tag{100.54}$$

or $\theta = -18.4°$. For the angle of arrival of the root locus at the pole $s = -1 + j$, we assign a point s_1 on the root loci for $K < 0$ near the pole. Drawing phasors from all the poles and the zero of $G(s)H(s)$ to s_1 and applying the angle condition in Eq. (100.47), we have

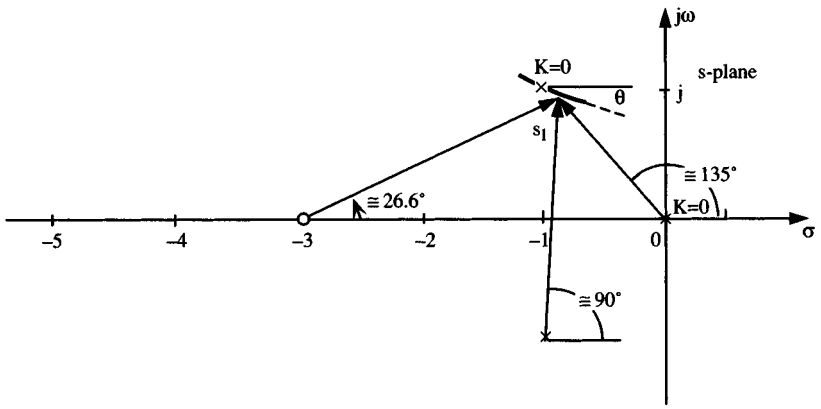

FIGURE 100.24 Angle of arrival and departure calculations.

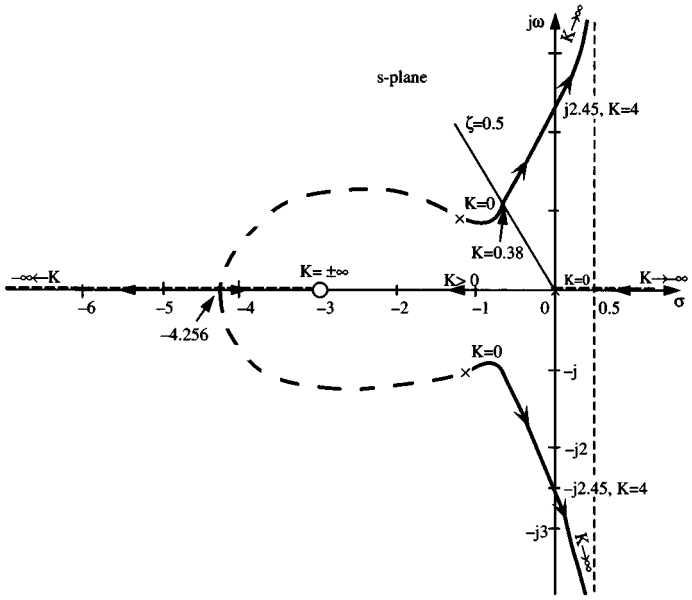

FIGURE 100.25 The complete root loci of $G(s)H(s) = K(s + 3)/[s(s^2 + 2s + 2)]$.

$$\angle G(s_1)H(s_1) = -\theta - 135° - 90° + 26.6° = 0° \tag{100.55}$$

Thus, the angle of arrival of the root locus for $K < 0$ is $\theta = 198.4°$. Similarly, we can show that the angles of arrival and departure of the root locus at $s = -3$ are 180° and 0°, respectively.

Intersection of the Root Loci with the Imaginary Axis. The points where the root loci intersect the imaginary axis (if there is any) in the s plane, and the corresponding values of K, may be determined by means of the Routh-Hurwitz stability criterion [Kuo, 1991a]. The root locus program can also be used on a computer to give the intersects.

The complete root loci in Fig. 100.25 show that the root loci intersect the imaginary axis at $s = \pm j2.45$, and the value of K is 4. The system is stable for $0 \le K < 4$.

Breakaway Points of the Root Loci. Breakaway points on the root loci correspond to multiple-order roots of the equation. At a breakaway point several root loci converge and then break away in different directions. The breakaway point can be real or complex. The latter case must be in complex conjugate pairs.

The breakaway points of the root loci of Eq. (100.37) must satisfy the following condition:

$$\frac{dG(s)H(s)}{ds} = 0 \tag{100.56}$$

On the other hand, not all solutions of Eq. (100.56) are breakaway points. To satisfy as a breakaway point, the point must also lie on the root loci, or satisfy Eq. (100.37). Applying Eq. (100.56) to the function $G(s)H(s)$ given in Eq. (100.50), we have the equation that the breakaway points must satisfy,

$$2s^3 + 11s^2 + 12s + 6 = 0 \tag{100.57}$$

The roots of the last equation are $s = -4.256$, $-0.622 + j0.564$ and $-0.622 - j0.564$. As shown in Fig. 100.25, only the solution $s = -4.256$ is a breakaway point on the root loci.

Root Loci of Digital Control Systems

The root locus analysis presented in the preceding subsections can be applied to digital control systems without modifying the basic principles. For a linear time-invariant digital control system, the transfer functions are expressed in terms of the z-transform rather than the Laplace transform. The relationship between the z-transform variable z and the Laplace transform variable s is

$$z = e^{Ts} \tag{100.58}$$

where T is the sampling period in seconds. Typically, the characteristic equation roots are solutions of the equation

$$1 + KGH(z) = 0 \tag{100.59}$$

where K is the variable gain parameter. The root loci for a digital control system are constructed in the complex z plane. All the properties of the root loci in the s plane apply readily to the z plane, with the exception that the stability boundary is now the unit circle $|z| = 1$. That is, the system is stable if all the characteristic equation roots lie inside the unit circle.

As an illustration, the open-loop transfer function of a digital control system is given as

$$G(z) = \frac{K(z + 0.1)}{z(z - 1)} \tag{100.60}$$

The characteristic equation of the closed-loop system is

$$z(z - 1) + K(z + 0.1) = 0$$

The root loci of the system are shown in Fig. 100.26. Notice that the system is stable for $0 \le K < 2.22$. When $K = 2.22$, one root is at $z = -1$, which is on the stability boundary.

Design with Root Locus

The root locus diagram of the characteristic equation of a closed-loop control system can be used for design purposes. The roots of the characteristic equation can be positioned in the s plane (or the z plane for digital control systems) to realize a certain desired relative stability or damping of the system. It should be kept in mind that the zeros of the closed-loop transfer function also affect the relative stability of the system, although the absolute stability is strictly governed by the characteristic equation roots.

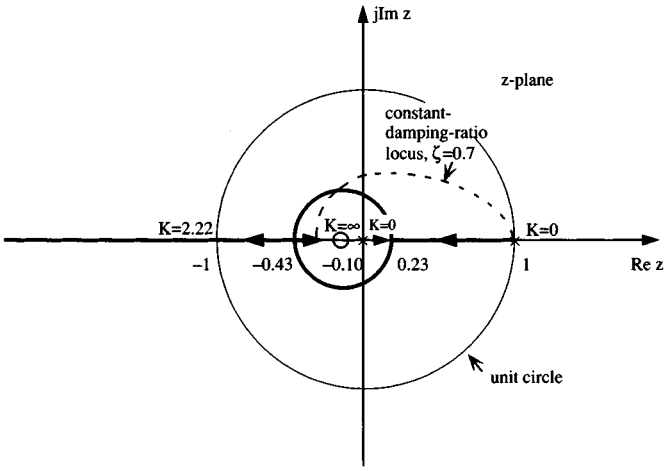

FIGURE 100.26 Root loci in the z plane for a digital control system.

As an illustrative example, the constant-damping ratio line for $\zeta = 0.5$ is shown in Fig. 100.25. The intersect of the $\zeta = 0.5$ line and the root locus corresponds to $K = 0.38$. Let us assume that we want to keep the relative damping at approximately 0.5 but the gain K should be increased tenfold. The following cascade controller is applied to the system [Evans, 1948]:

$$G_c(s) = \frac{1 + 5s}{1 + 50s} \tag{100.61}$$

The open-loop transfer function of the compensated system is now

$$G_c(s)G(s)H(s) = \frac{0.1K(s + 3)(s + 0.2)}{s(s + 0.02)(s^2 + 2s + 2)} \tag{100.62}$$

Figure 100.27 shows the root locus diagram of the compensated system for $K \geq 0$. The shape of the complex root loci is not appreciably affected by the controller, but the value of K that corresponds to a relative damping ratio of 0.5 is now approximately 3.9.

In a similar manner the root loci of digital control systems can be reshaped in the z plane for design. The constant-damping ratio locus in the z plane is shown in Fig. 100.26.

Defining Terms

Angles of departure and arrival: The slope of the root locus in the vicinity of a pole of $G(s)H(s)$ is measured as the angle of departure, and that in the vicinity of a zero of $G(s)H(s)$ is measured as the angle of arrival.

Asymptotes of root loci: The behavior of the root loci at $|s| = \infty$ *when the number of poles and zeros of* $G(s)H(s)$ *is not equal.*

Breakaway points of the root loci: Breakaway points on the root loci correspond to multiple-order roots of the equation.

Root locus: The trajectory of the roots of an algebraic equation with constant coefficient when a parameter varies.

100.5 Compensation

Charles L. Phillips and Royce D. Harbor

Compensation is the process of modifying a closed-loop control system (usually by adding a *compensator* or *controller*) in such a way that the compensated system satisfies a given set of design specifications. This section presents the fundamentals of compensator design; actual techniques are available in the references.

A single-loop control system is shown in Fig. 100.28. This system has the transfer function from input $R(s)$ to output $C(s)$

$$T(s) = \frac{C(s)}{R(s)} = \frac{G_c(s)G_p(s)}{1 + G_c(s)G_p(s)H(s)} \tag{100.63}$$

and the characteristic equation is

$$1 + G_c(s)G_p(s)H(s) = 0 \tag{100.64}$$

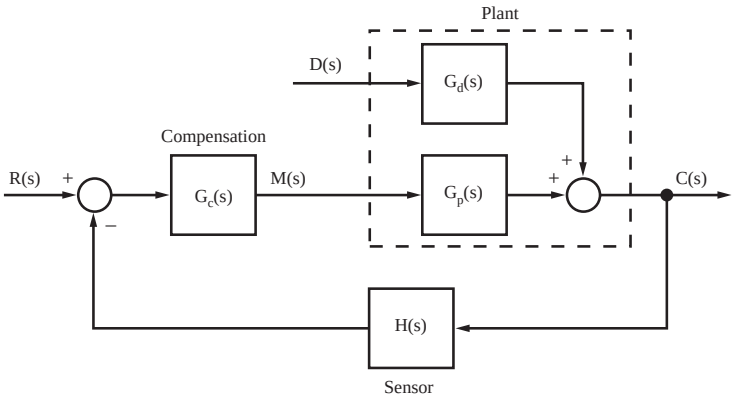

FIGURE 100.28 A closed-loop control system.

where $G_c(s)$ is the *compensator* transfer function, $G_p(s)$ is the *plant* transfer function, and $H(s)$ is the *sensor* transfer function. The transfer function from the disturbance input $D(s)$ to the output is $G_d(s)/[1 + G_c(s)G_p(s)H(s)]$. The function $G_c(s)G_p(s)H(s)$ is called the *open-loop function.*

Control System Specifications

The compensator transfer function $G_c(s)$ is designed to give the closed-loop system certain specified characteristics, which are realized through achieving one or more of the following:

1. Improving the transient response. Increasing the speed of response is generally accomplished by increasing the open-loop gain $G_c(j\omega)G_p(j\omega)H(j\omega)$ at higher frequencies such that the system bandwidth is increased. Reducing overshoot (ringing) in the response generally involves increasing the phase margin ϕ_m of the system, which tends to remove any resonances in the system. The phase margin ϕ_m occurs at the frequency ω_1 and is defined by the relationship

$$\left|G_c(j\omega_1)G_p(j\omega_1)H(j\omega_1)\right| = 1$$

   with the angle of $G_c(j\omega_1)G_p(j\omega_1)H(j\omega_1)$ equal to $(180° + \phi_m)$.
2. Reducing the steady-state errors. Steady-state errors are decreased by increasing the open-loop gain $G_c(j\omega)G_p(j\omega)H(j\omega)$ in the frequency range of the errors. Low-frequency errors are reduced by increasing the low-frequency open-loop gain and by increasing the type number of the system [the number of poles at the origin in the open-loop function $G_c(s)G_p(s)H(s)$].
3. Reducing the sensitivity to plant parameters. Increasing the open-loop gain $G_c(j\omega)G_p(j\omega)\ H(j\omega)$ tends to reduce the variations in the system characteristics due to variations in the parameters of the plant.
4. Rejecting disturbances. Increasing the open-loop gain $G_c(j\omega)G_p(j\omega)H(j\omega)$ tends to reduce the effects of disturbances [$D(s)$ in Fig. 100.28] on the system output, provided that the increase in gain does not appear in the direct path from disturbance inputs to the system output.
5. Increasing the relative stability. Increasing the open-loop gain tends to reduce phase and gain margins, which generally increases the overshoot in the system response. Hence, a trade-off exists between the beneficial effects of increasing the open-loop gain and the resulting detrimental effects of reducing the stability margins.

Design

Design procedures for compensators are categorized as either *classical methods* or *modern methods.* Classical methods discussed are:

- Ph ase-lag frequency response
- Phase-lead frequency response
- Phase-lag root locus
- Phase-lead root locus

Modern methods discussed are:

- Pole placement
- State estimation
- Optimal

Frequency Response Design

Classical design procedures are normally based on the open-loop function of the uncompensated system, $G_p(s)H(s)$. Two compensators are used in classical design; the first is called a *phase-lag compensator,* and the second is called a *phase-lead compensator.*

The general characteristics of phase-lag-compensated systems are as follows:

1. The low-frequency behavior of a system is improved. This improvement appears as reduced errors at low frequencies, improved rejection of low-frequency disturbances, and reduced sensitivity to plant parameters in the low-frequency region.
2. The system bandwidth is reduced, resulting in a slower system time response and better rejection of high-frequency noise in the sensor output signal.

The general characteristics of phase-lead-compensated systems are as follows:

1. The high-frequency behavior of a system is improved. This improvement appears as faster responses to inputs, improved rejection of high-frequency disturbances, and reduced sensitivity to changes in the plant parameters.
2. The system bandwidth is increased, which can increase the response to high-frequency noise in the sensor output signal.

The transfer function of a first-order compensator can be expressed as

$$G_c(s) = \frac{K_c(s/\omega_0 + 1)}{s/\omega_p + 1} \tag{100.65}$$

where $-\omega_0$ is the compensator zero, $-\omega_p$ is its pole, and K_c is its dc gain. If $\omega_p < \omega_0$, the compensator is phase-lag. The Bode diagram of a phase-lag compensator is given in Fig. 100.29 for $K_c = 1$.

It is seen from Fig. 100.29 that the phase-lag compensator reduces the high-frequency gain of the open-loop function relative to the low-frequency gain. This effect allows a higher low-frequency gain, with the advantages listed above. The pole and zero of the compensator must be placed at very low frequencies relative to the compensated-system bandwidth so that the destabilizing effects of the negative phase of the compensator are negligible.

If $\omega_p > \omega_0$ the compensator is phase-lead. The Bode diagram of a phase-lead compensator is given in Fig. 100.30 for $K_c = 1$.

It is seen from Fig. 100.30 that the phase-lead compensator increases the high-frequency gain of the open-loop function relative to its low-frequency gain. Hence, the system has a larger bandwidth, with the advantages listed above. The pole and zero of the compensator are generally difficult to place, since the increased gain of the open-loop function tends to destabilize the system, while the phase lead of the compensator tends to stabilize the system. The pole-zero placement for the phase-lead compensator is much more critical than that of the phase-lag compensator.

A typical Nyquist diagram of an uncompensated system is given in Fig. 100.31. The pole and the zero of a phase-lag compensator are placed in the frequency band labeled *A*. This placement negates the destabilizing

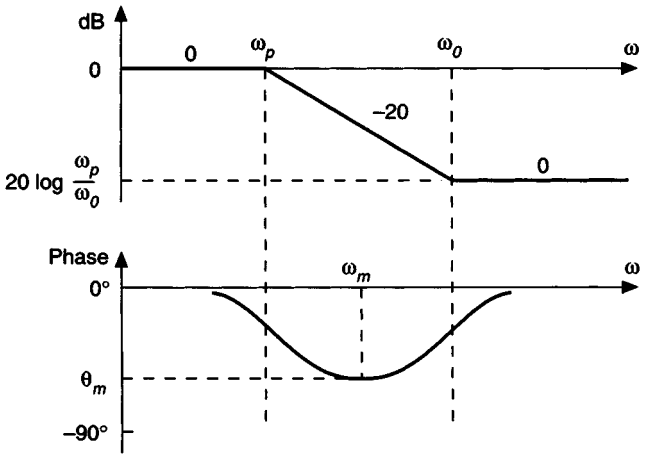

FIGURE 100.29 Bode diagram for a phase-lag compensator.

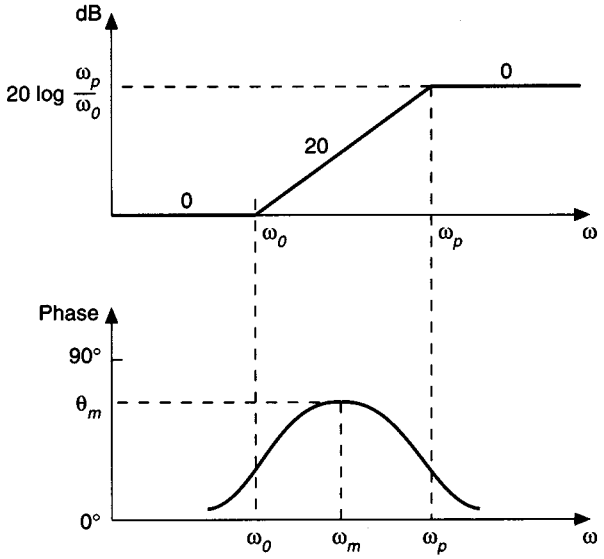

FIGURE 100.30 Bode diagram for a phase-lead compensator.

effect of the negative phase of the compensator. The pole and zero of a phase-lead compensator are placed in the frequency band labeled *B*. This placement utilizes the stabilizing effect of the positive phase of the compensator.

PID Controllers

Proportional-plus-integral-plus-derivative (PID) compensators are probably the most utilized form for compensators. These compensators are essentially equivalent to a phase-lag compensator cascaded with a phase-lead compensator. The transfer function of this compensator is given by

$$G_c(s) = K_P + \frac{K_I}{s} + K_D s \tag{100.66}$$

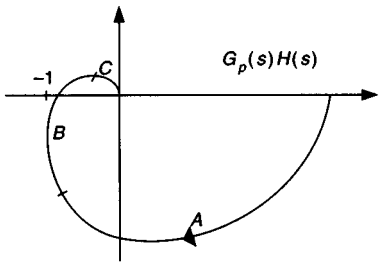

FIGURE 100.31 A typical Nyquist diagram for $G_p(s)H(s)$.

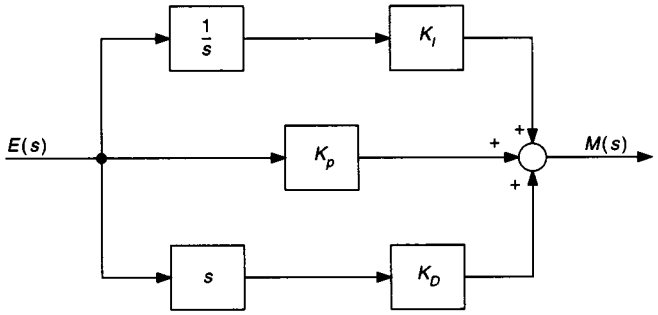

FIGURE 100.32 Block diagram of a PID compensator.

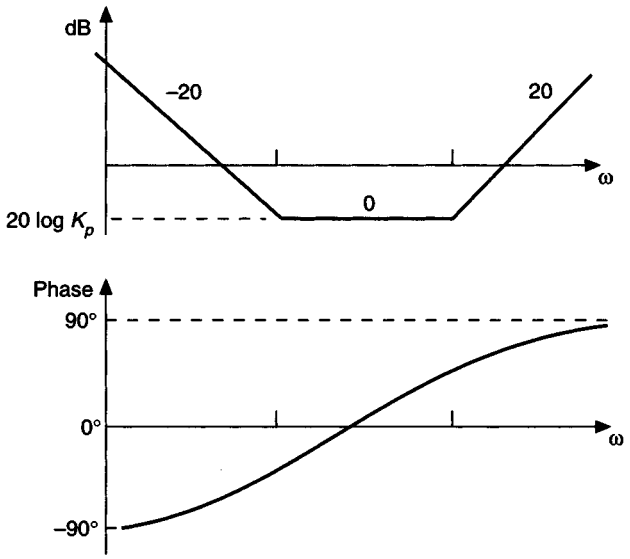

FIGURE 100.33 Bode diagram of a PID compensator.

A block diagram portrayal of the compensator is shown in Fig. 100.32. The integrator in this compensator increases the system type by one, resulting in an improved low-frequency response. The Bode diagram of a PID compensator is given in Fig. 100.33.

With $K_D = 0$, the compensator is phase-lag, with the pole in (100.65) moved to $\omega_p = 0$. As a result the compensator is type one. The zero of the compensator is placed in the low-frequency range to correspond to the zero of the phase-lag compensator discussed above.

With $K_I = 0$, the compensator is phase-lead, with a single zero and the pole moved to infinity. Hence, the gain continues to increase with increasing frequency. If high-frequency noise is a problem, it may be necessary to add one or more poles to the PD or PID compensators. These poles must be placed at high frequencies relative to the phase-margin frequency such that the phase margin (stability characteristics) of the system is not degraded. PD compensators realized using rate sensors minimize noise problems [Phillips and Harbor, 1991].

Root Locus Design

Root locus design procedures generally result in the placement of the two dominant poles of the closed-loop system transfer function. A system has two dominant poles if its behavior approximates that of a second-order system.

The differences in root locus designs and frequency response designs appear only in the interpretation of the control-system specifications. A root locus design that improves the low-frequency characteristics of the system will result in a phase-lag controller; a phase-lead compensator results if the design improves the high-frequency response of the system. If a root locus design is performed, the frequency response characteristics of the system should be investigated. Also, if a frequency response design is performed, the poles of the closed-loop transfer function should be calculated.

Modern Control Design

The classical design procedures above are based on a transfer-function model of a system. Modern design procedures are based on a *state-variable model* of the plant. The plant transfer function is given by

$$\frac{Y(s)}{U(s)} = G_p(s) \tag{100.67}$$

where we use $u(t)$ for the plant input and $y(t)$ for the plant output. If the system model is nth order, the denominator of $G_p(s)$ is an nth-order polynomial.

The state-variable model, or state model, for a single-input–single-output plant is given by

$$\begin{aligned} \frac{d\mathbf{x}(t)}{dt} &= \mathbf{A}\mathbf{x}(t) + \mathbf{B}u(t) \\ y(t) &= \mathbf{C}\mathbf{x}(t) \end{aligned} \tag{100.68}$$

$$y(t) = \mathbf{C}\mathbf{x}(t)$$

where $\mathbf{x}(t)$ is the $n \times 1$ state vector, $u(t)$ is the plant input, $y(t)$ is the plant output, $\mathbf{A}$ is the $n \times n$ *system matrix,* $\mathbf{B}$ is the $n \times 1$ *input matrix*, and $\mathbf{C}$ is the $1 \times n$ *output matrix*. The transfer function of (100.67) is an input-output model; the state model of (100.68) yields the same input-output model and in addition includes an internal model of the system. The state model of (100.68) is readily adaptable to a multiple-input–multiple-output system (*a multivariable system*); for that case, $u(t)$ and $y(t)$ are vectors. We will consider only single-input–single-output systems.

The plant transfer function of (100.67) is related to the state model of (100.68) by

$$G_p(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} \tag{100.69}$$

The state model is not unique; many combinations of the matrices **A, B,** and **C** can be found to satisfy (100.69) for a given transfer function $G_p(s)$.

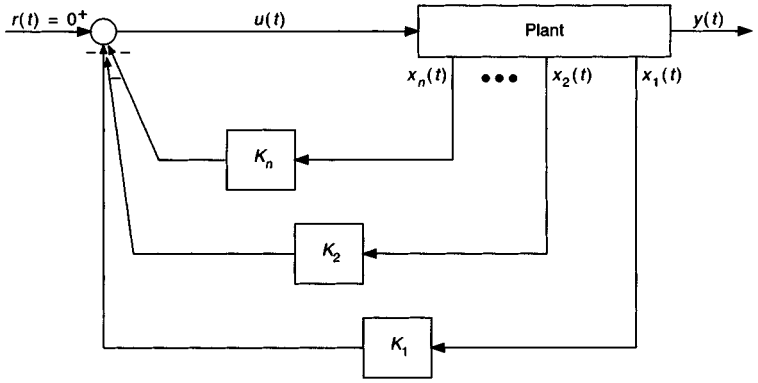

FIGURE 100.34 Implementation of pole-placement design.

Classical compensator design procedures are based on the open-loop function $G_p(s)H(s)$ of Fig. 100.28. It is common to present modern design procedures as being based on only the plant model of (100.68). However, the models of the sensors that measure the signals for feedback must be included in the state model. This problem will become more evident as the modern procedures are presented.

Pole Placement

Probably the simplest modern design procedure is *pole placement.* Recall that root locus design was presented as placing the two dominant poles of the closed-loop transfer function at desired locations. The pole-placement procedure places *all* poles of the closed-loop transfer function, or equivalently, all roots of the closed-loop system characteristic equation, at desirable locations.

The system design specifications are used to generate the desired closed-loop system characteristic equation $\alpha_c(s)$, where

$$\alpha_c(s) = s^n + \alpha_{n-1}s^{n-1} + \ldots + \alpha_1 s + \alpha_0 = 0 \tag{100.70}$$

for an nth-order plant. This characteristic equation is realized by requiring the plant input to be a linear combination of the plant states, that is,

$$u(t) = -K_1x_1(t) - K_2x_2(t) - \ldots - K_nx_n(t) = -\mathbf{K}\mathbf{x}(t) \tag{100.71}$$

where $\mathbf{K}$ is the $1 \times n$ feedback-gain matrix. Hence *all* states must be measured and fed back. This operation is depicted in Fig. 100.34.

The feedback-gain matrix $\mathbf{K}$ is determined from the desired characteristic equation for the closed-loop system of (100.70):

$$\alpha_c(s) = |sI - A + BK| = 0 \tag{100.72}$$

The state feedback gain matrix $\mathbf{K}$ which yields the specified closed-loop characteristic equation $\alpha_c(s)$ is

$$\mathbf{K} = [0\ 0\ \ldots\ 0\ 1][\mathbf{B}\ \mathbf{AB}\ \ldots\ \mathbf{A}^{n-1}\mathbf{B}]^{-1}\alpha_c(\mathbf{A}) \tag{100.73}$$

where $\alpha_c(\mathbf{A})$ is (100.70) with the scalar s replaced with the matrix $\mathbf{A}$. A plant is said to be *controllable* if the inverse matrix in (100.73) exists. Calculation of $\mathbf{K}$ completes the design process. A simple computer algorithm is available for solving (100.73) for $\mathbf{K}$.

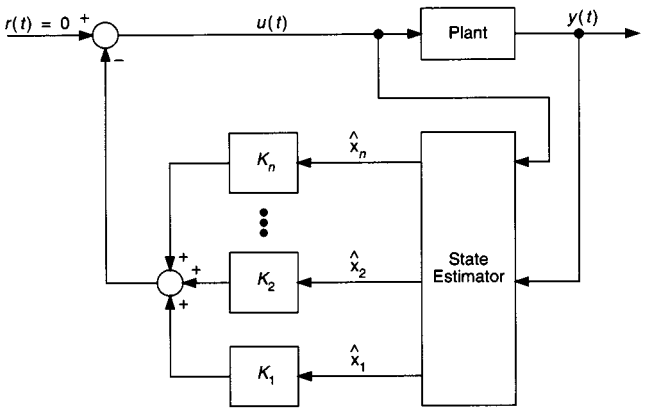

FIGURE 100.35 Implementation of observer-pole-placement design.

State Estimation

In general, modern design procedures require that the state vector $\mathbf{x}(t)$ be fed back, as in (100.71). The measurement of all state variables is difficult to implement for high-order systems. The usual procedure is to estimate the states of the system from the measurement of the output $y(t)$, with the estimated states then fed back.

Let the estimated state vector be $\hat{\mathbf{x}}$. One procedure for estimating the system states is by an *observer,* which is a dynamic system realized by the equations

$$\frac{d\hat{\mathbf{x}}(t)}{dt} = (\mathbf{A} - \mathbf{GC})\hat{\mathbf{x}}(t) + \mathbf{B}u(t) + \mathbf{G}y(t) \tag{100.74}$$

with the feedback equation of (100.71) now realized by

$$u(t) = -\mathbf{K}\hat{\mathbf{x}}(t) \tag{100.75}$$

The matrix $\mathbf{G}$ in (100.74) is calculated by assuming an nth-order characteristic equation for the observer of the form

$$\alpha_e(s) = |sI - A + GC| = 0 \tag{100.76}$$

The estimator gain matrix $\mathbf{G}$ which yields the specified estimator characteristic equation $\alpha_e(s)$ is

$$\mathbf{G} = \alpha_e(\mathbf{A})[\mathbf{C}\ \mathbf{CA}\ \ldots\ \mathbf{CA}^{n-1}]^{-T}[0\ 0\ \ldots\ 0\ 1]^T \tag{100.77}$$

where $[\cdot]^T$ denotes the matrix transpose. A plant is said to be *observable* if the inverse matrix in (100.77) exists. An implementation of the closed-loop system is shown in Fig. 100.35. The observer is usually implemented on a digital computer. The plant and the observer in Fig. 100.35 are both nth-order; hence, the closed-loop system is of order $2n$.

The observer-pole-placement system of Fig. 100.35 is equivalent to the system of Fig. 100.36, which is of the form of closed-loop systems designed by classical procedures. The transfer function of the controller-estimator (equivalent compensator) of Fig. 100.36 is given by

$$\mathbf{G}_{ec}(s) = \mathbf{K}[s\mathbf{I} - \mathbf{A} + \mathbf{GC} + \mathbf{BK}]^{-1}\mathbf{G} \tag{100.78}$$

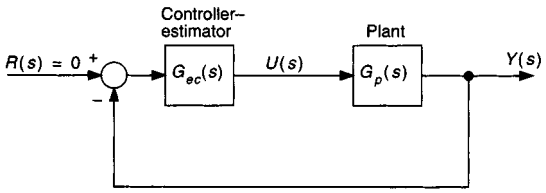

FIGURE 100.36 Equivalent system for pole-placement design.

This compensator is *n*th-order for an *n*th-order plant; hence, the total system is of order 2*n*. The characteristic equation for the compensated system is given by

$$\left|s\mathbf{I} - \mathbf{A} + \mathbf{BK}\right|\left|s\mathbf{I} - \mathbf{A} + \mathbf{GC}\right| = \alpha_c(s)\alpha_e(s) = 0 \tag{100.79}$$

The roots of this equation are the roots of the pole-placement design plus those of the observer design. For this reason, the roots of the characteristic equation for the observer are usually chosen to be faster than those of the pole-placement design.

Linear Quadratic Optimal Control

We define an optimal control system as one for which some mathematical function is minimized. The function to be minimized is called the *cost function*. For steady-state linear quadratic optimal control the cost function is given by

$$V_\infty = \int_t^\infty \left[\mathbf{x}^T(\tau)\mathbf{Q}\mathbf{x}(\tau) + Ru^2(\tau)\right] d\tau \tag{100.80}$$

where Q and R are chosen to satisfy the design criteria. In general, the choices are not straightforward. Minimization of (100.80) requires that the plant input be given by

$$u(t) = -R^{-1}\mathbf{B}^T\mathbf{M}_\infty\mathbf{x}(t) \tag{100.81}$$

where the $n \times n$ matrix $\mathbf{M}_\infty$ is the solution to the *algebraic Riccati equation*

$$\mathbf{M}_\infty\mathbf{A} + \mathbf{A}^T\mathbf{M}_\infty - \mathbf{M}_\infty\mathbf{B}R^{-1}\mathbf{B}^T\mathbf{M}_\infty + \mathbf{Q} = 0 \tag{100.82}$$

The existence of a solution for this equation is involved [Friedland, 1986] and is not presented here. Optimal control systems can be designed for cost functions other than that of (100.80).

Other Modern Design Procedures

Other modern design procedures exist; for example, *self-tuning control systems* continually estimate certain plant parameters and adjust the compensator based on this estimation. These control systems are a type of *adaptive control systems* and usually require that the control algorithms be implemented using a digital computer. These control systems are beyond the scope of this book (see, for example, Astrom and Wittenmark, 1984).

Defining Term

Compensation: The process of physically altering a closed-loop system such that the system has specified characteristics. This alteration is achieved either by changing certain parameters in the system or by adding a physical system to the closed-loop system; in some cases both methods are used.

100.6 Digital Control Systems

Raymond G. Jacquot and John E. McInroy

The use of the **digital computer** to control physical processes has been a topic of discussion in the technical literature for over four decades, but the actual use of a digital computer for control of industrial processes was reserved only for massive and slowly varying processes such that the high cost and slow computing speed of available computers could be tolerated. The invention of the integrated circuit microprocessor in the early 1970s radically changed all that; now microprocessors are used in control tasks in automobiles and household appliances, applications where high cost is not justifiable.

When the term *digital control* is used, it usually refers to the process of employing a digital computer to control some process that is characterized by continuous-in-time dynamics. The control can be of the open-loop variety where the control strategy output by the digital computer is dictated without regard to the status of the process variables. An alternative technique is to supply the digital computer with digital data about the process variables to be controlled, and thus the control strategy output by the computer depends on the process variables that are to be controlled. This latter strategy is a **feedback control** strategy wherein the computer, the process, and interface hardware form a closed loop of information flow.

Examples of dynamic systems that are controlled in such a closed-loop digital fashion are flight control of civilian and military aircraft, control of process variables in chemical processing plants, and position and force control in industrial robot manipulators. The simplest form of feedback control strategy provides an on-off control to the controlling variables based on measured values of the process variables. This strategy will be illustrated by a simple example in a following subsection.

In the past decade and a half many excellent textbooks on the subject of digital control systems have been written, and most of them are in their second edition. The texts in the References provide in-depth development of the theory by which such systems are analyzed and designed.

A Simple Example

Such a closed-loop or feedback control situation is illustrated in Fig. 100.37, which illustrates the feedback control of the temperature in a simple environmental chamber that is to be kept at a constant temperature somewhat above room temperature.

Heat is provided by turning on a relay that supplies power to a heater coil. The on-off signal to the relay can be supplied by 1 bit of an output port of the microprocessor (typically the port would be 8 bits wide). A second bit of the port can be used to turn a fan on and off to supply cooling air to the chamber. An analog-to-digital (A/D) converter is employed to convert the amplified thermocouple signal to a digital word that is then supplied to the input port of the microprocessor. The program being executed by the microprocessor reads the temperature data supplied to the input port and compares the binary number representing the temperature to a binary

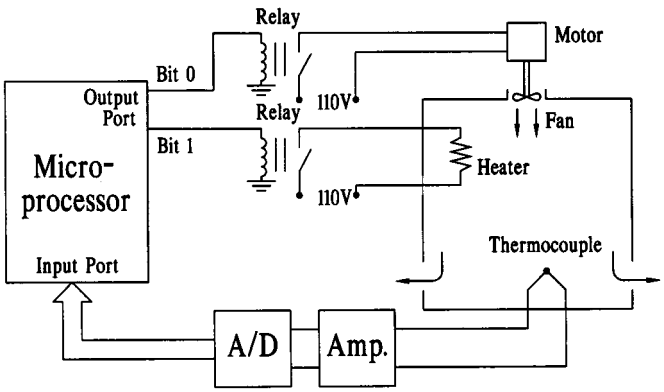

FIGURE 100.37 Microprocessor control of temperature in a simple environmental chamber.

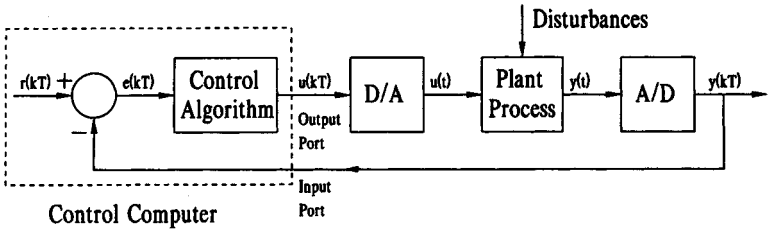

FIGURE 100.38 Closed-loop control of a single process variable.

version of the desired temperature and makes a decision whether or not to turn on the heater or the fan or to do nothing. The program being executed runs in a continuous loop, repeating the operations discussed above.

This simple on-off control strategy is often not the best when extremely precise control of the process variables is required. A more precise control may be obtained if the controlling variable levels can be adjusted to be somewhat larger if the deviation of the process variable from the desired value is larger.

Single-Loop Linear Control Laws

Consider the case where a single variable of the process is to be controlled, as illustrated in Fig. 100.38. The output of the plant $y(t)$ is to be sampled every T seconds by an A/D converter, and this sequence of numbers will be denoted as $y(kT)$, $k = 0, 1, 2, \ldots$. The goal is to make the sequence $y(kT)$ follow some desired known sequence [the reference sequence $r(kT)$]. Consequently, the sequence $y(kT)$ is subtracted from $r(kT)$ to obtain the so-called error sequence $e(kT)$. The control computer then acts on the error sequence, using some control algorithms, to produce the control effort sequence $u(kT)$ that is supplied to the digital-to-analog (D/A) converter which then drives the actuating hardware with a signal proportional to $u(kT)$. The output of the D/A converter is then held constant on the current time interval, and the control computer waits for the next sample of the variable to be controlled, the arrival of which repeats the sequence. The most commonly employed control algorithm or control law is a linear difference equation of the form

$$u(kT) = a_n e(kT) + a_{n-1} e((k-1)T) + \ldots + a_0 e((k-n)T)$$
$$+ b_{n-1} u((k-1)T) + \ldots + b_0 u((k-n)T) \qquad (100.83)$$

The question remains as to how to select the coefficients $a_0, \ldots, a_n$ and $b_0, \ldots, b_{n-1}$ in expression (100.83) to give an acceptable degree of control of the plant.

Proportional Control

This is the simplest possible control algorithm for the digital processor wherein the most current control effort is proportional to the current error or using only the first term of relation (100.83)

$$u(kT) = a_n e(kT) \tag{100.84}$$

This algorithm has the advantage that it is simple to program, while, on the other hand, its disadvantage lies in the fact that it has poor disturbance rejection properties in that if a_n is made large enough for good disturbance rejection, the closed-loop system can be unstable (i.e., have transient responses which increase with time). Since the object is to regulate the system output in a known way, these unbounded responses preclude this regulation.

PID Control Algorithm

A common technique employed for decades in chemical process control loops is that of proportional-plus-integral-plus-derivative (PID) control wherein a continuous-time control law would be given by

$$u(t) = K_p e(t) + K_i \int_0^t e(\tau) d\tau + K_d \frac{de}{dt} \tag{100.85}$$

This would have to be implemented by an analog filter.

To implement the design in digital form the proportional term can be carried forward as in relation (100.84); however, the integral can be replaced by trapezoidal integration using the error sequence, while the derivative can be replaced with the backward difference resulting in a computer control law of the form [Jacquot, 1995]

$$\begin{aligned} u(kT) = u((k-1)T) &+ \left(K_p + \frac{K_i T}{2} + \frac{K_d}{T} \right) e(kT) \\ &+ \left(\frac{K_i T}{2} - K_p - \frac{2K_d}{T} \right) e((k-1)T) + \frac{K_d}{T} e((k-2)T) \end{aligned} \tag{100.86}$$

where T is the duration of the sampling interval. The selection of the coefficients in this algorithm (K_p, K_d, and K_p) is best accomplished by the Ziegler-Nichols tuning process [Franklin et al., 1990].

The Closed-Loop System

When the plant process is linear or may be linearized about an operating point and the control law is linear as in expressions (100.83), (100.84), or (100.86), then an appropriate representation of the complete closed-loop system is by the so-called z-transform. The z-transform plays the role for linear, constant-coefficient difference equations that the Laplace transform plays for linear, constant-coefficient differential equations. This z-domain representation allows the system designer to investigate system time response, frequency response, and stability in a single analytical framework.

If the plant can be represented by an s-domain transfer function $G(s)$, then the discrete-time (z-domain) transfer function of the plant, the analog-to-digital converter, and the driving digital-to-analog converter is

$$G(z) = \left(\frac{z-1}{z} \right) Z \left\{ L^{-1} \left[\frac{G(s)}{s} \right] \right\} \tag{100.87}$$

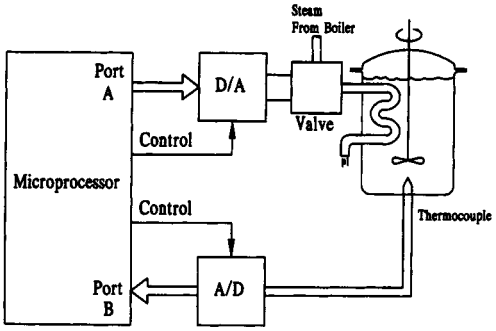

FIGURE 100.39 A computer-controlled thermal mixing tank.

where $Z(\cdot)$ is the z-transform and $L^{-1}(\cdot)$ is the inverse Laplace transform. The transfer function of the control law of (100.83) is

$$D(z) = \frac{U(z)}{E(z)} = \frac{a_n z^n + a_{n-1} z^{n-1} + \cdots + a_0}{z^n - b_{n-1} z^{n-1} - \cdots - b_0} \tag{100.88}$$

For the closed-loop system of Fig. 100.38 the closed-loop z-domain transfer function is

$$M(z) = \frac{Y(z)}{R(z)} = \frac{G(z)D(z)}{1 + G(z)D(z)} \tag{100.89}$$

where $G(z)$ and $D(z)$ are specified above. The characteristic equation of the closed-loop system is

$$1 + G(z)D(z) = 0 \tag{100.90}$$

The dynamics and stability of the system can be assessed by the locations of the zeros of (100.90) (the closed-loop poles) in the complex z plane. For stability the zeros of (100.90) above must be restricted to the unit circle of the complex z plane.

A Linear Control Example

Consider the temperature control of a chemical mixing tank shown in Fig. 100.39. From a transient power balance the differential equation relating the rate of heat added $q(t)$ to the deviation in temperature from the ambient $\theta(t)$ is given as

$$\frac{d\theta}{dt} + \frac{1}{\tau}\theta = \frac{1}{mc} q(t) \tag{100.91}$$

where τ is the time constant of the process and mc is the heat capacity of the tank. The transfer function of the tank is

$$\frac{\Theta(s)}{Q(s)} = G(s) = \frac{1/mc}{s + 1/\tau} \tag{100.92}$$

The heater is driven by a D/A converter, and the temperature measurement is sampled with an A/D converter. The data converters are assumed to operate synchronously, so the discrete-time transfer function of the tank and the two data converters is from expression (100.87):

$$G(z) = \frac{\Theta(z)}{Q(z)} = \frac{\tau}{mc} \frac{1 - e^{-T/\tau}}{z - e^{-T/\tau}} \tag{100.93}$$

If a proportional control law is chosen, the transfer function associated with the control law is the gain $a_n = K$ or

$$D(z) = K \tag{100.94}$$

The closed-loop characteristic equation is from (100.90):

$$1 + \frac{K\tau}{mc} \frac{1 - e^{-T/\tau}}{z - e^{-T/\tau}} = 0 \tag{100.95}$$

If a common denominator is found, the resulting numerator is

$$z - e^{-T/\tau} + \frac{K\tau}{mc}(1 - e^{-T/\tau}) = 0 \tag{100.96}$$

The root of this equation is

$$z = e^{-T/\tau} + \frac{K\tau}{mc}(e^{-T/\tau} - 1) \tag{100.97}$$

If this root location is investigated as the gain parameter K is varied upward from zero, it is seen that the root starts at $z = e^{-T/\tau}$ for $K = 0$ and moves to the left along the real axis as K increases. Initially it is seen that the system becomes faster, but at some point the responses become damped and oscillatory, and as K is further increased the oscillatory tendency becomes less damped, and finally a value of K is reached where the oscillations are sustained at constant amplitude. A further increase in K will yield oscillations that increase with time. Typical unit step responses for $r(k) = 1$ and $T/\tau = 0.2$ are shown in Fig. 100.40.

It is easy to observe this tendency toward oscillation as K increases, but a problem that is clear from Fig. 100.40 is that in the steady state there is a persistent error between the response and the reference $[r(k) = 1]$. Increasing the gain K will make this error smaller at the expense of more oscillations. As a remedy for this steady-state error problem and control of the dynamics, a control law transfer function $D(z)$ will be sought that inserts integrator action into the loop while simultaneously canceling the pole of the plant. This dictates that the controller have a transfer function of the form

$$D(z) = \frac{U(z)}{E(z)} = \frac{K(z - e^{-T/\tau})}{z - 1} \tag{100.98}$$

Typical unit step responses are illustrated in Fig. 100.41 for several values of the gain parameter. The control law that must be programmed in the digital processor is

$$u(kT) = u((k-1)T) + K[e(kT) - e^{-T/\tau}e((k-1)T)] \tag{100.99}$$

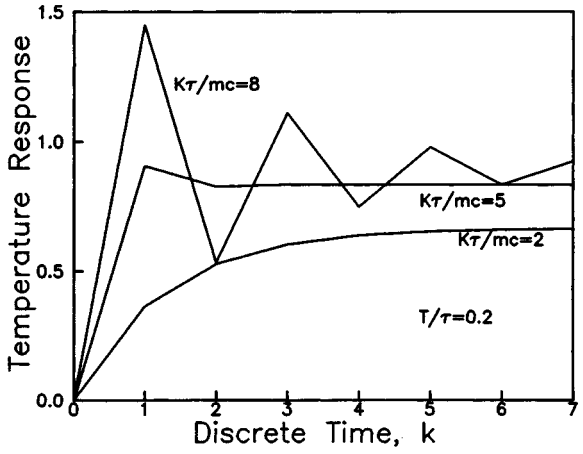

FIGURE 100.40 Step responses of proportionally controlled thermal mixing tank.

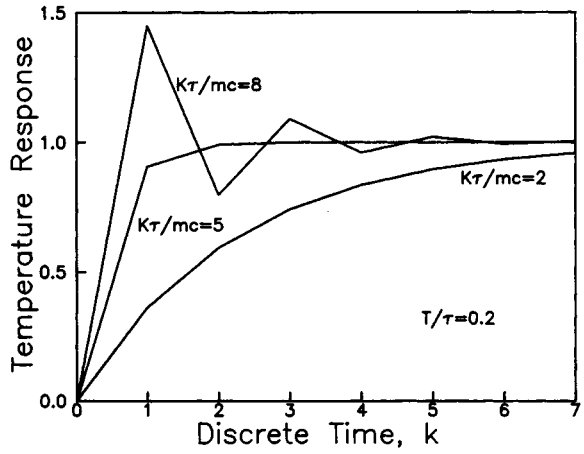

FIGURE 100.41 Step responses of the compensated thermal mixing tank.

The additional effort to program this over that required to program the proportional control law of (100.94) is easily justified since K and $e^{-T/\tau}$ are simply constants.

Defining Terms

Digital computer: A collection of digital devices including an arithmetic logic unit (ALU), read-only memory (ROM), random-access memory (RAM), and control and interface hardware.

Feedback control: The regulation of a response variable of a system in a desired manner using measurements of that variable in the generation of the strategy of manipulation of the controlling variables.

100.7 Nonlinear Control Systems[3]

Derek P. Atherton

The Describing Function Method

The describing function method, abbreviated as DF, was developed in several countries in the 1940s [Atherton, 1982], to answer the question: "What are the necessary and sufficient conditions for the nonlinear feedback system of Fig. 100.42 to be stable?" The problem still remains unanswered for a system with static nonlinearity, $n(x)$, and linear plant $G(s)$. All of the original investigators found limit cycles in control systems and observed that, in many instances with structures such as Fig. 100.42, the wave form of the oscillation at the input to the nonlinearity was almost sinusoidal. If, for example, the nonlinearity in Fig. 100.42 is an ideal relay, that is has an on-off characteristic, so that an odd symmetrical input wave form will produce a square wave at its output, the output of $G(s)$ will be almost sinusoidal when $G(s)$ is a low pass filter which attenuates the higher harmonics in the square wave much more than the fundamental. It was, therefore, proposed that the nonlinearity should be represented by its gain to a sinusoid and that the conditions for sustaining a sinusoidal limit cycle be evaluated to assess the stability of the feedback loop. Because of the nonlinearity, this gain in response to a sinusoid is a function of the amplitude of the sinusoid and is known as the describing function. Because describing function methods can be used other than for a single sinusoidal input, the technique is referred to as the single sinusoidal DF or sinusoidal DF.

The Sinusoidal Describing Function

For the reasons explained above, if we assume in Fig. 100.42 that $x(t) = a \cos \theta$, where $\theta = \omega t$ and $n(x)$ is a symmetrical odd nonlinearity, then the output $y(t)$ will be given by the Fourier series,

$$y(\theta) = \sum_{n=0}^{\infty} a_n \cos n\theta + b_n \sin n\theta, \tag{100.100}$$

$$\text{where } a_0 = 0, \tag{100.101}$$

[3]The material in this section was previously published by CRC Press in *The Control Handbook,* William S. Levine, Ed., 1996.

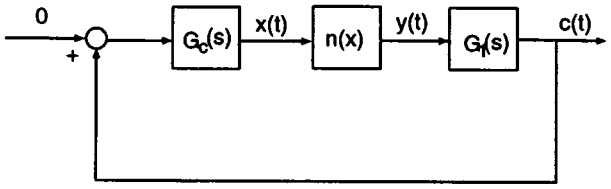

FIGURE 100.42 Block diagram of a nonlinear system.

$$a_1 = (1/\pi)\int_0^{2\pi} y(\theta)\cos\theta d\theta, \tag{100.102}$$

and

$$b_1 = (1/\pi)\int_0^{2\pi} y(\theta)\sin\theta d\theta. \tag{100.103}$$

The fundamental output from the nonlinearity is $a_1 \cos\theta + b_1 \sin\theta$, so that the describing function, DF, defined as the fundamental output divided by the input amplitude, is complex and given by

$$N(a) = (a_1 - jb_1)/a \tag{100.104}$$

which may be written

$$N(a) = N_p(a) + jN_q(a) \tag{100.105}$$

where

$$N_p(a) = a_1/a \text{ and } N_q(a) = -b_1/a\,. \tag{100.106}$$

Alternatively, in polar coordinates,

$$N(a) = M(a)e^{j\Psi(a)} \tag{100.107}$$

where

$$M(a) = \left(a_1^2 + b_1^2\right)^{1/2}/a$$

and

$$\Psi(a) = -\tan^{-1}(b_1/a_1). \tag{100.108}$$

If $n(x)$ is single valued, then $b_1 = 0$ and

$$a_1 = (4/\pi)\int_0^{\pi/2} y(\theta)\cos\theta d\theta \tag{100.109}$$

giving

$$N(a) = a_1/a = (4/a\pi)\int_0^{\pi/2} y(\theta)\cos\theta d\theta \tag{100.110}$$

Although Eqs. (100.102) and (100.103) are an obvious approach to evaluating the fundamental output of a nonlinearity, they are indirect, because one must first determine the output wave form $y(\theta)$ from the known nonlinear characteristic and sinusoidal input wave form. This is avoided if the substitution $\theta = \cos^{-1}(x/a)$ is made. After some simple manipulations,

$$a_1 = (4/a)\int_0^a x n_p(x) p(x) dx \tag{100.111}$$

and

$$b_1 = (4/a\pi)\int_0^a n_q(x) dx. \tag{100.112}$$

The function $p(x)$ is the amplitude probability density function of the input sinusoidal signal given by

$$p(x) = (1/\pi)(a^2 - x^2)^{-1/2}. \tag{100.113}$$

The nonlinear characteristics $n_p(x)$ and $n_q(x)$, called the inphase and quadrature nonlinearities, are defined by

$$n_p(x) = [n_1(x) + n_2(x)]/2 \tag{100.114}$$

and

$$n_q(x) = [n_2(x) - n_1(x)]/2 \tag{100.115}$$

where $n_1(x)$ and $n_2(x)$ are the portions of a double-valued characteristic traversed by the input for $\dot{x} > 0$ and $\dot{x} < 0$, respectively, When the nonlinear characteristic is single-valued, $n_1(x) = n_2(x)$, so $n_p(x) = n(x)$ and $n_q(x) = 0$. Integrating Eq. (100.111) by parts yields

$$a_1 = (4/\pi)n(0^+) + (4/a\pi)\int_0^a n'(x)(a^2 - x^2)^{1/2} dx \tag{100.116}$$

where $n'(x) = dn(x)/dx$ and $n(0^+) = \lim_{\epsilon\to\infty} n(\epsilon)$, a useful alternative expression for evaluating a_1.

An additional advantage of using Eqs. (100.111) and (100.112) is that they yield proofs of some properties of the DF for symmetrical odd nonlinearities. These include the following:

1. For a double-valued nonlinearity, the quadrature component $N_q(a)$ is proportional to the area of the nonlinearity loop, that is,

$$N_q(a) = -(1/a^2\pi)(\text{area of nonlinearity loop}) \tag{100.117}$$

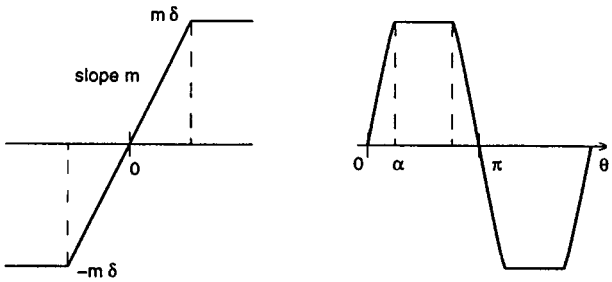

FIGURE 100.43 Saturation nonlinearity.

2. For two single-valued nonlinearities $n_\alpha(x)$ and $n_\beta(x)$, with $n_\alpha(x) < n_\beta(x)$ for all $0 < x < b$, $N_\alpha(a) < N_\beta(a)$ for input amplitudes less than b.
3. For a single-valued nonlinearity with $k_1 x < n(x) < k_2 x$ for all $0 < x < b$, $k_1 < N(a) < k_2$ for input amplitudes less than b. This is the sector property of the DF; a similar result can be obtained for a double-valued nonlinearity [Cook, 1973].

When the nonlinearity is single valued, from the properties of Fourier series, the DF, $N(a)$, may also be defined as:

1. the variable gain, K, having the same sinusoidal input as the nonlinearity, which minimizes the mean squared value of the error between the output from the nonlinearity and that from the variable gain, and
2. the covariance of the input sinusoid and the nonlinearity output divided by the variance of the input.

Evaluation of the Describing Function

To illustrate the evaluation of the DF two simple examples are considered.

Saturation Nonlinearity

To calculate the DF, the input can alternatively be taken as $a \sin \theta$. For an ideal saturation characteristic, the nonlinearity output wave form $y(\theta)$ is as shown in Fig. 100.43. Because of the symmetry of the nonlinearity, the fundamental of the output can be evaluated from the integral over a quarter period so that

$$N(a) = \frac{4}{a\pi} \int_0^{\pi/2} y(\theta) \sin \theta d\theta,$$

which, for $a > \delta$, gives

$$N(a) = \frac{4}{a\pi} \left[\int_0^{\alpha} ma \sin^2 \theta d\theta + \int_{\alpha}^{\pi/2} m\delta \sin \theta d\theta \right]$$

where $a = \sin^{-1} \delta/a$. Evaluation of the integrals gives

$$N(a) = (4m/\pi) \left[\frac{\alpha}{2} - \frac{\sin 2\alpha}{4} + \delta \cos \alpha \right]$$

which, on substituting for δ, give the result

$$N(a) = (m/\pi)(2\alpha + \sin 2\alpha). \tag{100.118}$$

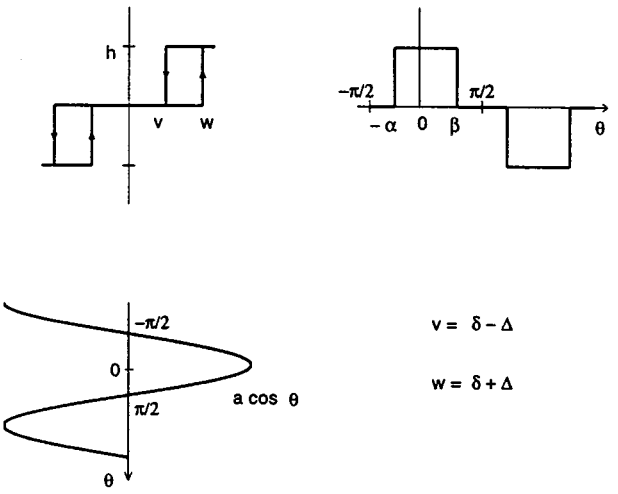

FIGURE 100.44 Relay with dead zone and hysteresis.

Because, for $a < \delta$, the characteristic is linear giving $N(a) = m$, the DF for ideal saturation is $mN_s(\delta/a)$ where

$$N_s(\delta/a) = \begin{cases} 1, & \text{for } a < \delta, \text{ and} \\ (1/\pi)[2\alpha + \sin 2\alpha], & \text{for } a > \delta, \end{cases} \tag{100.119}$$

where $a = \sin^{-1} \delta/a$.

Alternatively, one can evaluate $N(a)$ from Eq. (100.116), yielding

$$N(a) = a_1/a = (4/a^2\,\pi)\int_0^{\delta} m(a^2 - x^2)^{1/2}\,dx.$$

Using the substitution $x = a \sin \theta$,

$$N(a) = (4m/\pi)\int_0^{\alpha} \cos^2 \theta\, d\theta = (m/\pi)(2\alpha + \sin 2\alpha)$$

as before.

Relay with Dead Zone and Hysteresis

The characteristic is shown in Fig. 100.44 together with the corresponding input, assumed equal to $a \cos \theta$, and the corresponding output wave form. Using Eqs. (100.102) and (100.103) over the interval $-\pi/2$ to $\pi/2$ and assuming that the input amplitude a is greater than $\delta + \Delta$,

$$\begin{aligned} a_1 &= \left(2/\pi \int_{-\alpha}^{\beta} h \cos \theta\, d\theta\right) \\ &= (2h/\pi)(\sin \beta + \sin \alpha), \end{aligned}$$

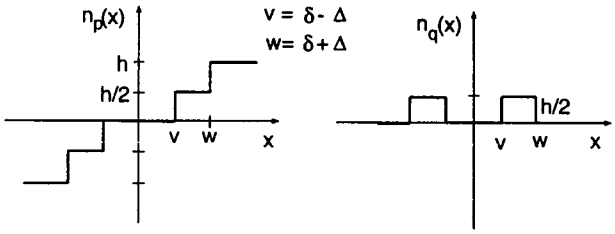

FIGURE 100.45 Function $n_p(x)$ and $n_q(x)$ for the relay of Figure 100.44.

$$\text{where } \alpha = \cos^{-1}\left[(\delta - \Delta)/a\right] \text{ and } \beta = \cos^{-1}\left[(\delta + \Delta)/a\right], \text{ and}$$

$$b_1 = (2/\pi)\int_{-\alpha}^{\beta} h \sin\theta d\theta$$

$$= (-2h/\pi)\left(\frac{(\delta + \Delta)}{a} - \frac{\delta - \Delta}{a}\right) = 4h\Delta/a\pi\,.$$

Thus

$$N(a) = \frac{2h}{a^2\pi}\left\{\left[a^2 - (\delta + \Delta)^2\right]^{1/2} + \left[a^2 - (\delta - \Delta)^2\right]^{1/2}\right\} - \frac{j4h\Delta}{a^2\pi}. \quad (100.120)$$

For the alternative approach, one must first obtain the in-phase and quadrature nonlinearities shown in Fig. 100.45. Using Eqs. (100.111) and (100.112),

$$a_1 = (4/a)\int_{\delta-\Delta}^{\delta+\Delta} x(h/2)p(x)dx + \int_{\delta+\Delta}^{a} xhp(x)dx,$$

$$= \frac{2h}{a\pi}\left\{\left[a^2 - (\delta + \Delta)^2\right]^{1/2} + \left[a^2 - (\delta - \Delta)^2\right]^{1/2}\right\},$$

and

$$b_1 = (4/a\pi)\int_{d-\Delta}^{\delta+\Delta}(h/2\,dx) = 4h\Delta/a\pi$$

$$= (\text{Area of nonlinearity loop})/a\pi$$

as before.

The DF of two nonlinearities in parallel equals the sum of their individual DFs, a result very useful for determining DFs, particularly of linear segmented characteristics with multiple break points. Several procedures [Altherton, 1982] are available for approximating the DF of a given nonlinearity either by numerical integration or by evaluating the DF of an approximating nonlinear characteristic defined, for example, by a quantized characteristic, linear segmented characteristic, or Fourier series. Table 100.3 gives a list of DFs for some commonly used approximations of nonlinear elements. Several of the results are in terms of the DF for an ideal saturation characteristic of unit slope, $N_s(\delta/a)$, defined in Eq. (100.119).

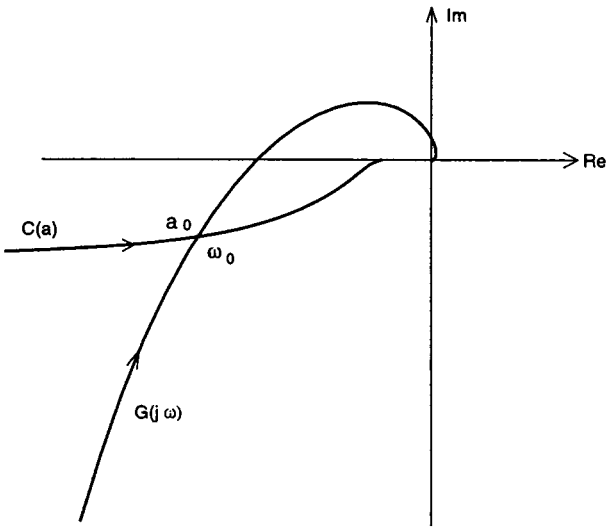

FIGURE 100.46 Nyquist plot showing solution for a limit cycle.

Limit Cycles and Stability

To investigate the possibility of limit cycles in the autonomous closed loop system of Fig. 100.42, the input to the nonlinearity $n(x)$ is assumed to be a sinusoid so that it can be replaced by the amplitude-dependent DF gain $N(a)$. The open loop gain to a sinusoid is thus $N(a)G(j\omega)$ and, therefore, a limit cycle exists if

$$N(a)G(j\omega) = -1 \tag{100.121}$$

where $G(j\omega) = G_c(j\omega)G_1(j\omega)$. As in general, $G(j\omega)$ is a complex function of ω and $N(a)$ is a complex function of a, solving Eq. (100.121) will yield both the frequency ω and amplitude a of a possible limit cycle.

A common procedure to examine solutions of Eq. (100.120) is to use a Nyquist diagram, where the $G(j\omega)$ and $C(a) = -1/N(a)$ loci are plotted as in Fig. 100.46, where they are shown intersecting for $a = a_0$ and $\omega = \omega_0$. The DF method indicates therefore that the system has a limit cycle with the input sinusoid to the nonlinearity, x, equal to $a_0 \sin(\omega_0 t + \phi)$, where ϕ depends on the initial conditions. When the $G(j\omega)$ and $C(a)$ loci do not intersect, the DF method predicts that no limit cycle will exist if the Nyquist stability criterion is satisfied for $G(j\omega)$ with respect to any point on the $C(a)$ locus. Obviously, if the nonlinearity has unit gain for small inputs, the point $(-1, j0)$ will lie on $C(a)$ and may be used as the critical point, analogous to a linear system.

For a stable case, it is possible to use the gain and phase margin to judge the relative stability of the system. However, a gain and phase margin can be found for every amplitude a on the $C(a)$ locus, so it is usually appropriate to use the minimum values of the quantities [Atherton, 1982]. When the nonlinear block includes dynamics so that its response is both amplitude and frequency dependent, that is $N(a, \omega)$, then a limit cycle will exist if

$$G(j\omega) = -1/N(a, \omega) = C(a, \omega). \tag{100.122}$$

To check for possible solutions of this equation, a family of $C(a, \omega)$ loci, usually as functions of a for fixed values of ω, is drawn on the Nyquist diagram.

An additional point of interest is whether when a solution to Eq. (100.120) exists the predicted limit cycle is stable. When there is only one intersection point, the stability of the limit cycle can be found using the Loeb criterion which states that if the Nyquist stability criterion indicates instability (stability) for the point on $C(a)$ with $a < a_0$ and stability (instability) for the point on $C(a)$ with $a > a_0$ the limit cycle is stable (unstable).

When multiple solutions exist, the situation is more complicated and the criterion above is a necessary but not sufficient result for the stability of the limit cycle [Choudhury and Atherton, 1974].

Normally in these cases, the stability of the limit cycle can be ascertained by examining the roots of the characteristic equation

$$1 + N_{i\gamma}(a)G(s) = 0 \tag{100.123}$$

where $N_{iy}(a)$ is known as the incremental describing function (IDF). $N_{iy}(a)$ for a single valued nonlinearity can be evaluated from

$$N_{i\gamma}(a) = \int_{-a}^{a} n'(x)p(x)dx \tag{100.124}$$

where $n'(x)$ and $p(x)$ are as previously defined. $N_{i\gamma}(a)$ is related to $N(a)$ by the equation

$$N_{i\gamma}(a) = N(a) + (a/2)\,dN(a)/da\,. \tag{100.125}$$

Thus, for example, for an ideal relay, making $\delta = \Delta = 0$ in Eq. (100.120) gives $N(a) = 4h/a\pi$, also found directly from Eq. (100.116), and, substituting this value in Eq. (100.125) yields $N_{i\gamma}(a) = 2h/a\pi$. Some examples of feedback system analysis using the DF follow.

Autotuning in Process Control

In 1943 Ziegler and Nichols [1943] suggested a technique for tuning the parameters of a PID controller. Their method was based on testing the plant in a closed loop with the PID controller in the proportional mode. The proportional gain was increased until the loop started to oscillate and then the value of gain and the oscillation frequency were measured. Formulae were given for setting the controller parameters based on the gain named the critical gain, K_c, and the frequency called the critical frequency, ω_c.

Assuming that the plant has a linear transfer function $G_1(s)$, then K_c is its gain margin and ω_c the frequency at which its phase shift is 180°. Performing this test in practice may prove difficult. If the plant has a linear transfer function and the gain is adjusted too quickly, a large amplitude oscillation may start to build up. In 1984 Astrom and Hagglund [1984] suggested replacing the proportional control by a relay element to control the amplitude of the oscillation. Consider therefore the feedback loop of Fig. 100.42 with $n(x)$ an ideal relay, $G_c(s) = 1$, and the plant with a transfer function $G_1(s) = 10/(s + 1)^3$. The $C(a)$ locus, $-1/N(a) = -a\pi/4h$, and the Nyquist locus $G(j\omega)$ in Fig. 100.47 intersect. The values of a and ω at the intersection can be calculated from

$$-a\pi/4h = \frac{10}{(1 + j\omega)^3} \tag{100.126}$$

which can be written

$$\text{Arg}\left(\frac{10}{(1 + j\omega)^3}\right) = 180°, \text{ and} \tag{100.127}$$

$$\frac{a\pi}{4h} = \frac{10}{(1 + \omega^2)^{3/2}}\,. \tag{100.128}$$

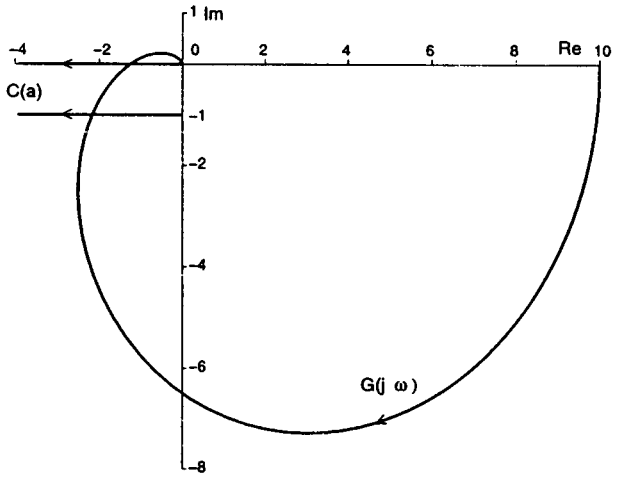

FIGURE 100.47 Nyquist plot $10/(s+1)^3$ and $C(a)$ loci for $\Delta = 0$ and $4h/\pi$.

The solution for ω_c from Eq. (100.127) is $\tan^{-1}\omega_c = 60°$, giving $\omega_c = \sqrt{3}$. Because the DF solution is approximate, the actual measured frequency of oscillation will differ from this value by an amount which will be smaller the closer the oscillation is to a sinusoid. The exact frequency of oscillation in this case will be 1.708 rads/sec in error by a relatively small amount. For a square wave input to the plant at this frequency, the plant output signal will be distorted by a small percentage. The distortion, *d*, is defined by

$$d = \left[\frac{\text{M.S. value of signal} \;-\; \text{M.S. value of fundamental harmonic}}{\text{M.S. value of fundamental harmonic}}\right]^{1/2} \tag{100.129}$$

Solving Eq. (100.128) gives the amplitude of oscillation a as $5h/\pi$. The gain through the relay is $N(a)$ equal to the critical gain K_c. In the practical situation where a is measured, K_c equal to $4h/a\pi$, should be close to the known value of 0.8 for this transfer function.

If the relay has an hysteresis of Δ, then with $\delta = 0$ in Eq. (100.120) gives

$$N(a) = \frac{4h\left(a^2 - \Delta^2\right)^{1/2}}{a^2\pi} - j\,\frac{4h\Delta}{a^2\pi}$$

from which

$$C(a) = \frac{-1}{N(a)} = \frac{-\pi}{4h}\left[\left(a^2 - \Delta^2\right)^{1/2} + j\Delta\right].$$

Thus on the Nyquist plot, $C(a)$ is a line parallel to the real axis at a distance $\pi\Delta/4h$ below it, as shown in Fig. 100.47 for $\Delta = 1$ and $h = \pi/4$ giving $C(a) = -(a^2 - 1)^{1/2} - j$. If the same transfer function is used for the plant, then the limit cycle solution is given by

$$-\left(a^2 - 1\right)^{1/2} - j = \frac{10}{\left(1 + j\omega\right)^3} \tag{100.130}$$

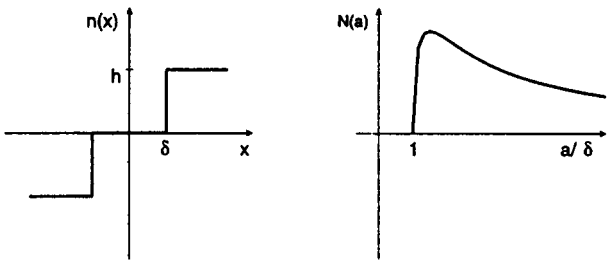

FIGURE 100.48 $N(a)$ for ideal relay with dead zone.

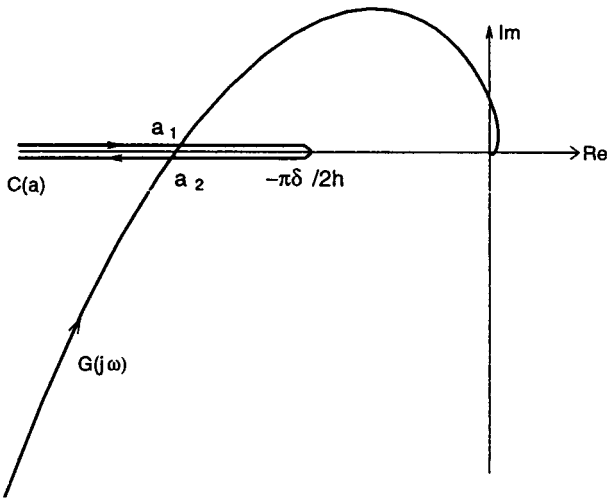

FIGURE 100.49 Two limit cycles: a_1, unstable; a_2, stable.

where $\omega = 1.266$, which compares with an exact solution value of 1.254, and $a = 1.91$. For the oscillation with the ideal relay, Eq. (100.123) with $N_{i\gamma}(a) = 2h/a\pi$ shows that the limit cycle is stable. This agrees with the perturbation approach which also shows that the limit cycle is stable when the relay has hysteresis.

Feedback Loop with a Relay with Dead Zone

For this example the feedback loop of Fig. 100.42 is considered with $n(x)$ a relay with dead zone and $G(s) = 2/s(s+1)^2$. From Equation 19.22 with $\Delta = 0$, the DF for this relay, given by

$$N(a) = 4h\left(a^2 - \delta^2\right)^{1/2} \Big/ a^2\pi \text{ for } a > \delta. \tag{100.131}$$

is real because the nonlinearity is single valued. A graph of $N(a)$ against a is in Fig. 100.48, and shows that $N(a)$ starts at zero, when $a = \delta$, increases to a maximum, with a value of $2h/\pi\delta$ at $a = \delta\sqrt{2}$, and then decreases toward zero for larger inputs. The $C(a)$ locus, shown in Fig. 100.49, lies on the negative real axis starting at $-\infty$ and returning there after reaching a maximum value of $-\pi\delta/2h$. The given transfer function $G(j\omega)$ crosses the negative real axis, as shown in Fig. 100.49, at a frequency of $\tan^{-1}\omega = 45°$, that, is $\omega = 1$ rad/sec and, therefore, cuts the $C(a)$ locus twice. The two possible limit cycle amplitudes at this frequency can be found by solving

$$\frac{a^2\pi}{4h\left(a^2 - \delta^2\right)^{1/2}} = 1$$

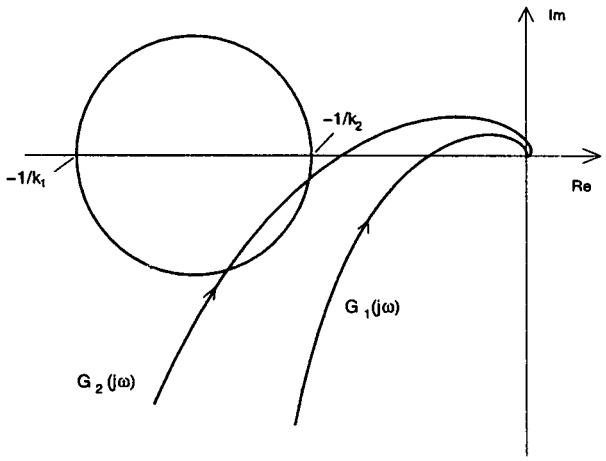

FIGURE 100.50 Circle criterion and stability.

which gives $a = 1.04$ and 3.86 for $\delta = 1$ and $h = \pi$. Using the perturbation method or the IDF criterion, the smallest amplitude limit cycle is unstable and the larger one is stable. If a condition similar to the lower amplitude limit cycle is excited in the system, an oscillation will build up and stabilize at the higher amplitude limit cycle.

Other techniques show that the exact frequencies of the limit cycles for the smaller and larger amplitudes are 0.709 and 0.989, respectively. Although the transfer function is a good low pass filter, the frequency of the smallest amplitude limit cycle is not predicted accurately because the output from the relay, a wave form with narrow pulses, is highly distorted.

If the transfer function of $G(s)$ is $K/s(s + 1)^2$, then no limit cycle will exist in the feedback loop, and it will be stable if

$$\left.\frac{K}{\omega\left(1 + \omega^2\right)}\right|_{\omega=1} < \frac{\pi d}{2h},$$

that is, $K < \pi\delta/h$. If $\delta = 1$ and $h = \pi$, $K < 1$ which may be compared with the exact result for stability of $K < 0.96$.

Stability and Accuracy

Because the DF method is an approximate procedure, it is desirable to judge its accuracy. Predicting that a system will be stable, when in practice it is not, may have unfortunate consequences. Many attempts have been made to solve this problem, but those obtained are difficult to apply or produce too conservative results [Mess and Bergen, 1975].

The problem is illustrated by the system of Fig. 100.42 with a symmetrical odd single-valued nonlinearity confined to a sector between lines of slope k_1 and k_2, that is, $k_1x < n(x) < k_2x$ for $x > 0$. For absolute stability, the circle criterion requires satisfying the Nyquist criterion for the locus $G(j\omega)$ for all points within a circle having its diameter on the negative real axis of the Nyquist diagram between the points $(-1/k_1, 0)$ and $(-1/k_2, 0)$, as shown in Fig. 100.50. On the other hand, because the DF for this nonlinearity lies within the diameter of the circle, the DF method requires satisfying the Nyquist criterion for $G(j\omega)$ for all points on the circle diameter, if the autonomous system is to be stable.

Therefore, for a limit cycle in the system of Fig. 100.42, errors in the DF method relate to its inability to predict a phase shift, which the fundamental harmonic may experience in passing through the nonlinearity, rather than an incorrect magnitude of the gain. When the input to a single-valued nonlinearity is a sinusoid together with some of its harmonics, the fundamental output is not necessarily in phase with the fundamental

input, that is, the fundamental gain has a phase shift. The actual phase shift varies with the harmonic content of the input signal in a complex manner, because the phase shift depends on the amplitudes and phases of the individual input components.

From an engineering viewpoint one can judge the accuracy of DF results by estimating the distortion, *d,* in the input to the nonlinearity. This is straightforward when a limit-cycle solution is given by the DF method; the loop may be considered opened at the nonlinearity input, the sinusoidal signal corresponding to the DF solution can be applied to the nonlinearity, and the harmonic content of the signal fed back to the nonlinearity input can be calculated. Experience indicates that the percentage accuracy of the DF method in predicting the fundamental amplitude and frequency of the limit cycle is less than the percentage distortion in the fedback signal. As mentioned previously, the DF method may incorrectly predict stability. To investigate this problem, the procedure above can be used again, by taking, as the nonlinearity input, a sinusoid with amplitude and frequency corresponding to values of those parameters where the phase margin is small. If the calculated fedback distortion is high, say greater than 2% per degree of phase margin, the DF result should not be relied on.

The limit-cycle amplitude predicted by the DF is an approximation to the fundamental harmonic. The accuracy of this prediction cannot be assessed by using the peak value of the limit cycle to estimate an equivalent sinusoid. It is possible to estimate the limit cycle more accurately by balancing more harmonics, as mentioned earlier. Although this is difficult algebraically other than with loops whose nonlinearity is mathematically simply described, for example a cubic, software is available for this purpose [McNamara and Atherton, 1987]. The procedure involves solving sets of nonlinear algebraic equations but good starting guesses can usually be obtained for the magnitudes and phases of the other harmonic components from the wave form fedback to the nonlinearity, assuming its input is the DF solution.

Compensator Design

Although the design specifications for a control system are often in terms of step-response behavior, frequency domain design methods rely on the premise that the correlation between the frequency and a step response yields a less oscillatory step response if the gain and phase margins are increased. Therefore the design of a suitable linear compensator for the system of Fig. 100.42 using the DF method, is usually done by selecting for example a lead network to provide adequate gain and phase margins for all amplitudes. This approach may be used in example 2 of the previous section where a phase lead network could be added to stabilize the system, say for a gain of 1.5, for which it is unstable without compensation. Other approaches are the use of additional feedback signals or modification of the nonlinearity $n(x)$ directly or indirectly [Atherton, 1982; Gelb and van der Velde, 1968].

When the plant is nonlinear, its frequency response also depends on the input sinusoidal amplitude represented as $G(j\omega, a)$. In recent years several approaches [Nanka-Bruce and Atherton, 1990; Taylor and Strobel, 1984] use the DF method to design a nonlinear compensator for the plant, with the objective of closed-loop performance independent of the input amplitude.

Closed-Loop Frequency Response

When the closed-loop system of Fig. 100.42 has a sinusoidal input $r(t) = R\sin(\omega t + \theta)$, it is possible to evaluate the closed-loop frequency response using the DF. If the feedback loop has no limit cycle when $r(t) = 0$ and, in addition, the sinusoidal input $r(t)$ does not induce a limit cycle, then, provided that $G_c(s)G_1(s)$ gives good filtering, $x(t)$, the nonlinearity input, almost equals the sinusoid $a \sin \omega t$. Balancing the components of frequency ω around the loop,

$$\begin{aligned} &g_c R \sin\left(\omega t + \theta - \phi_c\right) - a g_1 g_c M(a) \\ &\sin\left[\omega t + \phi_1 + \phi_c + \psi(a)\right] = a \sin \omega t \end{aligned} \tag{100.132}$$

where $G_c(j\omega) = g_c e^{j\phi_c}$ and $G_1(j\omega) = g_1 e^{j\phi_1}$. In principle Eq. (100.132), which can be written as two nonlinear algebraic equations, can be solved for the two unknowns a and θ and the fundamental output signal can then be found from

$$c(t) = aM(a)g_1 \sin\left[\omega t + \psi(a) + \phi_1\right] \tag{100.133}$$

to obtain the closed-loop frequency for R and ω.

Various graphical procedures have been proposed for solving the two nonlinear algebraic equations resulting from Eq. (100.132) [Levinson, 1953; Singh, 1965; West and Douce, 1954]. If the system is lightly damped, the nonlinear equations may have more than one solution, indicating that the frequency response of the system has a jump resonance. This phenomenon of a nonlinear system has been studied by many authors, both theoretically and practically [Lamba and Kavanagh, 1971; West et al., 1954].

The Phase Plane Method

The phase plane method was the first method used by control engineers for studying the effects of nonlinearity in feedback systems. The technique which can only be used for systems with second order models was examined and further developed for control engineering purposes for several major reasons,

1. The phase plane approach has been used for several studies of second order nonlinear differential equations arising in fields such as planetary motion, nonlinear mechanics and oscillations in vacuum tube circuits.
2. Many of the control systems of interest, such as servomechanisms, could be approximated by second order nonlinear differential equations.
3. The phase plane was particularly appropriate for dealing with nonlinearities with linear segmented characteristics which were good approximations for the nonlinear phenomena encountered in control systems.

The next section considers the basic aspects of the phase plane approach but later concentration is focused on control engineering applications where the nonlinear effects are approximated by linear segmented nonlinearities.

Background

Early analytical work [Andronov et al., 1966], on second order models assumed the equations

$$\begin{aligned} \dot{x}_1 &= P(x_1, x_2) \\ \dot{x}_2 &= Q(x_1, x_2) \end{aligned} \tag{100.134}$$

for two first-order nonlinear differential equations. Equilibrium, or singular points, occur when

$$\dot{x}_1 = \dot{x}_2 = 0$$

and the slope of any solution curve, or trajectory, in the $x_1 - x_2$ state plane is

$$\frac{dx_2}{dx_1} = \frac{\dot{x}_2}{\dot{x}_1} = \frac{Q(x_1, x_2)}{P(x_1, x_2)} \tag{100.135}$$

A second order nonlinear differential equation representing a control system can be written

$$\ddot{x} + f(x, \dot{x}) = 0 \tag{100.136}$$

If this is rearranged as two first-order equations, choosing the phase variables as the state variables, that is $x_1 = x$, $x_2 = \dot{x}$, then Eq. (100.136) can be written as

$$\dot{x}_1 = \dot{x}_2 \qquad \dot{x}_2 = -f(x_1, x_2) \tag{100.137}$$

which is a special case of Eq. (100.135). A variety of procedures has been proposed for sketching state [phase] plane trajectories for Eqs. (100.135) and (100.137). A complete plot showing trajectory motions throughout the entire state (phase) plane is known as a state (phase) portrait. Knowledge of these methods, despite the improvements in computation since they were originally proposed, can be particularly helpful for obtaining an appreciation of the system behavior. When simulation studies are undertaken, phase plane graphs are easily obtained and they are often more helpful for understanding the system behavior than displays of the variables x_1 and x_2 against time.

Many investigations using the phase plane technique were concerned with the possibility of limit cycles in the nonlinear differential equations When a limit cycle exists, this results in a closed trajectory in the phase plane. Typical of such investigations was the work of Van der Pol, who considered the equation

$$\ddot{x} - \mu(1 - x^2)\dot{x} + x = 0 \tag{100.138}$$

where μ is a positive constant. The phase plane form of this equation can be written as

$$\begin{aligned} \dot{x}_1 &= x_2 \\ \dot{x}_2 &= -f(x_1, x_2) = \mu(1 - x_1^2)x_2 - x_1 \end{aligned} \tag{100.139}$$

The slope of a trajectory in the phase plane is

$$\frac{dx_2}{dx_1} = \frac{\dot{x}_2}{\dot{x}_1} = \frac{\mu(1 - x_1^2)x_2 - x_1}{x_2} \tag{100.140}$$

and this is only singular (that is, at an equilibrium point), when the right hand side of Eq. (100.140) is 0/0, that is $x_1 = x_2 = 0$.

The form of this singular point which is obtained from linearization of the equation at the origin depends upon μ, being an unstable focus for $\mu < 2$ and an unstable node for $\mu > 2$. All phase plane trajectories have a slope of r when they intersect the curve

$$rx_2 = \mu(1 - x_1^2)x_2 - x_1 \tag{100.141}$$

One way of sketching phase plane behavior is to draw a set of curves given for various values of r by Eq. (100.141) and marking the trajectory slope r on the curves. This procedure is known as the method of isoclines and has been used to obtain the limit cycles shown in Fig. 100.51 for the Van der Pol equation with $\mu = 0.2$ and 4.

Piecewise Linear Characteristics

When the nonlinear elements occurring in a second order model can be approximated by linear segmented characteristics then the phase plane approach is usually easy to use because the nonlinearities divide the phase

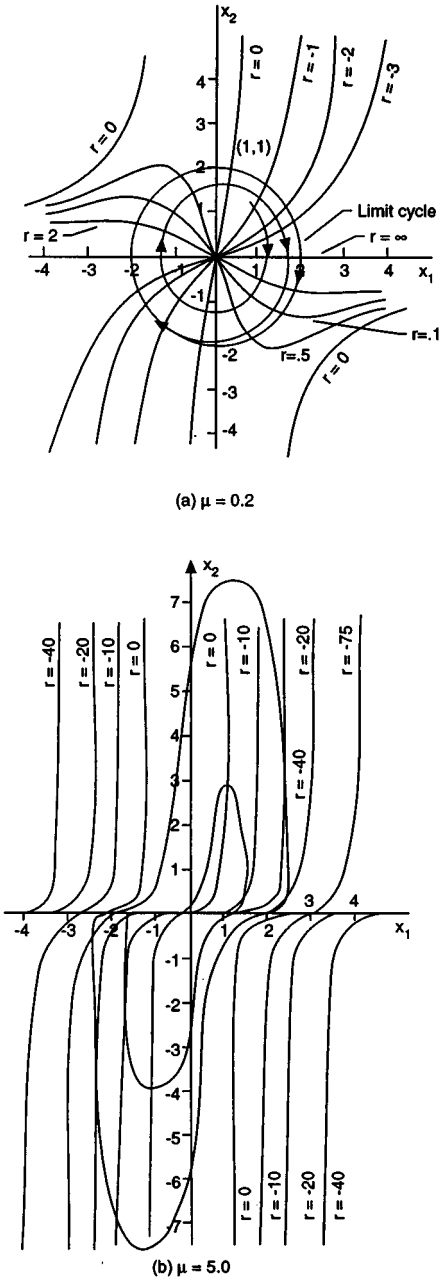

FIGURE 100.51 Phase portraits of the Van der Pol equation for different values, of μ.

plane into various regions within which the motion may be described by different linear second-order equations [Atherton, 1982]. The procedure is illustrated by the simple relay system in Fig. 100.52.

The block diagram represents an "ideal" relay position control system with velocity feedback. The plant is a double integrator, ignoring viscous (linear) friction, hysteresis in the relay, or backlash in the gearing. If the system output is denoted by x_1 and its derivative by x_2, then the relay switches when $-x_1 - x_2 = \pm 1$; the equations of the dotted lines are marked switching lines on Fig. 100.53.

Because the relay output provides constant values of ±2 and 0 to the double integrator plant, if we denote the constant value by *h*, then the state equations for the motion are

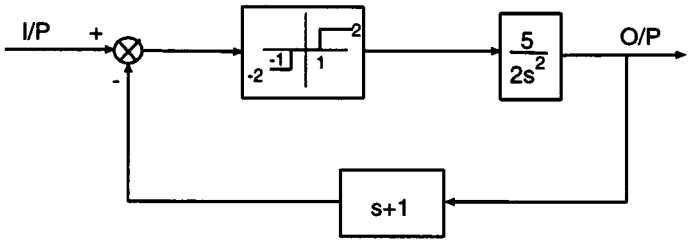

FIGURE 100.52 Relay system.

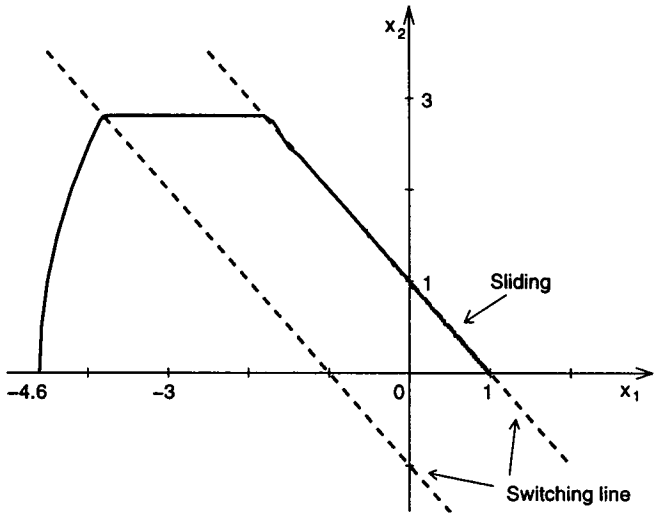

FIGURE 100.53 Phase plane for relay system.

$$\begin{aligned} \dot{x}_1 &= x_2 \\ \dot{x}_2 &= h \end{aligned} \tag{100.142}$$

which can be solved to give the phase plane equation

$$x_2^2 - x_{20}^2 = 2h\left(x_1 - x_{10}\right) \tag{100.143}$$

which is a parabola for h finite and the straight line $x_2 = x_{20}$ for $h = 0$, where x_{20} and x_{10} are the initial values of x_2 and x_1. Similarly, more complex equations can be derived for other second-order transfer functions. Using Eq. (100.143) with the appropriate values of h for the three regions in the phase plane, the step response for an input of 4.6 units can be obtained as shown in Fig. 100.53.

In the step response, when the trajectory meets the switching line $x_1 + x_2 = -1$ for the second time, trajectory motions at both sides of the line are directed towards it, resulting in a sliding motion down the switching line. Completing the phase portrait by drawing responses from other initial conditions shows that the autonomous system is stable and also that all responses will finally slide down a switching line to equilibrium at $x_1 = \pm 1$.

An advantage of the phase plane method is that it can be used for systems with more than one nonlinearity and for those situations where parameters change as functions of the phase variables. For example, Fig. 100.54 shows the block diagram of an approximate model of a servomechanism with nonlinear effects due to torque saturation and Coulomb friction.

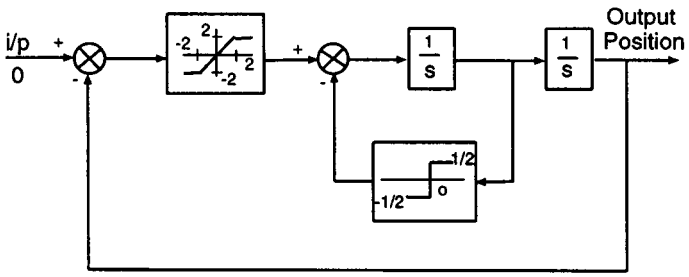

FIGURE 100.54 Block diagram of servomechanism.

The differential equation of motion in phase variable form is

$$\dot{x}_2 = f_s(-x_1) - (1/2)\,\mathrm{sgn}\,x_2 \tag{100.144}$$

where f_s denotes the saturation nonlinearity and sgn the signum function, which is +1 for $x_2 > 0$ and –1 for $x_2 < 0$. There are six linear differential equations describing the motion in different regions of the phase plane. For x_2 positive, Eq. (100.144) can be written

$$\dot{x}_1 + f_s(x_1) + 1/2 = 0$$

so that for

(a) x_2+ve, $x_1 < -2$, we have $\dot{x}_1 = x_2$, $\dot{x}_2 = 3/2$, a parabola in the phase plane.
(b) x_2+ve$|x_1| < 2$, we have $\dot{x}_1 = x_2$, $\dot{x}_2 + x_1 + 1/2 = 0$.
(c) x_2+ve, $x_1 > 2$, we have $\dot{x}_1 = x_2$, $\dot{x}_2 = -5/2$, a parabola in the phase plane. Similarly for x_2 negative,
(d) x_2–ve, $x_1 - 2$, we have $\dot{x}_1 = x_2$, $\dot{x}_2 = -5/2$, a parabola in the phase plane.
(e) x_2–ve, $|x_2| < 2$, we have $\dot{x}_1 = x_2$, $\dot{x}_2 + x_1 - 1/2 = 0$, a circle in the phase plane.
(f) x_2–ve,$x_1 > 2$, we have $\dot{x}_1 = x_2$, $\dot{x}_2 = -3/2$, a parabola in the phase plane.

Because all the phase plane trajectories are described by simple mathematical expressions, it is straightforward to calculate specific phase plane trajectories.

Discussion

The phase plane approach is useful for understanding the effects of nonlinearity in second order systems, particularly if it may be approximated by a linear segmented characteristic. Solutions for the trajectories with other nonlinear characteristics may not be possible analytically so that approximate sketching techniques were used in early work on nonlinear control. These approaches are described in many books, for example, [Blaquiere, 1966; Cosgriff, 1958; Cunningham, 1958; Gibson, 1963; Graham and McRuer, 1961; Hayashi, 1964, Thaler and Pastel, 1962; West, 1960]. Although the trajectories are now easily obtained with modern simulation techniques, knowledge of the topological aspects of the phase plane are still useful for interpreting the responses in different regions of the phase plane and appreciating the system behavior.

Further Information

Many control engineering text books contain material on nonlinear systems where the describing function is discussed. The coverage, however, is usually restricted to the basic sinusoidal DF for determining limit cycles in feedback systems. The basic DF method, which is one of quasilinearisation, can be extended to cover other signals, such as random signals, and also to cover multiple input signals to nonlinearities and feedback system analysis. The two books with the most comprehensive coverage of this are Gelb and Van der Velde [1968] and Atherton [1975]. More specialized books on nonlinear feedback systems usually cover the phase plane method and the DF, together with other topics such as absolute stability, exact linearization, etc.

100.8 Optimal Control and Estimation

John S. Bay and William T. Baumann

Consider the closed-loop feedback control of linear time-invariant, multi-input/multi-output (MIMO) state-space systems of the form:

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t) \end{aligned} \tag{100.145}$$

In this form, the vector $x \in \Re^n$ represents the internal state, $u \in \Re^p$ represents the input, and $y \in \Re^q$ represents the measured outputs. It is well known that if the system in Eq. (100.145) is *stabilizable* (i.e., its unstable part is ***controllable***), then it can be asymptotically stabilized with static state feedback. If it is ***detectable*** (i.e., its unstable part is ***observable***), then a state estimator can be found, whose state variables asymptotically approach the true state variables in Eq. (100.145). However, merely determining the state feedback gain or observer gain leaves considerable design freedom for satisfying criteria other than stabilization and asymptotic observation. In this chapter section, we will provide results of some basic techniques of optimal control and estimation, which provide a mechanism to find *optimal* feedback and **observer (estimator)** gains according to selected optimality criteria.

Linear Quadratic Regulators

The linear quadratic regulator (LQR) problem is to find an *optimal* control input $u^*(t)$ that minimizes the performance criterion

$$J(x,u) = \tfrac{1}{2} x^{\mathrm{T}}(t_f) S x(t_f) + \tfrac{1}{2} \int_{t_o}^{t_f} \left[x(t) Q x(t) + u^{\mathrm{T}}(t) R u(t) \right] dt \tag{100.146}$$

where S and Q are symmetric, ***positive-semidefinite*** weighting matrices; and R is a symmetric, *positive-definite* weighting matrix. In this criterion, the term $\frac{1}{2}x^{\mathrm{T}}(t_f)Sx(t_f)$ represents a penalty for the state at the final time t_f being different from zero. The term inside the integral, $x^{\mathrm{T}}(t)Qx(t)$, represents a penalty on the transient response of the state vector. The term $u^{\mathrm{T}}(t)Ru(t)$ represents a penalty on the size of the control input $u(t)$. We allow S and Q to be positive-semidefinite because we can generally tolerate unbounded state variables, provided they are not observed at the output. However, by forcing R to be positive-definite, we can guarantee that the process of minimizing Eq. (100.146) gives a bounded input. Minimization of this control energy is one of the primary reasons for using optimal control.

The optimal control $u^*(t)$ can be found via a number of techniques, including dynamic programming [Bay, 1999] and variational techniques [Kirk, 1970]. The result of any of these methods is that the optimal control $u^*(t)$ is a linear function of the state vector (linear state feedback) of the form:

$$u^*(t) = -R^{-1}B^{\mathrm{T}}P(t)x(t) \tag{100.147}$$

where the $n \times n$ matrix function $P(t)$ satisfies the following equation:

$$\dot{P} = PBR^{-1}B^{\mathrm{T}}P - Q - PA - A^{\mathrm{T}}P \tag{100.148}$$

Equation (100.148) is known as the differential matrix Riccati equation, and it is solved in backward time, with the end-time condition $P(t_f) = S$.

It may be noted that a reasonable optimization criterion may have no finite final time t_f. Instead, it may be desired that the controller be continually active, implying $t_f \to \infty$ and eliminating the possibility of the final state term in Eq. (100.146). In this case, the optimization criterion is more properly written as

$$J(x,u) = \tfrac{1}{2}\int_{t_o}^{\infty}\left[x^{\mathrm{T}}(t)Qx(t) + u^{\mathrm{T}}(t)Ru(t)\right]dt \tag{100.149}$$

Fortunately, this criterion simplifies the optimal control solution to the steady-state solution of the finite-time problem. That is, for the criterion of Eq. (100.149), the optimal control is

$$u^{*}(t) = -R^{-1}B^{\mathrm{T}}Px(t) \tag{100.150}$$

where in this case P is the matrix solution to the following algebraic Riccati equation:

$$0 = PBR^{-1}B^{\mathrm{T}}P - Q - PA - A^{\mathrm{T}}P \tag{100.151}$$

Such a steady-state optimal solution exists whenever the system (A, B) is stabilizable. Furthermore, this constant P is the unique positive-definite solution of Eq. (100.151) if and only if the pair (A, T) is detectable, where T is defined as the square-root of Q, $Q = T^{\mathrm{T}}T$. **Stabilizability** of (A, B) ensures convergence of the cost criterion integral Eq. (100.149), and detectability of (A, T) guarantees that no unstable part of $x(t)$ escapes integration as part of the integrand of Eq. (100.149).

We should point out also that for the corresponding discrete-time system:

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k) \\ y(k) &= Cx(k) + Du(k) \end{aligned} \tag{100.152}$$

minimization of the cost criterion:

$$J = \tfrac{1}{2}\sum_{k=k_0}^{\infty}\left[x^{\mathrm{T}}(k)Qx(k) + u^{\mathrm{T}}(k)Ru(k)\right] \tag{100.153}$$

over all inputs $u(k)$ results in the optimal control

$$u^{*}(k) = -\left[R + B^{\mathrm{T}}SB\right]^{-1}B^{\mathrm{T}}SAx(k) \tag{100.154}$$

where S is the solution to the corresponding discrete-time algebraic Riccati equation:

$$S = A^{\mathrm{T}}SA - A^{\mathrm{T}}SB\left[R + B^{\mathrm{T}}SB\right]^{-1}B^{\mathrm{T}}SA + Q \tag{100.155}$$

Note that in both the continuous- and the discrete-time infinite-horizon cases, the optimal control is actually static state feedback of the form $u = Kx$.

Optimal Estimation: The Kalman Filter

It was noted above that the optimal controller for the linear quadratic cost criterion takes the form of full-state feedback. However, it is often the case that the full state is not physically available for feedback. Rather, it is usually the *output* that is measurable, so that we prefer a technique that uses $y(t)$ (and possibly $u(t)$) to construct the control signal instead of the state $x(t)$.

The simple solution to this problem is to design an ***observer (or estimator)***, which produces an *estimated* state vector $\hat{x}(t)$. If this estimate asymptotically approaches the true state $x(t)$, then we can simply combine the observer and the state feedback to produce a feedback control $u(t) = K\hat{x}(t)$. That we can simply substitute the observed value $\hat{x}(t)$ for $x(t)$ in the feedback function is a fortunate property called the separation principle, which ensures that our controller calculations and observer calculations do not interfere with one another.

Just as we have improved static state feedback by introducing the optimal LQR above, we can take the principles of observer design and extend them with some guarantees of optimality. Such an optimal estimator is the Kalman filter.

The Kalman filter is derived assuming the system model:

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) + Gv(t) \\ y(t) &= Cx(t) + w(t) \end{aligned} \tag{100.156}$$

where $v(t)$ and $w(t)$ are two white, Gaussian, zero-mean, mutually uncorrelated noise signals with $E[w(t)v^{\mathrm{T}}(\tau)] = 0$ and

$$E\left[v(t)\right] = 0, \quad E\left[v(t)v^{\mathrm{T}}(\tau)\right] = V\delta(t-\tau) \tag{100.157}$$

and

$$E\left[w(t)\right] = 0, \quad E\left[w(t)w^{\mathrm{T}}(\tau)\right] = W\delta(t-\tau) \tag{100.158}$$

where $\delta(t)$ is the Dirac delta. Noise $v(t)$ is called the *plant noise*, and $w(t)$ is the *measurement noise*, often representing sensor noise. (By assuming these signals are first passed through auxiliary filters with specified dynamics, these noises can be made to resemble harmonic or narrow-band disturbances.)

The goal is now to design a system that produces an estimated state $\hat{x}(t)$ for Eq. (100.156) while rejecting the influence of the signals $v(t)$ and $w(t)$. To do this, we need the further assumptions that the system's initial state is guessed to be $x(t_0) = x_0$ and that this guess is uncorrelated with the plant and measurement noise:

$$E\left[x_0 v^{\mathrm{T}}(\tau)\right] = 0 \qquad E\left[x_0 w^{\mathrm{T}}(\tau)\right] = 0 \tag{100.159}$$

The covariance of the initial guess is defined as

$$E\left\{\left[x_0 - E(x_0)\right]\left[x_0 - E(x_0)\right]^{\mathrm{T}}\right\} \triangleq P_0 \tag{100.160}$$

The Kalman filter is the system that performs this estimation, rejecting the influence of the noise. The filter itself is given by the equation:

$$\dot{\hat{x}}(t) = A\hat{x}(t) + Bu(t) + L(t)\left[y(t) - C\hat{x}(t)\right] \tag{100.161}$$

which can be seen to resemble the standard full-order observer [Bay, 1999]. However, rather than choosing an observer gain L in Eq. (100.161) to simply stabilize the error dynamics of the observer, the *Kalman gain* $L(t)$ is

$$L(t) = P(t)C^{\mathrm{T}}W^{-1} \tag{100.162}$$

where $P(t)$ is the solution to the following differential Riccati equation:

$$\dot{P}(t) = AP(t) + P(t)A^{\mathrm{T}} - P(t)C^{\mathrm{T}}W^{-1}CP(t) + GVG^{\mathrm{T}} \tag{100.163}$$

whose initial condition is $P(t_0) = P_0$.

For the discrete-time system

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k) + Gv(k) \\ y(k) &= Cx(k) + w(k) \end{aligned} \tag{100.164}$$

with assumptions analogous to Eq. (100.157) through (100.158) for plant noise $v(k)$ and measurement noise $w(t)$, and with $E[(x_0 - E(x_0)(x_0 - E(x_0))^{\mathrm{T}}] \triangleq S_0$, the Kalman filter is given by the two-stage estimator

$$\bar{x}(k+1) = A\hat{x}(k) + Bu(k) \tag{100.165}$$

$$\hat{x}(k+1) = \bar{x}(k+1) + L(k+1)\left[y(k+1) - C\bar{x}(k+1)\right] \tag{100.166}$$

where the Kalman gain $L(k+1)$ is computed from the equation

$$L(k+1) = \left[AS(k)A^{\mathrm{T}} + GVG^{\mathrm{T}}\right]C^{\mathrm{T}}\left\{C\left[AS(k)A^{\mathrm{T}} + GVG^{\mathrm{T}}\right]C^{T} + W\right\}^{-1} \tag{100.167}$$

In Eq. (100.167), the term $S(k)$ is determined from the Riccati equation:

$$\begin{aligned} S(k+1) = &\left[I - L(k+1)C\right]\left[AS(k)A^{\mathrm{T}} + GVG^{\mathrm{T}}\right]\left[I - L(k+1)C\right]^{\mathrm{T}} \\ &+ L(k+1)WL^{\mathrm{T}}(k+1) \end{aligned} \tag{100.168}$$

with initial condition $S(k_0) = S_0$. (Note that these equations can be combined and rearranged to produce a number of alternate formulations.)

Equation (100.165) is often referred to as the *time update* equation. It represents the estimate of the state vector that results from knowledge of the system dynamics. Equation (100.166) is sometimes called the *measurement* update equation because it revises the time update with a so-called *innovations* term $L(y - \bar{y})$ that adjusts this time update according to the error between the output expected from the time update, $\bar{y}(k+1)$, and the actual, measured output, $y(k+1)$.

The matrices $P(t)$ in the continuous-time filter, and $S(k)$ in the discrete-time filter are the error covariance matrices for the state estimate. That is,

$$S(k) \triangleq E\left[e(k)e^{\mathrm{T}}(k)\right] \quad \text{and} \quad P(t) \triangleq E\left[e(t)e^{\mathrm{T}}(t)\right] \tag{100.169}$$

where $e(k) \triangleq x(k) - \hat{x}(k)$ and $e(t) \triangleq x(t) - \hat{x}(t)$. Thus, the size of these matrices is an indicator of the error variance in various components in the estimates, and it can be seen in Eq. (100.161) and (100.167) that as these covariances decrease, the estimators rely less and less on the innovations term and more on the system dynamics for an accurate estimate. Early in the estimation process, the situation is usually reversed, with the innovations having the larger effect.

Linear-Quadratic-Gaussian (LQG) Control

It can be shown that the Kalman filter is the *optimal* estimator for the state of system Eq. (100.156) or (100.164) in the sense that it minimizes the squared error due to the noise input terms. Therefore, it becomes a likely candidate for combination with the LQR of the previous section. Together, the combination of LQR and Kalman filter is known as the LQG (linear-quadratic-Gaussian) controller, and is a useful controller in many situations. This controller is optimal in the sense that it minimizes the expected root-mean-square value of the optimization criterion

$$\lim_{T\to\infty} E\left\{\frac{1}{T}\int_0^T x^{\mathrm{T}}(t)Qx(t) + u^{\mathrm{T}}(t)Ru(t)dt\right\}^{1/2} \tag{100.170}$$

when the noise inputs are unit variance white noise. In the frequency domain, this is equivalent to minimizing the H_2-norm

$$\|G\|_2 = \left\{\frac{1}{2\pi}\int_{-\infty}^{\infty} trace\left(G^*(j\omega)G(j\omega)\right)d\omega\right\}^{1/2} \tag{100.171}$$

of the transfer function G from the white noise inputs $\begin{bmatrix} v \\ w \end{bmatrix}$ to the output $z = \begin{bmatrix} Tx \\ R^{1/2}u \end{bmatrix}$ where $Q = T^{\mathrm{T}}T$, as before. We should point out that the so-called H_2 controller is equivalent to the LQG controller but provides a unified framework for control and observation that explains the striking similarity between the LQ controller equations and the Kalman filter equations (for example, in the Riccati equations of (100.148) and (100.63)). See Zhou and Doyle [1998] for further information.

H_∞ Control

The standard H_∞ control problem considers a system of the form

$$\begin{aligned} \dot{x} &= Ax + B_1 w + B_2 u \\ z &= C_1 x + D_{12} u \\ y &= C_2 x + D_{21} w \end{aligned} \tag{100.172}$$

where w is a deterministic disturbance input vector, y is the measured output vector, and z is a vector of variables to be controlled. The objective of H_∞ control is to minimize the H_∞ norm

$$\|G\|_\infty = \sup_\omega \bar{\sigma}\left[G(j\omega)\right] \tag{100.173}$$

(where $\bar{\sigma}$ denotes the maximum ***singular value*** of a matrix, and sup denotes "supremum," or least upper bound) of the transfer function G from the disturbance input w to the output z. In the time domain, the square of this

norm corresponds to the maximum possible energy magnification between the input and the output, where energy is defined as the integral of the square of a signal; for example, $\int_0^\infty w^T(t)w(t)dt$.

One of the major reasons for the development of H_∞ control is that many performance and robustness criteria for MIMO systems involve the maximum **singular value** of certain system transfer functions. To optimize the performance or robustness of these systems requires the minimization of the maximum singular value of these transfer functions, which is exactly the objective of H_∞ control.

From a disturbance rejection point of view, the H_∞ controller can be used to minimize the root-mean-square value of the controlled variable z due to the worst-case unit-energy disturbance w. This is to be contrasted with LQG (or H_2) controller, which minimizes the average response to a unit-variance random disturbance.

In practice, it is common to solve the suboptimal H_∞ problem where it is desired to find an output feedback controller such that $\|G\|_\infty < \gamma$, where γ is specified by the designer. For large values of γ, there will always be a solution to the problem. In fact, as γ approaches infinity in the equations below, the central H_∞ controller will approach the LQG controller. By decreasing the value of γ until just before a solution to the problem ceases to exist, the designer can get as close to the optimal H_∞ controller as desired. To ensure that a solution for some value of γ exists, the following standard assumptions on the system are made [Green and Limebeer, 1995]:

1. The pair (A, B_2) is stabilizable and the pair (A, C_2) is detectable
2. $D_{12}^T D_{12} = I$ and $D_{21}D_{21}^T = \mathrm{I}$
3. Rank $\begin{bmatrix} A - j\omega I & B_2 \\ C_1 & D_{12} \end{bmatrix} = n + m$ for all real ω
4. Rank $\begin{bmatrix} A - j\omega I & B_1 \\ C_2 & D_{21} \end{bmatrix} = n + q$ for all real ω

where n is the dimension of x, m is the dimension of u, and q is the dimension of y.

Under these assumptions, it can be shown that there exists a stabilizing, measurement feedback solution to the suboptimal H_∞ control problem if and only if the following three conditions are met.

1. The algebraic Riccati equation $X_\infty \tilde{A} + \tilde{A}^T X_\infty + \tilde{C}^T\tilde{C} - X_\infty (B_2B_2^T - \gamma^{-2} B_1B_1^T)X_\infty = 0$ has a positive semi-definite solution such that $\tilde{A} - (B_2B_2^T - \gamma^{-2} B_1B_1^T)X_\infty$ is stable, where $\tilde{A} = A - B_2D_{12}^T C_1$ and $\tilde{C}^T\tilde{C} = C_1^T(I - D_{12}D_{12}^T)C_1$.
2. The algebraic Riccati equation $\overline{A}Y_\infty + Y_\infty\overline{A}^T + \overline{B}\overline{B}^T - Y_\infty (C_2^TC_2 - \gamma^{-2}C_1^TC_1)Y_\infty = 0$ has a positive semi-definite solution such that $\overline{A} - Y_\infty (C_2^TC_2 - \gamma^{-2}C_1^TC_1)$ is stable, where $\overline{A} = A - B_1D_{12}^T C_2$ and $\overline{B}\overline{B}^T = B_1(I - D_{21}^T D_{12}) B_1^T$.
3. $\rho(X_\infty Y_\infty) < \gamma^2$, where $\rho(\cdot)$ denotes the maximum of the absolute values of the matrix's eigenvalues.

The so-called central controller that solves the suboptimal H_∞ problem can be written in a form that closely resembles the state-estimate feedback form of the LQG controller:

$$\begin{aligned} \dot{\hat{x}} &= A\hat{x} + B_1\hat{w}^* + B_2u + \left[B_1D_{21}^T + Z_\infty C_{2z}^T\right]\left(y - C_2\hat{x} - D_{21}\hat{w}^*\right) \\ u &= -F_\infty\hat{x} \\ \hat{w}^* &= \gamma^{-2}B_1^T X_\infty\hat{x} \end{aligned} \tag{100.174}$$

where $C_{2z} = C_2 + \gamma^{-2}D_{21}B_1^T X_\infty$, $F_\infty = D_{12}^T C_1 + B_2^T X_\infty$, and $Z_\infty = Y_\infty(I - \gamma^{-2}X_\infty Y_\infty)^{-1}$. The dynamic part of the above compensator can be interpreted as an estimate of the state assuming that the worst-case disturbance w^* is present. The control signal is a linear feedback of the estimated state, just as in the LQG case. Although the controller formulas above look more complicated than in the LQG case, this is largely due to the fact that the controlled variable z has a more general form in the H_∞ problem statement above. It should be noted, however, that unlike the LQG case, the solution of the Riccati equations is coupled in the H_∞ case due to condition 3 above.

Example

Consider the following state-space system, which represents a plant with two lightly damped modes at approximately $\omega_1 \approx 1$ and $\omega_2 \approx 3.2$:

$$\dot{x}(t) = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -1 & -.1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -10 & -.1 \end{bmatrix} x(t) + \begin{bmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ .2 & 0 \end{bmatrix} d(t) + \begin{bmatrix} 0 \\ 1 \\ 0 \\ -1 \end{bmatrix} u(t) \tag{100.175}$$

$$y(t) = \begin{bmatrix} 1 & 0 & .5 & 0 \end{bmatrix} x(t) + \begin{bmatrix} 0 & .01 \end{bmatrix} d(t)$$

Here, the term $d(t) = [d_1(t) \quad d_2(t)]^T$ is a vector whose first term represents the plant disturbance, and whose second term represents the measurement disturbance (deterministic). To pose the LQG control problem, we can propose minimizing the cost function

$$\int_0^\infty \left(x^T T^T T x + r u^2 \right) dt = \int_0^\infty z^T z \; dt \tag{100.176}$$

where

$$z \triangleq \begin{bmatrix} T \\ 0 \end{bmatrix} x + \begin{bmatrix} 0 \\ r \end{bmatrix} u \tag{100.177}$$

and $T = [.5 \quad 0 \quad -1 \quad 0]$. However, Eq. (100.175) and (100.177) are also in the form of Eq. (100.172), facilitating an H_∞ design that minimizes the H_∞ norm of the transfer function from the disturbance d to the controlled variable z. We can compare this design to an H_2 controller design that minimizes the H_2 norm (Eq. (100.176)). The two controllers will therefore minimize different norms of the same transfer function.

The results of this comparison are shown in the curves of Fig. 100.55. The distinguishing feature of this comparison is the flattening effect of the H_∞ controller. Although this is a plot of a frequency response magnitude and not the maximum **singular value,** it is apparent that theH_∞ controller is reducing the peak response, while the H_2 controller is reducing the average response and providing faster roll-off in the frequency domain.

Other Approaches

Although the LQG and H_∞ design methodologies are probably the most commonly used techniques for linear MIMO controller design, there are many other optimization-based techniques available. A well-developed theory exists for L_1 control, which minimizes the maximum magnification of the peak of the input signal using a linear programming algorithm [Dahleh and Diaz-Bobillo, 1995]. This approach departs from traditional controller design methodologies that have attempted to arrive at a set of formulas for the optimal controller. But with the advent of powerful computers, it makes sense to consider a problem solved if it can be reduced to a problem that can be efficiently solved using a computer algorithm. This is also the premise underlying the design methodology of *linear matrix inequalities*, in which the control design problem is reduced to a convex programming problem [Boyd et al., 1994].

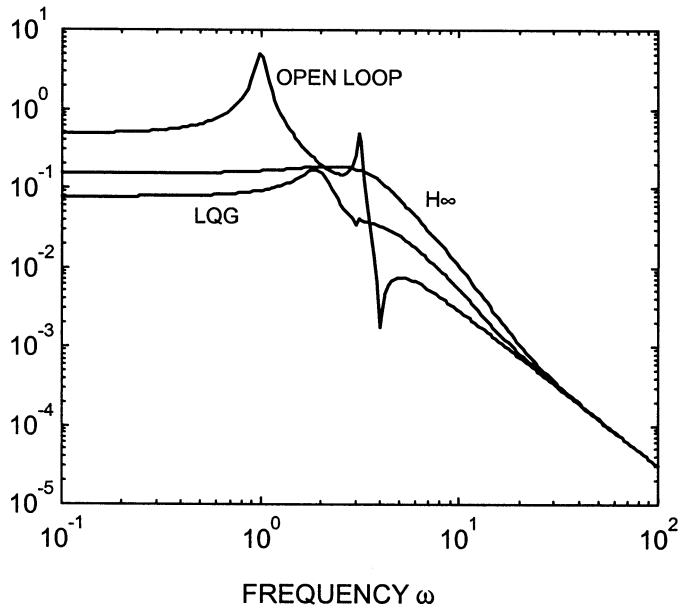

FIGURE 100.55 Frequency response of the closed-loop transfer function from d_1 to Tx, comparing the H_2 (LQG) and H_∞ control designs, using $r = 0.1$.

Defining Terms

Controllability: A linear system is said to be controllable if a control input exists that will drive a system with an arbitrary initial condition to a desired final state in a finite time.

Stabilizability: A linear system is said to be stabilizable if its unstable part is controllable.

Observability: A linear system is said to be observable if its state vector can be reconstructed from finite-length observations of its input and output.

Detectability: A linear system is said to be detectable if its unstable part is observable.

Positive-(semi)definite: A positive- (semi)definite matrix is a symmetric matrix A such that for any nonzero vector x, the quadratic form $x^T Ax$ is positive (non-negative).

Observer (or **estimator**)**:** A linear system whose state output approximates the state vector of a different system, rejecting noise and disturbances in the process.

Singular value: Singular values are non-negative real numbers that measure the magnification effect of an operator in the different basis directions of the operator's space.

Further Information

Optimal control and estimation is an actively growing field of control systems research. Classic texts in the area include [Kirk, 1970] and [Bryson and Ho, 1975] for optimal control systems, and [Anderson and Moore, 1979] for Kalman filtering, with the original source being [Kalman, 1960]. Further information on H_2 and H_∞ theory can be found in [Doyle, et al., 1989], [Zhou and Doyle, 1998], [Green and Limebeer, 1995], and [Francis, 1987].

100.9 Neural Control

Mo-Yuen Chow

Artificial intelligence had strong ties with automatic control during its early development stages several decades ago. Typical examples of these ties are the development of cybernetics, robotics, and early learning systems. Recent efforts to incorporate aspects of artificial intelligence into the design and operation of automatic control systems have focused on using techniques such as artificial neural networks, fuzzy logic, and expert systems. The application of one or more of these techniques in the design of control systems has come to be known as *intelligent control* [Antsaklis et al., 1994], a term questioned by some for its implications. Whether or not such systems should be classified as intelligent, they represent significant contributions to the field of automatic control, as evidenced by the rapidly growing wealth of literature devoted to the successful application of such systems to complex control problems [Chow and Menozzi, 1994a; 1994b; Chow and Teeter, 1997; Chow and Yee, 1991; Hunt et al., 1992; Miller et al., 1990; Nguyen and Widrow, 1990; Psaltis et al., 1988; Werbos, 1990].

The nonlinear functional mapping properties of Artificial Neural Networks (ANNs) are central to their use in system identification and control [Narendra and Parthasarathy, 1990]. Although a number of key theoretical problems remain, results pertaining to the approximation capabilities of neural networks demonstrate that they have great promise in the modeling and control of nonlinear systems. The artificial neural network technology has become increasingly popular as a tool for performing tasks such as automatic control, system identification, pattern recognition, and time series prediction. Most of the *conventional methods*, such as PI control, are based on mathematical and statistical procedures for the modeling of the system and the estimation of the optimal controller parameters. In practice, the plant to be controlled is often highly nonlinear and a mathematical model may be difficult to derive. In such cases, conventional techniques may prove to be suboptimal and may lack robustness in the face of modeling error, because they are only as accurate as the model that was used to design them. With the advancement of technology, however, sophisticated control using artificial neural network techniques has been developed and used successfully to improve the control of systems that cannot be easily handled by conventional control, thus giving rise to terminology such as *neural control* and *intelligent control.*

Usually, a human operator is responsible for adjusting the controller's parameters in order to use his/her own idea of good performance. Indirectly, the operator is performing a minimization of a cost function based on his/her knowledge. More generally, when confronted with a problem situation, humans execute a mapping between a set of events and the set of corresponding appropriate actions. The appropriateness of these actions is due to some basic acquired knowledge, or even instinct, that guides the initial stages of the mapping. Then, through experience and a set of implicit guidelines, the human learns to perform a better mapping. This is an ongoing process throughout a person's life. Similarly, an ANN, if given initial guidance, can learn to improve its performance through a set of guidelines, (e.g., minimize a cost function). In fact, a properly structured ANN can learn any arbitrarily complicated mapping [Cybenko, 1989; Rumelhart and McClelland, 1986; Werbos, 1974].

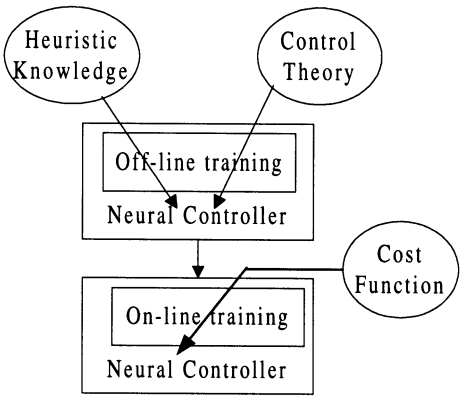

FIGURE 100.56 A two-step training process for a neural controller.

Successful adaptation of online neural controllers in many cases requires careful and substantial design effort. One of the common practices is to pre-train a neural controller offline, based on some simplified design methods, in the same way that a PI controller is designed based on *approximated* system models that can provide reasonable control performance, before putting the neural controller for online fine-tuning [Chow and Menozzi, 1993; Chow and Teeter, 1995; Teeter et al., 1996]. This approach, as shown in Fig. 100.56, can speed up the neural controller online adaptation process and increase the closed-loop online adaptation stability because the initial weights of the neural controller are much closer to the optimal final weights (if they exist) after the pre-training process. By learning online, the ANN controller can adapt to changing operating environments.

This chapter section briefly describes the feedforward net paradigm to facilitate the discussion of the *neural observer* and *neural controller* concepts in later sections. An example of using neural control for an HVAC system will then be provided to demonstrate its effectiveness for solving real-world problems.

Brief Introduction to Artificial Neural Networks

Increasing interest in studying the mechanisms and structure of the brain has led to the development of new computational models for solving problems such as pattern recognition, fast information processing, and adaptation. In the 1940s, McCulloch and Pitts studied the potential and capabilities of the interconnection of components based on a model of a biological neuron. Since then, many different models and architectures have been developed and analyzed for a variety of applications [Zurada, 1992]. One of the most common neuron models is shown in Fig. 100.57.

The inputs x to the neuron model are scaled by connection weights w and summed. An additional input b, often referred to as a *bias*, is added to this sum and the result becomes the input to a function $f(\cdot)$, called the *activation function*, which computes the output of the neuron. The bias can be considered as a connection weight for a constant input of +1. The terms *neuron model* and *neuron* are used interchangeably in this chapter section.

The individual neurons are not very powerful in terms of computation or representation, but the interconnection of neurons to form an *artificial neural network* (ANN) can provide a means of encoding complex relationships between input and output variables. Of the many ANN architectures that have been proposed, the *multilayer feedforward artificial neural network* (MFANN) shown in Fig. 100.58 is one of the most popular.

Bias terms have been omitted in Fig. 100.58 for simplicity. The layers between the input and output layers of an MFANN are usually referred to as *hidden layers* because their inputs and outputs are not measurable at the inputs or outputs of the network. It has been shown that an MFANN with a single hidden layer can approximate any continuous function to an arbitrary degree of accuracy [Cybenko, 1989; Werbos, 1974]. The process of adjusting ANN connection weights in an effort to obtain a desired input/output mapping is usually referred to as *training*. Training represents an optimization problem for which the solution is a set of weights that minimizes some measure of approximation error. The choices of activation functions, number of neurons, error measures, and optimization methods can significantly affect training results.

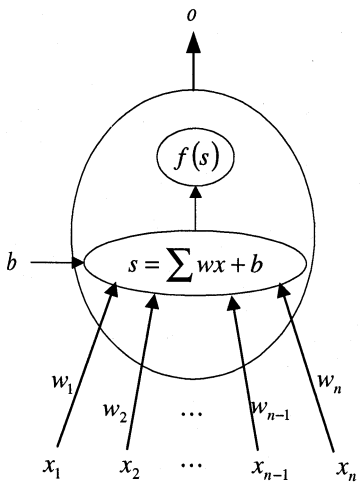

FIGURE 100.57 Computational model of a biological neuron.

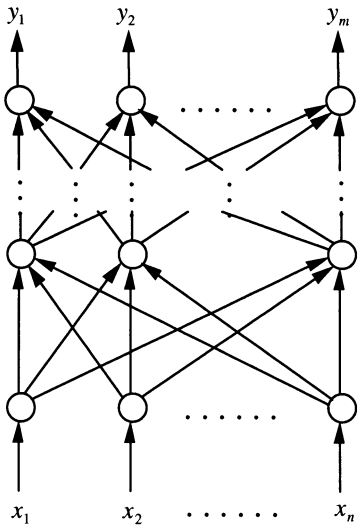

FIGURE 100.58 A multilayer feedforward ANN.

When the desired mapping is described by a set of input/output data, weights are usually modified after the presentation of each input/output pattern. This method is referred to as *pattern update* and represents an approximation of true gradient descent that is generally valid when a sufficiently small stepsize is used. *Batch update*, for which weight changes are accumulated over one sweep of the set of training patterns before being applied, is sometimes used in an effort to more closely mimic true gradient descent. Variants of back-propagation and other training methods can be found in [Zurada, 1992].

Neural Observer

The nonlinear functional mapping properties of *neural networks* are central to their use in identification and control [Chow and Teeter, 1995; Hunt et al., 1992; Poggio and Girosi, 1990; Teeter and Chow, 1998; Teeter et al. 1994]. Although a number of key theoretical problems remain, results pertaining to the approximation capabilities of neural networks demonstrate that they have great promise in the modeling of nonlinear systems. An important question in system identification is whether a system under study can be adequately represented within a given model structure [Hunt et al., 1992]. In the absence of such concrete theoretical results for neural networks, it is usually assumed that the system under consideration belongs to the class of systems that the chosen network is able to represent. Two system identification techniques are now introduced: *forward modeling* and *inverse modeling*.

The procedure of training a neural network to represent the forward dynamics of a system is often referred to as the *forward system identification* approach [Hunt et al., 1992]. A schematic diagram of this process is shown in Fig. 100.59.

The neural network is placed in parallel with the system, and the error, $\boldsymbol{e}$, between the system outputs, $\boldsymbol{y}$, and network outputs, $\hat{\boldsymbol{y}}$, is used to train the network. This represents a classical *supervised learning* problem for which the teacher (i.e., the system) provides target values (i.e., system outputs) directly in the output coordinate system of the learner (i.e., the network model) [Jordan and Rumelhart, 1991].

In an *inverse system identification* approach, a network is trained in an effort to model the inverse of the plant mapping [Hunt et al., 1992]. One of the simplest approaches, known as *direct inverse system identification*, is shown schematically in Fig. 100.60.

A synthetic training signal, $\boldsymbol{s}$, is introduced to the system, and the system output, $\boldsymbol{y}$, is used as the input to the network. The network output is compared to the training signal and this error is used to train the network.

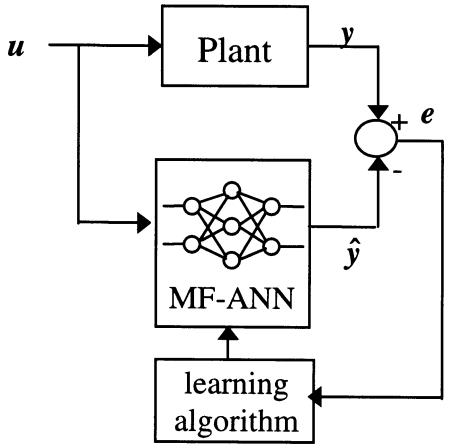

FIGURE 100.59 Forward system identification approach.

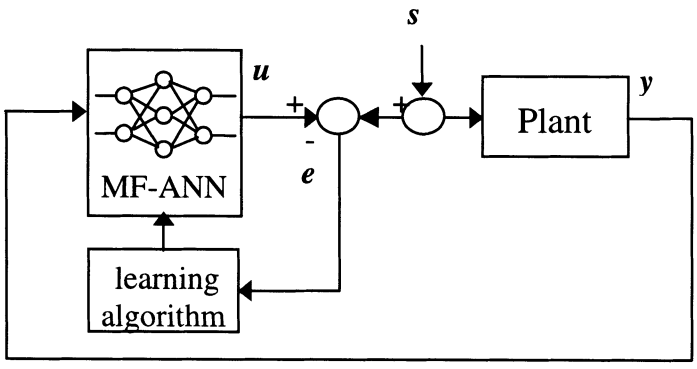

FIGURE 100.60 Direct inverse system identification approach.

The inverse modeling structure shown in Fig. 100.60 tends to force the network to represent the inverse of the plant, but there are potential drawbacks to this approach. The training signal must be chosen to sample over a wide range of system inputs, and the actual operational inputs may be difficult to define *a priori* [Jordan and Rumelhart, 1991]. This point is strongly related to the concept of persistent excitation discussed in adaptive control literature. A second drawback is that an incorrect inverse model can be obtained if the nonlinear system mapping is not one-to-one. An approach called *specialized inverse modeling* has been proposed in an effort to overcome these problems. The details of this approach can be found in [Psaltis et al., 1988]. The neural network identification models can be used in the adaptive control of unknown nonlinear plants.

Neural Control

A method of *direct adaptive control* is depicted in Fig. 100.61.

Methods for directly adjusting control parameters based on the output error e_c are generally not available. This is because the unknown nonlinear plant in Fig. 100.61 lies between the controller and the output error. Until such methods are developed, adaptive control of nonlinear plants must be performed using *indirect* methods [Narendra and Parthasarathy, 1990]. Figure 100.62 depicts a general method of indirect adaptive control using artificial neural networks.

Tapped delay lines (TDL) provide delayed inputs and outputs of the plant to the neural controller and neural observer. Error e_i is used to adapt the neural observer, while the parameters of the neural observer along with

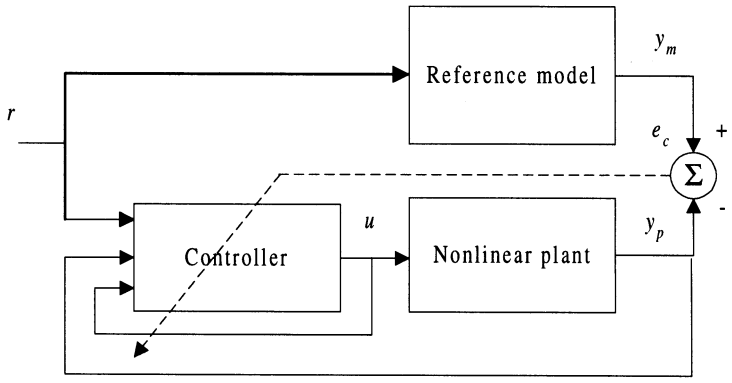

FIGURE 100.61 Direct adaptive control.

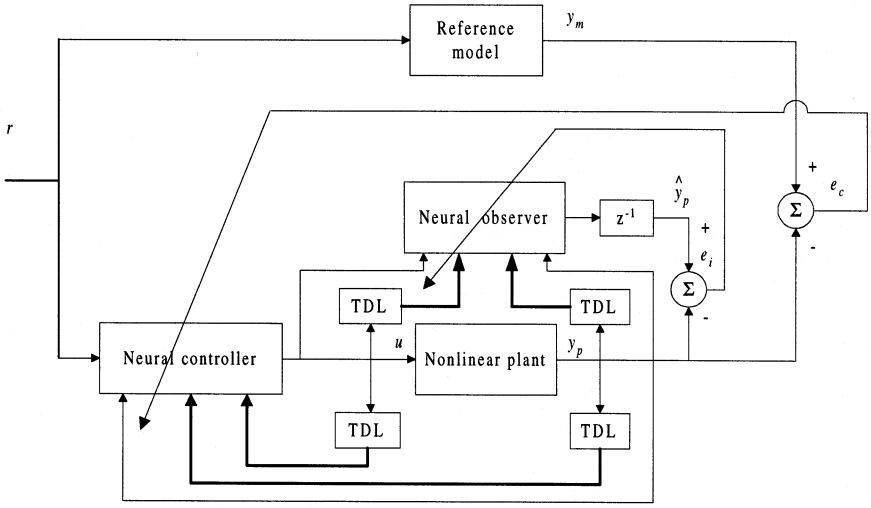

FIGURE 100.62 A method of indirect adaptive control using neural networks.

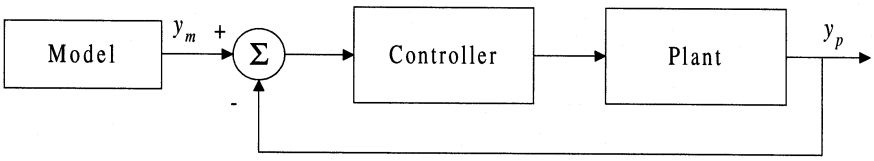

FIGURE 100.63 Explicit model-following.

error e_c are used to adapt the neural controller. The model reference approach depicted in Fig. 100.62 is commonly referred to as *implicit model-following* in adaptive control literature [Narendra and Annaswamy, 1989]. This type of model-following is performed when the dynamics of the closed-loop system are forced to asymptotically match the dynamics of the reference model. The method of *explicit model-following* is depicted in Fig. 100.63. In this case, the reference model acts as a prefilter, and the value of the system output is forced to asymptotically track the value of the reference model output [Narendra and Annaswamy, 1989].

A neural control and identification scheme can be described as the following: at each time step, the plant states are measured and a neural network controller computes the plant inputs. Controller parameters are then

adjusted between samples so that the system approaches optimal performance with respect to a given cost index. The general form of the cost index used to adapt the neural controller is:

$$J_k = \sum_{i=k+1}^{N} L\left(\mathbf{x}\left(i\right), \mathbf{u}\left(i\right)\right) \tag{100.178}$$

where L is the cost function as a function of system state $\mathbf{x}$ and control $\mathbf{u}$. Thus, at each time step, the goal is to minimize J_k subject to system dynamics and control constraints, with k denoting the current time step and N the prediction horizon.

The back-propagation training algorithm can be used to adapt neural networks for the identification and control of nonlinear plants [Teeter and Chow, 1998; Werbos, 1990]. For system identification, a network can be trained offline using plant input/output data obtained from simulation of a mathematical model or from observation of the physical system. When the network is used for adaptive identification, training can be performed using *batch update* with a window of sampled data, or with the *pattern update* method in which training patterns consist of past inputs and outputs measured at each sample time.

In order to adaptively train a neural *controller* using gradient descent, the partial derivatives of a cost index, J_k, with respect to the network weights, $\mathbf{w}$, must be obtained [Chow and Yee, 1991]. Let J_k have the form $J_k = L(\mathbf{y}(k+1),\mathbf{u}(k+1))+L(\mathbf{y}(k+2),\mathbf{u}(k+2)) + \ldots + L(\mathbf{y}(k+n),\mathbf{u}(k+n))$ where k is the current sample. For simplicity of notation, let $L(\mathbf{y}(k+i),\mathbf{u}(k+i))$ be denoted by $L(k+i)$. Application of the chain rule yields

$$\frac{\partial L\left(k+i\right)}{\partial \mathbf{w}} = \frac{\partial L\left(k+i\right)}{\partial \mathbf{u}\left(k\right)}\frac{\partial \mathbf{u}\left(k\right)}{\partial \mathbf{w}} = \left[\frac{\partial L\left(k+i\right)}{\partial \mathbf{y}\left(k+i\right)}\frac{\partial \mathbf{y}\left(k+i\right)}{\partial \mathbf{u}\left(k\right)} + \frac{\partial L\left(k+i\right)}{\partial \mathbf{u}\left(k+i\right)}\frac{\partial \mathbf{u}\left(k+i\right)}{\partial \mathbf{u}\left(k\right)}\right]\frac{\partial \mathbf{u}\left(k\right)}{\partial \mathbf{w}} \tag{100.179}$$

The $\partial\mathbf{u}(k)/\partial\mathbf{w}$ term can be calculated using the backpropagation approach since the controller is a neural network. The $\partial\mathbf{y}(k+i)/\partial\mathbf{u}(k)$ and $\partial\mathbf{u}(k+i)/\partial\mathbf{u}(k)$ terms are obtained using the neural controller and identifiers. First, future inputs and outputs of the plant are predicted. The partial derivatives are then obtained by recursively computing the input/output sensitivities of the plant and controller through i samples. This approach is often referred to as *back-propagation through time* [Chow and Yee, 1991; Werbos, 1990].

The training algorithm resembles methods used by Nguyen and Widrow [1990] and others for training a neural controller to achieve an end goal. In this case, however, the output *trajectory* is of interest and the training is performed in realtime (i.e., output values must be repeatedly predicted rather than observed over several trials). A flowchart of the control methodology is shown in Fig. 100.64.

After controller outputs are computed, the weights of the controller are adjusted N times before the next sample time. The value of N can be selected based on time constraints or convergence properties of the neural controller and observers. If N is large, the neural observers are inaccurate; and if a large prediction horizon is used, the adaptation of controller parameters may cause performance to deteriorate.

HVAC Illustration

In order to demonstrate the ability of the neural identification and control schemes to handle disturbances and changes in nonlinear plant dynamics, a Heat, Ventilation, and Air-Conditioning (HVAC) system where a thermal load is added and the actual output vs. the commanded output of each actuator is modified. The neural observers are adapted at each time step in one simulation, while adaptation of the observers is stopped at time step $k =$ 200 in another simulation. Both simulations are performed for 1000 time steps. The reference trajectory is plotted in Fig. 100.65, along with the output of the system that uses nonadaptive identifiers after time step $k =$ 200. Tracking errors for both simulations are plotted in Fig. 100.66, where T_3 is the temperature to be controlled and r is the reference signal to be tracked.

The performance of the system with nonadaptive observers deteriorates due to the disturbance and the changes in plant dynamics. In this case, adapting the neural observers enables them to more accurately predict

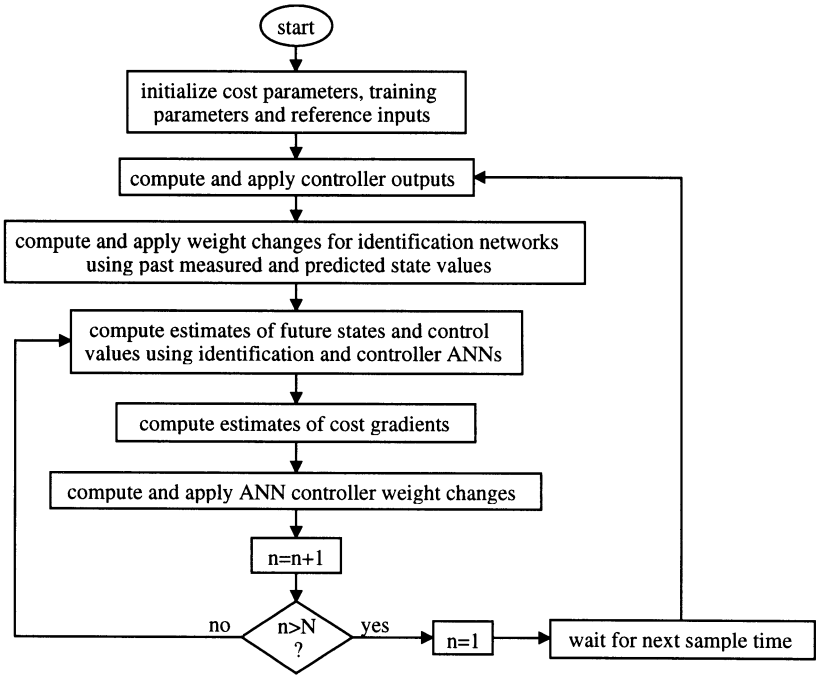

FIGURE 100.64 Flowchart of the neural control training methodology.

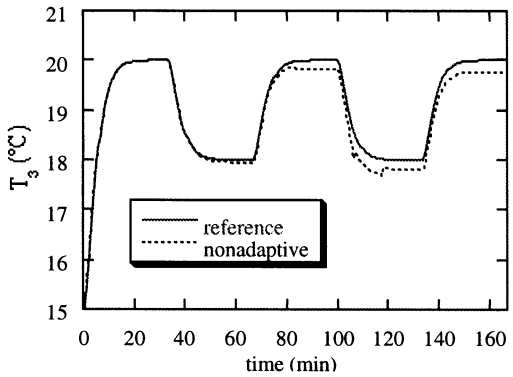

FIGURE 100.65 Reference and output trajectories using nonadaptive neural identifiers.

future states and inputs, and results in better tracking. It is important to select appropriate adaptation stepsizes for the observers because only one training pattern, consisting of the most recent set of plant inputs and states, is available for training. In order to compare the neural identification and control methodology with another potential control methodology, a PI-type controller has been designed for the HVAC system. Typical responses of the system with PI-type controller are shown in Fig. 100.67.

The simple PI-type controller satisfies the conservative performance specifications for the cases tested, but does not always use its resources efficiently. For example, if the outside air temperature of the HVAC system is close to the steady-state reference temperature, it may be more efficient to increase the room volumetric flow rate for a period of time in order to reduce the amount of heating or cooling performed by the heat exchanger. The neural and PI-type control schemes are tested using initial conditions $T_3(0) = 15°C$, a constant outside temperature of 22°C, and a steady-state reference value of 20°C. The tracking errors and heat exchanger outputs for both methods are shown in Figs. 100.68 and 100.69, respectively.

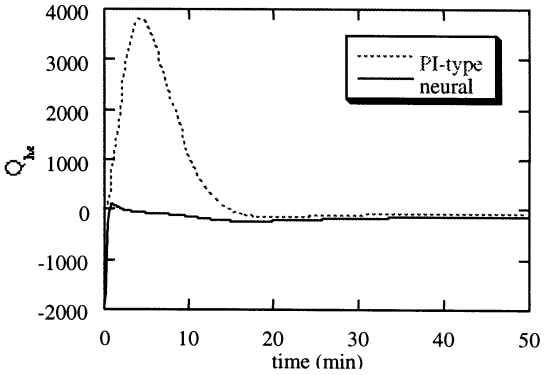

FIGURE 100.69 Heat exchanger outputs for the PI-type and neural control systems.

Conclusion

The use of neural networks for system identification and control provides a means of adapting a controller online in an effort to minimize a given cost index. The cost index includes typical measures associated with system performance and can be modified without significantly increasing the computational complexity of the adaptation process. For nonlinear systems, the identification networks demonstrate the capacity to learn changes in the plant dynamics. The performance of the neural control and identification methodology compares favorably with many types of conventional approaches.

101.1 Robot Configuration

Ty A. Lasky and Tien C. Hsia

Configuration is a fundamental classification for industrial robots. Configuration refers to the geometry of the robot manipulator, i.e., the manner in which the links of the manipulator are connected at each joint. The Robotic Industries Association (RIA) defines a robot as *a manipulator designed to move material, parts, tools, or specialized devices, through variable programmed motions for the performance of a variety of tasks*. With this definition, attention here is focused on industrial manipulator arms, typically mounted on a fixed pedestal base. Mobile robots and hard automation [e.g., Computer Numerical Control (CNC) machines] are excluded. The emphasis here is on serial-chain manipulator arms, which consist of a serial chain of linkages, where each link is connected to exactly two other links, with the exception of the first and last, which are connected to only one other link. Additionally, the first three links, called the major linkages, are focused on, with only a brief mention of the last three links, or wrist joints, also called the minor linkages.

Robot configuration is an important consideration in the selection of a manipulator. Configuration refers to the way the manipulator links are connected at each joint. Each link will be connected to the subsequent link by either a linear (sliding or prismatic) joint, which can be abbreviated with a P, or a revolute (or rotary) joint, abbreviated with an R. Using this notation, a robot with three revolute joints would be abbreviated as RRR, while one with a rotary joint followed by two linear (prismatic) joints would be denoted RPP. Each configuration type is well suited to certain types of tasks and ill suited to others. Some configurations are more versatile than others. In addition to the geometrical considerations, robot configuration affects the structural stiffness of the robot, which may be an important consideration. Also, configuration impacts the complexity of the forward and inverse **kinematics**, which are the mappings between the robot actuator (joint) space, and the Cartesian position and orientation of the robot end-effector, or tool.

There are six major robot configurations commonly used in industry. Details for each configuration are presented in subsequent subsections. The simplest configuration is the Cartesian robot, which consists of three orthogonal, linear joints (PPP), so that the robot moves in the x, y, and z directions in the joint space. The

cylindrical configuration consists of one revolute and two linear joints (RPP), so that the robot joints correspond to a cylindrical coordinate system. The spherical configuration consists of two revolute joints and one linear joint (RRP), so that the robot moves in a spherical, or polar, coordinate system. The articulated (arm-and-elbow) configuration consists of three revolute joints (RRR), giving the robot a somewhat human-like range of motion. The SCARA (Selectively Compliant Assembly Robot Arm) configuration consists of two revolute joints and one linear joint (RRP), arranged in a different fashion than the spherical configuration. It may also be equipped with a revolute joint on the final sliding link. The gantry configuration is essentially a Cartesian configuration, with the robot mounted on an overhead track system. One can also mount other robot configurations on an overhead gantry system to give the robot an extended workspace, as well as free up valuable factory floor space. The percentage usage of the first five configuration types is listed in Table 101.1. This table does not include gantry robots, which are assumed to be included in the Cartesian category. Additionally, this information is from 1988, and does not accurately represent current usage.

TABLE 101.1 Robot Arm Geometry Usage

Arm Geometry	Percent of Use
Cartesian	18
Cylindrical	15
Spherical	10
Articulated	42
SCARA	15

Source: V. D. Hunt, *Robotics Sourcebook,* New York: Elsevier, 1988. With permission.

In general, robots with a rotary base have a speed advantage. However, they have more variation in resolution and dynamics compared to Cartesian robots. This can lead to inferior performance if a fixed controller is used over the robot's entire workspace.

Cartesian Configuration

The Cartesian configuration consists of three orthogonal, linear axes, abbreviated as PPP, as shown in Fig. 101.1. Thus, the joint space of the robot corresponds directly with the standard right-handed Cartesian *xyz*-coordinate system, yielding the simplest possible kinematic equations. The work envelope of the Cartesian robot is shown in Fig. 101.2. The work envelope encloses all the points that can be reached by the robot arm or the mounting point for the end-effector or tool. The area reachable by an end effector or tool is not considered part of the work envelope. All interaction with other machines, parts, or processes must take place within this volume [Critchlow, 1985]. Here, the workspace of a robot is assumed to be equivalent to the work envelope.

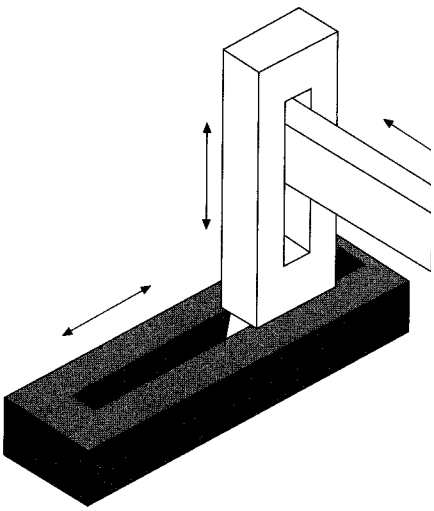

FIGURE 101.1 The Cartesian configuration. (*Source:* T. Owen, *Assembly with Robots*, Englewood Cliffs, N.J.: Prentice-Hall, 1985. With permission.)

There are several advantages to this configuration. As noted above, the robot is kinematically simple, since motion on each Cartesian axis corresponds to motion of a single actuator. This eases the programming of linear motions. In particular, it is easy to do a straight vertical motion, the most common motion in assembly tasks. The Cartesian geometry also yields a constant arm resolution throughout the workspace; i.e., for any configuration, the resolution for each axis corresponds directly to the resolution for that joint. The simple geometry of the Cartesian robot leads to correspondingly simple manipulator dynamics. The disadvantages of this configuration include inability to reach objects on the floor or points invisible from the base of the robot, and slow speed of operation in the horizontal plane compared to robots with a rotary base. Additionally, the Cartesian configuration requires a large operating volume for a relatively small workspace.

Cartesian robots are used for several applications. As noted above, they are well suited for assembly operations, as they easily perform vertical straight-line insertions. Because of the ease of straight-line motions, they are also well suited to machine loading and unloading. They are also used in clean room tasks.

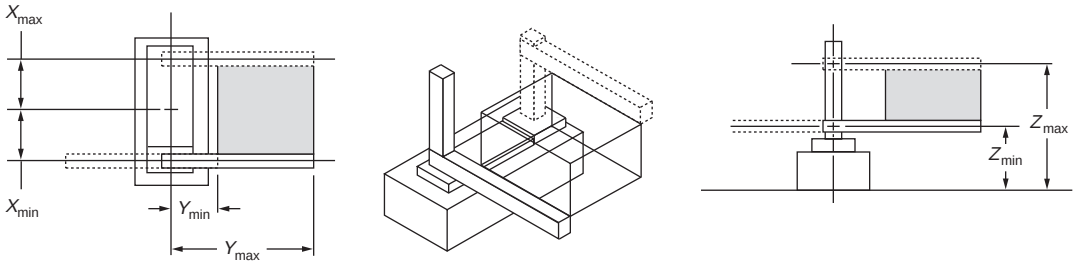

FIGURE 101.2 Cartesian robot work envelope.

Cylindrical Configuration

The cylindrical configuration consists of one vertical revolute joint and two orthogonal linear joints (RPP), as shown in Fig. 101.3. The resulting work envelope of the robot is a cylindrical annulus, as shown in Fig. 101.4. This configuration corresponds with the cylindrical coordinate system.

As with the Cartesian robot, the cylindrical robot is well suited for straight-line vertical and horizontal motions, so it is useful for assembly and machine loading operations. It is capable of higher speeds in the horizontal plane due to the rotary base. However, general horizontal straight-line motion is more complex and correspondingly more difficult to coordinate. Additionally, the end-point resolution of the cylindrical robot is not constant but depends on the extension of the horizontal linkage. A cylindrical robot cannot reach around obstacles. Additionally, if a monomast construction is used on the horizontal linkage, then there can be clearance problems behind the robot.

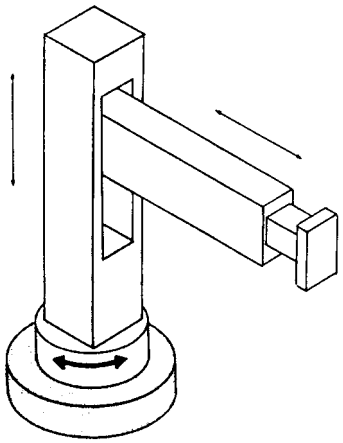

FIGURE 101.3 The cylindrical configuration. (*Source:* T. Owen, *Assembly with Robots*, Englewood Cliffs, N.J.: Prentice-Hall, 1985. With permission.)

Spherical Configuration

The spherical (or polar) configuration consists of two revolute joints and one linear joint (RRP), as shown in Fig. 101.5. This results in a set of joint coordinates that matches with the spherical coordinate system. A typical work envelope for a spherical robot is shown in Fig. 101.6.

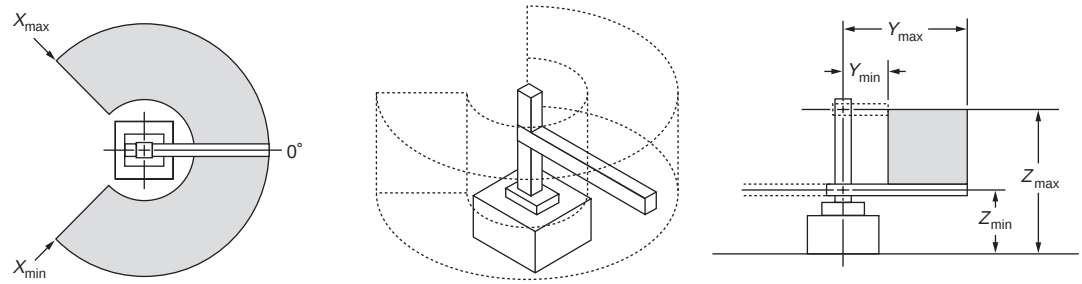

FIGURE 101.4 Cylindrical robot work envelope.

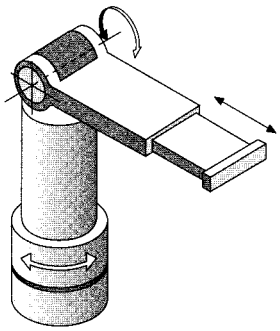

FIGURE 101.5 The spherical configuration. (*Source:* T. Owen, *Assembly with Robots*, Englewood Cliffs, N.J.: Prentice-Hall, 1985. With permission.)

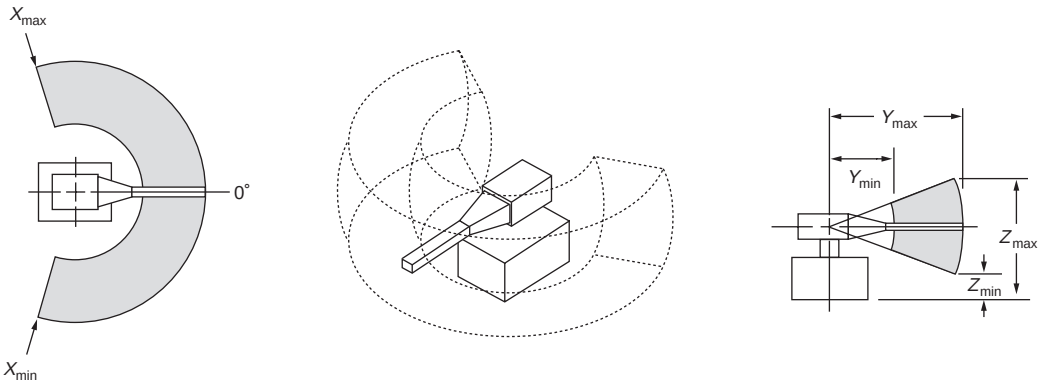

FIGURE 101.6 Spherical robot work envelope.

Spherical robots are typically heavy-duty robots. They have the advantages of high speed due to the rotary base, and a large work volume, but are more kinematically complex than either Cartesian or cylindrical robots. Generally, they are used for heavy-duty tasks in, for example, automobile manufacturing. They do not have the dexterity to reach around obstacles in the workspace. Spherical robots also do not have fixed resolution throughout the workspace.

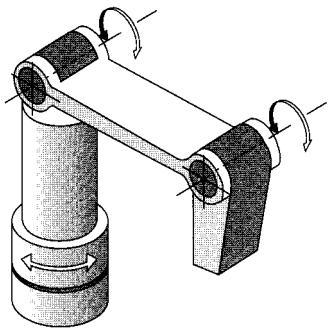

FIGURE 101.7 The articulated configuration. (*Source:* T. Owen, *Assembly with Robots*, Englewood Cliffs, N.J.: Prentice-Hall, 1985. With permission.)

Articulated Configuration

The articulated (or anthropomorphic, jointed, arm-and-elbow) configuration consists of three revolute joints (RRR), as shown in Fig. 101.7. The resulting joint coordinates do not directly match any standard coordinate system. A slice of a typical work envelope for an articulated robot is shown in Fig. 101.8.

The articulated robot is currently the most commonly used in research. It has several advantages over other configurations. It is closest to duplicating the motions of a human assembler, so there should be less need to redesign an existing workstation to utilize an articulated robot. It has a very large, dexterous work envelope; i.e., it can reach most points in its work envelope from a variety of orientations. Thus, it can more easily reach around or over obstacles in the workspace or into parts or machines. Because all the joints are revolute, high

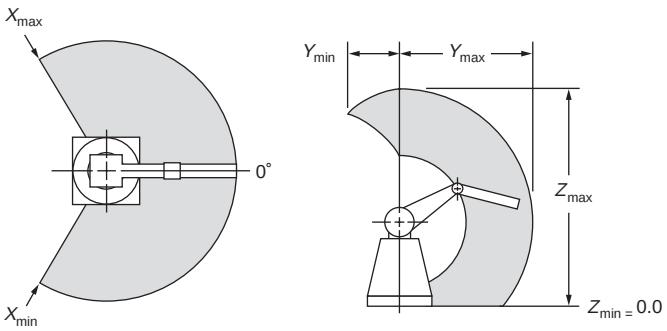

FIGURE 101.8 Articulated robot work envelope.

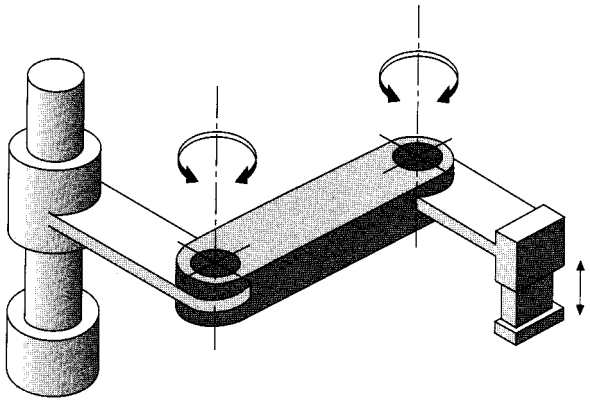

FIGURE 101.9 The SCARA configuration. (*Source:* T. Owen, *Assembly with Robots*, Englewood Cliffs, N.J.: Prentice-Hall, 1985. With permission.)

speeds are possible. The articulated arm is good for tasks involving multiple insertions, complex motions, and varied tool orientations. The versatility of this configuration makes it applicable to a variety of tasks, so the user has fewer limitations on the use of the robot. However, the same features that give this robot its advantages lead to certain disadvantages. The geometry is complex, and the resulting kinematic equations are quite intricate. Straight-line motion is difficult to coordinate. Control is generally more difficult than for other geometries, with associated increase in cost. Here again, arm resolution is not fixed throughout the workspace. Additionally, the dynamics of an articulated arm vary widely throughout the workspace, so that performance will vary over the workspace for a fixed controller. In spite of these disadvantages, the articulated arm has been applied to a wide variety of research and industrial tasks, including spray painting, clean room tasks, machine loading, and parts-finishing tasks.

SCARA Configuration

The SCARA (Selectively Compliant Assembly Robot Arm) configuration consists of two revolute joints and a linear joint (RRP), as shown in Fig. 101.9. This configuration is significantly different from the spherical configuration, since the axes for all joints are always vertical. In addition to the first three **degrees of freedom** (DOF), the SCARA robot will often include an additional rotation about the last vertical link to aid in orientation of parts. The work envelope of the SCARA robot is illustrated in Fig. 101.10. The SCARA configuration is the newest of the configurations discussed here, and was developed by Professor Hiroshi Makino of Yamanashi University, Japan.

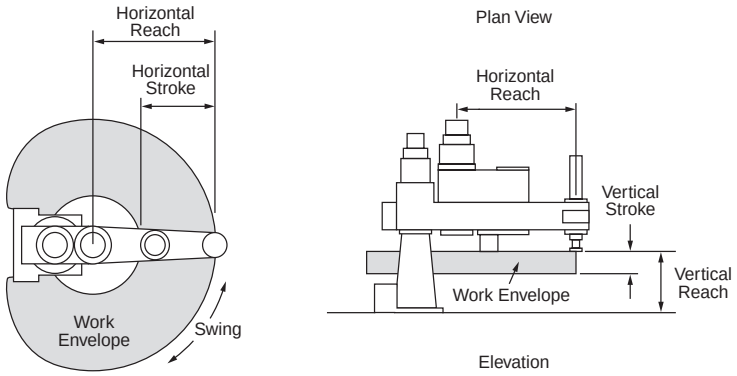

FIGURE 101.10 SCARA robot work envelope.

This configuration has many advantages and is quite popular in industry. The configuration was designed specifically for assembly tasks [Truman, 1990], so has distinct advantages when applied in this area. Because of the vertical orientation of the joints, gravity does not affect the dynamics of the first two joints. In fact, for these joints, the actuators can be shut off and the arm will not fall, even without the application of brakes. As the name SCARA implies, this allows compliance in the horizontal directions to be selectively varied; therefore, the robot can comply to horizontal forces. Horizontal compliance is important for vertical assembly operations. Because of the vertical linear joint, straight-line vertical motions are simple. Also, SCARA robots typically have high positional repeatability. The revolute joints allow high-speed motion. On the negative side, the resolution of the arm is not constant throughout the workspace, and the kinematic equations are relatively complex. In addition, the vertical motion of the SCARA configuration is typically quite limited. While the SCARA robot can reach around objects, it cannot reach over them in the same manner as an articulated arm.

Gantry Configuration

The gantry configuration is geometrically equivalent to the Cartesian configuration, but is suspended from an overhead crane and typically can be moved over a large workspace. It consists of three linear joints (PPP), and is illustrated in Fig. 101.11. In terms of work envelope, it will have a rectangular volume that sweeps out most of the inner area of the gantry system, with a height limited by the length of the vertical mast, and the headroom above the gantry system. One consideration in the selection of a gantry robot is the type of vertical linkage employed in the z axis. A monomast design is more rigid, yielding tighter tolerances for repeatability and accuracy, but requires significant headroom above the gantry to have a large range of z axis motion. On the other hand, a telescoping linkage will require significantly less headroom but is less rigid, with corresponding reduction in repeatability and accuracy. Other robot configurations can be mounted on gantry systems, thus gaining many of the advantages of this geometry.

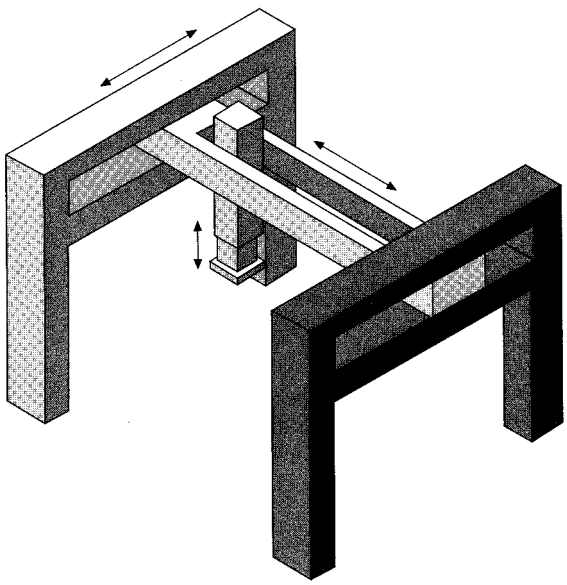

FIGURE 101.11 The gantry configuration. (*Source:* T. Owen, *Assembly with Robots*, Englewood Cliffs, N.J.: Prentice-Hall, 1985. With permission.)

Gantry robots have many advantageous properties. They are geometrically simple, like the Cartesian robot, with the corresponding kinematic and dynamic simplicity. For the same reasons, the gantry robot has a constant arm resolution throughout the workspace. The gantry robot has better dynamics than the pedestal-mounted Cartesian robot, as its links are not cantilevered. One major advantage over revolute-base robots is that its dynamics vary much less over the workspace. This leads to less vibration and more even performance than typical pedestal-mounted robots in full extension. Gantry robots are much stiffer than other robot configurations, although they are still much less stiff than Numerical Control (NC) machines. The gantry robot can straddle a workstation, or several workstations for a large system, so that one gantry robot can perform the work of several pedestal-mounted robots. As with the Cartesian robot, the gantry robot's simple geometry is similar to that of an NC machine, so technicians will be more familiar with the system and require less training time. Also, there is no need for special path or trajectory computations. A gantry robot can be programmed directly from a Computer-Aided Design (CAD) system with the appropriate interface, and straight-line motions are particularly simple to program. Large gantry robots have a very high payload capacity. Small, table-top systems can achieve linear speeds of up to 40 in./s (1.025 m/s), with a payload capacity of 5.0 lb (2.26 kg), making them suitable for assembly operations. However, most gantry robot systems are not as precise as other configurations, such as the SCARA configuration. Additionally, it is sometimes more difficult to apply a gantry robot to an existing workstation, as the workpieces must be brought into the gantry's work envelope, which may be harder to do than for a pedestal-mounted manipulator.

Gantry robots can be applied in many areas. They are used in the nuclear power industry to load and unload reactor fuel rods. Gantry robots are also applied to materials-handling tasks, such as parts transfer, machine loading, palletizing, materials transport, and some assembly applications. In addition, gantry robots are used for process applications such as welding, painting, drilling, routing, cutting, milling, inspection, and nondestructive testing.

The gantry robot configuration is the fastest-growing segment of the robotics industry. While gantry robots accounted for less than 5% of the units shipped in 1985, they are projected to account for about 30% of the robots by the end of the 1990s. One reason for this is summed up in Long [1990], which contains much more information on gantry robots in general:

> Currently gantry robot cells are being set up which allow manufacturers to place a sheet of material in the gantry's work envelope and begin automatic cutting, trimming, drilling, milling, assembly and finishing operations which completely manufacture a part or subassembly using quick-change tools and programmed subroutines.

Additional Information

The above six configurations are the main types currently used in industry. However, there are other configurations used in either research or specialized applications. Some of these configurations have found limited application in industry and may become more prevalent in the future.

All the above configurations are serial-chain manipulators. An alternative to this common approach is the parallel configuration, known as the Stewart platform [Waldron, 1990]. This manipulator consists of two platforms connected by three prismatic linkages. This arrangement yields the full six DOF motion (three position, three orientation) that can be achieved with a six-axis serial configuration but has a comparably very high stiffness. It is used as a motion simulator for pilot training and virtual reality applications. The negative aspects of this configuration are its relatively restricted motion capability and geometric complexity.

The above configurations are restricted to a single manipulator arm. There are tasks that are either difficult or impossible to perform with a single arm. With this realization, there has been significant interest in the use of multiple arms to perform coordinated tasks [Bonitz and Hsia, 1996]. Possible applications include carrying loads that exceed the capacity of a single robot, and assembling objects without special fixturing. Multiple arms are particularly useful in zero-gravity environments. While there are significant advantages to the use of multiple robots, the complexity, in terms of kinematics, dynamics, and control, is quite high. However, the use of multiple robots is opening new areas of application for robots.

Typical industrial robots have six or fewer DOF. With six DOF, the robot can, within its work envelope, reach arbitrary positions and orientations. At the edge of the work envelope, a six-DOF robot can attain only one orientation. To increase the geometric dexterity of the manipulator, it is useful to consider robots with more than six DOF, i.e., redundant robots. These robots are highly dexterous and can use the extra DOF in many ways: avoidance obstacle, joint torque minimization, kinematic **singularity** (points where the manipulator cannot move in certain directions) avoidance, bracing strategies where part of the arm is braced against a structure, which raises the lowest structural resonant frequency of the arm, etc. While the **redundant manipulator** configuration has many desirable properties, the geometric complexity has limited their application in industry.

For any of the six standard robot configurations, the orientation capability of the major linkages is severely limited. Thus, it is critical to provide additional joints, known as the minor linkages, to provide the capability of varied orientations for a given position. Most robots include a three-DOF revolute joint wrist that is connected to the last link of the major linkages. The three revolute axes will be orthogonal and will usually intersect in a common point, known as the wrist center point. Then, the kinematic equations of the manipulator can be partitioned into locating the Cartesian position of the wrist center point and then determining the orientation of a Cartesian frame fixed to the wrist axes.

Conclusions

Each of the six standard configurations has specific advantages and disadvantages. When choosing a manipulator for a task, the properties of the manipulator geometry are one of the most important considerations. If the manipulator will be used for a wide variety of tasks, one may need to trade off performance for any given task for the flexibility that will allow the manipulator to work for the various tasks. In such a case, a more flexible geometry should be considered. The future of robotics will be interesting. With the steady increase in computational capabilities, the more complex geometries, including redundant and multiple robots, are beginning to see increased applications in industry.

Defining Terms

Degrees of freedom: The number of degrees of freedom (DOF) of a manipulator is the number of independent position variables that must be specified in order to locate all parts of the manipulator. For a typical industrial manipulator, the number of joints equals the number of DOF.

Kinematics: The kinematics of the manipulator refers to the geometric properties of the manipulator. *Forward kinematics* is the computation of the Cartesian position and orientation of the robot end-effector given the set of joint coordinates. *Inverse kinematics* is the computation of the joint coordinates given the Cartesian position and orientation of the end-effector. The inverse kinematic computation may not be possible in closed form, may have no solution, or may have multiple solutions.

Redundant manipulator: A redundant manipulator contains more than six DOF.

Singularity: A *singularity* is a location in the workspace of the manipulator at which the robot loses one or more DOF in Cartesian space, i.e., there is some direction (or directions) in Cartesian space along which it is impossible to move the robot end-effector no matter which robot joints are moved.

101.2 Dynamics and Control

R. Lal Tummala

The primary purpose of the robot control system is to issue commands to joint actuators to faithfully execute a planned trajectory in the **tool space**. This may involve position control when the manipulator is following a trajectory through free space or a combination of position and force control if the manipulator is to react continuously to contact forces at the tool or end-effector.

Control systems can operate either in open loop or closed loop. In open-loop systems, the output has no effect on the input. On the other hand, closed-loop systems continuously sense the output and make appropriate adjustments to the input in order to keep the output at the desired level.

The majority of the current industrial robots use the **independent joint control** method and close the loop around the joints of the robot. The desired joint positions corresponding to a tool trajectory are either taught by using a *teach box* or generated by solving an inverse kinematics problem. The independent joint control method, however, is effective only at low speeds. As the speeds increase, the coupling effects between the joints increase and warrant the inclusion of these effects in the controller development. Advanced controller development and implementation based on full dynamics is one of the active areas of current research. New advances in sensor technology, faster computers, advanced robots such as direct drive arms and industrial competition provide new opportunities and motivation for accelerating the development and implementation of advanced controllers for robots in the near future.

Independent Joint Control of the Robot

The independent joint control method assumes that a single joint of a robot is moving while all the other joints are fixed. A typical joint position control system is shown in Fig. 101.12, where the actuator used is a dc servomotor [Luh, 1983]. In general, any one or a combination of electric motors and hydraulic or pneumatic pistons can be used to move the joint through the desired positions. These motors may be connected directly to the joint or indirectly through gears, chains, cables, or lead screws. The desired joint positions that are inputs to the position loops are obtained from the trajectory planner. The actual position of the joint is obtained by using a position sensor, such as a potentiometer or an optical encoder. An amplifier is used for increasing the system gain, denoted by K_a. The velocity feedback K_v is used to reinforce the effect of back emf for controlling

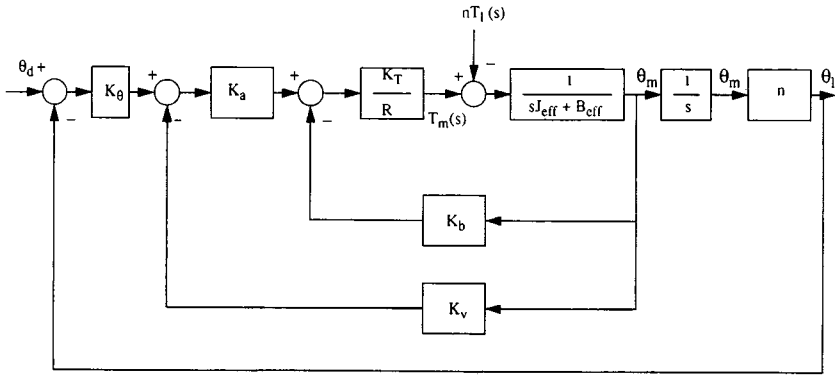

FIGURE 101.12 Closed-loop control of a robot joint. (*Source:* Adapted from J. Y. S. Luh, "Conventional controller design for industrial robots: A tutorial," *IEEE Trans. Systems, Man, Cybernetics,* vol. SMC-13, no. 3, June 1983. © 1983 IEEE.)

the damping of the system. This can be done either using a tachometer or computing the difference in angular displacements of the actuator shaft over a fixed time interval.

The design of the control system involves fixing the values of K_a and K_v to achieve the desired response. Consider the closed-loop transfer function of the system shown in Fig. 101.12 (assuming $nT_l = 0$),

$$\frac{\theta_l(s)}{\theta_d(s)} = \frac{nK_aK_TK_\theta}{s^2RJ_{\text{eff}} + s(RB_{\text{eff}} + K_TK_b + K_aK_TK_v) + nK_TK_aK_\theta} \tag{101.1}$$

where K_a = gain of the amplifier, K_T = torque constant of the motor, K_b = back emf constant, K_θ = position sensor constant (volts/rad), R = resistance of the motor winding (ohms), and n = gear ratio. θ_L = link position (rad) and θ_m = angular displacement at the actuator side (rad).

The effective inertia, J_{eff}, and damping, B_{eff}, are defined as

$$J_{\text{eff}} = J_m + n^2J_L \tag{101.2}$$

and

$$B_{\text{eff}} = B_m + n^2B_L \tag{101.3}$$

where J_m = total inertia on the motor side, B_m = damping coefficient at the motor side, J_L = inertia of the robot link, and B_L = damping coefficient at the load side.

This is a second-order system and stable for all values of K_a and K_v. The values of K_a and K_v are selected to achieve a desired transient response by fixing the damping ratio and the natural frequency of the system and are described below.

The characteristic equation for the above system is

$$s^2 + s\frac{RB_{\text{eff}} + K_TK_b + K_aK_TK_v}{RJ_{\text{eff}}} + \frac{nK_TK_aK_\theta}{RJ_{\text{eff}}} = 0 \tag{101.4}$$

This can be conveniently written as

$$s^2 + 2\zeta\omega_n s + \omega_n^2 = 0 \tag{101.5}$$

where the natural frequency ω_n and the damping ratio ζ of the system are given as

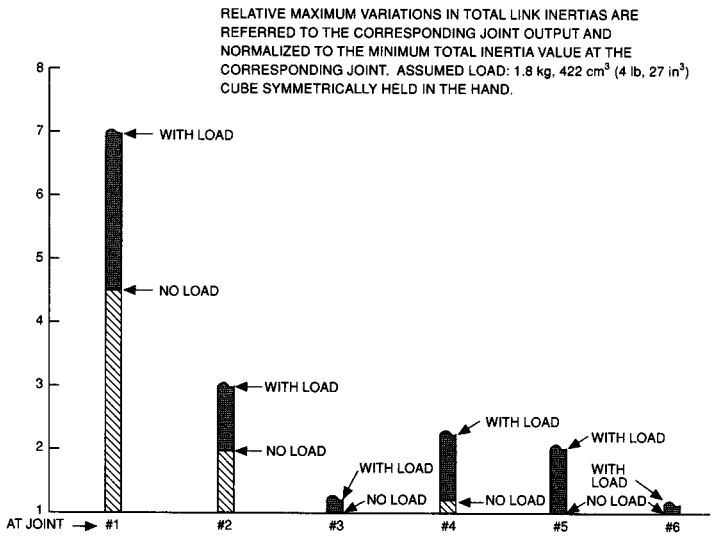

FIGURE 101.13 Variations of link inertias for JPL-Stanford manipulator. (*Source:* A.K. Bejczy, Jet Propulsion Lab, Pasadena, Calif., American Automatic Control Conference Tutorial Workshop, Washington, D.C., June 18, 1982.)

$$\omega_n = \sqrt{\frac{nK_aK_TK_\theta}{RJ_{\text{eff}}}} > 0 \tag{101.6}$$

$$\zeta = \frac{RB_{\text{eff}} + K_TK_b + K_aK_TK_v}{2\sqrt{nK_aK_TRJ_{\text{eff}}K_\theta}} \tag{101.7}$$

These systems are designed to operate with critical damping ($\zeta = 1$) because an underdamped system ($\zeta < 1$) has fast response but results in an overshoot, whereas an overdamped system ($\zeta > 1$) is too slow. However, this is not always possible, because the damping ratio given by Eq. (101.7) depends on B_{eff} and J_{eff} which vary during the actual operation of the manipulator. B_{eff} changes with age or repeated use of the manipulator. J_{eff} varies with the payload. For example, the variation of J_{eff} for the Stanford manipulator under various loading conditions is shown in Fig. 101.13. J_{eff} also varies with the configuration of the manipulator during the actual operation. So a compromise solution will be to design the controller such that $\zeta \geq 1$ throughout the intended operation.

The undamped natural frequency ω_n is selected to be no more than half the resonance frequency of the robot to avoid any structural damage to the robot [Paul, 1981]. These resonances are possible due to the flexibilities associated with the links of the robot and the shafts within the drive system, to name a few. These are called *unmodeled* resonances because they are not explicitly included in the model. In our case, if K_{eff} and J_{eff} are the effective stiffness and the inertias of the joint, respectively, then the resonance frequency ω_r is given by

$$\omega_r = \sqrt{\frac{K_{\text{eff}}}{J_{\text{eff}}}} \tag{101.8}$$

Since K_{eff} is difficult to estimate but constant for a given joint, we can experimentally determine the resonance frequencies for a known inertia and use this information for fixing the gain. Suppose ω is the resonance frequency for a given value of effective inertia J, then

$$\omega = \sqrt{\frac{K_{\text{eff}}}{J}} \tag{101.9}$$

To minimize the effects of unmodeled resonances, we use

$$\omega_n \leq \frac{\omega_r}{2} = \frac{\omega}{2}\sqrt{\frac{J}{J_{\text{eff}}}} \tag{101.10}$$

The selection of K_a and K_v depends on selecting ζ and ω_n. Using Eqs. (101.6) and (101.10), we can find an upper bound on K_a given by

$$K_a \leq \frac{J\omega^2 R}{4nK_T K_\theta} \tag{101.11}$$

The upper bound on K_v is obtained by setting $\zeta \geq 1$. Using Eq. (101.7),

$$RB_{\text{eff}} + K_T K_b + K_a K_T K_v \geq 2\sqrt{nK_a K_T R J_{\text{eff}} K_\theta} \tag{101.12}$$

Substituting the upper bound for K_a from Eq. (101.11), we get

$$K_v \geq \left(\omega R\sqrt{JJ_{\text{eff}}} - RB_{\text{eff}} - K_T K_b\right)\frac{4nK_\theta}{J\omega^2 R} \tag{101.13}$$

The steady-state errors to step position commands for the system shown in Fig. 101.12 are zero. However, in the presence of disturbances such as external load torques or **gravitational torques**, the system will have steady-state errors. For example, if T_L is the load torque as shown in Fig. 101.12, the available torque for the joint motion is given by

$$(J_{\text{eff}}s^2 + B_{\text{eff}}s)\,\theta_m(s) = T_m(s) - nT_L(s) \tag{101.14}$$

Using the superposition property, we get

$$\theta_L(s) = F_1(s)\theta_d(s) + F_2(s)T_L(s) \tag{101.15}$$

where

$$\begin{aligned} F_1(s) &= \frac{nK_a K_T K_\theta}{\Omega(s)} \\ F_2(s) &= -\frac{n^2 R}{\Omega(s)} \end{aligned} \tag{101.16}$$

$$\Omega(s) = RJ_{\text{eff}}s^2 + (RB_{\text{eff}} + K_b K_T + K_v K_a K_T)s + nK_a K_T K_\theta$$

Now if $T_L(s) = C_L/s$ and $\theta_d(s) = C_\theta/s$, then the steady-state error is

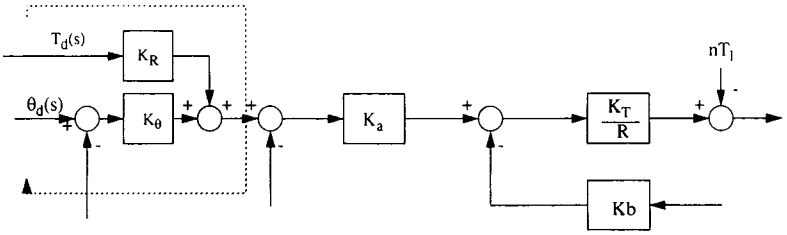

FIGURE 101.14 Feedback compensation method for disturbances. (*Source:* Adapted from J. Y. S. Luh, "Conventional controller design for industrial robots: A tutorial," *IEEE Trans. Systems, Man, Cybernetics,* vol. SMC-13, no. 3, June 1983. ©1983 IEEE.)

$$e_{ss} = \frac{nC_L R}{K_a K_T K_\theta} \tag{101.17}$$

Since the value of K_a has an upper bound, this error cannot be made arbitrarily small. A possible way to reduce this error is to add a feedforward term, as shown in Fig. 101.14 [Luh, 1983]. The feedforward signal $T_d(s)$ is chosen such that the steady-state error is zero. In this case,

$$T_d(s) = \frac{R}{K_T K_a K_R} n\hat{T}_L(s) \tag{101.18}$$

Similar considerations apply for other disturbances such as frictional torques and gravitational torques. Notice from Eq. (101.18) that the feedforward signal is a function of the estimated torque. The burden of determining these torques should not be underestimated. The other factor that was not mentioned earlier is the centrifugal torque, a nonlinear function of velocity. In the case of positioning applications, the velocity tends to zero as $t \to \infty$. However, if the robot is required to follow a conveyor with constant speed, then the input is a velocity. In this case, the centrifugal contribution will affect the steady-state velocity error. A feedforward compensation can be used in this case as well. Another method of compensating for the steady-state errors caused by gravitational and load torque disturbances is by adding an integral feedback (PID control), which of course increases the order of the system. The system is no longer stable for all values of the gains and thus adds another constraint in the selection of K_a and K_v.

So far we have considered the control of one joint of the robot while the other joints are fixed. Implementation of this control by successively positioning each joint while the other joints are fixed slows the robot operation and can also result in awkward hand motions, which is undesirable especially when the robot is supposed to follow a continuous path. Simultaneous fast motion of the joints, on the other hand, requires the inclusion of dynamic interactions between the joints. The controllers designed without considering these dynamic interactions tend to make the arm move slower and can potentially cause overshoots, oscillations, and path errors. To estimate the dynamic effects, one needs to obtain the equations of motion (dynamic models) of the robot. These equations are, in general, complex and take the form of coupled nonlinear differential equations.

Dynamic Models

Two of the most popular methods used to obtain dynamic models of the robot are the *Newton-Euler method* and the *Lagrange-Euler method*. The equations obtained using Lagrangian formulation are more suitable for the application of modern control theory than the recursive equations obtained using the Newton-Euler method. In the Lagrangian formulation, the dynamic models are obtained using kinetic and potential energies associated with the rigid bodies in motion. The derivation is systematic and conceptually simple. This method yields closed-form dynamic equations that explicitly express joint variables in terms of joint torques. To arrive

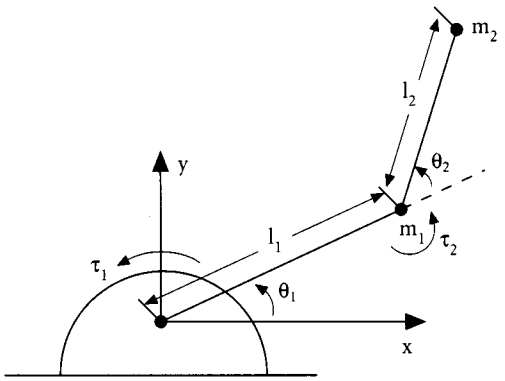

FIGURE 101.15 Two-degree-of-freedom planar manipulator.

at these equations, one starts with a set of generalized coordinates q_i, $i = 1, 2, 3, \ldots, n$, that completely locate the dynamic system and finds the total kinetic energy K and potential energy P of the system [Paul, 1981]. Then the equations of motion are given by

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = T_i \qquad \text{for } i = 1, 2, 3 \ldots n \tag{101.19}$$

where T_i is the generalized force and $L(q,q\cdot) = K - P$ is the Lagrangian. A simple example is given next to illustrate these ideas.

Example. Consider a planar arm with two degrees of freedom, shown in Fig. 101.15. For simplicity, we assume that the masses m_1 and m_2 of the links are represented by point masses at the end of the links. The link lengths are l_1 and l_2, respectively. The variables θ_1 and θ_2 are the joint angles. We know that the kinetic energy of a mass m moving at a linear velocity v is given by $1/2\ mv^2$ and the potential energy associated with a mass m located at a height h in a gravitational field is given by mgh, where g is the gravitational constant.

The kinetic energy K_1 for mass m_1 is found by observing that

$$\begin{aligned} x_1 &= l_1 \cos\theta_1 \\ y_1 &= l_1 \sin\theta_1 \\ v_1^2 &= \dot{x}_1^2 + \dot{y}_1^2 \\ K_1 &= \tfrac{1}{2} m_1 l_1^2 \dot{\theta}_1^2 \end{aligned} \tag{101.20}$$

Similarly, the kinetic energy K_2 for mass m_2 is given by

$$\begin{aligned} K_2 &= \tfrac{1}{2} m_2 v_2^2 \\ v_2^2 &= \dot{x}_2^2 + \dot{y}_2^2 \end{aligned} \tag{101.21}$$

From Fig. 101.15, we have

$$\begin{aligned} x_2 &= l_1 \cos\theta_1 + l_2 \cos(\theta_1 + \theta_2) \\ y_2 &= l_1 \sin\theta_1 + l_2 \sin(\theta_1 + \theta_2) \\ v_2^2 &= l_1^2\dot{\theta}_1^2 + l_2^2(\dot{\theta}_1 + \dot{\theta}_2)^2 + 2l_1 l_2 \cos\theta_2(\dot{\theta}_1^2 + \dot{\theta}_1\dot{\theta}_2) \end{aligned} \tag{101.22}$$

The potential energies for the masses m_i, $i = 1, 2$, are given by

$$\begin{aligned} P_1 &= m_1 g\, l_1 \sin\theta_1 \\ P_2 &= m_2 g[l_1 \sin\theta_1 + l_2 \sin(\theta_1 + \theta_2)] \end{aligned} \tag{101.23}$$

The next step is to form the Lagrangian,

$$L = \sum_{i=1}^{2} K_i - P_i$$

The dynamic model of the robot is obtained by using Eq. (101.19),

$$\tau_1 = \frac{d}{dt}\left[\frac{\partial L}{\partial \dot{\theta}_1}\right] - \frac{\partial L}{\partial \theta_1} \tag{101.24}$$

$$\tau_2 = \frac{d}{dt}\left[\frac{\partial L}{\partial \dot{\theta}_2}\right] - \frac{\partial L}{\partial \theta_2} \tag{101.25}$$

where τ_i, $i = 1, 2$, are the joint torques.

The equations for a general n-degrees-of-freedom robot can be derived by following the same procedure and are compactly written in the generalized coordinates q as

$$D(q)\ddot{q} + H(q, \dot{q}) + V\dot{q} + G(q) = \tau \tag{101.26}$$

where $D(q)$ is the $n \times n$ inertia matrix, $H(\cdot)$ is an $n \times 1$ vector describing the centripetal and Coriolis terms, V is the coefficient of friction and $G(q)$ is an $n \times 1$ vector describing gravitational torques. For the above example, $q_1 = \theta_1$ and $q_2 = \theta_2$. Thus,

$$D(\theta) = \begin{bmatrix} l_2^2 m_2 + 2 l_1 l_2 m_2 \cos\theta_2 + l_1^2 (m_1 + m_2) & l_2^2 m_2 + l_1 l_2 m_2 \cos\theta_2 \\ l_2^2 m_2 + l_1 l_2 m_2 \cos\theta_2 & l_2^2 m_2 \end{bmatrix} \tag{101.27}$$

$$H(\theta, \dot{\theta}) = \begin{bmatrix} -m_2 l_1 l_2 \sin\theta_2 \dot{\theta}_2^2 - 2 m_2 l_1 l_2 \sin\theta_2 (\dot{\theta}_1 \dot{\theta}_2) \\ (m_2 l_1 l_2 \sin\theta_2)\dot{\theta}_1^2 \end{bmatrix} \tag{101.28}$$

$$G(\theta) = \begin{bmatrix} m_2 l_2^2 g \cos(\theta_1 + \theta_2) + (m_1 + m_2) l_1 g \cos\theta_1 \\ m_2 l_2 g \cos(\theta_1 + \theta_2) \end{bmatrix} \tag{101.29}$$

where

$$\theta = \begin{bmatrix} \theta_1 \\ \theta_2 \end{bmatrix} \quad \dot{\theta} = \begin{bmatrix} \dot{\theta}_1 \\ \dot{\theta}_2 \end{bmatrix} \quad \ddot{\theta} = \begin{bmatrix} \ddot{\theta}_1 \\ \ddot{\theta}_2 \end{bmatrix} \tag{101.30}$$

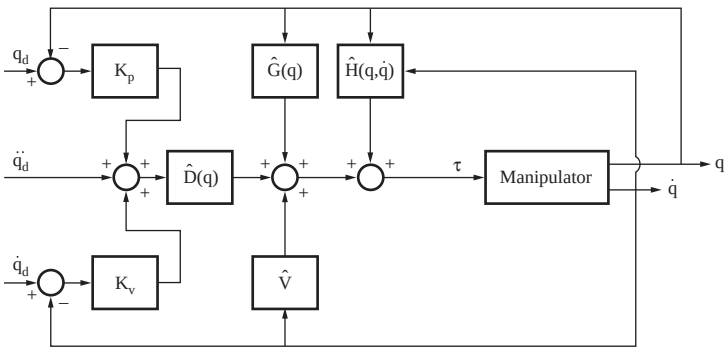

FIGURE 101.16 Computed torque method.

Notice that the inertia matrix $D(\theta)$ is a function of only the position θ. In general, the inertia matrix is symmetric and positive definite and thus invertible. The diagonal elements of this matrix represent the effective inertias at the respective joints, while the off-diagonal elements represent the coupling inertias. For example, the term $m_2l^2_2$ represents the effective inertia at the joint 2, and the term $l^2_2m_2 + l_1l_2m_2 \cos\theta_2$ represents the coupling inertia between joints 1 and 2, i.e., the effect of acceleration of joint 1 on joint 2.

The terms in the matrix $H(\cdot)$ contain all the terms associated with the **centripetal** and **Coriolis forces**. The terms that depend upon the square of the joint velocity are *centripetal forces*. The terms that contain the product of joint velocities are *Coriolis forces*. In our example, the term $-(m_2l_1l_2\sin\theta_2)\,\dot{\theta}^2_2$ represents the centripetal force acting at joint 1 due to the velocity at joint 2. Similarly, the term $(m_2l_1l_2\sin\theta_2)\,\dot{\theta}^2_1$ represents the centripetal force acting at joint 2 due to the velocity at joint 1. The term $-(2m_2l_1l_2\sin\theta_2)\,\dot{\theta}_1\dot{\theta}_2$ is the Coriolis force acting at joint 2 due to the velocities at joints 1 and 2.

The term $G(\theta)$ contains all the terms involving gravitational constant g. Note that these terms depend only on the position of the arm in the gravitational field. If the arm is operating in the gravity-free environment, then these terms become zero. The term $V\cdot\theta$ reflects the frictional forces present in the robot system. In our example, these terms are assumed to be zero. However, in practical robots a substantial amount of friction stiction can be present that if not considered will overestimate the torque available for accelerating the joints.

The above example illustrates that the existence of significant coupling between the joints, if ignored, can cause positioning and tracking errors when the joints are moving simultaneously. However, all these coupling terms become small at low speeds. In this case, independent joint control with appropriate compensations as discussed earlier may be quite adequate. As the operational speeds increase, one needs to take into consideration the full dynamics in the development of control algorithms.

Computed Torque Methods

Several control algorithms that incorporate dynamics have been developed. Many of these are variations of the computed torque method, which is similar to the feedback linearization method used for the control of nonlinear systems [Spong and Vidyasagar, 1989]. In the computed torque method shown in Fig. 101.16, the required input forces or torques are computed as follows:

$$\tau = \hat{D}(q)\left[\ddot{q}_d + K_v(\dot{q}_d - \dot{q}) + K_p(q_d - q)\right] + \hat{H}(q, \dot{q}) + \hat{V}\dot{q} + \hat{G}(q) \qquad (101.31)$$

where K_v and K_p are diagonal matrices with diagonal elements representing velocity and position gains. If this torque is chosen as the input in Eq. (101.26), and assuming that the model is accurate, i.e., $\hat{D}(q) = D(q)$, $\hat{H}(q,\dot{q}) = H(q,\dot{q})$ etc., we get

$$D(q)\left[\ddot{q}_d - \ddot{q} + K_v(\dot{q}_d - \dot{q}) + K_p(q_d - q)\right] = 0 \qquad (101.32)$$

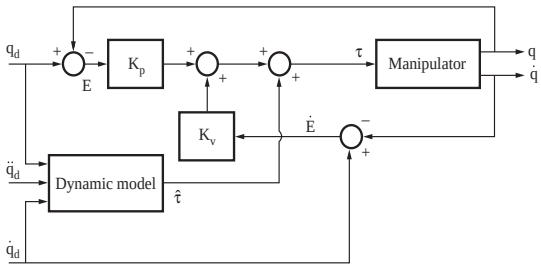

FIGURE 101.17 Dynamic model outside the feedback loop.

Since the inertia matrix, $D(q)$ is nonsingular, we get

$$\ddot{E} + K_v\dot{E} + K_pE = 0 \tag{101.33}$$

which represents a set of decoupled equations where the error $E = q_d - q$. If we select the values of K_v and K_p such that the characteristic roots of Eq. (101.33) have negative real parts, then E approaches zero asymptotically. Effectiveness of this algorithm depends heavily on two factors: (1) the accuracy of the model and (2) the ability to compute the coefficient matrices of the equations of motion in real time.

If the model is not an exact representation of the system, Eq. (101.33) becomes

$$\ddot{E} + K_v\dot{E} + K_pE = R(\ddot{q}, \dot{q}, q) \tag{101.34}$$

where R is the mismatch between the model and the actual dynamics of the robot. This is given by

$$R(\ddot{q}, \dot{q}, q) = \hat{D}^{-1}(q)[(D(q) - \hat{D}(q))\ddot{q} + (H(q, \dot{q}) - \hat{H}(q, \dot{q})) + G(q) - \hat{G}(q)] \tag{101.35}$$

Observe that if the model is an exact match, Eq. (101.34) leads to Eq. (101.33) and the convergence of q to q_d can be guaranteed.

Even if the model is accurate, the ability to compute the dynamics at sample rate (60 to100 Hz is typical) is still a problem. It is estimated that the Stanford manipulator requires 2000 floating-point additions and 1500 multiplications to compute all joint torques. A way to overcome this problem is to use the control scheme where the model is outside the feedback loop shown in Fig. 101.17, [Craig, 1989]. In this case, the desired torques are calculated *a priori* using the model given in Eq. (101.26) as follows:

$$\hat{\tau} = \hat{D}(q_d)\ddot{q}_d + \hat{H}(q_d, \dot{q}_d) + \hat{V}\dot{q}_d + \hat{G}(q_d) \tag{101.36}$$

Then from Fig. 101.17, we get

$$D\ddot{q} + H(q, \dot{q}) + V\dot{q} + G(q) = \hat{\tau} + K_v(\dot{q}_d - \dot{q}) + K_p(q_d - q) \tag{101.37}$$

If the mismatch between the model and the robot is small, then we get

$$D(\ddot{q}_d - \ddot{q}) + K_v(\dot{q}_d - \dot{q}) + K_p(q_d - q) = 0 \tag{101.38}$$

Since the inertia matrix is nonsingular, we can rewrite the above equation as

$$\ddot{E} + D^{-1}K_v\dot{E} + D^{-1}K_pE = 0 \tag{101.39}$$

where $E = q_d - q$ and can be made to go to zero asymptotically by selecting the gains K_v and K_p appropriately. This method has a definite advantage over the earlier method because the model need not be evaluated in real time. However, it does not provide complete decoupling because the inertia matrix is not diagonal. Furthermore, since the gains are continuously modified by the inertia matrix, the response is a function of the configuration and the payload. A way to circumvent this problem is to continuously modify the gains K_v and K_p. This obviously suggests an adaptive control approach.

Adaptive Control

In an attempt to reduce the errors caused by the mismatch of the model with the real system, several adaptive control schemes have been investigated. Model reference adaptive control (MRAC) is one such approach. Dubowsky and DesForges [1979] were the first to use this method for manipulator control. This method is illustrated in Fig. 101.18. They have chosen a linear second-order system with desired ζ and ω_n as a reference model for each joint. Their scheme works as long as the manipulator changes configuration slowly relative to the adaptation rate. Since then several researchers have extended the concepts well developed for linear systems to manipulator control. Two aspects that are central to all these methods are identification of the plant or its parameters and use of this new information to update the control law. An extensive review of recent work in this area is given by Craig [1988] and Hsia [1986]. In spite of many approaches suggested for this problem, no attempt has been made to implement these methods by the robot industry.

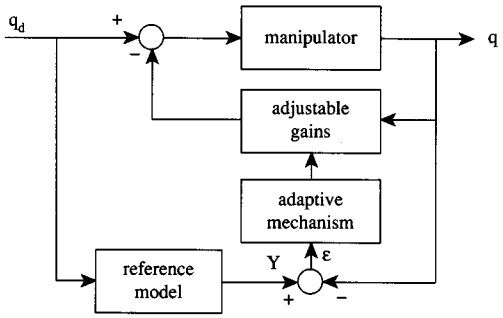

FIGURE 101.18 Model reference adaptive control.

Resolved Motion Control

So far we have discussed the methods to achieve desired joint motion. In practice, the desired motion is specified in terms of hand motions. Resolved motion control methods such as *resolved motion rate control (RMRC)* and *resolved motion acceleration control* have been suggested [papers by Whitney and Luh et al. in Brady et al., 1982]. In these methods, the joint motions are coordinated to achieve coordinated hand motion along any world coordinate axis. Given the relationship between the position and orientation of the hand, $x(t)$, and the joint coordinates $q(t)$ as

$$x(t) = f(q(t)) \tag{101.40}$$

then RMRC transforms the linear and angular velocity of the hand (end effector) to joint velocities using the relationship

$$\dot{q} = J^{-1}(q(t))\dot{x} \tag{101.41}$$

where $J(q(t))$ is the **Jacobian** matrix. Using the above equation, the combination of the joint rates for a given hand motion can be obtained. However, special consideration must be given when the inverse of the Jacobian matrix does not exist. This occurs when the dimension of $x(t)$ and $q(t)$ are not the same (robots with redundant

degrees of freedom) or when a nonredundant robot loses one or more degrees of freedom in its workspace (singular configurations).

Resolved motion acceleration control extends the concepts of RMRC by including desired acceleration of the hand as well. Differentiating Eq. (101.41) twice with respect to time, we get

$$\ddot{x} = J(q)\ddot{q} + \dot{J}(q, \dot{q})\dot{q}(t) \tag{101.42}$$

where $\ddot{x}$ is the acceleration of the hand and $\ddot{q}$ is the joint acceleration. To reduce the position and orientation errors of the hand to zero,

$$\ddot{x}(t) = \ddot{x}_d(t) + K_v[\dot{x}_d(t) - \dot{x}(t)] + K_p[x_d(t) - x(t)] \tag{101.43}$$

By selecting the gains K_p and K_v we can force the error $e(t) = x_d(t) - x(t)$ to zero as before. The desired joint acceleration can be obtained by from Eqs. (101.41) and (101.42), and is given as follows:

$$\ddot{q}(t) = J^{-1}(q)\begin{bmatrix} \ddot{x}_d(t) + K_v\left(\dot{x}_d(t) - \dot{x}(t)\right) \\ + K_p\left(x_d(t) - x(t) - \dot{J}(q, \dot{q})\dot{q}(t)\right) \end{bmatrix} \tag{101.44}$$

Since the inverse of the Jacobian is involved, this method suffers from drawbacks similar to the RMRC method.

Compliant Motion

The position control methods described above are not sufficient when the robot has to react continuously to contact forces at the end effector. Consider, for example, a simple operation of sliding a block of wood on a table along a desired path. Pure position control will not work because any small errors orthogonal to the table may result in the block either losing contact with the surface of the table or forcing the block through the table, which can either damage the table or the end effector. To perform this task, we need to control the position in the plane of the table and control force normal to the table. This is called *compliant motion control* and is required whenever the robot is in contact with its "environment." To perform the above task, for example, a coordinate system called a *compliance frame* or *constraint frame* is defined such that at each instant and along each axis the task can be expressed as a pure position control or pure force control. Suppose we associate a coordinate system with the z-axis normal to the table surface. Then to perform this task, we need to control the position along the x and y directions and force control in the z direction to maintain continuous contact with the table surface. In this case, the position along the z direction is not controlled because one cannot control both position and force in the same direction, just as we cannot control both voltage and current across a resistor. Hence, this framework will provide a natural separation between the axes that need to be position controlled and the axes that need to be force-controlled. This is the idea behind the hybrid position/force control developed by Raibert and Craig [1981]. Another approach for complaint motion control is the impedance control [Hogan, 1985]. Impedance control does not control the end-point position or force directly, rather a desired dynamic relationship between position and force (mechanical impedance). For a good comparison between these two approaches, the reader is referred to Asada and Slotine [1986].

In general, compliance motion control is very important whenever the robot is required to make contact with its "environment." This is true for many assembly tasks. Apart from the active methods of control discussed above, passive methods can be used to introduce the desired compliance. One such passive scheme is the use of a *remote center compliance* (RCC) device developed at Draper Laboratories. The RCC is a purely mechanical device consisting of a spring with six degrees of freedom that is inserted between the wrist and the end effector. By adjusting the stiffness of the springs, various levels of compliance can be obtained. However, passive methods suffer from lack of programmability achieved through active methods. Active control methods, however, require

sensing of contact forces and torques at the end effector. *Joint torque sensors, wrist sensors, fingertip tactile sensors,* and *force pedestals* can be used for this purpose.

Joint torque sensors, as the name implies, are placed at the joints of the manipulator. If **F** represent the vector of forces at the end effector, then the corresponding vector of joint torques is obtained by using $\tau = [J(q)]^T \mathbf{F}$, where $J(q)$ is the Jacobian and q are the generalized joint coordinates. Joint torque sensing has some drawbacks. First, to obtain the endpoint forces **F**, the Jacobian which changes with the configuration has to be inverted in real time. Second, the sensors at the joints not only measure the forces and torques applied at the hand but also those applied at the other points of the manipulator. *Wrist sensors* are better at reducing this uncertainty because they are placed close to the end effector and below the last powered joint of the manipulator. Several wrist sensors are available commercially with necessary electronics to obtain force/torque measurements at high speeds suitable for real-time force control. Another method for providing information about the gripping forces is by mounting *tactile sensors* at the fingertips. However, these may not be suitable in situations where high gripping forces are required. *Force pedestals* are employed when a common platform is used for many tasks. In this case, the platform is instrumented to measure interacting forces and torques.

Flexible Manipulators

The discussion so far assumed that the links of the robot are rigid. These are designed intentionally to minimize the vibrations. Most of the present-day industrial robots fall into this category. These robots, however, cannot handle objects heavier than about 5% their weight. In contrast, lightweight flexible arms consume less energy, achieve faster speeds, and can potentially perform precision assembly tasks. However, it is not possible to move these arms quickly without the onset of structural vibrations due to inadequate structural damping. Efforts have been underway to increase the damping without substantial increase in weight by using composite materials or actively controlling the vibrations, or both.

Defining Terms

Centripetal forces: Forces that are present during the robot motion. They depend upon the square of the joint velocities of the robot and tend to reduce the power available from the actuators.

Compliant motion: Motion of the manipulator (robot) when it is in contact with its "environment," such as writing on a chalkboard or assembling parts.

Coriolis forces: Forces/torques that depend upon the product of joint velocities.

Gravitational torques: Torques that depend upon the position of the robot in the gravitational field.

Independent joint control: A method where each joint is controlled as a single input/single output system. The coupling effects due to motion of other joints are either ignored or treated as disturbances.

Inverse kinematics: A model that maps end-effector positions and orientations to joint variables.

Jacobian of the manipulator: A matrix that maps the joint velocities into end effector velocities.

Tool space: Space of a 6×1 vector representing the positions and orientations of the tool or end effector of the robot.

101.3 Applications

Nicholas G. Odrey

An important utilization of robotics has traditionally been in manufacturing operations. By their very design and reprogrammable features, robots have enhanced the capabilities for flexibility in automation. Robot applications initially focused on replacing repetitive, boring, and hazardous manual tasks. Such initial applications required minimal control, programming, or sensory capability and have evolved to applications that use enhanced controller designs and sophisticated sensory capability. The first recorded commercial application of an industrial robot was at the Ford Motor Company in 1961 that used a Unimate robot to unload a die-casting machine. Since then, robots have been used in various manufacturing processes, fabrication, and assembly operations. Current issues relate to the degree of integration with the total manufacturing system and to the degree of autonomy and/or complexity one wishes to implement for a robotic system. In potential applications, it is necessary to determine the degree of sophistication that one wishes to implement coupled with a detailed economic analysis. The focus in this section is to present a practical implementation strategy for robots within a manufacturing environment, to review particular applications, and to discuss issues relevant to enhancing robot applications on the manufacturing shop floor. Such issues include sensors and their integration within an intelligent control system, the development of grippers for enhanced dexterity, and integration topics within a flexible **cellular manufacturing** system.

Justification

Reprogrammable automated devices such as robots provide the flexible automation capability for modern production systems. To evaluate a potential robotic application within a manufacturing environment, both technical and economic issues must be addressed. Typical technical issues include the choice of the number of **degrees of freedom** to perform a task, the level of controller and programming complexity, end effector and sensor choices, and degree of integration within the overall production system. Economic issues have typically been addressed from a traditional point of view, but it is important to note that other criteria should also be evaluated before a final decision is made to implement a robotic system. Such criteria may be both quantitative and qualitative.

Traditional economic approaches analyze investments and costs to compare alternative projects. Three methods are commonly used: (1) payback period method, (2) equivalent uniform annual costs (EUAC) method, and (3) return on investment (ROI). The payback method balances initial investment cost against net annual cash flow during the life of the project to determine the time required to recoup the investment. Many corporations today require relatively short (1- to 3-year) payback periods to justify an investment. In the current environment with the drive toward shortened product life cycles, it is not unusual to see payback period requirements of no greater than 1 year. The payback technique does not consider the time value of money and should be considered only as a first part attempt at justification.

The EUAC and ROI methods consider the time value of money (continuous or discrete compounding) and convert all investments, cash flows, salvage values, and any other revenues and costs into their equivalent uniform annual cash flow over the anticipated life of the project. In the EUAC method, the interest rate is known and set at a minimal acceptable rate of return, whereas the ROI method has the objective to determine the interest rate earned on the investment. Details to such techniques are presented in various engineering economy texts such as those by White et al. [1977] and Thuesen and Fabrycky [1989].

Various more sophisticated approaches have been taken to justify robotic and automated system implementation. Estimates of indirect factors such as taxes, capital gain or losses, variability consideration, and associated expected value analysis along with **decision tree analysis** and Markovian decision analysis [Michel, 1986] are but a few methods to justify such systems. Other factors to be recognized in robotic justification are that robots are reusable from one project to the next and there is a difference in production rates for a robotic implementation over a manual process. A changeover from a manual method to a robotic implementation would have the potential to affect revenues for any project. Many companies have also developed standard investment analysis forms for an economic evaluation of a proposed robot project. These forms are helpful in displaying costs and savings for a project. Groover et al. [1986] presents one such proposed form and gives several references to examples of forms specifically designed for projects devoted to robotics and related automation areas.

The aforementioned techniques are important in performing an economic justification for a proposed robotic installation. Still, in general, there are other issues that should be included in the overall analysis. These issues are of particular importance if one is considering installing a more comprehensive system such as a flexible manufacturing system that may include many robots and automated systems. As noted by Proth and Hillion [1990], these issues give rise to criteria that are both quantitative and qualitative. Quantitative criteria include not only reduced throughput time and work-in-process inventory but also criteria related to increased productivity coupled with fewer resources. Another measurable criterion is the reduction in management and monitoring staff as a result of smaller quantities and automatic monitoring by sensors. Quality improvement can also be measured both quantitatively and qualitatively. Qualitative benefits from quality improvement can include increased customer satisfaction, increased competitiveness, simplified production management, and other factors. It should be noted that any benefits and cost reductions for installation of an automated system are difficult to evaluate and reflect a long-term commitment of the corporation.

Strategic factors should be incorporated in the overall economic justification process, but they are difficult to access and incorporate due to their inherent complexity. Verk [1990] proposes a general framework that attempts to integrate both qualitative and quantitative factors in an economic justification process. The approach taken is being tested at Cincinnati Milacron and the Mazak Corporation.

Implementation Strategies

A logical approach is a prerequisite to robotic implementation within a manufacturing firm. The following steps have been proposed by Groover et al. [1986] to implement a robotic system:

1. Initial familiarization with the technology.
2. Plant survey to identify potential applications.
3. Selection of an application(s).
4. Selection of a robot(s) for the application(s).
5. Detailed economic analysis and capital authorization.
6. Plan and engineer the installation.
7. Installation.

It should be noted that a particular company may have nuances that could modify the above steps. Also of note is that the underlying issue is systems integration and any robotic application should consider total system impact as well as include the equipment, controllers, sensors, software, and other necessary hardware to have a fully functional and integrated system. Another good source of information on robot implementation is the text by Asfahl [1992].

Critical factors for the introduction of robotics technology within a corporation are management support and production personnel acceptance of the technology. Companies such as General Electric have developed checklists to determine the degree of workforce acceptance. Given that the above two factors are met, a plant survey is conducted to determine suitability for automation or robotic implementation. Two general categories of robot applications may be distinguished: (1) a project for a new plant, or (2) placing a robot project in an existing facility. We focus here on the latter category.

General considerations for a robot installation include hazardous, repetitive, or uncomfortable working conditions, difficult handling jobs, or multishift operations. High- and medium-volume production typically has many examples of repetitive operations. It can prove useful to investigate injury (particularly muscular) reports with medical personnel and ergonomics experts to identify potential manual operations that may be alleviated with the aid of robotics or automation. Multishift operations associated with high demand for a product are likely candidates for robot applications. As compared to manual work that typically has a high variable labor cost, a robot substitution would have a high fixed cost which can be distributed over the number of shifts plus a low variable cost. The overall effect of a robot application would then be to reduce the total operating cost.

Once potential robot applications are identified, one typically must determine which application is the best to pursue. Economic and technical criteria must both be considered. Usually, a simple application that is easy to integrate into the overall system is a good initial choice. A fundamental rule is to implement any straightforward application to minimize the risk of failure. The General Electric Company has been successful in choosing robot applications by considering the following technical criteria:

- Operation is simple and repetitive.
- Cycle time for the operation is greater than five seconds.
- Parts can be delivered with the proper POSE (position and orientation).
- Part weight is suitable (typical upper weight limit is 1100 lb).
- No inspection is required for the operation.
- One to two workers can be replaced in a 24-hour period.
- Setups and changeovers are infrequent.

A choice of a robot for a selected application can be a very difficult decision. Vendor information, expert opinion, and various sources such as the *Robotics Product Database* [Flora, 1989] can aid in the selection. Selection needs to consider the appropriate combination of parameters suitable for the application. These parameters or technical features include the degrees of freedom, the type of drive and control system, sensory capability, programming features, accuracy and precision requirements, and load capacity of the selected robot. Various point or weighing schemes can be applied to rate different robot models.

The planning and engineering of a robot installation must address many issues, including the operational methods to be employed, workcell design and its control, the choice or design of end effectors and other fixturing and tooling requirements, and sensory and programming requirements. In addition, one needs to focus on safety considerations for the workcell as well as overall systems integration. Computer-aided design (CAD) is very helpful to study potential **machine interference** and various layout problems as well as estimating various performance parameters. Various commercial CAD software packages exist to analyze such problems. One such example is McAuto's PLACE System. The study at this stage should consider the basic purpose and function of the planned workcell. Consideration needs to be given to analyzing the cycle time that is basic to determining the production rate. An approach developed by Nof and Lechtman [1982], called Robot Time and Motion (RTM), is useful for analyzing the cycle time of robots.

Applications in Manufacturing

Robots have proven to be beneficial in many industrial and nonindustrial environments. Here, we focus on applications within a traditional manufacturing (shop floor) setting and, in particular, on applications which fall into the following three broad categories:

1. Material handling and machine loading/unloading
2. Processing
3. Assembly and inspection

The discussion that follows is not all-inclusive but rather is intended to present (1) an overview of such applications and (2) a few of the more current topics which are impacting the shop floor, particularly as related to flexible manufacturing systems. In the latter case, such issues include developments in **sensor integration**, mobility, sensory interactive grippers/hands, and issues pertaining to intelligent machines and robots. An important reference for many if not all robotic topics is the *International Encylopedia of Robotics* edited by Dorf [1988].

Material Handling and Machine Loading/Unloading

Applications in this category pertain to the grasping and movement of a workpart or item from one location to another. General considerations for such applications pertain to the gripper design, distances moved, robot weight capacity, the POSE, and robot-dependent issues pertaining to the configuration, degrees of freedom, accuracy and precision, the controller, and programming features. POSE information is particularly important if there are no sensors (e.g. vision) to provide such information prior to pick-up. Specialized grippers have been designed for various applications in all three of the listed categories [Engelberger, 1980]. Quick-change wrists enabling the robot to change grippers (or tools in processing applications) during the production cycle have also become more common since their introduction [Vranich, 1984], as have multiple grippers mounted turret-like at the end of a robotic arm. Various factors need to be considered in the selection and design of grippers. One such checklist of factors can be found in Groover et al. [1986]. It should be noted that certain applications may require a high degree of accuracy and precision whereas others do not. Higher requirements result in more sophisticated drive mechanisms and controllers with associated increased costs.

Material handling applications are typically unsophisticated with minimal control requirements. Two- to four-degrees-of-freedom robots may be sufficient in many tasks. More sophisticated operations such as palletizing may require up to six degrees of freedom with stricter control requirements and more programming features. Various criteria that have proved to contribute to the success of material handling and machine load/unload applications can be found in Groover et al. [1986]. In addition, excellent examples and case studies on robotic loading/unloading are given in the text by Asfahl [1992].

Processing

Robotic processing applications are considered here to be those applications in which a robot actually performs work on a part and requires that the end effector is a tool. Examples include spot welding electrodes, arc welding, and spray-painting nozzles. The most common robotic applications in manufacturing processes are listed in Table 101.2 [Odrey, 1992a]. Many more processing applications are possible.

TABLE 101.2 Most Common Robotic Applications in Manufacturing Processes

Spot welding	Grinding
Continuous arc welding	Deburring
Spray coating	Polishing
Drilling	Wire brushing
Routing	Riveting
Waterjet cutting	Laser machining

Spot welding and arc welding represent two major applications of industrial robots. It has been noted that industrial robot usage in welding tasks may be as high as 40% [Ross, 1984]. Spot welding robots have found wide use in automotive assembly lines and have been found to improve weld quality and provide more consistent welds and better repeatability of weld locations. Continuous arc welding is a more difficult application than spot welding. Welding of dissimilar materials, variations in weld joints, dimensional variations from part to part, irregular edges, and gap variations are some of the difficulties encountered in the continuous arc welding processes. Typical arc welding processes include gas metal arc welding (GMAW), shielding metal arc welding (SMAW), i.e., the commonly known "stick" welding, and submerged arc welding (SAW). The most heavily employed

robotic welding process is GMAW in which a current is passed through a consumable electrode and into a base metal, and a shielding gas (typically CO_2, argon, or helium) minimizes contamination during melting and solidification.

In welding, a worker can compensate automatically by varying welding parameters such as travel speed, deposition rate by current adjustment, weave patterns, and multiple welds where required. Duplicating human welding ability and skill requires that industrial robots have sensor capability and complex programming capability. A wide variety of sensors for robotic arc welding are commercially available and are designed to track the welding seam and provide feedback information for the purpose of guiding the welding path.

Two basic categories of sensors exist to provide feedback information: noncontact sensors and contact sensors. Noncontact sensors include arc-sensing systems and machine vision systems. The former, also referred to as a *through-the-arc* system, uses feedback measurements via the arc itself. Specifically, measurements for feedback may be the current (constant-voltage welding) or the voltage (constant-current welding) obtained by programming the robot to perform a weave pattern. The motion results in measurements that are interpreted as vertical and cross-seam position. Adaptive positioning is possible by regulating the arc length (constant-current systems) as irregularities in gaps or edge variations are encountered.

Vision systems track the weld seam, and any deviations from the programmed seam path are detected and fed back to the controller for automatic tracking. Single-pass systems detect variations and make corrections in one welding pass. Double-pass systems first do a high-speed scan of the joint to record in memory deviations from the programmed seam path, with actual welding corrections occurring on the second "arc-on" pass. Single-pass systems give the advantages of reduced cycle time and of being able to compensate for thermal distortions during the welding operation. One recent example of a microcomputer-based single-pass system using a welding torch and laser-ranging sensor on a six-axis robot is given by Nayak and Ray [1990]. Their system, dubbed ARTIST for adaptive, real-time, intelligent, seam tracker, has a two-level integrated control system in which the high level contains rule-based heuristics and model-based reasoning to arrive at real-time decisions, whereas the low level enables tracking of a three-dimensional welding seam.

It should be noted that arc welding, like many manufacturing processes, is not well enough understood physically that one can formulate an exact mathematical model to describe the process. Attempts to optimize welding schedules for any arc welding process have led to expert systems for such processes [Tonkay and Knott, 1989]. Other examples of such work can be found in publications of the *Welding Journal* [e.g., Lucas, 1987; Fellers, 1987].

A robotic arc welding cell provides several advantages over manual welding operations. These advantages include higher productivity as measured by "arc-on" time, elimination of worker fatigue, decreased idle time, and improved safety. It is also important to correct upstream production operations to reduce variations. This is best accomplished during the design and installation phase of a robotic welding cell. During this phase, issues to consider include delivery of materials to the cell, fixtures and welding positioners, methods required for the processes, and any production and inventory control problems related to the efficient utilization and operation of the cell.

Other processing applications for robot use include spray coating and various machining or cutting operations. Spray coating is a major application in the automotive industry where robots have proven suitable in overcoming various hazards such as fumes, mist, nozzle noise, fire, and possible carcinogenic ingredients. The advantages of robotic spray coating are lower energy consumption, improved consistency of finish, and reduced paint quantities used. To install a robotic painting application, one needs to consider certain manual requirements. These include continuous-path control to emulate the motion of a human operator, a hydraulic drive system to minimize electrical spark hazards, and manual lead-through programming with multiple program storage capability [Groover, et al., 1986]. Newer schemes have considered geometric modeling, painting mechanics, and robot dynamics to output an optimal trajectory based on CAD data describing the objects [Suh et al., 1991]. The objective of such work is to plan an optimal robot trajectory that gives uniform coating thickness and minimizes coating time.

Machining operations utilizing robots typically employ end effectors that are powered spindles attached to the robot wrist. A tool is attached to the spindle to perform the processing operation. Examples of tools would be wire brushes or a grinding wheel. It should be noted that such applications are inherently flexible and have

the disadvantage that such operations would be less accurate than a regular machine tool. Finishing operations, such as deburring, have provided excellent opportunities for robotic application. Force control systems have proven particularly useful in regulating the contact force between the tool and the edge of the work to be deburred. One such example for robotic deburring is given by Stepien et al. [1987]. In general, force-torque sensors mounted at the robot wrist have proven extremely useful in many applications in processing and assembly operations. The Lord Corporation and JR3 are two manufacturers of such commercial sensors.

Assembly Applications

Automated assembly has become a major application for robotics. Assembly applications consider two basic categories: parts mating and parts joining. Parts mating refers to peg-in-hole or hole-on-peg operations, whereas joining operations are concerned not only with mating but also a fastening procedure for the parts. Typical fastening procedures could include powered screwdrivers with self-tapping screws, glues, or similar adhesives.

In parts-mating applications, remote center compliance (RCC) devices have proven to be an excellent solution. In general, compliance is necessary for avoiding or minimizing impact forces, for correcting positioning error, and for allowing relaxation of part tolerances. In choosing an RCC device, the following parameters need to be determined prior to an application:

- Remote center distance (center of compliance). This is the point about which the active forces are at a minimum. The distance is chosen by considering the length of the part and the gripper.
- Axial force capacity. Maximum designed axial force to function properly.
- Compressive stiffness. Should be high enough to withstand any press fitting requirements.
- Lateral stiffness. Refers to force required to deflect RCC perpendicular to direction of insertion.
- Angular stiffness. Relates to forces that rotate the part about the compliant center (also called the cocking stiffness).
- Torsional stiffness. Relates to moments required to rotate a part about the axis of insertion.

Other parameters also include the maximum allowable lateral and angular errors as determined by the size of the part and by its design. These errors must be large enough to compensate for errors due to parts, robots, and fixturing. Passive and instrumented (IRCC) devices have been developed for assembly applications. One such device that combines a passive compliance with active control is described by Xu and Paul [1992]. In addition, the SCARA (Selective Compliance Articulated Robot for Assembly) class of robots is stiff vertically but relatively compliant laterally.

Many opportunities exist for flexible assembly systems. Many of the issues for such systems have been addressed by Soni [1991]. The reader is also referred to the *Design for Robotic Assembly Handbook* [Boothroyd and Dewhurst, 1985] for quantitative methods to evaluate a product's ease of assembly by robots. Carter [1990] presents a method for determining robot assembly task time as derived from tests and industrial experience. Carter also addresses the relationship between product design and robotic assembly cycle time. Some of the current trends in automated assembly include coordinating multiple robots to increase the flexibility and reliability of an assembly cell [Coupes et al., 1989; Zheng and Sias, 1986], interaction with CAD databases to automatically generate assembly plans [Wolter, 1989; Nnaji, 1989] and the application of sensors to automatic assembly systems [Cook, 1991]. Meijer and Jonker [1991] consider an architecture for an intelligent assembly cell and its subsequent implementation. An article by Jarneteg [1990] considers the strategies necessary for developing adaptive assembly systems.

Inspection

Inspection involves checking of parts, products, and assemblies as a verification of conformation to the specification of the engineering design. With the emphasis on product quality, there is a growing emphasis for 100% inspection. Machine vision systems, robot-manipulated active sensing for inspection, and automatic test equipment are being integrated into total inspection systems. Robot application of vision systems include part location, part identification, and bin picking. Machine vision systems for inspection typically perform tasks which include dimensional accuracy checks, flaw detection, and correctness and completeness of an assembled product. Current vision inspection systems are predominantly two-dimensional systems capable of extracting

feature information, analyzing such information, and comparing to known patterns previously trained into the system. As documented by Nurre and Hall [1989], various techniques for three-dimensional measurements have also been developed by many researchers. Primary factors to be considered in the design or application of a vision system include the resolution and field of view of the camera, the type of camera, lighting requirements, and the required throughput of the vision system.

Machine vision application can be considered to have three levels of difficulty, namely, that (1) the object can be controlled in both appearance and position, (2) it can be controlled in either appearance or position, or (3) neither can be controlled. The ability to control both position and appearance requires advanced, potentially three-dimensional vision capabilities. The objective in an industrial setting is to lower the level of difficulty involved. It should be noted that inspection is but one category of robotic applications of machine vision. Two other broad categories are identification and visual servoing and navigation. In the latter case, the purpose of the vision system is to direct the motion of the robot based on visual input. The reader is directed to Groover et al. [1986] for further details.

Emerging Issues

Robotics, by definition, is a highly multidisciplinary field. Applications are broad, and even those applications focused on the manufacturing shop floor are too numerous to cover in full here. The reader is referred to the various journals published by the IEEE and other societies and publishers, a few of which have been listed in the references. Still, it is worthwhile to note a few issues relevant to manufacturing shop-floor applications that could have an impact over the next decade. These issues include gripper development, mobility, and intelligent robots. The objective of this work is the overall integration of a flexible manufacturing system.

In a manufacturing process or assembly operation, the actions required of a gripper will vary with the task. Much work has been done in developing multifigured hands such as the Utah-MIT hand, the Salisbury hand, and others with an increasing interest of adding tactile sensory input for dexterous manipulation [Allen et al., 1989]. As noted by Allen and his colleagues, robotic systems need to process multiple source data and be easily programmable for grasping and manipulation tasks. One study focused on capturing a machinist's skill in working with parts and tools and codifying this knowledge in a grip taxonomy has been done by Cutkosky and Wright [1986]. Their study suggests some general principles for the design, construction, and control of hands in a manufacturing (particularly machining) environment. The reader is also referred to the work of Feddema and Ahmad [1986] for the development of an algorithm for a static robot grasp for automated assembly and the work of Cutkosky [1991] on robotic grasping and manipulation. This latter work considers dynamic contact and the application of dynamic tactile sensors in manipulation tasks. An application to identify and locate circuit board fixtures within a robotic workcell that integrates a vision system with a tactile probe is given by DeMeter and Deisenroth [1987].

Automated guided vehicles (AGVs) currently dominate the movement of parts through a flexible manufacturing system (FMS). AGVs typically restrict the path to predetermined routes and subsequently decrease the "flexibility" of the system. Work is being done on mobile robots to address this issue. Research by Arkin and Murphy [1990] focuses on intelligent mobility within a manufacturing environment. The reader is also referred to the research of Wiens and Black [1992] who address a mobile robot system within a manufacturing cell as a means to increase the flexibility, capability, and capacity of a robot-based manufacturing cell.

The issues involved with intelligent robots have been surveyed by Nitzan [1985], where he notes that future proliferation of robotic applications will depend strongly on machine (robotic) intelligence. Such applications will lead to a greater diversity of applications and will not be just manufacturing oriented. The reader is also referred to work on intelligent machines by Weisbin [1986]. It should be noted that particular interest has been directed toward integration of multiple sensors as a means to enhance robot intelligence [Luo and Lin, 1989; Pin et al., 1991]. The text by Klafter et al. [1989] categorizes the major sensory needs for robotic tasks and gives valuable insights to current and future robotics applications. **Intelligent control** systems, particularly hierarchical control systems, are being developed by many organizations and research institutes [Odrey, 1992b]. Such systems are expected to have an impact both at the shop-floor level and the management levels of production facilities well into the next century.

Robotic Tools

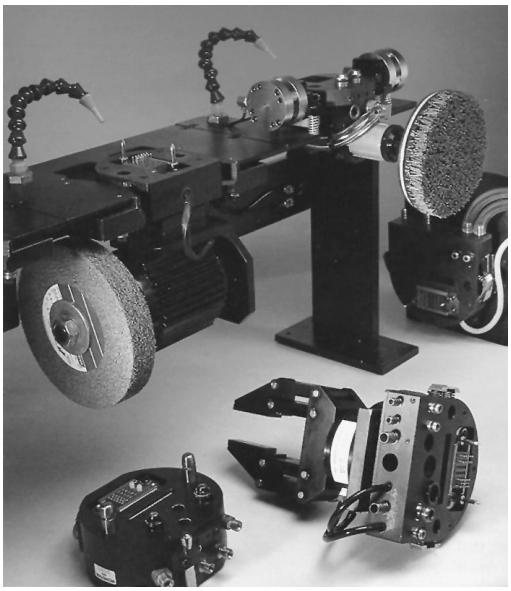
Robotics and Automation Corporation, Minneapolis, Minnesota, manufactures equipment for robotic systems, in particular a variety of tools known as "end effectors", devices attached to the end of a robot arm for picking up, grasping, manipulating, and transferring objects.

Among the company's newer products is the Automatic Robotics Tool-change System (ARTS), a system designed to meet the growing demand for multiple task work cells for welding and plasma spray functions that require grinding and finishing; deburring, deflashing, routing, hole drilling or parts replacement; and multiple tool disk operations.

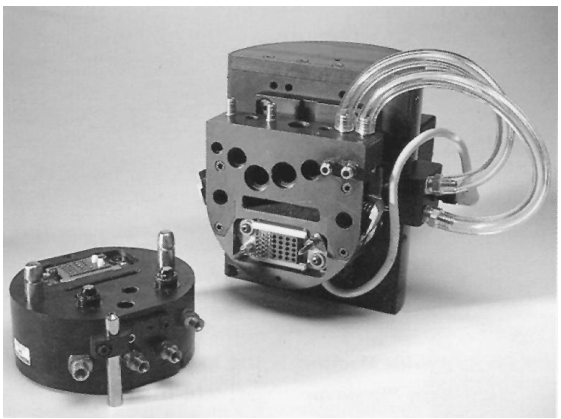
The ARTS systems were designed to work with the company's CFD (Constant/controlled Force Device) product line, a series of end effectors and bench mounted devices for controlling the constant pressure of abrasive tools used to deburr, grind, polish, and finish products fabricated by welding, casting, molding, forging, or machining.

Robotics and Automation Corporation's CFD line includes three end-of-arm devices and two bench-mounted devices. They do not require that the robot apply and control the force, only that it move along a normal programmed path over the work piece; the CFD applies and maintains the required processing pressure.

When the surface to be finished is very rough and course, several different grades of finishing media may be needed, as well as different speeds and power as the surface finish is transformed. To accommodate this multistep process within a single work cell, and with a single robot, Robotics and Automation Corporation developed the automated tool-change system.



The tool rack of the Automatic Robotics Tool-Change System includes a two-finger gripper; a grinder, a coated abrasive brush, and a welding torch. (Photo courtesy of National Aeronautics and Space Administration.)



The quick disconnect system allows changing tools with hydraulic, pneumatic, or electric power. (Photo courtesy of National Aeronautics and Space Administration.)

The ARTS-I is being used in industrial applications with six tool positions ranging from coarse sanding disks and abrasive wheels to cloth polishing wheels with motors of various horsepower. The ARTS-II allows a robot to exchange a welding torch for a CFD end effector to finish a welded assembly with a welding robot; using a second tool-changer (ARTS-I) enables finishing the surface conditioning process. (Courtesy of National Aeronautics and Space Administration.)

Defining Terms

Cellular manufacturing: Grouping of parts by design and/or processing similarities such that the group (family) is manufactured on a subset of machines which constitute a cell necessary for the group's production.

Decision tree analysis: Decomposing a problem into alternatives represented by branches where nodes (branch intersections) represent a decision point or chance event having probabilistic outcome. Analysis consists of calculating expected values associated with the chain of events leading to the various outcomes.

Degrees of freedom: The total number of individual motions typically associated with a machine tool or robot.

Intelligent control: A sensory-interactive control structure incorporating cognitive characteristics that can include artificial intelligence techniques and contain knowledge-based constructs to emulate learning behavior with an overall capacity for performance and/or parameter adaptation.

Machine interference: The idle time experienced by any one machine in a multiple-machine system that is being serviced by an operator (or robot) and is typically measured as a percentage of the total idle time of all the machines in the system to the operator (or robot) cycle time.

Sensor fusion: Combining of multiple sources of sensory information into one representational format.

Sensor integration: The synergistic use of multiple sources of sensory information to assist in the accomplishment of a task.

102.1 Avionics Systems

Cary R. Spitzer, Daniel A. Martinec, and Cornelius T. Leondes

Avionics (aviation electronics) systems perform many functions: (1) for both military and civil aircraft, avionics are used for flight controls, guidance, navigation, communications, and surveillance; and (2) for military aircraft, avionics also may be used for electronic warfare, reconnaissance, fire control, and weapons guidance and control. These functions are achieved by the application of the principles presented in other chapters of this handbook, e.g., signal processing, electromagnetic, communications, etc. The reader is directed to these chapters for additional information on these topics. This section focuses on the system concepts and issues unique to avionics that provide the traditional functions listed in (1) above.

Development of an avionics system follows the traditional systems engineering flow from definition and analysis of the requirements and constraints at increasing level of detail, through detailed design, construction, **validation,** installation, and maintenance. Like some of the other aerospace electronic systems, avionics operate in real time and perform mission- and life-critical functions. These two aspects combine to make avionics system design and **verification** especially challenging.

Although avionics systems perform many functions, there are three elements common to most systems: data buses, displays, and power. Data buses are the signal interfaces that lead to the high degree of integration found today in many modern avionics systems. Displays are the primary form of crew interface with the aircraft and, in an indirect sense, through the display of synoptic information also aid in the integration of systems. Power, of course, is the life blood of all electronics.

The generic processes in a typical avionics system are signal detection and preprocessing, signal fusion, computation, control/display information generation and transmission, and feedback of the response to the control/display information. (Of course, not every system will perform all of these functions.)

A Modern Example System

The B-777 Airplane Information Management System (AIMS) is the first civil transport aircraft application of the integrated, modular avionics concept, similar to that being used in the U.S. Air Force F-22. Figure 102.1 shows the AIMS cabinet with eight modules installed and three spaces for additional modules to be added as the AIMS functions are expanded. Figure 102.2 shows the AIMS architecture.

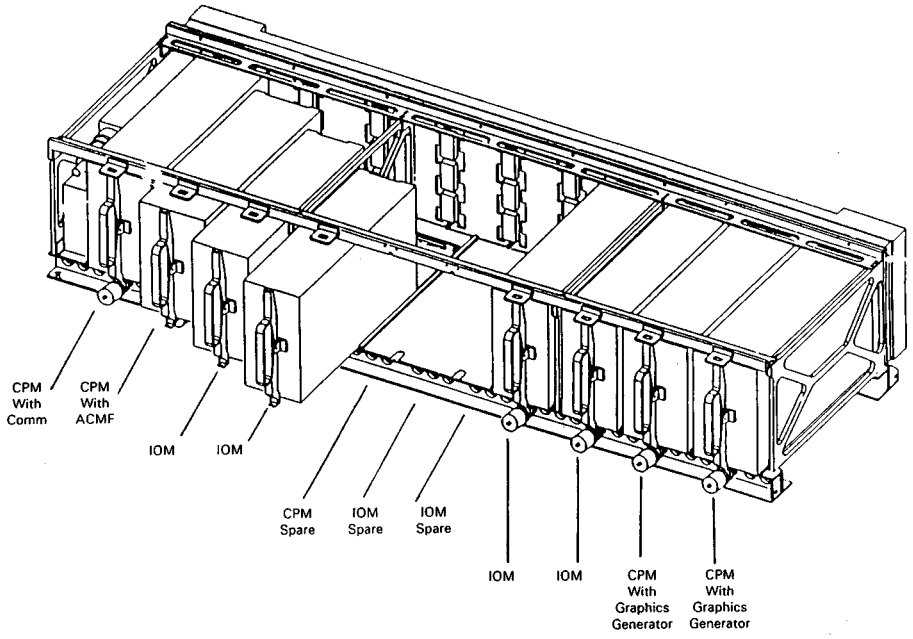

FIGURE 102.1 Cabinet assembly outline and installation (typical installation). (Courtesy of Honeywell, Inc.)

AIMS functions performed in both cabinets include flight management, electronic flight instrument system (EFIS) and engine indicating and crew alerting system (EICAS) displays management, central maintenance, airplane condition monitoring, communications management, data conversion and gateway (ARINC 429 and ARINC 629), and engine data interface. AIMS does not control the engines nor flight controls, nor operate any internal or external voice or data link communications hardware but does select the data link path as part of the communications management function. Subsequent generations of AIMS may include some of these latter functions.

In each cabinet the line replaceable modules (LRMs) are interconnected by dual ARINC 659 backplane data buses. The cabinets are connected to the quadraplex (not shown) or triplex redundant ARINC 629 system and fly-by-wire data buses and are also connected via the system buses to the three multifunction control display units (MCDU) used by flight crew and maintenance personnel to interact with AIMS. The cabinets transmit merged and processed data over quadruple redundant custom designed 100 Mhz buses to the EFIS and EICAS displays.

In the AIMS the high degree of function integration requires levels of system availability and integrity not found in traditional distributed, federated architectures. These extraordinary levels of availability and integrity are achieved by the extensive use of **fault-tolerant** hardware and software maintenance diagnostics and promise to reduce the chronic problem of unconfirmed removals and low mean time between unscheduled removals (MTBUR).

Figure 102.3 is a top-level view of the U.S. Air Force F-22 Advanced Tactical Fighter avionics. Like many other aircraft, the F-22 architecture is hybrid, part federated and part integrated. The left side of the figure is the highly integrated portion, dominated by the two Common Integrated Processors (CIPs) that process, fuse, and distribute signals received from the various sensors on the far left. The keys to this portion of the architecture are the Processor Interconnect (PI) buses within the CIPs and the High Speed Data Buses (HSDBs). (There are provisions for a third CIP as the F-22 avionics grow in capability.) The right side of the figure shows the federated systems including the Inertial Reference, Stores Management, Integrated Flight and Propulsion Control, and Vehicle Management systems and the interface of the latter two to the Integrated Vehicle System Control. The keys to this portion of the architecture are the triple or quadruple redundant AS 15531 (formerly MIL-STD-1553) command/response two-way data buses.

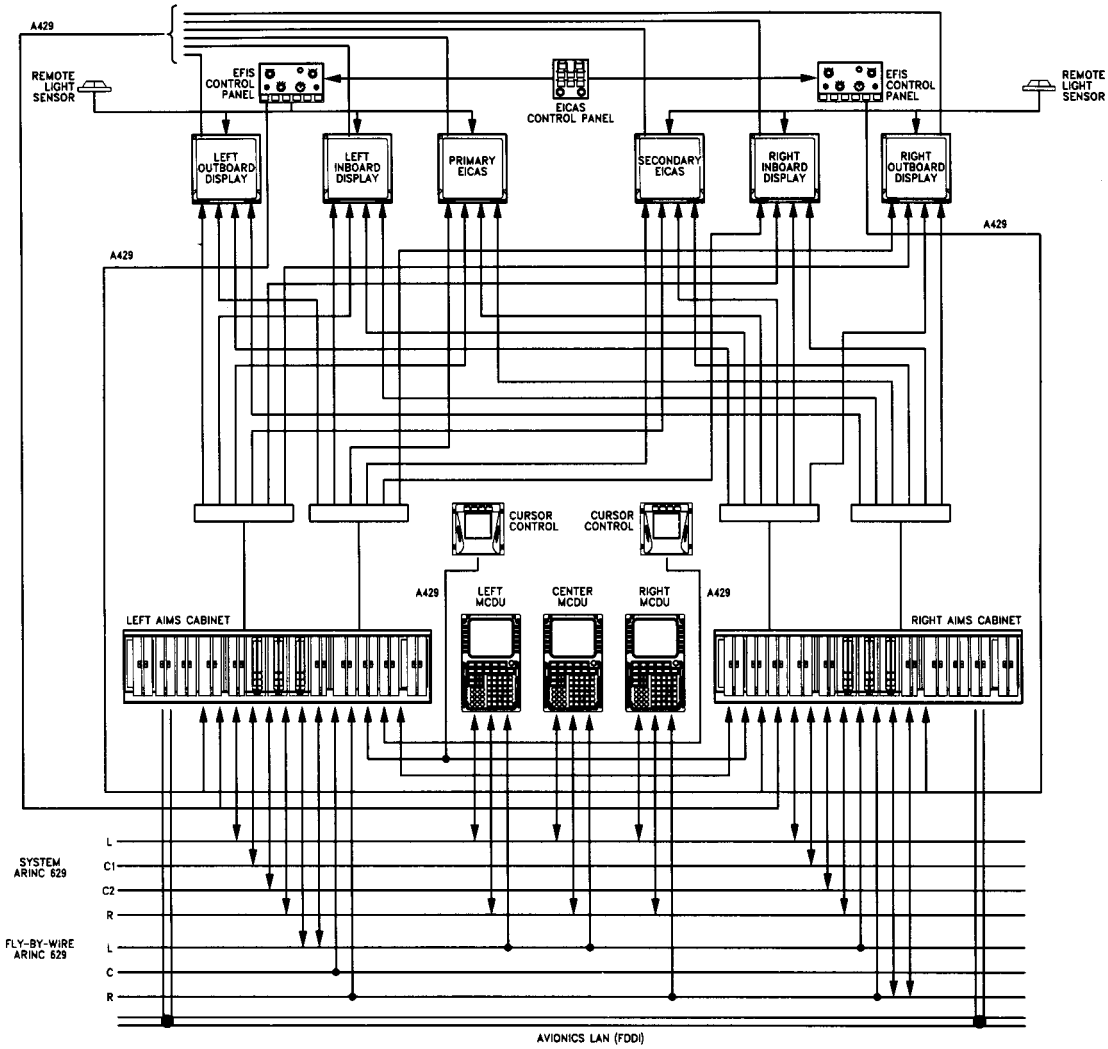

FIGURE 102.2 Architecture for AIMSbaseline configuration. (Courtesy of Honeywell, Inc.)

Data Buses

As noted earlier, data buses are the key to the emerging integrated avionics architectures. Table 102.1 summarizes the major features of the most commonly used system buses. MIL-STD-1553 and ARINC 429 were the first data buses to be used for general aircraft data communications. These are used today widely in military and civil avionics, respectively, and have demonstrated the significant potential of data buses. The others listed in the table build on their success.

Displays

All modern avionics systems use electronic displays, either CRTs or flat-panel LCDs that offer exceptional flexibility in display format and significantly higher reliability than electromechanical displays. Because of the very bright ambient sunlight at flight altitudes the principal challenge for an electronic display is adequate brightness. CRTs achieve the required brightness through the use of a shadow mask design coupled with narrow bandpass optical filters. Flat-panel LCDs also use narrow bandpass optical filters and a bright backlight to achieve the necessary brightness.

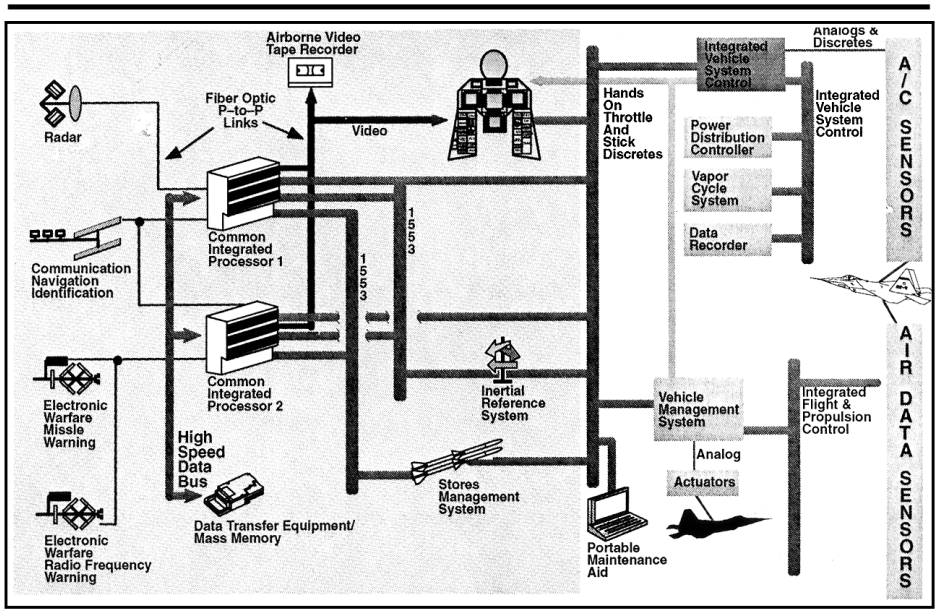

FIGURE 102.3 F-22 EMD Architecture.

TABLE 102.1 Characteristics of Common Avionics Buses

Bus Name	Word Length	Bit Rate	Transmission Media
MIL-STD-1553	20 bits	1 Mb/s	Wire
DOD-STD-1773	20 bits	TBS	Fiber optic
High-speed data bus	32 bits	50 Mb/s	Wire or fiber optic
ARINC 429	32 bits	14.5/100 kb/s	Wire
ARINC 629	20 bits	2 Mb/s	Wire or fiber optic
ARINC 659	32 bits	100 MB/s	Wire

Because of the intrinsic flexibility of electronic displays, a major issue is the design of display formats. Care must be taken not to place too much information in the display and to ensure that the information is comprehendible in high workload (aircraft emergency or combat) situations.

Power

Aircraft power is generally of two types: 28 vdc, and 115 vac, 400 Hz. Some 270 vdc is also used on military aircraft. Aircraft power is of poor quality when compared to power for most other electronics. Under normal conditions, there can be transients of up to 100% of the supply voltage and power interruptions of up to 1 second. This poor quality places severe design requirements on the avionics power supply, especially where the avionics are performing a full-time, flight-critical function. Back-up power sources include ram air turbines and batteries, although batteries require very rigorous maintenance practices to guarantee long-term reliable performance.

Software in Avionics

Most avionics currently being delivered are microprocessor controlled and are software intensive. The "power" achieved from software programs hosted on a sophisticated processor results in very complex avionics with many functions and a wide variety of options. The combination of sophistication and flexibility has resulted

Weather Information Systems

Weather is a critical factor in aircraft operations. It is the largest single contributor to flight delays and a major cause of aircraft accidents.

A study conducted for NASA by Ohio State University reported that the principal difficulties in making proper flight decisions are the timeliness and clarity of weather data dissemination.

To advance the technology of in-flight weather reporting, Langley Research Center developed in the early 1990's a cockpit weather information system known as CWIN (Cockpit Weather Information). The system draws on several commercial data sensors to create radar maps of storms and lightning, together with reports of surface observations.

Shown above is a CWIN display in the simulation cockpit of Langley's Transport Systems Research Vehicle, a modified jetliner used to test advanced technologies. The CWIN display is the lower right screen among the four center panel screens. By pushing a button, the pilot may select from a menu of several displays, such as a ceiling and visibility map, radar storm map, or lightning strike map. (Courtesy of National Aeronautics and Space Administration.)

in lengthy procedures for validation and certification. The **brickwalling** of software modules in a system during the initial development process to ensure isolation between critical and noncritical modules has been helpful in easing the certification process.

There are no standard software programs or standard software certification procedures. RTCA has prepared Document DO-178 to provide guidance (as opposed to strict rules) regarding development and certification of avionics civil software. The techniques for developing, categorizing, and documenting avionics civil software in DO-178 are widely used.

For military avionics software, the principal document is DOD-STD-498. This standard defines a set of activities and documentation suitable for the development of both weapon systems and automated information systems. Many software languages have been used in the past in avionics applications; however, today there is a strong trend for both military and avionics civil software to use Ada wherever reasonably possible.

The evolving definition of a standards for Applications Exchange (APEX) software promises to provide a common software platform whereby the specialized requirements of varying hardware (processor) requirements are minimized. APEX software is a hardware interface that provides a common link with the functional software within an avionics system. The ultimate benefit is the development of software independent of the hardware platform and the ability to reuse software in systems with advanced hardware while maintaining most, if not all, of the original software design.

CNS/ATM

The last decade of this century has seen much attention focused on Communication/Navigation/Surveillance for Air Traffic Management (CNS/ATM), a satellite-based concept developed by the Future Air Navigation System (FANS) Committees of the International Civil Aviation Organization (ICAO), a special agency of the United Nations. Many studies have predicted enormous economic rewards of CNS/ATM for both aircraft operators and air traffic services providers.

The new CNS/ATM system should provide for:

- Global communications, navigation, and surveillance coverage at all altitudes and embrace remote, offshore, and oceanic areas.
- Digital data exchange between air-ground systems (voice backup).
- Navigation/approach service for runways and other landing areas which need not be equipped with precision landing aids.

Navigation Equipment

A large portion of the avionics on an aircraft are dedicated to navigation. The following types of navigation and related sensors are commonly found on aircraft:

- Flight control computer (FCC)
- Flight management computer (FMC)
- Inertial navigation system (INS)
- Attitude heading and reference system (AHRS)
- Air data computer (ADC)
- Low range radio altimeter (LRRA)
- Radar
- Distance Measuring Equipment (DME)
- Instrument Landing System (ILS)
- Microwave Landing System (MLS)
- VHF OmniRange (VOR) Receiver
- Global Navigation Satellite System (GNSS)

Emphasis on Communications

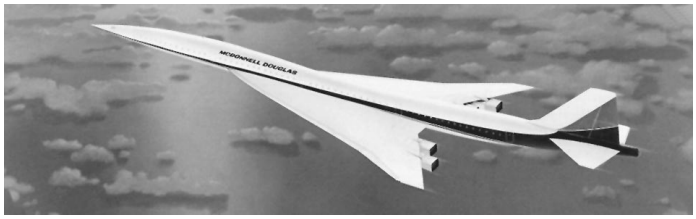
An ever-increasing portion of avionics is dedicated to communications. Much of the increase comes in the form of digital communications for either data transfer or digitized voice. Military aircraft typically use digital communications for security. Civil aircraft use digital communications to transfer data for improved efficiency of operations and RF spectrum utilization. Both types of aircraft are focusing more on enhanced communications to fulfill the requirements for better operational capability.

Various types of communications equipment are used on aircraft. The following list tabulates typical communications equipment:

- VHF transceiver (118–136 MHz)
- UHF transceiver (225–328 MHz/335–400 MHz for military)
- HF transceiver (2.8–24 MHz)
- Satellite (1530–1559/1626.5–1660.5 MHz, various frequencies for military)
- Aircraft Communications Addressing and Reporting (ACARS)
- Joint Tactical Information Distribution System (JTIDS)

In the military environment the need for communicating aircraft status and for aircraft reception of crucial information regarding mission objectives are primary drivers behind improved avionics. In the civil environment

High Speed Research



This McDonnell Douglas conceptual design for a Mach 2.4 supersonic transport is sized to carry about 300 passengers over a distance of 5,000 nautical miles. A NASA/industry high speed civil transport research effort is a first step toward determining whether such a plane can be economically viable and environmentally acceptable. (Photo Courtesy of National Aeronautics and Space Administration.)

Aircraft manufacturers of several nations are developing technology for the next plateau of international aviation: the long-range, environmentally acceptable, second generation supersonic passenger transport, which could be flying by 2010.

NASA's High Speed Research (HSR) program is intended to demonstrate the technical feasibility of a high speed civil transport (HSCT) vehicle. The program is being conducted as a national team effort with shared government/industry funding and responsibilities.

The team has established a baseline design concept that serves as a common configuration for investigations. A full-scale craft of this design would have a maximum cruise speed of Mach 2.4, only marginally faster than the Anglo-French Concorde supersonic transport. However, the HSCT would have double the capacity of the Concorde, and it would operate at an affordable ticket price.

Phase I of the HSR program, which began in 1990, focused on environmental challenges: engine emission effects on the atmosphere, airport noise, and sonic boom. Phase II, initiated in 1994, focuses on the technology advances needed for economic viability, principally weight reductions in every aspect of the baseline configuration. In materials, the HSR team is developing, analyzing, and verifying the technology for trimming the baseline airframe by 30 to 40%. In aerodynamics, a major goal is to minimize air drag to enable a substantial increase in range. Phase II also includes computational and wind tunnel analyses of the baseline HSCT and alternative designs. Additional research involves ground and flight simulations aimed at development of advanced control systems, flight deck instrumentation, and displays. (Courtesy of National Aeronautics and Space Administration.)

(particularly commercial transport), the desire for improved passenger services, more efficient aircraft routing and operation, safe operations, and reduced time for aircraft maintenance are the primary drivers for improving the communications capacity of the avionics.

The requirements for digital communications for civil aircraft have grown so significantly that the industry as a whole embarked on a virtually total upgrade of the communications system elements. The goal is to achieve a high level of flexibility in processing varying types of information as well as attaining compatibility between a wide variety of communication devices. The approach bases both ground system and avionics design on the ISO Open System Interconnect (OSI) model. This seven-layer model separates the various factors of communications into clearly definable elements of physical media, protocols, addressing, and information identification.

The implementation of the OSI model requires a much higher level of complexity in the avionics as compared to avionics designed for simple dedicated point-to-point communications. The avionics interface to the physical

medium will generally possess a higher bandwidth. The bandwidth is required to accommodate the overhead of the additional information on the communications link for the purpose of system management. The higher bandwidths pose a special problem for aircraft designers due to weight and electromagnetic interference (EMI) considerations. Additional avionics are required to perform the buffering and distribution of the information received by the aircraft. Generally a single unit, commonly identified as the communications management unit (CMU), will perform this function.

The CMU can receive information via RF transceivers operating in conjunction with terrestrial, airborne, or space-based transceivers. The capability also exists for transceiver pairs employing direct wire connections or very short-range optical links to the aircraft. The CMU also provides the routing function between the avionics, when applicable. Large on-board databases, such as an electronic library, may be accessed and provide information to other avionics via the CMU.

The increasing demand on data communication system capacity and flexibility is dictating the development of a system without the numerous limitations of current systems. Current communication systems require rather rigid protocols, message formatting, and addressing. The need for a more flexible and capable system has led to the initial work to develop an Aeronautical Telecommunications Network (ATN). The characteristics envisaged for the ATN are the initiation, transport, and application of virtually any type of digital message in an apparently seamless method between virtually any two end systems. The ATN is expected to be a continually evolving system.

Impact of "Free Flight"

"Free Flight" is a term describing an airspace navigation system in which the "normal" air traffic controls are replaced by the regular transmission of position information from the airplane to the ground. The ground system, by projecting the aircraft position and time, can determine if the intended tracks of two aircraft would result in a cohabitation of the same point in the airspace. This is commonly called "conflict probe". If a potential conflict occurs, then a message is transmitted to one or more of the aircraft involved to make a change to course and/or speed.

"Free Flight" dictates special requirements for the avionics suite. A highly accurate navigation system with high integrity is required. The communications and surveillance functions must exhibit an extremely high level of availability.

GNSS Avionics performing the position determination functions will require augmentation to achieve the necessary accuracy. The augmentation will be provided by a data communications system and will be in the form of positional information correction. A data communications system will also be required to provide the frequent broadcast of position information to the ground. A modified Mode S transponder squitter is expected to provide that function.

The free flight concept will require the equipage of virtually all aircraft operating within the designated free-flight airspace with a commensurate level of avionics capability. The early stages of the concept development uncovered the need to upgrade virtually all aircraft with enhanced CNS/ATM avionics. The air transport industry resolved this problem on older airplanes by developing improved and new avionics for retrofit applications. The new avionics design addresses the issues of increased accuracy of position and enhancement of navigation management in the form of the GNSS Navigation and Landing Unit (GNLU) housed in a single unit and designed to be a physical and functional replacement for the ILS and/or MLS receivers. A built-in navigator provides enhanced navigation functionality for the airplane. The GNSS can provide ILS lookalike signals and perform landing guidance functions equivalent to Category I.

Avionics in the Cabin

Historically, the majority of avionics have been located in the electronics bay and the cockpit of commercial air transport airplanes. Cabin electronics had generally been limited to the cabin interphone and public address system, the sound and central video system, and the lighting control system. More recently the cabin has been updated with passenger telephones using both terrestrial and satellite systems. The terrestrial telephone system operates in the 900-MHz band in the United States and will operate near 1.6 GHz in Europe. The satellite

system, when completely operational, will also operate near 1.6 GHz. Additional services available to the passengers are the ability to send facsimiles (FAXes) and to view virtually real-time in-flight position reporting via connection of the video system with the flight system. Private displays at each seat will allow personal viewing of various forms of entertainment including movies, games, casual reading, news programming, etc.

Avionics Standards

Standards play an important role in avionics. Military avionics are controlled by the various standards (MIL-STDs, DOD-STDs, etc.) for packaging, environmental performance, operating characteristics, electrical and data interfaces, and other design-related parameters. General aviation avionics are governed by fewer and less stringent standards. Technical Standard Orders (TSOs) released by the Federal Aviation Administration (FAA) are used as guidelines to ensure airworthiness of the avionics. TSOs are derived from and, in most cases, reference RTCA documents characterized as Minimum Operational Performance Standards and Minimum Avionics System Performance Standards. EUROCAE is the European counterpart of RTCA.

The commercial air transport industry adheres to multiple standards at various levels. The International Civil Aviation Organization (ICAO) is commissioned by the United Nations to govern aviation systems including but not limited to Data Communications Systems, On-Board Recorders, Instrument Landing Systems, Microwave Landing Systems, VHF OmniRange Systems, and Distance Measuring Equipment. The ICAO Standards and Recommended Practices (SARPS) control system performance, availability requirements, frequency utilization, etc. at the international level. The SARPS in general maintain alignment between the national avionics standards such as those published by EUROCAE and RTCA.

The commercial air transport industry also uses voluntary standards created by the Airlines Electronic Engineering Committee and published by Aeronautical Radio Inc. (ARINC). The ARINC "characteristics" define form, fit, and function of airline avionics.

Defining Terms

ACARS: A digital communications link using the VHF spectrum for two-way transmission of data between an aircraft and ground. It is used primarily in civil aviation applications.

Brickwalling: Generally used in software design in critical applications to ensure that changes in one area of software will not impact other areas of software or alter their desired function.

Distance measuring equipment: The combination of a receiver and a transponder for determining aircraft distance from a remote transmitter. The calculated distance is based on the time required for the return of an interrogating pulse set initiated by the aircraft transponder.

Fault tolerance: The built-in capability of a system to provide continued correct execution in the presence of a limited number of hardware or software faults.

JTIDS: Joint Tactical Information Distribution System using spread spectrum techniques for secure digital communication. It is used for military applications.

Validation: The process of evaluating a product at the end of the development process to ensure compliance with requirements.

Verification: (1) The process of determining whether the products of a given phase of the software development cycle fulfill the requirements established during the previous phase. (2) Formal proof of program correctness. (3) The act of reviewing, inspecting, testing, checking, auditing, or otherwise establishing and documenting whether items, processes, services, or documents conform to specified requirements (IEEE).

102.2 Communications Satellite Systems: Applications

Abdul Hamid Rana and William Check

The history of satellites began in 1957 when the Soviet Union launched Sputnik I, the world's first satellite. In the 1960s the commercial sector became actively involved in satellite communications with the launch of Telstar I by the Bell System followed by the use of a **geosynchronous orbit.** With this type of an orbit, an object 22,753 miles above the earth will orbit the earth once every 24 hours above the equator, and from the earth's surface appear to be stationary. The first geostationary orbit was achieved by NASA using a SYNCOM in 1963. The Communications Satellite Act was signed by the United States Congress in 1962 and created the Communications Satellite Corporation (COMSAT). This was followed by the formation of INTELSAT, an organization that is composed of over 120 countries and provides global satellite communication services. In the 1970s, multiple companies in the private sector in the United States began to operate their own domestic satellite systems. Today there are numerous companies providing this service in the United States: e.g., GE Americom, Hughes, Loral, COMSAT, and American Mobile Satellite Corporation. Other nations such as Canada, Australia, Indonesia, Japan, etc. have their own satellite systems. Several international and regional satellite systems have also been formed. Examples of these are INTELSAT, EUTELSAT, Intersputnik, ARABSAT, AsiaSat, etc. [Pritchard and Sciulli, 1986].

The satellite-based communications systems have significantly evolved over a three-decade period. In the 1960s, satellite communications for commercial use became a viable alternative because of the demand for reliable communications (telephony and voice). In the 1970s, technical innovations made larger, more powerful and more versatile satellites possible. Advanced modulation and multiple-access schemes resulted in smaller, less expensive **earth stations** and better service offerings that were lower cost and higher quality. In the 1980s **very small aperture terminals (VSATs)** emerged and the Ku-band frequency spectrum became widely used. In the 1990's satellites support data, voice, and video communications applications. The VSAT industry has given an overall boost to the entire satellite communication industry.

As new satellites are launched, they will have long-term applications which have expanded opportunities. These include private long-haul networks for internal communications, cable TV, pay TV, business voice and data, satellite news gathering, direct broadcast to the home, integrated VSATs, private international satellite service, high-definition TV, mobile service, personal communications, and ISDN. Disaster recovery planning increasingly includes satellites in order to overcome the coverage limitations of existing terrestrial networks. With the allocation of frequencies for personal communications, the promise of global communications and the reality of a personal phone will soon push satellite communications to a new age.

This section describes satellite communications from the application point-of-view. Since VSATs initiated the growth in satellite communication, a significant portion of the section is devoted to this topic. After a review of the satellites' launch and their characteristics, VSAT networks are discussed in detail. Video/audio applications are described next, along with the equipment necessary for these applications. The section is concluded with a summary of next-generation trends.

Satellite Launch

Launching a communications satellite into orbit is a complex and expensive process. This first stage in a satellite's airborne life may cost several million dollars. The cost for launching is primarily a function of the satellite's weight and size. Traditional geosynchronous communications satellites tend to be large and more costly to launch, although the more compact digital communications payloads and longer satellite life will reduce life cycle costs. Low earth orbit communications satellites tend to be smaller and more economical to launch, but will have shorter in orbit life.

A shortage of launch vehicles influenced the economics of the launch industry following the 1986 U.S. Space Shuttle *Challenger* disaster. The shortage has now given way to other launch alternatives. The dominant player in the satellite launch business is the French company Arianespace. Major U.S. players in the satellite launch business are Lockheed Martin, McDonnell Douglas, and Orbital Sciences Corporation. China and Russia have also begun providing launch services.

The launch of a satellite payload into the geosynchronous orbit involves many complex steps. Using the launch vehicle, the payload is first placed in a parking orbit. This is a nearly circular orbit which places the satellite approximately 300 km above the earth's surface. After reaching this orbit, the next step is to fire a motor known as the payload assist module (PAM) to place the payload in a transfer orbit. The PAM motor is discarded afterwards. The transfer orbit is an elliptical orbit whose perigee matches the parking orbit and whose apogee matches the geostationary orbit. Perigee is defined as the point in the orbit closest to the earth, while apogee is the point in the orbit furthest from the earth. The payload itself consists of the satellite with an apogee kick motor (AKM). Once in a transfer orbit, the AKM is fired at the point when the satellite has reached apogee. This firing will place the satellite in a nearly circular orbit. Final positioning of the satellite in geosynchronous orbit can then take place [Pritchard and Sciulli, 1986].

Spacecraft and Systems

A satellite spacecraft employs several major subsystems. These are propulsion, electrical, tracking, telemetry command and control, and the communications subsystem. Figure 102.4 is a diagram of a typical commercial satellite. The propulsion subsystem consists of thrusters oriented in north-south and east-west directions and is used to maintain the spacecraft in the proper orbit and orientation. An electrical subsystem is used to generate electricity in the spacecraft by means of solar cells. Backup batteries are used during periods of equinoxes. The solar cells are also used to charge the batteries. The tracking, telemetry, and command subsystem is used to receive commands from the controlling ground station, as well as to allow the ground station to monitor on-board systems.

The spacecraft requires some form of stabilization to prevent it from tumbling in space. There are two types of stabilization techniques: spin stabilization and three-axis stabilization. Spin stabilization uses an outside cylinder to spin, creating the effect of a gyroscope providing spacecraft stabilization. An internal platform is decoupled from the cylinder, whose orientation is fixed towards the earth. Three-axis stabilization uses internal gyros which sense movement of the spacecraft. Any movement in the axes is detected and can be compensated by firing thruster jets.

The communications subsystem consists of receiver and transmitter sections. The receiver system consists of wideband redundant units. The transmitter subsystem consists of separate amplifiers (transponders) for each channel utilized. Satellite systems make use of orthogonal polarized signals in order to transmit two signals simultaneously on the same frequency, a technique known as "frequency reuse." Two different polarization methods for signals are used: horizontal and vertical linear polarization, or clockwise and counterclockwise circular polarization.

Figure 102.5 shows a simplified block diagram of a typical satellite. A matrix-type switching arrangement is provided on the input and output of the transmitter subsystem for switching to backup transponders. This satellite is three-axis stabilized and operates at Ku-band. There are 16 operational transponders with a bandwidth of 54 MHz each. The employment of frequency reuse provides nearly 1000 MHz of usable bandwidth. Fourteen of the 16 operational transponders use 20-W traveling wave tube amplifiers (TWTA) to provide ground-commandable east or west regional coverage, for 48-state (CONUS) coverage. The remaining two transponders provide 50-state coverage using 27-W TWTAs. For the 50-state channels, one spare 27-W TWTA provides

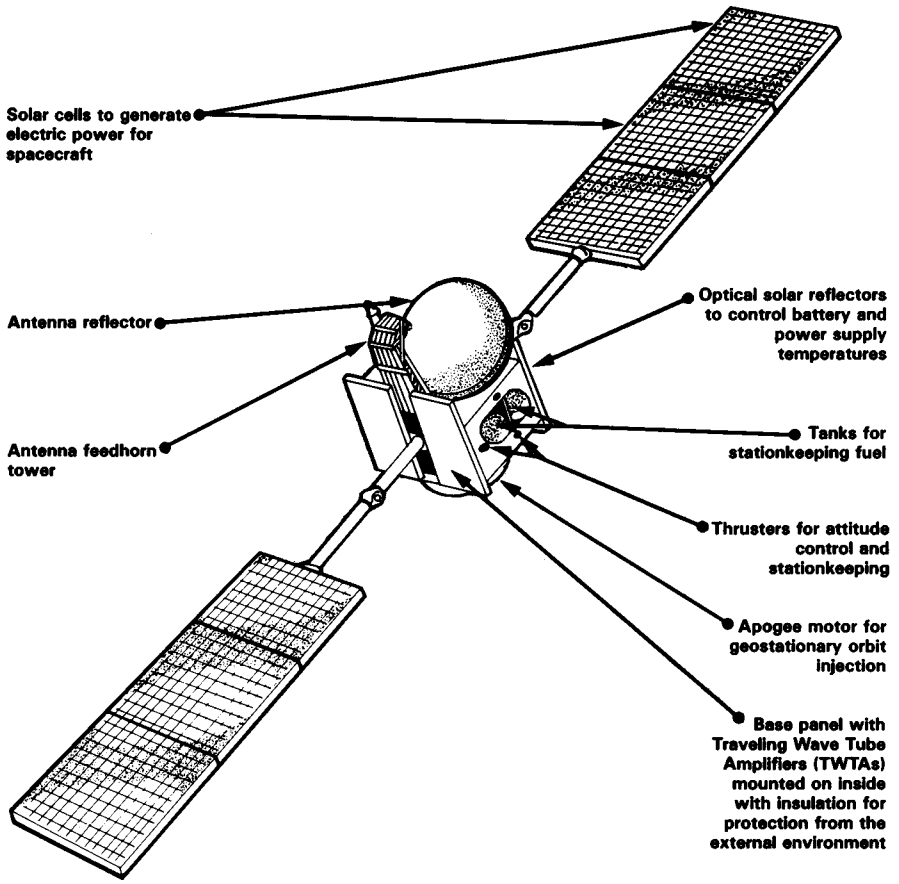

FIGURE 102.4 Simplified block diagram of a communications satellite.

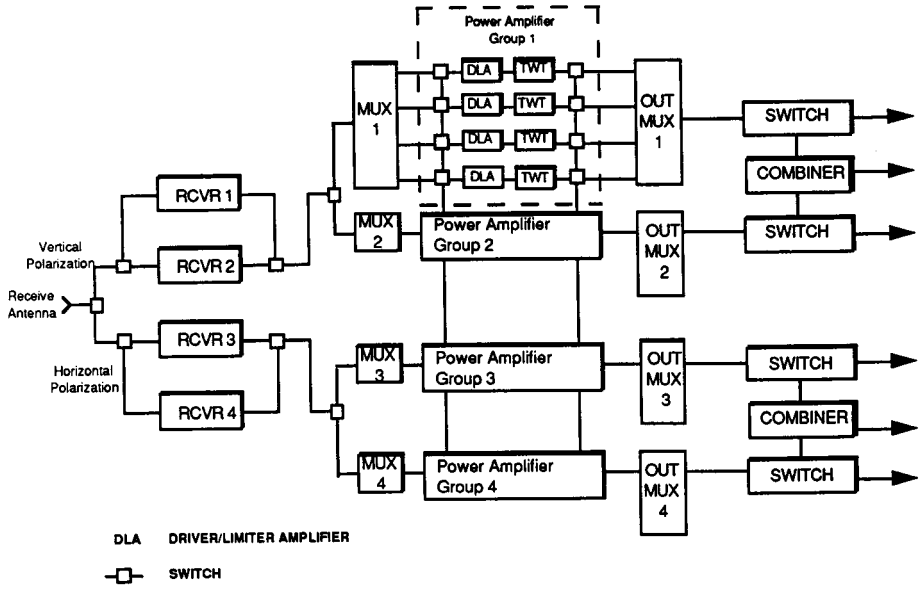

FIGURE 102.5 Simplified block diagram of GSTAR satellite.

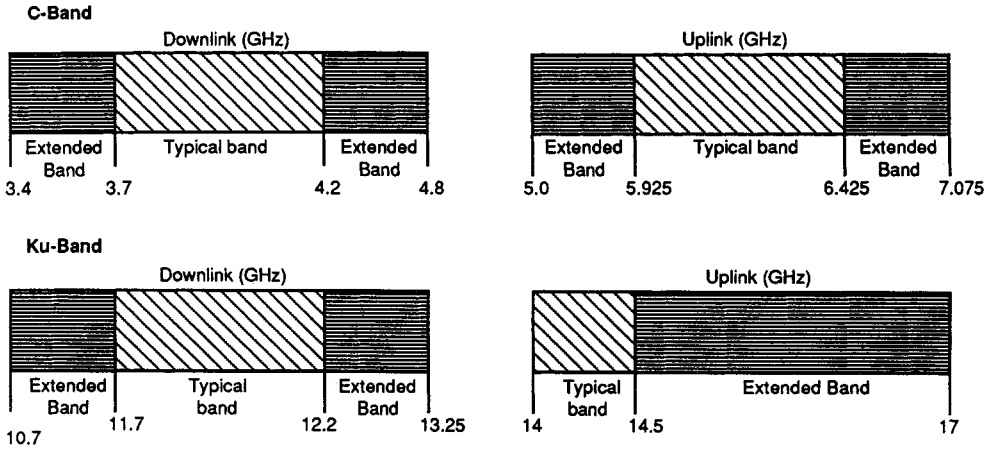

FIGURE 102.6 Ku- and C-band frequency allocation chart.

protection for the two operating TWTAs (3-for-2 redundancy). For the remaining transponder channels, 5 spare 20-W TWTAs provide protection for 14 operating TWTAs (19-for-14 redundancy). Redundant communications receivers are provided on a 4-for-2 basis.

The power radiated from a satellite is described as its effective radiated isotopic power (EIRP) and is the radiated power of the satellite in decibels referenced to one watt of power. The units are in dBW. The strength of the signal received on the ground is a function of the spacecraft location and that of the ground station and will vary depending upon location. A map of the signal strength contours is called the satellite's "footprint."

Geosynchronous Satellites

There are over 500 Ku-band and C-band satellites in geosynchronous orbit. These satellites are typically spaced anywhere between 1 to 3 degrees apart. Older satellites no longer in active service may be spaced less than one degree in an inclined orbit.

The frequency plan for C- and Ku-band satellite services is shown in Fig. 102.6. The typical transmit frequency band used for fixed satellite services in the Ku-band is 14.0–14.5 GHz. Receive frequency is 11.7–12.2 GHz. Some satellites also use the extended band. For C-band satellites, the typical operating transmit frequency is 5.925–6.425 GHz and the receive frequency is 3.7–4.2 GHz. The operating band was extended at WARC '79 to 7.075 GHz to be assigned to individual countries for domestic satellite systems. Ka-band satellites have downlinks in the frequency range 17–23 GHz and uplinks in the range 27–31 GHz. Some European and Japanese satellites operate in this range [Long, 1991].

The satellite performance data indicate a wide range of variation in the specifications among the various satellites. Most satellites have a design lifetime of 10 years. The newer GEO satellites tend to have an extended life of 12–15 years. Most domestic U.S. satellites have 24 transponders. The older generation of Asian satellites have very few transponders per satellite. Some planned satellites will have a large number of transponders. Nominal transponder bandwidths include 36, 54, and 72 MHz.

Satellite power is increasing in the newer generation of satellites. Lower-power satellites have an EIRP in the 20–35 dBW range. There are a significantly large number of medium-power satellites in the 35–45 dBW range. Newer high-power satellites tend to have power in the 50–60 dBW range. Direct broadcast satellites are planned for transponder power in the 60–120 W range. The power generally varies with polarization, frequency, and beam. Table 102.2 is a profile of typical satellite performance characteristics.

Mobile Satellite Systems

Mobile satellite systems encompass communications on land, in the air, or over the oceans ideally allowing a person to communicate with anyone anywhere [Long, 1991]. The Inmarsat system is a mobile communications system providing global coverage through a variety of communication paths. In the United States, the FCC has authorized American Mobile Satellite Corporation (AMSC) to provide domestic mobile satellite services. AMSC makes use of geostationary satellites to provide a domestic offering similar to the international offering of Inmarsat.

TABLE 102.2 Typical Satellite Performance

Satellite Operator	System Name	Configuration	EIRP in dBW at Edge	Comments
GE Americom	GSTAR series	Ku-band	38–48	Domestic coverage
	Spacenet series	C- and Ku-band	C-band: 34–36 Ku-band: 39	
Hughes Comm	Galaxy Series	C- and Ku-band	C-band: 34–38 Ku-band: 45–49.5	Domestic coverage
Intelsat	Intelsat VA (IBS)	C- and Ku-band	C-band: 20–26 Ku-band: 38–41	International service, worldwide
	Intelsat VI	C- and Ku-band	C-band: 20–26 Ku-band: 38–41	
	Intelsat VII	C- and Ku-band	C-band: 26–36 Ku-band: 41–46	
Eutelsat	Eutelsat I series	Ku-band	35–43.5	Covers all of Europe
	Eutelsat II	Ku-band	42–47	
NASDA-NTT (Japan)	Sakura 2	C- and Ka-band	C-band: 30 `Ka-band: 37	CS-4a, CS-4b in the Sakura series is scheduled for launch during 1992–94

Over the past two decades, there has been active work in the area of low earth orbit (LEO) satellite systems. In general, LEOs are designed to provide a full range of communication services, both voice and data. Proposed systems are designed to complement existing cellular communications technology. Several companies have proposed LEO systems and have made application to the FCC for a "Pioneer's Preference" license. This license allows the use of new and innovative technology. Motorola's Iridium system is potentially the largest, using 66 satellites to provide coverage over the entire globe.

Because of the low altitude of the orbit, LEO systems use multiple satellites to provide coverage over a regional area or over the entire globe. Satellites operating at a low orbit are less costly due to the reduced launch costs and reduced weight. However, a low orbit requires the use of multiple satellites since the low altitude of the system provides smaller beam coverage. Since these satellites are not geostationary, ground stations must track an LEO satellite as it passes overhead.

Due to potential growth of mobile satellite communications, several systems are proposed to be in operation in the 1990s. Examples of these systems are the Iridium, Globalstar, ICO, Orbcomm, Starsys, Odyssey, and Teledisc.

Direct Broadcast Satellites

The direct broadcast satellites (DBS) concept is to transmit programming directly to homes using a small receive-only antenna via high-powered satellites. Through the use of a high-powered satellite, a small receive-only satellite antenna may be used for home reception, with the ultimate goal to offer antennas less than one foot in diameter. High-powered DBS satellites use high-powered transponders, i.e., 60–120 W. To prevent interference into the small receive antennas at these high power levels, the DBS satellites will be spaced further apart in geosynchronous orbit.

The first efforts in DBS began in the early 1980s when COMSAT built several DBS satellites, but did not launch them. Internationally, many countries currently have DBS services. Several European countries have high-powered DBS satellites; many others use medium-powered satellites. The DBS industry in the United States is being revitalized by advances in digital video compression technology and the announcement of new players such as Hughes, Primestar, Echostar, etc. to offer DBS services. Hughes Communications and United States Satellite Broadcasting (USSB) system using a high-powered DBS satellite is in operation. As an alternative to the launch of a high-powered satellite, medium-powered DBS systems make use of existing satellites in orbit. However, larger home antennas are required, approximately 2 feet or greater in diameter. A medium-powered DBS in the U.S. is Primestar. Digital video compression techniques using the MPEG-2 standard are used to allow multiple video channels in a transponder. DIRECTV® service, launched in the summer of 1994 by Hughes Electronics, is an example of the direct satellite system.

Earth Stations

Earth stations are the interface point for communications to and from the satellite [Ha, 1986]. An earth station can be divided into two subsystems, the transmit chain and the receive chain. A common element between the transmit and receive chain is the antenna. Because of the large signal attenuation at RF frequencies, the earth station antenna must have high signal gain and be highly directional to focus the power to and from the satellite. A parabolic-shaped reflector antenna is used by earth stations since it can provide these characteristics.

The transmit chain consists of several major components: baseband equipment, modulators, frequency upconverters, high-power amplifiers (HPA), and combiner circuitry used to switch the output of the HPAs to the antenna. The receive chain uses a low-noise amplifier to receive the satellite signals, frequency downconverters, demodulator, and baseband equipment.

In the transit chain the signals are modulated, combined, and frequency-shifted with an upconverter to the desired satellite transmit frequency. After upconversion, the signals are amplified by HPAs. In a large earth station, there may be many HPAs which feed to a single antenna. These signals must be switched and combined appropriately. At microwave frequencies, waveguide combiners are used to route the output of the HPAs to the antenna.

In the receive chain, the counterpart to the HPA is the low-noise amplifier (LNA), which is used to amplify the signals received from the antenna. This amplifier must be designed for maximum gain with a very small noise contribution. The noise generated in this unit contributes significantly to the overall performance of the receive side of the earth station. Gallium arsenide (GaAs) FETs are commonly used in the amplifier section of the LNA because of their low-noise characteristics. The LNA feeds the signal to the frequency downconverter, which converts it to IF frequency suitable for demodulator.

A hub monitoring and control (M&C) system provides the monitoring and control of the RF equipment and baseband equipment. Redundant RF equipment is common at a hub, and the M&C system is used to monitor the components and provide automatic switchover in the event of equipment failure. Switchover between equipment can occur either by operator initiation or automatically by the M&C upon sensing an equipment failure.

Technical characteristics of *large earth stations* have been established for use with the INTELSAT system. INTELSAT categorizes two types of earth stations: multipurpose and special purpose. A multipurpose earth station can be used with any service, while a special-purpose earth station is restricted. Multipurpose standard A, B, and C earth stations have antenna diameters from 11 to 33 meters. Special-purpose standard D, E, and F earth stations have antenna diameters between 3.5 to 11 meters.

In addition to fixed earth stations, "portable" earth stations, called *transportables,* have been manufactured which can be taken to locations originating the programming. These transportables are usually mounted on a truck or trailer and include all the components necessary for an earth station. In the case of the transportable, the antenna size is selected to be as small as 4 meters in diameter. A transportable earth station is designed to be upgraded with "building blocks" to handle heavy, medium, and thin route traffic. Transportable earth stations are designed to meet the requirements for various applications such as temporary business communications, temporary carrier service, backup during the retrofit of an existing earth station, and disaster recovery.

Another type of earth station is the *flyaway.* This is a small remote satellite terminal which can be packed into suitcases for shipment on an airline for delivery anywhere in the world. These systems consist of a small antenna, RF unit, and baseband equipment to provide a complete satellite communications station. An example is an L-band version which provides audio communications via the Inmarsat system. Fitting into a small suitcase, it contains a telephone handset, RF electronics, and antenna that can be assembled to provide audio communications anywhere in the world. Mobile satellite terminals are even smaller, suitable to be carried as handheld or briefcase units.

VSAT Communication System

Advances in technology have revolutionized the satellite communications industry by deployment of very small aperture terminal (VSAT) networks for data, voice, and video communication. Since the mid-1980s, VSAT networks have become widely used in the oil, lodging, financial, auto, retail, and manufacturing industries. By the 1990s, VSATs were operating in C and Ku-bands. Also by the mid-1990s, over 70% of the VSAT market

TABLE 102.3 Typical VSAT Systems Features

Feature	Interactive	Point-to-point	Broadcast
Topology	Star	Point-to-point, mesh	Point-to-multipoint
Communication	Between hub and VSATs, VSAT to VSAT through hub	VSAT to VSAT	Hub to VSATs
Frequency	Ku-, C-band	Ku-, C-band	Ku-, C-band
Hub antenna	3–11 m	—	3–11m
VSAT antenna	0.9–2.4 m	1.8, 2.4 m	0.5–2.4 m
Hub to remote access	TDM, SCPC, spread spectrum	SCPC	SCPC, spread spectrum, FM[2]
Remote to hub access	ALOHA, reservation stream, CDMA	SCPC	—
Outbound data rate (Kbps)	56–512	9.6–2048	9.6–2048
Inbound data rate (Kbps)	9.6–256	9.6–2048	—
Modulation	BPSK, QPSK, DPSK	BPSK, QPSK	BPSK, QPSK, FM[2]
FEC	Rate 1/2, convolutional or block	Rate 1/2, convolutional	Rate 1/2, convolutional or block
Protocols	SDLC, Bisync, Async, X.25, TCP/IP Burroughs and others	Clear channel	Clear channel, synchronous, HDLC format

was accounted for by the retail, automotive, and financial industries. VSATs are making private networks a viable alternative for many companies, for applications such as point-of-sale, reservation systems, remote monitoring and control, branch office administration, financial transactions, etc. A VSAT is a small earth station suitable for installation at a customer's premises. A VSAT typically consists of antenna less than 2.4 m, an outdoor unit to receive and transmit signals, and an indoor unit containing the satellite and terrestrial interface units [Rana et al., 1990].

VSAT networks fall into three general categories: broadcast networks, point-to-point networks, and interactive networks. In a broadcast network, a centralized hub station broadcasts data, audio, and/or video to a group of receive-only VSATs. Low-cost receive-only VSATs can receive news, weather services, and financial information. Music distribution and video broadcast via broadcast networks is widely used. Point-to-point networks provide direct communication between two locations without the requirement of a large hub for data, voice, and image transmission. Variations of these networks include point-to-multipoint dedicated circuits or demand-assigned mesh topologies. Interactive networks are used for two-way communications services between a central hub station and a large number of VSATs in a star topology. Table 102.3 is a summary of the salient features of VSAT networks. VSATs are available for both C- and Ku-band frequency. Most VSAT systems use BPSK modulation with Rate 1/2 FEC. For interactive networks, the inbound channel is shared on contention basis to conserve space segment. More advanced systems use concatenated codes to improve performance. Recently, hybrid VSATs have been introduced to use terrestrial networks on the return channel. An example is the Hugh's Direct PC which uses a high speed satellite receive channel, and a low speed terrestrial return channel.

A critical element of VSAT networks is the network availability. The VSAT system availability is affected by three major components: effects of rain attenuation, equipment availability, and software availability. The effects of rain attenuation for Ku-band networks are significant. While link availability is usually specified at 99.5%, link performance can be optimized to nearly any desired value through the use of energy dispersion techniques or large antenna sizes. The network hardware must be highly reliable. Hub hardware should provide for optional redundancy and the ability to achieve better than 99.9% availability. The use of hub diversity and uplink power control can also be used to improve the network availability. The VSAT hardware availability is less catastrophic; the loss of one VSAT does not constitute network failure but may require a service call to rectify the problem. Hence, it is common to use nonredundant but highly reliable VSAT units. Software availability needs to be improved since software failures dominate the overall availability of interactive networks in existing VSAT products.

Interactive networks have been by far the most popular for data communication and audio/video overlays. The remaining portion of this section is devoted to these networks. An interactive VSAT system consists of a

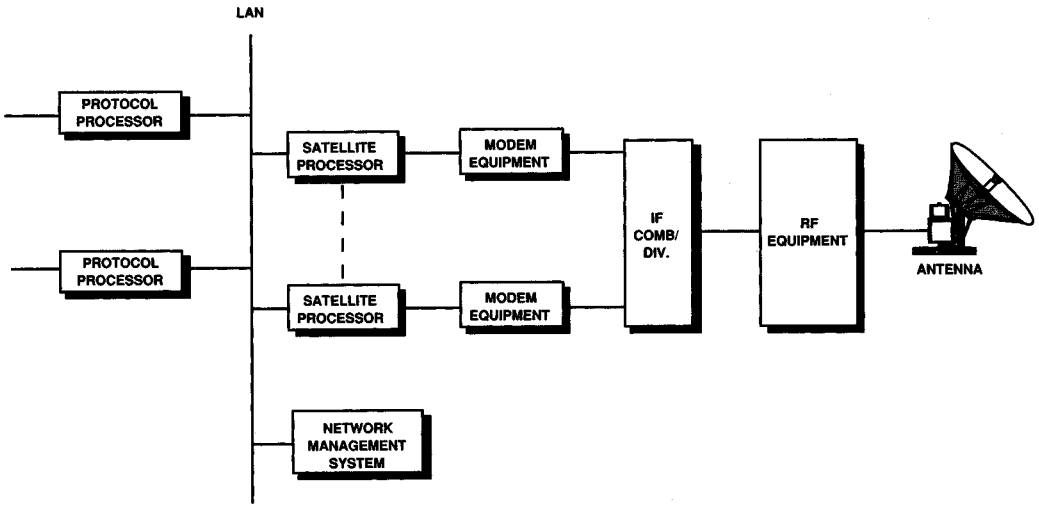

FIGURE 102.7 Block diagram of a hub.

hub, VSAT, network management system, and associated transmission and processing subsystems. These subsystems along with sophisticated **satellite access protocols** and terrestrial protocol interfaces make interactive networks a flexible and powerful communication medium.

Hub

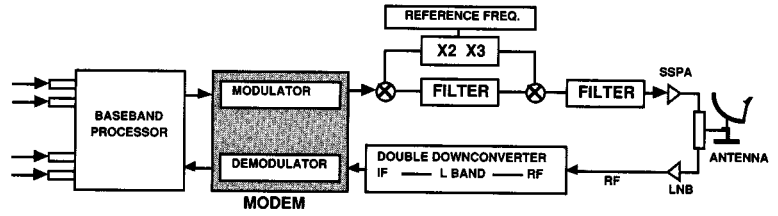
The hub performs all functions that are necessary to establish and maintain virtual connections between the central location and VSATs. In private dedicated networks, the hub is co-located with the user's data processing facility. In shared hub networks, the hub is connected to the user equipment via terrestrial backhaul circuits. Since the hub is a single point for failure in a star network, it is typically configured with 1:1 or 1:*N* redundancy. The hub consists of antenna, RF, and baseband equipment (Fig. 102.7). It will handle multiple channels of inbound and outbound data and often one or more channels of audio or video broadcast.

The hub antenna consists of a parabolic reflector and associated electrical and mechanical support equipment. The RF subsystem converts the modulated carrier to RF frequency, provides the necessary signal amplification, and transmits the resulting RF carrier to the antenna subsystem. It also receives RF signals from the antenna subsystem, provides low-noise amplification, RF/IF conversion, and passes the resulting IF carriers to the baseband equipment subsystem. The hub baseband equipment consists of the modem equipment and the processing equipment. The hub modems employ continuous modulators and burst demodulators. The processing equipment interfaces to the modem equipment and provides the satellite access processing and protocol processing for interface to the customer host.

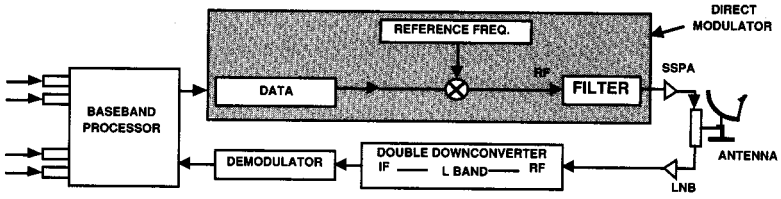
VSAT

The VSAT consists of an antenna, outdoor unit (ODU), interfacility link (IFL), and indoor unit (IDU). The IFL connects the IDU and ODU subsystems, providing the transmit and receive lines, monitor and control signals, and dc power for the ODU electronics. A single-cable IFL, in which all signals are multiplexed on the same cable, is usually used to reduce the cost of IFL. VSATs nominally use a 1.2- or 1.8-m offset feed parabolic antenna. Smaller antenna sizes are preferable to reduce the installation cost. Options for small antennas include the use of either a submeter parabolic reflector or a flat-plate antenna. The choice of antenna is a tradeoff among performance, installation cost, and aesthetic considerations.

The ODU consists of a solid-state power amplifier (SSPA), a low-noise amplifier, upconverter, and a downconverter. VSAT SSPA modules are usually between 1.0 to 3.0 W. The ODU cost can be significantly lowered by utilization of a low-power SSPA (0.1 to 0.5 W) consistent with obtaining the required output power. The VSAT receive side front end can be economically configured using an LNB. Low-cost HEMT LNBs are currently available with 50–60 dB gain and noise figures lower than 1.3 dB.



(a) Conventional VSAT



(b) VSAT using direct modulation.

FIGURE 102.8 Simplified VSAT block diagram.

Direct modulation of the RF carrier may lower the cost of the VSAT IF and RF electronics while consolidating modulation and upconversion functions. Direct modulation allows the design of a VSAT with fewer parts, smaller size, and lower weight than with traditional outdoor units. Figure 102.8 is a block diagram showing a conventional VSAT and a VSAT using direct modulation. An L-band receive interface between the ODU and IDU is preferable in order to receive audio and video overlays.

The IDU is located near the user terminal equipment. Major IDU functions include outbound carrier signal acquisition, tracking, demodulation, bit synchronization, burst modulation, and protocol processing. It also controls the operation of the ODU, monitors VSAT health, and responds to hub commands. The baseband processing system performs satellite channel access and protocol and customer interface processing functions. A video/audio port can be provided with an RF splitter at the IDU to separate the received audio/video signal for the optional video/ audio receiver.

Network Management System

The network management system (NMS) is a critical element of a VSAT network. Through the NMS, the user can have full control of his network, which is usually not possible in the case of terrestrial network facilities. The NMS generally provides a centralized management tool for hub and VSAT equipment configuration control, assignment of inbound and outbound satellite channels, network monitor and control, switchover to back-up equipment, network statistics collection, downline loading of new software, and report generation. In the shared hub environment, the hub operator controls the allocation of resources among various users and controls the RF transmission facility. The user must have the ability to manage his portion of the network transparent to other users. In the case of a dedicated hub, a single management entity can exert full control over the network, including RF transmission facilities.

The network management system standards community has defined five functional areas as requirements for network management systems. These areas are fault management, accounting management, configuration management, performance management, and security management. The VSAT network management system should be capable of interfacing with other network management systems by supporting a standard network management protocol. The protocol standard most widely accepted is the Simple Network Management Protocol (SNMP).

Transmission System

Most VSAT systems employ BPSK or QPSK modulation with rate R = 1/2, K = 7 convolutional coding and soft-decision Viterbi decoding on both the inbound and outbound channels. Differential phase shift keying (DPSK) modulation may be used to reduce the demodulator complexity and cost. DPSK is relatively insensitive

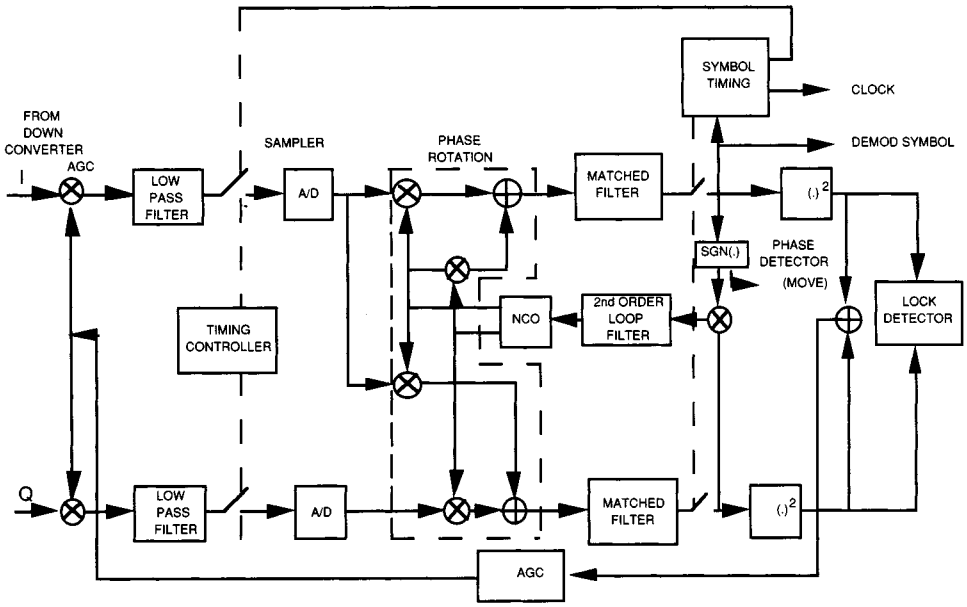


FIGURE 102.9 DSP demodulator functional diagram.

to phase noise and frequency offset, thus allowing the use of lower-cost LNBs in the VSAT terminals. However, as compared to BPSK, convolutionally encoded DPSK requires about 2 dB greater Eb/No at a BER of 10^{-5}. In addition, if operation is required below 10 dB, some form of low-level interleaving may be required.

In lieu of performing the VSAT demodulation function via the traditional analog circuit techniques, an all-digital implementation using digital signal processing (DSP) techniques may be considered. The merits of DSP include the development of a more testable, producible, maintainable, configurable, and cost-effective demodulator. Figure 102.9 presents an illustration of the DSP demodulator functions to be implemented using the DSP processor(s). The functions of the major blocks are as follows: phase locked loop (PLL) for carrier acquisition, narrowband Costas loop for data detection, external automatic gain control (AGC), dynamically advance/retard sampling to achieve optimum data sampling, and A/D converters for signal analog-to-digital conversion.

A VSAT system must employ frequency agility in the remote terminal to use an assigned block of frequencies within a transponder. Within the assigned frequency band, one or more outbound carriers and a number of inbound carriers are precisely located. On the VSAT receive or outbound side, the LNB output can be demodulated directly using a synthesizer-controlled local oscillator, or further downconversion can be used under synthesizer control to obtain the demodulator input signal at a standard IF frequency such as 70 or 140 MHz. In the inbound direction, channel selection can be accomplished by two methods. First, the carrier frequency of the modulator can be shifted to select the appropriate channel and a fixed upconverter may be used to obtain the RF signal. Second, the synthesizer output frequency may be multiplied up to RF to obtain the carrier, which may then be modulated directly with the data as described in Cannistraro and McCarter [1990].

Satellite Access Protocols

The multiple satellite access protocol is one of the most critical elements to the performance of a VSAT network. VSAT systems tend to be used in applications where message delay is critical and this protocol is the controlling element to the delay-throughput performance of the system. During the past 15 years, there have been numerous multiple-access protocols developed and simulated in the context of satellite packet communications [Raychaudhuri and Joseph, 1988]. Table 102.4 provides a comparison of throughput vs. delay for various satellite access protocols.

In the outbound or hub-to-VSAT direction, a TDM channel is employed. This channel may be regarded as a point-to-multipoint or broadcast channel with node selectivity being achieved by the use of addressing

TABLE 102.4 Random Multi-Access Protocols Comparison

	Throughput	Comments
Pure ALOHA	0.13–0.18	Low cost, good for variable-length messages
Slotted ALOHA	0.25–0.37	Good for fixed-length messages
Selective reject ALOHA	0.20–0.30	Variation of pure ALOHA with a modified algorithm
Tree CRA	0.40–0.49	Sensing capability for collision resolution, good for fixed-length messages
Announced retransmission random access (ARRA)	0.50–0.60	Uses modified algorithm of slotted ALOHA by announcement of transmission
Random access with notification	0.45–0.55	Uses partition for new and retransmitted message
CDMA	0.10–0.40	Used in spread spectrum systems, low delay

information embedded in the modulated data stream. The delay performance of this channel is essentially controlled by the queuing behavior of the hub. In the VSAT-to-hub direction, a large number of VSATs share the channel to conserve space segment. Most VSAT networks utilize a combination of slotted ALOHA protocol for the interactive component of the inbound traffic and a reservation TDMA scheme for any bulk data transfers. Most protocols are adaptive in the sense that as the channel traffic increases, they automatically evolve into reservation TDMA systems. Code division multiple access (CDMA) has been used in VSATs operating at C-band. CDMA permits more than one signal to simultaneously utilize the channel bandwidth in a noninterfering manner. This makes it possible to significantly increase the utilization and throughput of the channel.

Interface Capabilities

Most VSAT systems support common data communications protocols such as SDLC, X.25, Async, Bisync, TCP/IP, etc. Coexistence of different protocols is allowed in a network. A VSAT supports multiple ports with common interfaces such as RS232C, RS422, V.35, etc. VSAT networks typically must provide **protocol spoofing** to provide acceptable delay and throughput performance to the end-user application. To minimize the effect of satellite delay, the host computer front-end processor is emulated at the VSAT location, and multiple cluster controllers are emulated at the hub location. The polling associated with the front-end processor to cluster controller communication is not carried on the satellite link, but is instead emulated locally.

Video

Satellites are an excellent medium for video transmission since they can provide a broadcast capability with wide bandwidth. Video on satellites is ideal for applications such as videoconferencing, business TV, distance learning, satellite news gathering, etc.

Video Teleconferencing

Satellite communications provides a cost-effective and flexible means of interactive videoconferencing. Technological improvement in videocompression has resulted in low-cost codecs at data rates less than T1, and good quality videoconferencing is possible at data rates as low as 56 Kbps. Low-cost satellite terminals coupled with low-cost codecs are making videoconferencing via satellite affordable and practical for many organizations. Applications include all types of business meetings and technical information exchange such as management and staff meetings, new product introductions and updates, sales meetings, training, and market presentations. Videoconferencing allows people at different locations to meet with almost as much ease as being in the same room, providing benefits of increased productivity, reduced travel time and cost, and increased management visibility.

A generic videoconference system is presented in Fig 102.10. The system consists of a specially designed room, video/audio equipment, transmission equipment, monitor and control computer, and space segment. The video and audio feeds from the meeting room pass through the codec and are compressed. From the codec, the signal passes to the satellite modem for modulation. The radio frequency/terminal (RFT) upconverts the modulated carrier and amplifies it for transmission to the satellite. At the other site, the process is reversed.

A videoconferencing network features point-to-point, broadcast, or point-to-multipoint architectures. In a point-to-point system, two sites are configured for interactive conference with duplex audio and full motion video transmission. Videoconferencing broadcast is appropriate for formal presentations where the presenter

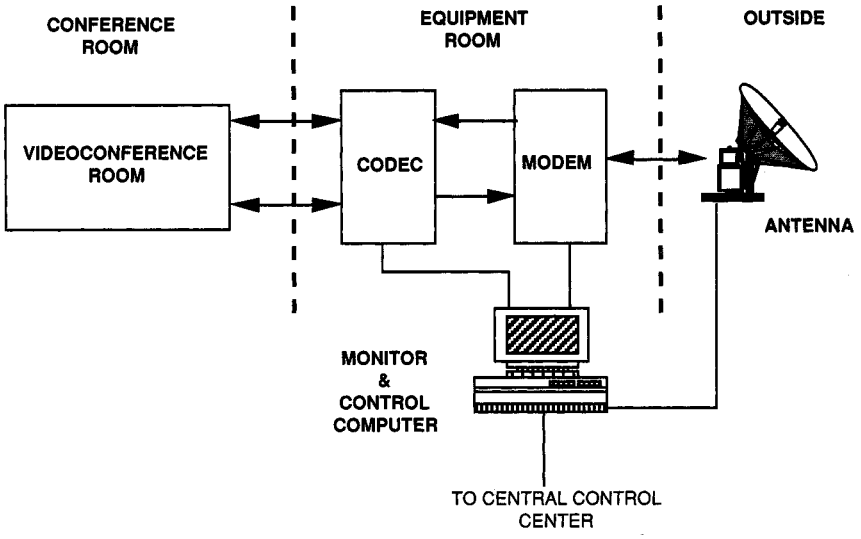

FIGURE 102.10 A generic videoconference system.

does not need to see the audience, such as a speech from a senior corporate executive. In a point-to-multipoint conference, multiple sites can receive a transmitting site. Two of the primary sites are fully interactive with each other. A feature called multipoint switching has been implemented in some commercial systems. This feature allows switching of receive and transmit sites during the conference. The multipoint switching feature can be provided using either a TDMA or SCPC system. A TDMA system allows multiple sites to transmit and receive in a mesh configuration. An economical multipoint switching system is possible with SCPC using only two transmit frequencies. In a "chair" controlled conference, the chair is assigned one of these frequencies for the duration of the conference. Dynamic allocation of the second frequency is controlled by the chair to any of the participating sites at any time during the conference.

Video Broadcast

Video broadcast over satellite is attractive for industry segments such as educational TV, distance learning, business television, and television receive-only (TVRO) applications. Business television allows users to transmit broadcast-quality video programming from a studio to any number of specified locations equipped with TVROs. A video broadcast capability, as an overlay to interactive data networks, is becoming increasingly popular for corporate presentations, education, and training.

A video uplink consists of a video exciter, HPA, antenna, and optionally an encryption system such as B-MAC (multiplexed analog component, version B) encoder, for business video broadcasts. Each remote VSAT must be configured to receive the video transmission. This involves adding a video receiver at each VSAT location that plugs into the VSAT IDU. Audio/video signals from the video receiver can be presented directly or through a B-MAC decoder to a standard TV monitor.

The digital compressed video signal can be used as a replacement for an analog video distribution. Digital coding technology can be used to compress video signals to reduce data rates to 2 Mbps or even lower and reproduce near broadcast-quality video. Distribution of digital video signals at such rates requires less transponder bandwidth and a smaller antenna at remote terminals. Compression techniques used are based on one or a combination of the following: inter/intra-frame prediction, adaptive differential transform, conditional replenishment, discrete cosine transform, adaptive prediction, motion compensation, and vector quantization [Patterson and Delp, 1990].

Satellite News Gathering

Satellite news gathering (SNG) is used for live, on-the-spot coverage and news exchanges with other commercial broadcast stations. This is made possible by the availability of occasional-use space segment and transportable earth stations on news trucks. An SNG systems consists of a compact earth station and video/audio transmission

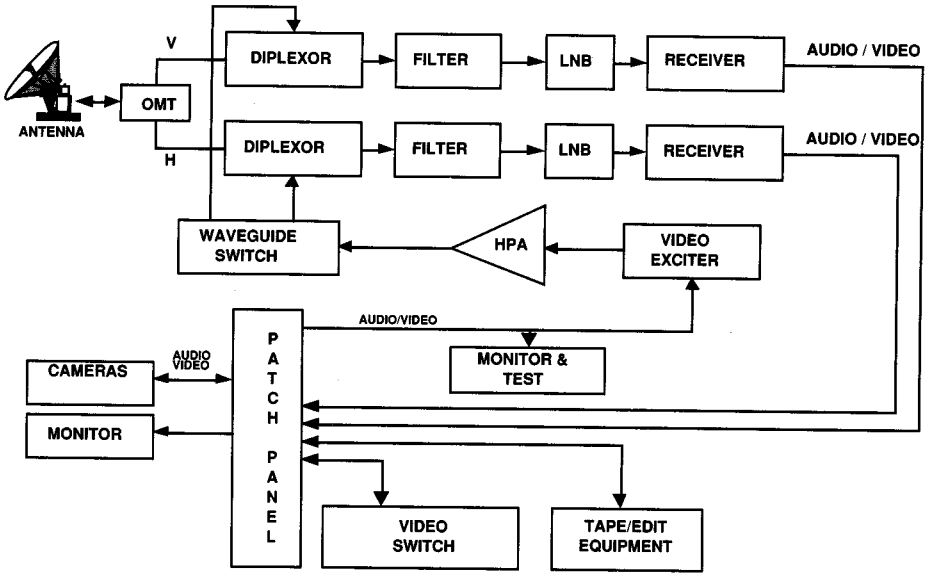

FIGURE 102.11 SNG vehicle video/audio system.

system on a truck. A duplex voice channel is used to coordinate between the space segment provider, studio, and the SNG truck.

Figure 102.11 presents a block diagram of a typical SNG system. The RF subsystem has a transmit path and two independent receive paths. The transmit path consists of an HPA and a frequency agile video exciter which modulates and upconverts the video signal to the satellite's RF frequency. A waveguide switch is used to select transmit polarization. Camera signals go simultaneously to tape for storage and for transmission over the satellite. A receive path is typically provided for both receive polarizations. Each path consists of a transmit reject filter and an LNB which downconverts to L-band. The received L-band signal passes through a video satellite receiver, from which point it can be routed to various monitor or test points or be routed to a tape device for recording and storage.

Audio

The use of commercial broadcast audio transmission via satellite began in the late 1970s with National Public Radio and Mutual Broadcasting using Western Union's WESTAR I satellite. The main application was to send high-quality audio to radio broadcast stations to transmit programming information. This type of system makes use of single channel per carrier (SCPC) satellite transmission, where each satellite channel corresponds to one audio channel. The entire satellite channel is FM modulated. Pre-emphasis is used over the channel to provide additional noise reduction. A variation of this technique, called multiple channel per carrier (MCPC), can be used to transmit multiple channels over a single satellite carrier. Figure 102.12 is a block diagram of the MCPC system.

As the marketplace searched for lower-cost systems, the FM^2 (or FM/FM) modulation technique evolved, allowing the use of low-cost FM receivers. Through a high-powered FM modulated carrier on the satellite, a low-cost audio and data broadcast receiver can be built. This FM/FM modulation technique is widely used to distribute audio and data on a low-cost basis.

In addition to audio broadcasts, satellite-based voice applications include point-to-point voice, multinode interactive voice, and voice over data VSATs. Point-to-point voice is most prevalently used for high-volume voice trunking for long-distance connectivity or transoceanic connectivity. A multinode, interactive voice architecture is ideal in providing voice connectivity to remote locations that are not serviced by terrestrial voice facilitates. Both mesh and star configurations are used to provide multinode voice connectivity. Automated satellite access control and resource allocation techniques are used to allow for granting requested on-demand

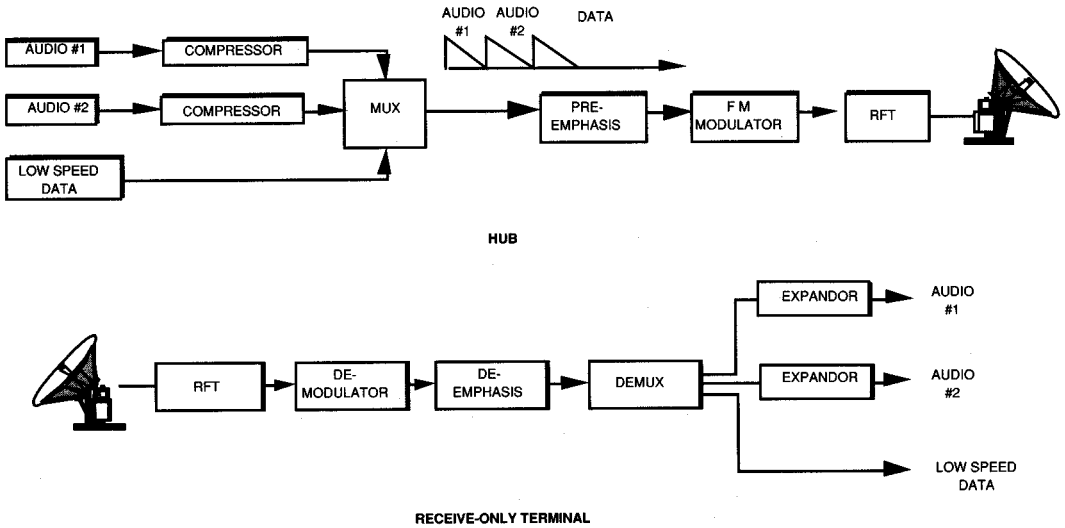

FIGURE 102.12 Block diagram of the MCPC system.

availability of voice connectivity. To support voice over data VSATs, an audio encoder is used to accept an analog voice signal, digitize and packetize it, and format it for transmission through the VSAT data network. A voice port may either be implemented as part of a "baseline" data/voice card or as an add-on stand-alone box.

The integrated data/voice system employs a TDM outbound carrier and shared inbound carriers for data and voice transmission. Two types of voice network communications alternatives may be implemented for voice channel communications: a poll/response access scheme and a reservation TDMA access scheme. With the poll/response access scheme, the hub polls the VSAT voice ports on a cyclic basis. The VSATs return their responses in the form of call requests or status updates. The number of sites in the voice network determines the rate at which VSATs are polled. Thus, this scheme is suitable for a small network. Excessive polling delays will be encountered for a network with a relatively large number of remotes.

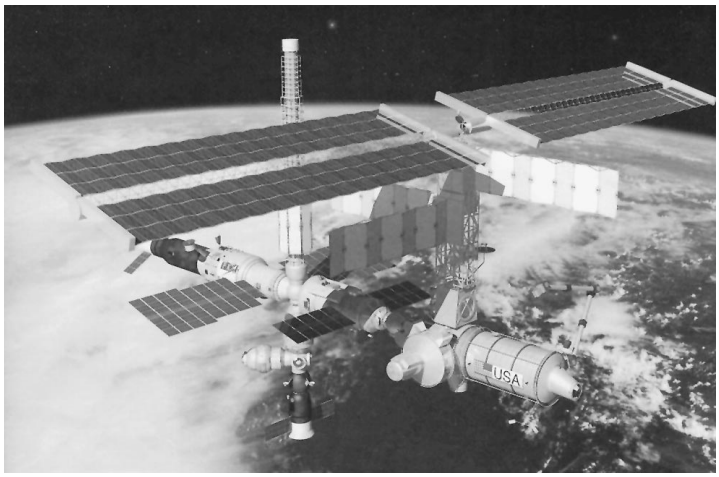
In reservation TDMA, on the other hand, voice call requests are serviced by the assignment (reservation) of a logical channel for inbound voice traffic. Although various means are implemented to avoid collisions on the satellite link, the time needed to reserve capacity on an inbound carrier may be lengthy, depending on traffic conditions. Therefore, call setup times are not as predictable as they are with the poll/response access scheme.

The VSAT design is ideally suited for digital compressed voice. Coding rates of 32, 16, and 9.6 kbps and lower can presently be achieved, depending on the compression technique employed. There are two classes of digitizing voice signals: waveform coding and vocoding. In waveform coding, the analog voice curve is coded and then reproduced by modeling its physical shape. Data rates are relatively high, i.e., higher than 9.6 kbps. Vocoding attempts to reproduce the analog voice curve by abstractly "identifying" the type and shape of the curve. Only a set of parameters is transmitted, describing the nature of the curve. Achieved data rates can be as low as 1.2 kbps.

Second-Generation Systems

The recent wave of satellites have much higher power than their predecessors. The Intelsat K satellite, for example, is equipped with 60-W TWTAs and serves increasing worldwide traffic, video, and VSAT services. Another example is the Telstar 4 satellite which has variable power up to 120 W for Ku-band transmissions and is being promoted to be HDTV compatible in preparation for expected widespread use of HDTV. Other trends in satellite design, i.e., NASA's advanced communication technology satellite (ACTS), include the use of multiple spot beams and onboard IF and/or baseband switching. Onboard switching coupled with electronically hopped spot beams and laser intersatellite links have been proposed. Spot beams provide higher satellite EIRP which permits small, low-cost VSATs to accommodate higher bit rate transmissions. The use of multiple-beam architectures also increases bandwidth availability through frequency reuse. Advances in multibeam satellites

International Space Station



The interim International Space Station will look like this. In the right foreground is the U.S. laboratory module and the station's airlock. In the center of the horizontal string of modules is the FGB energy block. The solar power array at the top is one of four that will provide power for the complete station. Below the tower is the Russian-built universal docking module and, at bottom, one of two crew transfer vehicles. (Photo courtesy of National Aeronautics and Space Administration.)

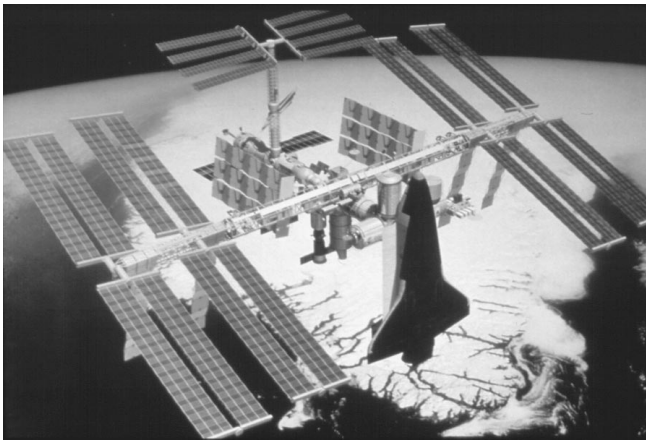
The International Space Station will be a permanent laboratory for human-monitored long term research in the unique environment of Earth-orbital space, an environment that cannot be duplicated on Earth for long duration experiments. This space station program draws upon the resources and scientific and technological expertise of 13 cooperating nations.

This project is being constructed in three phases. Phase I included the 1995 construction of two Boeing-built nodes (Node 1 and Node 2). The nodes will serve as connecting passageways between modules. Phase I was completed in early 1996 with the production of the U.S. laboratory module where astronauts will perform continuous scientific research.

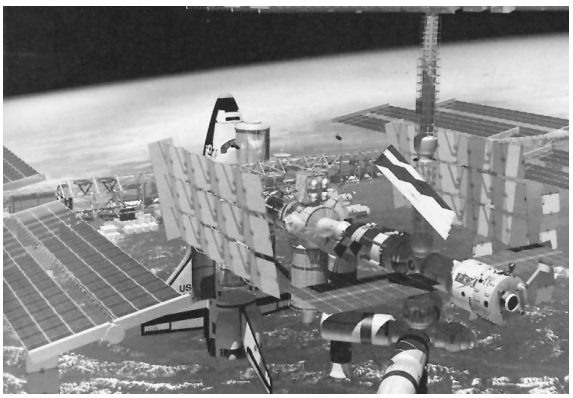
Phase II of the space station program begins in November 1997 with the launch of the FGB functional cargo block on a Russian *Proton* vehicle. The FGB is a 21-ton element that will provide altitude control and propulsion during the early assembly operations, plus solar power and berthing ports for additional modules. In May of 1998, the embryo space station will grow with the addition of the *Proton*-boosted Russian service module, which provides life support and habitation facilities, utilities, and thrusters. Then the crew transfer vehicle, a Russian Soyuz TM capsule, will be joined to the station. By June 1998, the first three-person crew will begin its orbital stay. Phase II will be completed in Spring of 1999.

In Phase III, the International Space Station will progress gradually to its ultimate status as a fully operational permanent orbital research facility. Among key additions to the core configuration are the remaining modules of the U.S.-built solar array; the Japanese experiment module, to be delivered in 2000; and the U.S. habitation module which contains the galley, toilet, shower, sleep stations, and medical facilities. With the delivery of a second Russian crew transfer vehicle in June 2002, the station will be virtually complete.

The completed station will measure 361 feet from tip to tip of the solar arrays. The pressurized living and working space is roughly equivalent to the passenger cabin volume of two Boeing 747 jetliners. The



A concept view of the International Space Station in its final configuration with a space shuttle orbiter docked at the fore port. The cylinder near the orbiter's nose is the U.S. centrifuge accommodation module. Below it, hidden by the orbiter, is the U.S. laboratory module, flanked by the European (left) and Japanese laboratories. (Photo courtesy of National Aeronautics and Space Administration.)



This concept view is of the station from the opposite (aft port) end. In the foreground (lower right) is the Russian service module, with living and working room for three crew members. Next, toward the center of the photo, is the FGB energy block, then (near the orbiter) the U.S. laboratory module. The vertically mounted cylinder below it is the U.S. habitation module. (Photo courtesy of National Aeronautics and Space Administration.)

space station will contain seven laboratories. In addition, the Japanese experiment module has an exposed "back porch" with 10 mounting spaces for experiments that require long duration with the space environment.

Beginning in 1997, there will be a total of 73 assembly and service flights until the station becomes fully operational in midyear 2002. (Courtesy of National Aeronautics and Space Administration.)

with onboard baseband processing allows some of the intelligence in the central hub and VSAT equipment to be moved to the satellite. The result is expected to be improved VSAT-to-VSAT communications and a platform to provide dynamic bandwidth allocation [Naderi and Wu, 1988].

The trend in deploying higher-power satellites has an inverse effect on the size of the earth station antenna. The earth stations are becoming smaller, less complex, and more cost effective. Private hubs are now typically in the range of 3.5 to 7.6 m and are not required to be staffed. Two-way VSATs antennas originally deployed in sizes from 1.2 to 1.8 m are now using elliptical or rectangular-shaped antennas with apertures equivalent to 1.0 m or less. Two-way ultra-small aperture terminals are also emerging. These lower-cost, lower-functionality earth stations are designed for thin route, niche-type applications such as point-of-sale and credit card transaction processing. The advances in DSP technology will continue to enhance the capabilities and performance while at the same time lowering the cost of VSATs. The advances in MMIC technology continue to miniaturize the RF components while increasing reliability.

With advances in digital signal processing and compression techniques, analog video and audio transmission will increasingly be converted to digital transmissions. The advanced compression techniques reduce the bandwidth requirements and allow for smaller and lower-cost VSAT antennas to be used. The continued technological advances in satellite technology and the emerging demand for more flexible communication services will generate new satellite communications applications, such as LAN interconnections and ISDN support [Murthy and Gordon, 1989]. Satellite communications will also play an increasing role in mobile communications on land, air, and on sea. In addition to telephony services, new services such as global distress and safety applications, global positioning, navigation, voice messaging, and data transmissions are now possible.

Defining Terms

Earth station: The interface point for communications to and from a satellite. An earth station (also known as a hub) consists of an antenna and transmit and receive subsystems.

Geosynchronous orbit: An orbit 22,753 miles above the earth in which an object will orbit the earth once every 24 hours above the equator and will appear to be stationary from the earth's surface.

Protocol spoofing: A technique used by VSAT networks to reduce the network delay. The satellite network emulates the host computer front-end processor at the VSAT location and emulates the multiple cluster controllers at the hub location.

Satellite access protocol: A set of rules by which a number of distributed VSATs communicate reliably over a shared satellite channel.

VSAT: Very small aperture terminal. A small earth station suitable for installation at a customer's premises. A VSAT typically consists of an antenna less than 2.4 m, an outdoor unit to receive and transmit signals, and an indoor unit containing the satellite and terrestrial interface units.

103.6 Summary

103.1 Scope

The focus of this chapter is not a detailed profile of a current or planned military C^3 **system** but it is rather on the issues and the technologies of the C^3 mission. Evolving technology, an evolving world order, and constant programmatic reorderings render such express descriptions to become rapidly outdated. Thus block diagrams of specific military systems (and listings of their acronyms) are de-emphasized. Of paramount interest is not electronics technology in isolation, but rather technology integrated into systems and analysis of these systems operating under complex real world environments that include technologically capable adversaries. The human commander or **decisionmaker,** as the principal action element in a C^3 system, is included explicitly in the system analysis.

103.2 Background

Electronics technology is nowhere more intensively and broadly applied than in military systems. Military systems are effective only through their command and control (C^2) and this is recognized by the fact that C^3 is a critical discipline within the military. Frequently systems will be denoted C^2I or C^3I rather than command and control. This adds to C^2 the essential area of **intelligence** and intelligence products derived from surveillance systems. All variants of these acronyms are to be considered equal, whether or not communications, intelligence, or surveillance have been left implicit or made explicit. Likewise the superscript notation is considered optional and interchangeable. The formal discipline of C3 within the military has not been matched by focused technical journals or university curricula due to its highly multidisciplinary nature.

Two definitions from a Joint Chiefs of Staff (JCS) publication [JCS, Pub. 1] capture the breadth of C2. This reference defines command and control as "The exercise of authority and direction by a properly designated commander over assigned forces in the accomplishment of his mission. Command and control functions are performed through an arrangement of personnel, equipment, communications, facilities, and procedures which are employed by a commander in planning, directing, coordinating and controlling forces and operations in the accomplishment of his mission."

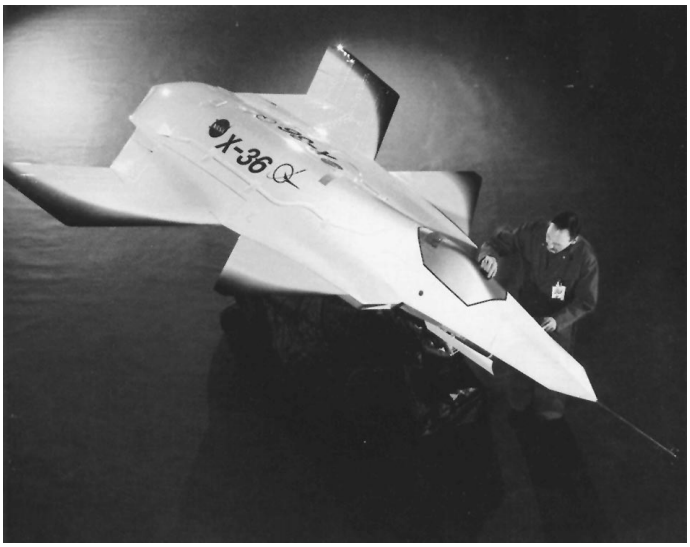
C2 systems are defined, with almost equal breadth, as "An integrated system comprised of doctrine, procedures, organizational structure, personnel, equipment, facilities, and communications which provides authorities at all levels with timely and adequate data to plan, direct and control their operations."

A Look Toward Future Flight

On March 19, 1996, NASA and McDonnell Douglas Corporation unveiled to the public a new subsonic flight vehicle designated X-36, a remotely piloted tailless research aircraft. The X-36 is designed to demonstrate the feasibility of future tailless military fighters that can achieve agility levels superior to those of today's aircraft.

In the absence of a tail, control of the X-36 is accomplished by a combination of thrust vectoring and innovative aerodynamic control features. Tailless fighter configurations offer reduced weight, increased range, and improvement in survivability. The X-36 is "flown" by a pilot located in a van at the flight test facility; a camera in the XX-36 cockpit relays instrument readings and displays to a console in the van. With a wing span of only 10.4 feet and a gross weight under 1,300 pounds, the X-36 is powered by a single turbofan originally designed as a cruise missile power plant.

The X-36 program is intended to establish confidence to incorporate these technologies in future piloted vehicles. This project exemplifies one aspect of a NASA aeronautical research and technology program that seeks to improve the performance, efficiency, and environmental characteristics of all types of planes and, additionally, addresses such infrastructure factors as air traffic control, navigation, and communications. (Courtesy of National Aeronautics and Space Administration.)



Designed jointly by NASA and McDonnell Douglas Corporation, the X-36 is a subscale, remotely piloted tailless vehicle for demonstrating technologies that could lead to lighter, longer-ranging, more survivable, more agile military fighter aircraft. (Photo courtesy of National Aeronautics and Space Administration.)

Though general, two points emerge from these definitions: (1) C^3 is multidisciplinary and (2) C^3 is a process which, to this point, includes only implicit roles for electronics technology. One military service, however, often refers to C^4 and C^4I or has even used C^4I^2 where the final C and second I refer to computers and interoperability, respectively, as acknowledgment of the increasing reliance on technology.

A C3 system can be visualized as shown in Fig. 103.1. Within the constraints imposed by organization, **doctrine,** and the skills of the personnel of the military unit, the commander plans and controls his forces. At a basic level, command and control is a resource allocation problem, which often must be solved under much tighter time horizons and subject to greater uncertainty levels than exist in civil applications.

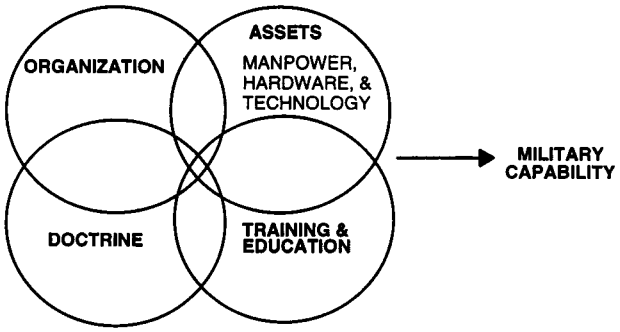


FIGURE 103.1 Components of C^3.

The four basic components display overlapped regions to indicate their inseparability. A portion of each category can be designed in isolation; a new antenna or a new radio with decreased size, weight, or power consumption has minimal impact on the other components. However, insertion of a broad new technology (e.g., a radio relay combined with a remotely piloted vehicle (RPV) or the networking of radios) has wide reaching consequences and it may take years to fully integrate into doctrine, training, and organization. The conjunction of the four areas, when specified with some detail, represents or contains an architecture. If the assets, the doctrine, and so on are limited to just one military function, then the aggregation is referred to as a mission architecture. Figure 103.2 depicts two approaches to achieving C3 architectures. The first [Fig. 103.2(a)] is essentially an aggregation and combination of existing assets and is referred to as a "bottom-up" architecture. The "top-down" version of architecture development [Fig. 103.2(b)] begins with earlier and high order perspective (and higher order oversight). Interfaces and interface standards become more important in top-down architectures; instead of numerous custom and unique interfaces, a minimal set of interface standards is desired. When new or updated equipment is designed or acquired it can be integrated without new interface developments, a key property of an **"open system" architecture.** A developing architecture of this type is entitled, at the Joint Chiefs of Staff level, "C4I for the Warrior." Service-specific top-down architectures are Copernicus (Navy), AirLand 2000 (Army), MTACCS (Marine Corps Tactical Command and Control System) and a yet unnamed Air Force architecture. Each of these are to be considered as evolving architectures and all reflect the impact and importance of scenarios with highly mobile nodes. The open system or top-down approach promotes interoperability between the developments of each service.

Capital investment constraints limit strict adherence to either architectural approach. MTACCS is a meta-system of seven independently developed systems and is best described as a hybrid architecture. Most communication systems within any of the above architectures existed prior to an architecture and thus have a hybrid nature.

Doctrine is a formalized description of military mission definitions and often includes the procedures to accomplish those missions. Doctrine will also often specify the organizational structure appropriate to the specific missions. Some military establishments adhere to strong doctrinal orientation, even down to strict dictation of technology developments. Other establishments treat doctrine as a loose guideline that can be liberally modified. One foreign military analyst observed that U.S. commanders did not seem to read their own doctrinal publications, and even if they did, would not feel compelled to follow them. A flexible military organization with flexible doctrine, however, can be constrained by inflexible hardware and software. Thus an emerging C3 emphasis is a technical focus on modular equipments, standard interfaces between equipments, "open system" architectures, and (software) programmable equipments.

The best way to understand military C3 is to view it as a set of adaptive control loops. The basic variable is information and most of the effort in C3 synthesis is devoted to information handling and management. The resource allocation problem with feedback found in C3 has obvious similarities to those found in corporate operations and public safety service operations. Each is characterized by multiple priorities, limited resources, timelines, and deadlines for performance. Measures of the consequences of a given action tend to be obscured both by its antecedent actions and by changing external **environments.** The external environment contains both continuous events (i.e., tracking of targets) and discontinuous events (i.e., an equipment failure or the onset of communications jamming).

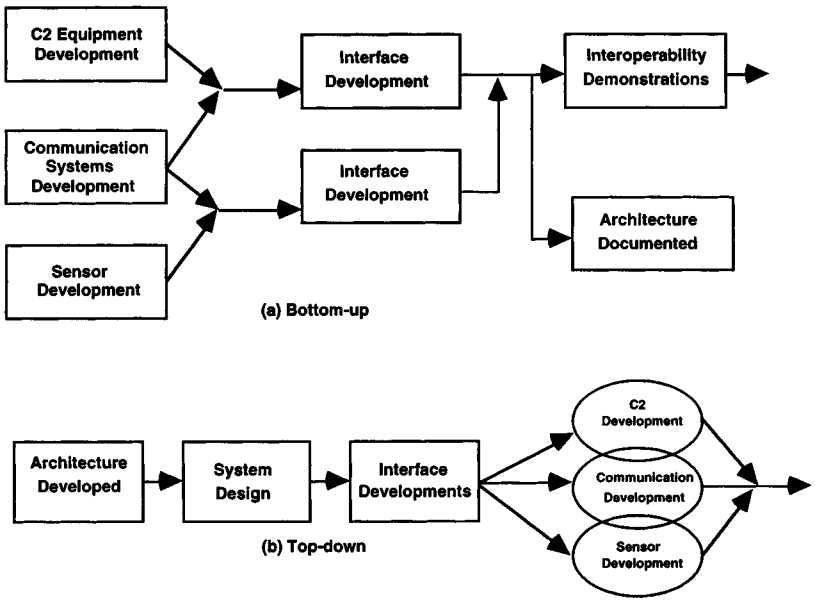

FIGURE 103.2 Architectural processes.

Command and control systems are examples of perhaps the most complex adaptive systems. In its *static* state, C3 assets are aggregates of sensors, processors, databases, humans (with their attributes and organizations), computer hardware/software, mobile platforms, weapons, and communication equipments distributed over wide areas. In the *dynamic* state these assets must be mapped into capabilities in the presence of uncertain or unexpected threats, evolving missions, changing environments, mixed with unreliable communications and possible deception. All can be expected to occur over extended geographic regions and at high tempos. In short, **C³ maps assets into capabilities**. The control processes require rapid and accurate decisionmaking; from this has come the need for heavy reliance on computer-based data systems and high-reliability communications. Despite the existence of fielded weapon systems capable of autonomous operation, the principal action element in the system is still human.

C3 system complexity arises primarily from the magnitude and mobility of the forces involved; forces that can be composed of up to thousands of mobile platforms and hundreds of thousands of personnel. To this is added the large amount of uncertainty present; uncertainty borne of the adversary, of human attributes, dynamics, hostile environments, and communications. Hundreds of radio frequency channels may be in simultaneous use supporting command, surveillance, intelligence, personnel, and logistics functions.

103.3 The Technologies of C³

The general scenario outlined in the previous sections is no longer accommodated by last generation technology of grease pencils, maps, and visual signaling. Technology covered in nearly every other chapter of this handbook is rapidly being incorporated into military C3 systems. Defense departments world wide continue to support technology developments from sub-micron microprocessing devices to global information systems.

Technologies with recent major impact on C3 are

a. Digital communications/data links/networking. The newer and critical role of digital (computer-computer) communications initially became possible through satellite communication systems. Tactical data links (short-range digital communications) have been enhanced by error control techniques such as coding, automatic repeat requests, and spread spectrum radios. Networking, a well-established commercial technique, is being developed for tactical applications. Networking offers survivability through alternate

routing, more efficient (shared) use of channel capacity, and interoperability between interconnected users. Commercial Integrated Services Digital Networks (ISDN) and Asynchronus Transfer Mode (ATM) technology is appearing in both global and nodal military applications. Traditional voice communications remain important; Department of Defense directives require all voice circuits to be secure or encrypted. Digitized voice techniques offer advantage in digital encryption and compression.

b. Space surveillance, terrestrial surveillance, data fusion. The quantity and quality of surveillance systems continues rapid growth utilizing sensors from ground-based, airborne, and space-based vantages. Remote sensing requirements continue to expand the need for real time digital data communications. Unmanned Airborne Vehicles (UAV) and Unmanned Underwater Vehicles (UUV) platform developments continue as a response to a broad range of C3I needs. Two classes of surveillance are active surveillance systems (radar, sonar, and optical) and passive systems (electronic surveillance measuring (ESM), acoustic, infrared and visual imagery). Passive techniques are preferred as they do not leave a signature that can be exploited by adversaries. A plethora of new sensor systems challenges the currently available communications, processors, and processing systems. Particularly challenging is both the fusion of the outputs of multiple similar sensors and also of dissimilar sensor systems. Fusion protocols and tracking algorithms, software intensive, claim an increasing fraction of available resources. With multiple new sensor systems, a technology challenge is the processing, correlation, and fusing of surveillance data into intelligence products and their distribution in a timely and usable form.

c. Computer-based data and information systems. From the communications and surveillance capabilities above, the objective has become formation of a consistent tactical picture throughout the operations theatre. Rapidly evolving processing technology allows vast amounts of data handling and management with corresponding shortening of control decisionmaking times. The ability to match computer processing capability with high data rate, reliable, and survivable computer-grade communications on a global basis to small mobile platforms is an ongoing challenge. Military information systems, in order to retain trusted functioning, require procedures for input data that may have been delayed, omitted, partial, inaccurate, or irrelevant (DOPII). Expanding amounts of software-based systems are needed as a response to increased tempo, data volume, and quality while reducting staff and manpower functions.

d. Architectures and architectural thinking. C3 assets, especially communications, are evolving as assets to be shared, controlled, and rapidly reallocated rather than be dedicated to a specific user. Joint and combined operations, requiring improved interoperability, are becoming common as operations become more regionalized. Two functions of focus, Battle Damage Assessment (BDA) and Indicators and Warnings (I&W), are best implemented when surveillance, communications, and intelligence are architecturally integrated. Integrated systems are also best for timely response to deception and false alarms. A current Navy direction is not to inundate the afloat commander with volumes of unsolicited data but rather have him request what is needed. This style, called information pull, represents a significant change from traditional information push. The impact on supporting communications is to give it a more "bursty" character, driven by external events.

e. Digital signal processing, programmable systems. Single-function C3 hardware is evolving to multifunction capability. Each node or platform will emerge with new capabilities that permits rapid and flexible reallocation. Current generation tactical military aircraft, as delivered, have virtually no additional space or weight allowance for new equipments. A desire is to evolve from costly retrofitting to a state of software insertion and integration. Traditional single-band radio systems will be replaced with **programmable multiband, multiwaveform systems.** Near real-time management and control of highly flexible, programmable systems will become a growing research and development thrust. Next generation cellular technology involving hybrids of frequency hopping, direct sequence spread, and time division spread spectrum techniques invokes new digital signal processing efforts. Also receiving development is Direct Satellite Broadcast (DSB) to tactical military units.

f. Interoperability and standards. C3I systems, with many dispersed nodes, rely heavily on computer-computer communications. Standards are being promoted by industry and government to simplify the development, acquisition, and insertion of new technology as well as to promote interoperability between

independently developed systems. Significantly the Department of Defense has edicted that commercial standards for electronics and telecommunications are to be utilized in preference to military standards in order to promote more rapid and lower cost acquisition of state-of-the-art technology. Two additional motivations for new standards are increased traffic requirements and increased system complexity. C3 applications and users have found significant benefit in increasing communication with programmatically unrelated data sources such as databases and sensors. There is an increase in internal communications as well. Also systems have become more complex, forcing programs to develop modularized architectures. Software is replacing hardware as the most complicated component of communications and C2 systems to design, build, and maintain. Modularized architectures are required to simplify development and enable insertion of new technologies.

The primary computer-to-computer communications architecture has been the Open Systems Interconnection (OSI) Reference Model. The OSI Reference Model has been successful as a layered architecture with well-defined interfaces and specified division of functions. The Department of Defense has committed to adopting an enhanced version of the OSI protocols, called the Government OSI Profile (GOSIP). OSI/GOSIP integration into C3 systems is lagging because of delays in accredited vendor implementations and the cost of upgrading the existing communications infrastructure. NATO is also adopting standards for their joint procurement policies; to a significant degree they overlap commercial standards.

OSI brings to C3 a set of application services that had not been previously available. For example, the OSI electronic mail standards (usually called X.400) provide message forwarding, distribution list creation and distribution, and obsolete message extraction among other services to users. In addition to the security protocols contained in the lower layers of the OSI stack, X.400 has its own security services such as message origin authentication, message flow confidentiality, message content integrity, and nonrepudiation of delivery, services that are highly desirable in C3 environments. OSI also has enhanced file transfer and management capabilities, systems management, directory, and transaction processing, among other application functions, all providing enhanced capability to C3 users.

g. Precision timing and position location (GPS). Navigation/position location historically is important and becomes more so in high dynamic maneuver warfare. With the introduction of the Global Positioning System (GPS), 3-dimensional positioning is available to the smallest of high-mobility nodes. Even with a less than complete satellite constellation, position accuracies can become less than 100 m.
h. Displays and workstations. High-resolution displays combined with programmable workstations and software lead to flexible node functions and consequently to flexible architectures. A C3 workstation could, in principle, support any of a number of C3I functions; a relocation of operators may be the only requirement to physically relocate a command node. Numerous decision aids are now being included within workstations and with their more comprehensive capability are now often described as decision support systems (DSS). Man-machine interface (MMI), as a result, grows in importance.
i. Software techniques. With the growing computational power and memory capability of microprocessor systems, C3 system performance will increasingly be determined by software performance. The cost and complexity of software appears to expand in proportion to host computer capability and is more frequently becoming a system limiting factor. ADA is dictated to be the common programming language of the Defense Department; however, exceptions can be approved. Verification and validation (V&V) of generated software and software maintainence have grown to necessitate organizational changes within the military. Software standards have also increased in importance in new C3 systems. POSIX standards (published as IEEE 1003) govern the software interfaces to operating system services in various computing platforms [NIST, 1990]. As such, they allow application programs written according to the standards to be reused. POSIX standardizes interfaces to security, networking, and diverse system services, including file management, memory and process management, and system administration services. POSIX.5 provides bindings for the ADA programming language.
j. Simulation and modeling. Both techniques are employed with the objective of designing or analyzing the performance of a C3I system. With the advent of faster computation, complex scenarios can be "gamed" in near real time, and modeling will then be within the decision aid realm.

103.4 The Dynamics of Encounters

Within dynamic systems, and the C3 systems that support them, it is important to identify and clarify time scales involved. Military engagements range from sub-second events such as local missile point defense to the long-term development and implementation of global strategy. Each involves basic aspects of decision and control theory: objectives, observations, and feedback and control. In the military environment, the observation aspect is especially complex, requiring the placement, collection, transmission, and aggregation of data from numerous dispersed sources. Control and decision techniques derived for one echelon level may be inappropriate for others, primarily due to the time available for the assessment and feedback process. Often, the impact of a decision will not be measurable before yet another control decision is required. Thus, the relative roles of automation and humans will be different at different levels. The human may have to project a decisionmaking consequence long before the system hardware/software can obtain measures of it.

As an example of encounter space-time domains, surface Navy echelon levels have order-of-magnitude scales as shown:

Organization Level	Time Scale of Interest	Geographic Extent (km)
Platform	seconds-minutes	10's
Battle Group	minutes-hours	100's
Fleet	hours-days	1000's
Theater	days-weeks	1000's +
Service/National	weeks-years	Global

At the platform level, the time scale range reflects engagement times which may include limited or local amounts of tracking. At the Battle Group level, the time scale corresponds to tasks such as maneuver, coordinated engagement, and track management.

Any of the organizational levels may additionally have planning functions that precede the operational time scales by up to months or years. The planning side includes events such as logistics, maintainence, training, and exercises, all of which contribute toward becoming a more capable combatant. Figure 103.3 portrays the planning and the operational or execution phases as well as portraying the adaptive control loop approach to C3. The lighter shaded feedback path is employed when it is required to compare status with the current plan. It is also available for adjustment when plans or objectives are modified. The execution phases are represented by the Stimulus-Hypothesis-Options-Response (SHOR) Paradigm suggested by Wohl [1981]. The control theoretic implications are apparent in the figure; the Stimulus-Hypothesis is a representation of situation assessment with its implicit uncertainty. Quickness and accuracy with which a military command organization can transverse the execution loop is a general measure of performance (MOP). Qualitatively it is generally accepted that the side with the best ability to transverse the SHOR execution loop will have a significant military advantage. In this light, attributes of the execution loop become a measure of effectiveness (MOE) of the C3 system in terms of operational outcomes. Rules of Engagement (ROE) impact tempo by reducing uncertainty or options available to the decisionmaker. Some scenarios develop with such quickness that the C3 system must react nearly reflexively (e.g., without consideration of possible options). One class of rules is made known to all the participants; if a particular manuever is observed, then a specified response will result.

The SHOR paradigm illustrates why counter-communications and counter-command and control are increasingly important operational and technical areas. Counter-C3 need only delay the process rather than disrupt or destroy it in order to be an effective technique. The Navy, for example, is now incorporating **electronic warfare** (EW) as a warfare area on equal status to the traditional anti-submarine (ASW), anti-aircraft warfare (AAW), and anti-surface warfare (ASUW) areas.

Control of the electromagnetic spectrum is becoming as critical as the control of the physical battlefield. Electronic counter-measures (ECM) such as jamming and deception are technical options available to the commander. Either adversary may elect to respond to the ECM threat by a series of electronic counter-counter measure (ECCM) techniques. Anti-jam (AJ) communications can employ a variety of techniques such as spread spectrum, power control, adaptive coding and feedback, multiple routes, and adaptive antenna arrays. A signal

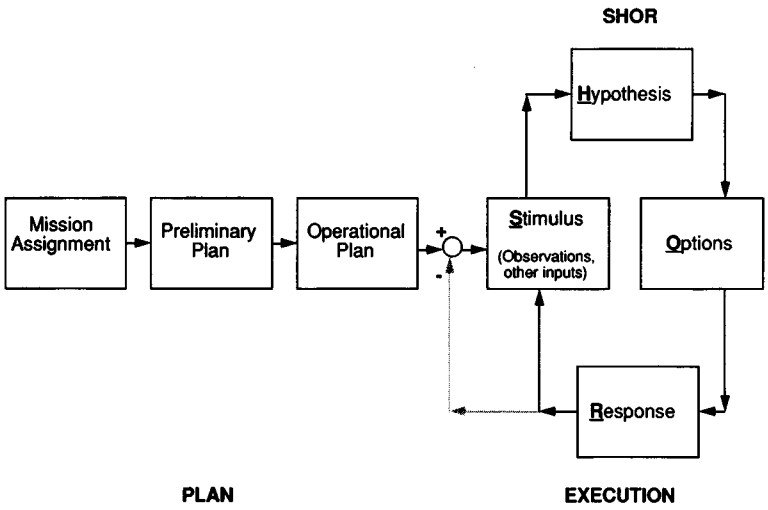

FIGURE 103.3 The planning and execution phases of operations.

may also be protected by making it difficult to intercept; some low probability of intercept (LPI) methods are again spread spectrum, directive antennas, power control, EM propagation strategies, and message brevity.

The SHOR paradigm has important advantages. First, it is generally applicable to all military echelon levels. Second, it represents a control process with its explicit dynamics rather than a relational or physical interconnection of system components. Finally, it puts focus on the roles of controlling and decisionmaking without a pre-bias on whether that function should be performed by humans or computers. The remaining challenge is to be able to describe both human and computer performance with a common type of representational framework.

103.5 The Role of the Human Decisionmaker in C^3

Designers of C3 systems often fail to acknowledge the fact that the "central, essential ingredients in any command and control system are not the things which they plan and design; rather they are the commanders and decisionmakers themselves" [Wohl, 1981]. Despite its centrality, designation of human roles is seemingly arbitrary and often controversial. In most system studies, the human decisionmaker is not thought of as an integral part of the system, but is instead given an external position as a "user" of data or an "input" to the rest of the system. Without a means of integrating the behavior of interrelated decisionmakers into a comprehensive description of system response, the proper hominal role is difficult to determine. To justify and support human action, a clear understanding of the benefits and limitations of human intervention is required.

The complexity and unpredictability of a C3 environment prompt the inclusion of hominal blocks. The ability to respond to changing operational conditions requires "intelligence," and in a C3 system this intelligence is distributed between people and algorithms. The human has a marvelous capacity for coping with vague and confusing data, making sense out of information so fragmentary that it would paralyze a computer. A computer information processing algorithm has, in turn, an unexcelled capability to process and display data at a rate that would bewilder a person. Proper marriage of humans and computers yields a robust system, quick to adapt to changes and capable of handling high data rates. For example, for the various subtasks found in the network management component of a C3 system, the relative roles of people and algorithms might be that shown in Fig. 103.4. With the advent of open system architectures, network management appears as a crucial resource allocation function. High speeds and large databases are best left within the domain of the computer, while those nodes demanding insight appropriately have a corporeal flavor.

A comprehensive C2 model is created by bringing together models of subsidiary elements. The form of these submodels should be as compliant as possible within constraints imposed by tractability. In any event, the model should display:

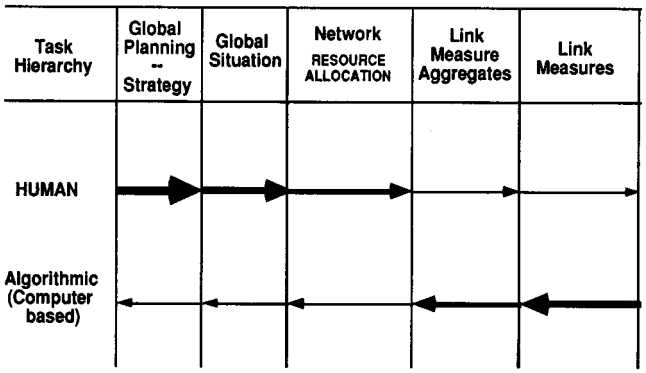

FIGURE 103.4 Control hierarchies.

1. An analytical structure permitting the evaluation of influence functions
2. Explicit communication dependence
3. Amenability to aggregation and disaggregation

Each of these desiderata arises in studies within the field of System Science, and this discipline would appear to provide the natural formalism for quantitative investigations of command and control systems. Athans articulates this view by observing that C3 systems "are characterized by a high degree of complexity, a generic distribution of the decision-making process among several decision making 'agents,' the need for reliable operation in the presence of multiple failures, and the inevitable interaction of humans with computer-based decision support systems and decision aids" [Athans, 1987]. It needs to be emphasized, however, that a C2 system differs from those commonly encountered in system theory in at least three primary ways:

1. Because command and control is at its essence a human decisionmaking activity, it is not sufficient to model only the sensors, computers, displays, etc. The hominal dynamics must be integrated with those of the electromechanical elements.
2. Any effective C3 system must have the capacity to evolve over time. Such systems are frequently established with a limited set of elements. Either for a specific operation or during their lifetime a subset of these elements will be modified or replaced, and their roles expanded or constricted as changing demands are placed upon the system. Hence, the system description must be more flexible than those in common use.
3. In contrast to conventional system design problems, there is no single nominal operating condition about which the system is maintained. Indeed, the critical attribute of a C3 system is its ability to respond to major changes in condition or state. In two Middle East naval events (USS *Stark*, *Vincennes*) the missile defense systems were set for a state that had just immediately changed. Furthermore, the system is often used in environments quite different from those envisioned in its design. Hence, the uncertain circumstances within which the decisionmakers must accomplish their tasks must be properly reflected in any system architecture.

A commander brings special skills to such a system, but some of them are difficult to quantify. For example, people have singular competence in:

1. Decisionmaking in semantically rich problem domains
2. Analogical reasoning and problem structuring
3. Information processing and application of heuristics

To properly identify a specific function for a human decisionmaker, the advantage accruing to his inclusion must be shown. Quantitative models of human responses have been developed in various ways, from ad hoc to purely normative. In the most promising of these, the form of the response dynamics of an individual commander is determined from the solution to an optimization problem. The optimization problem is framed by supposing that the decisionmaker strives to act in the most effective way, but is constrained by both cognitive

limitations and temporal pressures. When the decisionmaker's milieu and motivation are expressed in an analytical framework containing both the exogenous influences of the conflict and the endogenous predispositions generated by training and personal inclination, the input-output relation for the commander is, in principle, expressible as a set of differential equations with logical branching.

This fundamental modeling philosophy has been used successfully by several investigators. Wohl developed the SHOR model of decisionmaker action using the ideas from modern systems theory. The SHOR, in conjunction with planning models (see Fig. 103.3) can be phrased in analytical terms compatible with those of the electromechanical subsystems. With their common form, all of the submodels can be combined to create a comprehensive system description, integrating people with hardware and software algorithms. This model is useful in system architecture studies because it is applicable to all military echelon levels; it represents the fast dynamics of the system explicitly rather than by implicit relational blocks or physical interconnection of subsystem elements, and there is flexibility to allow whether a function is best performed by a human or by an algorithm.

A decisionmaker views a dynamic encounter as a temporally varying, geographically dispersed system subject to unpredictable events, both continuous and discrete. Because critical command decisions have an extended period of influence, the actions taken at different time scales cannot be isolated from each other. This issue of scale interaction comes to the fore particularly when hominal modeling is considered. In contrast to inanimate objects which usually have a single, natural time scale, the demands on a commander transcend the time scale divisions. A trained decisionmaker exhibits a wide spectrum of behaviors as both his tasks and operating environments change; the commander is the truly adaptive block in a command and control architecture. Athans referred to C3 systems as "event driven" because major changes in an engagement occur at isolated times and modulate the more frequent local irregularities [Athans, 1987]. He suggested that the proper model would be a hybrid in which "the state variables are both continuous and discrete." In this metapartitioning of the comprehensive state space, the discrete states represent global (or macro) occurrences that modulate the local (or micro) aspects. This decomposition is useful in formulating the human response model because people react differently in different time scales. The reaction to local phenomena has a reflexive quality. It is in this reaction to the infrequent, but pivotal, macroevents that the idiosyncracies thought to be particularly human are manifest.

To capture hominal behavior analytically, a framework delineating the intrinsic features of a C3 environment is required. At the macrolevel, the important attributes of a command and control environment are tempo, uncertainty, and complexity. The mission directed decisionmaker model (MDDM) described in Clapp and Sworder [1992] decomposes the C2 model in the hybrid form suggested by Athans. One block in the MDDM, the stimulus-hypothesis evaluation model (SHEM), quantifies relevant features of an engagement while representing the observation and situation assessment tendencies of the decisionmaker in terms of a few natural parameters. Because of its simple structure, the SHEM lends itself to the analysis of systems containing human decisionmakers.

To be more specific, the C2 environmental model must be flexible enough to portray the sudden, large-scale variations in circumstances which occur in operations. It is advantageous to phrase the model in such a way as to make explicit its dependence on events of macroscopic scale as well as the decisionmaker's response. The engagement model used in the MDDM has the form:

$$(d/dt)x_p = f(x_p, u_p, r_t) + g(x_p, u_p, r_t)w_t$$

where x_p is the "global" system state vector representing the external environment to which the decisionmaker seeks to respond. The decisionmaker's action variable is u_p. The process $\{w_t\}$ represents only one portion of the primitive randomness in the encounter—that associated with high-frequency uncertainty and various local disturbances. The supplementary process, $\{r_t\}$, indicates the mode of evolution of the encounter. Transitions in $\{r_t\}$ thus signify extensive events. These macro-events tend to have more temporal structure than that displayed by $\{w_t\}$, but the times of occurrence are typically unpredictable. Different values of r_t (sometimes called supervariables) are identified with different hypotheses delineating the macrostatus of the encounter. It is usually assumed that the number of modal hypotheses is finite.

Even with the aggregation implicit in the engagement model, the encounter dynamics are complex and nonlinear. A decisionmaker mentally converts the engagement dynamics into a hybrid equation with separate descriptions of local and global aspects. The input-output dynamics of the commander are expressed as an ordinary differential equation with updates at observation times. In Sworder et al. [1992], the ability of the SHEM to predict the response of a trained decisionmaker was investigated. An experiment measuring the proficiency of trained air-defense officers in differentiating hostile from friendly targets confirmed the utility of the SHEM.

103.6 Summary

C3I systems, commanders/decisionmakers, and decision aids all have a common performance objective. They must contribute to accurate and timely *situation assessments and responses* in scenarios that have a wide range of tempos, noise, clutter, uncertainty, and complexity.

The C3 system necessarily has the ability to rapidly acquire, process, and transfer large volumes of data over extended regions. Trained, experienced human decisionmakers excel at assessing complex patterns in highly cluttered environments and determining appropriate responses. Decision aids perform as a "smart" interface between these two dissimilar players. Electronics technology provides the means for designing increasingly capable C3 systems and is at its most effective when the system architecture allows flexible and dynamic interoperation of the various hardware "devices" with their trained and motivated decisionmakers.

Defining Terms

Command, control, communications (C^3): The process of mapping assets (resources available to the military commander) into capabilities. This control process is impacted by tempo, noise/clutter, and scenario complexity.

Decisionmaking: A commander's or operator's action that changes the status of his information or other assets under his control.

Doctrine: A formalized description of military mission definitions to include the procedures to accomplish those missions. Doctrine will also often specify the organizational structure appropriate to the specific mission.

Electronic warfare: Contention for the control of the electromagnetic (EM) spectrum, to allow active and passive EM sensing and communications while denying the same ability to adversaries. Includes deceptive EM techniques.

Environment: A set of objects outside the system, a change in whose attributes affects, and is affected by, the behavior of the system.

Information warfare: The protection, manipulation, degradation, and denial of information to include the traditional electronic warfare.

Intelligence: The aggregated and processed information about the environment, including potential adversaries, available to commanders and their staff.

Open system architecture: A layered architectural design that allows subsystems and/or components to be readily replaced or modified; it is achieved by adherence to standardized interfaces between layers.

Programmable radio system: Radios based on digital waveform synthesis and digital signal processing to allow simultaneous multiband, multiwaveform performance.

System: A set of objects with relations between them and their attributes or properties. It is embedded in an environment containing other interrelated objects.

Consistency

Consistency is a concept that can be easily understood if we first define the set of all possible models that could have produced the *a posteriori* information **y**, in accordance with the class of measurement noise:

$$\mathcal{S}(\mathbf{y}) \triangleq \left\{ g \in \mathcal{S} \,\middle|\, \mathbf{y} = E(g, \eta),\ \eta \in \mathcal{N} \right\} \tag{104.40}$$

Therefore, $\mathcal{S}(y) \subset \mathcal{S}$ is the smallest set of models, according to all the available input data (*a priori* and *a posteriori*), that are indistinguishable from the point of view of the input information. This means that with the knowledge of ($\mathbf{y}$, $\mathcal{S}$, $\mathcal{N}$) there is no way to select a smaller set of candidate models. The "size" of set $\mathcal{S}(\mathbf{y})$ places a lower bound on the identification error, which cannot be decreased unless we add some extra information to the problem. This lower bound on the uncertainty error holds for any identification algorithm and represents a type of *uncertainty principle* of identification theory.

The *a priori* and *a posteriori* information are consistent if and only if the set $\mathcal{S}(\mathbf{y})$ is non-empty; otherwise, there is no model in $\mathcal{S}$ that could have possibly generated the experimental output.

Identification Error

The *a priori* knowledge of the real system and measurement noise present in the experiment **y** is stated in terms of sets $\mathcal{S}$ and $\mathcal{N}$. The statement of the problem does not assign probabilities to particular models or noise; therefore, it is deterministic in nature. In addition, the modeling error should be valid no matter which model $g \in \mathcal{S}$ is the real plant (or $\eta \in \mathcal{N}$ the real noise vector) that induces a worst-case approach. In this deterministic worst-case framework, the identification error should "cover" all models $g \in \mathcal{S}$ that combined with all possible noise vectors $\eta \in \mathcal{N}$, are consistent with the experiments, i.e., $\mathcal{S}(\mathbf{y})$. In practice, however, the family of models conservatively covers this "tight" uncertainty set. Hence, it provides an upper bound for the distance from a model to the real plant. In this framework, the worst-case error is defined as follows:

$$d(\mathcal{A}) \triangleq \sup_{\eta \in \mathcal{N},\, g \in S} m\left\{ g,\ \mathcal{A}\left[\mathrm{E}(g, \eta), S, \mathcal{N} \right] \right\} \tag{104.41}$$

where $m(\cdot,\cdot)$ is a specific metric.

The identification algorithm $\mathcal{A}$ maps both *a priori* and *a posteriori* information to a candidate nominal model. In this case, the algorithm is said to be *tuned* to the *a priori* information; otherwise, if it only depends on the experimental data, it is called *untuned*. Almost all classical parameter identification algorithms ([6]) belong to the latter class.

The identification error (Eq. (104.41)) can be considered as *a priori*, in the sense that it takes into account all possible experimental outcomes consistent with the classes $\mathcal{N}$ and $\mathcal{S}$ *before* the actual experiment is performed. Since it considers all possible experimental data **y**, it is called a *global* identification error. A *local* error that applies only to a specific experiment **y** can be defined as follows:

$$e(\mathcal{A}, \mathbf{y}) = \sup_{g \in S(\mathbf{y})} m\left[g, \mathcal{A}(\mathbf{y}, S, \mathcal{N}) \right] \tag{104.42}$$

Clearly, we always have $e(\mathcal{A}, \mathbf{y}) \le e(\mathcal{A})$. To decrease the local error more experiments need to be performed, whereas to decrease the global error new *types* of experiments, compatible with new *a priori* classes, should be performed, for example, reducing the experimental noise and changing $\mathcal{N}$ accordingly.

Convergence

Now, what happens with the family of models when the amount of information increases? It is desirable to produce a "smaller" set of models as input data increases, i.e., model uncertainty should decrease. The set of models are expected to tend to the real system when the uncertainty of the input information goes to zero. Hence, an identification algorithm $\mathcal{A}$ is said to be convergent when its worst-case global identification error

$e(\mathcal{A})$ in Eq. (104.41) goes to zero as the input information tends to be "completed." The latter means that the "partialness" and "corruption" of the available information, both *a priori* and *a posteriori*, tend to zero simultaneously.

Input information is corrupted by measurement noise. Thus, "corruption" tends to zero when the set $\mathcal{N}$ is a singleton $\mathcal{N} = \{0\}$. On the other hand, partialness of information can disappear in two different ways. By *a priori* assumptions when the set $\mathcal{S}$ tends to have only one element (the real system) or *a posterior* measurements when the amount of experimental information is completed by the remaining (usually infinite) data points. This can be unified as follows. The available information (*a priori* and *a posteriori*) is completed when the consistency set $\mathcal{S}(\mathbf{y})$ tends to only one element: the real system. Hence, an identification algorithm $\mathcal{A}$ converges if and only if

$$\lim_{size\left[S(\mathbf{y})\right]\to 0} e\left(\mathcal{A}\right) = 0 \tag{104.43}$$

Note that as the consistency set $\mathcal{S}(\mathbf{y})$ reduces to a single element, the experiment operator tends to be invertible. Since the identification error is defined in a worst-case sense, its convergence is uniform with respect to the *a priori* sets $\mathcal{N}$ and $\mathcal{S}$.

Algorithms and Further Research Topics

There are robust identification algorithms that consider frequency domain experiments, called $\mathcal{H}_\infty$–identification, this being the norm that measures the identification error. The two main ones are the two-stage and the interpolation algorithms. From time-domain measurements, several ℓ_1-identification procedures are available.

Due to the fact that robust identification is a currently active research area, there are yet many theoretical and computational aspects that have not been fully developed. Among others, there are problems related to identifying unstable plants and nonuniformly spaced experimental samples. Also, sample complexity is a recent research direction, as well as the mixture of time and frequency experiments and parametric and nonparametric models.

A complete description of both frequency ($\mathcal{H}_\infty$) and time (ℓ^1) domain identification algorithms and a discussion of the issues mentioned above can be found, for example in [9].

Defining Terms

BIBO stable: A system is Bounded Input Bounded Output stable if for all bounded inputs and zero initial conditions, the corresponding output is also bounded. In the case of finite-dimensional linear time invariant systems, this definition is equivalent to having all the poles of the system in the open left half plane $Re(s) < 0$.

Control oriented identification: A deterministic identification procedure that starting from experimental data generates a model consistent with both this data and some *a priori* assumptions on the class of systems under consideration.

Robust stability and performance: A given property of a system (such as stability or performance) is *robust* if it holds for a *family of systems* that represents (and contains) the nominal plant.

Robustness margin: A quantitative measure of stability, given by the distance from the nominal model representing the system, to the nearest model lacking the property under consideration. Examples are the classical gain and phase margins.

105.1 Introduction

In principle the dynamic behavior of the human element in man-machine systems can be described in terms similar to those used to describe other system elements. There are, however, major complications in quantification because of the enormous versatility of the human engaged, simultaneously, as the on-going *architect* and modifier of the man-machine system itself and as an operating entity within that system. In other words, the adaptive and learning capabilities of the human permit both set-up and modification of the effective system structure and the subsequent self-improvement and tuning of the human dynamic characteristics within that structure.

The situations which are simplest to quantify are those in which the *machine* has time-stationary dynamic properties and the human has, after architectural, learning, and adaptation phases, achieved a similar state. Under these circumstances human dynamic operations can be characterized by quasi-linear describing functions and a remnant [Graham and McRuer, 1961] or operator-induced noise. This is the context here.

105.2 Several Natures of Man-Machine Control—A Catalog of Behavioral Complexities

Figure 105.1 [McRuer and Krendel, 1974] shows a general quasi-linear man-machine system with time-stationary properties. This diagram is suitable for the description of human behavior in an interactive man-machine system wherein the human responds to visually sensed inputs and communicates with the machine via a manipulator of some sort (e.g., control stick, wheel, pedal, etc.). This block diagram indicates the minimum needed number of major functional signal pathways internal to the human operator to characterize different behavioral features. The constituent human sensing, data processing, computing, and actuating elements are connected as internal signal processing pathways which can be "reconfigured" as the situation changes. Such reconfiguration is an aspect of human behavior as a system architect. Functional operations on internal signals within a given pathway may also be modified.

The specific internal signal organizational possibilities depicted in Fig. 105.1 have been discovered by manipulating experimental situations (e.g., by changing system inputs and machine dynamics) to isolate different combinations of the specific blocks shown [McRuer and Jex, 1967; McRuer and Krendel 1974; McRuer 1980].

To describe the parts of the figure start at the far right with the *controlled element.* This is the machine being controlled by the human. To its left is the actual interface between the human and the machine—the neuromuscular

Hazardous Environment Robotics

Deneb Robotics, Inc. is an internationally known leader in 3D graphics-based factory simulation, telerobotics, and virtual reality software used widely in the aerospace, automotive, defense, environmental, medical, nuclear, and research communities.

Among the company's broad software product line is TELEGRIP™, which provides 3D graphical interface for previewing, interactive programming, and real-time bilateral control of remote robotic devices. It provides operators a system for safe, quick, and efficient remediation of hazardous environments from a single point of control and input that is isolated from virtually all operator hazards.

Accurate 3D kinematic models of the robot and work space components allow the operator to preplan and optimize robot trajectories before the program is automatically generated. Control commands are monitored when running in autonomous, teleoperational, or shared control modes to assure procedural safety.

A video camera provides a Deneb Robotics engineer with a view of the robot. (Photo courtesy of National Aeronautics and Space Administration.)

actuation system, which is the human's output mechanism. This in itself is a complicated feedback control system capable of operating as an open-loop or combined open-loop/closed-loop system, although that level of complication is not explicit in the simple feedback control system shown here. In the diagram the neuromuscular system comprises limb, muscle, and manipulator dynamics in the forward loop and muscle spindle and tendon organ ensembles as feedback elements. Again, many more biological sensors and other elements are actually involved; this description is intended only to be generally indicative of the minimum level of complexity associated with the *human actuation elements.* All of these elements operate within the human at the level from the spinal cord to the periphery.

There are other sensor systems, such as joint receptors and peripheral vision, which indicate limb output position. These operate through higher centers and are subsumed in the *proprioceptive* feedback loop incorporating a block at the perceptual level further to the left in the diagram. If motion cues are present, these too can be associated in similar proprioceptive blocks with feedbacks from the controlled element output.

The other three pathways shown at the perceptual level correspond to three different types of control operations on the visually presented system inputs. Depending on which pathway is effectively present, the

A key feature of TELEGRIP is a video overlay option that utilizes video to calibrate 3D computer models with the actual environment. The video overlay technique is especially useful for on-line planning applications or teleoperations in remote, hazardous, or complex environments such as space, undersea, or nuclear sites.

A virtual reality calibration technique was developed for reliable and accurate matching of a graphically simulated environment in 3D geometry with actual video camera views. The system was designed for predictive displays with calibrated graphics that overlay in live video for telerobotics applications. For example, the system allows an operator to designate precise movements of a robot arm before sending the command to execute.

Following successful test of the video overlay techniques, an agreement was concluded with Deneb Robotics that allows the company to integrate video overlay into the commercially available TELEGRIP to expand its use in hazardous environment robotics. The operator can view the video image of the real world environment (upper right) and the computer's interpretation of the same scene using TELEGRIP. (Photo courtesy of National Aeronautics and Space Administration.)

control structure of the man-machine system can appear to be *open-loop*, or *combination open-loop/closed-loop*, or totally *closed-loop* with respect to visual stimuli.

When the *compensatory* block is appropriate at the perceptual level, the human controller acts in response to errors or controlled-element output quantities only. Only the Y_{pe} block "exists", with Y_{pi} and the precognitive block both equal to zero. With the compensatory pathway operational, continuous closed-loop control is exerted on the machine so as to minimize system errors in the presence of commands and disturbances. **Compensatory behavior** will characteristically be present when the commands and disturbances are random-appearing and when the only information displayed to the human controller consists of system errors or machine outputs. In the simple case where the describing function Y_{pe} is defined so as to account for the perceptual and neuromuscular components, the system is single-input/single-output, and the operator-induced noise is neglected, the closed-loop system output/input dynamics will be

$$\frac{m}{i} = \frac{Y_{pe}Y_c}{1 + Y_{pe}Y_c} \tag{105.1}$$

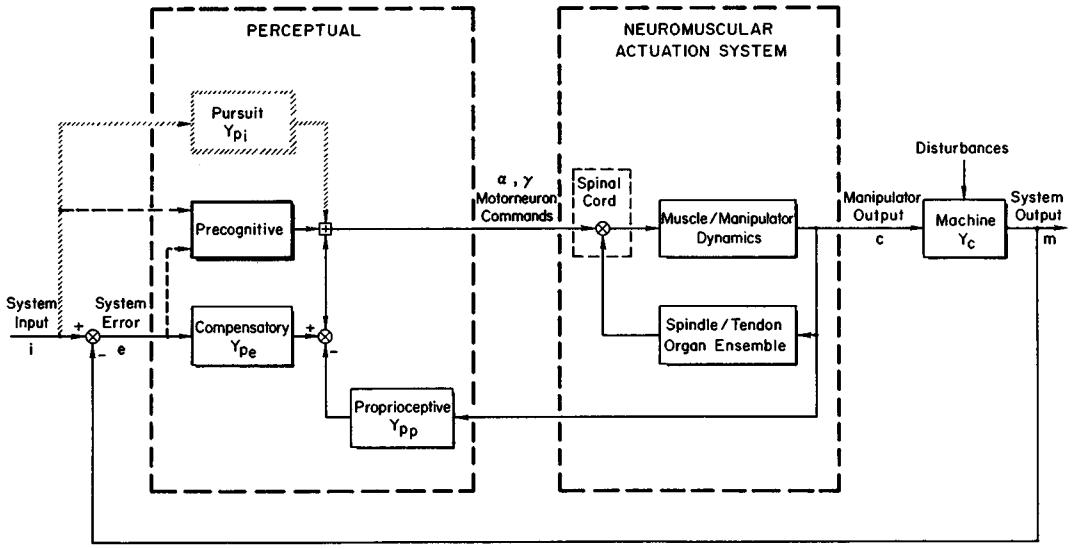

FIGURE 105.1 Major human operator pathways in a man-machine system.

and the error/input

$$\frac{e}{i} = \frac{1}{1 + Y_{pe}Y_c} \tag{105.2}$$

Thus, for compensatory situations, the man-machine system emulates the classic single-input/single-output feedback system. The output can be made to follow the input and the error can be reduced only by making the open-loop describing function large compared to 1 over the operating bandwidth of the system.

When the command inputs can be distinguished from the system outputs by virtue of the display (e.g., *i* and *m* are shown or detectable as separate entities relative to a reference) or preview (e.g., as in following a curved course) the *pursuit* block in Fig. 105.1 comes into play and joins the compensatory. The introduction of this new signal pathway provides an open-loop control in conjunction with the compensatory closed-loop error correcting action. The output/input dynamics of the man-machine system will then become

$$\frac{m}{i} = \frac{(Y_{pi} + Y_{pe})Y_c}{1 + Y_{pe}Y_c} \tag{105.3}$$

and the error/input describing function is

$$\frac{e}{i} = \frac{1 - Y_{pi}Y_c}{1 + Y_{pe}Y_c} \tag{105.4}$$

With the pursuit system organization the error can be reduced by the human's operations in two ways: by making the open-loop describing function large compared with 1 and by generating a pursuit path describing function which tends to be the inverse of the controlled element. This can, of course, only be done over a limited range of frequencies. The quality of the overall control in the pursuit case can, in principle, be much superior to that where only compensatory operations are possible.

An even higher level of control is possible. When complete familiarity with the controlled element dynamics and the entire perceptual field is achieved, the highly skilled human operator can, under certain conditions, generate neuromuscular commands which are deft, discrete, properly timed, scaled, and sequenced so as to result in machine outputs which are almost exactly as desired. These neuromuscular commands are selected

from a repertoire of previously learned control movements. They are conditioned responses which may be triggered by the situation and the command and control quantities, but they are not continuously dependent on these quantities. This pure open-loop programmed-control-like behavior is called **precognitive**. Like the pursuit pathway, it often appears in company with compensatory follow-up or simultaneous operations. This forms a dual-mode form of control in which the human's manual output is initially dominated by the precognitive action, which does most of the job, and is then completed when needed by compensatory error-reduction actions.

The above description of human action pathways available in man-machine systems has emphasized the visual modality. Similar behavior patterns can be exhibited to some extent in other modalities as well. Thus the human's interactions with machines can be even more extraordinarily varied than described here and can range completely over the spectrum from open-loop to closed-loop in character in one or more modalities.

105.3 Full-Attention Compensatory Operations—The Crossover Model

The compensatory pathways with manual control operations using the visual modality have been extensively studied. Thousands of experiments have been performed, and most of the adaptive features of human behavior associated with these kinds of operations are well understood. There are both classical control [e.g., McRuer and Krendel, 1974; and McRuer et al., 1990] and optimal control [e.g., Baron and Kleinman, 1969; Kleinman et al., 1970; Curry et al., 1976; and Thompson, 1990] theoretical formulations available to predict steady-state and dynamic performance.

By far the simplest human behavioral "law" for compensatory systems is the *crossover model*. This states that, for a particular controlled element transfer function, Y_c, the human operator adopts a describing function, Y_{pe}, such that the open-loop man-machine transfer characteristics appear as

$$Y_p Y_c = \frac{\omega_c e^{-\tau j\omega}}{j\omega} \tag{105.5}$$

The two parameters in the crossover model are the crossover frequency, ω_c, and an effective pure time delay, τ. The model applies only in the immediate region of the crossover frequency. The typical data shown in Fig. 105.2 illustrate how well this relationship is obeyed for a variety of subjects and a particular controlled element. The agreement with the amplitude ratio is excellent over a broad range of frequencies. The phase agreement is good in the region of the crossover frequency, ω_c, but departs somewhat at lower frequencies. Figure 105.2 also shows the *extended crossover model*. Here the effects in the crossover region of a potentially large number of low-frequency lags and leads (in the machine and/or the operator) are represented by a phase contribution given by $\exp(-j\alpha/\omega)$. Here the time constant $1/\alpha$ is a lumped-constant representation of myriad low-frequency phase characteristics. It is an appropriate approximation *only* in the general region of crossover and is not intended to extend to extremely low frequencies.

Fundamentally, the crossover model states that the human's transfer characteristics will be different for each set of machine dynamics, but that the form of the composite total open-loop dynamics will be substantially invariant. The effective time delay in Eq. (105.5) is a low-frequency approximation to the combination of all manner of high-frequency pure delays, lags, and leads, including a component representing the effects of

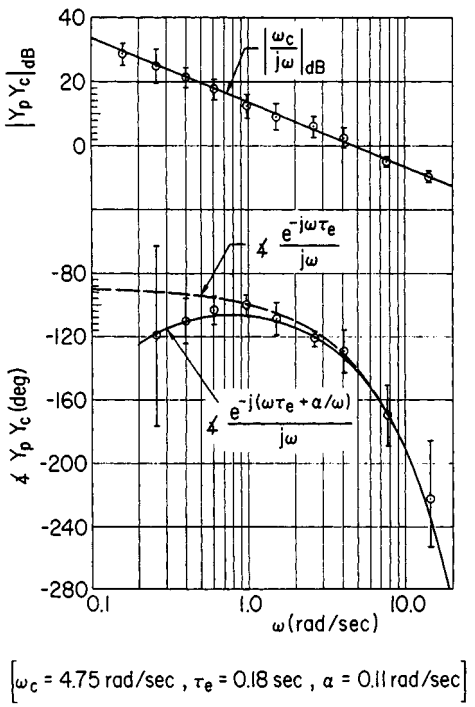

FIGURE 105.2 Data and crossover models for a simple rate-control-like controlled element.

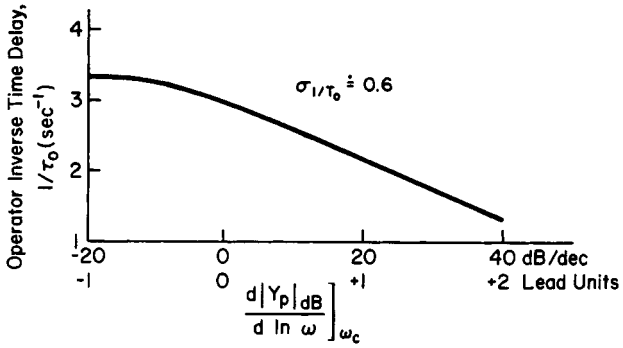

FIGURE 105.3 Variation of crossover model dynamic stimulus-response latency with degree of operator lead equalization.

the neuromuscular actuation system reflected to the crossover region. It follows that the effective time delay, τ, is not a constant. Its two major components are (1) the effective composite time delay of the controlled element (including manipulator effects)—the sum of the machine's lags minus leads at frequencies well above crossover and (2) the high-frequency dynamics of the human operator approximated by a pure delay which has an equivalent phase shift at frequencies within the crossover region. The latter includes a minimum of 0.1 second for the neuromuscular system and an additional increment which depends on the amount of lead generation required of the human to offset the controlled element deficiencies in order to make good the crossover model form. Figure 105.3 [McRuer and Krendel, 1974] shows this variation for a wide range of controlled elements (the neuromuscular delay component is included). More refined estimates are available [e.g., McRuer et al., 1990], but the above description is suitable for first-order estimates of behavior and dynamic performance.

Crossover Frequency for Full-Attention Operations

The crossover frequency tends to be constant for a given set of task variables (controlled-element form, inputs, disturbances, etc.). For example, as a controlled-element gain is changed, the human will change gain to compensate, resulting in the same crossover frequency. The maximum attainable crossover frequency, ω_u, will be

$$\omega_u = \frac{\pi}{2\tau} \tag{105.6}$$

This corresponds to zero phase margin. The nominal crossover frequency and associated pilot gain can be estimated from the condition to provide minimum mean-squared error in the presence of the appropriate form of continuous attention remnant. "Remnant" is operator-induced noise; as described below it depends on the nature of the operator's equalization and is larger when low-frequency lead is required to make good the crossover model. Thus, the need to generate lead impacts both the effective time delay and the remnant and, accordingly, the crossover frequency for which the minimum mean-squared error is obtained. The nominal crossover frequency for full-attention operations can be estimated [McRuer et al., 1990] using

	ω_c/ω_u
No Operator Lead	0.78
Low-Frequency Operator Lead	0.66

Remnant

The second component of the operator's response is operator-induced noise or remnant. Remnant can, in principle, result from several sources, but in single-loop systems with ideal linear manipulator characteristics

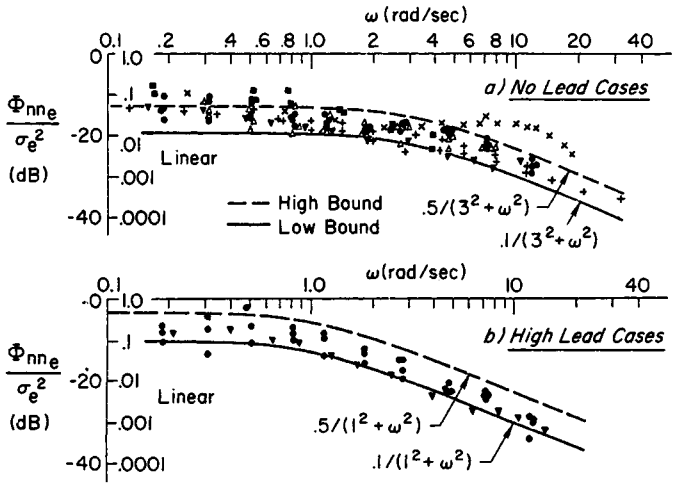

Figure 105.4 Normalized remnant spectra.

and no significant nonlinearities in the controlled element, the basic cause appears to be random time-varying behavior within the operator, which can be thought of as continuous random fluctuations in the effective time delay. The remnant can be described as a continuous, relatively broadband, power spectral density. Fig. 105.4 provides a cross-section of remnant data from several sources. It is very important to note that the magnitude of the power spectral density scales approximately with the mean-squared error.

Effects of Changes in the Task Variables

The task variable which has the most important effect on the trained operator's behavior is the controlled element dynamics. Indeed, the natures of human adaptive changes in adjusting to the controlled element is the main thrust of the crossover model and remnant discussion above. More generally, task variables other than the machine dynamics, as well as environmental and operator-centered variables, can change operator gain, and hence crossover frequency, effective time delay, and remnant. Accordingly, ω_c and τ variations become quantification measures of changes or differences in the task, environmental, and operator-centered variables expressed directly in terms of the operator's control actions.

A common example is the reduction of crossover frequency when the amplitude of the command or disturbance signals are very small. This reflects the human's indifference to small errors and constitutes the principal human behavioral nonlinearity in the crossover model context. Another example occurs in measuring the effects of training, where ω_c increases with trials until stable conditions are obtained for that particular subject and set of constant task and environmental conditions. Similarly, operator gain and remnant can be modified as a consequence of changes in operator-centered variables. A notable example is the decrease in gain and increase in remnant which accompanies alcohol ingestion.

Effects of Divided Attention

Human operators in man-machine systems are, in general, involved in two types of operations—control tasks and a diverse combination of monitoring/supervising/communicating/data-gathering/decision making activities referred to as "managerial tasks." While the operator's attention is "divided" between the control and managerial tasks, these are often performed nearly simultaneously as parallel processing operations.

By definition, control workload is highest when the operator's full attention is required for control purposes and when this attention is focused on only the most critical input information needed for closed-loop control. For this reason the full-attention crossover model and remnant for compensatory behavior treated above has received the major attention here. Estimates and considerations based on full-attention compensatory assumptions will generally be conservative. For instance, the dynamic performance of the overall man-machine system will typically be improved when additional cues and information provide the basis for the generation of pursuit behavior.

For a given situation the minimum divided attention level should be established by the demands of the control task. When divided attention conditions are present in compensatory situations the major effects on the control performance are reduced crossover frequency and increased system error. To a first order the divided attention effects on average crossover frequency are given in Fig. 105.5. Here the "control dwell fraction," is η, the proportion of the total time spent on the control task. There are many other complications and considerations [McRuer et al., 1990], but these require more than handbook treatment.

Figure 105.5 Effect of divided attention on processing bandwidth.

Defining Terms

Compensatory behavior: Human dynamic behavior in which the operator's actions are conditioned primarily by the closed-loop man-machine system errors.

Compensatory display: For the simplest case, a display which shows only the difference between the desired input command and the system output.

Precognitive behavior: Conditioned responses triggered by the total situation; essentially pure open-loop control.

Pursuit behavior: The human operator's outputs depend on system errors, as in compensatory behavior, but may also be direct functions of system inputs and outputs. The human response pathways make the man-machine system a combined open-loop, closed-loop system.

Pursuit display: In the simplest case, a display which shows input command, system output, and the system error as separable entities.

Further Information

The references of the chapter, especially Kleinman et al. [1970], McRuer and Krendel [1974], and McRuer et al. [1990], comprise a good cross section of detailed information on modeling aspects of man-machine systems. An excellect general text is T.B. Sheridan and W.R. Farrell, *Man-Machine Systems: Information, Control, and Decision Models of Human Performance*, Cambridge: MIT Press, 1974.

Encyclopedic coverage appears in K.R. Boff, L. Kaufman, and J.P. Thomas, *Handbook of Perception and Human Performance*, New York: Wiley, 1986, and K.R. Boff and J.E. Lincoln, "Engineering Data Compendium: Human Perception and Performance," Harry G. Armstrong Aerospace Medical Research Laboratory, Wright-Patterson Air Force Base, Ohio, 1988.

The aperiodic proceedings of the so-called "Annual Manual" contain a great deal of information about man-machine system developments. Since 1965 these have been published by NASA as SP's (NASA Special Publications) under the general heading of *NASA—University Conference on Manual Control.*

The text article emphasizes the dynamic behavior of the human, not the design of machine dynamics to achieve optimum characteristics in terms of man-machine system dynamic performance and human subjective approval. For these aspects of design, a comprehensive summary of models, references, and applications appears in "Advances in Flying Qualities," *AGARD Lecture Series LS-157,* 1988. Although the applications there are specifically for aerospace vehicle control, the principles illustrated apply to vehicles in general and to other machines subject to continuous control by a human operator.

As with other feedback control systems, system stability is a major consideration. In spite of the extraordinary adaptive properties intrinsic to human controllers, system instability is a rare but often unfavorable event. The nature of such man-machine oscillations and the design steps required to avoid them is treated extensively in Duane McRuer, *Pilot-Induced Oscillations and Human Dynamic Behavior,* NASA Contractor Report 4683, July 1995.

106.1 Introduction

Vehicular systems have evolved and incorporated advances from many other fields of technology over the past decade. Instrumentation and controls for the various modes (aircraft, marine vessels, cars, trucks, buses, and rail vehicles) resemble each other more every year. Technology from one mode of transportation used to be of little interest to practitioners of any other mode. A technology historian might notice similarities among the functions of airport beacons, lighthouses, traffic lights, and railroad signals, but the specialists in each field had little to say to each other. This is no longer the case. Computers, microprocessor controls, electronics, GPS, and advanced networking and radio technologies are being applied in all forms of passenger and freight transportation, from aviation to marine, highway, and rail transport. The vehicles are now considered in context with an entire system within a particular mode, which is increasingly viewed as part of an overall transportation environment encompassing more than one mode.

Although "multimodal" is a term that was coined by policy makers to facilitate equitable distribution of funding among transportation modes and to facilitate interfaces among them, it applies equally well to the supporting technologies of the original modes. All modes now utilize microprocessor controls in their subsystems. With microprocessor control has come additional diagnostic capability and the use of system level intelligence, linking all intelligent subsystems and analog sensors and controls. Propulsion of vehicles now varies by mode less than it used to. Because of microprocessors, propulsion can be controlled more precisely, allowing vehicles to use non-traditional energy sources and to switch from one source to another easily, even automatically. We do not yet have the ideal multimodal vehicle, capable of navigating, either automatically or by a driver/operator, through air, in water, on roads, and on rails, but technology is no longer a limiting factor. We have not yet achieved the best balance among modes so that the most appropriate mode is utilized for passenger or freight transportation, but the tools exist to make those decisions possible. (This section deals primarily with land transportation. See the index for aviation and maritime applications.)

106.2 Design Considerations

If design could begin with a clean slate, the first step would be to decide which mode of transportation and which power source is best suited for the application, based on geography, priority of the passenger or cargo to be transported, energy efficiency, safety, cost per mile, and other factors. However, this is not really possible because the factors relating to funding sources and existing infrastructure often outweigh any technical considerations.

Road Engine

George B. Selden
Patented November 5, 1895
#549,160

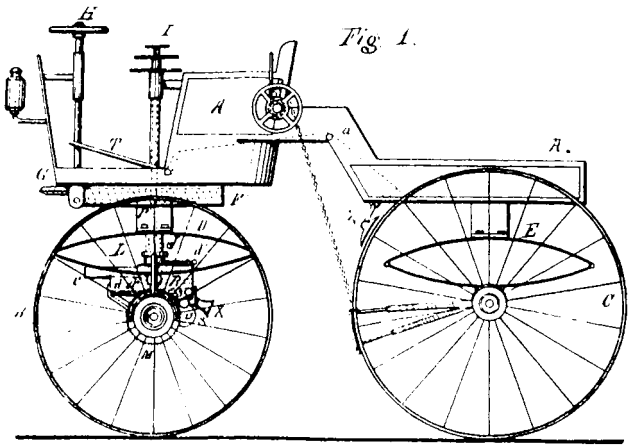
An excerpt from George Selden's patent application:

Be it known that I, George B. Selden, a citizen of the United States, residing in Rochester in the county of Monroe, in the state of New York, have invented an improved Road Engine, of which the following is a specification, reference being had to the accompanying drawings.

The object of my invention is the production of a safe, simple, and cheap road-locomotive light in weight, easy to control and possessed of sufficient power to overcome any ordinary inclination.

Perhaps one of the most famous patent lawsuits surrounded this patent applied for in 1879 by Selden, who was more of a patent attorney than an inventor. He sold the patent to Col. Allen Pope in 1899 who began to enforce the patent and won judgments against several car manufacturers—except one. They were forced to pay royalties on all vehicles they produced.

Henry Ford called the patent preposterous claiming that it didn't cover his vehicles that he had invented first. He refused to pay royalties and won a ruling in his favor in 1911, after millions had been paid out by his competitors. (Copyright © 1995, DewRay Products, Inc. Used with permission.)



Railroads, rail transit, buses, vans, and automobiles each have their own operating environments, although they are increasingly considered part of a system rather than simply as independent vehicles. Many of the underlying technologies are utilized across modal boundaries, but the basics of design remain highly dependent on mode.

Electrical systems are widely used in automobiles and trucks today and electronic systems currently make up about 10% of the value of a car. Electronic systems are currently used to control the engine, transmission, steering, braking, suspension, and traction. Many autos incorporate an integrated computer system for controlling the functions mentioned. In addition, electronic systems are used to display information such as speed and engine conditions.

Air bag inflation units use sensors and electronic controls to insure proper inflation within milliseconds after a collision.

As antilock brakes, **active suspensions**, and other computer-dependent technologies are fully utilized, electronic systems may constitute more than 20% of the value of a car. Much of the added computing power will be used for new technology for smart cars and smart roads, or ITS (intelligent transportation systems). The term refers to a varied assortment of electronics that provide real-time information on accidents, congestion, routing, and roadside services to drivers and traffic controllers. ITS encompass devices that would make vehicles more autonomous: collision-avoidance systems and lane-tracking technology that alert drivers to impending disaster or allow a car to drive itself. ITS also includes interfaces between personal traffic and mass transportation, particularly when rail traffic mixes with cars and at rail crossings, whether or not such crossings are protected by gates. Railroads and mass transit vehicles have many of the same internal subsystems as cars do, and also additional subsystems, for which cars may soon have analogous functions. The electrical and electronic systems and controls account for 15 to 30% of the cost of the vehicle.

The major vehicle subsystems include propulsion, braking, power conditioning, communication, passenger information (audio and visual), heating/air conditioning, door control, speed control, and monitoring and diagnostics. All of these subsystems interact with each other and many also interact with subsystems external to the vehicle.

Some of the initial design considerations for vehicles include:

- Will the vehicle interface with an existing fleet?
- Will the vehicle operate independently or as part of a consist, or both?
- What are the physical requirements, including dimensions, number of passengers (seated vs. standing)? Is the system (or portions of it) elevated, in tunnels, at grade, underground? Will the vehicles mix with or cross other types of traffic? Are ambient conditions exceptionally hot, cold, or dangerous?
- How closely must one vehicle (or consist) follow another and how fast must they be capable of traveling? Where, how often, and for how long will they stop?
- To what degree will the vehicles be automated; how much control will a human operator (and/or other crew) have and under what conditions?
- What kind of power is available, how will it be collected, and can energy generated during electric braking be returned to the power system?
- How will system and subsystem failures be handled, what kind of failures are acceptable, and to what degree (or for how long) will they be tolerated? How often and with what degree of expertise will the vehicles be serviced?

106.3 Land Transportation Classifications

Among land transportation vehicles, there are more subdivisions than the lay person might expect. In general, distinctions are based on vehicle size, weight, speed, and passenger or cargo capacity. Cars, trucks, mini-vans, vans, sport utility vehicles, etc. are familiar terms. There is some variation among them relative to the electronics embedded in the systems and the options available to the driver. The same is true for railroads, rail transit, and mass transit, although the distinctions among classifications are important to the manufacturers and operators of the equipment. The classifications include railroad, commuter rail, heavy rail, light rail, street car, trolley bus, bus, paratransit, and "people mover" or monorail.

106.4 Propulsion

By 1910 electric automobiles were commonplace. Nevertheless, they were replaced by gasoline-fueled automobiles by 1920 because electric cars operated at lower top speeds and over shorter ranges without recharging than gasoline cars could achieve. However, the availability of electric motive power remained a critical factor in the development of cities. Since the mid-1970s, when the electric vehicle reemerged as an appealing transportation option, many have recognized the potential of electric fleet vans. An **electric vehicle** uses electric energy storage, electric controls, and electric propulsion devices. Because the vans use batteries to drive their electric motors, they are well suited

to the short routes and regular schedules followed by vans in a company fleet. One such fleet van, the General Motors Griffon, is produced in England. Because the vans can be recharged regularly at night, they offer electric utilities a new off-peak demand. At the same time, electric vehicles run cleanly and burn no gasoline.

Increasing the distance an electric vehicle can travel on a single charge is the most significant factor in expanding the market for electric vans. The 60-mile (97-km) range of the Griffon makes it a replacement candidate for about 600,000 commercial fleet vehicles now operating in the United States. If advanced batteries doubled the range of a van to 120 miles, the potential market for these vehicles could top 2 million. A variety of electric cars has been introduced over the years, but none have enjoyed general use.

Products of combustion gradually were recognized as major air pollutants and fuels have been acknowledged as non-renewable resources, so alternatives have been sought with increasing diligence.

Today, electric motors are used more widely for rail vehicles than for cars, vans, or buses, although this is slowly changing (see above). Electric motors as a back-up mode for buses are becoming more common in certain areas where air pollution is considered a serious problem and in portions of systems, such as North American tunnels, where fumes from internal combustion can be hazardous.

Power distribution for rail vehicles ranges from three phase ac, at various voltages (usually collected from overhead wires), to several different dc voltages (usually collected from a "third rail"). Until recently (within the past 5 years in the U.S.), most electric traction motors utilized dc power. Today, most traction motors in new vehicles use ac power. Various techniques are used to cool the motors, depending on the operating environment. Collected power is conditioned continuously (see power "converters" and "inverters") to meet the motors' requirements and the power requirements of other vehicle systems, and also is stored to power critical on-board systems if power is lost.

Traction motors also are used for braking, which generates power that can be reconditioned and returned to the power system to power other vehicles or returned to the power grid. Power that cannot be returned or used elsewhere in the system is converted into heat by banks of large braking resistors. Electric braking is supplemented by mechanical braking systems which can be actuated pneumatically, hydraulically, and/or electrically. Coordination of propulsion and braking efforts, especially when traction surfaces are slippery, is an important design point.

Microprocessor controls have allowed optimization of automotive internal combustion processes to economize on fuel and minimize air pollution. Alternative fuels, such as natural gas, are becoming more common because the combustion process can be managed more uniformly, responsively, and safely than ever before.

Diesel electric locomotives have become the propulsion vehicle of choice for long haul freight railroads. Microprocessors control the combustion process which produces electricity to power electric motors when ac power is not available, such as on long sections of rail that are not yet electrified.

Dual mode buses utilize internal combustion when operating on the streets, but switch to electric power in tunnels. Dual mode rail vehicles or streetcars collect power from an overhead catenary or third rail, but can switch to battery power when they are not operating in electrified areas.

Improvements in battery technology (cost, life, power density, weight, and maintenance requirements) and solar power as a supplementary or primary source will improve the acceptance of alternatives to internal combustion and direct electric power.

106.5 Microprocessor Controls

All major vehicle subsystems and many minor ones are now microprocessor-controlled. Embedded microprocessors replace banks of relays and mechanical switches to perform functions on the vehicle and also to control functions that did not exist prior to the advent of microprocessors. Some major vehicle subsystems have several microprocessors handling different functions and coordinating analog and digital input and output signals.

Intelligent subsystems exchange information within a vehicle, among vehicles in a consist, and between the vehicle and its external environment. This information is exchanged through increasingly sophisticated networks, which may or may not use traditional wiring. There may also be a separate network or layers of error-checking to handle safety-critical data.

A human vehicle operator typically has status indicators, alarms, and controls. These have changed dramatically with the advances in microprocessor-controlled subsystems. The "glass cockpit" and "fly by wire" techniques

Power Applying Mechanism

Otto Zachow and William Besserdich
Patented December 29, 1908
#907,940

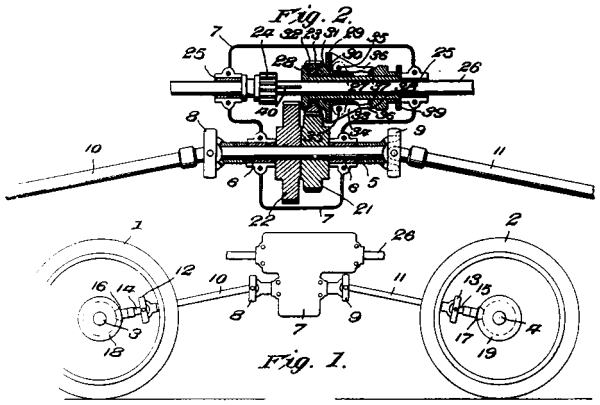
An excerpt from Otto Zachow and William Besserdich's patent application:

Our invention relates to new and useful improvements in power-applying mechanism and more particularly to that class adapted to be used in connection with motor-propelled vehicles, such as automobiles, or the like, and our object is to provide a mechanism of this class whereby the power may be applied to both the front and rear axles.

Early in this century, Otto Zachow and his friend, William Besserdich, had the idea of making all four wheels of their vehicle turn, when they slid into a ravine and got stuck. Out of frustration the four-wheel drive mechanism was invented.

At the beginning of World War I, they sold about 50 trucks equipped with the mechanism to Great Britain. When the United States entered the war, Zachow and Besserdich sold 3,750 trucks to the U.S. Army.

Today, four-wheel drive is available on a wide range of vehicles from small sport utilities to luxury imports. (Copyright © 1995, DewRay Products, Inc. Used with permission.)



developed for aviation generally transition to cars and trains as they are service-proven and as their cost decreases. A driver or train operator once had a few lights, a gauge or two, a throttle of some sort, and a brake handle or pedal. For vehicles that are not automated but are partially automated or allow manual operation at times, a human operator today is confronted by a dense array of dials, buttons, data and CCTV screens, LCD panels, microphones, and annunciators (audio and visual) of various types. In some cases there is far more information than an operator can use. In others, there is duplication between the old, analog indicators and controls and new, digital or "soft" controls on a touch screen.

There has been some resistance to technology advances, based on the perception that electronics are not as reliable as electromechanical devices (such as relays) and on a concern that they will be more complicated to troubleshoot and maintain than electro-mechanical and analog equipment.

106.6 Monitoring and Diagnostics

A great advantage of microprocessor-controlled systems is the degree to which they can be self-diagnosing. Each intelligent subsystem has internal self-diagnostics which include routines to perform initial tests on power-up, update checks for "hot" startup and continuous checking to assure that inputs and outputs are within expected ranges. Internal self-diagnostics are also capable of performing self-tests on request. When fault conditions are noted, typically there are internal resets to allow for inaccurate data, with faults being logged after a certain number of occurrences or duration of a fault condition.

The basis of any monitoring and diagnostics system is the underlying maintenance philosophy. Microprocessor controls make it possible to capture any combination of information from the intelligent subsystems. Information can then be processed and presented in a variety of ways, along with data from analog sensors which are not part of any intelligent system.

Information of interest includes operating status and existing or historical fault information. "Events" may include faults and also other expected actions that may or may not be considered faults. Historical information can include faults, events, and the status of parameters of interest associated with the fault. The amount of information that can be captured is limited only by the amount of memory provided and the speed at which it can be transferred. Typically, some (or all) of the memory is in a form that will allow the fault data to be preserved after power is lost or vehicles are shut down between operating periods.

Decisions on which information to capture, how often to sample, and how many samples to preserve are ideally based on what will be most valuable for troubleshooting existing faults and predicting future failures. A thorough understanding of each intelligent subsystem is needed in addition to an understanding of the environment in which it operates, including the other subsystems with which it interacts. It is also important to know what level of skill will be applied to interpreting the saved information. If the level of skill will be low, some degree of artificial intelligence can be designed into the diagnostics to guide a maintenance technician through the troubleshooting process.

The information needed to be collected is influenced by the target audience. The most detailed internal subsystem information is primarily used by engineers or specialized technicians to troubleshoot detailed failures or fine tune operation. A subset of less detailed information is used by maintenance staff to determine which components or sub-modules to replace or repair. A further subset of that information is used by a general troubleshooting staff to determine which subsystem is malfunctioning or which higher level modules to replace. An even smaller subset of operating status information and only a few major faults are needed by the operator, with a selection of that data being useful to a central control or maintenance dispatching facility if real time links are available. A variety of techniques are being used to present this information to the target audience(s) in ways and at times that are most appropriate.

"Event recorders" similar to the ones required on passenger airliners, capturing selected parameters, are now required by the FRA for railroads and are under consideration by industry standards groups for other modes.

Defining Terms

Active suspension: An electronically controlled suspension system for maintaining level suspension of a vehicle.

Consist: Two or more vehicles coupled together in a train. The vehicles may be identical or they may each lack a major subsystem (such as propulsion), whose functions may be handled by another vehicle in the consist.

Dual mode: Vehicles that are designed to switch manually or automatically from one type of propulsion to another, for instance from internal combustion to electric.

Electric braking: Use of traction motor to slow the vehicle.

Electric vehicle: Vehicle using electric energy storage, electric controls, and electric propulsion devices.

Traction motor: Electric motor that provides motive power to move vehicles.

107.1 New Concepts in Designing an Industrial Illuminating System

Determination of Illuminance Levels

Among the many new concepts for lighting design, the first to be discussed is the new method of determining **illuminance** levels. In the past when illuminating engineers wanted to find the recommended illuminance level for a given task, they would look in the lighting handbook to find a recommended level and then design an illuminating system for the task using the value as a minimum. This procedure provides very little latitude for fine-tuning an illumination design. In the new method, a more comprehensive investigation of required illuminance is performed according to the following steps:

1. Instead of a single recommended illuminance value, a category letter is assigned. Table 107.1 shows different category letters for a selected group of industries (partial only; for complete list see *IES Lighting Handbook* [1993]).
2. The category letters are used to define a range of illuminance. Table 107.2 details illuminance categories and illuminance values for generic types of activities in interiors.
3. From within the recommended range of illuminance, a specific value of illuminance is selected after consideration is given to the average age of workers, the importance of speed and accuracy, and the reflectance of task background.

The importance of acknowledging the speed and accuracy with which a task must be performed is readily recognized. Less obvious is the need to consider the age of workers and the reflectance of task background.

TABLE 107.1 Illuminance Categories for Selected Group of Industries

Area/Activity	Illuminance Category
Aircraft maintenance	[a]
Aircraft manufacturing	[a]
Assembly	
Simple	D
Moderately difficult	E
Difficult	F
Very difficult	G
Exacting	H
Automobile manufacturing	
Bakeries	
Mixing room	D
Face of shelves	D
Inside of mixing bowl	D
Fermentation room	D
Make-up room	
Bread	D
Sweet yeast-raised products	D
Proofing room	D
Oven room	D
Fillings and other ingredients	D

Dairy products	
Fluid milk industry	
Boiler room	D
Bottle storage	D
Bottle sorting	E

[a] Industry representatives have established a table of single illuminance values which, in their opinion, can be used. Illuminance values for specific operations can also be determined using illuminance categories of similar tasks and activities found in this table and the application of the appropriate weighting factors.

Source: IES Lighting Handbook, Application Volume.

TABLE 107.2 Illuminance Categories and Illuminance Values for Generic Types of Activities in Interiors

Type of Activity	Illuminance Category	Ranges of Illuminances		Reference Work-Plane
		Lux	Footcandles	
Public spaces with dark surroundings	A	20–30–50	2–3–5	
Simple orientation for short temporary visits	B	50–75–100	5–7.5–10	General lighting throughout spaces
Working spaces where visual tasks are only occasionally performed	C	100–150–200	10–15–20	
Performance of visual tasks of high contrast or large size	D	200–300–500	20–30–50	
Performance of visual tasks of medium contrast or small size	E	500–750–1,000	50–75–100	Illuminance on task
Performance of visual tasks of low contrast or very small size	F	1,000–1,500–2,000	100–150–200	
Performance of visual tasks of low contrast and very small size over a prolonged period	G	2,000–3,000–5,000	200–300–500	Illuminance on task, obtained by a combination of general and local (supplementary lighting)
Performance of very prolonged and exacting visual tasks	H	5,000–7,500–10,000	500–750–1,000	
Performance of very special visual tasks of extremely low contrast and small size	I	10,000–15,000–20,000	1,000–1,500–2,000	

Source: IES Lighting Handbook, Application Volume.

To compensate for reduced visual acuity, more illuminance is needed. Using the average age of workers as the age criterion is a compromise between the need of the young and the older workers and, therefore, a valid criterion.

Task background affects the ability to see because it affects **contrast**, an important aspect of visibility. More illuminance is required to enhance the visibility of tasks with poor contrast. Reflectance is calculated by dividing the reflected value by the incident value. The data given in Tables 107.3 and 107.4 are taken from the *IES Lighting Handbook* [1987] and are applied to provide a single value of illuminance from within the range recommended.

Illuminating system design can begin after the desired value of illuminance for a given task has been determined. Based on the *IES Handbook*, the zonal cavity method of determining the number of luminaires and lamps to yield a specified maintained luminance remains unchanged.

Illumination Computational Methods

Zonal Cavity Method. Introduced in 1964, the zonal cavity method of performing lighting computations has gained rapid acceptance as the preferred way to calculate number and placement of luminaires required to satisfy a specified illuminance level requirement. Zonal cavity provides a higher degree of accuracy than does the old lumen method, because it gives individual consideration to factors that are glossed over empirically in the lumen method.

Definition of Cavities. With the zonal cavity method, the room is considered to contain three vertical zones or cavities. Figure 107.1 defines the various cavities used in this method of computation. Height for luminaire to ceiling is designated as the ceiling cavity (h_{cc}). Distance from luminaire to the work plane is the room cavity (h_{rc}), and the floor cavity (h_{fc}) is measured from the work plane to the floor.

To apply the zonal cavity method, it is necessary to determine a parameter known as the "**cavity ratio**" (CR) for each of the three cavities. Following is the formula for determining the cavity ratio:

$$\text{cavity ratio} = \frac{5h\,(\text{room length} + \text{room width})}{(\text{room length} \times \text{room width})} \tag{107.1}$$

where h equals h_{cc} for ceiling cavity ratio (CCR), h_{rc} for room cavity ratio (RCR), h_{fc} for floor cavity ratio (FCR).

TABLE 107.3 Weighting Factors for Selecting Specific Illuminance Within Ranges A, B, and C

Occupant and Room Characteristics*	Weighting Factor		
	–1	0	+1
Workers' age (average)	Under 40	40 to 55	Over 55
Average room reflectance[1]	>70%	30 to 70%	<30%

Source: IES Lighting Handbook, Application Volume.

Note: This table is used for assessing weighting factors in rooms where a task is not involved.

1. Assign the appropriate weighting factor for each characteristic.
2. Add the two weights; refer to Table 107.2, Categories A through C:
   a. If the algebraic sum is –1 or –2, use the lowest range value.
   b. If the algebraic sum is 0, use the middle range value.
   c. If the algebraic sum is +1 or +2, use the highest range value.

*To obtain average room reflectance: determine the areas of ceiling, walls, and floor; add the three to establish room surface area; determine the proportion of each surface area to the total; multiply each proportion by the pertinent surface reflectance; and add the three numbers obtained.

TABLE 107.4 Weighting Factors for Selecting Specific Illuminance Within Ranges D through I

Task or Worker Characteristics	Weighting Factor		
	–1	0	+1
Workers' age (average)	Under 40	40 to 55	Over 55
Speed or accuracy*	Not important	Important	Critical
Reflectance of task background, %	>70%	30 to 70%	<30%

Source: IES Lighting Handbook, Application Volume.

Note: Weighting factors are based upon worker and task information.

1. Assign the appropriate weighting factor for each characteristic.
2. Add the two weights; refer to Table 107.2, Categories D through I:
   a. If the algebraic sum is –2 or –3, use the lowest range value.
   b. If the algebraic sum is –1, 0, or +1, use the middle range value.
   c. If the algebraic sum is +2 or +3, use the highest range value.

*Evaluation of speed and accuracy requires that time limitations, the effect of error on safety, quality, and cost, etc. be considered. For example, leisure reading imposes no restrictions on time, and errors are seldom costly or unsafe. Reading engineering drawings or a micrometer requires accuracy and, sometimes, speed. Properly positioning material in a press or mill can impose demands on safety, accuracy, and time.

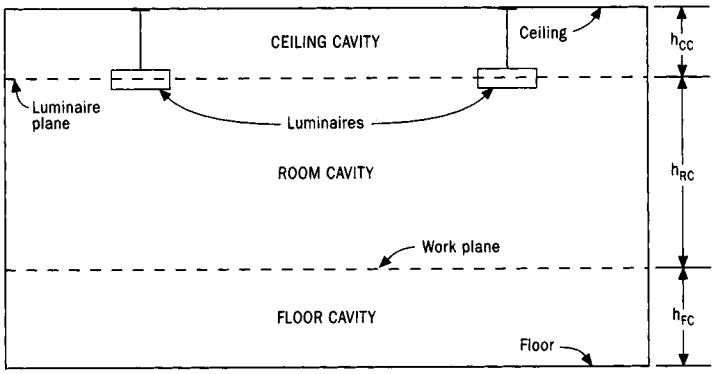

FIGURE 107.1 Basic cavity divisions of space.

Lumen Method Details. Because of the ease of application of the lumen method which yields the average illumination in a room, it is usually employed for larger areas, where the illumination is substantially uniform. The lumen method is based on the definition of a footcandle, which equals one lumen per square foot:

$$\text{footcandle} = \frac{\text{lumen striking an area}}{\text{square feet of area}} \tag{107.2}$$

In order to take into consideration such factors as dirt on the luminaire, general depreciation in lumen output of the lamp, and so on, the above formula is modified as follows:

$$\text{footcandle} = \frac{\text{lamps/luminaire} \times \text{lumens/lp} \times \text{CU} \times \text{LLF}}{\text{area/luminaire}} \tag{107.3}$$

In using the lumen method, the following key steps should be taken:

a. Determine the required level of illuminance.
b. Determine the **coefficient of utilization (CU)** which is the ratio of the lumens reaching the working plane to the total lumens generated by the lamps. This is a factor that takes into account the efficiency and the distribution of the luminaire, its mounting height, the room proportions, and the reflectances of the walls, ceiling, and floor. Rooms are classified according to shape by 10 room cavity numbers. The cavity ratio can be calculated using the formula given in Eq. (107.1). The coefficient of utilization is selected from tables prepared for various luminaires by manufacturers.
c. Determine the **light loss factor (LLF)**. The final light loss factor is the product of all the contributing loss factors. Lamp manufacturers rate filament lamps in accordance with their output when the lamp is new; vapor discharge lamps (fluorescent, mercury, and other types) are rated in accordance with their output after 100 hr of burning.
d. Calculate the number of lamps and luminaires required:

$$\text{no. of lamps} = \frac{\text{footcandles} \times \text{area}}{\text{lumens/lp} \times \text{CU} \times \text{LLF}} \tag{107.4}$$

$$\text{no. of luminaires} = \frac{\text{no. of lamps}}{\text{lamps/luminaire}} \tag{107.5}$$

e. Determine the location of the luminaire—luminaire locations depend on the general architecture, size of bays, type of luminaire, position of previous outlets, and so on.

Point-by-Point Method. Although currently light computations emphasize the zonal cavity method, there is still considerable merit in the point-by-point method. This method lends itself especially well to calculating the illumination level at a particular point where total illumination is the sum of general overhead lighting and supplementary lighting. In this method, information from luminaire **candlepower distribution** curves must be applied to the mathematical relationship. The total contribution from all luminaires to the illumination level on the task plane must be summed.

Direct Illumination Component. The angular coordinate system is most applicable to continuous rows of fluorescent luminaires. Two angles are involved: a longitudinal angle α and a lateral angle β. Angle α is the angle between a vertical line passing through the seeing task (point P) and a line from the seeing task to the end of the rows of luminaires. Angle α is easily determined graphically from a chart showing angles α and β

for various combinations of V and H. Angle β is the angle between the vertical plane of the row of luminaires and a tilted plane containing both the seeing task and the luminaire or row of luminaires. Figure 107.2 shows how angles α and β are defined. The direct illumination component for each luminaire or row of luminaires is determined by referring to the table of direct illumination components for the specific luminaire. The direct illumination components are based on the assumption that the luminaire is mounted 6 ft above the seeing task. If this mounting height is other than 6 ft, the direct illumination component shown in Table 107.5 must be multiplied by $6/V$, where V is the mounting height above the task. Thus the total direct illumination component would be the product of $6/V$ and the sum of the individual direct illumination components of each row.

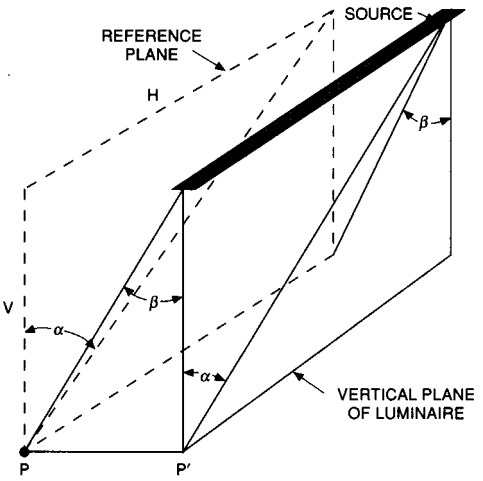

FIGURE 107.2 Definition of angular coordinate systems for direct illumination component.

Reflected Illumination Components on the Horizontal Surfaces. This is calculated in exactly the same manner as the average illumination using the lumen method, except that the reflected radiation coefficient (RRC) is substituted for the coefficient of utilization.

$$FC_{RH} = \frac{\text{lamps/luminaire} \times \text{lumens/lp} \times \text{RRC} \times \text{LLF}}{\text{area/luminaire}} \tag{107.6}$$

where RRC = LC_W + RPM ($LC_{CC} - LC_W$), LC_W = wall luminance coefficient, LC_{CC} = ceiling cavity luminance coefficient, and RPM = room position multiplier.

The wall luminance coefficient and the ceiling cavity luminance coefficient are selected for the appropriate room cavity ratio and proper wall and ceiling cavity reflectances from the table of luminance coefficients in the same manner as the coefficient of utilization. The room position multiplier is a function of the room cavity ratio and of the location in the room of the point where the illumination is desired. Table 107.6 lists the value of the RPM for each possible location of the part in the rooms of all room cavity ratios.

Figure 107.3 shows a grid diagram that illustrates the method of designating the location in the room by a letter and a number.

Reflected Illumination Components on the Vertical Surfaces. To determine illumination reflected to vertical surfaces, the approximate average value is determined using the same general formula, but substituting WRRC (wall reflected radiation coefficient) for the coefficient of utilization:

$$FC_{RV} = \frac{\text{lamps/luminaire} \times \text{lumens/lp} \times \text{WRRC} \times \text{LLF}}{\text{area/luminaire (on work plane)}} \tag{107.7}$$

where

$$\text{WRRC} = \frac{\text{wall luminance coefficient}}{\text{average wall reflectance}} - \text{WDRC} \tag{107.8}$$

where WDRC is the wall direct radiation coefficient, which is published for each room cavity ratio together with a table of wall luminance coefficients (see Table 107.5 for a specific type of luminance).

107.2 Factors Affecting Industrial Illumination

Basic Definitions

Illuminance. lluminance is the density of luminous lux on a surface expressed in either footcandles (lumens/ft^2) or lux (lx) (lux = 0.0929 fc).

Luminance (or photometric brightness). Luminance is the luminous intensity of a surface in a given direction per unit of projected area of the surfaces, expressed in candelas per unit area or in lumens per unit area.

Reflectance. Reflectance is the ratio of the light reflected from a surface to that incident upon it. Reflection may be of several types, the most common being specular, diffuse, spread, and mixed.

Glare. Glare is any brightness that causes discomfort, interference with vision, or eye fatigue.

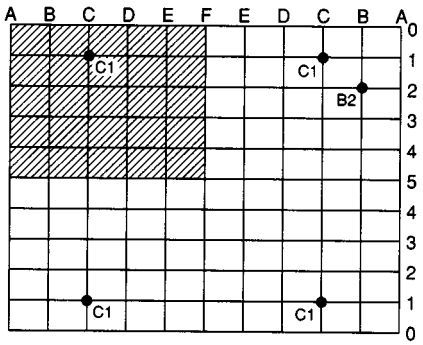

FIGURE 107.3 Grid diagram for locating points on the work plane.

Color Rendering Index (CRI). In 1964 the CIE (Commission Internationale de l'Eclairage) officially adopted the IES procedure for rating lighting sources and developed the current standard by which light sources are rated for their color rendering properties. The CRI is a numerical value for the color comparison of one light source to that of a reference light source.

Color Preference Index (CPI). The CPI is determined by a similar procedure to that used for the CRI. The difference is that CPI recognizes the very real human ingredient of preference. This index is based on individual preference for the coloration of certain identifiable objects, such as complexions, meat, vegetables, fruits, and foliage, to be slightly different than the colors of these objects in daylight. CPI indicates how a source will render color with respect to how we best appreciate and remember that color.

Equivalent Sphere Illumination (ESI). ESI is a means of determining how well a lighting system will provide task visibility in a given situation. ESI may be predicted for many points in a lighting system through the use of any of several available computer programs or measured in an installation with any of several different types of meters.

Visual Comfort Probability (VCP). Discomfort glare is most often produced by direct glare from luminances that are excessively bright. Discomfort glare can also be caused by reflected glare, which should not be confused with **veiling reflections**, which cause a reduction in visual performance rather than discomfort. VCP is based in terms of the percentage of people who will be expected to find the given lighting system acceptable when they are seated in the most undesirable location.

Factors and Remedies

Quality of illumination pertains to the distribution of luminaires in the visual environment. The term is used in a positive sense and implies that all luminaires contribute favorably to visual performance. However, glare, diffusion, reflection, uniformity, color, luminance, and **luminance ratio** all have a significant effect on visibility and the ability to see easily, accurately, and quickly. Industrial installations of poor quality are easily recognized as uncomfortable and possibly hazardous. Some of the factors are discussed in more detail below.

Direct Glare. When glare is caused by the source of lighting within the field of view, whether daylight or electric, it is defined as direct glare. To reduce direct glare, the following suggestions may be useful:

a. Decrease the brightness of light sources or lighting equipment, or both.
b. Reduce the area of high luminance causing the glare condition.
c. Increase the angle between the glare source and the line of vision.
d. Increase the luminance of the area surrounding the glare source and against which it is seen.

To reduce direct glare, luminaires should be mounted as far above the normal line of sight as possible and should be designed to limit both the luminance and the quality of light emitted in the 45–85 degree zone because such light may interfere with vision. This precaution includes the use of supplementary lighting equipment. There is such a wide divergence of tasks and environmental conditions that it may not be possible to recommend a degree of quality satisfactory to all needs. In production areas, luminaires within the normal field of view should be shielded to at least 25 degrees from the horizontal, preferably to 45 degrees.

Reflected Glare. Reflected glare is caused by the reflection of high-luminance light sources from shiny surfaces. In the manufacturing area, this may be a particularly serious problem where critical seeing is involved with highly polished sheet metal, vernier scales, and machined metal surfaces. There are several ways to minimize or eliminate reflected glare:

a. Use a light source of low luminance, consistent with the type of work in process and the surroundings.
b. If the luminance of the light source cannot be reduced to a desirable level, it may be possible to orient the work so that reflections are not directed in the normal line of vision.
c. Increasing the level of illumination by increasing the number of sources will reduce the effect of reflected glare by reducing the proportion of illumination provided on the task by sources located in positions causing reflections.

TABLE 107.7 Recommended Maximum Luminance Ratios for Industrial Areas

	Environmental Classification		
	A	B	C
(1) Between tasks and adjacent darker surroundings	3 to 1	3 to 1	5 to 1
(2) Between tasks and adjacent lighter surroundings	1 to 3	1 to 3	1 to 5
(3) Between tasks and more remote darker surfaces	10 to 1	20 to 1	*
(4) Between tasks and more remote lighter surfaces	1 to 10	1 to 20	*
(5) Between luminaires (or windows, skylights, etc.) and surfaces adjacent to them	20 to 1	*	*
(6) Anywhere within normal field of view	40 to 1	*	*

*Luminance ratio control not practical.

A—Interior areas where reflectances of entire space can be controlled in line with recommendations for optimum seeing conditions.

B—Areas where reflectances of immediate work area can be controlled, but control of remote surround is limited.

C—Areas (indoor and outdoor) where it is completely impractical to control reflectances and difficult to alter environmental conditions.

Source: *IES Lighting Handbook*, *Application Volume*.

d. In special cases, it may be practical to reduce the specular reflection by changing the specular character of the offending surface.

Distribution, Reflection, and Shadows. Uniform horizontal illuminance (maximum and minimum not more than one-sixth above or below the average level) is usually desirable for industrial interiors to permit flexible arrangements of operations and equipment and to assure more uniform luminance in the entire area.

Reflections of light sources in the task can be useful provided that the reflection does not create reflected glare. In the machining and inspection of small metal parts, reflections can indicate faults in contours, make scribe marks more visible, and so on.

Shadows from the general illumination systems can be desirable for accenting the depth and forms of various objects, but harsh shadows should be avoided. Shadows are softer and less pronounced when large diffusing luminaires are used or the object is illuminated from many sources. Clearly defined shadows are distinct aids in some specialized operations, such as engraving on polished surfaces, some type of bench layout work, or certain textile inspections. This type of shadow effect can best be obtained by supplementary directional lighting combined with ample diffused general illumination.

Luminance and Luminance Ratios. The ability to see details depends on the contrast between the detail and its background. The greater the contrast difference in luminance, the more readily the seeing task is performed. The eye functions most comfortably and efficiently when the luminance within the remainder of the environment is relatively uniform. In manufacturing, there are many areas where it is not practical to achieve the same luminance relationships as easily as in offices. Table 107.7 is shown as a practical guide to recommended maximum luminance ratios for industrial areas. To achieve the recommended luminance relationships, it is necessary to select the reflectances of all the finishes of the room surfaces and equipment as well as control of the luminance distribution of the lighting equipment. Table 107.8 lists the recommended reflectance values for industrial interiors and equipment. High-reflectance surfaces are desirable to provide the recommended luminance relationships and high utilization of light.

Color Quality of Light. In general, for seeing tasks industrial areas, there appears to be no effect upon visual acuity by variation in color of light. However, where color discrimination or color matching is a part of the work process, such as in the printing and textile industries, the color of light should be carefully selected. Color always has an effect on the appearance of the workplace and on the complexions of people. The illuminating system and the decorative scheme should be properly coordinated.

TABLE 107.8 Recommended Reflectance Values for Industrial Interiors and Equipment

Surfaces	Reflectance[1] (%)
Ceiling	80 to 90
Walls	40 to 60
Desk and bench tops, machines and equipment	25 to 45
Floors	not less than 20

[1]Reflectance should be maintained as near as practical to recommended values.

Source: *IES Lighting Handbook, Application Volume.*

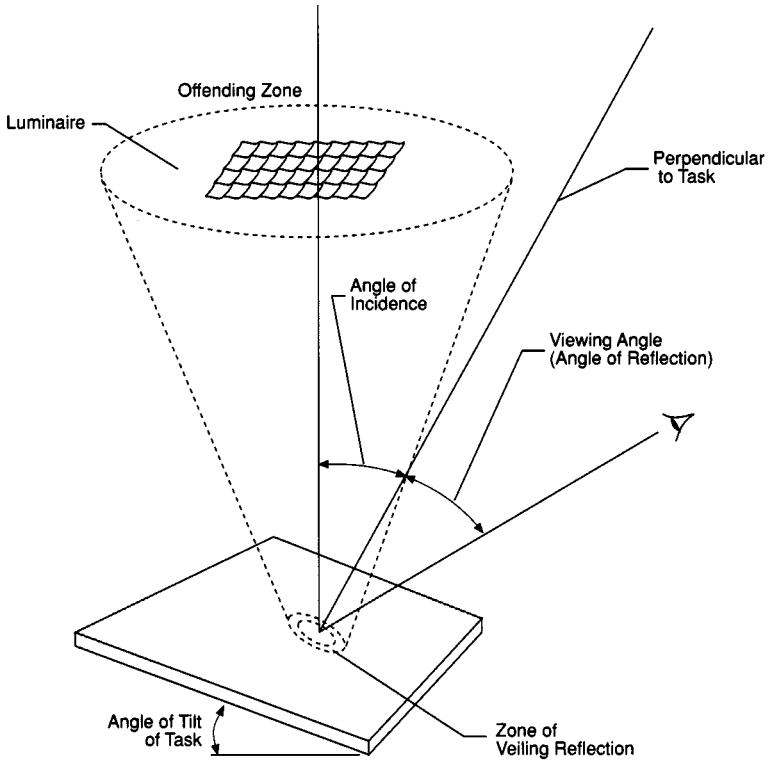

FIGURE 107.4 Diagram showing "offending zone" and zone of veiling reflection.

Veiling Reflections. Figure 107.4 shows that light would reflect into the eyes of the viewer from the "offending zone" and defines the zone of veiling reflection. Veiling reflection would diminish visibility, but the viewer would be unaware of it. The **contrast rendition factor (CRF)** can be applied as a measure of the amount of veiling reflection.

Another important factor is the **lighting effectiveness factor (LEF)**. An overall lighting system efficiency factor considers both the quality of light as reference to equivalent sphere illumination and the effects of veiling reflections. Light patterns such as "batwing" can help solve veiling reflection problems. Figure 107.5 shows the light distribution curve of a typical batwing luminaire.

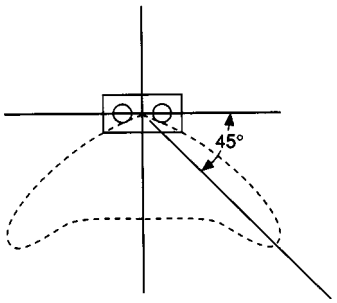

FIGURE 107.5 A typical "batwing" light distribution.

Daylighting

The daylight contribution should be carefully evaluated and should always be coordinated with a planned electric lighting system.

Fenestration. Fenestration has at least three useful purposes in industrial buildings:

a. For the admission, control, and distribution of daylight.
b. For a distant focus for the eyes, which relaxes the eye muscles.
c. To eliminate the dissatisfaction many people experience in completely closed-in areas.

An adequate electric lighting system should always be provided because of the wide variation in daylight.

Building Orientation. All fenestration should be equipped with control device appropriate to any luminance problems. Special attention should be given to glare control latitudes where fenestration frequently receives direct sunlight. Diffuse-glaring fixed or adjustable louvers are some of the control means that may be applied.

For an industrial building, windows in the sidewalls admit daylight and natural ventilation and afford occupants a view out. However, their uncontrolled luminance may be a problem. There are many control means to make daylight useful to workers' seeing tasks, resulting in energy savings as the ultimate goal.

107.3 System Components

Light Sources

Incandescent

a. Recent technology made possible a line of energy-saving incandescent lamps that use the rare gas krypton as a fill gas.
b. Reflector (R) lamps offer better utilization of the light provided by the lamp compared to a nonreflector type. In this family, there are R lamps, PAR (parabolic aluminized reflector) lamps, and a newer line ER (elliptical reflector) lamps which allow reduction of 50% or more in energy consumption.
c. Infrared Halogen (IR)—PAR lamps combine both the infrared heat-reflection technology and the regenerative halogen cleaning cycle to provide a dramatic increase in lamp efficacy (4% reduction in energy consumption). Available in 30, 60, and 100 W.

Fluorescent

a. Energy-efficient lamps are now available in all popular sizes and colors for most applications. Limitations of energy-saving reduced-wattage lamps are:
   - Ambient temperature must be above 60°F.
   - Used on high p.f. fluorescent ballasts only.
   - Not to be used where drafts of cold air are directed onto the lamp.
b. Typical energy savings are 6 W per lamp for the popular 4-ft 40-W replacement and 15 W per lamp for the 8-ft slimline 75-W replacement.
c. Compact fluorescent lamps are gaining popularity because they are energy efficient, fit into a small enclosed housing, and can be adapted for incandescent socket use.
d. Virtually all compact fluorescent lamps use the "rare earth" phosphors for good color rendition and lumen maintenance characteristics.
e. Utilizing advanced phosphor technology with the optimization of bulb diameter, 40-W lamps are now available that can be retrofitted in a F40 preheat or rapid-start circuit. The new lamp, which could save energy and improve color rendition requirement, has been legislated.
f. Refer to Tables 107.9 and 107.11 for the latest energy efficient lamps.

High-Intensity Discharge (HID)

Today HID lamps include mercury vapor, metal halide, high-pressure sodium, and low-pressure sodium lamps. Metal halide lamps offer the best opportunity from a color acceptability point of view. High-pressure sodium

lamps offer the highest luminous efficacy in an environment where color distinction is not critical. Since HID lamps have had very few problems in application, they are likely to experience further development in the coming years.

Ballasts

Fluorescent. Electronic ballasts are now available for the F40T12, the slimline, the new T8 lamps, and other energy-saving fluorescent lamps on both 120- and 277-V circuits. Using high-frequency ballasts, the efficacy can be raised by nearly 12%. Although electronic ballasts cost more than the standard core-coil ballasts, operating factors should reflect an appreciable reduction in life-cycle cost for a lighting system. There are two types of dimming ballasts: core and electronic. High-frequency ballasts can readily be used to dim fluorescent lamps over a wide range of light level. All external control wiring is low voltage or fiber-optic wiring.

A recent study indicates that 2 F40T12 lamps operated on an electronic ballast will attain an efficacy of 75–80 LPW versus 62 LPW for the same lamps if operated on a standard core-coil type ballast. With the dimmable electronically ballasted system, energy savings can be as high as 40% with respect to a core ballasted system.

High-Intensity Discharge. The choice of a ballast depends on economic considerations versus performance. A mercury lamp will operate from metal halide ballast, but the converse is not always true.

There are several different types of ballasts for high-pressure sodium lamps:

a. Reactor or lag ballast—Inexpensive, low power losses, and small in size.
b. Lead ballast —Fairly good regulation for both line and lamp voltage variation.
c. Magnetic regulated ballast—Provides best voltage regulation with change of either input voltage or lamp voltage. It is the most costly and has the greatest wattage loss.
d. Electronic ballast—Maintains a steady constant wattage output with changes in the source impedance as well as excellent regulation. During the life of a high-pressure sodium lamp, it can save 20% more energy by maintaining a constant wattage output in addition to the 15% intrinsic energy savings compared to an equivalent core-coil ballast.

Luminaires

Types of Industrial Luminaires. Selection of a specific type for an installation requires consideration of many factors: candlepower distribution, efficiency, shielding and brightness control, mounting height, lumen maintenance characteristics, mechanical construction, and environmental suitability for use in normal, hazardous, or special areas. In general there are five types in accordance with CIE classifications, namely, direct type, semi-direct type, direct-indirect type, semi-indirect type, and indirect type.

Figure 107.6 shows luminaire types with the percentage of total luminaire output emitted above and below horizontal.

Supplementary Luminaire Types. There are five major types based on the candlepower distribution and luminance:

Type S-I—directional
Type S-II—spread, high luminance
Type S-III—spread, moderate luminance
Type S- IV—uniform luminance
Type S-V—uniform luminance with pattern

High-Pressure Sodium. Proper luminaire design is the key to lighting efficiency. Newly developed luminaires use prismatic glass reflectors that are especially made for high-pressure sodium lamps. In addition to achieving maximum light utilization, they redirect the intense light source with excellent light cutoff and high-angle brightness control. Luminaire manufacturers recommend aluminum reflectors for all general-purpose industrial applications and glass-coated reflectors where maintenance practice is compatible with servicing glass.

Fluorescent. A new trend for lighting new buildings is the increased use of the reflectorized fixtures. This trend may be traced to an increase in the number of state and national lighting efficiency standards in recent

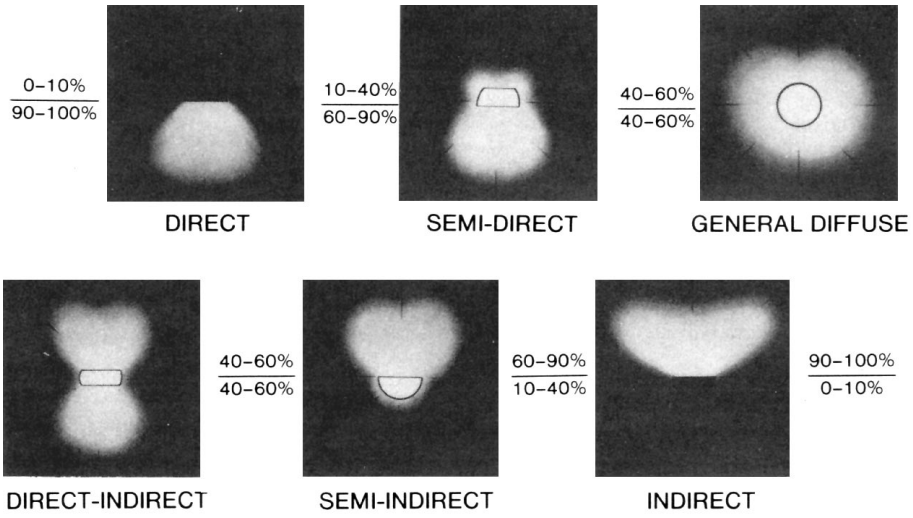

FIGURE 107.6 General lighting luminaire classifications.

years. However, these fixtures can create a "teardrop-like" distribution that may eliminate glare on a computer screen, but also reduces light to other areas.

107.4 Applications

Types of Industrial Illuminating Systems

Factory Illumination for Visual Tasks. The prime requirement for industrial illumination is to facilitate the performance of visual tasks through high-quality illumination. There are three types of lighting used in industrial areas.

- *General Lighting.* It should be designed to provide the desired level of illumination uniformly over the entire area. The variation of light level from point to point within the area should be within 17% of the selected level. A good general lighting system makes it possible to change the location of machinery without rearranging the lighting and also permits full utilization of floor space.
- *Localized General Lighting.* Within a general area there may be a few areas where tasks performed require a greater quantity of light and a different quality of light. When applied, care must be exercised to eliminate direct or reflected glare from the task and from other workers.
- *Supplementary Lighting.* Supplementary lighting is specified for different seeing tasks that require a specific amount or quality of light not readily obtained by standard general lighting methods. Supplementary lighting is a valuable industrial lighting tool. Typical problems arise where work is shielded from the general lighting system by an obstruction or its brightness is otherwise lowered where low contrast, such as scribe marks on steel, may lead to visual errors, and where the product moves too rapidly to be seen clearly by the unaided eye. To attain a good balance, it is important to coordinate the design of supplementary and general lighting with great care.

Security Lighting. Security lighting pertains to the lighting of building exterior and surrounding areas out to and including the boundaries of the property. Security lighting contributes to a sense of personal security and to the protection of property. It may be accomplished through:

- Surveillance lighting to detect and observe intruders.
- Protective lighting to discourage or deter attempts at entrance, vandalism, etc.
- Lighting for safety to permit safe movement of guards and other authorized persons.

Emergency Lighting. Emergency lighting is provided for use when the power supply for the normal lighting fails to ensure that escape routes can be effectively identified and used. Standby lighting is that part of emergency lighting that is sometimes provided to enable normal activities to continue.

The following are recommended minimum illumination requirements for exit signs and egress route:

- *Internally illuminated signs.* An illuminance of 54 lux (5 fc) on the face of the sign is usually specified.
- *Externally illuminated exit sign.* NFPA 101 requires 54 lux (5 fc) on the face of the sign.
- *Egress route.* The horizontal illuminance of any escape route should not be less than 1% of the average provided by the normal lighting, with a minimum average of 5 lux (0.5 fc) at floor level.
- *Location of egress luminaires.* A luminaire should be provided for each exit door and emergency exit door to provide sufficient light to a level of 30 lux (3 fc).

Summaries. In large industrial areas, all these lighting systems may be used. In small areas, localized general lighting may also serve as a substitute for general lighting. In this case, additional supplementary lighting may be required to increase the quantity or improve the quality of the illumination. Many factors must be considered in selecting a lighting system. It is not feasible to recommend one or two systems for all conditions. Because of the relationship of ceiling height to light utilization, most industrial applications call for either direct or semi-direct lighting systems.

Selection of the Equipment

In the selection of equipment, light sources, and luminaires, many variables must be considered. As with any list of variables, it is necessary for purpose of comparison to hold some factors constant. In industrial illumination that factor is usually mounting height and location.

High-Bay Areas. The work generally presents visual tasks that are not difficult because of large machinery and other objects. Illuminance levels for high-bay areas generally range from 50 to 150 fc, although more and more areas are being lighted with 200 and 300 fc. At a high mounting height, it is possible to obtain uniform illumination by using a few high-wattage sources rather than a larger number of low-wattage sources. For luminaires with medium and narrow distribution, greater mounting height or closer spacing is ordinarily required for uniform general illumination.

Regardless of mounting height, wide distribution luminaires are well suited for use in areas that are wide in respect to mounting height. Large machinery and objects tend to cut off light and cast shadows. Since this makes it difficult to see important vertical and angular surfaces, broad light distribution is essential.

High-intensity discharge or fluorescent luminaires for high-bay lighting may be enclosed, ventilated open, or nonventilated open. Enclosed luminaires are usually of a heavy-duty type with a gasketed glass cover to protect the reflector and light source from collection of dirt. The initial luminaire efficiency is lower and the equipment is more costly. Ventilated-open luminaires have largely replaced the nonventilated type.

As far as choices of lamps are concerned, metal halide and HPS are preferred over the mercury type. The use of fluorescent lamps in high-bay areas is limited. Only where the area proportions are such that the room cavity ratios are in the range of 1 to 3 may fluorescent lamps be acceptable. Only high or extra high output fluorescent in 8-ft sizes are recommended.

Medium- and Low-Bay Areas. Seeing tasks in medium- and low-bay areas are usually more difficult than those encountered in the high-bay areas. Increasing the size and reducing the brightness of the luminaires will improve visual comfort and will improve the visibility of specular objects. It may not improve the visibility of diffuse three-dimensional objects.

Luminaires used for general lighting in medium-bay areas are nearly always of the direct or semi-direct type, either fluorescent or wide distribution HID. They may be the ventilated or nonventilated type and the lamps may be shielded by louvers, baffles, or other devices. For lower mounting, the trend is toward the semi-direct type.

Some of the visual tasks involve specular or semi-specular objects, for which optimum lighting might be an indirect system. The quality of fluorescent sources, with their broad distribution of light, makes them a prime selection for medium- and low-bay lighting. When the proper quality control can be attained, low-wattage HID sources are finding an increasing number of low-bay applications.

107.5 System Energy Efficiency Considerations

Energy-Saving Lighting Techniques

Fluorescent Systems Considerations. Fluorescent lamps are sensitive to ambient temperatures. By using reduced wattage lamps or low-loss ballasts, less heat will be generated and the operating temperature point of the lamp will probably change. The critical area is the coldest spot on the bulb surface. Most fluorescent lamps will peak in light output at around a 100°F cold-spot temperature. For enclosed luminaire types that ordinarily operate the lamp at higher temperature, replacing standard lamps with high-efficacy, reduced wattage lamps may result in a net increase in luminaire output even though the reduced wattage lamps are rated for less output than are standard lamps.

Using Daylight. Daylight should be dealt with by first analyzing it and then establishing a design technique to integrate it with the electric lighting system. Daylight may be adequate in quantity and quality to reduce the electric lighting load and result in energy conservation. Poor quality of daylight may lead to discomfort and a loss in visibility that may result in a decrease in human performance and productivity.

Daylighting Design from Windows. The longhand design procedure involves two steps:

- Determine the quantity of illumination coming to the window surface.
- Use that quantity to determine the daylight contribution to the interior part of the space.

Once the contribution of illumination to the window surface has been calculated, two longhand methods are available to determine the illumination contribution to the space. The first method is to follow the point-by-point procedure, which makes two assumptions: (1) interreflected component is ignored and (2) the window is a uniform diffuse emitter. The second method is a lumen method that calculates illumination values at three points defined as the maximum, midway, and minimum. This method includes both the direct and interreflected components of illumination.

Task-Ambient Lighting. This is a particular form of nonuniform illumination that combines task illuminance and ambient illuminance. One advantage is improved energy efficiency. The task component of task-ambient lighting may take two forms: (1) furniture-mounted lighting built into a workstation or (2) floor-mounted fixtures that can be placed adjacent to a desk. The ambient lighting component may be supplied in two ways: (1) conventional luminaires on the ceiling or (2) indirect fixtures utilizing HID or fluorescent lamps with the output directed to the ceiling and adjacent walls. For ceiling-mounted troffers used for ambient lighting, a plug-in system of wiring should be considered so that luminaires can be relocated as task locations change.

Lighting Controls

In order to save energy, it is essential that minimum acceptable lighting levels be used during off-hours, cleaning periods, and for other nonpeak periods as is practical. The ultimate system of control would be to remotely control every fixture and to program the mode of operation, but this is hardly possible. Solid-state dimmers are available, or ballasts can be circuited in separate groupings. Solid-state controls are available for dimming entire areas of ballasted lights, but special ballasts are required and the controls could be expensive.

Manual control of a lighting system is often the least expensive, but also the least effective alternative. Automatic controls vary from a simple timer to a sophisticated computer system. Figure 107.7 shows a typical programmable lighting control scheme. A price versus benefit cost analysis will be required for each installation. The system should be programmed for normal operation and have a local manual override. A good convenient practice is to have lights switched in distributed groups so that areas can be lighted or darkened as conditions change.

Lighting and Energy Standards

In 1976, the Energy Research and Development Association (ERDA) contracted with the National Conference of States on Building Codes and Standards (NCSBCS) to codify ASHRAE 90-75. The resulting document was

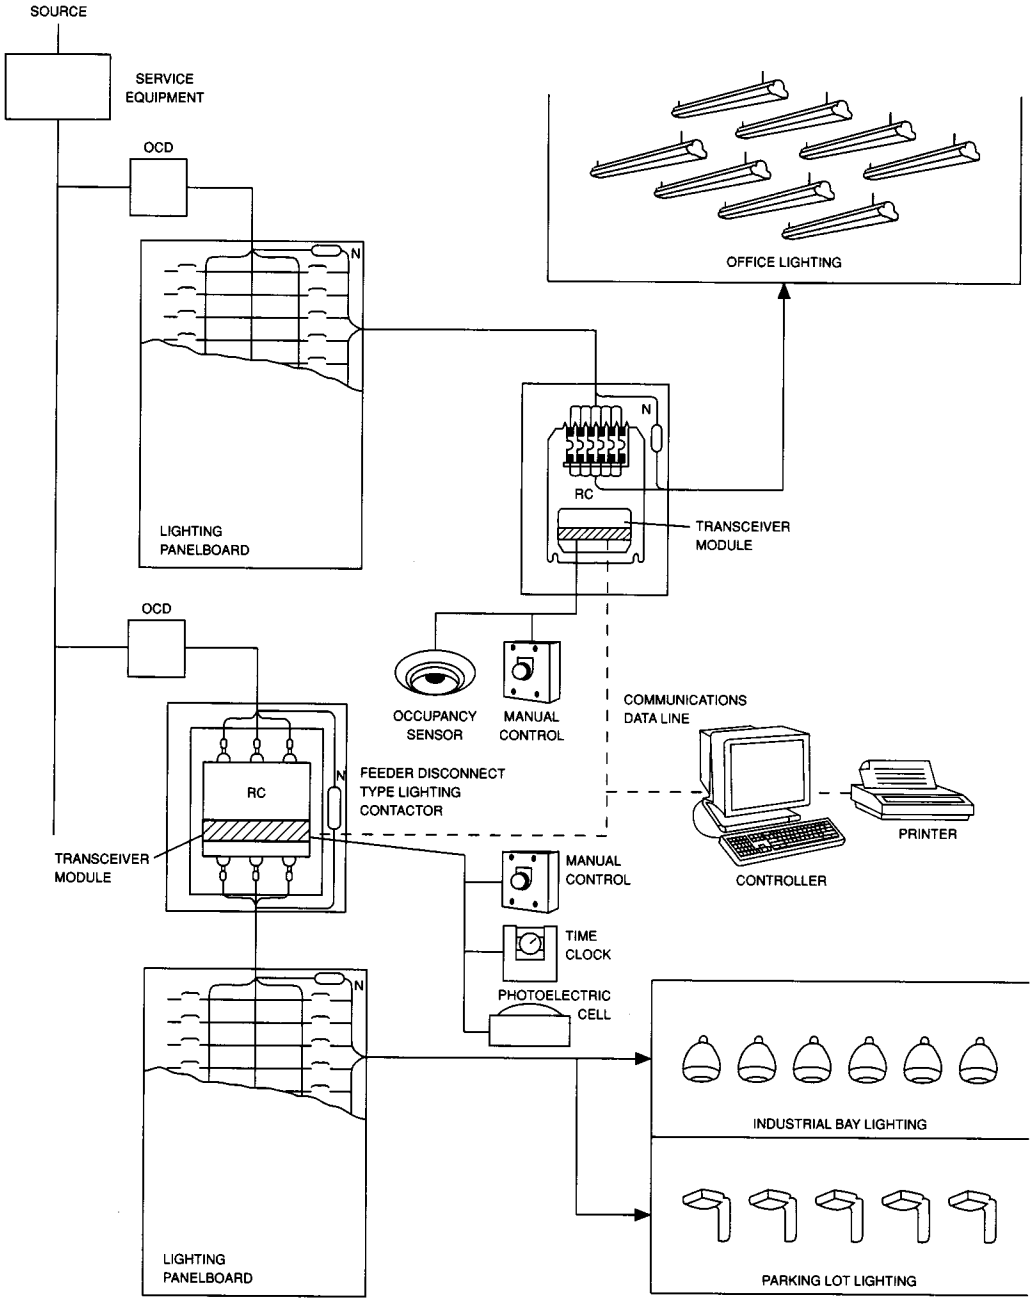

FIGURE 107.7 Programmable lighting control scheme.

called "The Model Code for Energy Conservation in New Buildings." The model code has been adopted by a number of states to satisfy the requirements of Public Laws 94-163 and 94-385.

There have been several revisions on the ANSI/ASHRAE/IES 90-75 since 1976. All were included in the lighting portion of ANSI/ASHRAE/IES 90A-1980, "Energy Conservation in New Building Design," and in EMS-1981, "IES Recommended Lighting Power Budget Determination Procedure."

ASHRAE/IES 90.1-1989, "Energy Efficient Design of New Buildings Except New Low-Rise Residential Buildings," is the third generation document on building energy efficiency since the first publication in 1975. This standard is intended to be a voluntary standard which can be adopted by building officials for state and local codes.

Lighting: The Next 10 Years

Many exciting developments are occurring in the lighting industry. However, one of the greatest challenges is the development of a replacement light source for the common cathode ray tube (CRT) found in televisions and other applications.

CRTs have gradually expanded from our primary information sources, televisions and computers, into scientific instrumentation, cars, and automatic teller machines. However, the inherent shortcomings of this technology are limiting the further development of existing and new applications that require display technology.

CRTs produce few lumens for the power they consume and are inherently large and heavy. Their many weaknesses are compounded in the area of big screen displays. The desire to view ever larger and higher resolution images is pushing the CRT beyond its practical limits. New lighting technologies applied to flat panel displays and projection systems could change the consumer television market if certain barriers are overcome.

One approach has been to adopt large area LCDs (which pose a significant engineering challenge) as the primary imaging device. However, these devices do not inherently emit light and would be useless in the dark without backlights. The light source of choice for this approach has been cold cathode fluorescent lamps, which are commonly applied in today's laptop computers.

We can expect to see unique lamp shapes and ingenious reflector systems developed to illuminate the LCD uniformly, without adding significantly to the overall depth of the display system. There is also a lot of work in the development of electroluminescent panels as an alternative to fluorescent lamps, although these devices present color difficulties as well as comparatively low efficacies.

Large-area LED image displays have already been fabricated since blue LEDs emerged in the marketplace. An array of red, green, and blue LEDs are mounted on a panel and individually addressed to generate all colors, including white. This approach will be redefined in the coming decade, but faces a number of challenges.

TABLE 107.9 The Proposed Efficiency Standards for Fluroescent Lamps

Lamp Type	Nominal Lamp Wattage	Minimum Average CRI	Minimum Average Lamp Efficacy
F40	>35 W	69	75
F40	≤35 W	45	75
F40/U	>35 W	69	68
F40/U	≤35 W	45	64
F96T12	>65 W	69	80
F96T12	≤65 W	45	80
F96T12/HO	>100 W	69	80
F96T12/HO	≤100 W	45	80

Note: The above excludes lamps designed for plant growth, cold temperature service, reflectorized/aperture, impact resistance, reprographic service, colored lighting, ultraviolet, and lamps with CRI of more than 82.

Another approach involves large-area plasma panels that are self-luminescent due to gas discharges. With this technology, the brightness improves considerably over that available from a CRT. Brilliant, high-resolution images have been achieved in medium screen sizes, but cost remains a problem and there is still the challenge of expanding the technology to even larger screen sizes.

The approach that is most likely to succeed during the next decade is the use of projection technology. These systems are fundamentally similar to slide or movie projectors where the film has been replaced by either a transmissive or reflective imaging device that provides a continuously variable image illuminated and projected onto a screen. The image can be front projected or rear projected.

The most pressing challenge remains: development of an illumination source that can provide a brighter image with better colors than CRT technology. If this can be achieved, other benefits will flow from the technology, with the potential to drastically reduce power consumption as well as cabinet size, weight, and cost. Furthermore, the inherent digital nature of the imaging panels would make the resulting product data compatible for the much touted merging of the Internet and television programming.

High-resolution rear projection televisions using lamps as the illumination source are already available in Japan from Sony and Sharp. We can expect to see this type of product in the U.S. market this year. However, the overall product cost, lamp life, and screen brightness all need improvement before this technology moves into the mainstream.

The technical challenge for the lighting industry is to produce a miniature point source that delivers high efficacy, high color temperature, and long lifetime. The challenge for the immediate future is to push the arc gap even smaller while extending the lamp life to be comparable to today's CRTs and maintaining lumen output and good color temperature. Furthermore, all these requirements have to be met at a very low cost.

The rewards for the successful manufacturer are immense, considering the size of the market, not to mention the spin-off markets that could pick up on this technology. During the next decade, we are sure to see a lot of exciting developments in this area, which will ultimately affect our daily activities. (Adapted from Ian Edwards, "Fundamentals of Lighting", *Optics & Photonics News,* Optical Society of America, 7(11), 20, 1996. With permission.)

Energy Policy Act

On October 25, 1992, the Energy Policy Act was signed into law by the President.

Among the many provisions, the act establishes energy efficiency standards for HVAC, lighting, and motor equipment; encourages establishment of a national window energy-efficiency rating system; and encourages state regulators to pursue demand-side-management (DSM) programs.

Under the bill, lighting manufacturers will have 3 years to stop making F96T12 and F96T12/HO 8 ft fluorescent lamps and some types of incandescent reflectors. Standard F40 lamps except in the SP and SPX or equivalent types of high color rendering lamps would also fade away. General service incandescent lamps to be axed would include those from 30 to 100 W, in 115 to 130 V ratings, having medium screw bases, of both reflector and PAR types, having a diameter larger than 2¾ in.

There are no immediate regulations impacting HID lamps. Within 18 months of the legislation's enactment, the Department of Energy (DOE) will determine the HID types for which standards could possibly save energy and publish testing requirements for these lamps.

As far as the general service lamps are concerned, the most common incandescent lamps — 40, 60, 75, 100, and 150 W — are not covered by an efficiency standard because there is no suitable method to ensure energy savings. These types, however, are covered by another provision of the law, namely the energy efficiency labeling standards.

TABLE 107.10 The Proposed Efficiency Standards for Incandescent Reflector Lamps

Nominal Lamp Wattage	Minimum Average Lamp Efficacy (LPW)
40–50	10.5
51–66	11.0
67–85	12.5
86–115	14.0
116–155	14.5

Note: The above excludes miniature, decorative, traffic signal, marine, mine, stage/studio, railway, colored lamps, and other special application types.

TABLE 107.11 1992 Energy Policy Act — Replacement Lamps

Present Type	W	Acceptable	W	Improved Type	W	Max. Savings	W
F96T12/CW	75	F96T12/CW/SS	60	F96T12/D41/SS	60	F096T8/741	59
F96T12/WW	75	F96T12/WW/SS	60	F96T12/D30/SS	60	F096T8/730	59

Effective April 28, 1994, the Federal Trade Commission (FTC) must provide manufacturers with labeling requirements for all lamps covered: fluorescent, incandescent, and reflector incandescent. Though not yet defined, the proposals include: an energy rating for the lamps, probably LPW (lumens per watt), and energy cost per year to operate the lamp. The energy efficiency label will then allow side-by-side comparison of two different lamp types, thus enabling consumers to make a more intelligent choice of lamps; taking into account not just the purchase price, but also the operating cost. Manufacturers must begin applying labels by April 28, 1995. Table 107.9 shows the proposed efficiency standards for the fluorescent lamps, and Table 107.10 shows the proposed efficiency standards for incandescent reflector lamps.

There is no requirement to replace all existing lamps in any installation. However, as these lamps burn out, the replacement must meet the new standards.

Replacement for popular fluorescent types includes reduced-wattage energy saving types. These lamps will meet the color and efficiency standards, as will the full wattage triphosphor lamps having a CRI over 69. Table 107.11 shows some types of replacement lamps. On the incandescent side, replacements for the standard incandescent spot and flood lamps will be lower wattage halogen type reflector lamps which do meet the LPW requirements. The halogen and halogen/infrared types of reflector lamps will remain the only type of such lamps on the market. ER and BR types, those intended for rough and vibration service will also be excluded here.

There is also a provision for lighting fixture manufacturers to come up with voluntary luminaire efficiency standards. If these standards are found to be inadequate, the DOE will come up with the mandatory efficiency standards.

The new Energy Policy Act is all-encompassing. It promises to change forever the way industries produce, distribute, and utilize the valued energy resources. The end result should be increased energy security, decreased environmental emissions, and cleaner air and water for all humankind.

Defining Terms

Candlepower distribution: A curve, generally polar, representing the variation of luminous intensity of a lamp or luminaire in a plane through the light center.

Cavity ratio (CR): A number indicating cavity proportions calculated from length, width, and height. It is further defined into ceiling cavity ratio, floor cavity ratio, and room cavity ratio.

Coefficient of utilization (CU): The ratio of the lumens reaching the working plane to the total lumens generated by the lamp. This factor takes into account the efficiency and distribution of the lumanaire, its mounting height, the room proportions, and the reflectances of the walls, ceiling, and floor.

Color preference index (CPI): Measure appraising a light source for appreciative viewing of colored objects or for promoting an optimistic viewpoint by flattery.

Color rendering index (CRI): Measure of the degree of color shift objects undergo when illuminated by the light source as compared with the color of those same objects when illuminated by a reference source of comparable color temperature.

Contrast: The relationship between the luminances of an object and its immediate background. It is equal to $(L_1 - L_2)/L_1$ where L_1 and L_2 are the luminances of the background and object. The ratio $\Delta L/L_1$ is also known as Weber's fraction where $\Delta L = L_1 - L_2$.

Contrast rendition factor (CRF): The ratio of visual task contrast with a given lighting environment to the contrast with sphere illumination.

Equivalent sphere illumination (ESI): The level of sphere illumination which would produce task visibility equivalent to that produced by a specific lighting environment.

Fenestration: Any opening or arrangement of opening (normally filled with media for control) for the admission of daylight.

Footcandle: The unit of illuminance when the foot is taken as the unit of length. It is the illuminance on a surface one square foot in area on which there is a uniformly distributed flux of one lumen.

Illuminance: The density of luminous flux on a surface expressed in either footcandles (lumens/ft^2) or lux (lx). (lux = 0.0929 fc)

Lighting effectiveness factor (LEF): The ratio of equivalent sphere illumination to ordinary measured or calculated illumination.

Light loss factor (LLF): The ratio of the illumination when it reaches its lowest level at the task just before corrective action is taken, to the initial level if none of the contributing loss factors were considered.

Luminance ratio: The ratio between the luminance of two areas in the visual field.

Veiling reflection: Regular reflections superimposed upon diffuse reflections from an object that partially or total obscure the details to be seen by reducing the contrast.

Visual comfort probability (VCP): This rating is based in terms of the percentage of people who will be expected to find the given lighting system acceptable when they are seated in most undesirable locations.

108.1 Introduction

Instruments are the means for monitoring or measuring physical variables. The basic elements of an instrumentation application are shown in Fig. 108.1. A physical system produces a *measurand, m*(*t*), shown as time-varying, which is transformed by a **transducer** into an electrical signal, *s*(*t*), that is then processed by an instrument to yield the desired output information variable, *i*(*t*). Producing meaningful information from physical variables requires conversion and processing. Electronic instruments require that physical variables be converted to electrical signals through a process of *transduction*, followed by signal *conditioning* and signal *processing* to obtain useful results.

108.2 Physical Variables

The measurand can be one of many physical variables; the type depends on the application. For example, in process control, typical measurands can include pressure, temperature, and flow. Representative physical variables with corresponding units are summarized in Table 108.1.

108.3 Transducers

Transducers convert one form of energy to another. To be useful for an electronic instrument, a transducer must produce an electrical output such as voltage or current to allow required signal conditioning and signal processing steps to be completed. A variety of transducers are available to meet a measurement requirement; some common examples are listed in Table 108.2. Transducers can be compared based on their operating principles, the measurand range, interface design, and reliability. Khazan [1994] gives a complete summary of transducer schemes.

Velocity	V	m/s
Voltage	V	volt, V

TABLE 108.2 Representative Transducers

Measurand	Transducer	Operating Principles
Displacement (Length)	Resistive Capacitive Inductive	Change in resistance, capacitance, or inductance caused by linear or angular displacement of transducer element
Force	Strain gage	Resistance, piezoresistivity
Temperature	Thermistor	Resistance
	Thermocouple	Peltier, seebeck effect
Pressure	Diaphragm	Diaphragm motion sensed by a displacement technique.
Flow	Differential pressure	Pressure drop across restriction
	Turbine	Angular velocity proportional to flow rate

108.4 Instrument Elements

Signal conditioning consists of amplification, filtering, limiting, and other operations that prepare the raw instrument input signal for further operations. The signal may be the output of a transducer or it may be an electrical signal obtained directly from an electronic device or circuit. Signal processing applies some algorithm to the basic signal in order to obtain meaningful information. Signal conditioning and processing operations may be performed using *analog* or *digital* circuit techniques, or using a combination of methods. There are a variety of trade-offs between them. For example, analog methods offer bandwidth advantages, whereas digital techniques offer advanced algorithm support and long-term stability. The use of microprocessors within an instrument makes it possible to perform many useful functions including calibration, linearization, conversion, storage, display, and transmission. A block diagram of a representative microprocessor-based instrument is shown in Fig. 108.2.

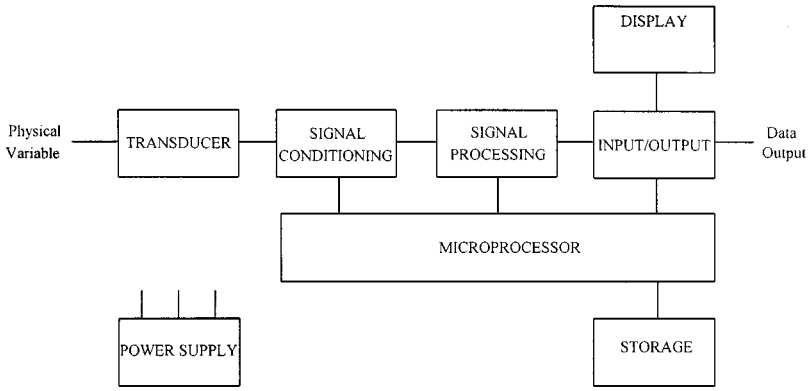

FIGURE 108.2 Block diagram of generalized, microprocessor-based instrument.

108.5 Instrumentation System

An instrument is never used in isolation. The instrumentation components contribute to an overall system response in a number of ways that are based on the **measurement system** elements present. These elements include: (1) sources, (2) interconnect, (3) device or system under test, (4) response measuring equipment, and (5) environmental variables. Figure 108.3 shows the elements of a typical instrumentation system.

108.6 Modeling Elements of an Instrumentation System

Best results are achieved when the instrumentation system is clearly understood, and its effects compensated for when practical. Lumped parameter modeling of the elements shown in Fig. 108.3 provides a means for determining the contribution each element makes to the overall system behavior. Of particular importance are the input and output impedances of each element. In addition, the effects of interconnect and environmental variables can also be modeled to determine their influence on the system. The relative dimensions of the measurement system with respect to the highest frequencies encountered—whether signal or noise—determine whether simplified circuit theory models, or generalized solutions to Maxwell's equations must be used. Generally, if measurement system dimensions are on the order of 1/20 of the shortest wavelength, simple circuit theory models can be used. Operation in this regime also allows impedance matching to be largely ignored; e.g., not requiring mandatory use of 50 Ω sources, 50 Ω transmission lines, and 50 Ω terminations which is commonly encountered in high-frequency systems. Table 108.3 summarizes several common instruments and input or output impedance models corresponding to Fig. 108.4. At low frequencies, interconnect can be modeled by ignoring the very low series resistance and inductance (Zs1, Zs2) terms, and considering only the shunt

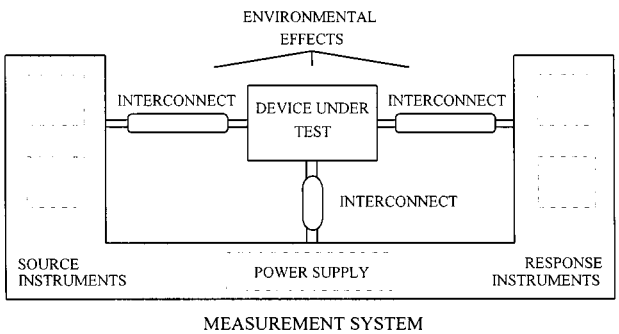

FIGURE 108.3 Fundamental elements of an instrumentation system.

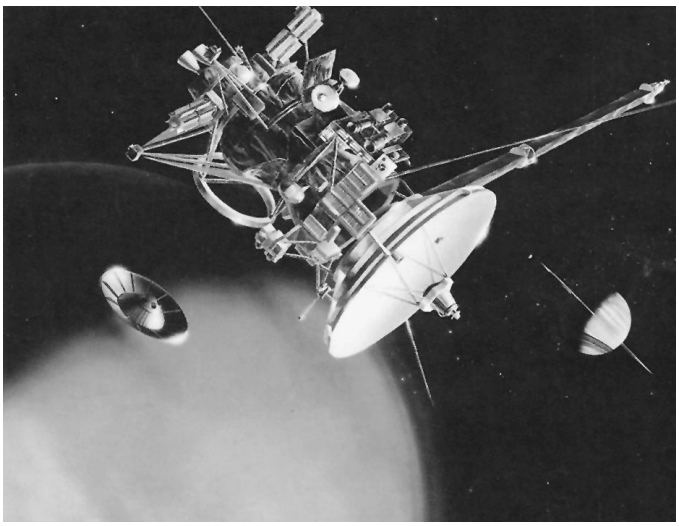
Cassini Spacecraft

One of NASA's latest planetary systems research segments is called the Discovery Program. This program is an effort to develop frequent, small planetary missions that perform high quality scientific investigations. Discovery missions planned for 1997 include the sending of a Mars lander to the planet and launching the Lunar Prospector to map the moon's surface composition.

The principle planetary mission of NASA's Discovery Program is the 1997 launch of Cassini. Cassini is a joint project of NASA, the European Space Agency (ESA), and the Italian Space Agency, and is managed by the Jet Propulsion Laboratory (JPL).

The flight vehicle consists of the main Cassini spacecraft and the ESA-built Huygens Probe, a 750-pound, six instrument package that will descend into the atmosphere of Saturn's moon Titan, which is believed to be chemically similar to the atmosphere of early Earth.

Launched towards the end of 1997, Cassini will make flybys of Venus and Jupiter en route to a rendezvous with Saturn in July 2004. Cassini will release the Huygens Probe during its first orbit, then make approximately 40 revolutions over a span of four years, while the spacecraft's 12 instruments conduct a detailed exploration of the whole Saturnian system, including Titan and the planet's other icy moons. (Courtesy of National Aeronautics and Space Administration.)



This artist's concept shows the Cassini spacecraft orbiting around Saturn, just after deploying a probe that will descend into the atmosphere of Saturn's moon Titan. Launched October 1997, Cassini will reach Saturn in July 2004 and orbit the planet for four years thereafter. (Photo courtesy of National Aeronautics and Space Administration.)

capacitance (Zp) which is in the range of 50 to 150 pF/m for different types of cable. At high frequencies, the characteristic impedance of the interconnect is used; e.g., 50 Ω or 75 Ω for commonly used coaxial cables; 120 Ω for twisted pair.

The response of an entire instrumentation system can be modeled by interconnecting the individual model elements. Figure 108.5 shows an example that was obtained by substituting models for an operational amplifier

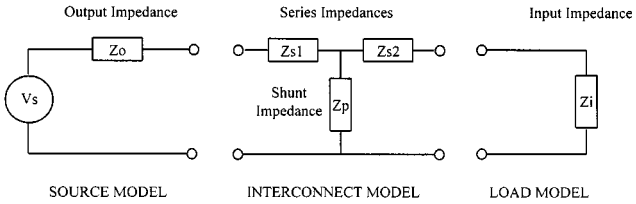

FIGURE 108.4 Simplified output and input models for instrument elements.

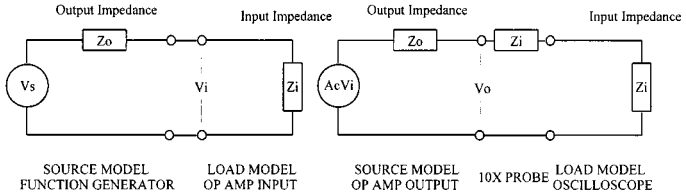

FIGURE 108.5 Model of representative instrumentation system. Each variable would be substituted as required. For example, Vs = 1.0sin2π1000t for a 0.707 Vrms, 1 kHz sine wave; Zo = 50 Ω for the FG501A; Zi = 1 kΩ for an op amp configured as an inverting amplifier with Ri = 1 kΩ; and gain of 10; AcVi = -10.0sin2π1000t; Zo = 1 Ω for low current output; Zi = 9 MΩ‖1.4 pF for a compensated 10X probe; and with Zi = 1 MΩ‖13 pF for the input model of the HP54601A oscilloscope.

(op amp) circuit (corresponds to the device under test in Fig. 108.3) that was driven by a function generator for the source, and that measured the response with an oscilloscope connected to the output of the op amp using a 10X probe. In this application, the impedance of the interconnect between the source and op amp can be neglected since the frequencies are low and the input impedance of the op amp is much greater than that of the cable. The circuit model of the compensated 10X probe contains a very high series impedance (9 MΩ‖1.14 pF) relative to the oscilloscope (1 MΩ‖13 pF) so it cannot be ignored.

The models can be used to determine the *frequency response* of the complete system which describes the magnitude and phase response of the system to sinusoidal, steady-state inputs. This can reveal the contribution of each element to the overall response and helps indicate which elements produce the dominant response. The graphical results of the frequency response analysis is termed a *Bode plot*. If each of N elements has an individual transfer function, $H_i(j\omega)$, $i = 1$ to N, then a composite transfer function can be found for the total system, $T(j\omega)$, which is generally not the simple product of each transfer function, $H_1(j\omega)\cdot H_2(j\omega)\cdot\ldots\cdot H_N(j\omega)$ due to loading effects between elements. The use of a circuit simulation program such as PSpice (MicroSim Corp.) simplifies the investigation into instrument behavior. A library of subcircuit models can be developed for each instrumentation and interconnect element to support measurement system loading effects analysis. For example, a PSpice subcircuit definition for the HP54601A oscilloscope is:

```
.SUBCKT HP54601A 1 2
Cin 1 2 13p
Rin 1 2 1MEG
.ENDS
```

TABLE 108.4 Noise Reduction Checklist

Source	Interconnect	Response
Shield enclosures	Shield leads	Shield enclosures
Filter inputs and outputs	Minimize loop area (twist leads)	Filter inputs and outputs
Limit bandwidth	Keep signal leads near ground	Limit bandwidth
Minimize loop areas	Separate low-, high-level signals	Minimize loop areas
	Keep signal and ground leads short	
	Low f: Use single ground	
	High f: Use multiple grounds

This network model would be added as a load to the output of the device under test in order to predict its loaded behavior.

108.7 Summary of Noise Reduction Techniques

Elimination of undesired measurement errors benefits from a systematic approach to identifying and solving noise problems. Source, interconnect, and response elements of a measurement system can be treated individually. Some techniques, such as shielding, are applicable to all three. Various combinations of techniques should be tried to achieve best results. There are many choices of grounding techniques that vary depending on whether elements are floating or ground-referred, and based on bandwidth. In general, multiple ground connections that create *ground loops* should be avoided. Difficult ground loop problems may require isolation or other techniques to interrupt the ground connection between elements. Table 108.4 summarizes a checklist of noise reduction techniques.

108.8 Personal Computer-Based Instruments

Many instrument functions are available for interface to personal computer (PC) systems. These range from plug-in cards that reside on the PC backplane to standalone instruments that communicate with the PC over standard interfaces such as RS-232 or IEEE-488. Software to control *data acquisition*, analysis, and display completes the computer-based instrument. Examples of such software include *Lab Windows* or *Lab View* (National Instruments), *HP VEE* (Hewlett-Packard), and *Testpoint* (Keithley-Metrabyte). Figure 108.6 shows a block diagram of an output screen developed using *Lab Windows* for an acoustic measurement application. A

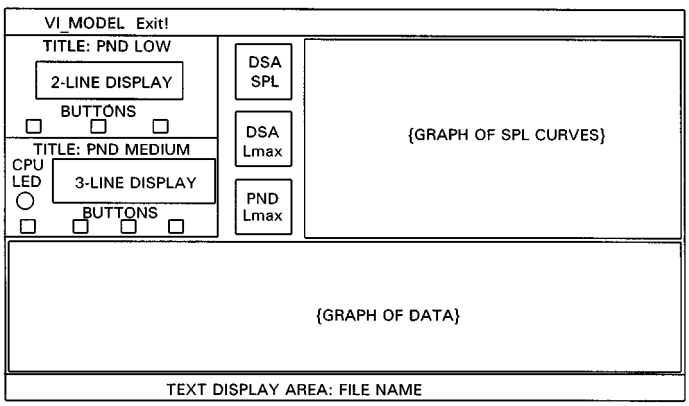

FIGURE 108.6 Example block diagram of a virtual instrument user interface.

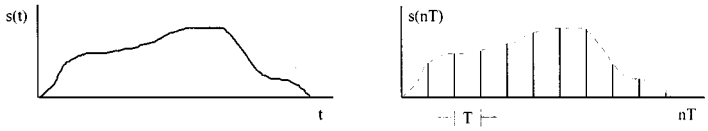

FIGURE 108.7 Sampling a continuous-time signal yields a discrete-time signal.

menu bar provides pull-down options. Several windows simultaneously display selection options and present results graphically and with text.

108.9 Modeling PC-Based Instruments

The approach outlined previously for modeling conventional measurement systems can be extended to PC-based instruments with one major difference: PC-based instruments by their nature are digital machines and perform functions in discrete time. Best performance of PC-based instrument systems must therefore consider *sampled data* effects. Figure 108.7 shows a data acquisition system modeled using an ideal sampler which instantaneously samples a continuous signal, $s(t)$, every T seconds. This yields a sequence, $s(nT)$, of discrete values that represent the value of the continuous signal at integer multiples of T seconds.

108.10 The Effects of Sampling

The Fourier transform of a sampled signal yields a frequency domain function that is periodic in frequency, with a period that is $1/f_s$. The *sampling theorem* states that in order to unambiguously preserve information, the sampling frequency, $f_s = 1/T$, must be at least twice the highest frequency present in the continuous-time signal. If f_s is less than twice the highest frequency, *aliasing* will occur. Aliased frequencies are indistinguishable from one another. A useful method for visualizing this result is through the use of an *aliasing diagram*. An example is shown in Fig. 108.8. Note that the *Nyquist frequency* is defined to be $f_s/2$.

108.11 Other Factors

Other important factors that should be considered when using PC-based instruments over manual counterparts are summarized in Table 108.5. Perhaps the most important choice is the selection of a minimum sampling rate for the data acquisition process. It must be chosen to meet the requirements of the Nyquist frequency. However, in order to ensure that no higher frequencies are present, an *anti-aliasing* low pass filter that eliminates energy above the Nyquist frequency should be employed. In order to provide sufficient transition bandwidth for the filter, a slightly higher sampling rate should generally be employed. A factor of 1.25 to 5 times the minimum f_s is a good compromise. Automated equipment may introduce substantial transients into the measurement system. Sufficient time must be provided for the resulting transients to settle to an acceptable error bound; for example, 1%.

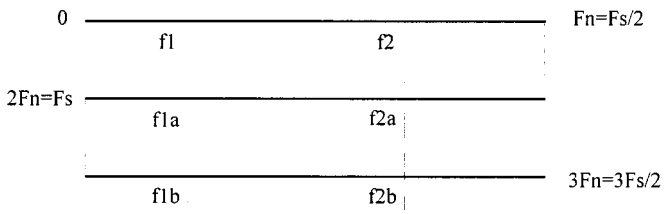

FIGURE 108.8 Aliasing diagram. The two baseband frequencies, f1 and f2, have aliases at frequencies that intersect the vertical dashed lines. For example, using a sampling frequency of 10 kHz (F_n = 5 kHz) with f1 = 1 kHz and f2 = 3.5 kHz, signals at 9 kHz (f_{1a}) and 11 kHz (f_{1b}) would be aliased to 1 kHz (f_1), while signals at 6.5 kHz (f_{2a}) and 13.5 kHz (f_{2b}) would be aliased to 3.5 kHz (f_2).

TABLE 108.5 Automated Measurement Factors

Factor	Consideration
Leveling	Frequency response measurements require use of a leveled generator. Alternatively, store a calibration curve.
Multiplexing	Measurements from multiple nodes require lead switching to shared instruments; consider these effects.
Sampling frequency	Must exceed the Nyquist frequency. Include an anti-aliasing filter. Manual instruments typically use integrating (dual-slope) analog-to-digital converters which give good noise rejection over integer numbers of line cycles. Faster sampling rates for ATE are achieved using successive-approximation or other techniques. User may have to perform averaging as a post-processing step in order to achieve acceptable signal-to-noise ratios.
Settling time	Allow sufficient time for transients to settle for both stimulus/response instruments and device under test.
Storage	Automatic measurements can produce large arrays of data at high speeds. Actual throughput to a hard disk may be much less than the maximum sampling rate of a data acquisition element (plug-in board, external instrument).
Triggering	Choices between free-running, external, and internal.

Defining Terms

Instrument: The means for monitoring or measuring physical variables. Usually includes transducers, signal conditioning, signal processing, and display.

Measurement system: The sum of all stimulus and response instrumentation, device under test, interconnect, environmental variables, and the interaction among the elements.

Transducer: A device that transforms one form of energy to an electrical output that can be processed by an instrument.

Virtual instrument: An instrument created through computer control of instrumentation resources with analysis and display of the data collected.

109.1 Introduction

Navigation is the determination of the position and velocity of a moving vehicle on land, at sea, in the air, or in space. The three components of position and the three components of velocity make up a six-component **state vector** that fully describes the translational motion of the vehicle because the differential equations of motion are of second order. Surveyors are beginning to use the same sensors as navigators but are achieving higher accuracy as a result of longer periods of observation, a fixed location, and more complex, non-real-time data reduction.

In the usual navigation system, the state vector is derived on-board, displayed to the crew, recorded on-board, or transmitted to the ground. Navigation information is usually sent to other on-board subsystems; for example, to the waypoint steering, engine control, communication control, and weapon-control computers. Some navigation systems, called *position-location systems*, measure a vehicle's state vector using sensors on the ground or in another vehicle (Section 109.5). The external sensors usually track passive radar returns or a transponder. Position-location systems usually supply information to a dispatch or control center.

Traditionally, *ship navigation* included the art of pilotage—entering and leaving port, making use of wind and tides, and knowing the coasts and sea conditions. However, in modern usage, navigation is confined to the measurement of the state vector. The handling of the vehicle is called *conning* for ships, *flight control* for aircraft, and *attitude control* for spacecraft.

The term *guidance* has two meanings, both of which are different than *navigation*:

1. Steering toward a destination of known position from the vehicle's present position, as measured by a navigation system. The steering equations on a planet are derived from a plane triangle for nearby destinations and from a spherical triangle for distant destinations.
2. Steering toward a destination without calculating the state vector explicitly. A guided vehicle homes on radio, infrared, or visual emissions. Guidance toward a *moving* target is usually of interest to military tactical missiles in which a steering algorithm assures impact within the maneuver and fuel constraints of the interceptor. Guidance toward a *fixed* target involves beam riding, as in the Instrument Landing System, Section 109.5.

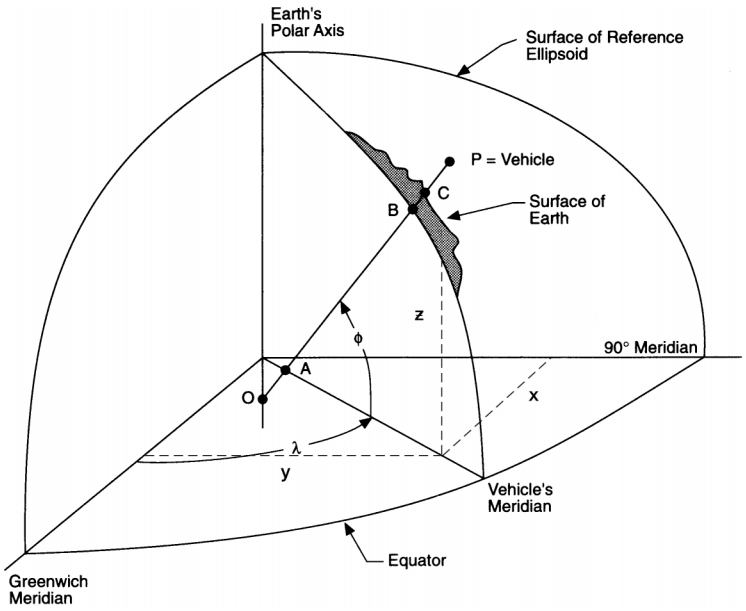

FIGURE 109.1 Latitude-longitude-altitude coordinate frame. ϕ = geodetic latitude; OP is normal to the ellipsoid at B; λ = geodetic longitude; h = $\overline{BP}$ = altitude above the reference ellipsoid = altitude above mean sea level.

109.2 Coordinate Frames

Navigation is with respect to a coordinate frame of the designer's choice. Short-range robots navigate with respect to the local terrain or a building's walls. For navigation over hundreds of kilometers (e.g., automobiles and trucks), various map grids exist whose coordinates can be calculated from latitude-longitude (Fig. 109.1). NATO land vehicles use a Universal Transverse Mercator grid. Long-range aircraft and ships navigate relative to an earth-bound coordinate frame, the most common of which are latitude-longitude-altitude and rectangular x, y, z (Fig. 109.1). The most accurate world-wide reference ellipsoid is described in [WGS-84, 1991]. Spacecraft in orbit around the earth navigate with respect to an earth-centered, inertially nonrotating coordinate frame whose *z* axis coincides with the polar axis of the earth and whose *x* axis lies along the equator. Interplanetary spacecraft navigate with respect to a sun-centered, inertially nonrotating coordinate frame whose *z* axis is perpendicular to the **ecliptic** and whose *x* axis points to a convenient star [Battin, 1987].

109.3 Categories of Navigation

Navigation systems can be categorized as:

1. *Absolute navigation systems* that measure the state vector without regard to the path traveled by the vehicle in the past. These are of two kinds:
   - Radio systems (Section 109.5). They consist of a network of transmitters (sometimes also receivers) on the ground or in satellites. A vehicle detects the transmissions and computes its position relative to the known positions of the stations in the navigation coordinate frame. The vehicle's velocity is measured from the Doppler shift of the transmissions or from a sequence of position measurements.
   - Celestial systems (Section 109.6). They measure the elevation and azimuth of celestial bodies relative to the land level and North. Electronic star sensors are used in special-purpose high-altitude aircraft and in spacecraft. Manual celestial navigation was practiced at sea for millennia (see Bowditch).
2. *Dead-reckoning navigation systems* that derive their state vector from a continuous series of measurements beginning at a known initial position. There are two kinds, those that measure vehicle heading and either

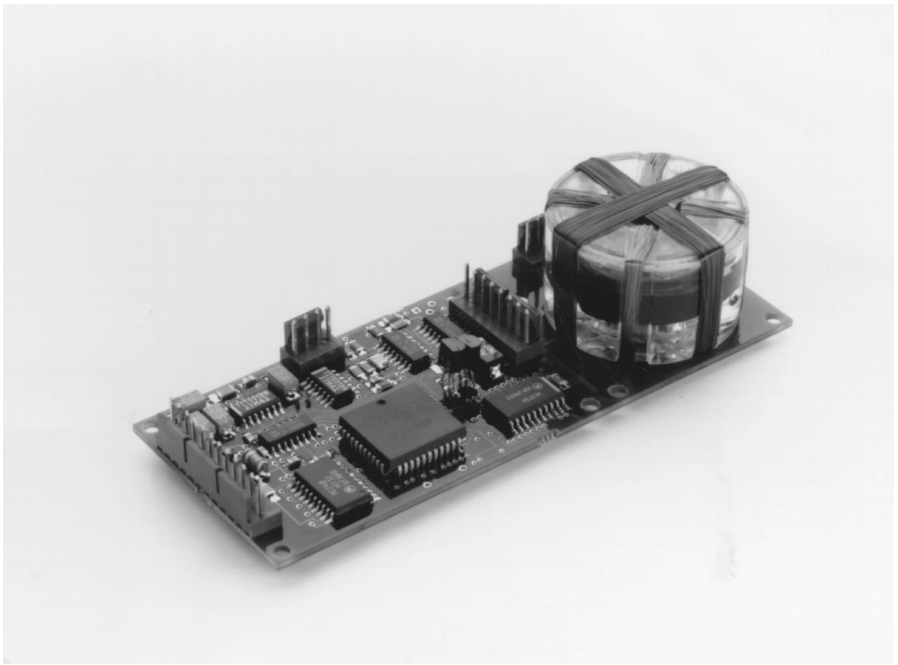

FIGURE 109.2 Saturated core ("flux-gate") magnetometer, mounted on a "compass engine" board. The two orthogonal sensing coils (visible) and the drive coil, wound on the toroidal core, measure two components of the magnetic field in the plane of the toroid. (Courtesy of KVH Industries, Inc.)

speed or acceleration (Section 109.4) and those that measure emissions from continuous-wave radio stations whose signals create ambiguous "**lanes**" (Section 109.5).

Dead reckoning systems must be reinitialized as errors accumulate and if power is lost.

3. *Mapping navigation systems* that observe and recognize images of the ground, profiles of altitude, sequences of turns, or external features (Section 109.7). They compare their observations to a stored database, often on compact disc.

109.4 Dead Reckoning

The simplest dead-reckoning systems measure vehicle heading and speed, resolve speed into the navigation coordinates, then integrate to obtain position (Fig. 109.3). The oldest heading sensor is the magnetic compass, a magnetized needle or electrically excited toroidal core (called a *flux* gate), as shown in Fig. 109.2. It measures the direction of the earth's magnetic field to an accuracy of 2 degrees at a steady velocity below 60-degrees magnetic latitude. The horizontal component of the magnetic field points toward *magnetic north.* The angle from true to magnetic north is called *magnetic variation* and is stored in the computers of modern vehicles as a function of position over the region of anticipated travel [Quinn, 1996]. *Magnetic deviations* caused by iron in the vehicle can exceed 30 degrees and must be compensated in the navigation computer or, in older ships, by placing compensating magnets near the sensor.

A more complex heading sensor is the *gyrocompass*, consisting of a spinning wheel whose axle is constrained to the horizontal plane (often by a pendulum). The ships' version points north, when properly compensated for vehicle motion, and exhibits errors less than a degree. The aircraft version (more properly called a *directional gyroscope*) holds any preset heading relative to earth and drifts at 50 deg/hr or more. Inexpensive gyroscopes (some built on silicon chips as vibrating beams with on-chip signal conditioning) are often coupled to magnetic compasses to reduce maneuver-induced errors.

The simplest speed-sensor is a wheel odometer that generates electrical pulses. Ships use a dynamic-pressure probe or an electric-field sensor that measures the speed of the hull through the conductive water. Aircraft

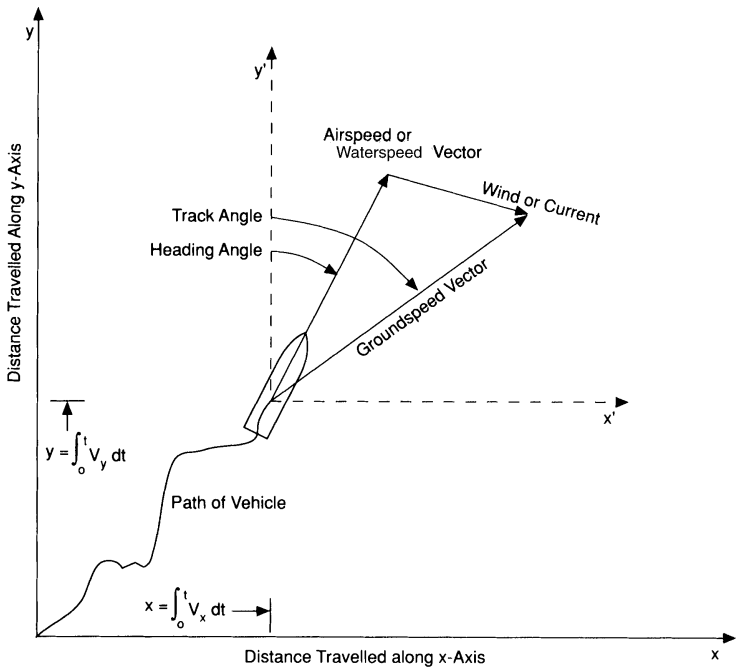

FIGURE 109.3 Geometry of dead reckoning.

measure the dynamic pressure of the air stream from which they derive airspeed in an *air-data* computer. The velocity of the wind or sea current must be vectorially added to that of the vehicle, as measured by a dynamic-pressure sensor (Fig. 109.3). Hence, unpredicted wind or current will introduce an error into the dead-reckoning computation. Most sensors are insensitive to the component of airspeed or waterspeed normal to their axis (*leeway* in a ship, *drift* in an aircraft). A Doppler radar measures the frequency shift in radar returns from the ground or water below the aircraft, from which speed is inferred. A Doppler sonar measures a ship's speed relative to the water layer or ocean floor from which the beam reflects. Multibeam Doppler radars or sonars can measure all the components of the vehicle's velocity. Doppler radars are widely used on military helicopters.

The most complex dead-reckoning system is an *inertial navigator* in which accelerometers measure the vehicle's acceleration while gyroscopes measure the orientation of the accelerometers. An on-board computer resolves the accelerations into navigation coordinates and integrates them to obtain velocity and position. The gyroscopes and accelerometers are mounted in either of two ways:

1. In servoed gimbals that angularly isolate them from rotations of the vehicle.
2. Fastened directly to the vehicle ("strap-down"), whereupon the sensors are exposed to the maximum angular rates and accelerations of the vehicle (Fig. 109.4).

Inertial-quality gyroscopes measure vehicle orientation within 0.1 degree for steering and pointing. Most accelerometers consist of a gram-sized proof-mass mounted on flexure pivots. The newest accelerometers, not yet of inertial grade, are etched into silicon chips. Older gyroscopes contained metal wheels rotating in ball bearings or gas bearings. The newest gyroscopes are evacuated cavities or optical fibers in which counter-rotating laser beams are compared in phase to measure the sensor's angular velocity relative to **inertial space** about an axis normal to the plane of the beams. Vibrating hemispheres and rotating vibrating tines are the basis of some navigation-quality gyroscopes (drift rates less than 0.1 deg/h).

Fault-tolerant configurations of cleverly oriented redundant gyroscopes and accelerometers (typically four to six) detect and correct sensor failures. Inertial navigators are used aboard naval ships, in airliners, in most military fixed-wing aircraft, in space boosters and entry vehicles, in manned spacecraft, in tanks, and on large mobile artillery pieces.

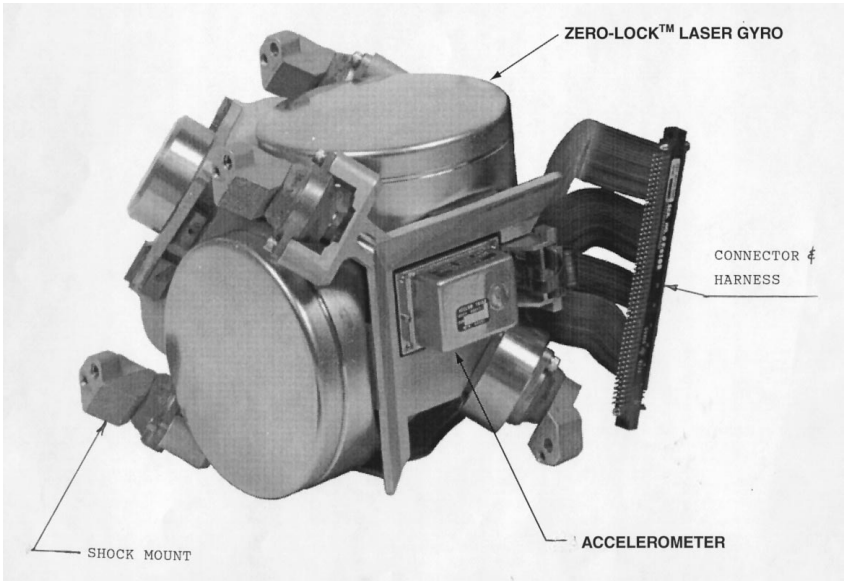

FIGURE 109.4 Inertial reference unit. Two laser gyroscopes (flat discs), an accelerometer, an electrical connector, and three shock mounts are visible. This unit is used in Airbuses and many military aircraft such as the F-18 and Comanche helicopter. (Courtesy of Litton Guidance and Control Systems.)

109.5 Radio Navigation

Scores of radio navigation aids have been invented and many of them have been widely deployed, as summarized in Table 109.1.

The most precise is the global positioning system (GPS), a network of 24 satellites and a half-dozen ground stations for monitoring and control. A vehicle derives its three-dimensional position and velocity from ranging signals at 1.575 GHz received from four or more satellites (military users also receive 1.227 GHz). The former Soviet Union deployed a similar system, called GLONASS. GPS offers better than 100-m ranging errors to civil users and 15-m ranging errors to military users. Simple receivers were available for less than $300 in 1997. They are used on highways, in low-rise cities, at sea, in aircraft, and in low-orbit spacecraft. GPS provides continuous worldwide navigation for the first time in history. It will make dead reckoning unnecessary on many vehicles and will reduce the cost of most navigation systems. Figure 109.5 is an artist's drawing of a GPS Block 2F spacecraft, scheduled for launch in the year 2002.

Differential GPS (DGPS) employs one or more ground stations at known locations, that receive GPS signals and transmit measured errors on a radio link to nearby ships and aircraft. DGPS improves accuracy (centimeters for fixed observers) and detects faults in GPS satellites. In 1997, the U.S. was conducting experiments with a nationwide DGPS system of about 25 stations. This *Wide Area Augmentation System* (WAAS) could eventually replace VORTAC and Category I ILS. A denser network of DGPS stations and GPS-emulating pseudolites, whose stations are located at airports, might replace ILS and MLS (below). In 1997, the cost, accuracy, and reliability of such a *Local Area Augmentation System* (LAAS) were still being compared to existing landing aids but marine LAAS were in operation for navigation into harbors in North America, the North Sea, and the Baltic Sea.

The most widely used marine radio aid in 1997 was Loran-C (see Table 109.1). The 100-kHz signals are usable within 1000 **nautical miles (nmi)** of a "chain" consisting of three or four stations. Chains cover the United States, parts of western Europe, Japan, Saudi Arabia, and a few other areas. The former Soviet Union has a compatible system called Chaika. The vehicle-borne receiver measures the difference in time of arrival of pulses emitted by two stations, thus locating the vehicle on one branch of a hyperbola. Two or more station pairs give a two-dimensional position fix whose typical accuracy is 0.25 nmi, limited by propagation uncertainties over the terrain between the transmitting station and the user. The measurement of 100-microsecond

TABLE 109.1 Worldwide Radio Navigation Aids

System	Frequency Hz	Band	Number of Stations	Number of Users in 1996 Air	Marine	Space	Land
Omega	10–13 kHz	VLF	8	15,000	10,000	0	0

*Standardized by International Civil Aviation Organization.

time difference is possible with low-quality clocks in the vehicles. Loran is also used by general aviation aircraft for en-route navigation and for nonprecision approaches to airports (in which the cloud bottoms are more than 200 feet above the runway). Loran service will probably be discontinued at the beginning of the 21st century.

The most widely used aircraft radio aid is VORTAC, whose stations offer three services:

1. Analog bearing measurements at 108 to 118 MHz (called VOR). The vehicle compares the phases of a rotating cardioid pattern and an omnidirectional sinusoid emitted by the ground station.
2. Pulse distance measurements (DME) at 1 GHz by measuring the time delay for an aircraft to interrogate a VORTAC station and receive a reply,
3. Tacan bearing information conveyed in the amplitude modulation of the DME replies from the VORTAC stations.

Omega is a worldwide radio aid consisting of eight radio stations that emit continuous sine waves at 10 to 13 kHz. Vehicles with precise clocks measure their range to a station by observing the absolute time of reception. Other vehicles measure the range differences between two stations in the form of phase differences between the received sinusoids. Differential Omega creates hyperbolic "lanes" that are 10 to 150 nmi wide. The lanes are indistinguishable from each other by measuring phase; hence the vehicle must count lanes from a point of known position. Errors are about 2 nmi due to radio propagation irregularities. Omega is used by submarines,

FIGURE 109.5 Global positioning satellite, Block 2F. (Courtesy of Rockwell.)

over-ocean general-aviation aircraft, and a few international air carriers. It was scheduled to be decommissioned in 1997.

Landing guidance throughout the western world, and increasingly in China, India, and the former Soviet Union, is with the Instrument Landing System (ILS). Transmitters adjacent to the runway create a horizontal guidance signal near 110 MHz and a vertical guidance signal near 330 MHz. Both signals are modulated such that the nulls intersect along a line in space that leads an aircraft from a distance of about 10 nmi to within 50 ft above the runway. ILS gives no information about where the aircraft is located along the beam except at two or three vertical *marker beacons*. Most ILS installations are certified to the International Civil Aviation Organization's (ICAO) *Category I*, where the pilot must abort the landing if the runway is not visible at an altitude of 200 ft. One hundred ILSs (in 1996) were certified to *Category II*, which allows the aircraft to descend to 100 ft before aborting for lack of visibility. *Category III* allows an aircraft to land at still lower weather ceilings. Category III landing aids are of special interest in Western Europe, which has the worst flying weather in the developed world. Category III ILS detects its own failures and switches to a redundant channel within one second to protect aircraft that are flaring-out (within 50 ft of the runway) and can no longer execute a missed approach. Once above the runway, the aircraft's bottom-mounted radar altimeter measures altitude and either the electronics or the pilot guides the flare maneuver. Landing aids are described by Kayton and Fried [1997].

Throughout the western world, civil aircraft use VOR/DME whereas military aircraft use Tacan/DME for en-route navigation. In the 1990s, China and the successor states to the Soviet Union were installing ICAO-standard navigation aids (VOR, DME, ILS) at their international airports and along the corridors that lead to them from the borders. Overflying western aircraft navigate inertially, with Omega, or with GPS. Domestic flights within the Soviet Union depended on radar tracking, non-directional beacons, and an L-band range-angle system called "RSBN". They will eventually upgrade to a satellite-based enroute and landing system.

U.S. Navy aircraft use a microwave scanning system at 15.6 GHz to land on aircraft carriers; NASA's space shuttle uses the Navy system to land at its spaceports. Another microwave landing system (MLS) at 5 GHz was supposed to replace the ILS in civil operations, especially for Categories II and III. However, experiments from

1990 to 1997 showed that differential GPS could achieve an accuracy better than 1 m as a landing aid. Hence, it is likely that a LAAS will replace or supplement ILS, which has been guaranteed to remain in service at least until the year 2010 (Federal Radionavigation Plan). NATO may use MLS or a LAAS as a portable landing aid for tactical airstrips.

All the space-faring nations operate worldwide radio networks that track spacecraft, compute their state vectors, and predict future state vectors using complex models of gravity, atmospheric drag, and lunisolar perturbations. NASA operates three tracking and data relay satellites (TDRS) that track spacecraft in low earth orbit with accuracies of 10 to 50 m and 0.3 m/s. Specialized ground-based tracking stations monitor and reposition the world's many communication satellites [Berlin, 1988]. Other specialized stations track and communicate with deep space probes. They achieve accuracies of 30 m and a few centimeters per second, even at enormous interplanetary distances, due to long periods of observation and precise orbit equations (see [Yuan, 1983]).

Position-location and position-reporting systems monitor the state vectors of many vehicles and usually display the data in a control room or dispatch center. Some vehicles derive their state vector from the ranging modulations; others merely report an independently derived position. Table 109.1 lists *Secondary Surveillance Radars* that receive coded replies from aircraft so they can be identified by human controllers and by collision-avoidance algorithms. The table also lists the U.S. NASA and military spacecraft-tracking networks (STDN and SCN). Tracking and reporting systems have long been in use at marine ports, for airplane traffic control and for space vehicles. They are increasingly being installed in fire trucks, police cars, ambulances, and delivery-truck fleets that report to a control center. The aeronautical bureaucracy calls them *Automatic Dependent Surveillance* (ADS) systems. The continuous broadcast of on-board-derived position (probably GPS-based) may become the basis of the worldwide air traffic control system of the early 21st century.

Several commercial communication satellites plan to offer digital-ranging services worldwide. The intermittent nature of commercial fixes would require that vehicles dead-reckon between fixes, perhaps using solid-state inertial instruments. Thus, if taxpayers insist on collecting fees for service, private comm-nav networks may replace the government-funded GPS and air-traffic communication network in the next century. Worldwide traffic control over oceans and undeveloped land areas would become possible.

Military communication-navigation systems measure the position of air, land, and naval vehicles on battlefields and report to headquarters; examples are the American Joint Tactical Information Distribution System (JTIDS) and the Position Location Reporting System (PLRS).

A worldwide network of SARSAT-COSPAS stations monitors signals from satellite-based transponders listening on 121.5, 243, and 406 MHz, the three international distress frequencies. Software at the listening stations calculates the position of Emergency Location Transmitters within 20 kilometers, based on the observed Doppler-shift history, so that rescue vehicles can be dispatched. Thousands of lives have been saved worldwide, from arctic bush-pilots to tropical fishermen.

109.6 Celestial Navigation

Human navigators use sextants to measure the elevation angle of celestial bodies above the visible horizon. The peak elevation angle occurs at local noon or midnight:

$$\text{elev angle (degrees)} = 90 - \text{latitude} + \text{declination}$$

Thus at local noon or midnight, latitude can be calculated by simple arithmetic. Tables of declination, the angle of the sun or star above the earth's equatorial plane, were part of the ancient navigator's proprietary lore. The declination of the sun was first publicly tabulated in the fifteenth century in Spain. When time became measurable at sea, with a chronometer in the nineteenth century and by radio in the twentieth century, off-meridian observations of the elevation of two or more celestial bodies were possible at any known time of night (cloud cover permitting). These fixes were hand-calculated using logarithms, then plotted on charts. In the 1930s, hand-held sextants were built that measured the elevation of celestial bodies from an aircraft using a bubble-level reference instead of the horizon. The accuracy of celestial fixes was 3–10 miles at sea and 5–20 miles in the air, limited by the uncertainty in the horizon and the inability to make precise angular measurements on a pitching, rolling vehicle. Kayton (1990) reviews the history of celestial navigation at sea and in the air.

The first automatic star trackers were built in the late 1950s. They measured the azimuth and elevation of stars relative to a gyroscopically stabilized platform. Approximate position measurements by dead reckoning allowed the telescope to point within a fraction of a degree of the desired star. Thus, a narrow field-of-view was possible, permitting the telescope and photodetector to track stars in the daytime. An on-board computer stored the right ascension and declination of 20–100 stars and computed the vehicle's position. Automatic star trackers are used in long-range military aircraft and on space shuttles in conjunction with inertial navigators. Clever design of the optics and of stellar-inertial signal-processing filters achieves accuracies better than 500 ft [Kayton and Fried, 1997].

Spacecraft use the line-of-sight to the sun and stars to measure orientation (for *attitude control*). Earth-pointing spacecraft usually carry horizon scanners that locate the center of the earth's carbon-dioxide disc. All spacecraft navigate by radio tracking from earth. When interplanetary spacecraft approach the target planet, the navigation computers (on earth) transform from sun-centered to planet-centered coordinates by observing star occultations and transmitting the images to earth for human interpretation. During the Apollo translunar missions, crews experimentally measured the angle between celestial bodies and the earth or moon with a specially designed manual sextant coupled to a digital computer which calculated the state vector. Other experiments have been made in which American and Soviet crews used manual sextants to observe the angle between celestial bodies and landmarks on earth, from which state vectors were calculated. Autonomous land vehicles on other planets and certain military spacecraft may need celestial navigation.

109.7 Map-Matching Navigation

As computer power grows, map-matching navigation is becoming more important. On aircraft, mapping radars and optical sensors present a visual image of the terrain to the crew. Automatic map-matchers have been built, since the 1960s, that correlate the observed image to stored images, choosing the closest match to update the dead-reckoned state vector. More commonly, aircraft and cruise missiles measure the vertical profile of the terrain below the vehicle and match it to a stored profile. Matching profiles, perhaps hourly, reduces the long-term drift of their inertial navigators. The profile of the terrain is measured by subtracting the readings of a baro-inertial altimeter (calibrated for altitude above sea level) and a radar altimeter (measuring terrain clearance). An on-board computer calculates the autocorrelation function between the measured profile and each of many stored profiles on possible parallel paths of the vehicle. The on-board inertial navigator usually contains a digital filter that corrects the drift of the azimuth gyroscope as a sequence of fixes is obtained. Hence the direction of flight through the stored map is known, saving the considerable computation time that would be needed to correlate for an unknown azimuth of the flight path. Marine versions profile the seafloor with a sonar and compare the measured profile to stored bottom maps.

GPS is adequate for automotive navigation except in high-rise cities, in tunnels, and on streets with heavy foliage. To fill coverage gaps, map-matching software can take advantage of the fact that the vehicle remains on roads. On the highway, dead-reckoning or GPS errors can be rectified to the nearest road. In cities, turns can be correlated with the nearest intersection of matching geometry. An accuracy of several meters is possible if all streets are included on the stored map (e.g., alleys, driveways, and parking garages).

The most complex mapping systems observe their surroundings, usually by digitized video, and create their own map of the surrounding terrain. Guidance software then steers the vehicle. In 1997, such systems were in development for hazardous sites such as nuclear plants, waste-disposal facilities, and battlefields, and for unmanned planetary exploration.

Delivery robots in buildings are furnished with a map and need only find their successive destinations while avoiding obstacles. They navigate by following stripes on the floor, by observing infrared beacons, or by observing the returns from on-board ultrasonic sonar or laser radar.

109.8 Navigation Software

Navigation software is sometimes embedded in a central processor with other avionic-system software, sometimes confined to one or more navigation computers. The navigation software contains algorithms and data

GPS Positioning System Delivers High Accuracy

A system for real-time differential GPS (DGPS) positioning will deliver submeter accuracy to Earth satellites and ground-based users worldwide. Developed at NASA's Jet Propulsions Laboratory, the system could improve real-time position accuracy to a few decimeters for single-frequency users and 10 cm or better for dual frequency users. In addition to high accuracy, the system provides nearly complete separation of GPS orbit and clock corrections and continuous determination of inter-frequency delay biases for all GPS satellites and reference receivers.

Key features include: the use of dynamic orbit estimation, which depends on high-accuracy satellite force models, signal models, geophysical models, and geometric models, in a Kalman filter formulation; use of real-time stochastic estimation to minimize orbit and clock errors arising from quasi-random variations in atmospheric propagation relays and solar radiation pressure; simultaneous processing of smoothed pseudorange and continuous carrier phase data; and use of the stable solar-magnetic reference frame, rather than an Earth-fixed frame, in computing the ionosphere corrections.

System operation began in January 1997. Early tests show approximate user differential range errors of less than 20 cm throughout the coverage area, with a North American reference network only. More comprehensive tests with additional global reference sites will be conducted. (Reprinted with permission of *NASA Tech Briefs,* 20(10), 30, 1996).

that process the measurements made by each sensor (e.g., inertial or air data). It contains calibration constants, initialization sequences, self-test algorithms, reasonability tests, and alternative algorithms for periods when sensors have failed or are not receiving information. In the simplest systems, the state vector is calculated independently from each sensor; most often, the navigation software contains multisensor algorithms that calculate the best estimate of position and velocity from several sensors. Prior to 1970, the best estimate was calculated from a least squares algorithm with constant weighting functions or from a frequency-domain filter with constant coefficients. Now, a *Kalman filter* calculates the best estimate from mathematical models of the dynamics of each sensor.

Digital maps, often stored on compact disc, are carried on some aircraft and land vehicles so position can be visually displayed to the crew. Military aircraft superimpose their navigated position on a stored map of terrain and cultural features to aid in the penetration of and escape from enemy territory. Civil operators had not invested in digital data bases as of 1996. Algorithms for waypoint steering and for control of the vehicle's attitude are contained in the software of the *flight management* and *flight control* subsystems.

Specially equipped aircraft (sometimes ships) are often used for the routine calibration of radio navigation aids, speed and velocity sensors, heading sensors, and new algorithms.

109.9 Design Trade-Offs

The designers of a navigation system conduct trade-offs for each vehicle to determine which navigation systems to use. Tradeoffs consider the following attributes:

- *Cost*, including the construction and maintenance of transmitter stations and the purchase of on-board electronics and software. Users are concerned only with the costs of on-board hardware and software.
- *Accuracy* of position and velocity, which is specified as a circular error probable (CEP, in meters or nautical miles). The maximum allowable CEP is often based on the calculated risk of collision on a typical mission.

- *Autonomy*, the extent to which the vehicle determines its own position and velocity without external aids. Autonomy is important to certain military vehicles and to civil vehicles operating in areas of inadequate radio-navigation coverage.
- *Time delay* in calculating position and velocity, caused by computational and sensor delays.
- *Geographic coverage*. Radio systems operating below 100 kHz can be received beyond line of sight on earth; those operating above 100 MHz are confined to line of sight. On other planets, new navigation aids—perhaps navigation satellites or ground stations—will be installed,
- *Automation*. The vehicle's operator (on-board crew or ground controller) receives a direct reading of position, velocity, and equipment status, usually without human intervention. The navigator's crew station disappeared in aircraft in the 1970s. Human navigators are becoming scarce, even on ships, in the 1990s, because electronic equipment automatically selects stations, calculates waypoint steering, and accommodates failures.

Defining Terms

Circular Error Probable (CEP): Radius of a circle, centered at the destination, that contains 50% of the navigation measurements from a large sample.

Ecliptic: Plane of earth's orbit around the sun.

Inertial Space: Any coordinate frame whose origin is on a freely falling (orbiting) body and whose axes are nonrotating relative to the fixed stars. It is definable within 10^{-7} degree/h.

Lanes: Hyperbolic bands on the earth's surface in which continuous-wave radio signals repeat in phase.

Nautical Mile (nmi): 1852 m, exactly. Approximately 1 min of arc on the earth's surface.

State vector: Six-component vector, three of whose elements are position and three of whose elements are velocity.

Update: The intermittent resetting of the dead-reckoned state vector based on absolute navigation measurements (see Section 109.3).

110.1 Introduction

Reliability engineering is a vast field and it has grown significantly during the past five decades (since World War II). The two major approaches to reliability assessment and prediction are (1) traditional methods based on probabilistic assessment of field data and (2) methods based on the analysis of failure mechanisms and physics of failure. The latter is more accurate, but is difficult and time consuming to implement. The first one, in spite of its many flaws, continues to be in use. Some of the many areas encompassing reliability engineering are reliability allocation and optimization, reliability growth and modeling, reliability testing including accelerated testing, data analysis and graphical techniques, quality control and acceptance sampling, maintenance engineering, repairable system modeling and analysis, software reliability, system safety analysis, Bayesian analysis, reliability management, simulation and Monte Carlo techniques, Failure Modes, Effects and Criticality Analysis (FMECA), and economic aspects of reliability, to mention a few.

Application of reliability techniques is gaining importance in all branches of engineering because of its effectiveness in the detection, prevention, and correction of failures in the design, manufacturing, and operational

Information Management System for Manufacturing Efficiency

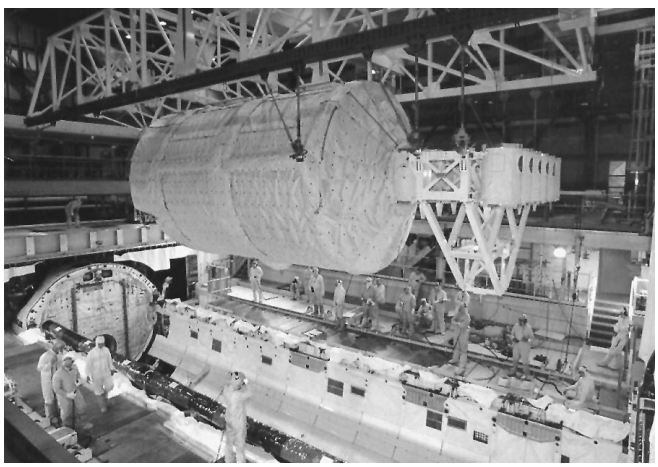
At current schedules, each of NASA's four Space Shuttle Orbiters must fly two or three times a year. Preparing an orbiter for its next mission is an incredibly complex process and much of the work is accomplished in the Orbiter Processing Facility (OPF) at Kennedy Space Center.

The average "flow" — the complete cycle of refurbishing an orbiter — requires the integration of approximately 10,000 work events, takes 65 days, and some 40,000 technician labor hours. Under the best conditions, scheduling each of the 10,000 work events in a single flow would be a task of monumental proportions. But the job is further complicated by the fact that only half the work is standard and predictable; the other half is composed of problem-generated tasks and jobs specific to the next mission, which creates a highly dynamic processing environment and requires frequent rescheduling.

For all the difficulties, Kennedy Space Center and its prime contractor for shuttle processing — Lockheed Space Operations Company (LSOC) — are doing an outstanding job of managing OPF operations with the help of a number of processing innovations in recent years. One of the most important is the Ground Processing Scheduling System, or GPSS. The GPSS is a software system for enhancing efficiency by providing an automated scheduling tool that predicts conflicts between scheduled tasks, helps human schedulers resolve those conflicts, and searches for near-optimal schedules.

GPSS is a cooperative development of Ames Research Center, Kennedy Space Center, LSOC, and a related company, Lockheed Missiles and Space Company. It originated at Ames, where a group of computer scientists conducted basic research on the use of artificial intelligence techniques to automate the scheduling process. A product of the work was a software system for complex, multifaceted operations known as the Gerry scheduling engine.

Kennedy Space Center brought Ames and Lockheed together and the group formed an inter-center/NASA contractor partnership to transfer the technology of the Gerry scheduling engine to the Space Shuttle program. The transfer was successfully accomplished and GPSS has become the accepted general purpose scheduling tool for OPF operations. (Courtesy of National Aeronautics and Space Administration.)



Kennedy Space Center technicians are preparing a Space Shuttle Orbiter for its next mission, an intricate task that requires scheduling 10,000 separate events over 65 days. A NASA-developed computer program automated this extremely complex scheduling job. (Photo courtesy of National Aeronautics and Space Administration.)

phases of products and systems. Increasing emphasis being placed on quality of components and systems, coupled with pressures to minimize cost and increase value, further emphasize the need to study, understand, quantify, and predict reliability and arrive at innovative designs and operational and maintenance procedures.

From the electrical engineering point of view, two (among several) areas that have received significant attention are electronic equipment (including computer hardware) and electric power systems. Other major areas include communication systems and software engineering. As the complexity of electronic equipment grew during and after World War II and as the consequences of failures in the field became more and more apparent, the U.S. military became seriously involved, promoted the formation of groups, and became instrumental in the development of the earliest handbooks and specifications. The great northeast blackout in the U.S. in November 1965 triggered the serious application of reliability concepts in the power systems area.

The objectives of this chapter are to introduce the reader to the fundamentals and applications of classical reliability concepts and bring out the important benefits of reliability considerations. Brief summaries of application aspects of reliability for electronic systems and power systems are also included.

110.2 Catastrophic Failure Models

Catastrophic failure refers to the case in which repair of the component is either not possible or available or of no value to the successful completion of the mission originally planned. Modeling such failures is typically based on life test results. We can consider the "lifetime" or "time to failure" T as a continuous random variable. Then,

$$P\left(\textit{survival up to time } t\right) = P\left(T > t\right) \equiv R\left(t\right) \tag{110.1}$$

where $R(t)$ is the **reliability** function. Obviously, as $t \to \infty$, $R(t) \to 0$ since the probability of failure increases with time of operation. Moreover,

$$P\left(\textit{failure at } t\right) = P\left(T \leq t\right) \equiv Q\left(t\right) \tag{110.2}$$

where $Q(t)$ is the unreliability function. From the definition of the distribution function of a continuous random variable, it is clear that $Q(t)$ is indeed the distribution function for T. Therefore, the failure density function $f(t)$ can be obtained as

$$f\left(t\right) = \frac{d}{dt} Q\left(t\right) \tag{110.3}$$

The **hazard rate function** $\lambda(t)$ is defined as

$$\lambda\left(t\right) \equiv \lim_{\Delta t \to 0} \frac{1}{\Delta t}\left[\begin{array}{l}\text{probability of failure in } (t, t+\Delta t), \\ \text{given survival up to t}\end{array}\right] \tag{110.4}$$

It can be shown that

$$\lambda\left(t\right) = \frac{f\left(t\right)}{R\left(t\right)} \tag{110.5}$$

The four functions, $f(t)$, $Q(t)$, $R(t)$, and $\lambda(t)$ constitute the set of functions used in basic reliability analysis. The relationships between these functions are given in Table 110.1.

TABLE 110.1 Relationships Between Different Reliability Functions

$f(t)$	$\lambda(t)$	$Q(t)$	$R(t)$
$f(t) = f(t)$	$\lambda(t) \exp\left[-\int_0^t \lambda(\xi)d\xi\right]$	$\frac{d}{dt} Q(t)$	$-\frac{d}{dt} R(t)$
$\lambda(t) = \frac{f(t)}{1 - \int_0^t f(\xi)d\xi}$	$\lambda(t)$	$\frac{1}{1 - Q(t)} \frac{d}{dt} (Q(t))$	$-\frac{d}{dt} [\ln R(t)]$
$Q(t) = \int_0^t f(\xi)d\xi$	$1 - \exp\left[-\int_0^t \lambda(\xi)d\xi\right]$	$Q(t)$	$1 - R(t)$
$R(t) = 1 - \int_0^t f(\xi)d\xi$	$\exp\left[-\int_0^t \lambda(\xi)d\xi\right]$	$1 - Q(t)$	$R(t)$

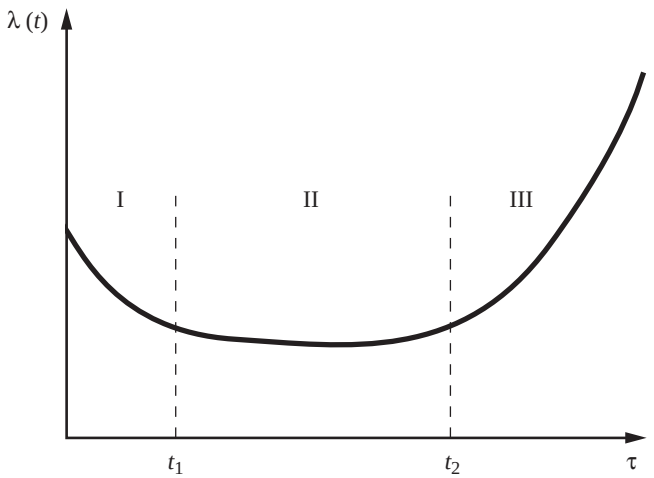


FIGURE 110.1 Bathtub-shaped hazard function

110.3 The Bathtub Curve

Of the four functions discussed, the hazard rate function $\lambda(t)$ displays the different stages during the lifetime of a component most clearly. In fact, typical $\lambda(t)$ plots have the general shape of a bathtub as shown in Fig. 110.1. The first region corresponds to wearin (infant mortality) or early failures during debugging. The hazard rate goes down as debugging continues. The second region corresponds to an essentially constant and low failure rate and failures can be considered to be nearly random. This is the useful lifetime of the component. The third region corresponds to wearout or fatigue phase with a sharply increasing hazard rate.

"Burn-in" refers to the practice of subjecting components to an initial operating period of t_1 (see Fig. 110.1) before delivering them to the customer. This eliminates all the initial failures from occurring after delivery to customers requiring high-reliability components. Moreover, it is prudent to replace a component as it approaches the wearout region, i.e., after an operating period of $(t_2\text{-}t_1)$. Electronic components tend to have a long useful life (constant hazard) period. Wearout region tends to dominate in the case of mechanical components.

110.4 Mean Time To Failure (MTTF)

The mean or expected value of the continuous random variable "time-to-failure" is the *MTTF*. This is a very useful parameter and is often enough to assess the suitability of components. It can be obtained using either the failure density function $f(t)$ or the reliability function $R(t)$ as follows:

$$MTTF = \int_0^\infty t\,f(t)dt \quad \text{or} \quad \int_0^\infty R(t)dt \tag{110.6}$$

In the case of repairable components, the repair time can also be considered as a continuous random variable with an expected value of *MTTR*. The mean time between failures, *MTBF*, is the sum of *MTTF* and *MTTR*. Since for well-designed components *MTTR*<<*MTTF*, *MTBF* and *MTTF* are often used interchangably.

110.5 Average Failure Rate

The average failure rate over the time interval 0 to T is defined as

$$AFR(0, T) \equiv AFR(T) = -\frac{\ln R(T)}{T} \tag{110.7}$$

110.6 *A Posteriori* Failure Probability

When components are subjected to a burn-in (or wearin) period of duration T, and if the component survives during $(0, T)$, the probability of failure during $(T, T+t)$ is called the *a posteriori* failure probability $Q_c(t)$. It can be found using

$$Q_c(t) = \frac{\int_T^{T+t} f(\xi)d\xi}{\int_T^\infty f(\xi)d\xi} \tag{110.8}$$

The probability of survival during $(T, T+t)$ is

$$R(t|T) = 1 - Q_c(t) = \frac{\int_{T+t}^\infty f(\xi)d\xi}{\int_T^\infty f(\xi)d\xi} = \frac{R(T+t)}{R(T)} = \exp\left[-\int_T^{T+t} \lambda(\xi)d\xi\right] \tag{110.9}$$

110.7 Units for Failure Rates

Several units are used to express failure rates. In addition to $\lambda(t)$ which is usually in number per hour, *%/K* is used to denote failure rate in percent per thousand hours and *PPM/K* is used to express failure rate in parts per million per thousand hours. The last unit is also known as *FIT* for "fails in time". The relationships between these units are given in Table 110.2.

TABLE 110.2 Relationships Between Different Failure Rate Units

	λ(#/hr)	%K	PPM/K (FIT)
λ =	λ	10^{-5} (%/K)	10^{-9}(PPM/K)
%/K =	10^{5} λ	%/K	10^{-4}(PPM/K)
PPM/K (FIT) =	10^{9} λ	10^{4} (%/K)	PPM/K

110.8 Application of the Binomial Distribution

In an experiment consisting of n identical independent trials, with each trial resulting in success or failure with probabilities of p and q, the probability P_r of r successes and $(n\text{-}r)$ failures is

$$P_r = {}_nC_r\, p^r\left(1 - p\right)^{n-r} \tag{110.10}$$

If X denotes the number of successes in n trials, then it is a discrete random variable with a mean value of (np) and a variance of (npq).

In a system consisting of a collection of n identical components with a probability p that a component is defective, the probability of finding r defects out of n is given by the P_r in Eq. (110.10). If p is the probability of success of one component and if at least r of them must be good for system success, then the system reliability (probability of system success) is given by

$$R = \sum_{k=r}^{n} {}_nC_k\, p^k\left(1 - p\right)^{n-k} \tag{110.11}$$

For systems with **redundancy**, $r < n$.

110.9 Application of the Poisson Distribution

For events that occur "in-time" at an average rate of λ occurrences per unit of time, the probability $P_x(t)$ of exactly x occurences during the time interval $(0\ ,\ t)$ is given by

$$P_x\left(t\right) = \frac{\left(\lambda t\right)^x e^{-\lambda t}}{x!} \tag{110.12}$$

The number of occurrences X in $(0,\ t)$ is a discrete random variable with a mean value μ of (λt) and a standard deviation σ of $\sqrt{\lambda t}$. By setting $X = 0$ in Eq. (110.12), we obtain the probability of no occurrence in $(0,t)$ as $e^{-\lambda t}$. If the event is failure, then no occurrence means success and $e^{-\lambda t}$ is the probability of success or system reliability. This is the well-known and often-used exponential distribution, also known as the constant-hazard model.

110.10 The Exponential Distribution

A constant hazard rate (constant λ) corresponding to the useful lifetime of components leads to the single-parameter exponential distribution. The functions of interest associated with a constant λ are:

$$f\left(t\right) = \lambda e^{-\lambda t},\ \ t > 0 \tag{110.13}$$

$$R(t) = e^{-\lambda t} \tag{110.14}$$

$$Q(t) = Q_c(t) = 1 - e^{-\lambda t} \tag{110.15}$$

The *a posteriori* failure probability $Q_c(t)$ is independent of the prior operating time T, indicating that the component does not degrade no matter how long it operates. Obviously, such a scenario is valid only during the useful lifetime (horizontal portion of the bathtub curve) of the component.

The mean and standard deviation of the random variable "lifetime" are

$$\mu \equiv MTTF = \frac{1}{\lambda} \qquad \text{and} \qquad \sigma = \frac{1}{\lambda} \tag{110.16}$$

110.11 The Weibull Distribution

The Weibull distribution has two parameters, a scale parameter α and a shape parameter β. By adjusting these two parameters, a wide range of experimental data can be modeled in system reliability studies.

The associated functions are

$$\lambda(t) = \frac{\beta t^{\beta-1}}{\alpha^{\beta}}; \ \alpha > 0, \ \beta > 0, \ t \geq 0 \tag{110.17}$$

$$f(t) = \frac{\beta t^{\beta-1}}{\alpha^{\beta}} \exp\left[-\left(\frac{t}{\alpha}\right)^{\beta}\right] \tag{110.18}$$

$$R(t) = \exp\left[-\left(\frac{t}{\alpha}\right)^{\beta}\right] \tag{110.19}$$

With $\beta = 1$, the Weibull distribution reduces to the constant hazard model with $\lambda = (1/\alpha)$. With $\beta = 2$, the Weibull distribution reduces to the Rayleigh distribution.

The associated *MTTF* is

$$MTTF = \mu = \alpha\Gamma\left(1 + \frac{1}{\beta}\right) \tag{110.20}$$

where Γ denotes the gamma function.

110.12 Combinatorial Aspects

Analysis of complex systems is facilitated by decomposition into functional entities consisting of subsystems or units and by the application of combinatorial considerations and network modeling techniques.

A **series** or **chain structure** consisting of n units is shown in Fig. 110.2. From the reliability point of view, the system will succeed only if all the units succeed. The units may or may not be physically in series. If R_i is the probability of success of the ith unit, then the series system reliability R_s is given as

$$R_s = \prod_{i=1}^{n} R_i \tag{110.21}$$

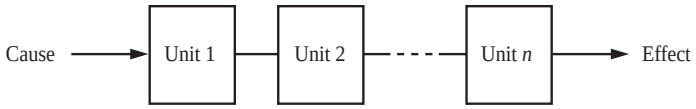

FIGURE 110.2 Series or chain structure.

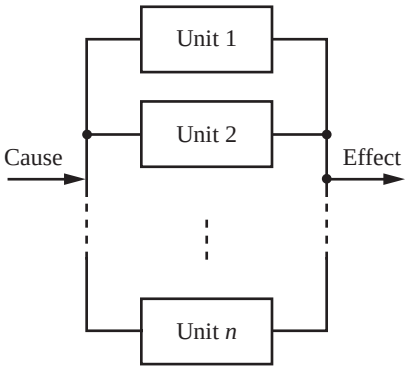

FIGURE 110.3 Parallel structure.

if the units do not interact with each other. If they do, then the conditional probabilities must be carefully evaluated.

If each of the units has a constant hazard, then

$$R_s(t) = \prod_{i=1}^{n} \exp(-\lambda_i t) \tag{110.22}$$

where λ_i is the constant failure rate for the ith unit or component. This enables us to replace the n components in series by an equivalent component with a constant hazard λ_s where

$$\lambda_s = \sum_{i=1}^{n} \lambda_i \tag{110.23}$$

If the components are identical, then $\lambda_s = n\lambda$ and the *MTTF* for the equivalent component is $(1/n)$ of the *MTTF* of one component.

A **parallel structure** consisting of n units is shown in Fig. 110.3. From the reliability point of view, the system will succeed if any one of the n units succeeds. Once again, the units may or may not be physically or topologically in parallel. If Q_i is the probability of failure of the ith unit, then the parallel system reliability R_p is given as

$$R_p = 1 - \prod_{i=1}^{n} Q_i \tag{110.24}$$

if the units do not interact with each other (meaning independent).

If each of the units has a constant hazard, then

$$R_p(t) = 1 - \prod_{i=1}^{n} \left[1 - \exp(-\lambda_i t)\right] \tag{110.25}$$

and we do not have the luxury of being able to replace the parallel system by an equivalent component with a constant hazard. The parallel system does not exhibit constant-hazard behavior even though each of the units has constant-hazard.

The *MTTF* of the parallel system can be obtained by using Eq. (110.25) in (110.6). The results for the case of components with identical hazards λ are: $(1.5/\lambda)$, $(1.833/\lambda)$, and $(2.083/\lambda)$ for $n = 2$, 3, and 4 respectively. The largest gain in *MTTF* is obtained by going from one component to two components in parallel. It is uncommon to have more than two or three components in a truly parallel configuration because of the cost involved. For two non-identical components in parallel with hazard rates of λ_1 and λ_2, the *MTTF* is given as

$$MTTF = \frac{1}{\lambda_1} + \frac{1}{\lambda_2} - \frac{1}{\lambda_1 + \lambda_2} \tag{110.26}$$

An r-out-of-n structure, also known as a partially redundant system, can be evaluated using Eq. (110.11). If all the components are identical, independent, and have a constant hazard of λ, then the system reliability can be expressed as

$$R(t) = \sum_{k=r}^{n} {}_nC_k\, e^{-k\lambda t}\left(1 - e^{-\lambda t}\right)^{n-k} \tag{110.27}$$

For $r = 1$, the structure becomes a parallel system and for $r = n$, it becomes a series system.

Series-parallel systems are evaluated by repeated application of the expressions derived for series and parallel configurations by employing the well-known network reduction techniques.

Several general techniques are available for evaluating the reliability of complex structures that do not come under purely series or parallel or series parallel. They range from inspection to cutset and tieset methods and connection matrix techniques that are amenable for computer programming.

110.13 Modeling Maintenance

Maintenance of a component could be a scheduled (or preventive) one or a forced (corrective) one. The latter follows in-service failures and can be handled using Markov models discussed later. Scheduled maintenance is conducted at fixed intervals of time, irrespective of the system continuing to operate satisfactorily.

Scheduled maintenance, under ideal conditions, takes very little time (compared to the time between maintenances) and the component is restored to an "as new" condition. Even if the component is not repairable, scheduled maintenance postpones failure and prolongs the life of the component. Scheduled maintenance makes sense only for those components with increasing hazard rates. Most mechanical systems come under this category. It can be shown that the density function $f_T^*(t)$ with scheduled maintenance included can be expressed as

$$f_T^*(t) = \sum_{k=0}^{\infty} f_1(t - kT_M) R^k(T_M) \tag{110.28}$$

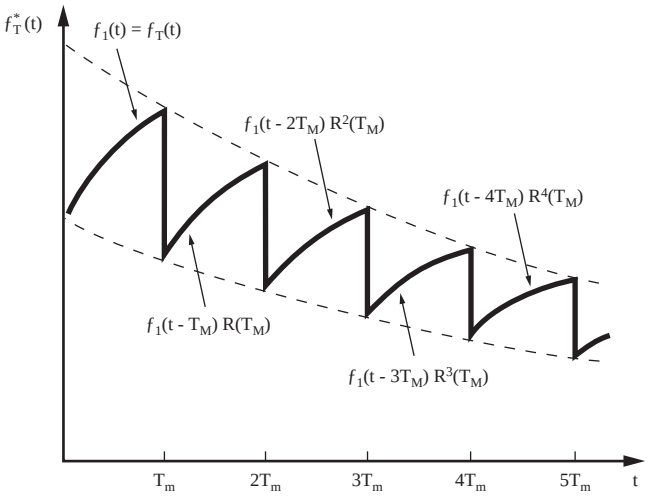

FIGURE 110.4 Density function with ideal scheduled maintenance incorporated.

$$\text{where } f_1(t) = \begin{cases} f_T(t) \text{ for } 0 < t \le T_M \\ 0 \qquad \text{otherwise} \end{cases} \tag{110.29}$$

$$R(t) = \text{component reliability function}$$

$$T_M = \text{time between maintenances, constant}$$

$$\text{and } f_T(t) = \text{original failure density function}$$

In Eq. (110.28), $k = 0$ is used only between $t = 0$ and $t = T_M$; $k = 1$ is used only between $t = T_M$ and $t = 2T_M$ and so on.

A typical $f_T^*(t)$ is shown in Fig. 110.4. The time scale is divided into equal intervals of T_M each. The function in each segment is a scaled-down version of the one in the previous segment, the scaling factor being equal to $R(T_M)$. Irrespective of the nature of the original failure density function, scheduled maintenance gives it an exponential tendency. This is another justification for the widespread use of exponential distribution in system reliability evaluations.

110.14 Markov Models

Of the different Markov models available, the discrete-state continuous-time Markov process has found many applications in system reliability evaluation, including the modeling of repairable systems. The model consists of a set of discrete states, called the state space, in which the system can reside and a set of transition rates between appropriate states. Using these, a set of first order differential equations are derived in the standard vector-matrix form for the time-dependent probabilities of the various states. Solution of these equations incorporating proper initial conditions gives the probabilities of the system residing in different states as functions of time. Several useful results can be gleaned from these functions.

110.15 Binary Model for a Repairable Component

The binary model for a repairable component assumes that the component can exist in one of two states—the UP state or the DOWN state. The transition rates between these two states, S_0 and S_1, are assumed to be constant

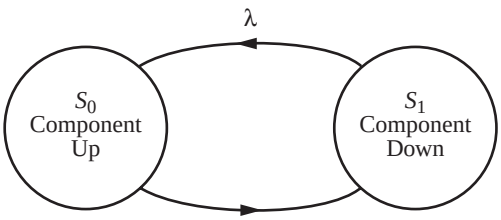

FIGURE 110.5 State space diagram for a single reparable component.

and equal to λ and μ. These transition rates are the constant failure and repair rates implied in the modeling process and their reciprocals are the *MTTF* and *MTTR*, respectively. Figure 110.5 illustrates the binary model.

The associated Markov differential equations are

$$\begin{bmatrix} P_0'(t) \\ P_1'(t) \end{bmatrix} = \begin{bmatrix} -\lambda & \mu \\ \lambda & -\mu \end{bmatrix} \begin{bmatrix} P_0(t) \\ P_1(t) \end{bmatrix} \tag{110.30}$$

with the initial conditions

$$\begin{bmatrix} P_0(0) \\ P_1(0) \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \tag{110.31}$$

The coefficient matrix of Markov differential equations, namely $\begin{bmatrix} -\lambda & \mu \\ \lambda & -\mu \end{bmatrix}$ is obtained by transposing the matrix of rates of departures $\begin{bmatrix} 0 & \lambda \\ \mu & 0 \end{bmatrix}$ and replacing the diagonal entries by the negative of the sum of all the other entries in their respective columns. Solution of (110.30) with initial conditions as given by (110.31) yields:

$$P_0(t) = \frac{\mu}{\lambda + \mu} + \frac{\lambda}{\lambda + \mu} e^{-(\lambda+\mu)t} \tag{110.32}$$

$$P_1(t) = \frac{\lambda}{\lambda + \mu}\left[1 - e^{-(\lambda+\mu)t}\right] \tag{110.33}$$

The limiting, or steady-state, probabilities are found by letting $t \to \infty$. They are also known as limiting **availability** A and limiting unavailability U and they are

$$P_0 \equiv \frac{\mu}{\lambda + \mu} \equiv A \quad \text{and } P_1 = \frac{\lambda}{\lambda + \mu} \equiv U \tag{110.34}$$

The time-dependent $A(t)$ and $U(t)$ are simply $P_0(t)$, and $P_1(t)$ respectively.

Referring back to Eq. (110.14) for a constant hazard component and comparing it with Eq. (110.32) which incorporates repair, the difference between $R(t)$ and $A(t)$ becomes obvious. Availability $A(t)$ is the probability

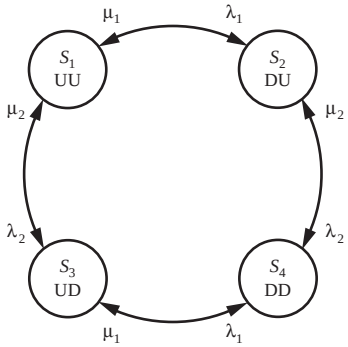

FIGURE 110.6 State space diagram for two dissimilar reparable components.

that the component is up at time t and reliability $R(t)$ is the probability that the system has continuously operated from 0 to t. Thus, $R(t)$ is much more stringent than $A(t)$. While both $R(0)$ and $A(0)$ are unity, $R(t)$ drops off rapidly as compared to $A(t)$ as time progresses. With a small value of $MTTR$ (or large value of μ), it is possible to realize a very high availability for a repairable component.

110.16 Two Dissimilar Repairable Components

Irrespective of whether the two components are in series or in parallel, the state space consists of four possible states. They are: S_1 (1 up, 2 up), S_2 (1 down, 2 up), S_3 (1 up, 2 down), and S_4 (1 down, 2 down). The actual system configuration will determine which of these four states corresponds to system success and failure. The associated state-space diagram is shown in Fig. 110.6. Analysis of this system results in the following steady-state probabilities:

$$P_1 = \frac{\mu_1 \ \mu_2}{\text{Denom}}\ ;\ P_2 = \frac{\lambda_1 \ \mu_2}{\text{Denom}}\ ;\ P_3 = \frac{\lambda_2 \ \mu_1}{\text{Denom}}\ ;\ P_4 = \frac{\lambda_1 \ \lambda_2}{\text{Denom}} \tag{110.35}$$

$$\text{where Denom} \equiv (\lambda_1 + \mu_1)(\lambda_2 + \mu_2) \tag{110.36}$$

For components in series, $A = P_1$ and $U = (P_2 + P_3 + P_4)$ and the two components can be replaced by an equivalent component with a failure rate of $\lambda_s = (\lambda_1 + \lambda_2)$ and a mean repair duration of r_s where

$$r_s \cong \frac{\lambda_1 \ r_1 + \lambda_2 \ r_2}{\lambda_s} \tag{110.37}$$

Extending this to n components in series, the equivalent system will have

$$\lambda_s = \sum_{i=1}^{n} \lambda_i \quad \text{and} \quad r_s \cong \frac{1}{\lambda_s} \sum_{i=1}^{n} \lambda_i \ r_i \tag{110.38}$$

$$\text{and system unavailability} = U_s \cong \lambda_s \ r_s = \sum_{i=1}^{n} \lambda_i \ r_i \tag{110.39}$$

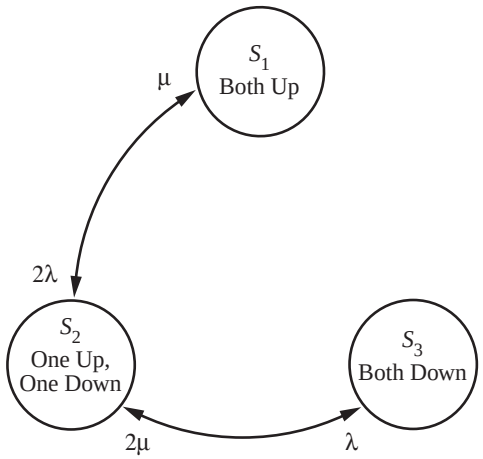

FIGURE 110.7 State space diagram for two identical reparable components.

For components in parallel, $A = (P_1 + P_2 + P_3)$ and $U = P_4$ and the two components can be replaced by an equivalent component with

$$\lambda_p \cong \lambda_1(\lambda_2 r_1) + \lambda_2(\lambda_1 r_2) \quad \text{and} \quad \mu_p = \mu_1 + \mu_2 \tag{110.40}$$

$$\text{and system unavailability} = U_p = \lambda_p(1/\mu_p) \tag{110.41}$$

Extension to more than two components in parallel follows similar lines. For three components in parallel,

$$\mu_p = (\mu_1 + \mu_2 + \mu_3) \quad \text{and} \quad U_p = \lambda_1\lambda_2\lambda_3 r_1 r_2 r_3 \tag{110.42}$$

110.17 Two Identical Repairable Components

In this case, only three states are needed to complete the state space. They are: S_1:Both UP; S_2: One UP and One DOWN; and S_3:Both DOWN. The corresponding state space diagram is shown in Fig. 110.7. Analysis of this system results in the following steady-state probabilities:

$$P_1 = \left(\frac{\mu}{\lambda + \mu}\right)^2; P_2 = \frac{2\lambda}{\mu}\left(\frac{\mu}{\lambda + \mu}\right)^2; P_3 = \left(\frac{\lambda}{\lambda + \mu}\right)^2 \tag{110.43}$$

110.18 Frequency and Duration Techniques

The expected residence time in a state is the mean value of the passage time from the state in question to any other state. Cycle time is the time required to complete an "in" and "not-in" cycle for that state. Frequency of occurrence (or encounter) for a state is the reciprocal of its cycle time. It can be shown that the frequency of occurrence of a state is equal to the steady-state probability of being in that state times the total rate of departure from it. Also, the expected value of the residence time is equal to the reciprocal of the total rate of departure from that state.

Under steady-state conditions, the expected frequency of entering a state must be equal to the expected frequency of leaving that state (this assumes that the system is "ergodic", which will not be elaborated for lack

of space). Using this principle, frequency balance equations can be easily written (one for each state) and solved in conjunction with the fact that the sum of the steady-state proabilities of all the states must be equal to unity to obtain the steady state probabilities. This procedure is much simpler than solving the Markov differential equations and letting $t \to \infty$.

110.19 Applications of Markov Process

Once the different states are identified and a state-space diagram is developed, Markov analysis can proceed systematically (probably with the help of a computer in the case of large systems) to yield a wealth of results useful in system reliability evaluation. Inclusion of installation time after repair, maintenance, spare, standby systems, and limitations imposed by restricted repair facilities are some of the many problems that can be studied.

110.20 Some Useful Approximations

1. For an r-out-of-n structure with failure and repair rates of λ and μ for each, the equivalent *MTTR* and *MTTF* can be approximated as

$$MTTR_{eq} = \frac{MTTR\ of\ one\ component}{n - r + 1} \tag{110.44}$$

$$MTTF_{eq} = \begin{pmatrix} MTTF \\ of\ one \\ component \end{pmatrix} \left(\frac{MTTF}{MTTR}\right)^{n-r} \left\{\frac{(n-r)!\,(r-1)!}{n!}\right\} \tag{110.45}$$

2. Influence of weather must be considered for components operating in an outdoor environment. If λ and λ' are the normal weather and stormy weather failure rates, λ' will be much greater than λ and the average failure rate λ_f can be approximated as

$$\lambda_f \cong \left(\frac{N}{N+S}\right)\lambda + \left(\frac{S}{N+S}\right)\lambda' \tag{110.46}$$

where N and S are the expected durations of normal and stormy weather.
3. For well-designed high-reliability components, the failure rate λ will be very small and $\lambda t << 1$. Then, for a single component,

$$R(t) \cong 1 - \lambda t \quad \text{and} \quad Q(t) \cong \lambda t \tag{110.47}$$

and for n dissimilar components in series,

$$R(t) \cong 1 - \sum_{i=1}^{n} \lambda_i t \quad \text{and} \quad Q(t) \cong \sum_{i=1}^{n} \lambda_i t \tag{110.48}$$

For the case of n identical components in parallel,

$$R(t) \cong 1 - (\lambda t)^n \quad \text{and} \quad Q(t) \cong (\lambda t)^n \tag{110.49}$$

For the case of an r-out-of-n configuration,

$$Q(t) \cong {}_nC_{(n-r+1)}(\lambda t)^{n-r+1} \tag{110.50}$$

The approximations detailed in (3) are called rare-event approximations.

110.21 Application Aspects

Electronic systems utilize large numbers of similar components over which the designer has very little control. Quality control methods can be used in the procurement and manufacturing phases. However, the circuit designer has no control over the design reliability of the devices except in cases such as custom-designed integrated circuits. In addition, electronic components cannot be inspected easily because of encapsulation. Although gross defects can be easily detected by suitable testing processes, defects that are not immediately effective (for example, weak mechanical bond of a lead-in conductor, material flaws in semiconductors, defective sealing, etc.) primarily contribute to unreliability. Temperature and voltage are the predominant failure-accelerating stresses for the majority of electronic components. As weaker components fail and are replaced by better ones, the percentage of defects in a population is reduced, resulting in a decreasing hazard rate. Wearout is rarely of significance in the failure of electronic components and systems. The designer should be careful to ensure that the loads (voltage, current, temperature) are within rated values and strive for a design that minimizes hot spots and temperature rises. Parameter drifts and accidental short circuits at connections can also lead to system failures. The circuit designer can follow a few basic rules to significantly improve electronic system reliability: reduce the number of adjustable components; avoid selection of components on the basis of parameter values obtained by testing; assemble components such that adjustments are easily accessible; and partition circuits into subassemblies for easy testing and diagnosis of problems.

Power systems are expected to provide all customers a reliable supply of electric power upon which much of modern life depends. Power systems are also very large, consisting of scores of large generators, hundreds of miles of high-voltage transmission lines, thousands of miles of distribution lines, along with the necessary transformers, switchgear, and substations interconnecting them. Reliability at the customer level can be improved by additional investment; the challenge is to balance reliability and the associated investment cost against the cost of energy charged to customers. This should be done in the presence of a number of random inputs and events: generator outages, line outages (which are highly weather dependent), random component outages, and uncertainties in the load demand (which is also weather dependent). Probabilistic techniques to evaluate power system reliability have been used effectively to resolve this problem satisfactorily. The system is divided into a number of subsystems and each one is analyzed separately. Then, composite system reliability evaluation techniques are employed to combine the results and arrive at a number of quantifiable reliability indices as inputs to managerial decisions. The major subsystems involved are generation, transmission, distribution, substations, and protection systems. Care should be taken to ensure that reliabilities of different parts of the system conform to each other and that no part of the system is unusually strong or weak. Obviously, different levels of reliability will be required for different parts of the system depending on the impacts of failures at different points on the interconnected power system.

110.22 Reliability and Economics

Reliability and economics are very closely related. Issues such as the level of reliability required, the amount of additional expenditures justified, where to invest the additional resources to maximize reliability, how to achieve a certain level of overall reliability at minimum cost, and how to assess the cost of failures and monetary equivalent of non-monetary items are all quite complex and not purely technical. However, once managerial decisions are made and reliability goals are set, certain well-proven techniques such as incorporating redundancy, improving maintenance procedures, selecting better quality components, etc. can be employed by the designer to achieve the goals.

Defining Terms

Availability: The availability $A(t)$ is the probability that a system is performing its required function successfully at time t. The steady-state availability A is the fraction of time that an item, system, or component is able to perfom its specified or required function.

Bathtub curve: For most physical components and living entities, the plot of failure (or hazard) rate vs. time has the shape of the longitudinal cross-section of a bathtub and hence its name.

Hazard rate function: The plot of instantaneous failure rate vs. time is called the hazard function. It cleary and distinctly exhibits the different life cycles of the component.

MTTF: The mean time to failure is the mean or expected value of "time to failure".

Parallel structure: Also known as a completely redundant system, it describes a system that can succeed when at least one of two or more components succeeds.

Redundancy: Refers to the existence of more than one means, identical or otherwise, for accomplishing a task or mission.

Reliability: The reliability $R(t)$ of an item or system is the probability that it has performed successfully over the time interval from 0 to t. In the case of non-repairable systems, $R(t) = A(t)$. With repair, $R(t) \leq A(t)$.

Series structure: Also known as a chain structure or non-redundant system, it describes a system whose success depends on the success of all of its components.

111.1 Introduction

The importance of electronics technology for consumers, and the electronics sector for the global economy, is already substantial and continues to grow rapidly. Such growth and innovation coupled with the global concerns for the environment and the need to better manage the resources of the earth pose many challenges for the electronics industry. While thought of as a "clean" industry, the technological advances made by the industry creates a significant demand on the earth's resources. As an example, the amount of water required in the production of semiconductors, the engines that motor most of today's electronic gadgets, is enormous—about 2000 gallons to process a single silicon wafer. Building silicon chips requires the use of highly toxic materials, albeit in relatively low volumes. Similarly, printed wiring boards present in most electronic products and produced in high volume use large amounts of solvents or gases which are either health hazards, ozone depleting, or contribute to the greenhouse effect and contain lead solder. The challenge for the industry is to continue the innovation that delivers the products and services that people want yet find creative solutions to minimize the environmental impact, enhance competitiveness, and address regulatory issues without impacting quality, productivity, or cost; in other words, to become an industry that is more "eco-efficient". Eco-efficiency is reached by the delivery of competitively priced goods and services that satisfy human needs and support a high quality of life, while progressively reducing ecological impacts and resource intensity, to a level at least in line with the earth's estimated carrying capacity.

Like sustainable development, a concept popularized by the Brundtland Report, *Our Common Future*, the notion of eco-efficiency requires a fundamental shift in the way environment is considered in industrial activity. Sustainable development—"development that meets the needs of the present without compromising the ability of future generations to meet their own needs" [World Commission on Environment and Development, 1987]—contemplates the integration of environmental, economic, and technological considerations to achieve continued human and economic development within the biological and physical constraints of the planet. Both eco-efficiency and sustainable development provide a useful direction, yet they prove difficult to operationalize and cannot guide technology development. Thus, the theoretical foundations for integrating technology and environment throughout the global economy are being provided by a new, multidisciplinary field known as "**industrial ecology**".

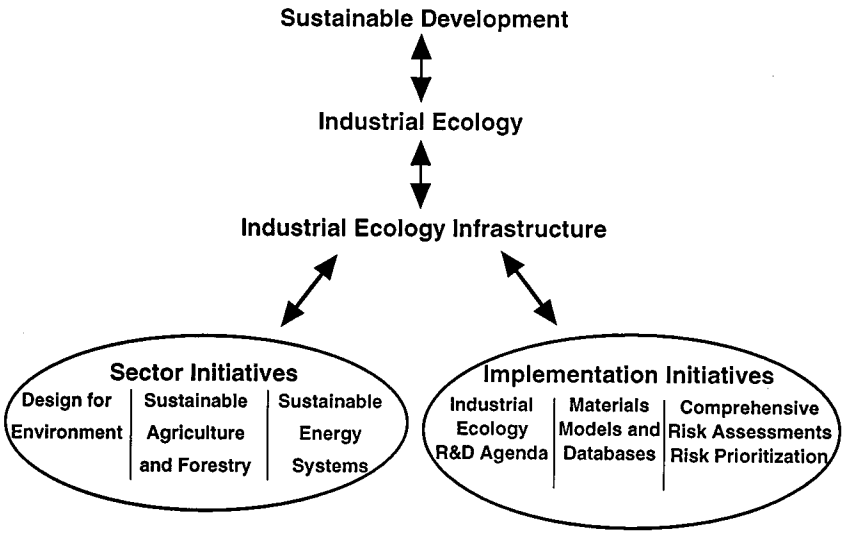

FIGURE 111.1 Industrial ecology framework.

The ideas of industrial ecology, which have begun to take root in the engineering community, have helped to established a framework within which the industry can move toward realizing sustainable development. The electrical, electronics, and telecommunications sectors are enablers of sustainability because they allow the provision of increasing quality-of-life using less material and energy, respectively, "**dematerialization**" and "**decarbonization**". This chapter will provide an introduction into industrial ecology and its implications for the electronics industry. Current activities, initiatives, and opportunities will also be explored, illustrating that the concomitant achievement of greater economic and environmental efficiency is indeed feasible in many cases.

111.2 Industrial Ecology

Industrial ecology is an emerging field that views manufacturing and other industrial activity including forestry, agriculture, mining, and other extractive sectors, as an integral component of global natural systems. In doing so, it takes a systems view of design and manufacturing activities so as to reduce or, more desirably, eliminate the environmental impacts of materials, manufacturing processes, technologies, and products across their life cycles, including use and disposal. It incorporates, among other things, research involving energy supply and use, new materials, new technologies and technological systems, basic sciences, economics, law, management, and social sciences.

The study of industrial ecology will, in the long run, provide the means by which the human species can deliberately and rationally approach a desirable long-term global carrying capacity. Oversimplifying, it can be thought of as "the science of sustainability". The approach is "deliberate" and "rational", to differentiate it from other, unplanned paths that might result, for example, in global pandemics, or economic and cultural collapse. The endpoint is "desirable", to differentiate it from other conceivable states such as a Malthusian subsistence world, which could involve much lower population levels, or oscillating population levels that depend on death rates to maintain a balance between resources and population levels. Figure 111.1 illustrates how industrial ecology provides a framework for operationalizing the vision of sustainable development.

As the term implies, industrial ecology is concerned with the evolution of technology and economic systems such that human economic activity mimics a mature biological system from the standpoint of being self-contained in its material and resource use. In such a system, little if any virgin material input is required, and little if any waste that must be disposed of outside of the economic system is generated. Energetically, the system can be open, just as biological systems are, although it is likely that overall energy consumption and intensity will be limited.

Although it is still a nascent field, a few fundamental principles are already apparent. Most importantly, the evolution of environmentally appropriate technology is seen as critical to reaching and maintaining a sustainable state. Unlike earlier approaches to environmental issues, which tended to regard technology as neutral at best, industrial ecology focuses on development of economically and environmentally efficient technology as key to any desirable, sustainable global state.

Also, environmental considerations must be integrated into all aspects of economic behavior, especially product and process design, and the design of economic and social systems within which those products are used and disposed. Environmental concerns must be internalized into technological systems and economic factors. It is not sufficient to design an energy efficient computer, for example; it is also necessary to ensure that the product, its components, or its constituent materials can be refurbished or recycled after the customer is through with it—all of this in a highly competitive and rapidly evolving market. This consideration implies a comprehensive and systems-based approach that is far more fundamental than any we have yet developed.

Industrial ecology requires an approach that is truly multidisciplinary. It is important to emphasize that industrial ecology is an objective field of study based on existing scientific and technological disciplines, not a form of industrial policy. It is profoundly a systems oriented and comprehensive approach which poses problems for most institutions—the government, riddled with fiefdoms; academia, with rigid departmental lines; and private firms, with job slots defined by occupation. Nonetheless, it is all too frequent that industrial ecology is seen as an economic program by economists, a legal program by lawyers, a technical program by engineers, and a scientific program by scientists. It is in part each of these; more importantly, it is all of these.

Industrial ecology has an important implication, however, of special interest to electronics and telecommunications engineers, and thus deserving of emphasis. The achievement of sustainability will, in part, require the substitution of intellectual and information capital for traditional physical capital, energy, and material inputs. Environmentally appropriate electronics, information management, and telecommunications technologies and services—and the manufacturing base that supports them—are therefore enabling technologies to achieve sustainable development. This offers unique opportunities for professional satisfaction, but also places a unique responsibility on the community of electrical and electronics engineers. We in particular cannot simply wait for the theory of industrial ecology to be fully developed before taking action.

111.3 Design for Environment

Design for Environment (DFE) is the means by which the precepts of industrial ecology, as currently understood, can in fact begin to be implemented in the real world today. DFE requires that environmental objectives and constraints be driven into process and product design, and materials and technology choices.

The focus is on the design stage because, for many articles, that is where most, if not all, of their life cycle environmental impacts are explicitly or implicitly established. Traditionally, electronics design has been based on a correct-by-verification approach, in which the environmental ramifications of a product (from manufacturing through disposition) are not considered until the product design is completed. DFE, by contrast, takes place early in a product's design phase as part of the concurrent engineering process to ensure that the environmental consequences of a product's life cycle are understood before manufacturing decisions are committed.

It is estimated that some 80 to 90% of the environmental impacts generated by product manufacture, use, and disposal are "locked-in" by the initial design. Materials choices, for example, ripple backwards towards environmental impacts associated with the extractive, smelting, and chemical industries. The design of a product and component selection control many environmental impacts associated with manufacturing, enabling, for example, substitution of no-clean or aqueous cleaning of printed wiring boards for processes that release ozone depleting substances, air toxics, or volatile organic compounds that are precursors of photochemical smog. The design of products controls many aspects of environmental impacts during use—energy efficient design is one example. Product design also controls the ease with which a product may be refurbished, or disassembled for parts or materials reclamation, after consumer use. DFE tools and methodologies offer a means to address such concerns at the design stage.

Obviously, DFE is not a panacea. It cannot, for example, compensate for failures of the current price structure to account for external factors, such as the real (i.e., social) cost of energy. It cannot compensate for deficiencies

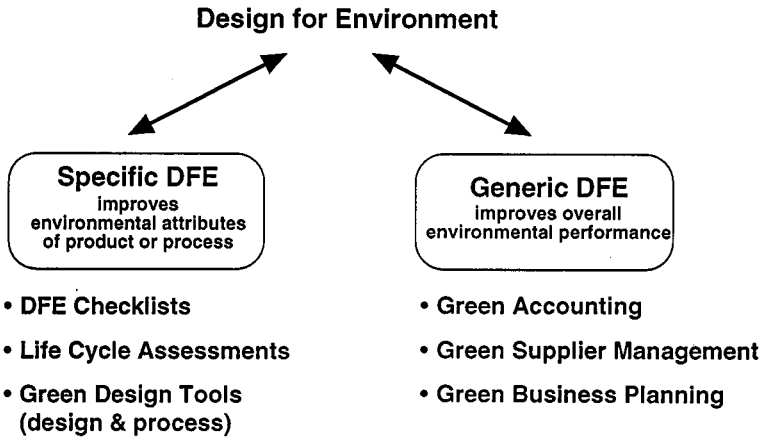

FIGURE 111.2 Examples of DFE activities within the firm.

in sectors outside electronics, such as a poorly coordinated, polluting, or even non-existent disposal and material recycling system in some areas of the world. Moreover, it is important to realize that DFE recognizes environmental considerations as on par with other objective and constraints—such as economic, technological, and market structure—not as superseding or dominating them. Nonetheless, if properly implemented, DFE programs represent a quantum leap forward in the way private firms integrate environmental concerns into their operations and technology.

It is useful to think of DFE within the firm as encompassing two different groups of activities as shown in Fig. 111.2. In all cases, DFE activities require inclusion of life-cycle considerations in the analytical process. The first, which might be styled "generic DFE", involves the implementation of broad programs that make the company's operations more environmentally preferable across the board. This might include, for example, development and implementation of "green accounting" practices, which ensure that relevant environmental costs are broken out by product line and process, so that they can be managed down. The "standard components" lists maintained by many companies can be reviewed to ensure that they direct the use of environmentally appropriate components and products wherever possible. Thus, for example, open relays might be deleted from such lists, on the grounds that they "can't swim", and thus might implicitly establish a need for chlorinated solvent, as opposed to aqueous, cleaning systems.

Contract provisions can be reviewed to ensure that suppliers are being directed to use environmentally preferable technologies and materials where possible. For example, are virgin materials being required where they are unnecessary? Do contracts, standards, and specifications clearly call for the use of recycled materials where they meet relevant performance requirements? Likewise, customer and internal standards and specifications can be reviewed with the same goal in mind.

The second group of DFE activities can be thought of as "specific DFE". Here, DFE is considered as a module of existing product realization processes, specifically the "Design for X", or DFX, systems used by many electronics manufacturers. The method involves creation of software tools and checklists, similar to those used in Design for Manufacturability, Design for Testability, or Design for Safety modules that ensure relevant environmental considerations are also included in the design process from the beginning. The challenge is to create modules which, in keeping with industrial ecology theory, are broad, comprehensive, and systems-based, yet can be defined well enough to be integrated into current design activities.

The successful application of DFE to the design of electronic systems requires the coordination of several design and data-based activities, such as environmental impact metrics; data and data management; design optimization, including cost assessments; and others. Failure to address any of these aspects can limit the effectiveness and usefulness of DFE efforts. Data and methodological deficiencies abound, and the challenge is great, yet experience at world class companies such as AT&T, Digital, IBM, Motorola, Siemens Nixdorf, Volvo, and Xerox indicate that it can be done. AT&T, for example, is testing a draft DFE practice; baselining the environmental attributes of a telephone at different life cycle stages to determine where meaningful environmental

improvements in design can be achieved; and developing software tools that can inform environmentally preferable design decisions [Seifert, 1995]. In Sweden, the government and Volvo have developed a relatively simple Environment Priority Strategies for Environmental Design, or EPS, system which uses Environmental Load Units, or ELUs, to inform materials choices during the design process. In Germany, Siemens Nixdorf has developed an "Eco-balance" system to help it make design choices that reflect both environmental and economic requirements. Xerox is a world leader in designing their products for refurbishment using a product life extension approach.

More broadly, the American Electronics Association (AEA) Design for Environment Task Force has created a series of White Papers discussing various aspects of Design for Environment and its implementation. The Microelectronics and Computer Technology Corporation (MCC) has published a comprehensive study [Lipp *et al.*, 1993] of the environmental impacts of a computer workstation, which is valuable not only for its technical findings, but for the substantial data and methodological gaps the study process identified. The Society of Environmental Toxicology and Chemistry (SETAC) and others, especially in Europe, are working on a number of comprehensive life-cycle assessment (LCA) methodologies designed to identify and prioritize environmental impacts of substances throughout their life cycle. The International Organization for Standards (ISO) is in the process of creating an international LCA standard. The IEEE Environment, Health and Safety Committee, formed in July, 1992, to support the integration of environmental, health, and safety considerations into electronics products and processes from design and manufacturing, to use, to recycling, refurbishing, or disposal has held a series of annual symposium on electronics and the environment. The proceedings from these symposia are valuable resources to the practitioners of DFE.

111.4 Environmental Implications for the Electronics Industry

Global concerns and regulations associated with environmental issues are increasingly affecting the manufacturing and design of electronic products, their technology development, and marketing strategies. No point illustrates this better than the German Blue Angel **Eco-Labeling** scheme for personal computers (the Blue Angel is a quasi-governmental, multi-attribute eco-labeling program). The Blue Angel requirements are numerous and span the complete life-cycle of the computers. Examples of some the requirements include: modular design of the entire system, customer-replaceable subassemblies and modules, use of non-halogenated flame retardants, and take back by manufacturers at the end of the product life. Market requirements such as these, focused on products and integrating as they do environmental and technology considerations, cannot possibly be met by continuing to treat environmental impact as an unavoidable result of industrial activity, i.e., as overhead. These requirements make environmental concerns truly strategic for the firm.

Perhaps the most familiar example of "a new generation of environmental management" requirements which will have enormous effects on electronics design is "**product take back**". These programs, such as the one mentioned in the Blue Angel labeling scheme, are being introduced in Germany and other countries for electronics manufacturers. They generally require that the firm take its products back once the consumer is through with them, recycle or refurbish the product, and assume responsibility for any remaining waste generated by the product. Other members of the European Union and Japan are among others considering such "take back" requirements. Similarly, the emergence of the international standard, **ISO 14000**, which includes requirements for environmental management systems, methodologies for **life cycle assessment** and environmental product specifications will have vast implications for the electronics industry. Though technically voluntary, in practice these standards in fact become requirements for firms wishing to engage in global commerce. These examples represent a global trend towards proactive management of business and products in the name of the environment.

111.5 Emerging Technology

New tools and technologies are emerging which will influence the environmental performance of electronic products and help the industry respond to the regulatory "push" and the market "pull" for environmentally responsible products. In the electronics industry, technology developments are important not only for the end-products, but

for components, recycling, and materials technology as well. Below is a brief summary of technology developments and their associated environment impacts as well as tools to address the many environmental concerns facing the industry.

The electronics industry has taken active steps toward environmental stewardship, evidenced by the formulation of the IEEE Environment, Safety and Health Committee, the 1996 Electronics Industry Environmental Roadmap published by MCC, and chapters focused on environment in The National Technology Roadmap for Semiconductors. Moves such as this, taken together with the technical sophistication of control systems used in manufacturing processes, have allowed the electronics industry to maintain low emission levels relative to some other industries. Despite the industry's environmental actions, the projected growth in electronics over the next 10 to 20 years is dramatic and continued technological innovation will be required to maintain historically low environmental impacts. Moreover, the rapid pace of technological change generates concomitantly high rates of product obsolescence and disposal, a factor that has led countries such as Germany and the Netherlands to focus on electronics products for environmental management.

Environmental considerations are not, of course, the only forces driving the technological evolution in the electronics industry. Major driving forces, as always, also include price, cost, performance, and market/regulatory requirements. However, to the extent that the trend is toward smaller devices, fewer processing steps, increased automation, and higher performance per device, such evolution will likely have a positive environmental impact at the unit production level, i.e., less materials, less chemicals, less waste related to each unit produced. Technology advances that have environmental implications at the upstream processing stage may well have significant benefits in the later stages of systems development and production. For example, material substitution in early production stages may decrease waste implications throughout the entire process. Since both semiconductors and printed wiring boards are produced in high volume and are present in virtually all electronic products ranging from electronic appliances, to computers, automotive, aerospace, and military applications, we will briefly examine the impact of these two areas of the electronic industry.

Integrated Circuits

The complex process of manufacturing semiconductor integrated circuits (IC) often consists of over a hundred steps during which many copies of an individual IC are formed on a single wafer. Each of the major process steps used in IC manufacturing involves some combination of energy use, material consumption, and material waste. Water usage is high due to the many cleaning and rinsing process steps. Absent process innovation, this trend will continue as wafer sizes increase, driving up the cost of water and waste water fees, and increasing mandated water conservation.

Environmental issues that also require attention include the constituent materials for encapsulants, the metals used for connection and attachment, the energy consumed in high-temperature processes, and the chemicals and solvents used in the packaging process. Here, emerging packaging technologies will have the effect of reducing the quantity of materials used in the packaging process by shrinking IC package sizes. Increasing predominance of plastic packaging will reduce energy consumption associated with hermetic ceramic packaging.

Printed Wiring Boards

Printed wiring boards represent the dominant interconnect technology on which chips will be attached and represents another key opportunity for making significant environmental advances. PWB manufacturing is a complicated process and uses large amounts of materials and energy (e.g., 1 MegaW of heat and 220 kW of energy is consumed during fabrication of prepeg for PWBs). On average, the waste streams constitutes 92%—and the final product just 8%—of the total weight of the materials used in PWB production process. Approximately 80% of the waste produced is hazardous and most of the waste is aqueous, including a range of hazardous chemicals. Printed wiring boards are not recycled because the removal of soldered subassemblies is costly and advanced chip designs require new printed wiring boards to be competitive. As a result, the boards are incinerated and the residual ash buried in hazardous waste landfills due to the lead content (from lead solder).

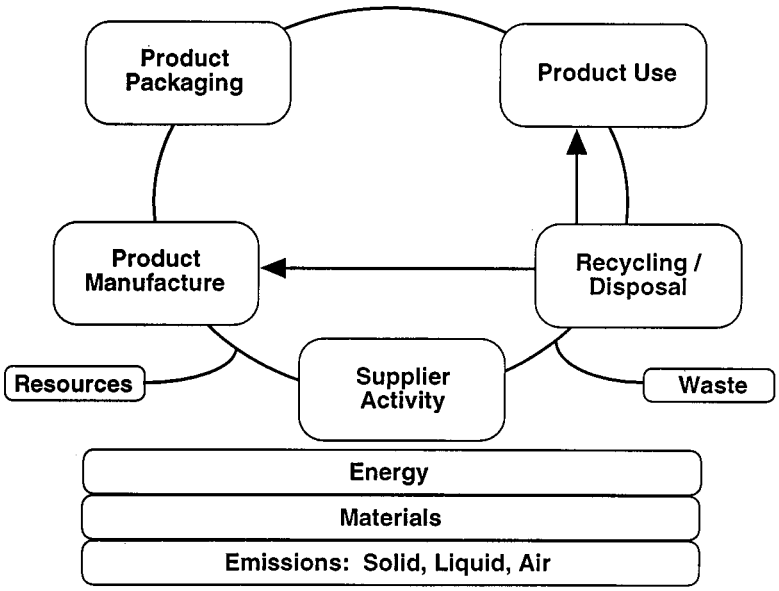

FIGURE 111.3 Design for environment: systems-based, life cycle approach.

111.6 Tools and Strategies for Environmental Design

The key to reducing the environmental impact of electronic products will be the application of DFE tools and methodologies. Development of CAD/CAM tools based on environmental impact metrics, materials selection data, cost, and product data management are examples of available or clearly foreseeable tools to assist firms in adopting DFE practices.

These tools will need to be based on life cycle assessment, the objective process used to evaluate the environmental impacts associated with a product and identify opportunities for improvement. Life cycle assessment seeks to minimize the environmental impact of the manufacture, use, and eventual disposal of products without compromising essential product functions. Figure 111.3 shows the life stages that would be considered for electronic products (i.e., the life cycle considered has been bounded by product design activities). The ability of the electronics industry to operate in a more environmentally and economically efficient mode, use less chemicals and materials, and reduce energy consumption will require support tools that can be used to evaluate both product and process designs. To date, many firms are making immediate gains by incorporating basic tools like DFE checklists, design standards and internal databases on chemicals and materials, while other firms are developing sophisticated software tools that give products environmental scores based on the product's compliance with a set of predetermined environmental attributes. These software tools rely heavily on environmental metrics (typically internal to the firm) to assess the environmental impact and then assign a score to the associated impact.

Other types of tools that will be necessary to implement DFE will include tools to characterize environmental risk, define and build flexible processes to reduce waste, and support dematerialization of processes and products. The following sections provide a brief review of design tools or strategies that can be employed

Design Tools

Environmental design tools vary widely in the evaluation procedures offered in terms of the type of data used, method of analysis, and the results provided to the electronic designer. The tool strategies range in scope from assessment of the entire product life cycle to the evaluation of a single aspect of its fabrication, use, or disposal. Today's DFE tools can be generally characterized as either life cycle analysis, recyclability analysis, manufacturing analysis, or process flow analysis tools.

The effectiveness of these design tools is based both on the tool's functionality as well as its corresponding support data. One of the biggest challenges designers face with regards to DFE is a lack of reliable data on materials, parts, and components needed to adequately convey the impact and trade-offs of their design decisions. To account for these data deficiencies, a number of environmental design tools attempt to use innovative, analytical methods to estimate environmental impacts: while necessary, this indicates they must be used with care and an understanding of their assumptions.

Although DFE provides a systems-based, life cycle approach, its true value to the system designer is lost unless the impact of DFE decisions on other relevant economic and performance measures (i.e., cost, electrical performance, reliability, etc.) can be quickly and accurately assessed. Trade-off analysis tools that have DFE embedded can perform process flow-based environmental analysis (energy/mass balance, waste stream analysis, etc.) concurrently with non-environmental cost and performance analysis so that system designers can accurately evaluate the impact of critical design decisions early.

Design Strategies

Design strategies such as lead minimization through component selection, and the reduction of waste resulting from rapid technological evolution through modular design, help to minimize the environmental impact of electronic products. Although at this time no suitable lead-free alternatives exist for electronic interconnections, designers can still minimize the lead content of electronic designs. Surface mount technology requires less solder than through-hole technology. New interconnection technologies, such as microball grid array and direct chip attachment, also require less solder. The environmental benefits increase with the use of these advanced interconnection technologies.

The rapid advancement of the electronics industry has created a time when many products become obsolete in less than five years' time. Electronic products must be built to last, but only until it is time to take them apart for rebuilding or for reuse of material. This means employing modular design strategies to facilitate disassembly for recycle or upgrade of the product rather than replacement. Designers must extend their views to consider the full utilization of materials and the environmental impact of the material life cycle as well as the product life cycle.

Conclusion

The diverse product variety of the electronics industry offers numerous opportunities to curtail the environmental impact of the industry. These opportunities are multidimensional. Services made possible through telecommunications technology enable people to work from home reducing emissions that would be generated by traveling to work. Smaller, faster computers and the Internet require less material usage, reducing the energy demand during processing and waste generated during fabrication. All these represent examples of how the electronics industry provides enablers of sustainability.

Global concerns and regulations associated with environmental issues are increasingly affecting the manufacturing and design of the electronics industry. Environmental management standards, "take back" programs, ISO 14000 standards development activity, and eco-label requirements represent a sample of the initiatives driving the industries move to more environmentally efficient practices. While the industry has initiated some activities to address environmental concerns, the future competitiveness of the industry will depend on improvements in environmental technology in manufacturing, accurate assessment of the environmental impact of products and process, and design products that employ design for environment, reuse, and recycleability. Industrial ecology offers a framework for analyzing the environmental effects of the electronics industry which is complicated by the rapid pace of change.

Defining Terms

Decarbonization: The reduction, over time, of carbon content per unit energy produced. Natural gas, for example, produces more energy per unit carbon than coal; equivalently, more CO_2 is produced from coal than from natural gas per unit energy produced.

Dematerialization: The decline, over time, in weight of materials used in industrial end products, or in the embedded energy of the products. Dematerialization is an extremely important concept for the environment because the use of less material translates into smaller quantities of waste generated in both production and consumption.

Design for environment (DFE): The systematic consideration of design performance with respect to environment over the full product and process life cycle from design through manufacturing, packaging, distribution, installation, use, and end of life. It is proactive to reduce environmental impact by addressing environmental concerns in the product or process design stage.

Eco-label: Label or certificate awarded to a product that has met specific environmental performance requirements. Some of the most widely known eco-labels include Germany's Blue Angel, Nordic White Swan, and U.S. Green Seal.

Industrial ecology: The objective, multidisciplinary study of industrial and economic systems and their linkages with fundamental natural systems.

ISO 14000: Series of international standards fashioned from the ISO 9000 standard which includes requirements for environmental management systems, environmental auditing and labeling guidelines, life cycle analysis guidelines, and environmental product standards.

Life cycle assessment (LCA): The method for systematically assessing the material use, energy use, waste emissions, services, processes, and technologies associated with a product.

Product take back: Program in which manufacture agrees to take back product at the end-of-life (typically at no cost to the consumer) and disposal of product in an environmentally responsible matter.

112.1 Introduction

The use of computers in the design of control systems has a long and fairly distinguished history. It begins before the dawn of the modern information age with the analog computing devices that were used to create tables of ballistic data for artillery and anti-aircraft gunners and continues to the present day in which modern desktop machines have computing power undreamed of when the classical and modern control theories were laid down in the middle years of the twentieth century.

Modern computer-aided control system design (CACSD) has been made possible by the synthesis of several key developments in computing. The development and continued dominance of high-level procedural languages such as FORTRAN enabled the development and distribution of standard mathematical software. The emergence of fully interactive operating systems such as UNIX and its user "shells" influenced the development of CACSD packages which have been constructed along similar lines. The ready availability and cheapness of raster-graphic displays has provided the on-screen display of data from control systems analysis, the creation of tools for modeling control systems using familiar block diagrams and have the potential to make order-of-magnitude improvements in the ease-of-use, ease-of-manipulation, and efficiency of the interaction between the control designer, his model, analysis tools, and end-product—software for embedded controllers. The driving force of all these developments is the seemingly continual increase in computing power year-on-year and the result has been to make computers accessible to large numbers of people while at the same time making them easier to use.

A control engineer often describes systems through the use of block diagrams. This is not only the traditional graphical representation of a control system, it is also an almost discipline-independent, and thus universally understandable, representation for dynamic systems. The diagrams may also constitute a complete documentation

[1]Originally published as "Computer-Aided Control Systems Design", Chapter 23, pp 429–442, in Levine, W. S. (Ed.), *The Control Handbook,* CRC Press, 1995.

of the designed system. Block diagrams are self-documenting and, when appropriately annotated, may form complete and consistent specifications of control systems. It is, therefore, not surprising that a number of tools for modeling (control) systems through block diagrams have emerged on the market over the last 5 to 10 years.

In addition to serving as a documentation aid, the overall cost and cycle time for developing complex controllers is radically reduced if analysis/simulation code and/or real-time code is automatically generated from the block-diagrams. This eliminates time-consuming manual coding, and avoids the introduction of coding bugs.

In this chapter, we explore the state-of-the-art in CACSD. We begin with a brief survey of the tools that have been developed over the years. We then focus on the matrix environments that provide the current standard and attempt to explain why they are important. We also examine modern block-diagram editors, simulation and code generation tools, and finally allow ourselves to speculate on the future.

112.2 A Brief History of CACSD

The term computer-aided control system design may be defined as:

> The use of digital computers as a primary tool during the modeling, identification, analysis, and design phases of control engineering.

CACSD tools and packages typically provide well-integrated support for the analysis and design of linear plant and controllers although many modern packages also provide support for the modeling, simulation, and linearization of nonlinear systems and some have the capability of implementing a control law in software.

Figure 112.1 (adapted and updated from Rimvall [1987,1988]) illustrates the development of CACSD packages over the last four decades. In order to put events into proper context, other key influencing factors, chiefly hardware and software developments, are also shown. In this section we describe the background to the emergence of CACSD tools in more detail, starting with technological developments and then moving on to user interface aspects. The aim is to understand the current state-of-the-art by examining the historical context in which these tools have been developed.

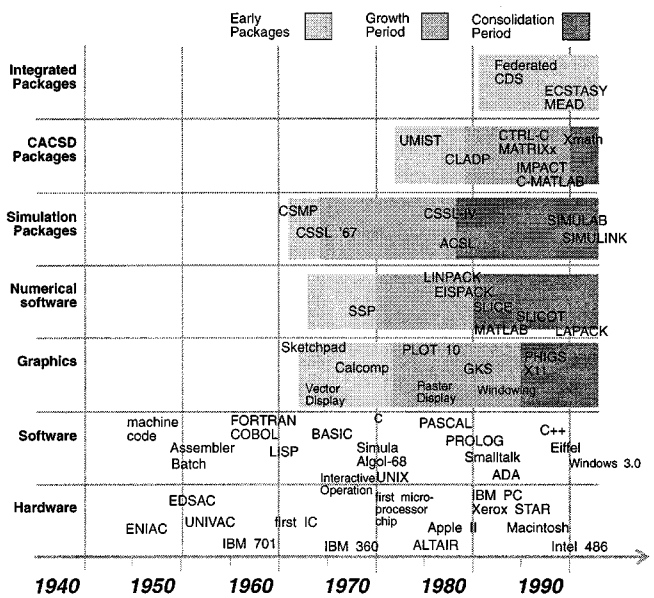

FIGURE 112.1 The historical development of interactive CACSD tools showing the availability of related hardware and software. Some actual products are included to indicate the state-of-the-art.

Technological Developments

Computing Hardware

Since 1953, there has been a phenomenal growth in the capabilities and power of computing hardware. Observers estimate that the power of computing devices (in terms of both execution speed and memory availability) has doubled every second to third year, whereas the size and cost (per computational unit) of the hardware has halved at approximately the same rate.

In terms of CACSD, the chief effect of these developments has been to widen the range of applications for computing and at the same time to make computers, and therefore the applications, widely available to practitioners in all branches of the subject. For example control engineers, control theorists, and control implementors all benefit as described below.

- Desk-top machines which are orders of magnitude more powerful than mainframe machines of two decades ago provide the means by which CACSD can be brought to the data analysis, model building, simulation, performance analysis and modification, control law synthesis, and documentation that is the day-to-day work of the control engineer.
- Without powerful computing hardware, many of the complex algorithms developed by control theorists for both analysis and implementation would otherwise be impractical.
- Embedded computer systems, which implement controllers, smart actuators, and smart sensors, are routinely used to implement the control laws developed by control engineers and control theorists.

System Software

The development of system software, such as operating systems, programming languages and program execution environments, has been slower than that of hardware, but is nonetheless impressive. Less impressive is the steadily increasing cost of application software, estimated at about 80% of the total installation cost of a computing system, which developments in computer science have been largely unable to reduce. We are, in fact, in the midst of a software crisis, dating from about 1968, which is the result of ever increasing improvements in hardware. Such improvements increase the possibilities for software, raise the expectations of users, and therefore raise the stakes in software production faster than improvements in software development technology has been made.

High Level Languages

The invention of FORTRAN was a major breakthrough in engineering computing. A high-level language, FORTRAN and the *compilers* that convert it into machine code, allowed engineers to write programs in a language that was sufficiently close to mathematical notation so as to be quite natural. Since its invention, numerous other high-level languages have been created, although FORTRAN continues to dominate engineering "number-crunching". For the implementation of control algorithms, assembly languages are still popular although high(er) level languages such as C, which is the predominant systems programming language, MODULA, and ADA are gaining acceptance in the market place.

Graphical Displays

Engineers are, in general, more comfortable with pictures than with text as a means of communicating their ideas. Hence, the wide availability of graphical displays is of prime importance to many areas of engineering computing. Indeed, the development of computer graphics has been the means by which certain control systems design techniques, such as multivariable control systems analysis, have been made practicable. Computer graphics have also been instrumental in providing improvements in human-machine interfaces such as schematic systems input and direct manipulation interfaces with windows, icons, pull-down menus, and pop-up dialog boxes. Further improvements in user interfacing techniques such as *hypermedia* will continue to rely on developments in display technology.

For modern CACSD, the most significant development in display technology has been the development of cheap, high-resolution *raster graphics displays,* although, historically, great strides were made with less well

known and more expensive *vector refresh* and *vector storage* display technology. The prime feature of raster-scan technology is that an area of the image may be made to appear to move on the screen by the application of simple logical operations. Raster graphics displays are, therefore, ideal for building direct manipulation graphics applications such as block diagram editors, which will be discussed later. They are not so well suited to the direct display and manipulation of vector images, which are a key part of many engineering graphics applications. For example, it is difficult to move part of a vector image such as a bode-plot without destroying the rest of the picture or to display sloping lines that look smooth at low resolutions. However, the dominance of the technology has been a factor in ensuring that the deficiencies in the technology can be overcome by clever software.

Quality Numerical Software

Following the invention of FORTRAN there was a gradual development of useful general purpose subroutines that could be archived into libraries, distributed, and shared. This lead eventually to the development of standard subroutine libraries such as EIS-PACK [Smith et al., 1977], LINPACK [Dongarra et al., 1979], and LAPACK [Anderson et al., 19789] (for solving eigenvalue problems and sets of linear equations) which have had a direct influence on the development of CACSD.

Simulation Languages

For many years before the predominance of digital computers, dynamic system behavior was simulated using analog and hybrid computers. *Digital simulation* began to take over from analog and hybrid simulation during the mid-1960s. Digital simulation programs can be used to model a wider range of nonlinear phenomena more reliably than analog or hybrid computers, at the cost of losing real-time and introducing quantization problems. However, the disadvantages of the technology are more than outweighed by improvements in modeling possibilities and increases in productivity. Digital simulation has superseded analog computation in all but a few specialized areas.

The first digital simulation systems were FORTRAN programs. Eventually, special purpose languages emerged which allowed statements written in a form close to state equation notation to be translated into FORTRAN which enabled the engineer to concentrate on the problem description. In 1967, a standard language called CSSL (Continuous Systems Simulation Language) [Augustin et al., 1967] was proposed by the U.S. Simulation Council and this forms the basis of most simulation languages in use today.

User Interfaces

Over the years, user interaction with computers has become progressively more direct. In the very early days, the user interface was another human being. These "operators" were gradually replaced by *operating systems* which provided communication first through the medium of punch-card and paper tape, then later by teletype machines, text-based visual display units, and, most recently, by windowed graphical user interfaces. Along with this change, there has been a corresponding change in style for CACSD tools. Batch mode programs were collected into "packages" and provided with question and answer or menued interfaces. These, in turn, have been largely superceded by command driven interfaces and direct-manipulation graphical user interfaces, currently used only for specialized tasks such as block-diagram input, will have a wider role in future CACSD packages.

CACSD Packages of Note

As the supporting technology has developed, control engineers mainly working in academia have been actively engaged in developing tools to support developments in control theory and in combining these tools into packages. Early pioneering work was carried out in Europe where the emphasis was on frequency response methods for multivariable control systems analysis and design. Some of the first CACSD packages were developed in the mid-1970s. In the U.S., control theory was concentrated in the time domain and made use of

state-space models. Several packages of tools for state-space design were created and reached maturity in the late 1970s. These packages were usually written in FORTRAN and made use of a question-and-answer interface. Some of the better packages made use of standard numerical libraries such as EISPACK and LINPACK, but many made use of home-grown algorithms with sometimes dubious numerical properties.

One of the earliest standardization efforts was concerned with algorithms and there have been several attempts to create standard CACSD libraries. One of these, SLICOT [van den Boom et al., 1991], is still ongoing. But it has to be admitted that such efforts have had little success in the marketplace. The real break-through came with the development of the "matrix environments", which are discussed in the next section. Currently, although many research groups continue to develop specialist tools and packages in conventional languages such as FORTRAN, most CACSD tool-makers now use these matrix environments as a high-level language for creating "toolboxes" of tools.

112.3 The State of the Art in CACSD

In this section we shall describe the matrix environments that have come to dominate CACSD, that is, the analysis, synthesis, and design of linear controllers for linear plants. We shall then move on to examine some of the requirements of CACSD which are less well served by the current generation of tools.

Consolidation of CACSD

As can be seen in Fig. 112.1, the 1980s was a decade of consolidation during which CACSD technology matured. Menu driven and Q&A dialogs were superseded by command languages. The matrix environment has become the *de facto* standard for CACSD.

The reasons for this are due to the simplicity of the data structures and the interface model and the *flexibility* of the package. We illustrate these properties using MATLAB (MATrix LABoratory) [Moler, 1980], the original matrix environment. Originally designed as a teaching program for graduate students, giving interactive access to the linear algebra routines EISPACK and LINPACK, MATLAB was released into the public domain in around 1980.

In MATLAB, matrices and matrix operations are entered into the computer in the straightforward fashion illustrated in Fig. 112.2.

This elegant treatment of linear algebra readily appealed to control scientists who realized that it was equally applicable to the solution of "modern control" problems based on linear state-space models (Fig. 112.3).

```

FIGURE 112.2 Entering and manipulating matrices in MATLAB. In this example, a matrix is defined and its eigenvectors and eigenvalues are determined.

```
>>  A = [0,1,0;0,0,1;-2,-3,4];
>>  B = [0, 0, 1];
>>  C = [1, 0, 0];
>>  poles = eig(A)

poles =
   -0.4142
    2.0000
    2.4142

>>  stable = all(poles < 0)

stable =

     0
>>
```

FIGURE 112.3 Using state-space matrices. A simple stability test showing the power of the matrix functions built-in to MATLAB. The Boolean function 'all' returns the value TRUE (or 1) if all the elements of the argument are non-zero. The argument is itself a vector of Boolean values (that is, those values of the vector of the poles of the A matrix that are negative). By treating matrices as "first-class objects", MATLAB provides many such opportunities for avoiding loops and other control structures required to do similar tasks in conventional languages.

```
function qs = control(a, b)
% Returns the controllability matrix [b, ab, a^2b, ...]
% used as: qs = control(a, b)
[ma, na] = size(a); [mb, nb] = size(b);
if ma != na
        error('Non-square A matrix')
elseif ma != mb
        error('Unequal number of rows in A and B')
else
        qs = b; k = b;
        for i = 2:ma;
                k = a*k; qs = [qs, k];
        end
end
```

FIGURE 112.4 The extension of MATLAB by means of "macro" or M-files. Here is a routine for determining the controllability of a state-space model.

However, powerful though the basic "matrix calculator" capabilities of MATLAB are, its real flexibility is due to its support of *macro files*. A macro file (M-file), in its simplest form, is just a collection of ordinary MATLAB commands which ar stored in a file. When called, such a "script" of commands is executed just as if it had been typed by the user. MATLAB's real strength lies in its ability to use M-files to create new functions. Such a function is defined in Fig. 112.4. Once defined in this way, the new function can be executed as if it was a part of the language (Fig. 112.5).

```
>>  qs=control(A,B)

qs =

     0     0     1
     0     1     4
     1     4    13

>>
```

FIGURE 112.5 Using a user-defined function as an extension to MATLAB.

By creating a set of functions in this way, it is relatively easy to build up a "toolbox" of useful functions for a particular application domain. This is exactly what happened shortly after the release of the original MATLAB. Entrepreneurs quickly realized that if they cleaned up the code, added control oriented data types and functions and some graphics capability, MATLAB could be resold as a proprietary CACSD package. So, based mainly on the state-space methods in vogue in the U.S., several packages, such as MATRIXx and Ctrl-C, emerged and were a great success.

MATLAB itself underwent further development. It was rewritten in C for efficiency and enhanced portability and released as a commercial product in 1985. Like its competitors, the main market was initially the CACSD market, where, supported by two sets of toolbox extensions called the Control and Signal Processing Toolboxes, MATLAB made rapid inroads into academia and industry. A recent development has been the provision of add-on graphical input of system models, in the form of block diagrams, support for "point-and-click" nonlinear simulation, and enhanced graphical functionality. At least one package, MATRIXx, has evolved further by the addition of data structures and more sophisticated support for macro development. The result is the package X-Math described by Floyd et al. [1991].

A Critique of Matrix Environments for CACSD

MATLAB and similar matrix environments are far from completely ideal. Rimvall [1987] gave the following requirements for a CACSD environment which are largely still valid today.

- Software packages must support the same entities used by human specialists in the field.
- The basic commands of an interactive environment must be fast yet flexible.
- CACSD packages should support an algorithmic interface.
- The transition from basic use to advanced use must be gradual.
- The system must be transparent.
- Small and large systems should be equally treated by the user interface.
- The system must be able to communicate with the outside world.

Matrix environments do not meet all of these requirements. The following sections give a critical review of the state-of-the-art.

Support of Control Entities

For a control engineer, the entities of interest are

- numerical descriptions of systems (state-space models, transfer functions, etc.)
- symbolic elements for general system equations
- graphical elements for the definition of system topologies
- support of large-scale data management, e.g., in the form of a relational database
- support of small-scale data management, e.g., in the form of spreadsheets
- graphical displays of numerical computations, possibly together with graphical interaction for requirement specifications, etc.

MATLAB was developed by a numerical analyst for numerical analysts. Such people need, and MATLAB provides, only one data structure, the complex matrix. It is a credit to its flexibility that the package can be adapted to a control engineer's needs by the careful use of convention and toolbox extensions (Fig. 112.6), but the price paid is increased complexity.

Take, as a simple example, single-input single-output control systems design. For each element in the system model, i.e., plant, controller, feedback network, the user has to look after four matrices for a state-space model or two polynomials for a transfer function. He cannot simply refer to the "transfer function G", but must refer instead to the numerator and the denominator polynomials (see Fig. 112.7) that stand for G. These polynomials can, in turn, only be distinguished from row vectors by convention and context.

In MATRIXx, this problem was avoided by using packing techniques and a special data-structure so that, for example, the state-space model in Fig. 112.3, would have been stored as shown in Fig. 112.8 and additional data would be stored in the workspace of the program so that the A, B, C, D matrices could be later extracted when needed.

Such packing schemes are quite widely used by toolbox writers to overcome the limitations imposed by the two-dimensional matrix. One is usually advised, but not required, to manipulate such structures only through

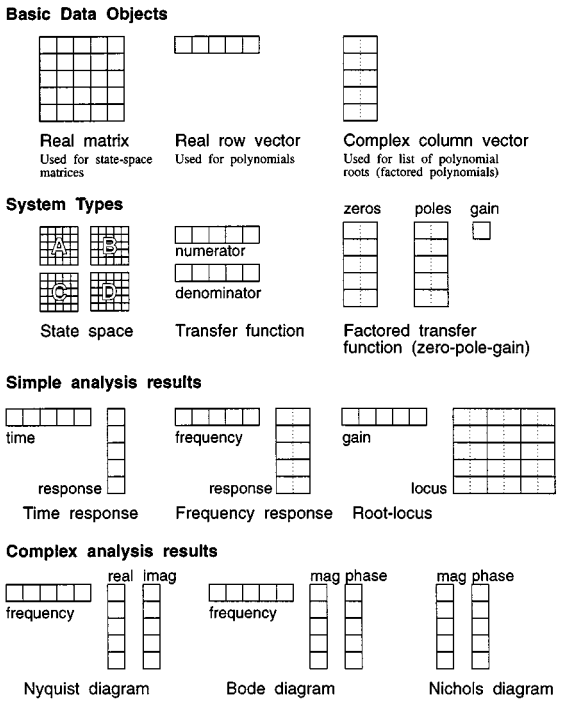

FIGURE 112.6 Some of the MATLAB conventions used to support control engineering data types.

```
>> % Plant: G(s) = 5/s(s^2 + 2s + 1)
>>  num_G = 5; den_G = conv([1 0],[1 2 1]);
>> % Controller: Gc(s) = 15(s + 1)/(s + 2)
>>   K_Gc = 15; Z_Gc = -1; P_Gc = -2;
>>   [num_Gc,den_Gc] = zp2tf(K_Gc,Z_Gc,P_Gc);
>> % Feedback: H(s) = 1/(s + 10)
>>   num_H = 1; den_H = [1 10];
```

FIGURE 112.7 Defining a control system in MATLAB.

```
>>  G = [ 0,  1, 0, 0
          0,  0, 0, 0
         -2, -3, 4, 1
          1,  0, 0, 0]
>> % size(A) = [3,3], size(B) = [3,1], size(C) = [1,3]
```

FIGURE 112.8 A packed "system matrix", additional values would have to be included to store the sizes of the relevant elements but these are not shown for clarity.

the packing and unpacking routines that usually accompany the toolbox code. For example, the packed state-space model might have a function `sstosys` to pack the data and `systoss` to unpack it into separate components as shown in Fig. 112.9. The advantage is that once packed, the state-space model *G* can be used in processing as if it was the single system object it represents. To see this, compare the code for simulation and analysis of a system given in Fig. 112.10(a) with the MATLAB Control System Toolbox code given in Fig. 112.10(b).

However, aside from the problem that packed data structures may be accidently used as ordinary matrices, there is a more severe problem that results from a lack of standardization. There are now a number of toolboxes

```
>>  G = sstosys(A,B,C,D);
>>  [a,b,c,d] = sstosys(G)

A =    1   0   0
       0   0   1
      -2  -3   4

B =    0
       0
       1

C =   1 0 0

D = 0
>>
```

FIGURE 112.9 Packing and unpacking system models.

```

>>   rlocus(Go)
```

a) Using packed data

```
>>  [Go_A,Go_B,Go_C,Go_D] = ...
       series(Gc_A,Gc_B,Gc_C,Gc_D,G_A,G_B,G_C,G_D)
>>  rlocus(Go_A,Go_B,Go_C,Go_D)
```

b) Using non-packed data, the MATLAB control systems toolbox

FIGURE 112.10 Use of a packed datastructure to simplify interaction.

that are used in CACSD, and none of them takes a standard approach to packing data structures. Thus, the data structures used in the Multivariable Control Systems Toolbox are completely incompatible with those used in the Systems Identification Toolbox, which itself is incompatible with the standard Control Systems Toolbox. The consequence is that each toolbox must supply conversion tools and the situation is similar to the problems faced with integrating data from two different packages.

There is, therefore, an identified need for matrix environments to provide a wider range of data types, preferably user definable. These would be used in the same way as record datatypes are used in conventional programming systems and would be considerably safer to use since the types expected and returned by functions could be specified in advance and the scope for misuse would be much reduced. In addition, the need to invent new types for each application would be somewhat reduced. This approach has been taken in the matrix environment X-Math and similar features are planned for a future release of MATLAB. Some of the other requirements listed above, such as graphical systems input, graphical display of results, and spreadsheet data manipulation, are covered to a greater or lesser extent by the current generation of matrix environments. The others, namely symbolic data processing and database support, are not but are considered to be outside the scope of this article.

Fast Yet Flexible Command Language

MATLAB clearly satisfies this criterion as is evidenced by the natural interaction shown in Fig. 112.3. For CACSD use, it is debatable whether the principle still holds, mainly because of the way that the package entities needed for control have to be constructed and managed by the user. Nonetheless, no-one could complain that matrix environments are not flexible: the growing number of new control applications for them provides ample evidence of that.

Algorithmic Interface

The support of an algorithmic interface is simply a recognition of the fact that no package developer can anticipate the requirements of every user. So, the package must be extensible by provision of user-defined

macros and functions. MATLAB has these, and their provision is clearly important to the users of the package and developers of toolbox extensions. However, there is a limit to the software robustness of the mechanisms that MATLAB provides. MATLAB is an un-typed language, all data structures used in extensions to MATLAB are implemented in terms of collections of matrices and vectors. It is therefore up to the programmer to develop conventions for using these data items such that the algorithms work properly. A strongly typed language, in which the user must specify the nature of each data object before it is used, is a much safer basis on which to provide extensions that are to be used by many other people.

Transition From Basic to Advanced Use

The user of a CACSD package is faced with two different types of complexity: the complexity of the user interface and the complexity of the underlying theory and algorithms. In both cases extra guidance is needed for novice users. Typically, the designers of CACSD packages do not wish to stand in the way of the expert users, so they provide direct access to the whole package and interfere in the use of the package as little as possible. This creates problems for novice or infrequent users of the package—novices because they are coming to the package without any knowledge of it, infrequent users because they have probably forgotten most of what they learned the last time they used the package.

In MATLAB, the user interface is deceptively simple. One can take a short tutorial and learn the basic concepts and underlying principles in perhaps one hour. But what happens when one is finished with the tutorial and wants to do some actual work? The sheer number of commands in the system can be overwhelming. In basic MATLAB there are some two hundred commands, add a few toolboxes and the number quickly increases. The only way to find out how to use a command is to know its name. If you don't know the name you can list all the commands available, but since each command name is limited to eight characters, there is not necessarily going to be any relationship between command name and command function. Having found a command the next step is to learn how to use it. In a research prototype CACSD package called IMPACT, Rimvall and Bomholt [1985] provided a latent question and answer mode feature which switches from normal command entry to step by step elicitation of parameters when requested by the user. Other ways of overcoming some of these difficulties [Rimvall, 1988] include providing a means of loading toolboxes only when they are needed, thereby reducing the instantaneous "name-space", and providing operator overloading so that the same named procedure in X-Math [Floyd et al., 1991] and enables, for example, the multiplication operator '*' to mean matrix multiplication, series combination of systems, polynomial convolution, or time response evaluation depending on the types of the operands.

Transparency

This is a fundamental principle of software engineering that simply means that there should be no hidden processing or reliance on side effects on which the package depends for its correct operation. Everything the package does and the package itself should, at all times, be under the complete control of the user.

Scalability

This simply means that account should always be taken of the limitations of numerical algorithms. The package should warn the user when limits are reached and the algorithms should thereafter 'degrade gracefully'. It is surprising how many applications have been programmed with artificial limits set on various arrays which is fine so long as the user never presents the package with a problem that its designer never believed would ever be tackled (an inevitable event). Most matrix environments are limited only by the available memory.

"Open Systems"

The need to transfer data to other systems is simply a recognition that no one package can do all things equally well. In many applications, it makes sense to pass a processing task onto an expert. The ability of a package to be able to exchange data (both import and export) is the main feature of so-called open systems. At the very least it must be possible to save data in a form that can be retrieved by an external program. MATLAB and its

cousins provide basic file transfer capabilities, but the ideal CACSD package would have some link to a much more convenient data sharing mechanism such as could be provided by a database.

Other Desirable Features

- *Form or menu drive input* is often more useful than a functional command driven interface for certain type of data entry. A good example is the plotting of results where the selection of options and parameters for axis scaling, tick marks, etc. are more conveniently specified by means of a dialog box than by a series of function calls. Such a facility is provided in X-Math's graphics.
- *Graphical input* is useful for defining systems to be analyzed. Today, most of the major packages provide block diagram input, usually tied to nonlinear simulation. What is rarer is graphical input of more application-specific system representations such as circuit diagrams.
- *Strong data typing,* as already discussed, is useful for toolbox developers since it provides a robust means of developing extra algorithms within the context of the CACSD package. On the other hand, there is a fine balance between the needs of the algorithm developer and the algorithm implementor. The former is probably best served by a type-less environment in which it is easy and quick to try out new ideas (such an environment is often called a *rapid-prototyping environment*). The latter, who needs to ensure that the algorithms will work properly under all conditions, needs strong typing to ensure that this can be guaranteed. A similar dichotomy between inventors and implementors can be observed in software engineering.
- *Data persistence.* Unless explicitly saved, CACSD data is not maintained between sessions. Neither can data easily be shared between users. The evolution of models and results over time cannot be recorded. Hence, CACSD packages need database support.
- *Matrix environments only support numerical computation.* It is often useful to be able to manipulate a symbolic representation of a control system. Delaying the replacement of symbolic parameters for numerical values for as long as possible can often yield great insight into such properties as stability, sensitivity, and robustness.

112.4 CACSD Block-Diagram Tools

As we have discussed in the previous sections, the 1980s was an important decade for control engineering. Apart form new theories, better design methods, and more accurate numerical algorithms, this was the decade when powerful and easy-to-use interactive CACSD tools were put on the average control engineer's desk. Through the use of interactive and extendible programs, new methods and algorithms could be easily implemented and quickly brought to bear on real control engineering problems. Yet despite this tremendous improvement in the availability of good control design environments, the total cost and cycle time for a complex control design was still perceived by many groups and companies as being too high. One of the major remaining bottlenecks was the manual conversion of a control design into testable simulation code and, at a later stage, the conversion of the eventual design into the actual embedded real-time controller code.

A control engineer often describes a system through the use of block diagrams of different kinds. To bypass the bottleneck between theoretical design and actual real-time implementation, systems which took engineering block diagrams and automatically converted them into simulation and/or real-time code started to emerge in the middle of the 1980s. As an early example, already in 1984 General Electric decided to develop a block-diagram-based tool with automatic code generation capabilities. This program allowed draftspersons to enter control block diagrams and automatically convert the functionality of these diagrams into real-time code. Although it used limited graphics, this GE-Internal "Autocode" program successfully produced code at 50% of the cost of traditionally generated code, primarily due to error reduction of not hand coding. This reduction of costs provided the evidence that automatic translation of block diagrams is both feasible and desirable. However, due to advances in both computer graphics and code-generation techniques, the first tool was obsolete by the late 1980s. In recent years, several commercial block-diagram-based tools have become available. These

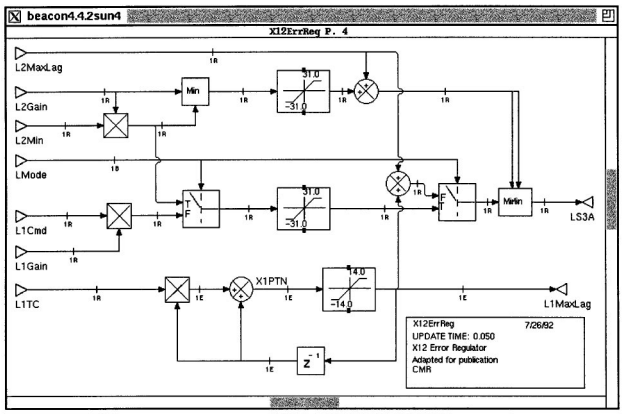

FIGURE 112.11 A signal-flow diagram in the BEACON system.

tools include System Build from Integrated Systems Incorporated, ModelC from Systems Control Technology, the PC-Based XAnalog from Xanalog, Simulab/Simulink from the Mathworks, and BEACON from General Electric. Some of these tools primarily serve as interfaces to analysis packages such as MATRIXx (System-Build), CTRL-C (Model-C), and MATLAB (Simulink). In some cases they can also be used to directly generate a computer language such as FORTRAN, ADA, or C. A summary of an early 1989 evaluation of the suitability of using System Build, CTRL-C, and Grumman's Protoblock for engine control is given in [Spang et al., 1993].

Basic Block-Diagram System Representations

Some basic user requirements fulfilled by most modern block-diagram oriented CACSD packages are

1. A simple-to-use graphical user-interface that can be used with little or no training. The graphical interface is usually based on the Macintosh, MS-Windows, and/or the X-Window System standard.
2. A set of rules for drawing controls-oriented diagrams, sometimes adhering to a standard diagram representations such as IEC-1331 or Petri Nets.
3. An object-based representation of the diagram entities and their graphical behavior. The underlying package must retain a semantical understanding of the diagram so that, for example, pertinent information such as signal types, dimensions, and ranges are propagated through the diagram, or connecting lines are retained when objects are moved.
4. Hierarchical structure which allows individual blocks to reference either other block diagrams or external modules (e.g., pre-coded system primitives).
5. Efficient internal simulation capabilities and/or real time code generation capabilities including optimization of execution speed and/or memory allocation.

As a consequence of the last two points, the block-diagram tools must have an open architecture so that the created modules can be associated with external code in a modular fashion. There are two main reasons for this:

- When the block-diagrams are used to simulate a physical system, the resulting models must frequently be interfaced with already existing submodels (e.g., from various FORTRAN libraries).
- When real-time controllers are implemented, the auto-generated code must be interfaced with operating system code and other "foreign" software.

All of today's block-diagram CACSD tools use hierarchical *signal-flow diagrams* as their main system representation. As illustrated in Fig. 112.11, a signal-flow diagram is a directed graph with the nodes representing standard arithmetic, dynamic and logic control blocks such as adders, delays, various filters, nonlinear blocks, and Boolean logic blocks. The connections between the blocks represent "signal" information which is

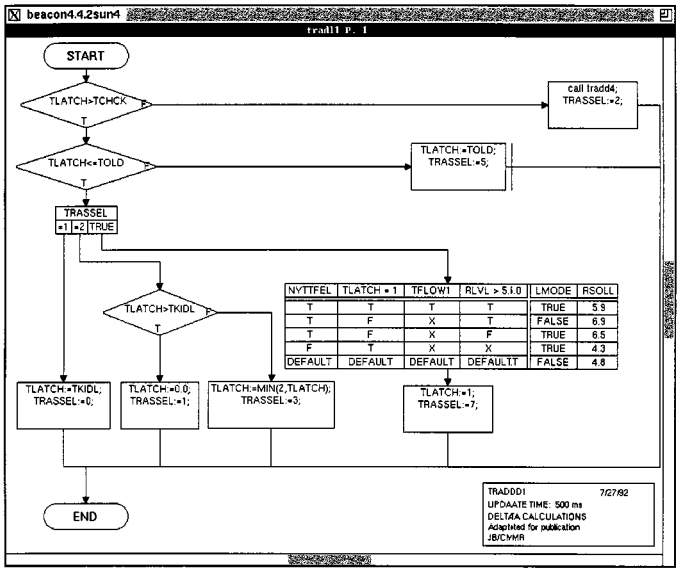

FIGURE 112.12 A BEACON control-flow block diagram.

transmitted from one block to another. The connections also indicate the order of execution of the various blocks. Signal flow diagrams are ideal for describing the dynamics of a system or controller.

Some CACSD packages also support some alternate system representation better suited for the logic and sequencing portion of a controller. Possible representations include *ladder-logic, dynamic truth-tables, flowcharts, Petri-nets,* or *state-transition diagrams.*

Figure 112.12 shows a typical control flow diagram or flowchart. The connections in this case represent the order of execution. The triangular blocks are decision blocks while the square blocks are variable assignment blocks written in a PASCAL-like language. Also shown are a multiway branch and a truth table. BEACON requires that the control flow diagrams produce structured code which equivalently means that a diagram can be implemented as a sequence of if-then-else statements without go-to's.

Hierarchies greatly facilitate the drawing and organization of diagrams. They provide appropriate levels of abstraction so that individual diagrams can be understood without clutter from details. Hierarchies simplify individual diagrams, making the resulting code easier to test. One can build up a set of subdiagram libraries which can be linked into possibly several higher level diagrams. Some block-diagram editors also allow the mixing of various diagram types in a hierarchical fashion (e.g., to call a low-level signal-flow diagram implementing a control-law scheme from a decision-making flow-chart diagram).

The graphical modeling environments cannot be viewed as replacements for the matrix environments described in the previous sections, as most of the block-diagram environments have very limited analytical capabilities (usually only simulation and linearization). However, many of today's block diagram tools have been developed as companion packages by the same commercial vendors that also sell matrix environments. Through linearization, it thus becomes possible to transform a non-linear block diagram to a linear representation which can then be analyzed and used for design in the matrix environment. Unfortunately, such automatic transformations are only available between tools from the same vendor, cross-translations between arbitrary tools are not possible.

Architectures of Block-Diagram Systems

To illustrate typical features and capabilities of a block-diagram oriented simulation or code-generation package, examples will be drawn from BEACON, a CACSD environment developed at GE between 1989 and 1995. There

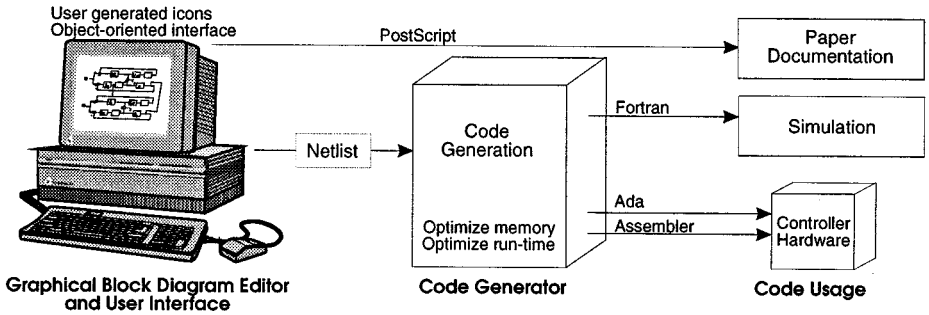

FIGURE 112.13 The BEACON architecture.

are, of course, many other block diagram systems, but being commercial products, the essential features are difficult to describe in detail. That said, another system that is well documented and worthy of study is the BlockEdit tool which was part of ECSTASY, a CACSD package developed in the UK in the late 1980s [Munro and Jobling, 1994]. BEACON has been in production use within GE since the first quarter of 1992. Through the use of BEACON, the company has been able to substantially reduce the overall cost and cycle time for developing complex controllers. The automatic generation of code not only eliminates the time-consuming manual coding, but also avoids the manual introduction of bugs into the code.

BEACON allows the user to graphically design a complete real-time controller as a series of hierarchical block diagrams. These diagrams can thereafter be automatically converted into a variety of computer languages for either control analysis, simulation, or real-time computer code, as illustrated in Fig. 112.13.

As shown in this figure, the BEACON system consists of three major components:

1. A graphical block-diagram editor with which the engineer designs the system to be simulated/coded [Spang et al., 1993]. Within this editor, the user may also create new graphical icons representing various numerical or logical blocks.
2. A netlist generated from the diagram and containing a full description of that diagram. The netlist format is keyword-oriented, it has a syntax resembling that of a higher-level language such as Pascal or Ada. To allow a variety of code generators and other uses such as the generation of I/O or termination lists or the automatic generation of test cases, all of the information except graphical location contained in the block diagram is written to the ASCII nestlist file.
3. An automatic code generator which translates the block diagrams into simulation and/or real-time computer code [Rimvall et al., 1993].

The BEACON architecture is one of the most open and extendible in the industry, allowing for straightforward extensions to the capability of the system and easy interfacing to other systems. Therefore, the architecture of other block diagram environments is often variants of that of BEACON. Some of the most common differences found in other systems are:

- *Built-in simulation capabilities.* Many of today's commercial systems have a non-linear simulation engine directly built into the system, avoiding BEACON's explicit translation step. Simulation results may then also be directly displayed on or accessed from the original diagram (e.g., in the form of time histories). This allows the user to see immediately the effects of any changes made to the diagram. One drawback of this approach is that these non-compiled approaches all have some kind of threaded-code or interpretative model execution, leading to much slower simulations than explicitly compiled simulation models such as those coming out of BEACON. Some systems allow for either of the two approaches.
- *The avoidance of an explicit netlist.* Many systems have a monolithic architecture with no direct access to the information in a modeled system. This prevents users from directly interfacing the block-diagram editor to other tools or filters (as often performed on a quite *ad-hoc* basis by the users within GE).
- *No code-generation.* Some older systems have built-in simulation capabilities only, with no generation of real-time or explicit simulation code.

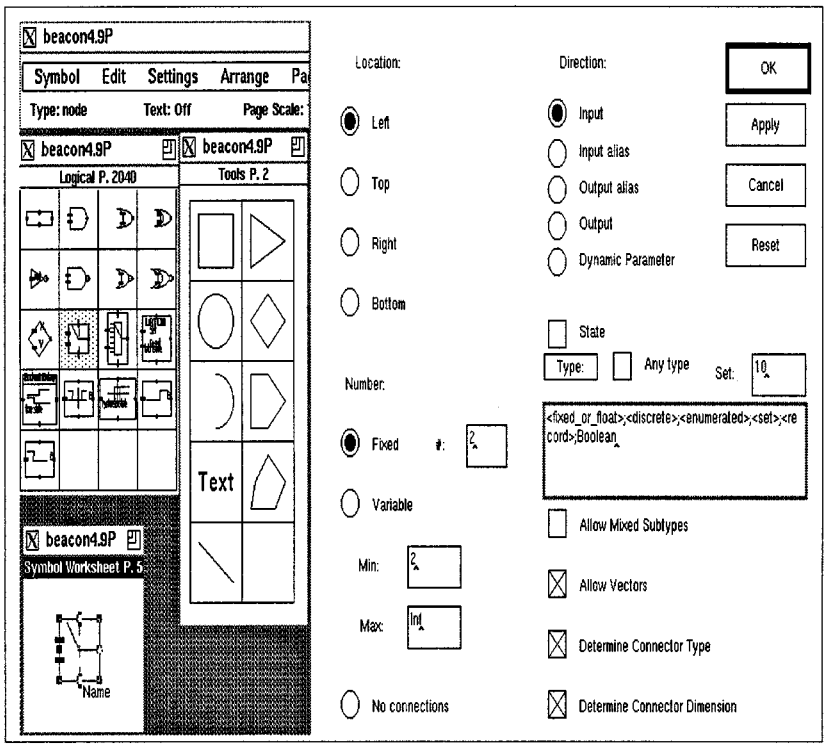

FIGURE 112.14 The BEACON symbol editor.

Open-Architectures of Block-Diagram Editors

Flexible block-diagrams have the capability of allowing users to develop or modify the graphical representation of symbols to meet the needs of various applications. In addition, it must be possible to add or modify the semantical meaning of the new or changed graphical symbols for simulation- or code-generation purposes.

The Editing of Block-Diagram Symbols

In BEACON, all symbols were developed using a Symbol Editor as shown in Figs. 112.14 and 112.15. This graphical editor is similar to most other object-oriented graphical editors, with the additional ability to describe diagram connectivity and the display of changing parameter values on the symbol itself. Each symbol is made up of a variety of separate objects (shapes) that are grouped together.

In Fig. 112.14, we see a Symbol Editor session, with the edited Switch symbol in the lower left window. The drawing primitives with its graphical shapes is the one in the middle. The large window to the right is an example of a block attributes window. In this case, it is the connectivity definition attributes for the left edge of the switch block; these attributes are used to define the sides and vertices which allow inputs or outputs, the allowed number of connections, vector dimension, and types.

Associated with most BEACON block symbols is a parameter form. These forms are unique for each individual block, allowing the user to define the parameters of the block and the specific function. For example, the integrator allows specification of the type of integration to be implemented as well as rate limits and initial conditions.

The forms are constructed during palette design using the Forms Editor shown in Fig. 112.15. To the left of the screen we see the actual parameter form of the Integrator block. In the middle we have the palette from which the primitive form elements may be picked. Each primitive forms object, such as text/value boxes and action buttons, have definable characteristics that will vary from element to element. To the right of Fig. 112.15 we see the characteristics of the data-input box for the parameter “lower limit”.

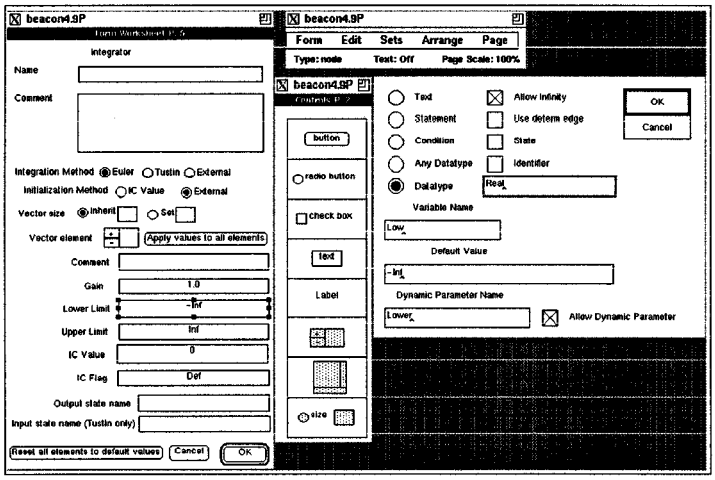

FIGURE 112.15 Examples of block parameter forms.

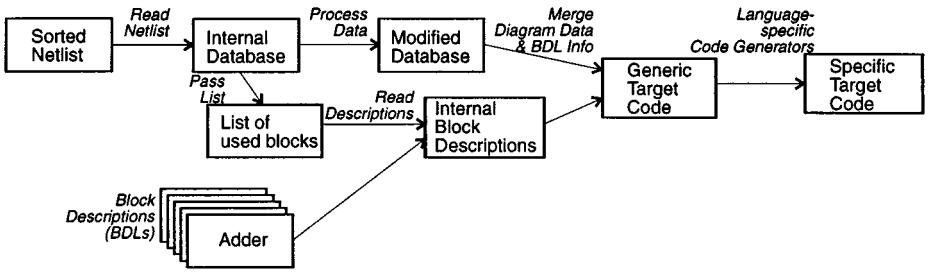

FIGURE 112.16 General principle of the workstation-based code generator.

The Functional Description of Symbols

The BEACON code generator will process a netlist into FORTRAN, Ada, C, or 68000 code. It accomplishes this by merging the block ordering information, the connectivity information, and the block-specific parameter values found in the netlist with block-specific functional descriptions of each block type. These block descriptions are stored separately from the netlist. This process is illustrated in Fig. 112.16.

Each block type supported by BEACON (e.g., adder, integrator, switch) will have a single block definition describing the functionality of the block. Whenever a new block symbol is added using the graphical Symbol Editor, a corresponding block definition file must be added to the system too. This block definition is written in "BEACON Block-Definition Language" (BDL), a special-purpose structured language that contains all the necessary elements for describing block connectivity, block parameters, and algorithms, as well as implementational detail such as fixed-point scaling.

Code From Signal-Flow Diagrams

The code resulting from a signal-flow diagram is a well-structured and yet locally optimized implementation of the diagram. It has the following characteristics:

- Through processing the sorted netlist, each block on the diagram is individually mapped onto the target language. Named blocks, e.g., `LIMAXLAG` in Fig. 112.11, are preceded by a comment stating that name in the code.

- Each connection on the diagram corresponds to a memory location in the code. To ensure readable code, each labeled connection, e.g., `X1PTN` in Fig. 112.11, is explicitly declared as a variable in the code. Unlabeled connections are mapped into reusable temporary variables or, in the case of assembler code, temporarily used registers. This ensures a locally optimized and yet fully readable code.
- States and other variables explicitly named on the diagram retain their name in the code. Unnamed states are automatically assigned unique names.
- Each numerical value is directly inserted into the code using the appropriate format of the target language and arithmetic type/precision used.

Code From Control-Flow Diagrams

Control-flow diagrams are processed in a similar manner to signal-flow diagrams. The main difference is that while a signal flow diagram uses a fixed set of blocks with well-defined semantics (the block interconnections and block parameters being the only variants between two blocks of the same type), the blocks in control-flow diagrams may contain arbitrary expressions, assignment statements, and/or procedure calls (as shown in Fig. 112.12). These BEACON language constructs must be translated into the primitives of each target language.

The BEACON graphical editor ensures that control-flow diagrams are well structured, i.e., that the diagram can be mapped into structured code. The automatic translation of large truth-tables into complex structured code is particularly time-saving.

Conclusions

In this chapter we have reviewed the tools available for the computer-aided design of control systems. The main features of the current state-of-the-art are analysis tools built around a "matrix environment" and modeling, simulation, and code generation tools constructed around the block diagram representation. For the most part, control systems analysis and design is done from a textual interface and modeling, simulation, and code generation rely on a graphical user interface. There are links between the two "environments", usually provided by some form of linearization.

Future CACSD environments will have to give equal emphasis to "control data objects" as they now do for matrices. This is becoming urgent as the number of specialist toolboxes being written for MATLAB and similar packages increases. Only by having a set of commonly approved data-types can the further development of incompatible data formats *within a single package* be prevented. Rimvall has defined an extended MATLAB-compatible command language to overcome such problems and the issues are discussed in [Rimvall and Wette, 1993].

As graphical user interfaces become more popular on computing devices, the possibilities for interactive manipulation of systems will have to be explored. We expect that graphical tools for control systems analysis and design will become common-place over the next few years and may eventually replace textual interfaces for most users.

A final important area for development of CACSD will be driven by the need to embed control systems design into information systems for enterprise integration. To some extent this is already happening with the need for multidisciplinary teams of engineers to work on common problems. The computer-based support of such projects requires facilities for the development and exchange of models, the storage of design data, version control, configuration management, project management, and computer-supported cooperative work. It is likely that CACSD will have to develop into a much more open set of tools supported by databases, networks, and distributed computation. The implications of some of these developments are discussed in [Barker et al., 1993].

Essential tremor is the most common neurological movement disorder in the U.S. The condition afflicts more than one million people, usually age 45 and older, in the U.S. alone. Thanks to Medtronic, Inc., the world's leading medical technology company specializing in implantable and invasive therapies, help for this debilitating condition is in sight.

The Activa Tremor Control System, shown above, uses an implanted device, similar to a cardiac pacemaker, to deliver electrical stimulation to block or override brain signals that cause tremor. The system allows the stimulation level to be adjusted to the needs of each patient.

Patients in Canada, Europe, and Australia are already using the Activa Tremor Control System. In the U.S. it has been recommended unanimously for marketing clearance by the Neurological Device Panel Advisory Committee to the U.S. Food and Drug Administration. (Photo courtesy of Medtronic, Inc.)

TECHNOLOGICAL INNOVATION in the twentieth century has progressed at such an accelerated pace that it has permeated almost every facet of our lives. This is especially true in the field of medicine and the delivery of health care services. Although the art of medicine has a long history, the evolution of a health care system capable of providing a wide range of positive therapeutic treatments in the prevention and cure of illnesses is a decidedly new phenomenon. Of particular importance in this evolutionary process has been the establishment of the modern hospital as the center of a technologically sophisticated health care system. In the process, the discipline of *biomedical engineering* has emerged as an integrating medium for two dynamic professions, medicine and engineering, assisting in the struggle against illness and diseases by providing materials, tools, and techniques (such as signal and image processing and artificial intelligence) that can be utilized for research, diagnosis, and treatment by health care professionals.

Today, biomedical engineering is an interdisciplinary branch of engineering heavily based both in engineering and in the life sciences. It ranges from theoretical, nonexperimental undertakings to state-of-the-art applications. It can encompass research, development, implementation, and operation. Accordingly, like medical practice itself, it is unlikely that any single person can acquire expertise that encompasses the entire field. As a result, there are now a great number of biomedical engineering specialists to cover this broad spectrum of activity. Yet because of the interdisciplinary nature of this activity, there is considerable interplay and overlapping

of interest and effort between them. For example, biomedical engineers engaged in the development of biosensors may interact with those interested in prosthetic devices to develop a means to detect and use the same bioelectric signal to power a prosthetic device. Those engaged in automating the clinical chemistry laboratory may collaborate with those developing expert systems to assist clinicians in making clinical decisions based upon specific laboratory data. The possibilities are endless.

There are seven major career areas in biomedical engineering: (1) application of engineering system analysis and modeling (computer simulation) to biological problems; (2) measurement or monitoring of physiological signals; (3) diagnostic interpretation via signal processing techniques of bioelectric data; (4) therapeutic and rehabilitation procedures and devices; (5) prosthetic devices for replacement or augmentation of bodily functions; (6) computer analysis of patient-related data; and (7) medical imaging, i.e., the graphic display of anatomical detail or physiological function. Biomedical engineers, therefore, engage in the following pursuits:

- Design of instrumentation for human physiology research
- Monitoring astronauts and maintenance of life in space
- Research in new materials for implanted artificial organs
- Development of new diagnostic instruments for blood analysis
- Computer modeling of the function of the human heart
- Writing software for analysis of medical research data
- Analysis of medical device hazards for the U.S. government
- Monitoring the physiological functions of animals
- Development of new diagnostic imaging systems
- Design of telemetry systems for patient monitoring
- Design of biomedical sensors for measurement of human physiological systems variables
- Research on artificial intelligence (AI) and development of expert systems for diagnosis of diseases
- Design of closed-loop control systems for drug administration
- Modeling of the physiological systems of the human body
- Design of instrumentation for sports medicine
- Development of new dental materials
- Design of computers and communication aids for the handicapped
- Research in pulmonary fluid dynamics (biorheology)
- Study of the biomechanics of the human body

This list is not intended to be all-inclusive, for there are many other applications that utilize the talents and skills of the biomedical engineer. In fact, the list of activities of biomedical engineers depends upon the medical environment in which they work. This is especially true for the "clinical engineers," i.e., biomedical engineers employed in hospitals or clinical settings.

The utilization of biomedical engineers offers great potential benefit in the identification of problems and needs of our present health care delivery system that can be solved using existing engineering technology and systems methodology. Consequently, the field of biomedical engineering offers hope in the continuing battle to provide high-quality health care at reasonable cost. The purpose of this section, therefore, is to provide a broad overview of biomedical engineering topics of interest to electrical engineers.

Nomenclature

Symbol	Quantity	Unit
C	resistivity	Ω
C	proton density	
C_m	membrane capacitance	F
d	diameter	m
D	lateral beamwidth	
f_d	doppler shift	Hz
f_L	Larmour frequency	Hz
F	Faraday constant	
Γ	pressure reflection coefficient	
I_{mt}	minimum threshold current	A
I_t	threshold current	A
k	propagation constant	
L	internodal distance	m
m	mass	g
n	valence of ion	
p	pressure	N/m
Q_T	threshold charge	C
R	universal gas constant	
R	transmembrane resistance	Ω
σ	conductivity	S/m
t_d	decay time	s
t_r	rise time	s
T	absolute temperature	K
V	membrane potential	V
W	nodal gap width	
Z	valence of substance	
Z	acoustic impedance	W

113.1 Neuroelectric Principles

J. Patrick Reilly

Natural bioelectric processes are responsible for nerve and muscle function. These processes can be affected by externally applied electric currents that are intentionally introduced through medical devices or unintentionally introduced through accidental exposure (electric shock). A thorough treatment of this topic is given in Reilly [1992].

Externally applied electric currents can excite nerve and muscle cells. Muscle can be stimulated directly or indirectly through the nerves that enervate the muscle. Thresholds of stimulation of nerve are generally well below thresholds for direct stimulation of muscle. An understanding of neuroelectric principles is a valuable foundation for investigation into both sensory and muscular responses to electrical stimulation.

Figure 113.1 illustrates functional components of sensory and motor (muscle) **neurons**. The illustrated nerve fibers are **myelinated**, i.e., covered with a fatty layer of insulation called *myelin* and having *nodes of Ranvier* where the myelin is absent. The conducting portion of the nerve fiber is a long, hollow structure known as an **axon**. The axon plus myelin sheath is frequently referred to as a nerve **fiber**, or neuron. Bundles of neurons are called *nerves*.

The body is equipped with a vast array of sensors (receptors) for monitoring its internal and external environment. Electrical stimulation generally involves the *somatosensory* system, i.e., the system of receptors found in the skin and internal organs. Other specialized receptors include those in the visual and auditory systems and chemical receptors by which neurons communicate with one another.

The somatosensory receptors can be classified as mechanoreceptors, thermoreceptors, chemoreceptors, and nociceptors. Numerous specializations of mechanoreceptors respond to specific attributes of mechanical stimulation. Thermoreceptors are specialized to respond to either heat or cold stimuli. Nociceptors are unresponsive until the stimulus reaches the point where tissue damage is imminent and are usually associated with pain. Many nociceptors are responsive to a broad spectrum of noxious levels of mechanical, heat, and chemical stimuli. The muscles are equipped with specialized receptors to monitor and control muscle movement and posture. Figure 113.1 illustrates a *pacinian corpuscle*, which responds to the onset or termination of a pressure stimulus applied to the skin.

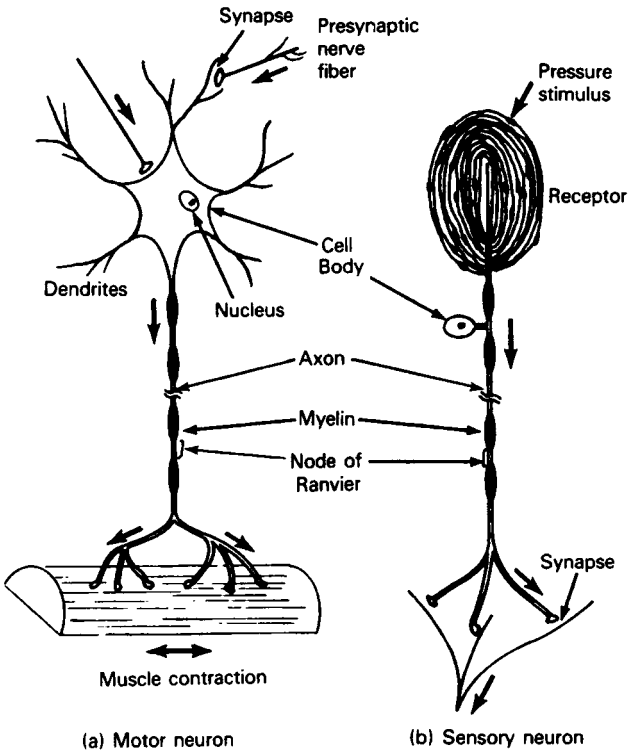

FIGURE 113.1 Functional components of (a) motor and (b) sensory neurons. Arrows indicate the direction of information flow. Signals are propagated across synapses via chemical neurotransmitters and elsewhere by membrane depolarization. Synapses are inside the spinal column. The sizes of the components are drawn on a distorted scale to emphasize various features.

When a sensory receptor is stimulated, it produces a voltage change called a *generator potential*. The generator potential is graded: if you squeeze a pacinian corpuscle, for example, it produces a voltage; if you squeeze it harder, it produces a greater voltage. The generator potential initiates a sequence of events that leads to a propagating **action potential** (a "nerve impulse" in common parlance).

The functional boundary of the biological cell is a thin (about 10 nm) bimolecular lipid and protein structure called a **membrane**. Electrochemical forces across the membrane regulate chemical exchange across the cell. The medium within the cell (the *plasm*) and outside the cell (the *interstitial fluid*) is composed largely of water containing various ions. The difference in the concentration of ions inside and outside the cell causes an electrochemical force across the cell membrane. The membrane is a semipermeable dielectric that allows some ionic interchange. Under conditions of electrochemical equilibrium (no net force in either direction), the membrane will attain a potential described by the *Nernst* equation

$$V_m = \frac{RT}{FZ} \ln \frac{[S]_o}{[S]_i} \tag{113.1}$$

where $[S]_i$ and $[S]_o$ represent the concentrations of ionic substance S inside and outside the cell, R is the universal gas constant, T is absolute temperature, F is the Faraday constant (number of coulombs per mole of charge), and Z is the valence of substance S. Using the values $R = 8.31$ J/mol K, $T = 310$ K, $F = 96{,}500$ C/mol, and $Z = +1$ (for a monovalent cation), converting to the base 10 logarithm, and expressing V_m in millivolts, we obtain

$$V_m = 61 \log \frac{[S]_o}{[S]_i} \tag{113.2}$$

In a quiescent state, nerve and muscle cells maintain a membrane potential typically around –60 to –90 mV, with the inside of the cell negative relative to the outside. Two ions that are involved in the electrical response of nerve and muscle are Na^+ and K^+. The concentration of these ions inside and outside the cell dictates the Nernst potential according to Eq. (113.2). Example concentrations in $\mu M/cm^3$ for a nerve axon would be $[Na^+]_i = 50$, $[Na^+]_o = 460$, $[K^+]_i = 400$, and $[K^+]_o = 10$. The Na^+ potential is found to be around +60 mV; the K^+ potential is found to be somewhat more negative than the resting potential. Obviously, the cell maintains in a state of electrochemical disequilibrium. The energy that maintains this force is derived from the metabolism of the cell—a dead cell will eventually revert to a state of equilibrium. Considering the transmembrane potential (≈100 mV), and its small thickness (≈10 nm), the electric field across the membrane is enormous (≈10 MV/m).

The membrane is semipermeable; that is, it is a lossy dielectric which allows the passage of certain ions. The ionic permeability varies substantially from one ionic species to another. The ionic channels in the excitable membrane will vary their permeability in response to the transmembrane potential; this property distinguishes the excitable membrane from the ordinary cellular membrane, and it supports propagation of nerve impulses.

The electrodynamics of the excitable membrane of unmyelinated nerves were first described in detail in the Nobel prize work of Hodgkin and Huxley [1952]. This work was later extended to the myelinated nerve membrane by Frankenhaeuser and Huxley [1964]. Figure 113.2 illustrates an electrical model of the Hodgkin-Huxley membrane, which consists of nonlinear conductances for Na^+ and K^+ and a linear leakage element. The potential sources shown in the diagram are the Nernst potentials for the particular ions as given by Eq. (113.2). The capacitance term C_m is formed by the dielectric membrane separating the conductive media on either side. The conductances g_{Na} and g_K apply to Na^+ and K^+ channels; the conductance g_L is a general "leakage" channel that is not specific to any particular ion. The g_{Na} and g_K conductivities are highly dependent on the voltage applied across the membrane as described by a set of nonlinear differential equations. When the membrane is in the resting state, $g_{Na} << g_K$, and the membrane potential moves toward the Nernst potential for Na^+. In this depolarized state, the membrane is said to be excited. The transition between the resting and excited condition of the membrane occurs rather abruptly when the membrane potential has been depolarized by roughly 15 mV. After excitation, the ionic channel conductances vary again, causing the membrane to revert back to its resting potential.

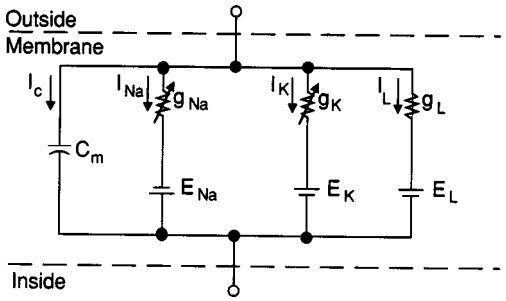

FIGURE 113.2 Hodgkin-Huxley membrane model.

The duration of the excited state lasts roughly 1 ms. The progression of the membrane voltage during the period of excitation and recovery is termed an *action potential*. After the membrane has been excited, it cannot be reexcited until a recovery period, called the **refractory period**, has passed.

Figure 113.3 illustrates the processes that support the propagation of an action potential. Consider that point A on the axon is depolarized. The local depolarization causes ionic transfer between adjacent points on the axon, thus propagating the region of depolarization. If depolarization were initiated from an external electrical source on a resting membrane at point A, an action potential would propagate in both directions away from the site of stimulation. The body's natural condition, however, is to initiate an action potential at the terminus of the axon, which then propagates in only one direction.

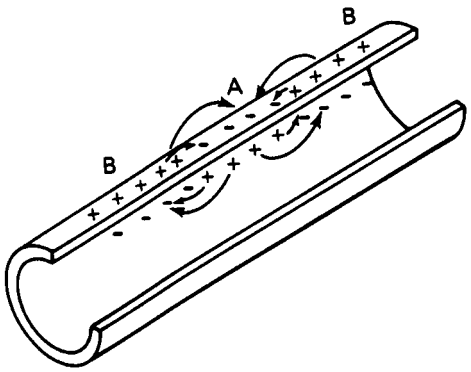

FIGURE 113.3 Spread of the depolarization wave front along an axon. Depolarization occurring in region A results in charge transfer from the adjacent regions.

Electrical Model for Nerve Excitation

Myelinated fibers have much lower thresholds of excitation than unmyelinated fibers. Accordingly, the myelinated fiber is an appropriate choice for electrical stimulation studies.

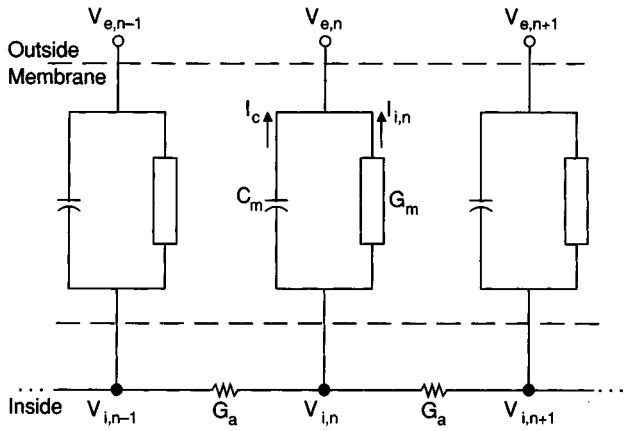

FIGURE 113.4 Equivalent circuit model for electrical excitation of myelinated nerve fiber. The membrane conductance G_m is described by nonlinear ionic conductances, similar to the representation in Fig. 113.2.

Figure 113.4 illustrates an electrical model for myelinated nerve as originally formulated by McNeal [1976]. The myelin internodes are treated as perfect insulators and the nodes as individual circuits consisting of capacitance C_m and an ionic conductance term. The nodes are interconnected through the internal axon medium by conductances G_a. The current flowing in the biological medium creates voltage disturbances $V_{e,n}$ at the exterior of the nodes.

The current emanating from the nth node is the sum of capacitive and ionic currents described by

$$C_m \frac{dV_n}{dt} + I_{i,n} = G_a(V_{i,n-1} - 2V_{i,n} + V_{i,n+1}) \tag{113.3}$$

where C_m is the membrane capacitance at the node, V_n is the transmembrane potential, $I_{i,n}$ is the total ionic current, and $V_{i,n}$ is the internal voltage. In this expression, V_n is taken relative to the resting potential, such that $V_n = 0$ applies to the membrane resting potential. The ionic current flux is the sum of individual ionic terms (similar to the representation in Fig. 113.4),

$$I_{i,n} = \pi dW(J_{\mathrm{Na}} + J_{\mathrm{K}} + J_L + J_P) \tag{113.4}$$

where the J terms are ionic current densities as described by a set of nonlinear differential equations developed by Frankenhaeuser and Huxley [1964] for a myelinated nerve membrane. Other relationships are

$$G_a = \frac{\pi d^2}{4\rho_i L} \tag{113.5}$$

$$C_m = c_m \pi dW \tag{113.6}$$

where d is the axon diameter at the node, ρ_i is the resistivity of the internal axon medium, L is the internodal distance, W is the nodal gap width, and c_m is the membrane capacitance per unit area. The relationship between the axon diameter d and the fiber diameter D (including myelin) is $d \approx 0.7D$. The voltage V_n across the membrane is

$$V_n = V_{i,n} - V_{e,n} \tag{113.7}$$

where $V_{i,n}$ and $V_{e,n}$ are the internal and external nodal voltages with reference to a distant point in the conducting medium outside the axon. Substituting Eq. (113.7) into (113.3) results in

$$\frac{dV_n}{dt} = \frac{1}{C_m}[G_a(V_{n-1} - 2V_n + V_{n+1} + V_{e,n} - 2V_{e,n} + V_{e,n+1}) - I_{i,n}] \tag{113.8}$$

For application to an unmyelinated fiber, Eq. (113.8) may be analogously expressed in continuous form as

$$\tau_m \frac{\partial V}{dt} - \lambda^2 \frac{\partial^2 V}{\partial x^2} + V = \lambda^2 \frac{\partial^2 V_e}{\partial x^2} \tag{113.9}$$

where V and V_e are membrane voltage and external voltage, respectively, at longitudal position x. Equation (113.9) can be derived from first principles, or can be obtained from (113.8) by substituting $C_m = c_m \pi d \Delta x$, $G_a = \pi d^2/(4\rho_i \Delta x)$, $G_m = g_m \pi d \Delta x$, where d is the fiber diameter, Δx is the longitudinal increment, ρ_i is the axoplasm resistivity (in Ωcm) internal to the fiber, c_m is capacitance per unit area, and g_m is conductance times unit area. Continuous and discrete spatial derivatives are connected by $\partial^2 V/\partial x^2 \approx (V_{n-1} - 2V_n + V_{n+1})/\Delta x^2$; $\partial^2 V_e/\partial x^2 \approx (V_{e,n-1} - 2V_{e,n} + V_{e,n+1})/\Delta x^2$; τ_m is the member time constant given by c_m/g_m; λ is the membrane space constant given by $\lambda = (r_m/r_i)^{1/2} = (d\rho_m/4\rho_i))^{1/2}$, and ρ_m is the membrane specific resistance (in Ωcm^2). An additional relationship is $I_{i,n} = V/G_m$.

If one treats λ as a constant, then (113.9) describes the membrane response only during its sub-threshold (linear) phase. For membrane depolarization approaching the threshold of excitation, membrane conductance of ionic constituents becomes highly nonlinear, as noted above — it is this nonlinear behavior that leads to nerve excitation.

The left-hand side of Eq. (113.9) is the so-called cable equation that was developed by Oliver Heaviside over 100 years ago in connection with the analysis of the first transatlantic telegraphy cable. The right-hand side is a driving function due to the external field in the biological medium. For additional information on cable theory as applied to the excitable membrane, the reader is directed to Jack et al. [1983].

One conclusion that can be drawn from Eqs. (113.8) and (113.9) is that a second spatial derivative of voltage (or equivalently a first derivative of the electric field) must exist along the long axis of an excitable fiber in order to support excitation. Nevertheless, excitation is possible in a locally constant electric field where the fiber is terminated or where it bends. The orientation change or the termination creates the equivalent of a spatial derivative of the applied field. Stimulation at "ends and bends" can be the dominant mode of excitation in many cases.

The external voltages in Eq. (113.8) are dependent on the distribution of current within the biological medium. For a point electrode in an isotopic medium, for instance, we can determine these voltages by

$$V_{e,n} = \frac{\rho_e I}{4\pi r_n} \tag{113.10}$$

where r_n is the distance between the stimulating electrode and the nth node and ρ_e is the resistivity of the external medium. For a uniform current density flowing in a direction parallel to the fiber axis, the external voltages are determined by

$$V_{e,n} = V_{e,1} + ELn \tag{113.11}$$

where $V_{e,1}$ is a reference voltage at the terminal node, L is the internodal distance, n is the node number, and E is the electric field in the medium. The electric field is related to current density by $J = E\sigma$, where $\sigma = 1/\rho_e$ is the conductivity of the medium and J is the current density. Since the response of the electrical model is independent of $V_{e,1}$, we may assume $V_{e,1} = 0$ for convenience in Eq. (113.11).

The internodal distance L is proportional to fiber diameter D through the relationship $L/D \approx 100$. Other fiber diameter relationships are expressed in Eqs. (113.5) and (113.6). Because of these relationships, thresholds of electrical stimulation will vary inversely with fiber diameter. The distribution of myelinated nerve diameters found in human peripheral nerve or skeletal muscle typically ranges from 5 to 20 μm.

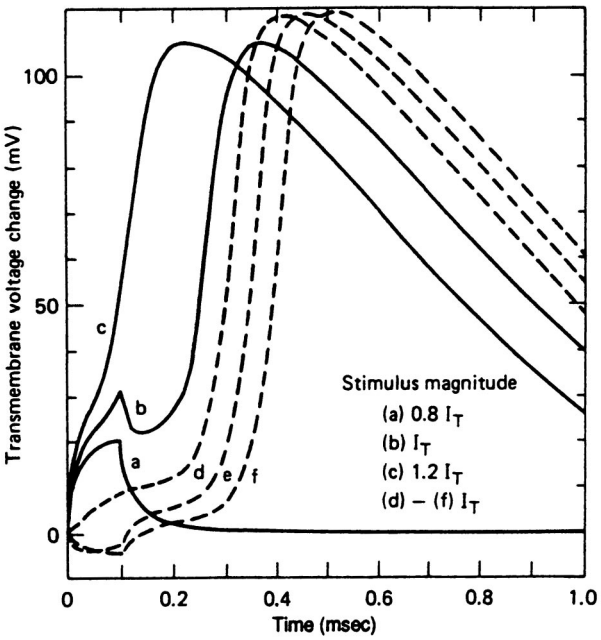

FIGURE 113.5 Response of myelinated nerve model to rectangular monophasic current of 100 ms duration, 20-μm diameter fiber, point electrode 2 mm from central node. Solid lines show response at node nearest electrode for three levels of current. I_T denotes threshold current. Dashed lines show propagated response at next three adjacent nodes for a stimulus at threshold. (*Source:* J. P. Reilly, V. T. Freeman, and W. D. Larkin, "Sensory effects of transient electrical stimulation—Evaluation with a neuroelectric model," *IEEE Trans. Biomed. Eng.*, vol. BME-32, no. 12, pp. 1001–1011, © 1985 IEEE.)

Figure 113.5 illustrates the response of the myelinated nerve model of Fig. 113.4 to a rectangular current stimulus [Reilly et al., 1985]. The example is for a small cathodal electrode that is 2 mm radially distant from a 20-μm fiber and directly above a central node. The transmembrane voltage ΔV is scaled relative to the resting potential. The solid curves show the response at the node nearest the stimulating electrode. Response *a* is for a pulse that is 80% of the threshold current, *b* is at threshold, and *c* is 20% above threshold. The threshold stimulus pulse in this example has an amplitude I_T of 0.68 mA. Response *a* is similar to that of a linear network with a parallel resistor and capacitor and charged by a brief current pulse. Responses *b* and *c* demonstrate the highly nonlinear response of the excitable membrane. The dashed curves in Fig. 113.5 show the membrane response to a threshold stimulus at the three nodes adjacent to the one nearest the stimulating electrode. The time delay implies a propagation velocity of 43 m/s, which is typical of a 20-μm fiber. The membrane response seen in curves *b* through *f* illustrates the action potential described earlier. The action potential is typically described as an "all-or-nothing" response; that is, its amplitude is not normally graded—either the axon is excited, or it is not.

The threshold current needed for excitation is highly dependent on its duration and waveshape. A common format for representing the response of a nerve is through **strength-duration curves**, i.e., the plot of the threshold of excitation versus the duration of the stimulating current. We can determine the threshold of excitation by "titrating" the stimulus current between a threshold and no-threshold condition.

Figure 113.6 illustrates strength-duration curves derived from the myelinated nerve model described previously under the same conditions applying to Fig. 113.5. Three types of stimulus current apply to Fig. 113.6: a monophasic constant current pulse, a symmetric biphasic rectangular current, and a single cycle of a sine wave. The phase duration indicated on the horizontal axis applies to the initial cathodal half cycle for the two biphasic waves. Stimulus magnitude is given in terms of peak current on the right vertical axis and in terms of the charge in a single monophasic phase of the stimulus on the left vertical axis. The charge is computed by $Q = It_p$ for the rectangular waveforms and $Q = (2/\pi)It_p$ for the sinusoidal waveforms (I is threshold current and t_p is phase duration).

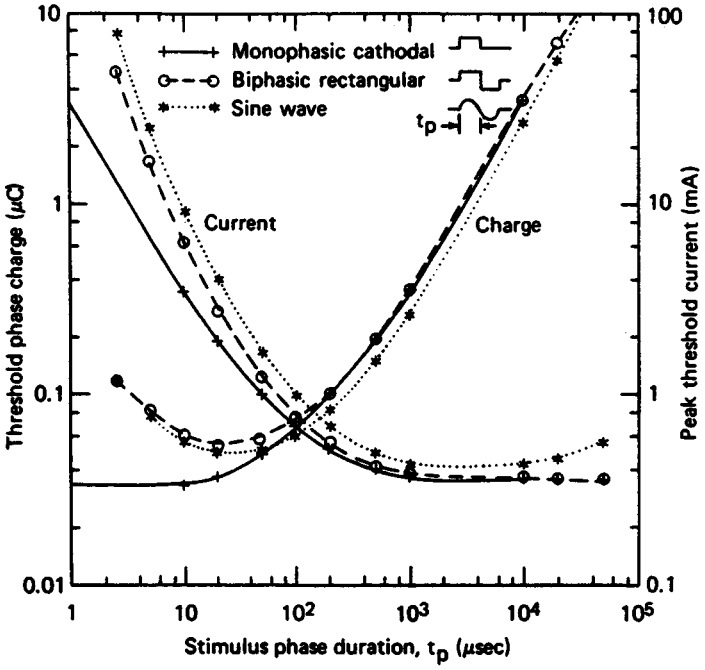

FIGURE 113.6 Strength/duration relationships derived from the myelinated nerve model: current thresholds and charge thresholds for single-pulse monophasic and for single-cycle biphasic stimuli with initial cathodal phase, point electrode 2 mm distant from 20 μm fiber. Threshold current refers to the peak of the stimulus waveform. Charge refers to a single phase for biphasic stimuli. (*Source:* J. P. Reilly, V. T. Freeman, and W. D. Larkin, "Sensory effects of transient electrical stimulation—Evaluation with a neuroelectric model," *IEEE Trans. Biomed. Eng.*, vol. BME-32, no. 12, pp. 1001–1011, © 1985 IEEE.)

The solid curve labeled "current" is of the type that is most often represented as a strength-duration curve. For this curve, the minimum threshold current occurs for long-stimulus durations and is called the *rheobasic current*, or simply **rheobase**. The duration consistent with twice the rheobase is called the **chronaxie**. The solid curve in Fig. 113.6 labeled "charge" gives the area under the rectangular current pulse. The threshold charge is a minimum for short-duration stimuli.

Mathematical curve fits to the strength-duration curves for monophasic rectangular stimuli are

$$\frac{I_T}{I_o} = \frac{1}{1 - e^{-t/\tau e}} \tag{113.12}$$

and

$$\frac{Q_T}{Q_o} = \frac{t/\tau_e}{1 - e^{-t/\tau e}} \tag{113.13}$$

where I_T is threshold current, Q_T is threshold charge, I_o is the minimum threshold current for long-duration stimuli, Q_o is the minimum threshold charge for short-duration stimuli, and τ_e is an experimentally determined strength-duration time constant. It is readily shown that chronaxie = $\tau_e \ln 2 = 0.693\tau_e$ in this formulation.

Values of I_o and Q_o vary considerably with experimental parameters such as electrode size and location and the size of the neuron. Values of τ_e also vary considerably with experimental conditions: a value around 250 μs is typical for both sensory and motor nerve excitation via cutaneous electrodes, and values around 125 μs are observed for stimulation of axons by small electrodes. Much longer time constants are associated with direct stimulation of muscle cells.

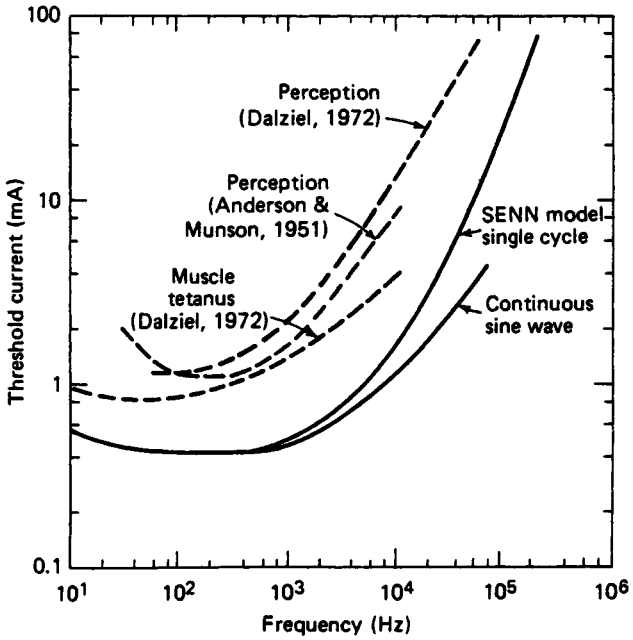

FIGURE 113.7 Strength-frequency curves for sinusoidal current stimuli. Dashed curves are from experimental data. Solid curves apply to myelinated nerve model. Experimental curves have been shifted vertically to facilitate comparisons.

The current reversal of a biphasic stimulus can reverse a developing action potential that was elicited by the initial phase. As a result, a biphasic pulse may have a higher threshold than a monophasic pulse as suggested by the biphasic thresholds in Fig. 113.6. The degree of biphasic threshold elevation is magnified as the stimulus duration is reduced.

A sinusoidal current is a special case of a biphasic stimulus. Sinusoidal threshold response can be represented by strength-frequency curves, as shown by the solid curves in Fig. 113.7 for the myelinated nerve model. Several experimental curves have been included in the figure; these have been shifted vertically to facilitate comparisons. Notice that the myelinated nerve model predicts a lower threshold for stimulation by a continuous sine wave as compared with a single cycle.

The strength-frequency curve follows a U-shaped function, with a minimum at mid frequencies and an upturn at both low and high frequencies. At low frequencies the slow rate of change of the sinusoid prevents the membrane capacitance from building up a depolarizing voltage because membrane capacitance is counteracted by membrane leakage. This process describes the neural property known as *accommodation*, i.e., the adaptation of a nerve to a slowly varying or constant stimulus. The high-frequency upturn occurs because of the canceling effects of a current reversal on the membrane voltage change. An empirical fit to strength-frequency curves is

$$I_t = I_o K_H K_L \tag{113.14}$$

where I_t is the threshold current, I_o is the minimum threshold current, and K_H and K_L are high- and low-frequency terms, defined, respectively, as

$$K_H = \left[1 - \exp\left(-\frac{f_e}{f}\right)\right]^{-a} \tag{113.15}$$

and

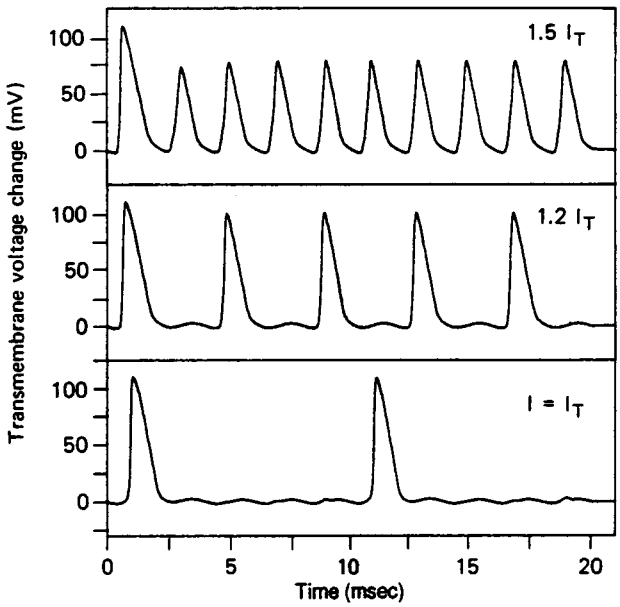

FIGURE 113.8 Model response to continuous sinusoidal stimulation at 500 Hz. The lower panel depicts the response to a stimulus current set at threshold level (I_T) for a single-cycle stimulus. Upper panels show responses for stimulation 20 and 50% above the single-cycle threshold. (*Source:* J. P. Reilly, V. T. Freeman, and W. D. Larkin, "Sensory effects of transient electrical stimulation—Evaluation with a neuroelectric model," *IEEE Trans. Biomed. Eng.*, vol. BME-32, no. 12, pp. 1001–1011, © 1985 IEEE.)

$$K_L = \left[1 - \exp\left(-\frac{f}{f_o}\right)\right]^{-b} \tag{113.16}$$

where f_e and f_o are constants that determine the points of upturn in the strength-frequency curve at high and low frequencies, respectively. An upper limit of $K_L \leq 4.6$ is assumed for Eq. (113.16) to account for the fact that excitation may be obtained with finite dc currents. An empirical fit of Eqs. (113.15) and (113.16) to the mylinated nerve model thresholds indicates that $a = 1.45$ for a single-cycle stimulus and $a = 0.9$ for a continuous stimulus; $b = 0.8$ regardless of stimulus duration. The value of I_o will depend on various conditions of stimulation, including the size of the electrode, its location on the body, and the location of the stimulated nerve.

With continuous sinusoidal stimulation, it is possible to produce a series of action potentials that are phase-locked to the individual sinusoidal cycles, as noted in Fig. 113.8. This makes the sinusoidal stimulus much more potent than a single pulse of the same phase duration. This potency is a consequence of the fact that perceived magnitude for neurosensory stimulation and muscle tension for neuromuscular stimulation both increase with the rate of action potential production.

Defining Terms

Action potential: A propagating change in the conductivity and potential across a nerve cell's membrane; a nerve impulse in common parlance.

Axon: The conducting portion of a nerve fiber—a roughly tubular structure whose wall is composed of the cellular membrane and which is filled with an ionic medium.

Chronaxie: The minimum duration of a unidirectional square-wave current needed to excite a nerve when the current magnitude is twice rheobase.

Fiber, nerve: A single nerve cell; a neuron—classified on the presence or absence of myelin. Myelinated nerve cells have diameters typically in the range 2 to 20 μm and conduction velocities of 5 to 120 m/s; unmyelinated nerves have diameters from 0.3 to 1.3 μm and conduction velocities of 0.6 to 2.3 m/s. Fiber lengths may be up to 1 m. The term nerve usually refers to a bundle of nerve fibers.

Membrane: The functional boundary of a cell. Nerve cells possess membranes that are excitable by virtue of their nonlinear electrical conductance properties (see Action potential).

Myelinated nerve: A nerve fiber insulated with a fatty substance called myelin and having periodically exposed *nodes of Ranvier.*

Neuron: A nerve cell. Sensory neurons carry information from sensory receptors in the peripheral nervous system to the brain; motor neurons carry information from the brain to the muscles.

Refractory period: A period of time after the initiation of an action potential during which further excitation is impossible (absolute refractory period) or requires a greater stimulus (relative refractory period).

Rheobase: The minimum current necessary to cause nerve excitation—applicable to a long-duration current (e.g., several milliseconds).

Strength-duration curve: A curve expressing the functional relationship between the threshold of excitation of a nerve fiber and the duration of a unidirectional square-wave electrical stimulus.

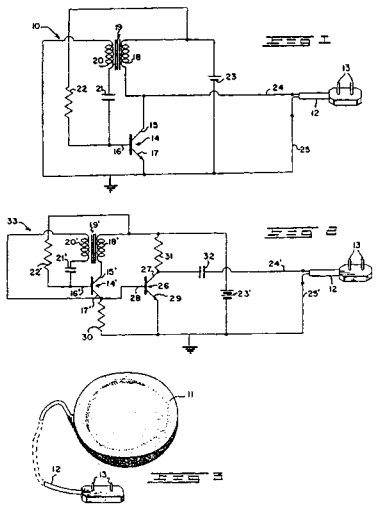
113.2 Bioelectric Events

L. A. Geddes

Bioelectric signals are exploited for the diagnostic information that they contain. Such signals are often used to monitor and guide therapy. Although all living cells exhibit bioelectric phenomena, a small variety produce potential changes that reveal their physiological function. The most familiar bioelectric recordings are the electrocardiogram, ECG (which reflects the excitation and recovery of the whole heart), the electromyogram, EMG (which reflects the activity of skeletal muscle), and the electroencephalogram, EEG (which reflects the activity of the outer layers of the brain, the cortex). The following paragraphs will describe (1) the origin of



Medical Cardiac Pacemaker

Wilson Greatbatch
Patented October 9, 1962
#3,057,356

An excerpt from Greatbatch's patent application:

The primary object of this invention is to provide an improved artificial cardiac pacemaker for restoring satisfactory heart rhythm to a heart which is functioning inadequately due to conduction defects in the auricular-ventricular bundle.

Another object of this invention is to provide an artificial cardiac pacemaker requiring low power consumption, so that battery operation is feasible for long uninterrupted periods without battery replacement.

Another object of this invention is to provide an artificial cardiac pacemaker which may be directly connected to the surface of the ventricle of the heart.

A still further object of this invention is to provide an artificial cardiac pacemaker which is constructed from materials compatible to the body environment and is of such an electrical and mechanical configuration, that permanent implantation of the device within the human body is both feasible and practical.

Greatbatch's pacemaker was the first to be compact enough and use such low power that it could be implanted within the body and run for five years before requiring battery replacement. Wilson Greatbatch, Inc. is a leading producer of pacemaker batteries and other medical products. (Copyright © 1995, DewRay Products, Inc. Used with permission.)

all bioelectric phenomena; (2) the nature of the electrical activity of the heart, skeletal muscle, and the brain; and (3) the characteristics of instrumentation used to display these events.

Origin of Bioelectricity

Cell membranes resemble charged capacitors operating near the dielectric breakdown voltage. Assuming a typical value of 90 mV for the transmembrane potential and a membrane thickness of 100 Å, the voltage gradient across the membrane is 0.9×10^5 V/cm. A typical value for the capacitance is about 1 μF/cm^2.

The transmembrane charge is the result of a **metabolic process** that creates ionic gradients with a high concentration of potassium ions (K^+) inside and a high concentration of sodium ions (Na^+) outside. There are concentration gradients for other ions, the cell wall being a semipermeable membrane that obeys the Nernst equation (60 mV/decade concentration gradient for univalent ions). The result of the ionic gradient is the transmembrane potential that, in the cells referred to earlier, is about 90 mV, the interior being negative with respect to the exterior. Figure 113.9 illustrates this concept for a cylindrical cell.

The transmembrane potential is stable in inexcitable cells, such as the red blood cell. However, in excitable cells, a reduction in transmembrane potential (either physiological or induced electrically) results in excitation, characterized by a transmembrane ion flux, resulting from a membrane permeability change. When the transmembrane potential is reduced by about one-third, Na^+ ions rush in; K^+ ions exit slightly later while the cell depolarizes, reverse polarizes, then repolarizes. The resulting excursion in transmembrane potential is a propagated action potential that is characteristic for each type of cell. In Fig. 113.10 are shown the action potentials of (A) a single cardiac ventricular muscle cell, (C) a skeletal muscle cell, and (E) a nerve cell. In (B) and (D), the ensuing muscular contractions are shown. An important property of the action potential is that it is propagated without decrement over the entire surface of the cell, the depolarized region being the stimulus for adjacent polarized regions. In contractile cells it is the action potential that triggers release of mechanical energy as shown in Figs. 113.10(B) and (D).

Law of Stimulation

Although action potentials are generated physiologically, it should be obvious that excitable cells can be made to respond by the application of a negative pulse of sufficient current density (I) and duration (d) to reduce the transmembrane potential to a critical value by removing charge, thereby reducing the membrane potential to the threshold potential (TP), as shown in Fig. 113.9. The law of stimulation is $I = b/(1 - e^{-d}/\tau)$, where b is the threshold current density for an infinitely long-duration pulse and τ is the cell membrane time constant, being different for each type of excitable tissue. Figure 113.11 is a plot of the threshold current (I) versus duration (d) for mammalian cardiac muscle, sensory receptors, and motor nerve. This relationship is known as the *strength-duration curve.*

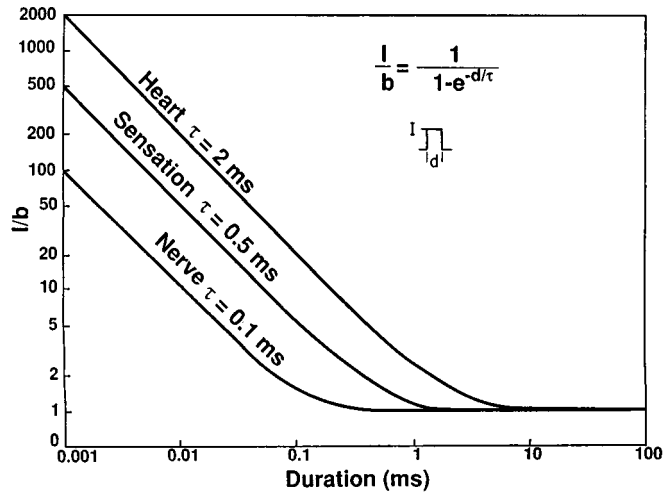

FIGURE 113.11 The strength-duration curve for heart, sensory receptors, and motor nerve. I is the stimulus current, b is the rheobasic current, and τ is the membrane time constant. The stimulus duration is d.

Recording Action Potentials

Action potentials of single excitable cells are recorded with transmembrane electrodes (micron diameter) only in research studies. When action potentials are used for diagnostic purposes, extracellular electrodes are used that are both large and distant from the population of cells which become active and recover. The depolarization

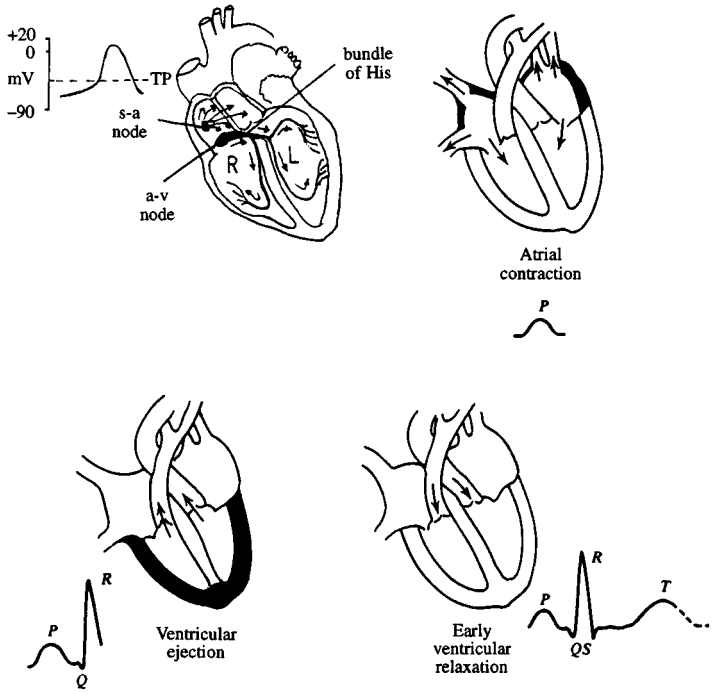

FIGURE 113.12 Genesis of the ECG. The SA node is the pacemaker, setting the rate. Excitation is propagated from the atria to the AV node, then to the bundle of His, and to the ventricular muscle via the Purkinje fibers. The SA node has a decreasing membrane potential that reaches the threshold potential (TP), resulting in spontaneous excitation (inset).

and repolarization processes send small currents through the conducting environmental tissues and fluids, resulting in a time-varying potential field. Appropriately placed electrodes allow recording the electrical activity of the bioelectric generators. However, the waveforms of such recordings are vastly different from those of the transmembrane action potentials shown in Fig. 113.10. By using cable theory, it is possible to show that such extracellular recordings resemble the second derivative of the excursion in transmembrane potential [Geddes and Baker, 1989]. Despite the difference in waveform, extracellular recordings identify the excitation and recovery processes very well.

The Electrocardiogram (ECG)

Origin

The heart is two double-muscular pumps. The atria pump blood into the ventricles, then the two ventricles contract. The right ventricle pumps venous blood into the lungs, and the left ventricle pumps oxygen-rich blood into the aorta. Figure 113.12 is a sketch of the heart and great vessels, along with genesis of the ECG.

The ECG consists of two parts: the electrical activity of the atria and that of the ventricles. Both components have an excitation wave and a recovery wave. Within the right atrium is a specialized node of modified cardiac muscle, the sinoatrial (SA) node, that has a spontaneously decreasing transmembrane potential which reaches the threshold potential (TP), resulting in self-excitation (Fig. 113.12, upper left). Therefore the SA node is the cardiac pacemaker, establishing the heart rate. The SA node action potential stimulates the adjacent atrial muscle, completely exciting it and giving rise to the first event in the cardiac cycle, the P wave, the trigger for atrial contraction. Atrial excitation is propagated to another specialized node of tissue in the base of the ventricles, the atrioventricular (AV) node, the bundle of His and the Purkinje fibers. Propagation of excitation over the ventricles gives rise to the QRS, or simply the R wave, which triggers ventricular contraction. Meanwhile during the QRS wave, the atria recover, giving rise to the T_p wave, following which the atria relax. The T_p wave

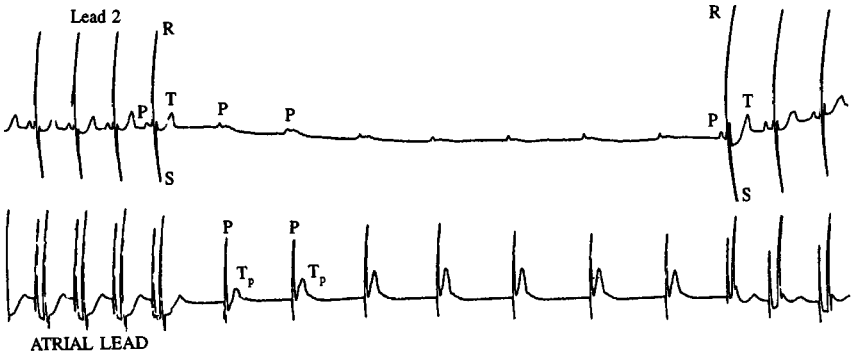

FIGURE 113.13 Lead 2 ECG and an atrial lead. In the center of the record AV block was produced, showing the P waves in lead 2 and the P and T_p waves in the atrial lead.

is not ordinarily seen in the ECG because it is obscured by the ventricular QRS wave. During the QRS wave the ventricles contract, then relax following their recovery potential, the T wave; Fig. 113.12 summarizes this sequence.

Ordinarily the T_p wave is not visible. However, if the propagation of excitation from the atria to the ventricles is blocked, the T_p wave can be seen. Figure 113.13 is a record of the ECG from a limb lead and a recording from a lead within the right atrium in a subject with transient AV block. Note that the sharp P wave in the atrial lead coincides with the P wave in the limb recording and that the atrial lead shows both P and T_p waves, easily identified during AV block.

Clinical Significance

From the foregoing it can be seen that the ECG is only a timing signal; there is no dynamic information in its amplitude. Nonetheless, by observing the orderly P-QRS-T sequence it is possible to determine if the excitatory and recovery processes in the heart are functioning normally.

Disturbances in the orderly timing of the cardiac cycle are elegantly displayed by the ECG. For example, each atrial excitation may not be delivered to the AV node. AV block exists when there is less than a 1/1 correspondence between the P and QRS complexes (Fig. 113.13).

Figure 113.14(1) shows a normal ECG and Fig. 113.14(2) illustrates a 2/1 AV block with two P waves for each QRS-T complex. Complete AV block exists when none of the atrial excitations reach the AV node, as shown in Fig. 113.14(3). In this case the ventricles developed their own rhythm, which was slow; cardiac output is low, and in such a situation an artificial pacemaker must be implanted.

For many reasons, the atria develop a rapid rate called *atrial tachycardia* or *supraventricular tachycardia.* A very rapid atrial rate is designated *atrial flutter* [Fig. 113.14(4)]. With both atrial tachycardia and flutter, the atrial contractions are coordinated, although the ventricular pumping capability is reduced owing to inadequate filling time. The ventricles are driven at a rapid rate, and cardiac output is low.

Atrial fibrillation is an electrical dysrhythmia in which all the atrial muscle fibers are contracting and relaxing asynchronously and there is no atrial pumping. This dysrhythmia [Fig. 113.14(5)] causes the ventricles to be excited at a very rapid and irregular rate. Cardiac output is reduced, and the pulse is rapid and irregular in force and rate.

If the propagation of excitation in the ventricles is impaired by damage to the bundle of His, the coordination of excitation and contraction is impaired and reveals itself by a widening of the QRS wave, and often a notch is present; Fig. 113.14(6) illustrates right (RBBB) and left (LBBB) bundle-branch block. These waveforms are best identified in the chest (V) leads.

All parts of the heart are capable of exhibiting rhythmic activity, there being a rhythmicity hierarchy from the SA node to the ventricular muscle. In abnormal circumstances the atria and ventricles can generate spontaneous beats. Such ectopic excitations do not ordinarily propagate normally, and therefore the ECG waveforms are different. Figure 113.14(7) illustrates ventricular **ectopic beats** in which the first (l) Q-S,T wave arose at the apex and the second (2) R-S,T wave arose at the base of the ventricles. The coupled (bigeminus)

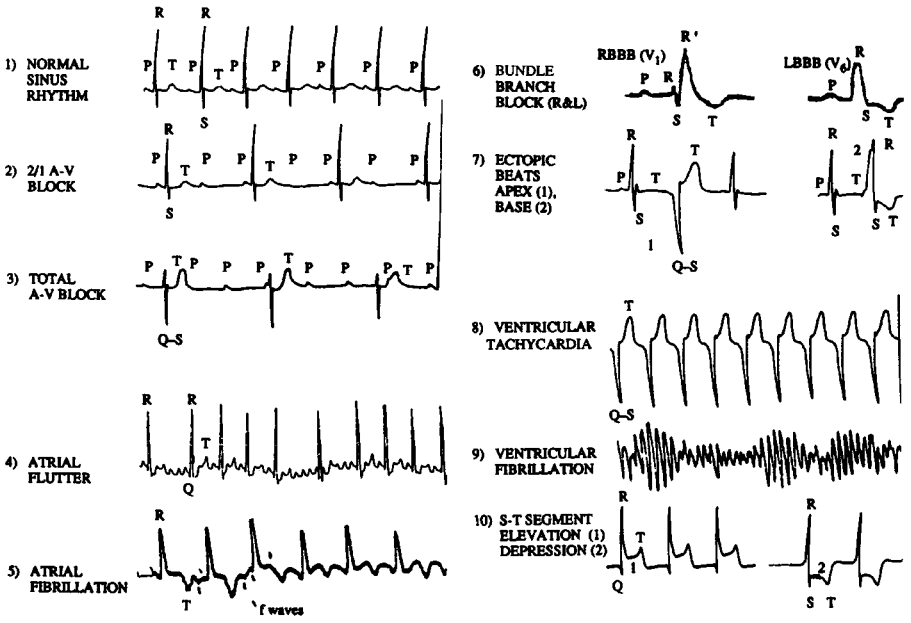

FIGURE 113.14 ECG waveforms.

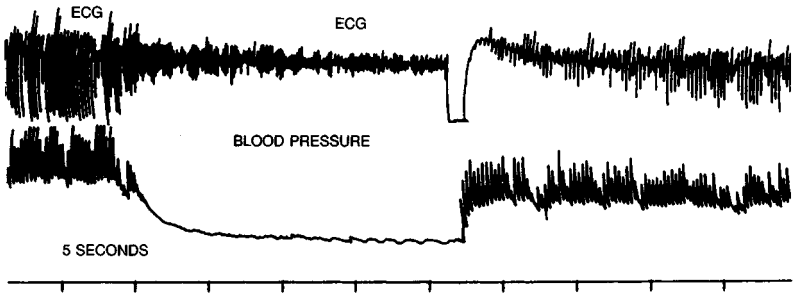

FIGURE 113.15 The electrocardiogram (ECG) and blood pressure during ventricular tachycardia (left), which progressed to ventricular fibrillation (center). A strong transchest shock was applied to defibrillate the ventricles that resumed pumping with the tachycardia returning (right).

beat usually produces no arterial pulse because of inadequate time for filling of the ventricles and poor coordination of the contraction.

The ventricles may become so excitable that they develop a rapid rhythm called *ventricular tachycardia,* as shown in Fig 113.14(8). In this situation the pumping capability is diminished owing to the high rate that impairs filling and to impaired coordination of contraction. Ventricular fibrillation is a condition in which all of the ventricular muscle fibers contract and relax independently and asynchronously. Pumping ceases and cardiac output falls to zero. The ECG [Fig. 113.14(9)] exhibits rapid oscillations of waxing and waning amplitude at a rate of 800 to 1500 per minute. Ventricular fibrillation is lethal unless the circulation is restored within a few minutes, first by cardiopulmonary resuscitation (CPR) and then by electrical defibrillation. The latter technique employs the delivery of a substantial pulse of current through the heart applied directly or with transchest electrodes. Figure 113.15 illustrates ventricular tachycardia (left), ventricular fibrillation (center), and defibrillation (right), with the restoration of pumping.

When a region of the ventricles is deprived of its coronary artery blood supply, the cells in this region lose their ability to generate action potentials and to contract. These cells remain depolarized while they are dying and do not contribute to genesis of the QRS-T complex. Instead, there appears a shift in the portion of the

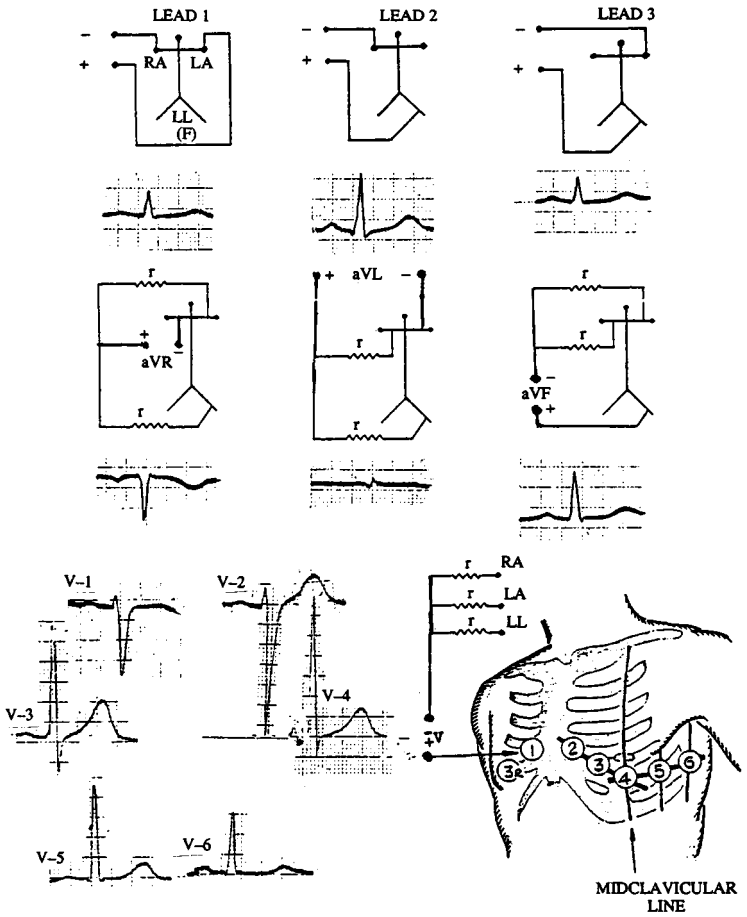

FIGURE 113.16 The limb and chest (V) leads.

ECG between the S and T waves, i.e., there is an S-T segment shift. This is the cardinal sign of a **myocardial infarction** (heart attack) and is almost always accompanied by chest pain (angina pectoris). Figure 113.14(10) illustrates the ECG in myocardial infarction. Whether the S-T segment displacement is up (1) or down (2) depends on the region of the ventricles injured, as well as the lead used to record the ECG.

ECG Leads

The spread of excitation and recovery over the atria and ventricles varies in direction with time. Therefore, excitation and recovery are vectors, and the location of body-surface electrodes is important. For this reason, standard electrode sites have been adopted, as shown in Fig. 113.16. There are three standard limb leads, three augmented (a) limb leads, and six chest (V) leads, the latter being monopolar. The reference for the monopolar chest leads is the centerpoint of three resistors (r), each joined to one of the limb electrodes. The right leg is used to ground the subject. Each lead "sees" a different region of the heart. The use of so many leads allows quick and easy identification of the direction of propagation of excitation (and recovery) by merely inspecting the amplitudes of the waveforms in the various leads. If excitation (or recovery) travels orthogonal to a lead axis, the net amplitude will be zero or very small. If excitation (or recovery) travels parallel to a lead axis, the amplitude of the wave will be maximum. Figure 113.16 illustrates the amplitudes of the P, QRS, and T waves for the 12 ECG leads. Note that leads 1, 2, 3, aVR, aVL, and aVF identify the vector projections in the frontal plane. Leads V_{1-6} identify the vector components in a quasi-horizontal plane. There are normal values for the amplitudes and durations for the P, QRS, and T waves as well as their vectors. The interested reader can find more on ECG in the many handbooks on this subject. Two good, recently published texts are by Chou [1991] and Phillips and Feeney [1990].

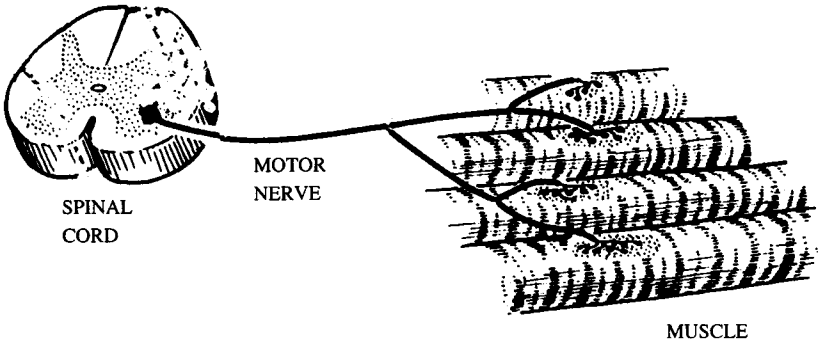

FIGURE 113.17 The functional unit of the muscular system, the motor unit, consisting of a nerve cell located within the spinal cord, its axon, and the muscle fibers that it innervates.

Instrumentation

Standards of performance evolved from recommendations by the American Medical Association in 1950 and the American Heart Association in 1954 and 1967. These recommendations have been collected and expanded into an American National Standard, published by the Association for the Advancement of Medical Instrumentation (AAMI) [1991]. The title of the document is "Diagnostic Electrocardiographic Devices." This document not only lists all the performance and labeling requirements, but also provides useful information on testing ECGs and should be consulted by those contemplating construction of an ECG. Only some of the highlights of the standard will be presented here.

The ECG is displayed by a direct-writing pen that employs a heated stylus writing on thermosensitive paper. Two chart speeds are used, 25 and 50 mm/s. The rulings on the paper represent 40 ms when the standard speed (25 mm/s) is used. The amplitude sensitivity is 10 mm for a 1-mV input signal. The sinusoidal frequency response extends from 0.05 to 100 Hz for the 30% attenuation points. The input stage is a differential amplifier with an input impedance in excess of 2.4 MΩ The common-mode rejection ratio (CMRR) is measured with a 20-V (rms) 60-Hz generator with an output impedance of 51,000 Ω connected in series with a 10-pF capacitor. The 60-Hz CMRR should be in excess of 5000. The maximum dc leakage current through any patient electrode is 0.2 μA.

Electromyography (EMG)

The electrical activity of skeletal muscle is monitored to assess the integrity of the motor nerve that supplies it and to evaluate recovery of the motor nerve following injury to it. The EMG is also characteristically altered in many degenerative muscle diseases. Although muscle action potentials can be detected with skin-surface electrodes, a monopolar or bipolar needle electrode is used in clinical EMG. The electrical activity is displayed on an oscilloscope screen and monitored aurally with a loudspeaker.

Contraction of Skeletal Muscle

The functional unit of the muscular system is the motor unit, consisting of a nerve cell located within the spinal cord, its axon (nerve fiber), and the group of muscle fibers that it innervates, as shown in Fig. 113.17. Between the nerve fiber and the muscle fibers is the myoneural junction, the site where acetylcholine is liberated and transmits excitation to the muscle fibers. The number of muscle fibers per nerve fiber is called the innervation ratio, which ranges from 1:1 to about 1000:1; the former ratio is characteristic of the extraocular muscles, and the latter is typical for the postural muscles.

A single stimulus received by the nerve fiber physiologically, or a single stimulus delivered to it electrically, will cause all the innervated muscle fibers to contract and relax; this response is called a *twitch*. Figure 113.10(C) and (D) illustrates the relationship between the muscle action potential and twitch. Note that the action potential is almost over before contraction begins and the contraction far outlasts the duration of the action potential.

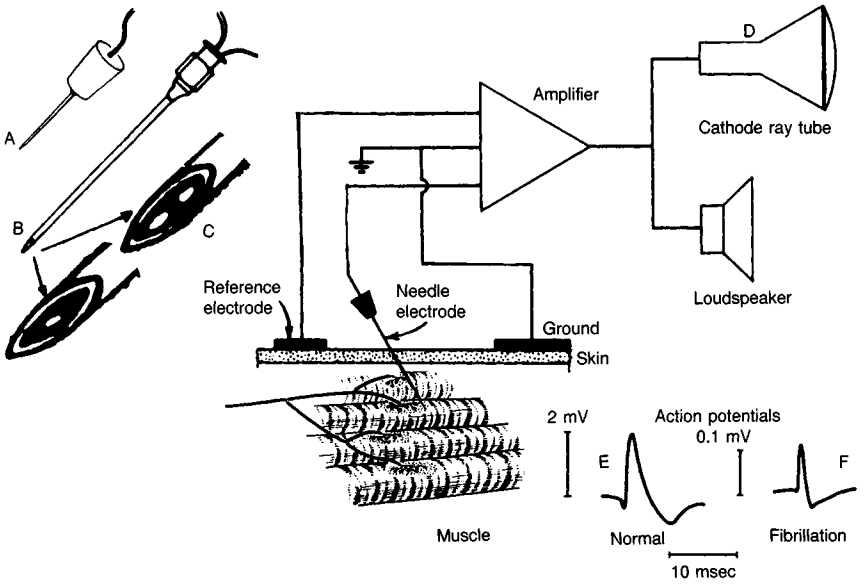

FIGURE 113.18 Equipment used for electromyography. (A) Needle electrode, (B) hypodermic monopolar and (C) bipolar electrodes, (D) the recording apparatus, (E) skeletal muscle action potential, and (F) fibrillation potential.

If multiple stimuli are delivered to a single motor-nerve fiber with an increasing frequency, the twitches fuse into a sustained (tetanic) contraction whose force is much more than that of a twitch. This occurs because each action potential liberates contractile energy. The critical fusion frequency depends on the type of muscle, but in general it is about 25 to 40 per second.

The force developed by a whole muscle consisting of thousands of motor units is graded in two ways: (l) by the frequency of nerve impulses in each nerve fiber and (2) by the number of motor units that are activated.

Clinical EMG

When the electrical activity of skeletal muscle is examined for diagnostic purposes, an insulated needle electrode, bare only at the tip [Fig. 113.18(A)], is inserted into the muscle and paired with a skin-surface electrode. Another skin-surface electrode is used to ground the subject. Occasionally a coaxial needle electrode [Fig. 113.18(B)] or a bipolar hypodermic needle electrode [Fig. 113.18(C)] is used. In the latter case the outer sleeve is used as the ground. A high-gain, differential amplifier, oscilloscope, and loudspeaker are used, as shown in Figure 113.18(D).

In a normal subject at rest, the electrical activity monitored during insertion of the needle electrode consists of a short burst of muscle action potentials displayed on the oscilloscope and heard in the loudspeaker. These action potentials are called *insertion* potentials and subside quickly in the normal muscle. When the muscle is at rest, there is no electrical activity (electrical silence). If the muscle is contracted voluntarily, the frequency of action potentials increases with the force developed by the muscle. However, there is no linear or constant relationship between these two events. Each action potential, called a *normal motor-unit* potential, lasts a few milliseconds to the first zero crossing, as shown in Fig. 113.18(E).

There is considerable art associated with placing the exploring electrode. If the electrode tip is not adjacent to contracting muscle fibers, the sound of the action potential is muffled and electrode adjustment is required. The same is true for detecting fibrillation potentials (see below).

If the nerve cell in the spinal cord or the nerve fiber supplying a muscle is damaged, the muscle cannot be contracted voluntarily or reflexly (by tapping the tendon) and is therefore paralyzed. In the absence of therapeutic intervention and with the passage of time, the nerve beyond the damaged site dies and the muscle fibers start to degenerate. In about 2 1/2 to 3 weeks in humans, the individual muscle fibers start to contract and relax spontaneously and randomly, producing short-duration, randomly occurring action potentials called

fibrillation potentials [Fig. 113.18(F)], which are displayed on the oscilloscope screen and heard as clicks in the loudspeaker. Although there is electrical activity, the muscle develops no net force. The fibrillation potentials persist as long as there are viable muscle fibers. In such a denervated muscle, insertion of the needle electrode elicits a vigorous train of short-duration insertion potentials that resemble fibrillation potentials with a frequency of about 1 to 10 per second. If the damaged ends of the nerve are brought together surgically, the central end of the nerve will start to grow slowly and reinnervate the muscle. Gradually the fibrillation potentials disappear, although the muscle is still not able to be contracted. Long before there is visible evidence of muscle contraction, if the subject is presented with the EMG display and asked to contract the affected muscle, primitive muscle action potentials can be elicited. With the passage of time, the fibrillation potentials disappear and there is electrical silence at rest and primitive (nascent) motor-unit activity occurs with voluntary contraction. Later when reinnervation is complete, only normal motor-unit potentials are present with voluntary contraction and electrical silence at rest.

The EMG is also used to diagnose some degenerative muscle and related nerve disorders. *Myotonia* is a degenerative disease of muscle fibers in which the muscle relaxes poorly. Insertion of the needle electrode elicits an intense burst of insertion potentials that sound like a thunderstorm in the loudspeaker. A similar response is obtained by tapping the muscle. When relaxation does occur, there is electrical silence. Voluntary contraction produces normal action potentials along with shorter-duration action potentials from the diseased muscle fibers.

Myasthenia gravis is a disease in which there is impairment of transmission of acetylcholine across the myoneural junctions to the muscle fibers. As a result, muscle contraction cannot be sustained. Because the muscle fibers are normally innervated, there are no fibrillation potentials. With voluntary contraction, normal action potentials occur, and if the disease is severe, the action potentials decrease in frequency as the force of contraction decreases and soon sustained muscle contraction cannot be maintained.

Muscular dystrophy is a degenerative disease of muscle fibers in which there is **atrophy** of some fibers, swelling in others, and an increase in sarcolemmal and connective tissue with the deposition of fat. Insertion of the needle electrode elicits a vigorous burst of short-duration, high-frequency action potentials. Typically at rest there are no fibrillation potentials. With voluntary contraction, the action potentials are short in duration, high in frequency, and produce a whirring sound in the loudspeaker. As fatigue supervenes, the frequency and amplitude decrease.

The reader who is interested in obtaining more information on EMG will find it in books by Cohen and Brumlik [1969] and Marinacci [1955]. Both contain a wealth of clinical information.

Instrumentation

As yet there is no American National Standard for EMG, although steps are being taken in this direction. As shown in Fig. 113.18, the EMG is displayed in two ways: (1) visually with an oscilloscope and (2) aurally with a loudspeaker. Both are needed to enable acquisition and analysis of the EMG.

Buchtal et al. [1954] stated that the principal frequency components for the human EMG require a bandwidth of 1 Hz to 10 kHz. It has been found that a time constant of about 50 ms is satisfactory, which corresponds to a low-frequency –3-db point of 3 Hz. For needle electrodes with a tip diameter of 0.1 mm or larger, the input impedance (one side to ground) should not be lower than that of a 500-kΩ resistor in parallel with less than 25-pF capacitance.

Smaller-area electrodes require a higher input impedance [Geddes et al., 1967]. The cable used to connect the needle electrode to the amplifier should not add more than 250 pF to the input capacitance. The common-mode rejection ratio (CMRR) should be in excess of 5000.

Electroencephalography (EEG)

The electrical activity of the brain can be recorded with electrodes on the scalp, on the exposed brain, or inserted into the brain. The latter method is used in research studies. When recordings are made with brain-surface (cortex) electrodes, the recording is called an electrocorticogram (ECoG). With scalp electrodes, the recording is designated an electroencephalogram (EEG) that is displayed by direct-inking pens using a chart speed of 3 cm/s. Typically 8 to 12 channels are recorded simultaneously.

Although the brain consists of about 10^{14} neurons, the EEG reflects the electrical activity of the outer layer, the cortex, which is the seat of consciousness. The type of electrical activity depends on the location of the electrodes and the level of alertness. The frequency and amplitude are profoundly affected by alertness, drowsiness, sleep, hyperventilation, anesthesia, the presence of a tumor, head injury, and epilepsy. The clinical correlation between cerebral disorders and the voltage and frequency spectra is well ahead of the physiological explanations for the waveforms.

Recording Technique

Both bipolar [Fig. 113.19(A)] and monopolar [Fig. 113.19(B)] techniques are used. With monopolar recording, one side of each amplifier is connected to a reference electrode, usually on the earlobe. With bipolar recording, the amplifiers are connected between pairs of scalp electrodes in a regular order. With both types of recording, one-half the number of channels is connected to electrodes on the opposite side of the head. In this way, the electrical activity from homologous areas of the brain can be compared at a glance.

With the bipolar method illustrated in Fig. 113.19(A), abnormal activity located under electrode X will be revealed as a phase reversal in adjacent channels. With monopolar recording using the earlobe reference electrode [Fig. 113.19(B)] the abnormal activity under electrode X will be largest in the channel connected to that electrode and smaller in the adjacent channels.

In clinical EEG, 21 electrodes are applied to the scalp in what is known as the 10-20 system. This array was established by the International Federation of EEG Societies in 1958. The 10-20 system employs skull landmarks as reference points to locate the electrodes.

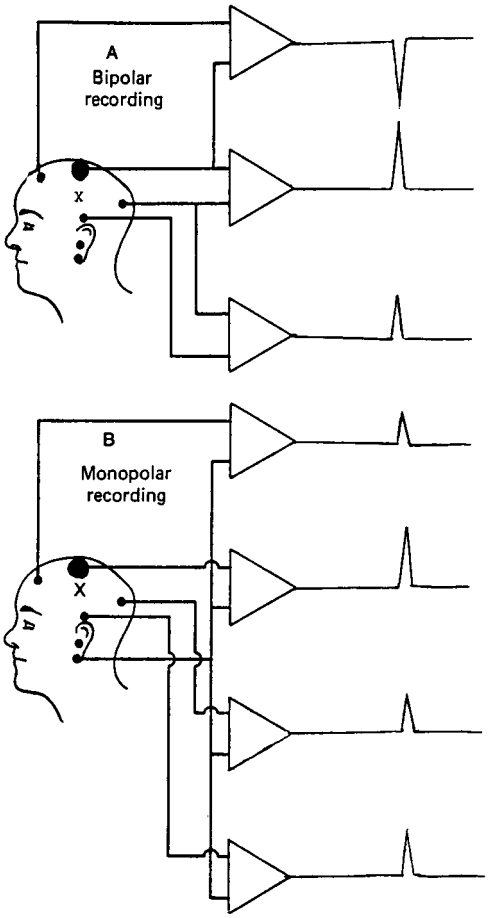

FIGURE 113.19 Methods of recording the EEG. (A) The bipolar and (B) the monopolar method. Note how abnormal activity under electrode X is revealed by the two techniques.

The Normal EEG

In the normal resting adult, the EEG displays a fluctuating electrical activity having a dominant frequency of about 10 Hz and an amplitude in the range of 20 to 200 μV. This activity is called the *alpha rhythm* and ranges in frequency from about 8 to 12 Hz, being most prominent in the **occipital** and **parietal** areas. It may occupy as much as half the record. The alpha rhythm increases in frequency with age from birth and attains its adult form by about 15 to 20 years. The alpha rhythm is most prominent when the eyes are closed and in the absence of concentration. Opening the eyes, engaging in patterned vision, or performing such cerebral activity as mental arithmetic diminishes or abolishes the alpha rhythm. Figure 113.20 presents a good example of this phenomenon.

Although the alpha rhythm is the most prominent electrical activity, other frequencies are present. For example, there is a considerable amount of low-voltage, high-frequency (beta) activity ranging from 18 to 30 Hz. It is usually found in the frontal part of the brain. However, the normal electroencephalogram contains waves of various frequencies (in the range of 1 to 60 Hz) and amplitudes, depending on the cerebral state. To establish communication among electroencephalographers, a terminology has been developed to describe waveforms and their frequencies; Table 113.1 presents a glossary of these terms.

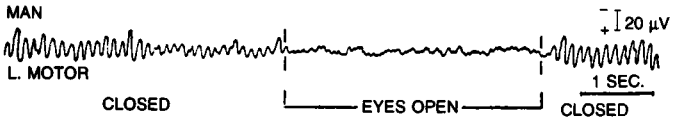

FIGURE 113.20 The EEG of a relaxed human subject with eyes closed and open. Note that the record is dominated with alpha rhythm (8–12 Hz) when the eyes are closed. (*Source:* Derived in part from M.A.B. Brazier, *The Electrical Activity of the Nervous System,* London: Sir Isaac Pitman & Sons, Ltd., 1951. With permission.)

TABLE 113.1 EEG Waveform Terminology

Waveform	Frequency, Hz	Conditions
Alpha	8–12	Parietal-occipital, associated with the awake and relaxed subject, prominent with eyes closed.
Beta	18–30	More evident in frontal-parietal leads, seen best when alpha is blocked.
Delta	1–3.5	Associated with normal sleep and present in children less than 1 year old, also seen in organic brain disease.
Theta	4–7	Parietal-temporal, prominent in children 2 to 5 years old.
Sleep spindle (sigma)	12–14	Waxing and waning of a sinusoidal-like wave having the envelope that resembles a spindle, seen during sleep.
Lambda	Transient	Visually evoked, low-amplitude, occipital wave, resulting from recognition of a new visual image.
Spike and wave	ca. 3	Sharp wave (spike) followed by rounded wave associated with petit mal epilepsy.

Drowsiness and sleep affect the normal EEG profoundly. Figure 113.21 illustrates the typical changes that occur as a subject goes to sleep. With drowsiness, the higher-frequency activity which is associated with alertness or excitement and the alpha rhythm that dominates the waking record in the relaxed state are replaced by a characteristic cyclic sequence of changes which constitute the focus of a new specialty devoted to sleep physiology, in which the EEG is used to identify different stages of sleep.

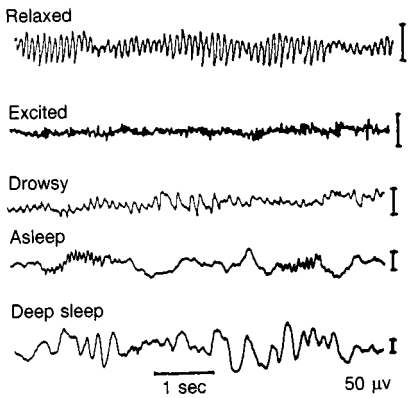

FIGURE 113.21 The EEG of a subject going to sleep.

Rapid, deep breathing (hyperventilation) at a rate of 30 per minute for about 3 min reduces the partial pressure of carbon dioxide in the blood which reduces cerebral blood flow. A typical EEG response consists of large-amplitude, bilaterally synchronous, frontally prominent waves with a frequency of 4 to 7 per second. The frequency usually decreases with increasing hyperventilation. The lack of bilateral symmetry is an indication of abnormality.

Anesthesia dramatically alters the EEG in a manner that depends on the type and amount of anesthetic given. Despite differences among anesthetic agents, some important similarities accompany anesthesia. The first change is replacement of the alpha rhythm with low-voltage high-frequency activity that accompanies the analgesia and delirium stages. Thus the EEG resembles that of an alert or excited subject, although the subject is not appropriately responsive to stimuli; usually the response is excessive and/or inappropriate. From this point on, the type of EEG obtained with deepening anesthesia depends on the type of anesthetic. However, when a deeper level of anesthesia is reached, the EEG waveform becomes less dependent on the type of anesthetic. Large-amplitude low-frequency waves begin to dominate the record, and with deepening anesthesia their frequency is reduced and they begin to occur intermittently. With very (dangerously) deep anesthesia, the record is flat (i.e., isoelectric). Complicating interpretation of the EEG in anesthesia are the effects of **hypoxia, hypercapnia**, and hypoglycemia, all of which mimic deep anesthesia.

Clinical EEG

The EEG plays a valuable role in identifying intracranial pathology. The clinical utility relies on recognition of patterns of frequency, voltage, and waveform. Localization of abnormal areas is provided by the multiple scalp electrodes and recording channels.

The EEG has its greatest value as an aid in the diagnosis and differentiation of the many types of epilepsy, a condition in which groups of neurons in the brain become hyperexcitable and, depending on their location, produce sensory, motor, and/or **autonomic** manifestations. The epilepsies associated with cortical lesions are often detected by the scalp EEG. The EEG in epileptics is usually abnormal between, as well as during, attacks. The EEG provides information on the location of the area (or areas) of abnormal neuronal activity.

Petit mal epilepsy is characterized by a transient loss (few to 20 s) of conscious thought, although motor activity may continue. Often there are eye movements and blinking. The EEG shows a characteristic 3 per second spike-and-wave pattern [Fig. 113.22(A)]. Psychomotor epilepsy is characterized by sensory hallucinations and abnormal thoughts, often with stereotyped behavior. During the attack, the subject is stuporous and the EEG [Fig. 113.22(B)] has a characteristic pattern. Jacksonian, or motor, epilepsy starts in a specific area of the motor cortex and is preceded by an aura, a characteristic sensation perceived by the subject. The convulsion starts with localized muscle twitching that often starts in the face, hand, arm, then spreads over the entire body as a generalized convulsion; Fig. 113.22(C) shows the onset of a convulsion. Consciousness is lost during and for a short time after the fit. The EEG provides information on the origin of the abnormal discharge in the motor cortex. Grand mal epilepsy is characterized by a contraction all the muscles (tonic phase), then jerking (clonic phase). Consciousness is lost, and the subject is in a coma for some time following the attack. The EEG [Fig. 113.22(D)] shows high-voltage, high-frequency waves that progress over the entire cortex.

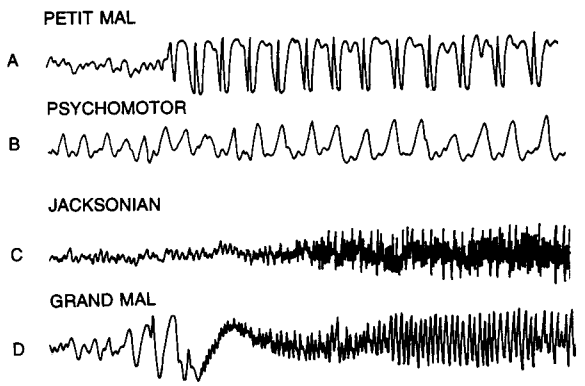

FIGURE 113.22 EEG waveforms in epilepsy: (A) petit mal, (B) psychomotor, (C) Jacksonian, and (D) grand mal.

Traumatic epilepsy results from injury to the brain. It is believed that contraction of scar tissue acts as a stimulus to adjacent nerve cells which discharge rhythmically, the excitation spreading to a grand mal convulsion. The EEG provides information on the origin of the abnormal discharge.

Tumors are associated with low-frequency (delta) waves. However, other intracranial lesions also produce slow waves. Although the EEG can identify the location of tumors, usually it cannot differentiate between brain injury, infection, and vascular accident, all of which produce low-frequency waves. Interpretation of the EEG always includes other clinical information.

For those wishing to delve deeper into EEG, additional information can be found in most textbooks of medical physiology. The three-volume *Atlas of EEG,* authored by Gibbs and Gibbs [1952], contains a wealth of information on EEG in epilepsy and includes a vast array of eight-channel EEGs.

Instrumentation

The American EEG Society [1986] published guidelines for the performance of EEG machines. The guidelines recommended a minimum of eight channels. Chlorided silver disks or gold electrodes, adhered to the scalp with collodion, are recommended; needle electrodes are not. A chart speed of 3 cm/s is standard, and a recording sensitivity of 5 to 10 μV/mm is recommended. The frequency response extends from 1 to 70 Hz for the –3-dB points.

Evoked Potentials

With the availability of signal averaging using a digital computer, it is possible to investigate the integrity of the neural pathways from peripheral sense organs to the cortex by using appropriate stimuli (e.g., clicks, light

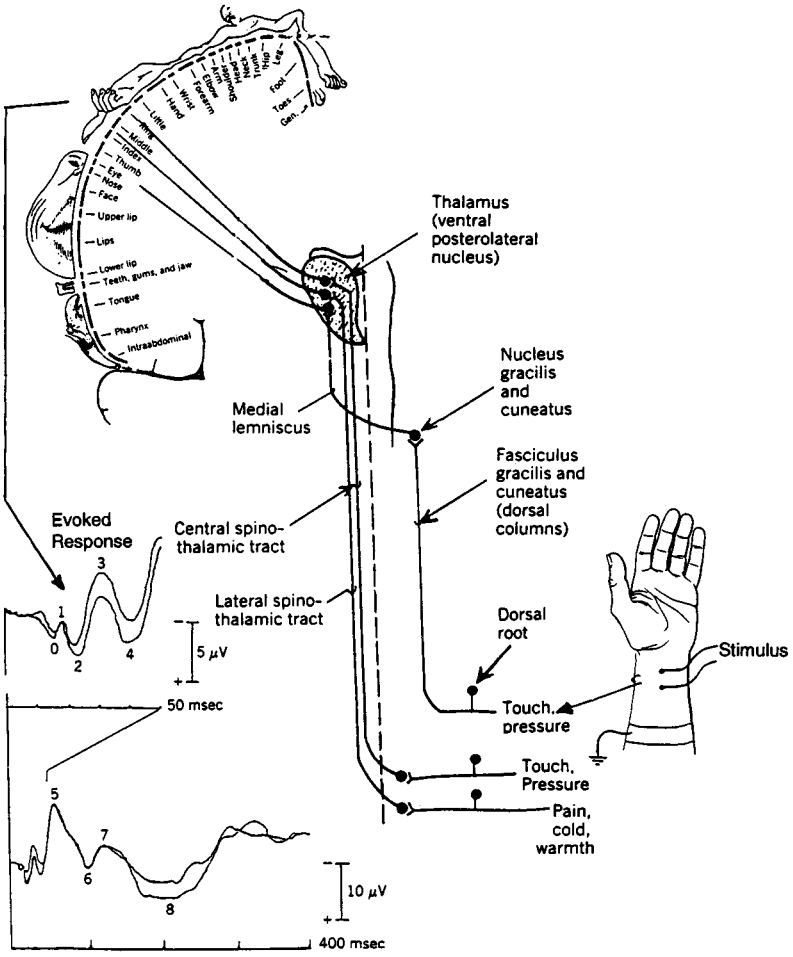

FIGURE 113.23 Pathways from the peripheral sense organs to the cortex and the topographical distribution of sensation along the cortex with Penfield's homunculus. Also shown are the stimulating electrodes on the wrist and the SSEPs recorded from the contralateral cortex. (*Source:* SSEPs redrawn from T. W. Picton, "Evoked cortical potentials, how? what? and why?," *Am. J. EEG Technol.*, vol. 14, no. 4, pp. 9–44, 1974. With permission.)

flashes, or current pulses). Usually the stimulus consists of a few hundred to about 1000 pulses, averaged to produce the somatosensory-evoked potential (SSEP). Likewise, it is possible to evaluate the integrity of the neural pathways from the motor cortex to peripheral muscles by applying multiple short-duration current pulses to scalp electrodes and recording nerve and/or muscle action potentials with skin-surface electrodes. Such recordings are called motor-evoked potentials (MEPs). With both SSEPs and MEPs, the largest responses appear on the opposite side of the body from the stimulus.

Because the responses are in digital form, they can be written out in hard-copy format. With SSEPs, the response consists of many waves occurring at various times after the stimulus. To permit close examination of the various waveforms, several displays are presented, each with a different time axis. Figure 113.23 presents a sketch of the neural pathways from the periphery to the cortex, showing the topographic distribution of sensation along the cortex using the homunculus created by Penfield, described in detail in 1968. Also shown in Fig. 113.23 is a typical SSEP obtained by stimulating the median nerve with skin-surface electrodes connected to an isolated (i.e., not grounded) stimulator output circuit. Note the remarkably low amplitude of the responses that were obtained by averaging the response to 240 stimuli. Note also that the first display showed the responses from 0 to 50 ms and the second display presented the responses in the 0- to 400-ms interval.

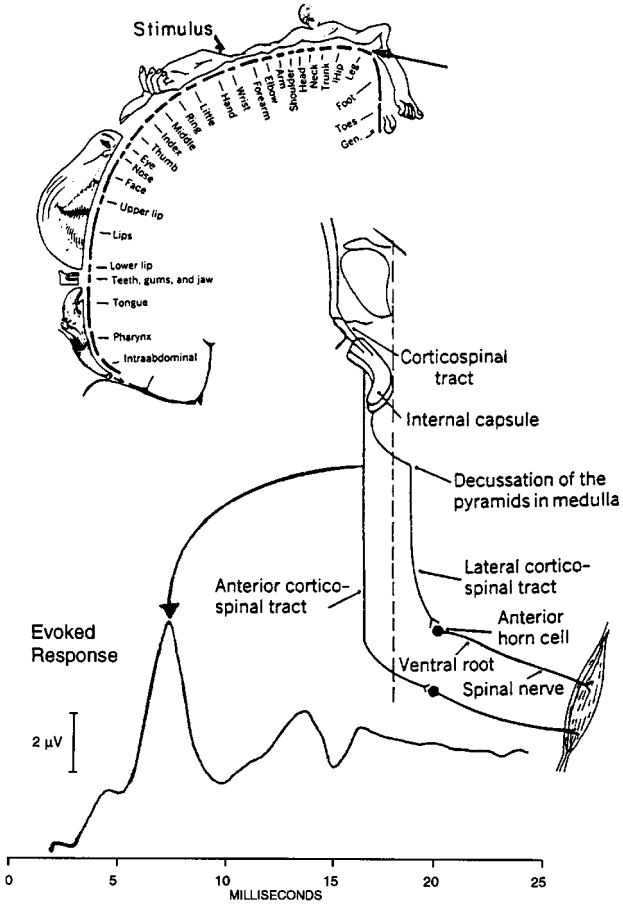

FIGURE 113.24 Neural motor pathways from the cortex to a typical muscle. The motor areas are represented by Penfield's homunculus. A train of 240 stimuli delivered to the motor cortex provided the average MEP detected with electrodes placed over the spinal column in this patient to whom a muscle paralytic drug was given; therefore the MEPs are from the spinal cord. (*Source:* Redrawn from Levy et al., 1984, and Penfield and Rasmussen, 1968.)

Figure 113.24 shows the motor pathways from the motor cortex to a typical muscle. The cortical motor areas are represented by Penfield's homunculus. A train of 250 stimuli were applied between electrodes on the scalp and in the mouth. The motor-evoked potentials were recorded with skin-surface electrodes over the spinal column. The MEP of a patient in whom the muscles were paralyzed is also shown in Fig. 113.24. Because the muscles were paralyzed, the MEPs shown in the figure represent action potentials in the spinal cord. Note the prominent peaks at 7 and 14 ms. These peaks provide information on the path taken by the nerve impulses initiated in the motor cortex.

Although there is no ANSI standard for evoked-potential recording, the American EEG Society [1986] published guidelines for equipment performance and recording techniques. This information should be consulted by those contemplating entry into this field.

Magnetic (Eddy-Current) Stimulation

When scalp electrodes are used to stimulate the brain, there is considerable skin sensation under the electrodes owing to the high perimeter current density [Overmeyer et al. 1979]. It has been found that sufficient eddy current can be induced in living tissue by discharging an energy-storage capacitor into an air-cored coil placed on the skin. This mode of stimulation is almost without skin sensation; by some it is called "ouchless stimulation"

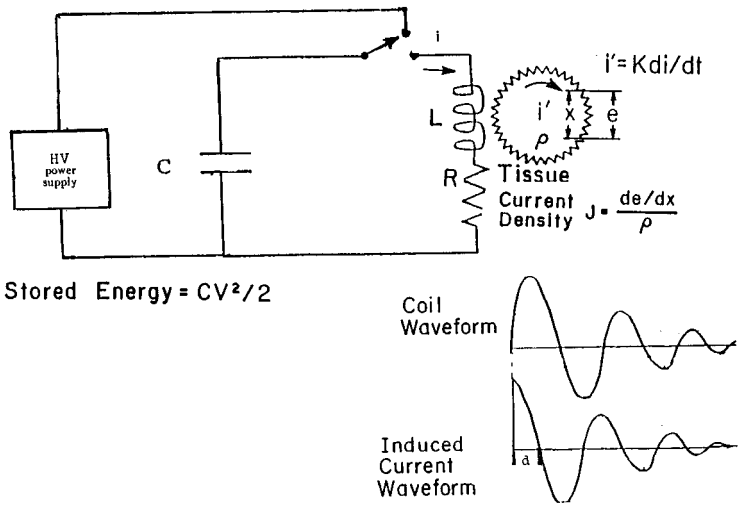

FIGURE 113.25 Simplest type of magnetic (eddy-current) stimulator and coil and induced current waveforms.

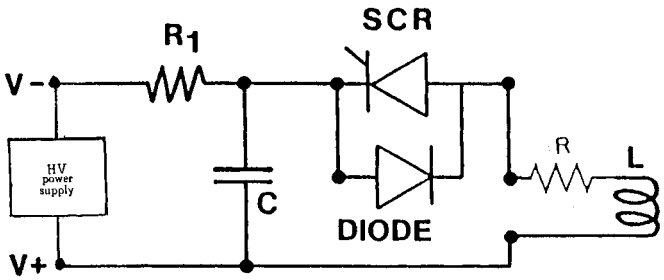

FIGURE 113.26 Magnetic (eddy-current) stimulator that recovers energy stored in the magnetic field.

and it can be used to stimulate the brain, peripheral nerves, and the heart. The parameters associated with eddy-current stimulation are kiloamperes, Teslas/sec, milliohms, microhenries, microseconds, and low damping. Because the forces on the coil conductors are very large, special care is required in fabricating such coils.

Stimulators

With **magnetic** (eddy-current) **stimulation**, three circuits and two coil geometries are used. The simplest circuit is illustrated in Fig. 113.25, which shows a capacitor (C) being discharged into the stimulating coil (L). The induced current (i) is proportional to the rate of change (di/dt) of the coil current (i). The resistance (R) in the entire circuit is low and the coil current is an underdamped sinusoid. The tissue is stimulated by the induced current density $J = k(de/dx)/\rho$, where de/dx is the induced voltage gradient, ρ is the tissue resistivity, and k is a constant that depends on coil geometry and target distance. The effective stimulus duration (d) is from the onset of the induced current to the first zero crossing as shown in Fig. 113.25. Typical durations (d) range from 20 to 200 μsec. When the damping is low, the multiple pulses of induced current can elicit responses, providing the period is longer than the refractory period of the tissue being stimulated. Note that the capacitor voltage falls to zero and the capacitor must be recharged to deliver the next stimulus.

The second type of eddy-current stimulator employs energy recovery and is shown in Fig. 113.26. The charged capacitor (C) is discharged into the stimulating coil (L) by triggering a silicon-controlled rectifier (SCR). By placing a diode across the SCR as shown, some of the energy stored in the magnetic field can be recovered to recharge the capacitor. In this way, the power supply need only deliver a modest amount of current to restore the charge on the capacitor.

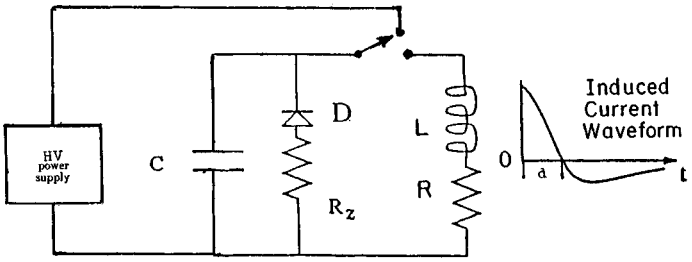

FIGURE 113.27 Method of using a diode (D) and current-limiting resistor (Rz) to avoid reverse polarity on the energy-storage capacitor (C).

With the circuits shown in Figs. 113.25 and 113.26, it is necessary to use non-polarized capacitors. When a long-duration pulse is desired, it is more practical to employ electrolytic capacitors because of their high energy storage per unit of weight. When employing electrolytic capacitors, it is necessary to prevent reverse charging. To achieve this goal, a diode (D) and a series current-limiting resistor (Rz) are placed across the capacitor, as shown in Fig. 113.27. The resulting induced current waveform is shown on the right.

Stimulating Coils

Air-cored coils are used because all known ferromagnetic materials saturate at the high flux densities used with eddy-current stimulation. Two types of coils are used: (1) annular and (2) coplanar, sometimes called figure eight, osculating, or butterfly. Most coils are annular in shape and the radius is chosen on the basis of the distance to the target tissue to be stimulated.

Nyenhuis et al. [1991] analyzed the factors pertaining to the optimum design of such annular coils and calculated the magnetic-field energy and ohmic heating. They found that the magnetic field energy exhibits a broad minimum when the coil outer radius is between two and five times the target distance. Ohmic heating in the coil decreases as the radius of the coil increases. Increasing annular width results in a small reduction in field energy and coil heating; thin coils (small height) reduce the field energy but increase heating. A reasonable compromise between efficiency and coil size is a coil with an outer diameter that is twice the distance between the coil surface and the underlying target tissue to be stimulated and whose height and annular width are 0.2 and 0.6 that of the mean radius, respectively.

The induced electric field gradient (*de/dx*) is maximum at the perimeter of an annular coil. Weissman and Epstein [1992] plotted the electric field induced in a saline volume conductor due to an annular coil; Fig. 113.28a is the result which shows a maximum over the perimeter of the coil.

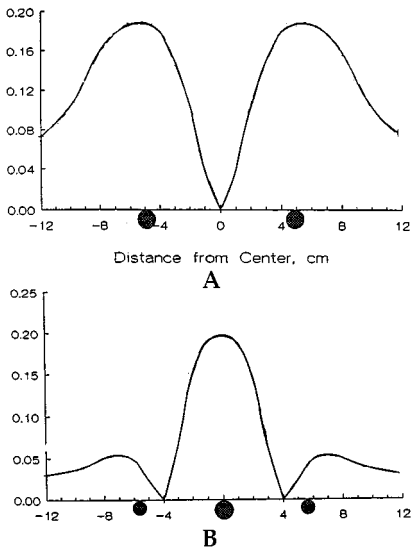

FIGURE 113.28 Induced electric field (de/dx) for a single annular coil (a) and for a pair of coplanar annular coils (b). (Redrawn from [Weissman and Epstein 1992]).

Eddy-current stimulation is very energy inefficient when compared to direct tissue stimulation with electrodes. To improve the efficiency, investigators have sought strategies to concentrate (focus) the magnetic field without the use of ferromagnetic material. Ueno et al. [1988] introduced what they called the figure-of-eight coil of the type shown in Fig. 113.29 in which the current in the conductors where the two coils touch is in the same direction, thereby concentrating the field. Note that the currents in the two coils are in opposite directions; hence the magnetic fields (B1, B2) are in opposite directions. With this coil configuration and current direction, the induced electric field is a maximum over the site where the coils touch, as shown in Fig. 113.28b. Although the use of a pair of coils increases the efficiency of magnetic stimulation, it makes coil placement more critical.

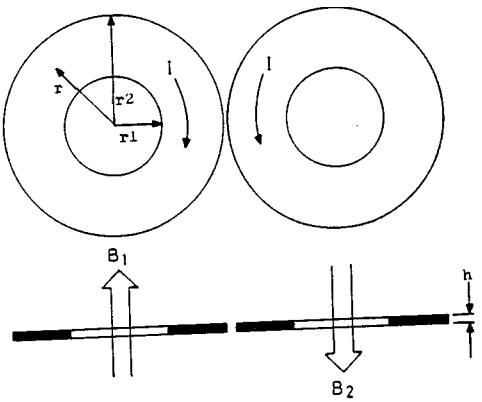

FIGURE 113.29 Current (I) and magnetic field (B) direction in the coplanar (figure-of-eight) coil.

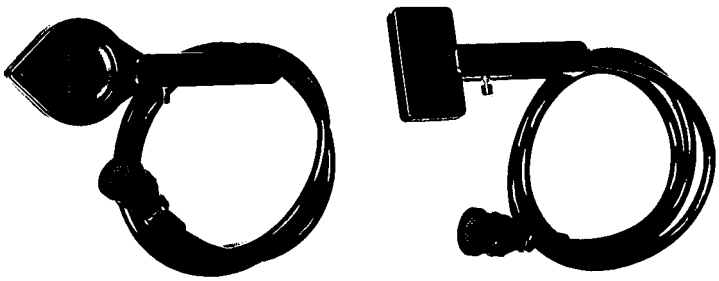

FIGURE 113.30 Commercially available coils for magnetic (eddy-current) stimulation. (Courtesy of Cadwell, Kennewick, WA 99336).

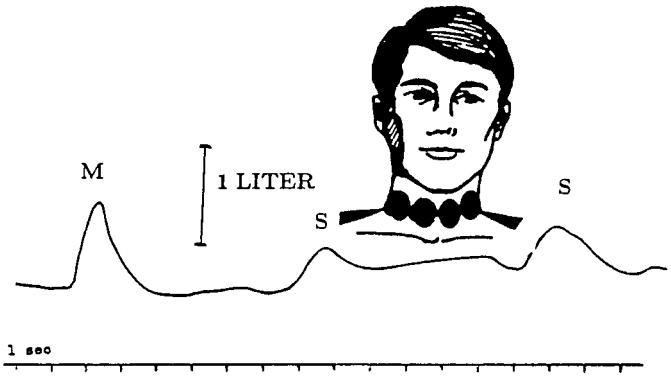

FIGURE 113.31 Magnetically induced inspiration (M) produced by a train of eddy-current stimuli applied to both phrenic nerves with two pairs of coplanar coils at the base of the neck. S = spontaneous breaths.

Figure 113.30a shows a commercially available annular coil and Fig. 113.30b shows the figure-of-eight (Butterfly™) coil. These coils can be used for stimulating the brain or peripheral nerve. Proper location of the coil with respect to the target tissue is essentials (see Fig. 113.28 for locations of maximum *de/dx*).

Many types of excitable tissue can be stimulated by eddy current. Geddes et al. [1991] investigated its use to produce inspiration in humans by stimulating both phrenic nerves at the base of the neck. The phrenic nerves cause the diaphragm to contract, thereby producing inspiration. By using two series-connected pairs of coplanar coils, each pair angled at 150°, current pulses at 25/sec were delivered from a 50 μF capacitor charged

to 1200 volts, the magnetically induced inspiration (M) of 900 mL shown in Fig. 113.31 was produced. To make this record, the subject first hyperventilated, then stopped breathing and the magnetic stimulator was turned on for about 1 sec. The breaths marked S are spontaneous breaths with a volume of 400 mL.

Cardiac muscle has been stimulated to contract with single pulses of eddy current. The first to achieve this feat was Bourland et al. [1990] who applied a coplanar coil to the left chest of an anesthetized dog. Blood pressure and the electrocardiogram were recorded and the heart was stopped by right vagal stimulation, during which time a pulse of current was delivered to the coplanar coils and a ventricular contraction was produced, showing an inverted QRS wave in the ECG and a blood-pressure pulse.

That it is difficult to stimulate the heart with a pulse of eddy current can be assessed by the parameters of the stimulator used by Bourland et al. [1990] which employed a 682 μF capacitor, charged to 9900 volts, and discharged into the 220 μH coplanar coil assembly. The peak current was 17,000 amps and the stored energy was 33,421 joules. The duration of the induced current pulse was 690 μsec. This stimulator was used by Mouchawar et al. [1992], who reported mean current and energy thresholds for cardiac stimulation in the range of 9200 amps and 11,850 joules.

From the foregoing it is clear that the ventricles can be caused to contract with pulses of eddy current. However, if it is desired to pace at 60/min. (1/sec), the power needed is 11.85 kilowatts, hardly a practical value for domestic or hospital use.

Summary and Conclusion

Although eddy-current stimulation of excitable tissue is quite popular now, the first report was by d'Arsonval [1896], who reported seeing bright flashes in the visual field (phosphenes) when the head was placed in a coil carrying 30 amperes of 42 Hz current (see Geddes translation [1991]). It is now known that stimulation of the retinal receptors in the eye produces such phosphenes.

Magnetic stimulation is largely used to excite nerve cells in the brain and spinal cord. The diagnostic information is contained in the time between the stimulus and the response (action potential). The same measure is used when peripheral nerve is stimulated.

A major advantage of magnetic stimulation is that no electrodes are required and the skin need not be exposed to apply the stimuli. However, the main advantage is that the skin sensation is very mild. A major disadvantage is the high energy needed to induce sufficient eddy current density to achieve stimulation. When repetitive pulses are required, the power drawn by the magnetic stimulator may require a 60-Hz AC energy source of 220 or 440 volts. Moreover, with repetitive stimulation, coil heating becomes a problem. The availability of magnetically permeable materials that saturate at several orders of magnitude above presently available materials would be of benefit to the field of magnetic (eddy-current) stimulation.

This section has focused only on the three most prominent bioelectric events, those of the heart, skeletal muscle, and brain. The eye, ear, sweat glands, and many types of smooth muscle produce action potentials that are used for their diagnostic value, as well as being the subject of on-going research. The reader interested in delving deeper into this field can find such information in a book by Geddes and Baker [1989].

Defining Terms

Atrophy: Wasting of cells deprived of nourishment.
Autonomic: That part of the nervous system which controls the internal organs.
Ectopic beat: A heart beat that originates from other than the normal site.
Hypocapnia: A condition of reduced carbon dioxide in the blood.
Hypoxia: A reduced amount of oxygen.
Magnetic stimulation: Eddy current stimulation.
Metabolic process: The method by which cells use oxygen and produce carbon dioxide and heat.
Myocardial infarction: A heart attack in which a region of the heart muscle is deprived of blood and soon dies.
Occipital: The back of the brain.
Parietal: The side of the brain.

113.3 Application of Electric and Magnetic Fields in Bone and Soft Tissue Repair

C. Polk

History

As early as 1962 in the United States [Bassett and Becker, 1963], and even earlier—1957—in Japan [Fukada and Yasuda, 1957] it was shown that electric potential differences appear across both living and dead bone subjected to mechanical stress. Bassett and Becker observed that these stress-generated electrical signals decayed very slowly in comparison with similarly initiated signals in piezoelectric crystals and concluded [Bassett and Becker, 1963] that piezoelectric phenomena "while probably present, were not the sole cause of these potentials." Later analysis and experiments established that the observed signals were primarily due to ion displacement within the porous regions and multiple fluid-filled channels present in all bone. The early observations already suggested that direct application of an externally generated voltage might have an effect on bone development. This was shown to be the case by Bassett et al. [1964] who found that a dc current of the order of 1 μA (corresponding to a current density of approximately 0.01 A/m^2) produced massive osteogenesis near the cathode when electrodes were implanted into the femur of living dogs.

Having shown that application of a dc electric field to nonexcitable, connective tissue cells can produce effects similar to those elicited by mechanical stress, Bassett and his co-workers realized that clinical exploitation of these phenomena would require surgical implantation of electrodes with attendant danger of infection. They proceeded therefore to explore whether noninvasive, inductive coupling that gave waveforms similar to those endogenously produced by mechanical stress could lead to beneficial bone development. In 1974 they reported favorable results obtained with pulsed electromagnetic fields on dogs [Bassett et al., 1964]. Signals of this type have generally been identified as **PEMF** (pulsed electromagnetic field) in the orthopedics/electrical stimulation community for the last 20 years and have been applied successfully in a large number of cases for the repair of **nonunions** [Grossling et al., 1992]. In Germany relatively large-amplitude, low-frequency (<20 Hz) sinusoidal magnetic fields have been used for both bone repair and wound healing [Kraus, 1984].

Although the noninvasive PEMF treatment for nonunions (fractures that fail to heal) became—at least in the United States—the most widely used clinical application of subradio frequency fields, several investigators pursued the application of dc electric fields through implanted electrodes and the application of higher-frequency currents through electrode contacts placed on the skin surface to enhance bone repair [Brighton et al., 1979]. At the same time mostly laboratory investigations, *in vitro* and on animals, explored the application of all three modalities—PEMF, implanted dc electrodes, and higher-frequency coupling through skin electrodes—to produce blood vessel regeneration (**angiogenesis**), soft tissue healing, nerve repair or regeneration, and regression of tumors. Claimed to be useful in edema and pain management and for acceleration of wound repair is pulsed radio frequency (PRF), mainly the diathermy frequency of 27.12 MHz assigned by the FCC, at an average power level that should usually produce only very moderate tissue heating [Kloth and Ziskin, 1996; Markov, 1995]. Motivated by the suggested clinical applications, a large number of basic science investigations have been initiated, and are continuing today, with the object of understanding the mechanisms through which low-intensity electric and magnetic fields affect cells and living tissue. Some of these are reviewed briefly in the subsection Mechanisms and Dosimetry.

Devices for Bone and Cartilage Repair

In the United States medical devices are approved for clinical use only after it has been shown to the satisfaction of the U.S. Food and Drug Administration (FDA) that they are not only safe, but also effective. This is a much more stringent requirement than the mere demonstration of safety demanded presently in most European countries (although some EEC countries are considering moving toward approval criteria that are similar to those used in the United States). The United States laws governing the sale of medical devices for clinical use are also much more restrictive than the controls over implementation of new surgical procedures that involve only informal medical peer review. Even organized multi-patient clinical trials require not more than approval

TABLE 113.2 Electrical Bone Growth Stimulators Approved by the U.S. FDA as of July 1, 1996

Manufacturer FDA "PMA" Number* FDA Docket Number	Device	Indications	Technology	Approved	Text References

by a local hospital-based institutional review board. The FDA Office of Device Evaluation does approve some new devices, after careful review, for clearly limited clinical trials. However, information on such limited, temporary approval is not made available. Table 113.2 therefore shows only those devices which are presently (July 1, 1996) approved and does not include experimental systems which may be undergoing currently limited clinical trials. Some of the latter are discussed further on, based only on information furnished by manufacturers or available from the published medical literature.

The devices listed in Table 113.2 are approved for one of three applications: the treatment of *nonunions* (fractures that have failed to heal after standard treatment involving setting and stabilization with casts), congenital **pseudoarthroses** [Bassett, 1984], and promotion of spinal fusion. Although many animal experiments (and possibly a few human trials, especially in Europe) have evaluated the application of electric or magnetic fields for acceleration of fresh fracture healing and for reversal of osteoporosis, no devices are currently approved in the United States for these purposes.

Classified by electrical and mechanical characteristics, the devices in Table 113.2 are either:

1. Noninvasive:
   a. Generating time-varying magnetic fields applied by coils to the affected body part (A, B, C, D, and H).
   b. Generating time-varying electric fields applied through skin-surface electrodes (**capacitively coupled**) (E).
2. Invasive: dc applied from an implanted battery (F, G).

A signal typical for some PEMF (A, C, D) devices is illustrated in Fig. 113.32. Part A shows the magnetic field versus time and Part B the corresponding electric field induced into a linear, isotropic medium. The waveform shown on Part B can be measured by a probe coil having a sufficiently large number of turns. The frequency spectrum of the electric field is shown in Fig. 113.33. Signals used by the different manufacturers are protected by patents, and FDA approval is for particular signal parameters within specified tolerances on time and amplitude. The pseudoarthrosis signal used by Electrobiology, Inc. (EBI) (B in Table 113.2) consists of single pulses repeated at a rate of 72 pps rather than the pulse bursts illustrated in Figs. 113.32 and 113.33. Each magnetic field pulse increases from zero to 3.5 mT in 380 μs and then decreases slowly to zero in approximately 4.5 ms. The signals that are now in use have evolved considerably from those employed in the initial studies, and some have little resemblance to the endogenous electrical signals elicited by mechanical stress.

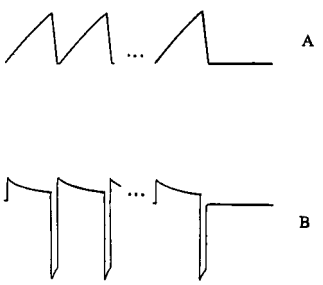

FIGURE 113.32 A typical PEMF signal (signal A of Table 113.2). (A) Magnetic field versus time. (B) Electric field ($\propto \partial B/\partial t$) versus time. Signal consists of 15 pulse bursts per second. Each burst is 4.5 ms long and contains 20 pulses. In each pulse the magnetic field increases from 0 to approx. 2 mT during 200 μs, decreases to 0 again during 23 μs, and is equal to 0 for 2 μs before the next 225-μs sequence begins.

The PEMF signals employed by the various manufacturers in the United States and Europe can have several different pulse shapes, rise and decay times, pulse widths, pulse repetition rates, and amplitudes. Since it has been shown (see Mechanisms and Dosimetry) that all these variables can have a profound effect on the biological action of a particular signal, it is essential that reports on effectiveness or lack of effectiveness of PEMF give an exact description of the signal which was used. Unfortunately the medical literature is replete with examples where this information is either incomplete or completely absent. Details of shape, orientation, and location of the application coil or coils are also important, since these parameters, together with pulse amplitude and shape, determine the nature of the magnetic and electric field at the location of the injured tissue. If the amplitude of the axially directed magnetic flux density B is constant over some region of radius R within the cross section of a circular cylinder, the induced electric field is

$$\bar{E} = -\left(\frac{\partial B}{\partial t}\right)\frac{r}{2}\,\hat{\phi} \tag{113.17}$$

provided the material of the cylinder is electrically homogeneous and isotropic. In Eq. (113.17) $r < R$ is the distance from the center of the cylinder and $\hat{\phi}$ is a unit vector in the circumferential direction. For magnetic fields varying sinusoidally as $B_0 \cos \omega t$, $\bar{E} = \omega B_0(r/2) \sin \omega t\, \hat{\phi}$. Since most biological objects are neither homogeneous nor isotropic, the actual induced electric fields at various points in the tissue or cells may deviate substantially from the values given by Eq. (113.17) [Polk and Song, 1990; Van Amelsfort, 1990]. Equation (113.17) is useful only for *estimating* the spatial *average* value of the induced electric field, which depends in the bone environment on the point-to-point variation of the electrical properties of muscle, fat, cartilage, periosteum (outer bone membrane), and bone marrow.

Current pulses of the PEMF devices are usually produced by the discharge of capacitor banks controlled by a timing network. The applicator coil cannot be interchanged among different devices because its inductance and resistance are a part of the discharge network. While earlier bone growth stimulators employed Helmholtz coil-pair arrangements, most present devices have single coils which can be custom-shaped for particular limbs. Figure 113.34 shows a typical system sold by EBI. This unit is driven by rechargeable batteries, and the control unit (shown in Fig. 113.34) includes an elapsed-time clock to measure the total time of stimulation of the fracture being treated. A typical treatment time can be between 2 and 10 h/day over a period of 6 months.

The so-called capacitively coupled device (E in Table 113.2) generates a continuous sine wave at a frequency of 60 kHz. The total current through the skin contains a not negligible conduction component since conductive contact is made between the applicator electrodes and the skin that represents a "leaky" capacitor. Electric fields produced at the tissue level by this device are between 1 and 50 V/m [Pollack and Brighton, 1989]. These levels

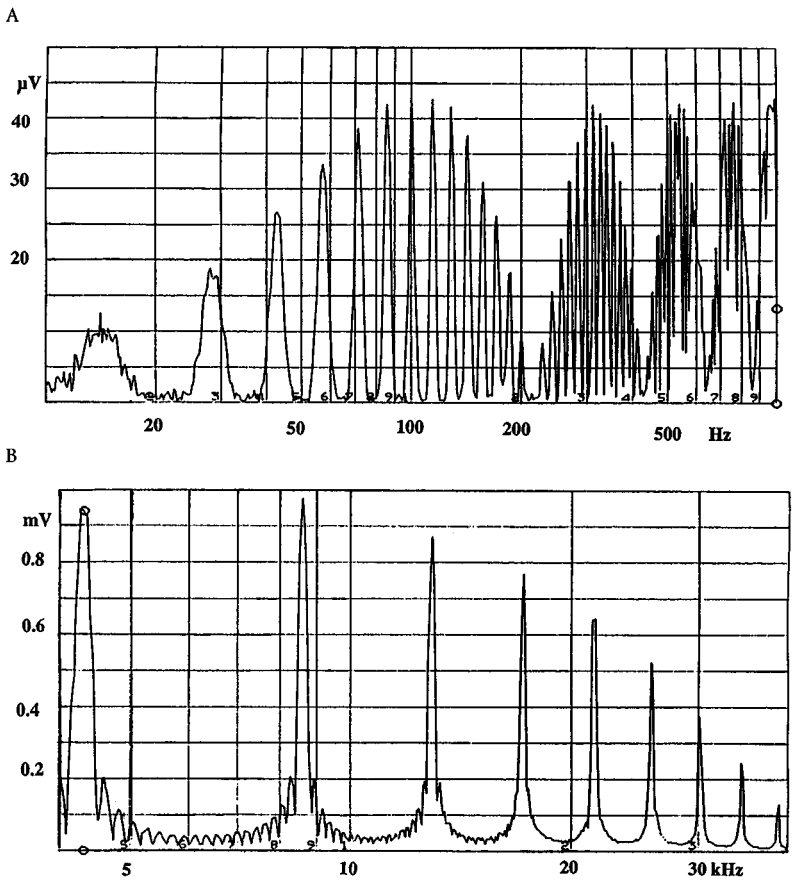

FIGURE 113.33 Electric field spectrum $|E(\omega)|$ of signal in Fig. 113.32 as measured by the output from an air-core coil (0.6 cm mean diameter, 65 turns). (A) 10 Hz to 1 kHz (50 μV full scale); (B) 4 to 40 kHz (1 mV full scale).

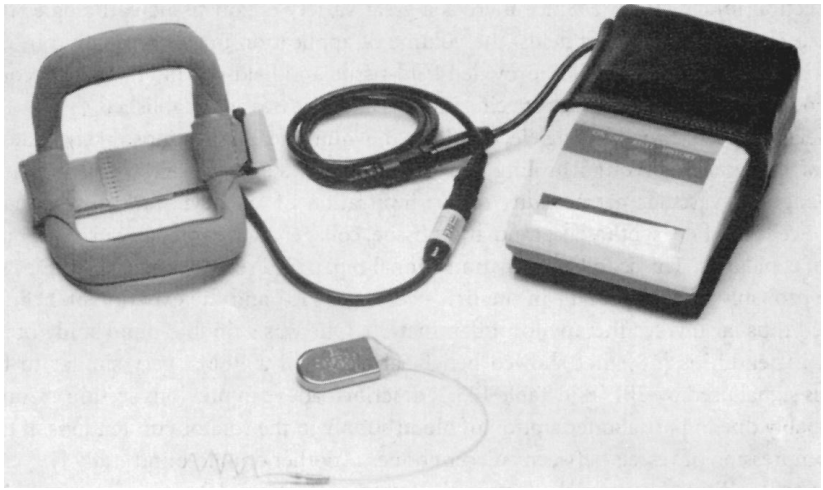

FIGURE 113.34 PEMF applicator and control unit and implantable dc stimulating device (battery with wire electrode) manufactured by Electrobiology, Inc. (systems A and G of Table 113.2). (Photograph courtesy of Electrobiology, Inc.)

are very much higher than the average amplitude of the electric fields produced in tissue by PEMF devices and also higher than the instantaneous peak values produced by some of the PEMF systems. It is interesting to note here that *in vitro* experiments with truly capacitively coupled fields showed enhancement of bone cell proliferation at very much lower amplitude (10^{-5} V/m) when the frequency of the continuous sine wave was 10 Hz rather than 60 kHz [Fitzsimmons et al., 1986]. The most recent addition to FDA approved non-invasive systems (H in Table 113.2) employs a sinusoidally time varying 76.6 Hz, 40 μT field superimposed on a DC field of 20 μT. Possible reasons for using this AC/DC "resonance" combination are discussed in the Mechanisms and Dosimetry section.

An invasive (implantable) dc device (F, G in Table 113.2) is also shown on Fig. 113.34. The small (approximately $4 \times 2 \times 0.5$ cm) titanium case contains a long-life battery that is connected to it. The case acts as the anode, and two (shown) or four titanium wires act as the cathode. The amplitude of the continuous current is between 5 μA (for some spinal fusion applications) and 20 μA (for nonunion of long bones). The cathodes are placed at the location where bone growth is to be enhanced, for example, at the vertebrae that are surgically fused, while the case is placed in a convenient location at some distance from the bone. Treatment details and success rates, in comparison with surgical procedures without use of dc stimulation, are discussed in the medical literature [Nerubay et al., 1986].

Although not used or approved for use in the United States, the German "Magnetodyn" system [Kraus, 1984] is interesting not only because it employs sinusoidal magnetic fields between 2 and 20 Hz but also because it relies on metallic implants that are used for fixation of the bone to act as the "secondary" of a "transformer" whose primary is the external applicator. Sometimes an implanted pickup coil ("secondary") is connected to fixation bars or to screws (electrically insulated from the bars) on each side of a pseudoarthrotic gap. With this system, peak electric fields of 40 V/m and current densities of 5 A/m^2 have been produced in the gap.

A PEMF signal (similar to B in Table 113.2) has also been used experimentally to arrest **osteonecrosis** (bone death possibly due to vascular impairment or toxic agents) of the femoral head. Application for 8 h/day over 12 months gave substantially better results than the standard surgical (decompression) treatment [Aaron and Steinberg, 1991].

Soft Tissue Repair and Nerve Regeneration

No electric or magnetic system to aid nerve regeneration or soft tissue repair is approved by the FDA at the present time for nonexperimental therapy. However, considerable animal and *in vitro* experimentation in this country and abroad suggests the clinical usefulness of electric currents for soft tissue repair [Canaday and Lee, 1991] and possibly also to enhance repair of nerve fibers that have sustained crush or transsection injury [Ito and Bassett, 1983; Siskin et al., 1990]. Since there is a great variety of soft tissue pathologies that could respond to electric or magnetic fields, the volume of application in this area could in the future become larger than in orthopedics, provided field-tissue and field-cell interactions become better understood and clinical benefits for specific injuries and diseases are established. A pulsed radio frequency (PRF) device sold in the U.S. by Electropharmacology, Inc., of Pompano Beach, FL, produces 27.12 MHz pulses of 65 microsecond duration. Pulse repetition rates can be selected between 80 and 600 pps and peak output power is adjustable between 174 and 363 watts. Thus, the highest possible average power delivered into the 9-in. diameter inductive applicator is 14.16 watt. ("Inductive" applicator means that the applicator is designed to make the ratio of electric to magnetic field in its immediate vicinity much less than the 377 Ω wave impedance of free space; thus, the magnetic field is maximized in the "near field" region). Coupling to living tissue at 27.12 MHz without impedance matching is rather poor [Polk, 1995]. If it is assumed that only 20% of the 14.16 W average power is absorbed by the tissue, application for the recommened treatment period of 30 min would correspond to an energy transfer of 1.2 kilocalories. If the mass of the local region to which this energy is applied is of the order of 2 kg, this would correspond to a temperature increase of 0.6°C in the absence of cooling by blood circulation or convection. In any case, although "the PRF modality was originally reported as a non-thermal biophysical treatment of infections" [Ginsberg, 1934; Markov and Pilla, 1995], the device is likely to produce at least moderate tissue heating when applied with maximum output settings. The Electropharmacology "MRT Softpulse Model 912" is marketed for clinical use in the U.S. under FDA rules which permit continued sale of

devices that are substantially equivalent to older equipment (in this case "Diapulse") in use before the enactment of present FDA rules.

Beneficial effects of time-varying electric fields in wound healing are most likely related to promotion of *angiogenesis*. Wound healing consists of several stages, the first being inflammation, when changes in vascular permeability occur; infiltration of leucocytes and macrophages takes place; and cells migrate, synthesize granulation tissue, collagen, and proteoglycans, and initiate formation of capillaries. This is followed by transitional repair and remodeling phases. Electrical currents are probably only important in the first two stages [Canaday and Lee, 1991] and the experimental clinical trials performed thus far involve therapy for inflammation. One was a double-blind study of persistent rotator cuff tendinitis [Binder et al., 1984] that showed beneficial effects of a PEMF very similar to the pseudarthrosis signal used by EBI (B in Table 113.2, described above in previous section). Cuff tendinitis is probably due to partial interruption of blood supply to the rotator cuff tendons of the shoulder by compression of vessels between adjacent bones. Another double-blind study [Ieran et al., 1990] employing a PEMF signal indicated beneficial effects in the treatment of skin ulcers.

Other clinical trials [Bentall, 1986] and animal experiments involved irradiation of wounds with pulsed high and very high frequencies between 3 and 44 MHz, at power levels from 73 μW to 15 W, employing pulse widths between 65 and 100 μs and pulse repetition frequencies between 200 Hz and 1 kHz. A commonly used animal model for wound healing is the McFarlane skin flap involving partial excision of a rectangular skin section on the back of the rat. Survival of the flap depends mainly on blood supply, with vascularization of the skin flap being an indirect measure of treatment success. The EBI signal shown on Fig. 113.33 (A in Table 113.2) is reported to have decreased skin flap necrosis when exposure was for 6 h/day for 3 days, while exposure for 18 h on the first day after injury had no observable effect [Luce and Bryant, 1986]. Exposure with a triangular, symmetric and almost continuous magnetic field (18-ms triangular pulse, followed by 2-ms pause) at a frequency of 50 Hz (8-mT peak to peak value) produced a significant increase in wound contraction in rats (in comparison with controls) who were exposed to the field for 30 min immediately after surgery and for the same period thereafter every 12 h. In an effort to determine what type of signals are most beneficial for the acceleration of wound healing, skin flap necrosis was observed under exposure to sinusoidal magnetic fields at constant $\partial B/\partial t$ of 0.5 T/s using frequencies of 20, 72, and 500-Hz [Sisken and Herbst, 1990]. While signals at 20 and 72 Hz significantly decreased necrosis after 7 days, the 500-Hz signal was ineffective.

Very soon after some types of bone injury and pathology were first treated with PEMF, the effects of PEMF on peripheral nerve regeneration became subjects of investigation. Improved neural function that appeared as an unintended "side effect" in the clinical treatment of nonunions led Kort et al. [1980] to a systematic investigation of PEMF effects on neural regeneration in rats. Other investigators employed other animal models and also compared PEMF with direct current as agents for neural regeneration. More recent work [Siskin et al., 1990] employed a PEMF signal consisting of 20-ms pulses at a repetition rate of 2 pulses per second with **exponential rise** and **decay times** of, respectively, 0.5 and 1 ms. Amplitudes were 0.3 mT for experiments with crush lesions of the sciatic nerve in rats and 0.05 mT for stimulation *in vitro* of neurite outgrowth in dorsal root ganglia. Estimated values for the mean induced electric field pulses were 5 mV/m in the animal experiments and 0.7 mV/m in the 60-mm-diameter culture dishes of the *in vitro* work. Stimulation for 2 h per day of the *in vitro* cultures produced approximately 50% enhancement of neurite outgrowth in comparison with controls after 2 days.

The *in vivo* experiments using the 0.3-mT pulse produced "a 22% increase in the rate of regeneration relative to controls" as measured by a standardized test of reflex response. A very interesting observation was that animals exposed to the 0.3-mT field for 4 h/day for 7 days *prior* to the crush injury, who received *no* treatment after injury, responded similarly to those treated postinjury. Analysis of extracts from sciatic nerve segments after sacrifice of the animals showed that treatment with PEMF changed the molecular weight distribution of synthesized polypeptides.

A report on a very limited (13 subjects) clinical trial [Ellis, 1987] of spinal nerve stimulation in para- and quadriplegics employing pulsed electric current introduced by needle electrodes produced "encouraging results" in terms of increased sensory perception and motor function. The signal obtained from a Chinese multipurpose therapy apparatus was described as follows: "The pulsed-wave generator produced a biphasic wave form of 2 ms duration with an initial slow positive deflection followed by an 80-μs rise time to its maximal negative deflection and subsequent asymptotic decay. This wave shape was pulsed in ramped bursts of 200 pulses per

second for 1.5 s with 0.75 s rest time before the next ramped burst. Peak-to-peak voltages of approximately 30 V were common, and current flow was on the order of 1 mA."

The diathermy frequency of 27.12 MHz used for PRF therapy has also been employed, with ELF amplitude modulation, to induce sleep. At least one double blind study [Reite et al., 1994] has shown the effectiveness for this purpose of "Low Energy Emission Therapy" (LEET). In this application, the 27.12 MHz carrier is periodically amplitude modulated with a 42.7 Hz sine wave for 3 s and then interrupted for 1 s during a 15-min treatment period. The signal is applied by means of an electrically conducting mouthpiece in direct contact with the oral mucosa. "The estimated local SAR ("specific absorption rate") is less than 10 W/kg in the oral mucosa and 0.1 to 100 mW/kg in brain tissue, with high SAR values only in the conduction area between tongue and mouth piece" [Reite et al., 1994]. The RF electrical field strength in the fluid surrounding neurons is calculated to be in the range of the ELF electrical fields generated by normal brain activity. No information is available on either positive or negative long term health effects, if any, due to treatment with this device.

Mechanisms and Dosimetry

Although clinical effects of electric currents, PEMF, and sinusoidal electric and magnetic fields are well documented, and although some specific biochemical results have been obtained *in vitro* or in animal experiments that suggest explanation of bone and soft tissue effects, the mechanism of field-to-cell or field-to-protein transduction is presently not understood. As a consequence, optimum "dose" (what field magnitude for how long) and optimum waveshapes or frequencies for particular clinical applications are unknown, and dosimetry relies largely on trial and error methods.

It is known that electrokinetic or **streaming potentials** rather than piezoelectricity make the principal contribution to electric potentials generated by mechanically stressed bone [Gross and Williams, 1982; Lavine and Grodzinsky, 1987]. Thus potential differences appear when mechanical loading displaces fluid that contains "counterions" which normally reside opposite ions fixed to cell or intercellular matrix surfaces. These potentials are likely to play a role in intercellular signaling and in bone as well as cartilage and soft tissue development. While the original intent of electrical bone therapy was to simply mimic endogenously generated fields, a much wider range of signals was found to be clinically useful. Furthermore it was found later that some weak ionic currents ($\approx 5 \times 10^{-2}$ A/m^2) [Levine and Grodzinsky, 1987] appear endogenously without mechanical stress and that extremely weak sinusoidal electric fields can produce profound effects on cells *in vitro*. For example, both cell number and phosphotase activity in monolayers of osteoblasts (bone forming cells) was significantly affected by a magnetically induced (1.8 mT) 30 Hz electrical field estimated to be 0.6 mV/m [McLeod et al., 1993]. Sinusoidally alternating fields between 50 and 300 Hz, as small as 0.6 mV/m, were shown to affect ATP splitting activity of the membrane enzyme Na, K-ATPase [Blank and Soo, 1992]. A 60-Hz magnetic field of 1.2 NT was reported to inhibit the oncostatic action of the hormone melatonin on estrogen positive human breast cancer cells ("MCF-7") *in vitro* [Liburdy et al.]. Calcium metabolism was affected significantly in mitogen-activated lymphocytes by a 4-μT, 16-Hz magnetic field (in the presence of a 23.4-μT dc magnetic field) that induced an average electric field of about (2) 10^{-5} V/m [Yost and Liburdy, 1992]. Sinusoidal 15-Hz magnetic fields at the 0.5-mT level, giving an estimated mean electric field in the affected tissue of less than 10^{-3} V/m, significantly affected cartilage development in immature rats [Ciombor et al., 1991].

It is likely that the mechanism involved when direct currents are directly applied to injured bone (or other tissue) differs from the transduction sequence which must be acting when low-intensity alternating fields are employed. Even the 5-μA continuous current of the implantable devices (F, G in Table 113.2) when distributed over an (estimated) 5-cm^2 area corresponds to a steady electric field of 1 V/m in bone tissue of 0.01-S/m conductivity. This value is large compared with the average (but not the peak) fields induced by some PEMF devices and very large compared with the average fields induced in tissue by other PEMF devices [Rubin et al., 1989] or the mV/m ELF sinusoidal fields that affect cartilage and bone development [Ciomber et al., 1991; McLeod and Rubin, 1990]. For example, if one assumes a mean radius of 4 cm for a particular human bone fracture, one obtains from Eq. (113.17) the electric field values between 0.18 and 1.74 V/m shown on Table 113.3. When electrodes are implanted, as for the dc signals, chemical reactions at the electrodes may play a role in bone and cartilage formation. For example, the reaction at a stainless steel cathode involves consumption of dissolved oxygen and increase in local pH [Lavine and Grodzinsky, 1987].

TABLE 113.3 Electric Field (V/m) Induced by PEMF Signals at Radius of 4 cm into Electrically Uniform Medium; B Perpendicular to Plane in which Radius is Defined

	Positive Peak	Negative Peak	Average of Rectified Signal
PEMF device A (Table 113.2, Figs. 113.25, 113.26)	0.2	1.74	0.024
PEMF device B (Table 113.2)	0.18	0.015	$(1.4)\ 10^{-4}$

If the mechanism of interaction were to involve simple charge transfer by the applied electric field, it would be useful to compare the magnitude of the charge transferred by a single pulse, within a specified volume, with the random charge fluctuation due to thermal excitation during the pulse. An equation due to Einstein [1956] gives the mean square value of the charge fluctuation δq in terms of Boltzmann's constant k, the absolute temperature T, the conductance G of the current-carrying region, and the observation time t:

$$<\delta q^2> = 2GkTt \tag{113.18}$$

It is then easy to find the electric field required to transfer during time t a charge at least equal to δq over the length of a conductance of volume v (v = length × cross-sectional area) and uniform conductivity σ. One obtains

$$E \geq \left(\frac{2kT}{v\sigma t}\right)^{1/2} \tag{113.19}$$

Assuming bone tissue with conductivity 10^{-2} S/m, a physiological temperature of 37°C, an interaction volume of 10^{-14} m^3 (about equal to the volume of a cell with 10-μm radius), and an observation time of 200 μs equal to the duration of the positive pulse of device A, one obtains from Eq. (113.19) a minimum value of 6.6 V/m. Unless v and σ can be assumed to be much larger, this would indicate that the values given in Table 113.3 should be below thermal noise. If one considers, instead of charge transfer over some as yet unknown path, the voltage induced by the applied field across the membrane of the idealized spherical cell with 10-μm radius, and compares the energy of the repetitive pulse below 100 Hz—where biological action apparently occurs [McLead and Rubin, 1990]—with the thermal noise voltage given by

$$<V_n^2> = 4kTR\ (\Delta f) \tag{113.20}$$

where (Δf) is the bandwidth and R the transmembrane resistance, one finds again that the electric field due to the PEMF devices would be at best only marginally above thermal noise. The induced electric fields of the *in vitro* experiments mentioned above are also clearly below thermal noise.

It is possible to obtain somewhat better signal-to-noise ratios if one considers either larger interaction volumes (assuming electrical phenomena involving the intercell volume), elongated cells, or cells connected by gap junctions [Polk, 1992]. It is also important to note that in the extremely inhomogeneous biological system, the actual electric field at a particular point can be considerably larger or smaller than its spatial average. Nevertheless very substantial improvement of signal-to-noise ratios would require signal averaging and limitation of bandwidth by resonance phenomena [Weaver and Astumian, 1990; Adair, 1991]. Weak steady and time-varying magnetic fields could also be detected above thermal equilibrium noise by ferrimagnetic single-domain particles that have recently been detected in the human brain [Kirschvink et al., 1992]. In addition, the applicability of Eqs. (113.18) and (113.20) is questionable, because living systems are often far from thermal equilibrium. For example, only mitogen-stimulated—and not quiescent—lymphocytes are affected by weak electric and magnetic fields [Yost and Liburdy, 1992]. Also, some molecules inside cells may at times be involved in systematic and guided rather than random thermal motion [Hoffman, 1992].

Several attempts have been made to construct theoretical models that would explain narrowband resonances in biological systems. Experiments to confirm or reject these hypotheses have thus far given ambiguous results.

One theory assumes that ion transfer through cell membranes is affected by cyclotron resonance [Liboff and McLeod, 1988]. It is based on the fact that the cyclotron resonance frequency $\omega_c = 2\pi f_c$ of several physiologically important ions of charge Q and mass m, in the steady magnetic field B_0 of the earth, falls into the ELF range:

$$\omega_c = \frac{QB_0}{m} \tag{113.21}$$

For example, the Ca^{2+} ion has a resonance frequency of 16 Hz in a dc field of 21.0 μT. However, it has been pointed out that the collision frequency in the physiological environment would be very much larger than the cyclotron frequency and would therefore wipe out any resonance motion, that the usually hydrated ions would have a total mass larger than m, and that the energy gain caused by an alternating field of frequency ω_c (as in a cyclotron) would require an orbital radius larger by many orders of magnitude than a typical cell radius [Polk, 1986]. Another theory postulates that the binding of Ca^{2+} to the protein calmodulin (ubiquitous in all vertebrates) should be affected by magnetic fields at frequencies ω_c and ω_c/n (where n is an integer) [Lednev, 1991; Adair, 1992]. This mechanism involves Zeeman splitting at ELF, due to B_0, of infrared vibrational modes that are chemically or thermally excited.

Some experiments showing a resonant cell response at the frequency given by (113.21) could not be replicated, while others were performed only over a very narrow frequency range. Nevertheless, apparently successful attempts have been made to stimulate bone cell proliferation at these field combinations [Fitzsimmons *et al.,* 1991]. The "Orthologic" device (H in Table 113.2) employs an experimentally determined and apparently clinically useful combination of a 20 μT static field with a 40 μT 76.6 Hz alternating field. This frequency lies near the fifth harmonic (76.2 Hz) of the calcium ion resonance frequency given by Eq. (103.21); however, since the device is always used in the presence of the geomagnetic field of the order of 50 μT, the total DC magnetic field parallel to the 76.6 Hz field can have any value between 0 and 70 μT which would essentially eliminate unique determination of a 76.6 Hz "resonance".

To clarify the sequence of biological events that occurs when PEMF signals are applied to developing bone, the following *in vivo* experiment was performed [Aaron et al., 1989]. Twenty-five milligrams of demineralized rat bone matrix in powdered form was implanted along the thoracic musculature of immature rats. This powder recruits cells from the surrounding tissue leading to formation of cartilage within 6 to 10 days; thereafter progressive calcification occurs, leading to formation of fibrous particles by days 12 to 14 and formation of a small bone ("ossicle"). These developments were compared in a large number of paired rats, with equal numbers unexposed and exposed (8 h/day) to the PEMF signal illustrated on Figs. 113.32 and 113.33 (A in Table 113.2). Estimates of the mean electric fields in the exposed tissues give values equal to about one-fourth of those listed on line 1 in Table 113.3. Chemical and histological analysis of ossicles harvested from animals, sacrificed on every second day, showed that exposure to this PEMF signal at the applied level significantly increased both rate and quantity of cartilage formation and enhanced maturation of the subsequent bone. The experimenters concluded that field exposure either enhanced recruitment or proliferation of cartilage precursor cells, increased differentiation of precursor to cartilage cells, or accelerated maturation of cartilage cells.

Getting even closer to fundamental events at the cellular level, both signals A and B (Table 113.2) were used to expose cultured mouse bone cells and mouse skin fibroblasts, as well as explanted mouse pineal cells in organ culture [Luben, 1993]. In all three cases various chemical procedures were employed to examine "beta-adrenergic **receptors**." These are cell surface protein strands that span the cell membrane and emerge from it; they mediate cell response to agents such as epinephrine (= adrenaline) or norepinephrine through so-called **G proteins** which act essentially as molecular amplifiers at the interior surface of the cell. Other G proteins are involved in the response to growth factors. The arrangement of the exposure coils and culture plates was such as to give mean electric fields equal to about one-tenth of the values shown in Table 113.3. Exposures were of 4 h duration. Specific types of G proteins were stimulated by the A signal, others by the B signal. The total number of binding sites on the cells was not affected, but the affinity of the receptors for specific hormones was changed, suggesting a change in receptor conformation. It is interesting to compare this work, which employed peak values of the order of 10^{-2} V/m and time average values not greater than 2 (10^{-3}) V/m, with

other *in vitro* experiments showing effects on enzyme activity at the cell surface by ELF sinusoidal fields between 5 (10^{-4}) V/m and 30 V/m [Blank, 1992]. Related experiments at higher field intensities and the theory of field effects on catalysis [Robertson and Astumian, 1991] also show that electric field action at the exterior of the cell surface can be translated via enzyme-catalyzed chemical reactions to the cell interior.

Defining Terms

Angiogenesis: Formation of blood vessels.

ATPase: An enzyme that converts adenosine triphosphate (ATP) to adenosine diphosphate (ADP); energy released thereby spontaneously in hydrolysis is used to drive an energy requiring reaction such as one producing muscle movement.

Capacitively coupled fields or currents: Fields applied to the affected limb by electrodes touching the skin (the current from the electrodes has both displacement and conduction components).

Chondrogenesis: Formation of cartilage.

Exponential decay time t_d: *Defined by* $B = B_0 \exp(-t/t_d)$

Exponential rise time t_r: *Defined by* $B = B_0[1 - \exp(-t/t_r)]$

G protein: Guanine nucleotide-binding protein, serves to couple receptors to cell membrane-associated enzymes for purposes of signal transduction.

LEET: Low energy emission therapy.

Nonunion: Bone fracture that fails to heal within normally expected period with conventional management.

Osteoblast: A bone-forming cell.

Osteonecrosis: Death of bone within a living vertebrate.

PEMF: Pulsed electromagnetic field.

PRF: Pulsed radio frequency.

Pseudoarthrosis: Formation of a pseudojoint in a broken or not completely formed bone (usually of congenital origin).

Receptor: Large protein molecule that usually protrudes from, and is embedded in, the membrane of a eucaryotic (nucleus-containing) cell. The part of the receptor outside the cell binds only to selected molecules that then cause chemical activity of proteins bound to the end at the cell interior. Activity continues as long as a single molecule (for example, of a hormone, the first "messenger") is bound to the exterior part, and many molecules of a "second messenger" are released on the cell interior.

Streaming potential: Potential difference produced when liquid pressure displaces "counterions" that are normally held by electrostatic forces near ions of the opposite sign embedded in the surface of a stationary material.

114.1 Introduction

Any instrumentation system can be described as having three fundamental components: a sensor, a signal processor, and a display and/or storage device. Although all these components of the instrumentation system are important, the sensor serves a special function in that it interfaces the instrument with the system being measured. In the case of biomedical instrumentation a **biomedical sensor** (which in some cases may be referred to as a biosensor) is the interface between the electronic instrument and the biologic system. There are some general concerns that are very important for any sensor in an instrumentation system regarding its ability to effectively carry out the interface function. These concerns are especially important for biomedical sensors, since the sensor can affect the system being measured and the system can affect the sensor performance. Sensors must be designed so that they minimize their interaction with the biologic host. It is important that the presence of the sensor does not affect the variable being measured in the vicinity of the sensor as a result of the interaction between the sensor and the biologic system. If the sensor is placed in a living organism, that organism will probably recognize the sensor as a foreign body and react to it. This may in fact change the quantity being sensed in the vicinity of the sensor so that the measurement reflects the foreign body reaction rather than a central characteristic of the host.

Similarly, the biological system can affect the performance of the sensor. The foreign body reaction might cause the host to attempt to break down the materials of the sensor as a way to remove it. This may, in fact, degrade the sensor package so that the sensor can no longer perform in an adequate manner. Even if the foreign body reaction is not strong enough to affect the measurement, just the fact that the sensor is placed in a warm, aqueous environment may cause water to eventually invade the package and degrade the function of the sensor.

Finally, as will be described below, sensors that are implanted in the body are not accessible for calibration. Thus, such sensors must be extremely stable so that frequent calibrations are not necessary.

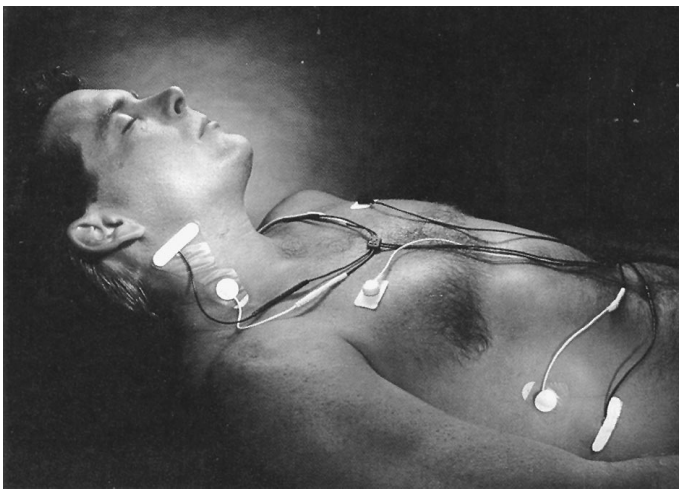
Biomedical sensors can be classified according to how they are used with respect to the biologic system. Table 114.1 shows that sensors can range from noninvasive to invasive as far as the biologic host is concerned. The most noninvasive of biomedical sensors do not even contact the biological system being measured. Sensors of radiant heat or sound energy coming from an organism are examples of noncontacting sensors. **Noninvasive sensors** can also be placed on the body surface. Skin surface thermometers, biopotential electrodes, and strain gauges placed on the skin are examples of noninvasive sensors. Indwelling sensors are those which can be placed into a natural body cavity that communicates with the outside. These are sometimes referred to as minimally invasive sensors and include such familiar sensors as oral-rectal thermometers, intrauterine pressure transducers, and stomach pH sensors. The most invasive sensors are those that need to be surgically placed and that

Cardiac Monitor

The basic method of assessing heart function is thermodilution, a procedure that involves insertion of a catheter into the pulmonary artery and is demanding in terms of cost, equipment, and skilled personnel time. For monitoring astronauts in flight, NASA needed a system that was non-invasive and considerably less complex.

In 1965, Johnson Space Center contracted with the University of Minnesota to explore the then-known but little-developed concept of impedance cardiography (ICG) as a means of astronaut monitoring. A five-year program led to the development of the Minnesota Impedance Cardiograph (MIC), an electronic system for measuring impedance changes across the thorax that would be reflective of cardiac function and blood flow from the heart's left ventricle into the aorta. ICG clearly had broad potential for hospital applications but further development and refinement was needed. A number of research institutions and medical equipment companies launched development of their own ICGs, using MIC technology as a departure point. Among them were Renaissance Technologies, Inc., Newtown, Pennsylvania, and Drexel University of Philadelphia, who jointly developed the IQ System. The system provides a simple, repeatable, non-invasive way of assessing cardiac function at dramatically reduced cost. The IQ System is in wide use in hospital intensive care units, emergency rooms, operating rooms, and laboratories in the U.S. and abroad.

IQ has two basic elements: the non-invasive, disposable patient interface known as IQ-Connect and the touch screen monitor, which calculates and displays cardiac output values and trends. The hardware design of the original MIC was retained but IQ has advanced automated software that features the signal processing technology known as TFD (Time Frequency Distribution). TFD provides three-dimensional distribution of the hemodynamic signals being measured, enabling visualization of the changes in power, frequency, and time. This clinically proven capability allows IQ to measure all cardiac events without using estimation techniques required in some earlier systems. (Courtesy of National Aeronautics and Space Administration.)



The IQ-Connect interface electronically measures impedance changes across the thorax to reflect heart function. (Photo courtesy of National Aeronautics and Space Administration.)

involve some tissue damage associated with their installation. For example, a needle electrode for picking up electromyographic signals directly from muscles; a blood pressure sensor placed in an artery, vein, or the heart itself; or a blood flow transducer positioned on a major artery are all examples of invasive sensors.

We can also classify sensors in terms of the quantities that they measure. **Physical sensors** are used in measuring physical quantities such as displacement, pressure, and flow, while **chemical sensors** are used to determine the concentration of chemical substances within the host. A subgroup of the chemical sensors that are concerned with sensing the presence and the concentration of biochemical materials in the host are known as **bioanalytical sensors**, or sometimes they are referred to as biosensors.

In the following paragraphs we will look at each type of sensor and present some examples as well as describe some of the important issues surrounding these types of sensors.

114.2 Physical Sensors

Physical variables associated with biomedical systems are measured by a group of sensors known as physical sensors. A list of typical variables that are frequently measured by these devices is given in Table 114.2. These quantities are similar to physical quantities measured by sensors for nonbiomedical applications, and the devices used for biomedical and nonbiomedical sensing are, therefore, quite similar. There are, however, two principal exceptions: pressure and flow sensors.

The measurement of blood pressure and blood flow in humans and other animals remains a difficult problem in biomedical sensing. Direct blood pressure measurement refers to evaluation of the blood pressure using a sensor that is in contact with the blood being measured or contacts it through an intermediate fluid such as a physiologic saline solution. Direct blood pressure sensors are invasive. Indirect blood pressure measurement involves a sensor that does not actually contact the blood. The most familiar indirect blood pressure measurement is the sphygmomanometer cuff that is usually used in most medical examinations. It is a noninvasive instrument. Until recently, the primary sensor used for direct blood pressure measurement was the unbonded strain gauge pressure transducer shown in Fig. 114.1. The basic principle of this device is that a differential pressure seen across a diaphragm will cause that diaphragm to deflect. This deflection is then measured by a displacement transducer. In the unbonded strain gauge sensor a closed chamber is covered by a flexible diaphragm. This diaphragm is attached to a structure that has four fine gauge wires drawn between it and the chamber walls. A dome with the appropriate hardware for coupling to a pressure source covers the diaphragm on the side opposite the chamber such that when the pressure in the dome exceeds the pressure in the chamber, the diaphragm is deflected into the chamber. This causes two of the fine wires to stretch by a small amount while the other two wires contract by the same amount. The electrical resistance of the wires that are stretched increases while that of the wires that contract decreases. By connecting these wires, or more correctly these unbonded strain gauges, into a Wheatstone bridge circuit, a voltage proportional to the deflection of the diaphragm can be obtained.

In recent years semiconductor technology has been applied to the design of pressure transducers. Silicon strain gauges that are much more sensitive than their wire counterparts are formed on a silicon chip, and micromachining technology is used to form this portion of the chip into a diaphragm with the strain gauges integrated into its surface. This structure is then incorporated into a plastic housing and dome assembly. The entire sensor can be fabricated and sold inexpensively so that disposable, single-use devices can be made. These

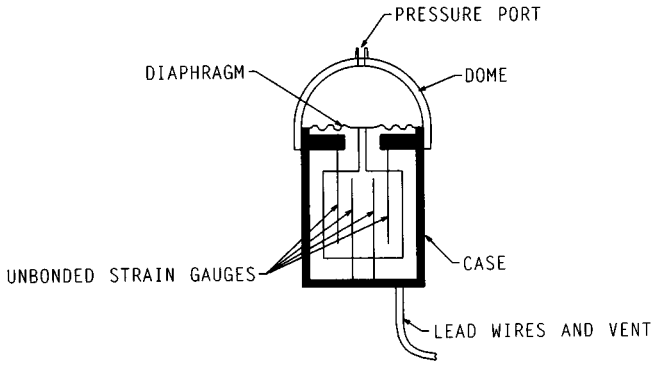

FIGURE 114.1 An unbonded strain gauge pressure transducer.

have the advantage that they are only used on one patient and they do not have to be cleaned and sterilized between patients. By using them on only one patient, the risk of transmitting blood-borne infections is eliminated.

In biomedical applications pressure is generally referenced to atmospheric pressure. Therefore, the pressure in the chamber of the pressure transducer must be maintained at atmospheric pressure. This is done by means of a vent in the chamber wall or a fine bore, flexible capillary tube that couples the chamber to the atmosphere. This tube is usually included in the electrical cable connecting the pressure transducer to the external instrumentation such that the tube is open to the atmosphere at the cable connecter.

In using this sensor to measure blood pressure the dome is coupled to a flexible plastic tube, and the dome and tube are filled with a physiological saline solution.[1] As described by Pascal's Law, the pressure in the dome, and hence against the diaphragm, will be the same as that at the tip of the tube provided the tip of the tube is at the same horizontal level as the dome. Thus by threading the tube into a blood vessel, an invasive procedure, the blood pressure in that vessel can be transmitted to the dome and hence the diaphragm of the pressure transducer. The pressure transducer will, therefore, sense the pressure in the vessel. This technique is known as external direct blood pressure measurement, and the flexible plastic tube that enters the blood vessel is known as a catheter. It is important to remember that the horizontal level of the blood pressure transducer dome must be the same as that of the tip of the catheter in the blood vessel to accurately measure the pressure in that vessel without adding an error due to the hydrostatic pressure in the catheter.

In addition to problems due to hydrostatic pressure differences between the chamber and the dome, catheters introduce pressure errors as a result of the dynamic properties of the catheter, fluid, dome, and diaphragm. These properties as well as air bubbles in the catheter, or obstructions due to clotted blood or other materials, introduce resonances and damping. These problems can be minimized by utilizing miniature pressure transducers fabricated using microelectronic semiconductor technology that are located at the tip of a catheter rather than at the end that is external to the body. A general arrangement for such a pressure transducer is shown in Fig. 114.2. As with the disposable sensors, strain gauges are integrated into the diaphragm of the transducer such that they detect very small deflections of this diaphragm. Because of the small size, small diaphragm displacement, and lack of a catheter with a fluid column, these sensors have a much broader frequency response, give a clearer signal, and do not have any hydrostatic pressure error.

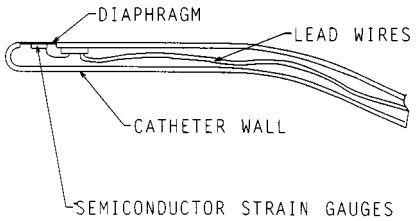

FIGURE 114.2 A catheter tip pressure transducer.

[1]It must be pointed out that the use of such a sensor is not limited to blood pressure measurement. The strain gauge pressure sensor can be used to measure the pressure of any fluid to which it is appropriately coupled.

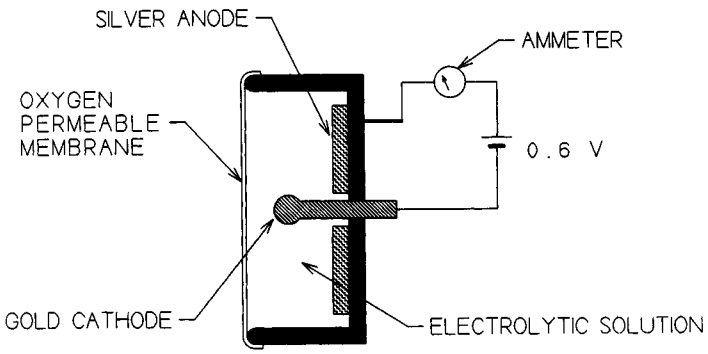

FIGURE 114.3 The Clark electrode, an amperometric electrochemical sensor of oxygen.

Although the indwelling catheter tip pressure transducer appears to solve many of the problems associated with the external pressure transducer, there are still important problems in pressure transducer design that need to be addressed. Long-term stability of pressure transducers is not very good. This is especially problematic for venous pressure measurements which are carried out at relatively low pressure. Long-term changes in baseline pressure require pressure transducers to be frequently adjusted to be certain of zero pressure. While this can be done relatively easily for external and indwelling pressure transducers, there is no way to carry out this procedure for implanted transducers, since there is not a way to establish zero pressure at the sensor. Thus devices that have very low long-term baseline drift are essential for implantable applications.

The packaging of the pressure transducer also represents a problem that needs to be addressed. Packaging must both protect the transducer and be biocompatible. It also must allow the appropriate pressure to be transmitted from the biologic fluid to the diaphragm. The amount of packaging material required should be kept at a minimum so as not to substantially increase the size of implantable or indwelling sensors. Furthermore, the material must be mechanically stable so that it does not swell or contract, since this will most likely change the baseline pressure seen by the sensor. These problems need to be overcome before miniature pressure transducers can be used reliably in implantable applications.

114.3 Chemical Sensors

There are many biomedical problems where it is necessary to know the concentration of a particular substance in a biological sample. Chemical sensors provide the interface between an instrument and the specimen to allow one to determine this concentration. These sensors can be used on a biological specimen taken from the host and tested in a laboratory, or they can be used for *in vivo* measurements either as noninvasive or invasive sensors, the latter being the most frequently used.

4. Nuclear magnetic resonance

There are many types of chemical sensors used in biomedical instrumentation. Table 114.3 lists some general categories of sensors. Electrochemical and optical sensors are most frequently used for biomedical measurements both *in vivo* and *in vitro*. An example of an electrochemical sensor is the Clark electrode illustrated in Fig. 114.3. This consists of an electrochemical cell separated from the specimen being measured by an oxygen-permeable membrane. The cell is driven at a fixed potential of 600 mV, and under these conditions the following reaction occurs at the noble metal cathode:

$$O_2 + 4e^- + H_2O \rightarrow 4OH^-$$

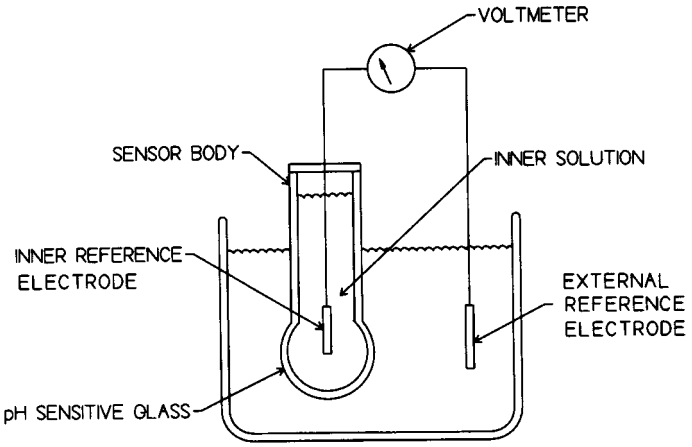

FIGURE 114.4 A glass electrode pH sensor.

This reaction involves the reduction of molecular oxygen that diffuses into the cell through the oxygen-permeable membrane. Since the other components of the reaction are in abundance, the rate of the reaction is limited by the amount of oxygen available. Thus, the rate of electrons used at the cathode is directly related to the available oxygen. In other words, the cathode current is proportional to the partial pressure of oxygen in the specimen being measured.

The electrochemical cell is completed by the silver anode. The reaction at the anode involves forming the low-solubility salt, silver-chloride, from the anode material itself and the chloride ion contained in the electrolyte. The cell is designed so that these materials are also in abundance so that their concentration does not affect the sensor performance. This type of sensor is an example of an **amperometric** electrochemical sensor.

Another type of electrochemical sensor that is frequently used in biomedical laboratories is the glass pH electrode illustrated in Fig. 114.4. The acidity or alkalinity of a solution is characterized by its pH. This quantity is defined as

$$\text{pH} = -\log_{10}[\text{H}^+]$$

where $[\text{H}^+]$ is the activity of the hydrogen ions in solution, a quantity that is related to the concentration of the hydrogen ions. This sensor only works in an aqueous environment. It consists of an inner chamber containing an electrolytic solution of known pH and an outer solution with an unknown pH that is to be measured. The membrane consists of a specially formulated glass that will in essence allow hydrogen ions to pass in either direction but will not pass other chemical species. If the concentration of hydrogen ions in the external solution is greater than that in the internal solution, there will be a gradient forcing hydrogen ions to diffuse through the membrane into the internal solution. This will cause the internal solution to have a greater positive charge than the external solution so that an electrical potential and, hence, an electric field will exist across the membrane. This field will counteract the diffusion of hydrogen ions due to the concentration difference and so an equilibrium will be eventually established. The potential across the membrane at this equilibrium condition will be related to the hydrogen ion concentration difference (or more accurately the activity difference) between the inner and outer solutions. This potential is given by the Nernst equation

$$E = -\frac{RT}{nF}\ln\left(\frac{a_1}{a_2}\right)$$

where E is the potential measured, R is the universal gas constant, T is the absolute temperature, n is the valence of the ion, and a_1 and a_2 are the activities of the ions on each side of the membrane. Thus the potential measured across the glass membrane will be proportional to the pH of the solution being studied. At room temperature

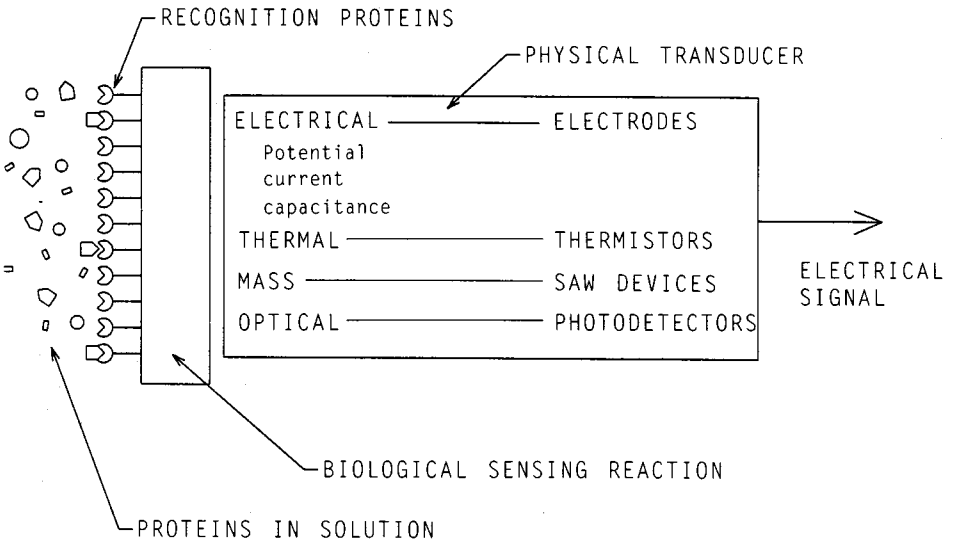

FIGURE 114.5 A generalized bioanalytical sensor.

the theoretical sensitivity of the electrode is approximately 60 mV/pH. It is not practical to measure the potential across the membrane directly and so reference electrodes, sensors that can be used to measure electrical potential of an electrolytic solution, are used to contact the solution on either side of the membrane to measure the potential difference across it. The reference electrodes and the glass membrane are incorporated into the structure shown in Fig. 114.4 known as a glass pH electrode. This is an example of a **potentiometric** measurement made using an ion-selective membrane.

There are other types of ion-selective membrane potentiometric chemical sensors that are used for biomedical applications. The membranes of these sensors determine the ion being sensed. The membrane can be based upon glass or a polymeric material such as polyvinyl chloride, but the key component is the substance that is added to the membrane that allows it to selectively pass a single ion.

Important problems in the development of chemical biomedical sensors are similar to those discussed above for the pressure sensor. Issues of long-term stability and packaging are critical to the success of a chemical sensor. The package is even more critical in chemical sensors than it was in pressure sensors in that the package must protect portions of the sensor that require isolation from the solutions being measured while it provides direct contact of the chemically sensitive portions of the sensor to the solution. The maintenance of a window through the package for this contact represents a critical aspect of sensor development. Frequent calibration is also necessary for chemical sensors. Just about every type of chemical sensor requires some sort of calibration using a standard solution with known concentration of the **analyte** being sensed. The best calibration method is a two-point procedure where two standards are used to establish the slope and the intercept of the calibration line. Some chemical sensors have stable slopes but need to be calibrated in terms of the baseline or intercept. In this case a single-point calibration can be used.

114.4 Bioanalytical Sensors

A special class of sensors of biological molecules has evolved in recent years. These bioanalytical sensors take advantage of one of the following biochemical reactions: (1) enzyme-substrate, (2) antigen-antibody, or (3) ligand-receptor. The advantage of using these reactions in a sensor is that they are highly specific for a particular biological molecule, and sensors with high sensitivity can be developed based upon these reactions. The basic structure of a bioanalytical sensor is shown in Fig. 114.5. There are two principal portions of the sensor. The first contains one component of the biological sensing reaction such as the enzyme or the antibody, and the second component involves a means of detecting whether the biological reaction has taken place. This second portion of a bioanalytical sensor is made up of either a physical or chemical sensor that serves as the detector

of the biological reaction. As illustrated in Fig. 114.5, this detector can consist of an electrical sensor such as used in electrochemical sensors, a thermal sensor, a sensor of changes in capacitance, a sensor of changes in mass, or a sensor of optical properties.

An example of a bioanalytical sensor is a glucose sensor. The first portion of the sensor contains the enzyme glucose oxidase. This enzyme promotes the oxidation of glucose to glucuronic acid and consumes oxygen in the process. Thus, by placing an oxygen sensor along with the glucose oxidase in the bioanalytical sensor, one can determine the amount of glucose oxidized by measuring the amount of oxygen consumed. An even better approach is to have two identical sensor structures in the same package. The only difference is that only one of the sensors contains the enzyme. When there is no glucose present, both sensors will measure the same oxygen partial pressure. The presence of glucose, however, will cause the sensor with the glucose oxidase to have a reduced partial pressure of oxygen due to the oxygen consumption of the reaction. By making a differential measurement of oxygen partial pressure with both sensors, other factors that can cause an apparent change in oxygen partial pressure such as temperature will have a much lower effect than if a single sensor was used.

Stability problems are important for bioanalytical sensors, especially those that are used for long-term measurements. Not only are the stability issues the same as for the physical and chemical sensors, but they are also related to preservation of the biological molecules used in the first stage of the sensor. These molecules can often be degraded or destroyed by heat or exposure to light. Even aging can degrade some of these molecules. Thus, an important issue in dealing with bioanalytical sensors is the preservation of the biochemical components of the sensor. Not all biochemical reactions are entirely reversible, and so the bioanalytical sensors based on them will not be reversible as well. This may be acceptable for some applications but not for others and must be taken into consideration in choosing a bioanalytical sensor.

114.5 Applications

Biomedical sensors and instrumentation are used in biomedical research and patient care applications. In terms of patient care, sensors are used as a part of instruments that carry out patient screening by making measurements such as blood pressure using automated apparatus. Specimen analysis is another important application of biomedical sensors in patient care. This can include analyses that can be carried out by the patients themselves in their homes such as is done with home blood glucose analyzers. Instrumentation based upon biomedical sensors can be used in the physician's office for carrying out some chemical analyses of patient specimens such as urinalysis or elementary blood chemistries such as serum glucose and electrolytes. Sensors also are a part of large multicomponent automatic blood analyzers used in the central clinical laboratory of major medical centers.

Another application for biomedical sensors is in patient monitoring. Sensors represent the front end of critical care monitors used in the intensive care unit and in the operating and recovery rooms. Measurements cover a wide range of biomedical variables such as continuous recordings of blood pressure and transcutaneous measurement of the partial pressure of carbon dioxide in the blood. The performance of these instruments is strongly dependent on biomedical sensors. Patient monitoring can also be carried out in the various clinical units of the hospital. Devices such as ambulatory cardiac monitors that allow patients to be observed while they are free to move around if they desire are becoming important in clinical care in "step-down" units for patients who have completed their stay in the intensive care unit. Patient monitoring has even made its way into the home. Home cardiorespiratory monitors are thought to have some potential value in identifying infants at risk of sudden infant death.

114.6 Summary

Sensors serve an important function in biomedical instrumentation systems in that they provide the interface between the electronic instrument and the biologic system being measured. Very often the quality of the instrument is based upon the quality of the sensor at the instrument's front end. Although electronic signal processing has been developed to a high level, the signals are no better than the quality of the sensors that provide them. Although there have been many advances in biomedical sensor technology, many problems remain. Biomedical sensors will continue to be an import area for research and development in biomedical engineering.

Defining Terms

Amperometric sensor: An electrochemical sensor that determines the amount of a substance by means of an oxidation-reduction reaction involving that substance. Electrons are transferred as a part of the reaction, so that the electrical current through the sensor is related to the amount of the substance seen by the sensor.

Analyte: The substance being measured by a chemical or bioanalytical sensor and instrumentation system.

Bioanalytical sensor: A special case of a chemical sensor for determining the amount of a biochemical substance. This type of sensor usually makes use of one of the following types of biochemical reactions: enzyme-substrate, antigen-antibody, or ligand-receptor.

Biomedical sensor: A device for interfacing an instrumentation system with a biological system such as a biological specimen or an entire organism. The device serves the function of detecting and measuring in a quantitative fashion a physiological property of the biologic system.

Chemical sensor: The interface device for an instrumentation system that determines the concentration of a chemical substance.

Noninvasive sensor: The interface device of an instrumentation system that measures a physiologic variable from an organism without interrupting the integrity of that organism. This device can be in direct contact with the surface of the organism or it can measure the physiologic quantity while remaining remote from the organism.

Physical sensor: An interface device at the input of an instrumentation system that quantitatively measures a physical quantity such as pressure or temperature.

Potentiometric sensor: A chemical sensor that measures the concentration of a substance by determining the electrical potential between a specially prepared surface and a solution containing the substance being measured.

Further Information

Research reports on biomedical sensors appear in many different journals ranging from those that are concerned with clinical medicine through those that are engineering and chemistry oriented. Three journals, however, represent major sources of biomedical sensor papers. These are listed as follows:

The *IEEE Transactions on Biomedical Engineering* is a monthly journal devoted to research papers on biomedical engineering. Papers on biomedical sensors frequently appear, and the February 1986 issue was devoted entirely to the topic of biomedical sensors. For more information or subscriptions, contact IEEE Service Center, 445 Hoes Lane, P.O. Box 1331, Piscataway, NJ 08855-1331.

The international journal *Medical and Biological Engineering and Computing* is published bi-monthly by the International Federation for Medical and Biological Engineering. This journal also contains frequent reports on biomedical sensors and related topics. Subscription information can be obtained from Peter Peregrinus Ltd., P.O. Box 96, Stevenage, Herts SG12SD, United Kingdom.

The journal *Biomedical Instrumentation and Technology* is published by the Association for the Advancement of Medical Instrumentation. This bimonthly journal has reports on biomedical instrumentation for clinical applications, and these include papers on biomedical sensors. Subscription information can be obtained from Hanley and Belfus, 210 S. 13th Street, Philadelphia, PA 19107.

There are also several scientific meetings that include biomedical sensors. The major meeting in the area is the international conference of the IEEE Engineering in Medicine and Biology Society. An extensive book or CD ROM of extended abstracts for this meeting is published each year by the IEEE. Further information can be obtained by contacting the IEEE at the address listed above.

Joseph D. Bronzino

Electroencephalograms (EEGs) are recordings of the minute (generally less than 300 μV) electrical potentials produced by the brain. Since 1924, when Hans Berger reported the measurements of rhythmic electrical activity on the human scalp, it has been suggested that these patterns of bioelectrical origin may provide clues regarding the neuronal bases for specific behaviors and has offered great promise to reveal correlations between pathological processes and the electrical activity of specific regions of the brain.

Over the years, EEG analyses have been conducted primarily in clinical settings, to detect gross organic pathologies and the epilepsies, and in research facilities to quantify the central effect of new pharmacological agents. As a result of these efforts, cortical EEG patterns have been shown to be modified by a wide variety of variables including biochemical, metabolic, circulatory, hormonal, neuroelectric, and behavioral factors. In the past, interpretation of the EEG was limited to visual inspection by a trained electroencephalographer capable of distinguishing normal activity from localized or generalized abnormalities of particular types from relatively long EEG records. This approach has left clinicians and researchers alike lost in a sea of EEG paper records. Computer technology has permitted the application of a host of methods to quantify EEG changes. With this in mind, this section provides an introduction to some of the basic concepts underlying the generation of the EEG, a review of the basic approaches used in quantifying alterations in the EEG, and some insights regarding quantitative electrophysiology techniques.

The Language of the Brain

The mass of brain tissue is composed of bundles of nerve cells (neurons) which constitute the fundamental building blocks of the nervous system. Figure 115.1 is a schematic drawing of just such a cell. It consists of three major components: the cell body (or soma), the receptor zone (or dendrites), and the axon, which carries electrical signals from the soma to target sites such as muscles, glands, or other neurons. Numbering approximately 20 billion in each human being, these tiny cells come in a variety of sizes and shapes. Although neurons are anatomically distinct units having no physical continuity between their processes, the axon ends on the soma and the dendrites of other cells in what is called a synapse. Under the microscope this often stands out as a spherical enlargement at the end of the axon to which various names have been given, for example, boutons,

end-plate, or synaptic terminals. This ending does not actually make physical contact with the soma or dendrite but is separated by a narrow cleft (gap) of approximately 100 to 200 Å (10^{-9} m) wide. This is known as the synaptic cleft. Each of these synaptic endings contains a large number of submicroscopic spherical structures (synaptic vesicles) that can be detected only under an electron microscope. These synaptic vesicles, in turn, are essentially "chemical carriers" containing transmitter substance that is released into the synaptic cleft on excitation.

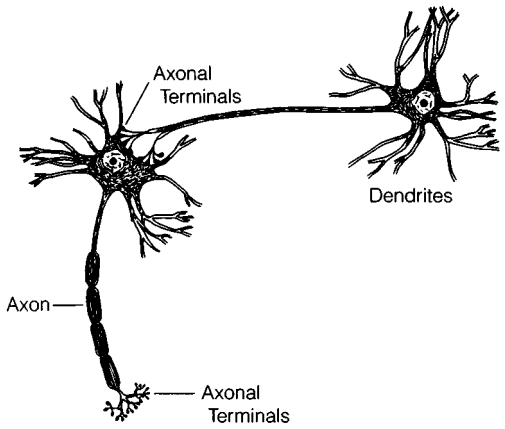

FIGURE 115.1 Basic structure of the neuron.

When an individual neuron is excited, an electrical signal is transmitted along its axon to many tiny branching, diverging fibers near its far end. These axonal terminals end as synapse on a large number of other neurons. When an electrical pulse arrives at the synapse, it triggers the release of a tiny amount of transmitter substance which crosses the synaptic cleft thereby altering the membrane potential of the receiving neuron. If the change is above a certain threshold value, the neuron is activated and generates an action potential of its own which is propagated along its axon, and the process is repeated.

Neurons are involved in every conceivable action taken by the body, whether it is to control its own internal environment or to respond to changes in the external world. As a result, they are responsible for such essential functions as:

- Accepting and converting sensory information into a form that can be processed within the nervous system by other neurons.
- Processing and analyzing this information so that an "integrated portrait" of the incoming data can be obtained.
- Translating the final outcome or "decision" of this analysis process into appropriate electrical or chemical form needed to stimulate glands or activate muscles.

Evolution has played a role in the development of these unique neurons and in the arrangement and development of interconnections between nerve cells in the various parts of the brain. Since the brain is a most complex organ, it contains numerous regions designed for specific tasks. One might, in fact, consider it to be a collection of organs arranged together to act in the harmony of activity we recognize as the individual's state of consciousness or as life itself. Over the years, anatomists and physiologists have identified and named most pathways (tracts), most groups of neurons (nuclei), and most of the major parts of the human brain. Such attention to detail is certainly not necessary here. It will serve our purpose to simply provide a broad overview of the organization of the brain and speak of three general regions: the brainstem, cerebellum, and the cerebral cortex.

The brainstem, or old brain, is really an extension and elaboration of the spinal chord. This section of the brain evolved first and is the location of all the centers that control the regulatory systems, such as respiration, necessary for physical survival of the organism. In addition, all sensory pathways find their way into the brainstem, thereby permitting the integration of complex input patterns to take place within its domain.

Above the brainstem is a spherical mass of neuronal tissue called the cerebellum. This remarkable structure is a complex monitor and modifier of body movements. The cerebellum does not initiate movements, but only modifies motor control activated in other areas. Cerebellar operation is not only dependent on evolutionary development, but relies heavily on actual use and patterns of learned motor behavior acquired throughout life. It is for this reason that the movements of a gymnast are smooth and seemingly effortless.

The most conspicuous part of all in the human brain is the cerebral cortex. Compared to most mammals, it is so large in man that it becomes a covering that surrounds and hides most of the other regions of the brain. Wrinkled and folded, the cerebral tissue is literally pressed into the limited space allocated to it. Although it has been possible to ascertain that certain cortical areas such as visual cortex, the sensory projection area, and the motor strip are associated with specific functions, the overall operation of this complex structure is still

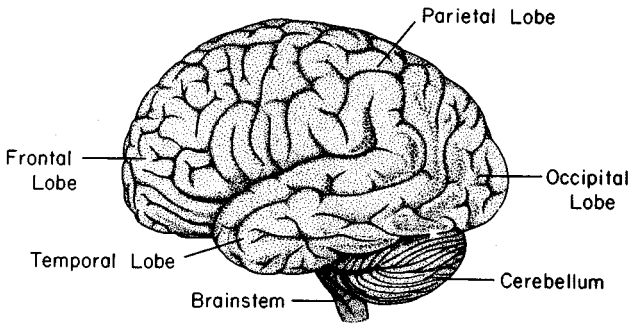

FIGURE 115.2 Major divisions of the cerebral cortex.

not completely understood. However, for the sake of convenience, it has been arbitrarily divided (based primarily on anatomical considerations) into the following areas: frontal lobe, parietal lobe, temporal lobe, and occipital lobe (Fig. 115.2). Each of these segments of the cortex, which is the source of intellectual and imaginative capacities, includes millions of neurons and a host of interconnections.

It is generally agreed that brain function is based on the organization of the activity of large numbers of neurons into coherent patterns. Since the primary mode of activity of these nerve cells is electrical in nature, it is not surprising that a composite of this activity can be detected in the form of electrical signals. Of extreme interest, then, are the actual oscillations, rhythms, and patterns seen in the cryptic flow of electrical energy coming from the brain itself, i.e., in the EEG.

Historical Perspective

In 1875, Caton published the initial account of the recording of the spontaneous electrical activity of the brain from the cerebral cortex of an experimental animal. The amplitude of these electrical oscillations was so low, that is, on the order of microvolts, that Caton's discovery is all the more amazing because it was made 50 years before suitable electronic amplifiers became available. In 1924, Hans Berger, of the University of Jena in Austria, carried out the first human EEG recordings using electrical metal strips pasted to the scalps of his subjects as electrodes and a sensitive galvanometer as the recording instrument. Berger was able to measure the irregular, relatively small electrical potentials (i.e., 50 to 100 μV) coming from the brain. By studying the successive positions of the moving element of the galvanometer recorded on a continuous roll of paper, he was able to observe the resultant patterns in these brain waves as they varied with time. From 1924 to 1938, Berger laid the foundation for many of the present applications of electroencephalography. He was the first to use the word electroencephalogram in describing these brain potentials in man. Berger noted that these brain waves were not entirely random, but instead displayed certain periodicities and regularities. For example, he observed that although these brain waves were slow (i.e., exhibited a synchronized patter of high amplitude and low frequency, <3 Hz) in sleep and states of depressed function, they were faster (i.e., exhibited a desynchronized pattern of low amplitude and high frequency, 15–25 Hz) during waking behavior. He suggested, quite correctly, that the brain's activity changed in a consistent and recognizable fashion when the general status of the subject changed, as from relaxation to alertness. Berger also concluded that these brain waves could be greatly affected by certain pathological conditions after noting the marked increase in the amplitude of these brain waves brought about by convulsive seizures. However, in spite of the insights provided by these studies, Berger's original paper published in 1929 did not excite much attention. In essence, the efforts of this most remarkable pioneer were largely ignored until similar investigations were carried out and verified by British investigators.

It was not until 1934 when Adrian and Matthews published their classic paper verifying Berger's findings that the reality of human brain waves was accepted and EEG studies were put on a firmly established basis. One of their primary contributions was the identification of certain rhythms in the EEG, regular oscillations at approximately 10–12 Hz in the occipital lobes of the cerebral cortex. They found that this alpha rhythm in the EEG would disappear when the brain displayed any type of attention or alertness or focused on objects in the visual field. The physiological basis for these results, the "arousing influence" of external stimuli on the

cortex, was not formulated until 1949 when Moruzzi and Magoun demonstrated the existence of widely spread pathways through the central reticular core of the brainstem capable of exerting a diffuse activating influence on the cerebral cortex. This reticular activating system has been called the brain's response selector because it alerts the cortex to focus on certain incoming information while ignoring other. It is for this reason that a sleeping mother will immediately be awakened by her crying baby or the smell of smoke, and yet ignore the traffic outside her window or the television still playing in the next room. An in-depth discussion of these early studies is beyond the scope of this presentation; however, for the interested reader an excellent historical review of this early era in brain research has been recorded in a fascinating text by Brazier [1968].

EEG Recording Techniques

Scalp recordings of spontaneous neuronal activity in the brain, identified as the EEG, allow measurement of potential changes over time between a signal electrode and a reference electrode [Kondraski, 1986]. Compared to other biopotentials, such as the electrocardiogram, the EEG is extremely difficult for an untrained observer to interpret. As might be expected, partially as a result of the spatial mapping of functions onto different regions of the brain, correspondingly different waveforms are visible, depending on electrode placement. Recognizing that some standardization was necessary for comparison of research as well as clinical EEG records, the International Federation in Electroencephalography and Clinical Neurophysiology adopted the 10–20 electrode placement system, [Jasper, 1958]. Additional electrodes to monitor extracerebral contaminants of the EEG such as eye movement, EKG, and muscle activity are essential. The acquisition of EEG for quantitative analysis should also require the ability to view the EEG during collection on a polygraph or high-resolution video display.

Since amplification, filtering, and digitization determine the frequency characteristics of the EEG and the source of potential artifacts, the acquisition parameters must be chosen with an understanding of their effects on signal acquisition and subsequent analysis. Amplification, for example, increases the amplitude range (volts) of the analog-to-digital (A/D) converter. The resolution of the A/D converter is determined by the smallest amplitude of steps that can be sampled. This is calculated by dividing the voltage range of the A/D converter by 2 to the power of the number of bits of the A/D converter. For example, an A/D converter with a range of ±5 V with 12-bit resolution can resolve samples as small as ±2.4 mV. Appropriate matching of amplification and A/D converter sensitivity permits resolution of the smallest signal while preventing clipping of the largest signal amplitudes.

The bandwidth of the filters and the rate of digitization determine the frequency components of interest that are passed, while other frequencies outside the band of interest that may represent potential artifacts, such as aliasing, are rejected. A filter's characteristics are determined by the rate of the amplitude decrease at the bandwidth's upper and lower edges. Proper digital representation of the analog signal depends on the rate of data sampling, which is governed by the Nyquist theorem that states that data sampling should be at least twice the highest frequency of interest.

In addition to the information available from spontaneous electrical activity of the EEG, the brain's electrical response to sensory stimulation can contribute data as to the status of cortical and subcortical regions activated by sensory input. Due to the relatively small amplitude of a stimulus-evoked potential as compared to the spontaneous EEG potentials, the technique of signal averaging is used to enhance the stimulus-evoked response. Stimulus averaging takes advantage of the fact that the brain's electrical response is time-locked to the onset of the stimulus and the nonevoked background potentials are randomly distributed in time. Consequently, the average of multiple stimulus responses will result in the enhancement of the time-locked activity, while the averaged random background activity will approach zero. The result is an evoked response that consists of a number of discrete and replicable peaks that occur, depending upon the stimulus and the recording parameters, at predicted latencies from the onset of stimulation. The spatial localization of maximum peak amplitudes has been associated with cortical generators in primary sensory cortex.

Instrumentation required for EEG recordings can be simple or elaborate [Kondraski, 1986]. (Note: Although the discussion presented in this section is for a single-channel system it can be extended to simultaneous multichannel recordings simply by multiplying the hardware by the number of channels required. In cases that do not require true simultaneous recordings, special electrode selector panels can minimize hardware requirements.) Any EEG system consists of electrodes, amplifiers (with appropriate filters) and a recording device.

Commonly used scalp electrodes consist of Ag-AgCl disks, 1 to 3 mm in diameter, with a very flexible long lead that can be plugged into an amplifier. Although it is desirable to obtain a low-impedance contact at the electrode ski interface (less than 10 kΩ), this objective is confounded by hair and the difficulty of mechanically stabilizing the electrodes. Conductive electrode paste helps obtain low impedance and keep the electrodes in place. A type of cement (collodion) is used to fix small patches of gauze over electrodes for mechanical stability, and leads are usually taped to the subject to provide some strain relief. Slight abrasion of the skin is sometimes used to obtain better electrode impedances, but this can cause irritation and sometimes infection (as well as pain in sensitive subjects).

For long-term recordings, as in seizure monitoring, electrodes present major problems. Needle electrodes, which must be inserted into the tissue between the surface of the scalp and skull, are sometimes useful. However, the danger of infection increases significantly. Electrodes with self-contained miniature amplifiers are somewhat more tolerant because they provide a low-impedance source to interconnecting leads, but they are expensive. Despite numerous attempts to simplify the electrode application process and to guarantee long-term stability, none has been widely accepted.

Instruments are available for measuring impedance between electrode pairs. The procedure is recommended strongly as good practice, since high impedance leads to distortions that may be difficult to separate from actual EEG signals. In fact, electrode impedance monitors are built into some commercial devices for recording EEGs. Standard dc ohmmeters should not be used, since they apply a polarizing current that causes build-up of noisy electrode potential at the skin-electrode interface. Commercial devices apply a known-amplitude sinusoidal voltage (typically 1 kHz) to an electrode pair circuit and measure root mean square (rms) current, which is directly related to the magnitude of the impedance.

From carefully applied electrodes, signal amplitudes of 1 to 10 μV can be obtained. Considerable amplification (gain = 10^6) is required to bring these levels up to an acceptable level for input to recording devices. Because of long electrode leads and the common electrically noisy environment where recordings take place, differential amplifiers with inherently high input impedance and high common mode rejection ratios are essential for high-quality EEG recordings.

In some facilities, special electrically shielded rooms minimize environmental electrical noise, particularly 60-Hz alternating current (ac) line noise. Since much of the information of interest in the EEG lies in the frequency bands less than 40 Hz, low-pass filters in the amplifier can be switched into attenuate 60-Hz noise sharply.

For attenuating ac noise when the low-pass cutoff is greater than 60 Hz, many EEG amplifiers have notch filters that attenuate only frequencies in a narrow band centered around 60 Hz. Since important signal information may also be attenuated, notch filtering should be used as a last resort; one should try to identify and eliminate the source of interference instead.

In trying to identify 60-Hz sources to eliminate or minimize their effect, it is sometimes useful to use a dummy source, such as a fixed 100-kΩ resistor attached to the electrodes. An amplifier output represents only contributions from interfering sources. If noise can be reduced to an acceptable level (at least by a factor of 10 less than EEG signals) under this condition, one is likely to obtain uncontaminated EEG records.

Different types of recording instruments obtain a temporary or permanent record of the EEG. The most common recording device is a pen or chart recorder (usually multichannel) that is an integral part of most commercially available EEG instruments. The bandwidth of clinical EEGs is relatively low (less than 40 Hz) and therefore within the frequency response capabilities of these devices. Recordings are on a long sheet of continuous paper (from a folded stack), fed past the moving pen at one of several selectable constant speeds. The paper speed translates into distance per unit time or cycles per unit time, to allow EEG interpreters to identify different frequency components or patterns within the EEG. Paper speed is selected according to the monitoring situation at hand: slow speeds (10 mm/s) for observing the spiking characteristically associated with seizures and faster speeds (up to 120 mm/s) for the presence of individual frequency bands in the EEG.

In addition to (or instead of) a pen recorder, the EEG may be recorded on a multichannel frequency modulated (FM) analog tape recorder. During such recordings, a visual output device such as an oscilloscope or video display is necessary to allow visual monitoring of signals, so that corrective action (reapplying the electrodes and so on) can take place immediately if necessary.

Sophisticated FM cassette recording and playback systems allow clinicians to review long EEG recordings over a greatly reduced time, compared to that required to flip through stacks of paper or observe recordings as they occur in real time. Such systems take advantage of time compensation schemes, whereby a signal recorded at one speed (speed of the tape moving past the recording head of the cassette drive) is played back at a different, faster speed. The ratio of playback to recording speed is known, so the appropriate correction factor can be applied to played-back data to generate a properly scaled video display. A standard ratio of 60:1 is often used. Thus, a trained clinician can review each minute of real-time EEG in 1 s. The display appears to be scrolled at a high rate horizontally across the display screen. Features of these instruments allow the clinician to freeze a segment of EEG on the display and to slow down or accelerate tape speed from the standard playback as needed. A time mark channel is usually displayed as one of the traces as a convenient reference (vertical "tick" mark displayed at periodic intervals across the screen).

Computers can also be recording devices, digitizing (converting to digital form) one or several amplified EEG channels at a fixed rate. In such sampled data systems, each channel is repeatedly sampled at a fixed time interval (sample interval) and this sample is converted into a binary number representation by an A/D converter. The A/D converter is interfaced to a computer system so that each sample can be saved in the computer's memory. A set of such samples, acquired at a sufficient sampling rate (at least two times the highest frequency component in the sampled signal), is sufficient to represent all the information in the waveform. To ensure that the signal is band-limited, a low-pass filter with a cutoff frequency equal to the highest frequency of interest is used. Since physically realizable filters do not have the ideal characteristics, the sampling rate is usually greater than two times the filter's cutoff frequency. Furthermore, once converted to a digital format, digital filtering techniques can be used.

On-line computer recordings are only practical for short-term recordings or for situations in which the EEG is immediately processed. This limitation is primarily due to storage requirements. For example, a typical sampling rate of 128 Hz yields 128 new samples per second that require storage. For an 8-channel recording, 1,024 samples are acquired per second. A 10-minute recording period yields 614,400 data points. Assuming 8-bit resolution per sample, over 0.5 megabyte (MB) of storage is required to save the 10-minute recording.

Processing can consist of compression for more efficient storage (with associated loss of total information content), as in data record or epoch averaging associated with evoked responses, or feature extraction and subsequent pattern recognition, as in automated spike detection in seizure monitoring.

Frequency Analysis of the EEG

In general, the EEG contains information regarding changes in the electrical potential of the brain obtained from a given set of recording electrodes. These data include the characteristic waveform with its variation in amplitude, frequency, phase, etc. and the occurrence of brief electrical patterns, such as spindles. Any analysis procedure cannot simultaneously provide information regarding all of these variables. Consequently, the selection of any analytic technique will emphasize changes in one particular variable at the expense of the others. This observation is extremely important if one is to properly interpret the results obtained by any analytic technique. In this chapter, special attention is given to frequency analysis of the EEG.

In early attempts to correlate the EEG with behavior, analog frequency analyzers were used to examine single channels of EEG data. Although disappointing, these initial efforts did introduce the utilization of frequency analysis to study gross brain wave activity. Although, **power spectral analysis**, i.e., the magnitude square of Fourier transform, provides a quantitative measure of the frequency distribution of the EEG, it does so as mentioned above, at the expense of other details in the EEG such as the amplitude distribution, as well as the presence of specific patterns in the EEG.

The first systematic application of power spectral analysis by general-purpose computers was reported in 1963 by Walter; however, it was not until the introduction of the **fast Fourier transform (FFT)** by Cooley and Tukey in the early 1970s that machine computation of the EEG became commonplace. Although an individual FFT is ordinarily calculated for a short section of EEG data (e.g., from 1 to 8 s epoch), such segmentation of a signal with subsequent averaging over individual modified periodograms has been shown to provide a consistent estimator of the power spectrum, and an extension of this technique, the compressed spectral array, has been particularly useful for computing EEG spectra over long periods of time. A detailed review of the

development and use of various methods to analyze the EEG is provided by Givens and Redmond [1987].

Figure 115.3 provides an overview of the computational processes involved in performing spectral analysis of the EEG, i.e., including computation of auto and **cross spectra** [Bronzino, 1984]. It is to be noted that the power spectrum is the autocorrellogram, i.e., the correlation of the signal with itself. As a result, the power spectrum provides only magnitude information in the frequency domain; it does not provide any data regarding phase. The power spectrum is computed by:

$$P(f) = \mathrm{Re}^2[X(f)] + \mathrm{Im}^2[X(f)] \tag{115.1}$$

where $X(f)$ is the Fourier transform of the EEG.

Power spectral analysis not only provides a summary of the EEG in a convenient graphic form, but also facilitates statistical analysis of EEG changes which may not be evident on simple inspection of the records. In addition to absolute power derived directly from the power spectrum, other measures calculated from absolute power have been demonstrated to be of value in quantifying various aspects of the EEG. Relative power expresses the percent contribution of each frequency band to the total power and is calculated by dividing the power within a band by the total power across all bands. Relative power has the benefit of reducing the intersubject variance associated with absolute power that arises from intersubject differences in skull and scalp conductance. The disadvantage of relative power is that an increase in one frequency band will be reflected in the calculation by a decrease in other bands; for example, it has been reported that directional shifts between high and low frequencies are associated with changes in cerebral blood flow and metabolism. Power ratios between low (0–7 Hz) and high (10–20 Hz) frequency bands have been demonstrated to be an accurate estimator of changes in cerebral activity during these metabolic changes.

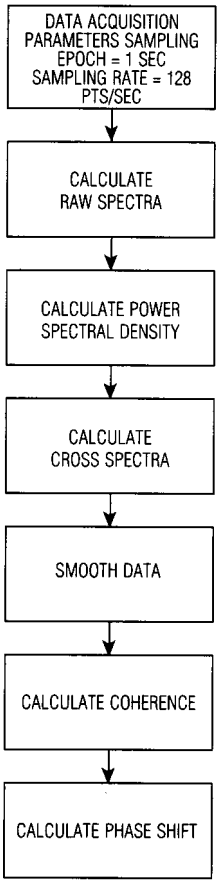

FIGURE 115.3 Block diagram of measures determined from spectral analysis.

Although the power spectrum quantifies activity at each electrode, other variables derivable from FFT offer a measure of the relationship between activity recorded at distinct electrode sites. Coherence (which is a complex number), calculated from the cross-spectrum analysis of two signals, is similar to cross-correlation in the time domain. The **magnitude squared coherence (MSC)** values range from 1 to 0, indicating maximum or no synchrony, respectively, and are independent of power. The temporal relationship between two signals is expressed by phase, which is a measure of the lag between two signals for common frequency components or bands. Phase is expressed in units of degrees, 0° indicating no time lag between signals or 180° if the signals are of opposite polarity. Phase can also be transformed into the time domain, giving a measure of the time difference between two frequencies.

Cross spectrum is computed by:

$$\text{Cross spectrum} = X(f)\ Y^*(f) \tag{115.2}$$

where $X(f)$, $Y(f)$ are Fourier transforms and * indicates complex conjugates and coherence is calculated by

$$\text{Coherence} = \frac{\text{Cross spectrum}}{\sqrt{PX(f) - PY(f)}} \tag{115.3}$$

Since coherence is a complex number, the phase is simply the angle associated with the polar expression of that number. MSC and phase represent measures that can be employed to investigate the cortical interactions of cerebral activity. For example, short (intracortical) and long (cortico-cortical) pathways have been proposed

as the anatomic substrate underlying the spatial frequency and patterns of coherence. Therefore, discrete cortical regions linked by such fiber systems should demonstrate a relatively high degree of synchrony, whereas the time lag between signals, as represented by phase, quantifies the extent to which one signal leads another.

Nonlinear Analysis of the EEG

As mentioned earlier, the EEG has been studied extensively using signal-processing schemes, most of which are based on the assumption that the EEG is a linear, gaussian process. Although linear analysis schemes are computationally efficient and useful, they only utilize information retained in the autocorrelation function (i.e., the second-order cumulant). Additional information stored in higher-order cumulants is therefore ignored by linear analysis of the EEG. Thus, while the power spectrum provides the energy distribution of a stationary process in the frequency domain, it cannot distinguish nonlinearly coupled frequencies from spontaneously generated signals with the same resonance condition [Nikias and Raghvveer, 1987].

There is evidence showing that the amplitude distribution of the EEG often deviates from gaussian behavior. It has been reported, for example, that the EEG of humans involved in the performance of mental arithmetic task exhibits significant nongaussian behavior. In addition, the degree of deviation from gaussian behavior of the EEG has been shown to depend to the behavioral state, with the state of slow-wave sleep showing less gaussian behavior than quiet waking, which is less gaussian than rapid eye movement (REM) sleep [Ning and Bronzino, 1989a,b]. Nonlinear signal-processing algorithms such as bispectral analysis are therefore necessary to address nongaussian and nonlinear behavior of the EEG in order to better describe it in the frequency domain.

But what exactly is the bispectrum? For a zero-mean, stationary process $\{X(k)\}$, the bispectrum, by definition, is the Fourier transform of its third-order cumulant (TOC) sequence:

$$B(\omega_1, \omega_2) = \sum_{m=-\alpha}^{a} \sum_{n=-\alpha}^{a} C(m, n) e^{-j(w_1 m + w_2 n)} \tag{115.4}$$

The TOC sequence $\{C(m, n)\}$ is defined as the expected value of the triple product

$$C(m, n) = E\{X(k)X(k + m)X(k + n)\} \tag{115.5}$$

If process $X(k)$ is purely gaussian, then its third-order cumulant $C(m, n)$ is zero for each (m, n), and consequently, its Fourier transform, the bispectrum, $B(\omega_1, \omega_2)$ is also zero. This property makes the estimated bispectrum an immediate measure describing the degree of deviation from gaussian behavior. In our studies [Ning and Bronzino, 1989a,b], the sum of magnitude of the estimated bispectrum was used as a measure to describe the EEG's deviation from gaussian behavior, that is,

$$D = \sum_{(\omega_1 \omega_2)} |B(\omega_1, \omega_2)| \tag{115.6}$$

Using bispectral analysis, the existence of significant quadratic phase coupling (QPC) in the hippocampal EEG obtained during REM sleep in the adult rat was demonstrated [Ning and Bronzino, 1989a,b, 1990]. The result of this nonlinear coupling is the appearance, in the frequency spectrum, of a small peck centered at approximately 13 to 14 Hz (beta range) that reflects the summation of the two theta frequency (i.e., in the 6- to 7-Hz range) waves. Conventional power spectral (linear) approaches are incapable of distinguishing the fact that this peak results from the interaction of these two generators and is not intrinsic to either.

To examine the phase relationship between nonlinear signals collected at different sites, the *cross-bispectrum* is also a useful tool. For example, given three zero-mean, stationary processes "$x_j(n) j = 1, 2, 3\}$, there are two conventional methods for determining the cross-bispectral relationship, *direct* and *indirect*. Both methods first divide these three processes into M segments of shorter but equal length. The direct method computes the

Fourier transform of each segment for all three processes and then estimates the cross-bispectrum by taking the average of triple products of Fourier coefficients over M segments, that is,

$$B_{x_1x_2x_3}(\omega_1, \omega_2) = \frac{1}{M}\sum_{m=1}^{M} X_1^m(\omega_1)X_2^m(\omega_2)X_3^{m*}(\omega_1 + \omega_2) \tag{115.7}$$

where $X_j^m(\omega)$ is the Fourier transform of the mth segment of $\{x_j(n)\}$, and * indicates the complex conjugate.

The indirect method computes the third-order cross-cumulant sequence for all segments:

$$C_{x_1x_2x_3}^m(k, l) = \sum_{n\epsilon\tau} x_1^m(n)x_2^m(n + k)x_3^m(n + l) \tag{115.8}$$

where τ is the admissible set for argument n. The cross-cumulant sequences of all segments will be averaged to give a resultant estimate:

$$C_{x_1x_2x_3}(k, l) = \frac{1}{M}\sum_{m=1}^{M} C_{x_1x_2x_3}^m(k, l) \tag{115.9}$$

The cross-bispectrum is then estimated by taking the Fourier transform of the third-order cross-cumulant sequence:

$$B_{x_1x_2x_3}(\omega_1, \omega_2) = \sum_{k=-\alpha}^{\alpha}\sum_{l=-\alpha}^{\alpha} C_{x_1x_2x_3}(k, l)^{-j(\omega_1 k+\omega_2 l)} \tag{115.10}$$

Since the variance of the estimated cross-bispectrum is inversely proportional to the length of each segment, computation of the cross-bispectrum for processes of finite data length requires careful consideration of both the length of individual segments and the total number of segments to be used.

The cross-bispectrum can be applied to determine the level of cross-QPC occurring between $\{x_1(n)\}$ and $\{x_2(n)\}$ and its effects on $\{x_3(n)\}$. For example, a peak at $Bx_1x_2x_3(\omega_1, \omega_2)$ suggests that the energy component at frequency $\omega_1 + \omega_2$ of $\{x_3(n)\}$ is generated due to the QPC between frequency ω_1 of $\{x_1(n)\}$ and frequency ω_2 of $\{x_2(n)\}$. In theory, the absence of QPC will generate a flat cross-bispectrum. However, due to the finite data length encountered in practice, peaks may appear in the cross-bispectrum at locations where there is no significant cross-QPC. To avoid improper interpretation, the cross-bicoherence index, which indicates the significance level of cross-QPC, can be computed as follows:

$$bic_{x_1x_2x_3}(\omega_1, \omega_2) = \frac{B_{x_1x_2x_3}(\omega_1, \omega_2)}{\sqrt{P_{x_1}(\omega_1)P_{x_2}(\omega_2)P_{x_3}(\omega_1 + \omega_2)}} \tag{115.11}$$

where $P_{xj}(\omega)$ is the power spectrum of process $\{x_j(n)\}$. The theoretical value of the bicoherence index ranges between 0 and 1, i.e., from nonsignificant to highly significant.

In situations where the interest is the presence of QPC and its effects on $\{x(n)\}$, the cross-bispectrum equations can be modified by replacing $\{x_1(n)\}$ and $\{x_3(n)\}$ with $\{x(n)\}$ and $\{x_2(n)\}$ with $\{y(n)\}$, that is,

$$B_{xyz}(\omega_1, \omega_2) = \frac{1}{M}\sum_{m=1}^{M} X^m(\omega_1)\ Y^m(\omega_2)\ X^{m*}(\omega_1 + \omega_2) \tag{115.12}$$

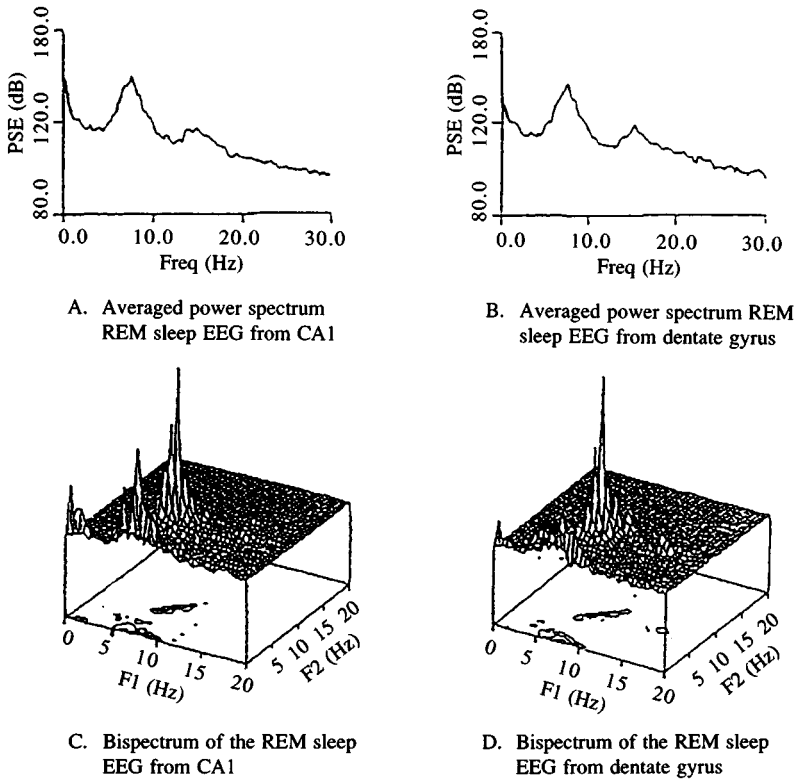

FIGURE 115.4 A and B represent the averaged power spectra of 80 4-s epochs of REM sleep (sampling rate = 128 Hz) obtained from hippocampal CA1 and the dentate gyrus, respectively. Note that both spectra exhibit clear power peaks at 7-Hz (theta) and 14-Hz (beta) frequencies. C and D represent the bispectrum of these same epochs from CA1 and the dentate gyrus, respectively. Computation of the bicoherence index at 7 Hz shows significant quadratic phase coupling at this frequency, indicating that the 14-Hz peak is not spontaneously generated, but results from quadratic phase coupling.

In theory, both methods will lead to the same cross-bispectrum when data length is infinite. However, with finite data records, direct and indirect methods generally lead to cross-bispectrum estimates with different shapes (Fig. 115.4). Therefore, like power spectrum estimation, users have to choose an appropriate method to extract the information desired.

Topographic Mapping

Computerized tomography (CT) and magnetic resonance imaging (MRI) have demonstrated the impact of spatial displays on data interpretation and analysis. Similarly, mapping techniques have been applied to electrophysiologic data to depict the spatial information available from multielectrode recordings. This effort has been assisted by the development and implementation of low-cost, high-resolution graphic displays on microcomputer systems. The data are frequently presented as two-dimensional topographic color maps [Zappulla, 1991]. In the time domain, color values depict the changes in potential across the scalp at each time point. This is exemplified by mapping peaks of an evoked potential or the spatial distribution of an epileptic spike. Temporal changes in the spatial distribution of voltage can be presented graphically as a series of maps constructed at adjacent time points or by cartooning the topographic maps over the time interval of interest. In the frequency domain, color coding can be used to spatially map power, covariance, and phase values. These maps may be constructed for the broadband activity or for selective frequency components.

Unlike CT and MRI displays where each picture element or pixel value represents real data, most of the pixels comprising an EEG and ER topographic map consist of interpolated values. This is because the activity

from a finite number of electrodes represents a sampling of the spatial activity over the scalp. Consequently, the remaining values of the map located outside the electrode positions must be estimated from this sampled activity. One technique for deriving these values is linear interpolation. In the case of a four-point interpolation, the map is divided into boxes whose corners are defined by real data. The interpolated points within the boxes are calculated by the weighted sum of the four real data points, based on their distance from the interpolated point. Although linear interpolation is the most popular technique, polynomial regression and surface spline interpolation have been employed as alternative procedures. These methods reduce the discontinuities inherent in linear interpolation and offer better estimates of extreme values. Polynomial regression has the additional advantage of permitting quantitative comparisons between maps by taking into account the topographic information represented in the map.

Maps can be presented in any of several projections to assist in interpretation [Zappulla, 1991]. The most common projection is the top view which presents the spatial distribution of variables from all leads simultaneously. Lateral, posterior, and anterior projections highlight focal areas of interest. Although mapping presents a method by which spatial information can be efficiently communicated, it is important to be alert to the artifacts that can arise from map construction and manipulation. Topographic spatial artifacts that can lead to misinterpretation include ring enhancement around a spike using source-derivation references, spatial aliasing arising from linear interpolation which causes maximal activity to be mapped at electrode sites, the enhancement of activity away from the midline, and the attenuation of midline activity on amplitude asymmetry maps (centrifugal effect).

The quality of the spatial information derivable from EEG recordings depends upon the number of recording electrodes, the choice of the reference electrode, and the conductive properties of intracranial and extracranial structures. The localization of cortical activity from scalp recordings assumes that the potentials recorded from the scalp reflect cortical activity generated in proximity to the recording electrode. Therefore, the greater the density of recording electrodes, the more accurate the estimate of the spatial distribution of scalp potentials and the localization of cortical generators. However, since the distance between the cortical source and recording electrode, as well as the low conductivity of the skull, results in a selective attenuation of small dipole fields, most available EEG information can be obtained with an average scalp-electrode spacing of 2 cm.

Topographic maps are constructed from monopolar electrodes referenced to a common cephalic (linked ears or mandible, chin and nose) or noncephalic (linked clavicles or a balanced sternum-vertebra) electrode. Although the reference electrode should be free of any EEG activity, in practice most cephalic electrodes contain some EEG activity, while noncephalic electrodes are a potential source of EKG or muscle activity. Differential amplification of an EEG-contaminated reference electrode can decrease or cancel similar activity in neighboring electrodes, while at electrodes distant from the reference, the injected activity will be present as a potential of opposite polarity. Similarly, noncerebral potentials can be injected into scalp electrodes and misinterpreted as cerebral activity. Therefore, a nonneutral reference electrode can result in misleading map configurations. Several techniques have been applied to circumvent this problem. The construction of multiple maps using several different references can sometimes assist in differentiating active and reference electrode activity. This can be accomplished by acquiring serial EEG records using different references. Alternatively, various references can be acquired simultaneously during acquisition, and various montages can be digitally reconstructed, post hoc.

A more computationally intensive method for localizing a source at an electrode involves calculating the local source activity at any one electrode based on the average activity of its neighbors, weighted by their distance from the source. The technique has the advantage of suppressing potentials that originate outside the measurement area and weighing factors for implementing source deviation techniques for each of the electrodes in the 10–20 system are available.

Another reference technique, the average head reference, uses the average activity of all active electrodes as the common reference. In this approach, the activity at any one electrode will vary depending upon the activity at the site of the reference electrode, which can be anywhere on the recording montage. Therefore, for N number of recording electrodes, each being a potential reference, there are $N - 1$ possible voltage measurements at each instant of time for each electrode. Maps constructed using the average head reference represent a unique solution to the problem of active reference electrodes in that the average reference produces an amplitude-weighted reference-free map of maximal and minimal field potentials. Power maps constructed from the average reference

best depict the spatial orientation of the generating field, and the areas with extreme values are closest to the generating processes [Zappulla, 1991].

Topographical maps represent an efficient format for displaying the extensive amount of data generated by quantitative analysis. However, for reasons discussed above, the researcher and clinician must be cautious in deriving spatial and functional conclusions from mapped data. Although the replicability of map configurations across subjects or experimental conditions may represent a useful basis for experimental and diagnostic classification, judgments concerning the localization of cortical generators or functional localization of cerebral activity are less certain and more controversial. Research continues on defining models and validating assumptions that relate scalp potentials to cortical generators in an attempt to arrive at accurate mathematical solutions that can be applied to mapping functions.

Defining Terms

Bispectra: Computation of the frequency distribution of the EEG exhibiting nonlinear behavior.
Cross spectra: Computation of the energy in the frequency distribution of two different electrical signals.
Electroencephalogram (EEG): Recordings of the electrical potentials produced by the brain.
Fast Fourier transform (FFT): Algorithms that permit rapid computation of the Fourier transform of an electrical signal, thereby representing it in the frequency domain.
Magnitude squared coherence (MSC): A measure of the degree of synchrony between two electrical signals at specific frequencies.
Power spectral analysis: Computation of the energy in the frequency distribution of an electrical signal.
Quadratic phase coupling: A measure of the degree to which specific frequencies interact to produce a third frequency.

115.2 The Electrocardiograph

Edward J. Berbari

The electrocardiogram (**ECG**) is the recording on the body surface of the electrical activity generated by the heart. It was originally observed by Waller in 1889 using his pet bulldog as the signal source and the capillary electrometer as the recording device. In 1903 Einthoven enhanced the technology by using the string galvanometer as the recording device and using human subjects with a variety of cardiac abnormalities. Einthoven is chiefly responsible for introducing some concepts still in use today including the labeling of the various waves, defining some of the standard recording sites using the arms and legs, and developing the first theoretical construct whereby the heart is modeled as a single time varying dipole. We also owe the "EKG" acronym to Einthoven's native Dutch language where the root word "cardio" is spelled with a "k".

In order to record an ECG waveform, a differential recording between two points on the body is made. Traditionally each differential recording is referred to as a lead. Einthoven defined three leads numbered with the Roman numerals I, II, and III. They are defined as:

$$\mathrm{I} = V_{LA} - V_{RA} \tag{115.13}$$

$$\mathrm{II} = V_{LL} - V_{RA} \tag{115.14}$$

$$\mathrm{III} = V_{LL} - V_{LA} \tag{115.15}$$

where *RA* = right arm, *LA* = left arm, and *LL* = left leg. Because the body is assumed to be purely resistive, at ECG frequencies, the four limbs can be thought of as wires attached to the torso. Hence lead I could be recorded from the respective shoulders without a loss of cardiac information. Note that these are not independent and the following relationship holds: II = I + III.

For 30 years the evolution of the ECG proceeded when F. N. Wilson [1934] added concepts of a "unipolar" recording. He created a reference point by tying the three limbs together and averaging their potentials so that individual recording sites on the limbs or chest surface would be differentially recorded with the same reference point. Wilson extended the biophysical models to include the concept of the cardiac source enclosed within the volume conductor of the body. He erroneously thought that the central terminal was a true zero potential. However, from the mid-1930s until today the 12 leads composed of the three limb leads, three leads in which the limb potentials are referenced to a modified **Wilson terminal** (the augmented leads [Goldberger, 1942]), and six leads placed across the front of the chest and referenced to the Wilson terminal form the basis of the standard **12-lead ECG**. Figure 115.5 summarizes the 12-lead set. These sites are historically based, have a built in redundancy, and are not optimal for all cardiac events. The voltage difference from any two sites will record an ECG, but it is these standardized sites with the massive 90-year collection of empirical observations that has firmly established their role as the standard. Figure 115.6 is a typical or stylized ECG recording from lead II. Einthoven chose the letters of the alphabet from P to U to label the waves and to avoid conflict with other physiologic waves being studied at the turn of the century. The ECG signals are typically in the range of ±2 mV and require a recording bandwidth of 0.05–150 Hz. Full technical specification for ECG equipment has been proposed by both the American Heart Association [1984] and the Association for the Advancement of Medical Instrumentation [Bailey et al., 1990].

There have been several attempts to change the approach for recording the ECG. The vectorcardiogram used a weighted set of recording sites to form an orthogonal *XYZ* lead set. The advantage here was minimum lead set but in practice it gained only a moderate degree of enthusiasm among physicians. Body surface mapping

Infrared Camera

NASA, teaming with an industry partner, has developed a revolutionary infrared camera that offers important applications not only in aerospace research but in other areas such as air transportation, environment monitoring, and medicine.

An innovative feature of the infrared camera shown is its use of highly sensitive quantum-well photodetectors of QWIPS. The greater sensitivity of long wavelength QWIPS could allow physicians to detect tumors using thermographic techniques; improve pilots' night vision to allow better landings; and enable environmental scientists to monitor pollution and weather patterns with enhanced measurement accuracy. Other possible applications include law enforcement, industrial process control, search and rescue, and military antimissile surveillance.

The camera weighs only 9.9 pounds and measures 4.4 inches wide, 10.3 inches deep, and 7.2 inches long. The prototype plugs into a wall socket for power but the camera can be converted readily to battery power for portability.

Because infrared light detectors must operate at extremely low temperatures, the camera contains a Stirling cryocooler, a closed-cycle refrigerator about the size of a fist that cools the camera from room temperature to about 343 degrees below zero Fahrenheit in about 10 minutes.

The camera was developed by the Center for Space Microelectronics Technology at the Jet Propulsion Laboratory in cooperation with Amber, a Raytheon company. (Courtesy of National Aeronautics and Space Administration.)

This revolutionary infrared camera, developed by an industry/government team, has broad applications in medicine, environment monitoring, industrial processing, and law enforcement, as well as in aerospace research. (Photo courtesy of National Aeronautics and Space Administration.)

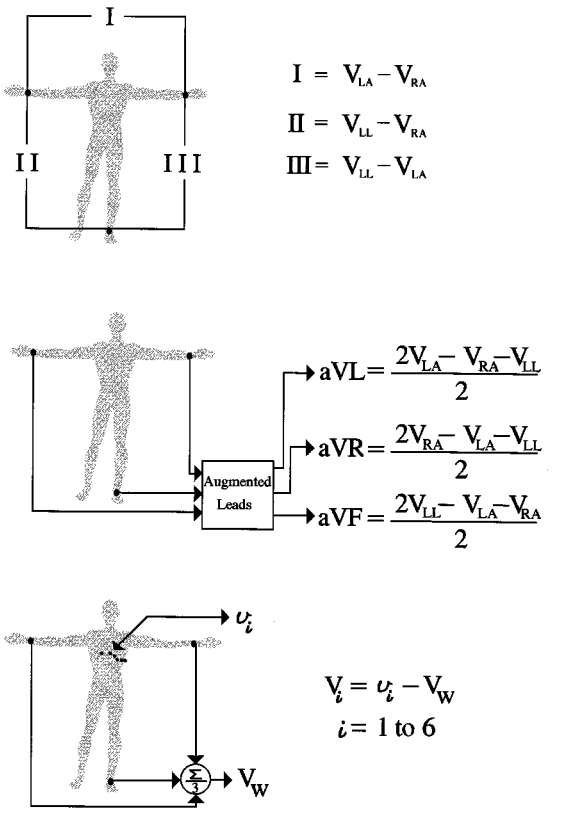

FIGURE 115.5 The 12-lead ECG is formed by the three bipolar surface leads: I, II, and III; the augmented Wilson terminal referenced limb leads: *aVR, aVL, aVF;* and the Wilson terminal referenced chest leads: V_1, V_2, V_3, V_4, V_5, and V_6.

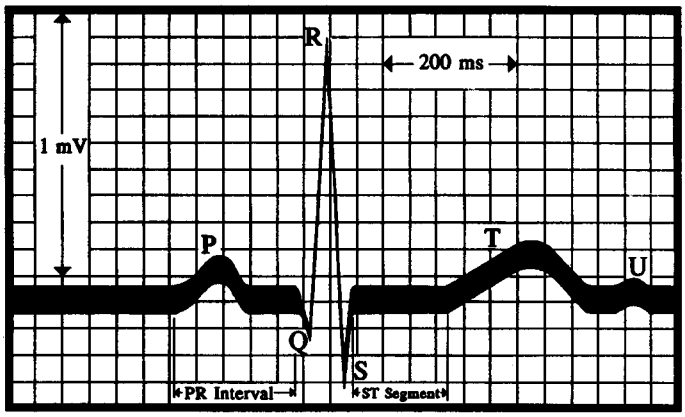

FIGURE 115.6 Stylized version of a normal lead II recording showing the P wave, QRS complex, and the T and U waves. The PR interval and the ST segment are significant time windows. The peak amplitude of the QRS is about 1 mV. The vertical scale is usually 1 mV/cm. The time scale is usually based on mm/s scales with 25 mm/s being the standard form. The small boxes of the ECG are 1×1 mm.

refers to the use of many recording sites (>64) arranged on the body so that isopotential surfaces could be computed and analyzed over time. This approach still has a role in research investigations. Other subsets of the 12-lead ECG are used in limited mode recording situations such as the tape recorded ambulatory ECG

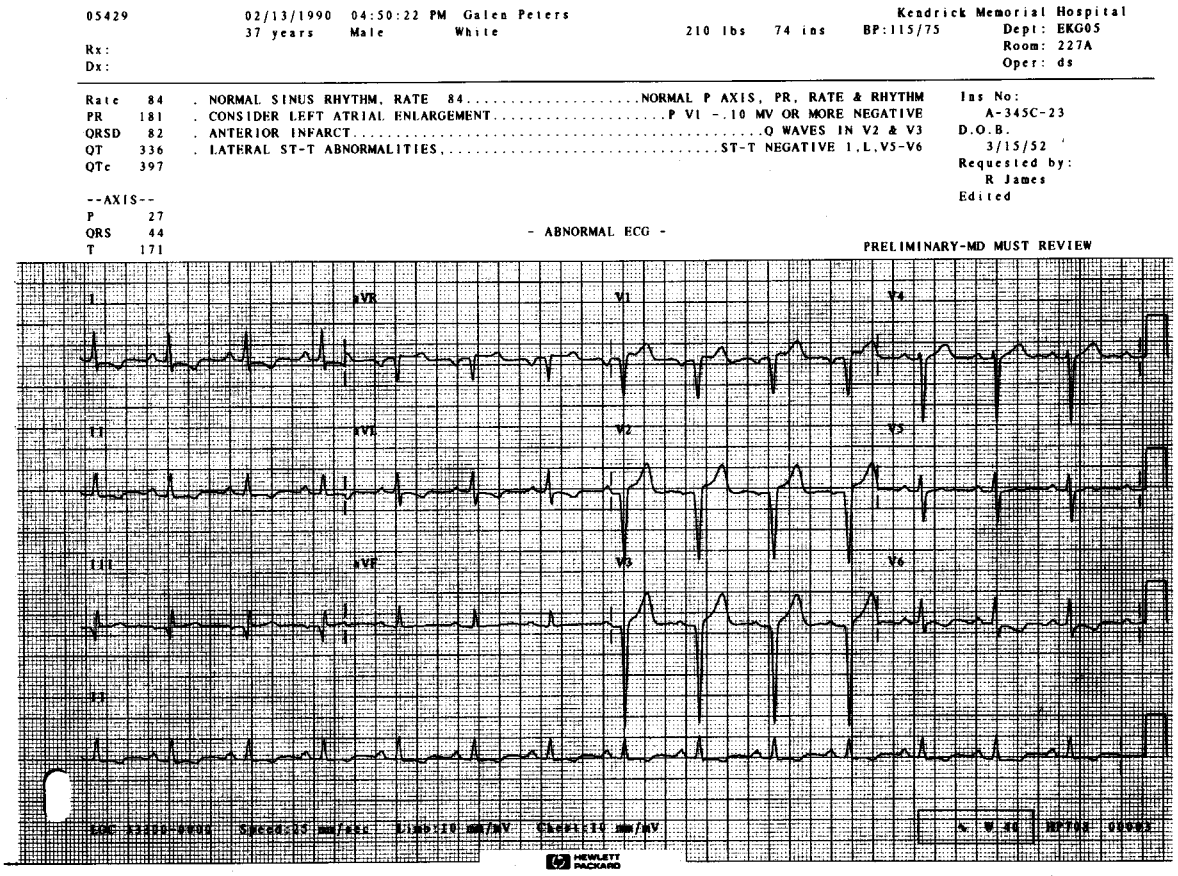

FIGURE 115.7 Example of an interpreted 12-lead ECG. A 2 1⁄2-second recording is shown for each of the 12 leads. The bottom trace is a continuous 10-second rhythm strip of lead II. Patient information is given in the top area, below which is printed the computerized interpretive statements. (Tracing is courtesy of the Hewlett-Packard Co., Palo Alto, CA.)

(usually two leads) or in intensive care monitoring at the bedside (usually one or two leads) or telemetered within regions of the hospital from patients who are not confined to bed (one lead). The recording electronics of these ECG systems have followed the typical evolution of modern instrumentation, e.g., vacuum tubes, transistors, ICs, and microprocessors.

Application of computers to the ECG for machine interpretation was one of the earliest uses of computers in medicine [Jenkins, 1981]. Of primary interest in the computer-based systems was the replacement of the human reader and the elucidation of the standard waves and intervals. Originally this was performed by linking the ECG machine to a centralized computer via phone lines. The modern ECG machine is completely integrated with an analog front end, a 12- to 16-bit A/D converter, a computational microprocessor, and dedicated I/O processors. These systems compute a measurement matrix derived from the 12 lead signals and analyze this matrix with a set of rules to obtain the final set of interpretive statements. The depiction of the 12 analog signals and this set of interpretive statements form the final output, with an example shown in Fig. 115.7. The physician will over-read each ECG and modify or correct those statements which are deemed inappropriate. The larger hospital-based system will record these corrections and maintain a large database of all ECGs accessible by any combination of parameters, e.g., all males, older than 50, with an inferior myocardial infarction.

More recently the high-resolution ECG (**HRECG**) as been developed whereby the digitized ECG is signal averaged to reduce random noise (Berbari et al., 1973, 1977). This approach, coupled with post averaging high-pass filtering, is used to detect and quantify low-level signals (≈1.0 μV) not detectable with standard approaches. This computer-based approach has enabled the recording of events which are predictive of future life-threatening cardiac events [Berbari et al., 1978; Simson, 1981].

Physiology

The heart has four chambers; the upper two chambers are called the atria and the lower two chambers are called the ventricles. The atria are thin-walled, low-pressure pumps which receive blood from venous circulation. Located in the top right atrium are a group of cells which act as the primary pacemaker of the heart. Through a complex change of ionic concentration across the cell membranes (the current source) an extracellular potential field is established which then excites neighboring cells and a cell-to-cell propagation of electrical events occurs. Because the body acts as a purely resistive medium, these potential fields extend to the body surface [Geselowitz, 1989]. The character of the body surface waves depends upon the amount of tissue activating at one time and the relative speed and direction of the activation wavefront. Therefore the pacemaker potentials which are generated by a small tissue mass are not seen on the ECG. As the activation wavefront encounters the increased mass of atrial muscle, the initiation of electrical activity is observed on the body surface and the first ECG wave of the cardiac cycle is seen. This is the P wave and it represents activation of the atria. Conduction of the cardiac impulse proceeds from the atria through a series of specialized cardiac cells (the A-V node and the His-Purkinje system) which again are too small in total mass to generate a signal large enough to be seen on the standard ECG. There is a short relatively isoelectric segment following the P wave. Once the large muscle mass of the ventricles is excited, a rapid and large deflection is seen on the body surface. The excitation of the ventricles causes them to contract and provides the main force for circulating blood to the organs of the body. This large wave appears to have several components. The initial downward deflection is called the Q wave, the initial upward deflection is the R wave, and the terminal downward deflection is the S wave. The polarity and actual presence of these three components depends upon the position of the leads on the body as well as a multitude of abnormalities that may exist. In general, the large ventricular waveform is generically called the QRS complex regardless of its makeup. Following the QRS complex is another short relatively isoelectric segment. After this short segment the ventricles return to their electrical resting state and a wave of repolarization is seen as a low-frequency signal called the T wave. In some individuals a small peak occurs at the end or after the T wave and is called the U wave. Its origin has never been fully established but is believed to be a repolarization potential.

Instrumentation

The general instrumentation requirements for the ECG have been addressed by professional societies through the years [American Heart Association, 1984; Bailey et al., 1990]. Briefly, they recommend a system bandwidth 0.05–150 Hz. Of great importance in ECG diagnosis is the low-frequency response of the system because shifts in some of the low-frequency regions, e.g., the ST segment, have critical diagnostic value. While the heart rate may only have a 1-Hz fundamental frequency, the phase response of typical analog high-pass filters is such that the system corner frequency must be much smaller than the 3-dB corner frequency where only the amplitude response is considered. The system gain depends upon the total system design. The typical ECG amplitude is ± 2mV and if A/D conversion is used in a digital system, then enough gain to span the full range of the A/D converter is appropriate.

To first obtain an ECG the patient must be physically connected to the amplifier front end. The patient/amplifier interface is formed by a special bioelectrode which converts the ionic current flow of the body to the electron flow of the metallic wire. These electrodes typically rely on a chemical paste or gel with a high ionic concentration. This acts as the transducer at the tissue-electrode interface. For short-term applications silver-coated suction electrodes or "sticky" metallic foil electrodes are used. Long-term recordings, such as the case for the monitored patient, require a stable electrode/tissue interface and special adhesive tape material surrounds the gel and a Ag^+/Ag^+Cl electrode.

At any given time, the patient may be connected to a variety of devices, e.g., respirator, blood pressure monitor, temporary pacemaker, etc., some of which will invade the body and provide a low resistance pathway to the heart. It is essential that the device not act as a current source and inject the patient with enough current to stimulate the heart and cause it to fibrillate. Some bias currents are unavoidable for the system input stage and recommendations are that these leakage currents be less than 10 μA per device. This not only applies to the normal setting but if a fault condition arises whereby the patient comes in contact with the high voltage side of the ac power lines, then the isolation must be adequate to prevent 10 μA of fault current as well. This mandates that the ECG reference ground not be connected physically to the low side of the ac power line or

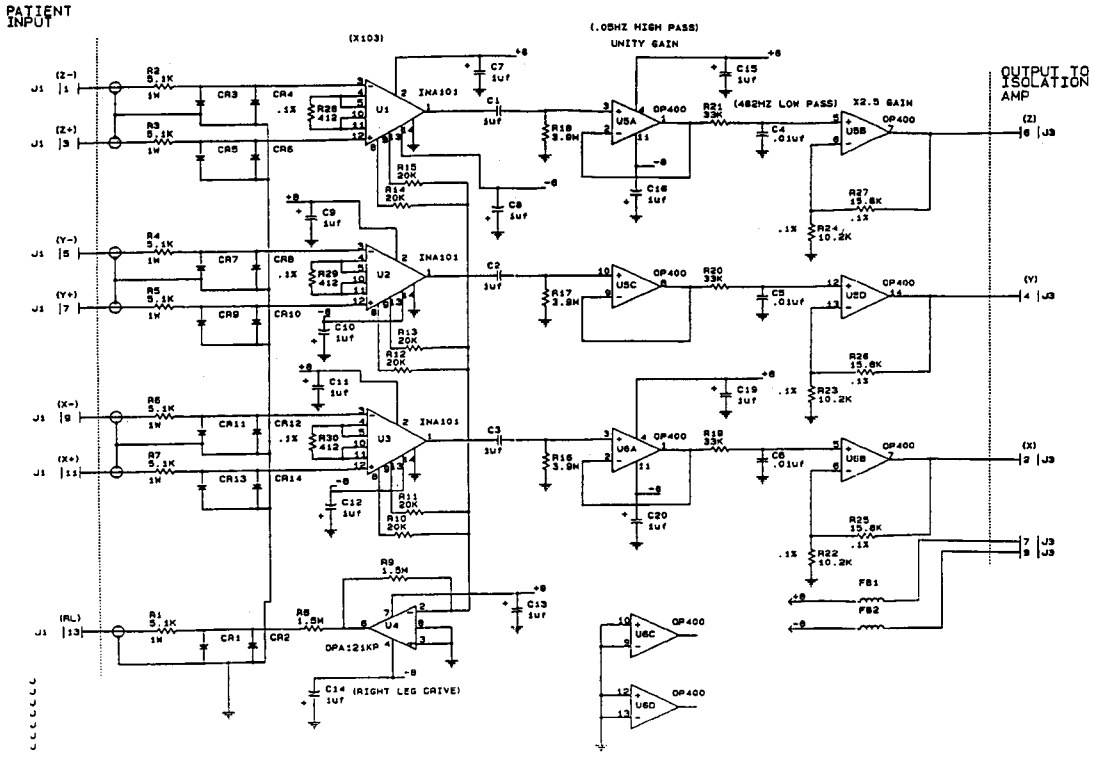

FIGURE 115.8 This schematic represents a typical three-lead *XYZ* amplifier set used in a high-resolution ECG. The instrumentation amplifier (INA101) and bandpass filter (OP400) for each channel are on the isolated side of the power supply. The diode pairs and 4.1 kΩ resistors on each lead wire provide high-voltage defibrillation protection. The outputs of each differential amplifier are averaged through an amplifier (OPA121) and provide the right leg drive. (Schematic is courtesy of Corazonix Corp., Oklahoma City.)

its third wire ground. For ECG machines the solution has typically been to AM modulate a medium-frequency carrier signal (≈400 kHz) and use an isolation transformer with subsequent demodulation. Other methods of signal isolation can be used but the primary reason for the isolation is to keep the patient from being part of the ac circuit in the case of a patient to power line fault. In addition, with many devices connected in a patient monitoring situation it is possible that ground loop currents will be generated. To obviate this potential hazard a low-impedance ground buss is often installed in these rooms and each device chassis will have an external ground wire connected to the buss. Another unique feature of these amplifiers is that they must be able to withstand the high-energy discharge of a cardiac defibrillator.

Figure 115.8 shows a three-channel ECG amplifier schematic used in a high-resolution ECG system. The patient is dc coupled to the front end differential, instrumentation amplifier. The first stage of gain is relatively low (≈100) because there can be a significant signal drift due to a high static charge on the body or low-frequency offset potentials generated by the electrolyte in the tissue/electrode interface. In this particular amplifier the signal is bandpass filtered prior to the isolation stage. To further limit the high floating potential of the patient and to improve the system common mode rejection a driven ground is usually used. This ground is simply an average of the limb potentials inverted by a single amplifier and connected to the right leg.

Older style ECG machines recorded one lead at a time, then evolved to three simultaneous leads. This necessitated the use of switching circuits as well as analog weighting circuits to generate the various 12 leads. This is usually eliminated in modern digital systems by using an individual single-ended amplifier for each electrode on the body. Each potential signal is then digitally converted and all of the ECG leads can be formed mathematically in software. This would necessitate a nine-amplifier system. By performing some of the lead calculations with the analog differential amplifiers this can be reduced to an eight-channel system. Thus only

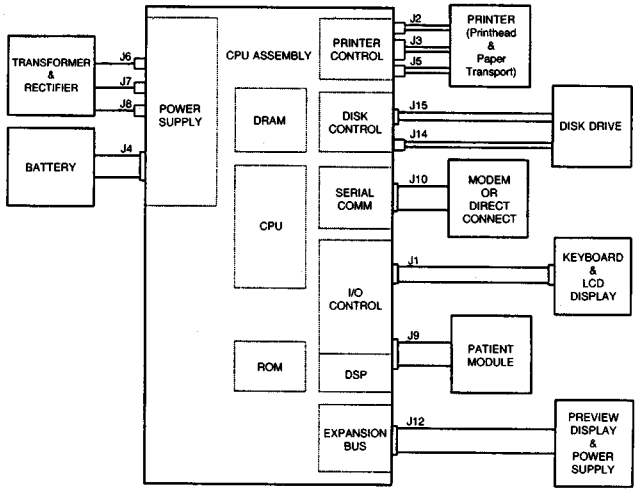

FIGURE 115.9 Block diagram of a microprocessor-based ECG system. It includes all of the elements of a personal computer class system, e.g., 80386 processor, 2 Mbytes of RAM, disk drive, 640 × 480 pixel LCD display, and is battery operable. In addition, it includes a DSP56001 chip and multiple controllers which are managed with a real-time, multitasking operating system. (Diagram is courtesy of the Hewlett-Packard Co., Palo Alto, Calif.)

the individual chest leads V_1 through V_6 and any 2 of the limb leads, e.g., I and III, are needed to calculate the full 12-lead ECG. Figure 115.9 is a block diagram of a modern digital-based ECG system. This system uses up to 13 single-ended amplifiers and a 16-bit A/D converter, all within a small lead wire manifold or amplifier lead stage. The digital signals are optically isolated and sent via a high-speed serial link to the main ECG instrument. Here the 32-bit CPU and DSP chip perform all of the calculations and a hard copy report is generated (Fig. 115.7). Notice that each functional block has its own controller and the system requires a real-time, multitasking operating system to coordinate all system functions. Concomitant with the data acquisition is the automatic interpretation of the ECG. These programs are quite sophisticated and are continually evolving. It is still a medical/legal requirement that these ECGs be over-read by the physician.

High-resolution capability is now a standard feature on most digitally based ECG systems or as a stand-alone microprocessor-based unit [Berbari, 1988]. The most common application of the HRECG is to record very low-level (≈1.0 μV) signals which occur after the QRS complex but are not evident on the standard ECG. These "late potentials" are generated from abnormal regions of the ventricles and have been strongly associated with the substrate responsible for a life-threatening rapid heart rate (ventricular tachycardia). The typical HRECG is derived from three bipolar leads configured in an anatomic *XYZ* coordinate system. These three ECG signals are then digitized at a rate of 1000–2000 Hz/channel, time aligned via a real-time QRS correlator, and summated in the form of a signal average. Signal averaging will theoretically improve the signal-to-noise ratio by the square root of the number of beats averaged. The underlying assumptions are that the signals of interest do not vary, on a beat-to-beat basis, and that the noise is random. Figure 115.10 has four panels depicting the most common sequence for processing the HRECG to measure the late potentials. Panel A depicts a three-second recording of the *XYZ* leads close to normal resolution. Panel B was obtained after averaging 200 beats and with a sampling frequency of 10 times that shown in panel A. The gain is also five times greater. Panel C is the high-pass filtered signal using a partially time reversed digital filter having a second-order Butterworth response and a 3-dB corner frequency of 40 Hz [Simson, 1981]. Note the appearance of the signals at the terminal portion of the QRS complex. A common method of analysis, but necessarily optimal, is to combine the filtered *XYZ* leads into a vector magnitude $(X^2 + Y^2 + Z^2)^{1/2}$. This waveform is shown in panel D. From this waveform several parameters have been derived such as total QRS duration, including late potentials, the rms voltage value of the terminal 40 ms, and the low-amplitude signal (LAS) duration from the 40-μV level to the end of the late potentials. Abnormal values for these parameters are used to identify patients at high risk of ventricular tachycardia following a heart attack.

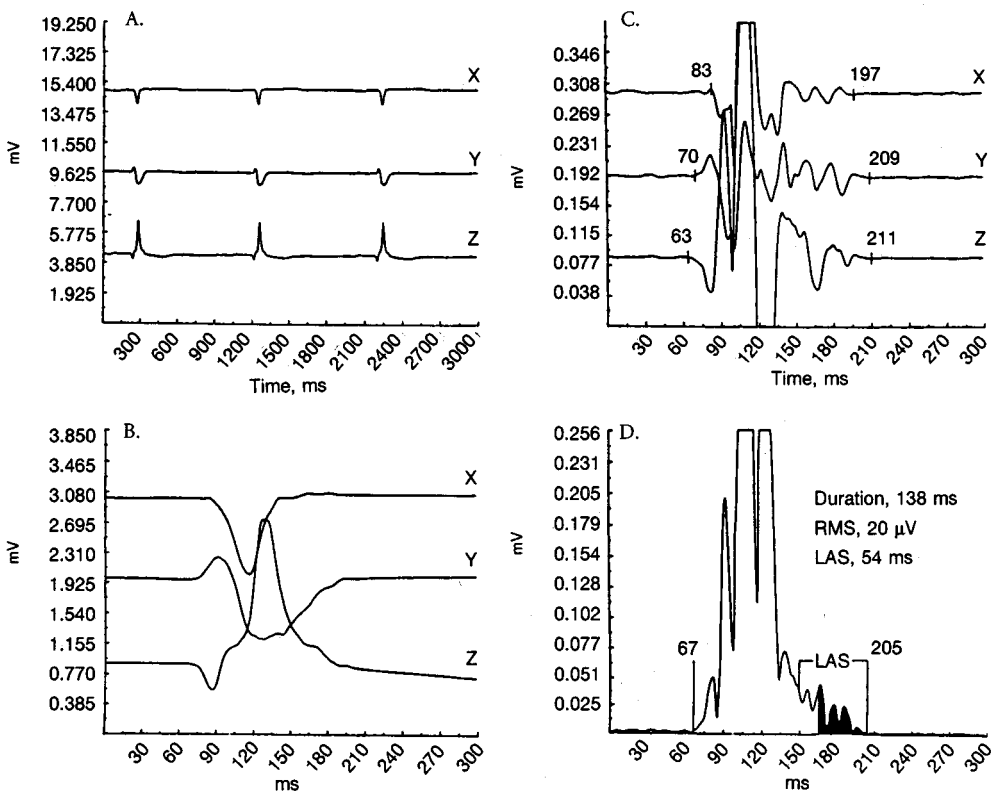

FIGURE 115.10 The signal processing steps typically performed to obtain a high-resolution ECG are shown in panels A–D. See text for a full description.

Conclusions

The ECG is one of the oldest instrument-bound measurements in medicine. It has faithfully followed the progression of instrumentation technology. Its most recent evolutionary step, to the microprocessor-based system, has allowed for an enhanced, high-resolution ECG which has opened new vistas of ECG analysis and interpretation.

Defining Terms

12-lead ECG: Twelve traditional ECG leads comprising the standard set.

ECG: Abbreviation for the device (electrocardiograph) or the output (electrocardiogram) depicting the body surface recording of the electrical activity of the heart.

ECG lead: Differential signal depicting one channel of the ECG record.

HRECG: High-resolution ECG used to detect microvolt-level cardiac potentials most commonly by signal averaging.

Wilson central terminal: Reference point for forming most of the standard ECG leads. It is the average of the right arm, the left arm, and the left potentials. It is a time-varying reference.

115.3 Pacemakers/Implantable Defibrillators

Philip L. Johnson and William M. Smith

The heart is an amazing machine. Throughout an average lifetime, it contracts over 2.5 billion times to pump blood throughout the body. Without its proper function, an individual will die within minutes. The heart consists of four chambers. The upper two chambers, the **atria,** are used as primers for the lower two chambers, the **ventricles,** which serve as the main pump. Blood delivery will be inefficient if the atria and ventricles do not pump in mechanical synchrony (**AV synchrony**). Optimum efficiency occurs when the atria contract slightly before the ventricles. Electrical depolarization waves are responsible for controlling the contractions of the heart and thus maintaining AV synchrony. The depolarization waves originate from a specialized set of cells, known as the **sinus node,** that are modulated by neural input and are located in the top of the right atrium. The sinus

node is the heart's natural pacemaker. It is part of the atrioventricular (AV) conduction system, which serves to distribute the wavefronts throughout the heart and to connect the otherwise electrically isolated atria and ventricles. A normal depolarization wave spreads across the **atria** causing them to contract first, and then, after a brief delay while traversing the AV conduction system, across the ventricles causing them to contract shortly thereafter. With such a demanding, complex organ, it is no wonder there are multiple ways by which it can fail. Failures in the electrical system, known as **arrhythmias**, may impair the contraction sequence and compromise blood flow. These failures are often the result of some underlying heart disease, but may also have a genetic etiology. While antiarrhythmic drugs have been available for some time, contemporary treatment of arrhythmias relies heavily on two types of implantable medical devices: pacemakers and implantable cardioverter defibrillators.

Bradyarrhythmias

Bradyarrhythmias are defined as heart rates that are abnormally slow (<60 b.p.m.) [Katz, 1992]. They are generally caused by either **sinus node** disease or AV conduction disorders. In the former, disease of the body's natural pacemaker cells often results in an unnaturally slow heart rate and significant patient discomfort. Also, the heart rate may not increase in response to exercise due to a loss of neural control of the sinus node, which will inhibit the patient from performing strenuous activities; this is known as chronotropic incompetence. AV conduction disease results from a pathology of the cells that electrically connect the atria and the ventricles. This can result in inefficient blood delivery due to a loss of **AV synchrony.** Pacemakers are commonly used to attempt to restore a natural heart rate, AV synchrony, and chronotropic competence in patients with these and other diseases. Approximately 115,000 pacemakers are implanted in the U.S. every year [Ellenbogen, 1996].

Tachyarrhythmias

Tachyarrhythmias are generally defined as heart rates that are abnormally or inappropriately fast (>100 b.p.m.) [Katz, 1992]. There are many different types of tachyarrhythmias (tachycardias). They are caused by "runaway" depolarization wavefronts that may continue to rapidly activate the same tissue over and over again by a process known as reentry. This can result from a number of underlying physiological problems, such as dying tissue with altered conduction properties due to a blocked coronary artery, around which the wavefront can propagate. The atria and the ventricles can both experience tachycardia. Although somewhat debilitating, atrial tachycardias are not immediately life threatening; however, most ventricular tachycardias are life threatening. The most serious ventricular tachycardia, ventricular **fibrillation,** has been defined as the rapid, disorganized, and asynchronous contraction of ventricular muscle [Epstein and Ideker, 1995] during which the heart's ability to distribute blood to the body is completely compromised. If not immediately treated with a defibrillating electrical shock, loss of life will follow in only minutes. Ventricular fibrillation is the most common cause of sudden cardiac death, of which nearly 400,000 people die annually in the U.S. alone [Gillum, 1989]. The Implantable Cardioverter Defibrillator (ICD) was developed in an attempt to terminate ventricular fibrillation and prevent sudden death from occurring.

Pacemakers

The pacemaker is a medical device capable of controlling the heart rate through a set of implanted electrode leads (Fig. 115.11). The first devices in 1958 were simple, fixed rate oscillators controlled by two transistors [Elmquist and Senning, 1960]. Weighing more than 180 grams, they had a lifetime of around 3 years and paced only the ventricles [Sanders and Lee, 1996]. More sophisticated dual-chamber pacemakers, which sense and pace both the atria and the ventricles independently, were introduced in the late 1970s [Funke, 1982]. Modern pacemakers have shrunk to less than 15 grams (6 ccs) and evolved into sophisticated, implantable computers capable of complex pacing algorithms, telemetry, extensive diagnostics, data storage, and a lifetime greater than 5 years [Sanders and Lee, 1996].

Clinical Indications

Pacemakers are generally indicated for three major disorders, including sinus node disease, AV conduction system disorders, and certain atrial tachyarrhythmias, as well as other less-common pathologies. There are varying degrees of each of these disorders, and the severity of the symptoms and age of the patient may suggest

Figure 115.11 The Guidant/CPI Discovery family of pacemakers. (Courtesy of Guidant/CPI, St. Paul, MN.)

if a pacemaker is warranted. Symptoms may include syncope, dizziness, seizures, heart failure, depression, and dementia. Although bradycardia accounts for the majority of implantations, pacemakers can be used to treat some tachycardias. Antitachycardia pacing is a special type of pacing that may be indicated for atrial or ventricular tachycardias; however, when managing ventricular tachycardias, an ICD is preferable to a pacemaker so that, if the tachycardia degenerates into ventricular **fibrillation,** it can be halted with a **defibrillation** shock. Pacemaker implants may be permanent or temporary.

Surgery

A pacemaker implant is a fairly standard procedure in which the pacing leads are inserted intravenously into the heart and the pacemaker is implanted subcutaneously in a pocket on the chest just below the clavicle. A number of veins have been used to implant the leads, but the cephalic and the subclavian veins are the most common. Access to either of these veins is obtained from the same incision that is used to form the pocket on the chest. A number of tools, such as guidewires, dilator sheaths, and fluoroscopy (real time X-ray), are used to work the lead down the veins into position in the right side of the heart. Depending on the type of pacemaker used, one or two leads may be implanted. In dual-chamber pacemakers, a lead is required in both the **ventricles** and the **atria**. Figure 115.12 shows a diagram of a typical dual-chamber system in the body. The right ventricular lead is usually implanted first and is advanced to the right ventricular apex, where it is fixed. The atrial lead is then advanced to the right atrial appendage, where it is also fixed. A pacing system analyzer is used to test for sufficient electrode contact by measuring impedance, pacing thresholds, and sensing thresholds. The pacing threshold is the smallest charge necessary to stimulate cardiac tissue and initiate a depolarizing wavefront. The

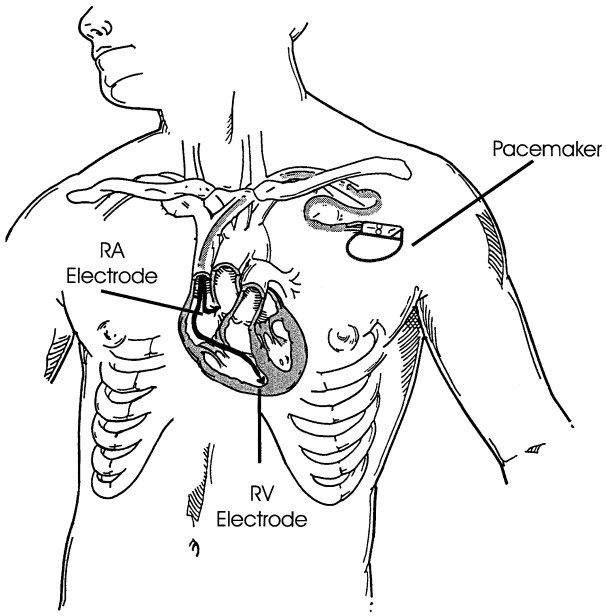

Figure 115.12 Placement of a dual-chamber pacemaker in the body and the leads in heart. The right atrial (RA) electrode is placed in the right atrial appendage and the right ventricular (RV) electrode is placed in the right ventricular apex. Both electrodes are capable of pacing and sensing.

sensing threshold is the smallest acceptable amplitude and slew rate of a sensed cardiac signal. Electrode repositioning may be required if efficient pacing and sensing are not realized. The leads are then connected to the pacemaker, sutured in place to prevent significant pacemaker movement, and the pocket is closed. Pacemaker programming can be accomplished through a wireless telemetry system.

Design

The pacemaker must be able to reliably detect the wavefronts on the **atria** and the ventricles, determine their rate, determine if the chambers are synchronized, and intervene in the appropriate chamber if these conditions are not met. Some patients may receive continuous pacing, while others may rarely need pacing at all. The pacemaker must perform over a period of greater than 5 years, in all types of environments, with maximum reliability, and using the smallest, most comfortable design possible. In addition, it must be adaptable to various types of patients through remotely programmable parameters and informative diagnostics. A pacemaker system is made up of three major components, including the leads, the pulse generator, and the programmer. The pulse generator (i.e., the pacemaker itself) houses all of the controlling and pacing electronics in a biologically compatible titanium shell. The leads provide the electrical link from the pulse generator to the heart. The programmer allows the physician to remotely program the pacemaker parameters and assess pacemaker function through a telemetry system.

Programmer

The programmer provides a bi-directional wireless link to the implanted pacemaker through a telemetry wand. The physician can program parameters that customize functions, check battery capacity, send functional commands to the pacemaker, check for past events, and monitor realtime or stored electrograms measured from the implanted electrodes. Diagnostics provide an invaluable tool for the physician to assess patient welfare, and a well-designed programmer will effectively display this information. Because of the overwhelming availability of parameters and functions built into modern pacemakers, the programmer is an essential part of the pacemaker system. The major problem associated with current telemetry systems is the speed of data transfer. Transfer speeds will need to be significantly increased in the future to keep pace with the increasing number of available diagnostics.

Leads

The purpose of the pacemaker lead(s) is to provide a link between the pulse generator and the cardiac tissue in order to efficiently sense and stimulate the heart. The majority of leads are inserted intravenously and attached to the inside of the heart. Modern leads are composed of five major parts, including the connector, conductor(s), insulation, electrode(s), and a fixation mechanism [Kay, 1996]. The electrode design is critical to minimizing current drain during pacing while ensuring reliable sensing. It has been shown that the pacing threshold is a function of the current density at the electrode [Stokes and Bornzin, 1985]. Minimizing the radius of the electrode will maximize current density and therefore reduce the pacing threshold and current drain. In addition, a small radius will increase the electrode resistance, which also helps to reduce current drain. Conversely, it has been shown that a large electrode surface area decreases sensing impedance and electrode polarization [Kay, 1996]. Electrode polarization is caused by a buildup of charge on the cardiac tissue after a stimulation pulse and can affect the electrode's ability to sense properly. The ideal electrode would, therefore, minimize the radius while maximizing the surface area [Sinnaeve et al., 1987]. This has been accomplished by building electrodes with a small radius but with complex microscopic mesh or porous structure to maximize surface area [Kay, 1996; Bornzin et al., 1983]. Electrode material varies among manufacturers, but is often comprised of a platinum alloy. The conductor serves as the electrical pathway between the pulse generator and the electrodes. It must have low impedance and be able to withstand repeated flexing due to heart motion. This is generally accomplished using a nickel alloy and coiling the wire to resist stress. There will be one conductor in the lead for unipolar configurations and two conductors for bipolar. Unipolar leads use a single electrode at the tip of the lead with the reference being the metal shell of the pacemaker. Bipolar leads use two closely spaced electrodes near the tip of the lead, which is helpful in rejecting external noise when sensing. The conductor must be insulated by a material that can withstand flexing and is resistant to harsh biological conditions. Silicone rubber and polyurethane are two commonly used insulating materials. The connector pin provides a physical link between the lead and the pulse generator and was standardized by an international meeting of manufacturers to avoid confusion when mixing brands of leads and pacemakers [Calfee and Saulson, 1986]. Finally, the fixation mechanism is responsible for holding the lead in place on the heart. The two major types of fixation are known as active and passive fixation. The most common active mechanism involves a helical screw that is advanced into the tissue [Markewitz et al., 1988]. The most common passive mechanism uses flexible tines that become entrapped in the cardiac tissue [Furman et al., 1979]. Fibrous tissue often grows around the fixation mechanism due to tissue injury. This further stabilizes the lead but can cause pacing thresholds to increase over time. A good fixation mechanism will minimize tissue injury while ensuring a stable anchor. Some designs use a steroid-eluting electrode to minimize and stabilize fibrous tissue growth [Timmis et al., 1983].

Pulse Generator

The primary function of the pulse generator is to interpret the information gained from the atrial and ventricular electrodes and other sensors to determine if the patient requires pacing and to deliver the pacing pulses, if necessary. A number of sophisticated algorithms are applied by the pacemaker to determine when pacing is necessary. The pulse generator also performs several secondary functions, such as telemetry and diagnostics. A hermetically sealed titanium shell is used to house the electronics of the pulse generator because titanium is a strong, lightweight metal that is biocompatible with human tissue and does not corrode. Figure 115.13 shows a block diagram of a typical pacemaker pulse generator. A battery supplies the power for the electronics as well as for the pacing pulses. The sensing circuitry is used to amplify the electrical signals that are present on the heart in order to determine the heart rate. If rate-adaptive sensors are used (discussed below), additional sensing circuitry is needed. The output circuitry generates the pacing pulses by storing a charge on a capacitor so it can be delivered to the heart on demand. The backup pacing circuit is capable of asynchronously pacing either the **atria** or the **ventricles** at a preprogrammed rate in the event of excess noise. It also serves as a rate-limiting protection circuit to prevent the heart from being paced at an excessive rate due to a main system failure. The pacing control consists of timing circuitry and logic sections; it is responsible for interpreting sensed data and reacting with an appropriate pacing response. A microprocessor can be integrated with the pacing control and is often utilized as an overall system control to allow for flexibility of design. Memory in the form of RAM and ROM is required to store the microprocessor program, pacing parameters, and diagnostics. The telemetry

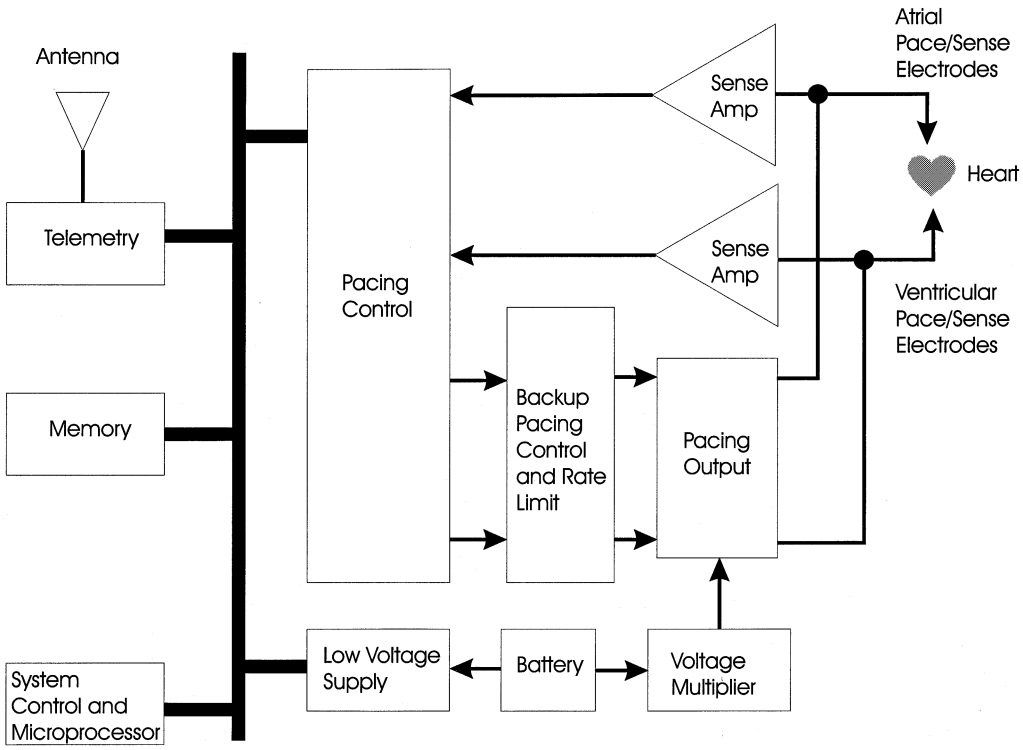

Figure 115.13 Block diagram of typical dual-chamber pacemaker components.

circuit is capable of swapping information with the programmer and is activated by a magnetic reed switch. The above circuits are currently built using CMOS integrated circuits, VLSI design, and hybrid technology. Continuing advances in the electronics industry will allow for further size reductions.

Battery

The battery for a pacemaker must be a safe and reliable energy source with a high energy density capable of supplying several microamperes for longer than 5 years. In addition, it must be possible to reliably predict the end of its life so that the pulse generator can be replaced before pacing fails. Because the battery accounts for the majority of pacemaker volume, these requirements must be met while ensuring that the battery is as small as possible. Nearly all modern pacemakers use lithium-iodine technology [Sanders and Lee, 1996]. This battery has a high energy density and a low internal self-discharge, which combine to give a longer lifetime than past batteries. Lithium serves as the anode, iodine combined with poly-2-vinyl pyridine serves as the cathode, and a semisolid layer of lithium iodide serves as the electrolyte. The cell is hermetically sealed to prevent corrosion. A new battery produces 2.8 V and declines linearly to 2.4 V near the end of its life. Either multiple batteries in series or voltage multipliers can be used to achieve voltages greater than 2.8 V. The status of the battery can be determined by several methods and can be telemetered out to the physician. The current drain of the device ultimately determines the lifetime of the battery and is dependent on many factors, such as circuit operating current, electrode impedance, and frequency, duration, and amplitude of the output pulses. Significant improvements in these areas have enabled the pacemaker battery to shrink in size.

Amplifier Sense System

The purpose of the amplifier sense system is to reliably detect the rate of electrical activity of the heart so that the pacemaker can determine if there is a need for therapy. The amplifier must have a high input impedance to ensure adequate signal amplitude. The system must reject all forms of external noise so that no inappropriate counting occurs. The electrical activity on the heart is manifested as deflections in an electrogram measured

by the sense electrodes. There are multiple deflections in an electrogram during one heartbeat due to near-field and far-field cardiac activity. In a ventricular electrogram, the far-field activity is associated with the depolarization of the **atria** (P waves), and the near-field activity is associated with the depolarization (R waves) and repolarization (T waves) of the ventricles. The R waves, which are the largest and fastest deflections, indicate a depolarization wavefront located directly below the sensing electrode and are, therefore, used as a means to count the heart rate. Circuitry used to sense R waves usually involves voltage comparators and slew rate detectors. Since the R wave deflection normally has a larger amplitude and faster slew rate than the other deflections, the circuitry can use reference thresholds to detect the R waves. The thresholds may be dynamic and determined by a complicated algorithm that has been termed autosensing [Jacobson and Kroiss, 1996; Castro et al., 1996; Kim, 1998]. In addition, there may be a brief amplifier blanking period after an R wave is detected during which all further deflections are ignored (so as to avoid potential inappropriate sensing of following T waves). In dual-chamber pacemakers, it is necessary to measure an atrial electrogram in addition to the ventricular electrogram. Similar detection strategies are employed in the atria; however, due to the large mass of the ventricles compared to the atria, the far-field ventricular activity in an atrial electrogram is more difficult to reject. A sensed cardiac event is marked by a digital pulse that is input into the timing circuitry. The timing circuitry determines if the heart rate is too slow and also controls all amplifier blanking periods and pacing rates.

In addition to far-field effects, many other sources of external noise exist in an electrogram, such as motion artifact, electrode polarization, noise from the skeletal muscles, and environmental noise (e.g., 60-Hz noise and cellular phones). Using bandpass filters and closely spaced bipolar electrodes minimizes external noise. In the event of extreme interference, backup pacing circuits can assume control and asynchronously pace the heart until the noise is gone.

Output Circuitry

The output circuitry is responsible for delivering the pacing pulses through the electrodes to the cardiac tissue in order to artificially control (capture) the heart. Because the amount of energy needed for capture can vary over the lifetime of a patient (e.g., due to changing electrode impedance or position) and between different patients, it is necessary to be able to deliver a controlled amount of energy per pacing pulse. Many pacemakers use an output voltage much higher than the pacing threshold to ensure capture for every pulse; however, this may unnecessarily waste energy. The minimum reliable pulse voltage necessary for capture is desired in order to minimize the current drain on the battery. Autocapture algorithms are capable of monitoring every pulse for capture and adjusting the output voltage to the minimum necessary value on demand [Jones et al., 1999]. This feature will become more prevalent in future pacemakers. Timing circuitry and output amplifiers are used to control the frequency, pulse width, and amplitude of the stimuli. Capacitors controlled by electronic switches physically deliver the energy. The capacitors are charged by the battery up to the desired voltage in between pacing pulses and then discharged into the heart by the switches at the proper timing. Voltage multipliers can be used to double or triple the battery voltage if necessary.

Rate Adaptive Pacing

An important feature of modern pacemakers is their ability to modulate the heart rate based on the metabolic needs of the body. There are many conditions that call for heart rate modulation, such as exercise, fever, stress, or sleep. Because it is under neural control, the ideal rate modulator is a normally functioning **sinus node.** In the case that the patient has atrioventricular conduction problems, the sinus node and the atria may still be functional; therefore, atrial sensing may be used by the pacemaker to regulate the ventricular rate. Patients with sinus node disease or atrial **arrhythmias,** however, require an artificial means of regulating heart rate. Many attempts have been made to design metabolic sensors that can be used to naturally modulate the heart rate. Control variables tested include blood pH [Cammilli, 1977], blood temperature [Alt et al., 1986], venous blood oxygen saturation [Eityzgrlf et al., 1982], respiratory rate [Rossi et al., 1983], minute ventilation [Alt et al., 1987], vibration [Anderson et al., 1983], acceleration [Matula et al., 1992], right ventricular pressure [Yee and Bennett, 1995], and QT interval [Donaldson and Rickards, 1983]. The ideal sensor would be reliable, have low current drain, require no additional surgery, and accurately reflect metabolic needs. All of the above sensors could potentially be used to reflect metabolic needs; however, only a few are currently practical and in use. The most common sensors in pacemakers today are the activity sensors, which attempt to indicate activity level by

transducing vibration and acceleration. Piezoelectric crystals functioning as strain gauges can be mounted to the inside of the pacemaker to detect mechanical vibrations [Anderson and Moore, 1986]. In addition, accelerometers can be mounted directly to the hybrid circuit to detect acceleration [Kay, 1996]. Although both of these sensors are subject to motion that may not be due to exercise, accelerometers have generally proven to be more proportional to exercise than strain gages [Kay, 1996]. Another sensor that has been successfully integrated into pacemakers is the minute ventilation sensor. Minute ventilation is representative of the amount of air a person breathes and can be estimated by measuring the transthoracic impedance over time. This can be accomplished by emitting a train of very small pulses from one pole of a bipolar pacing electrode and measuring the voltage between the other pole and the pacemaker can [Nappholz et al., 1986]. The impedance calculated from the measured voltage rises when a person breathes in and falls when the person breathes out. Combining activity sensors with minute ventilation sensors has proven to be a clinically successful approach to estimating metabolic needs during exercise [Alt et al., 1995].

Future

There are many exciting advancements currently under development for pacemakers. Efforts are being concentrated on making devices more sophisticated but less complicated [Jones et al., 1999]. One approach to realizing these goals is to expand the number and ability of the automatic features, such as autosense and autocapture algorithms. Pacemakers are trending toward automatic self-optimization abilities that are based on the individual patient's needs. Improvements in rate adaptive sensors and algorithms are key to realizing this goal and represent an area of significant research. In the future, integrated circuit technology will allow for much smaller and more efficient designs. This, in addition to improved battery technology, will allow for increased memory, advanced signal processing, and faster telemetry. More memory will permit more extensive patient diagnostics. These diagnostics will be displayed on advanced programmer interfaces that are more clinically relevant. Pacemaker lead research may ultimately yield single-pass leads, capable of pacing and sensing in both the atria and the **ventricles.** Finally nontraditional pacemaker uses are currently being explored. A major area of interest is in the treatment of congestive heart failure (CHF). CHF is a debilitating and deadly disease characterized by an enlarged heart that is incapable of pumping adequate blood to the body. It is possible that the size of the heart facilitates an electromechanical asynchrony between the ventricles. Recent studies have shown that appropriately positioned and timed pacing stimuli can help to improve cardiac output by synchronizing the ventricles [Foster et al., 1994; Bakker et al., 1994].

Implantable Cardioverter Defibrillators

The Implantable Cardioverter Defibrillator (ICD) was first conceived of by Dr. Michael Mirowski in the mid-1960s [Mirowski et al., 1970]. He imagined a device that would continuously monitor the hearts of high-risk individuals for life-threatening **arrhythmias** and intervene by electrical shock to restore normal sinus rhythm.Just over a decade later, the first patient was successfully implanted with an ICD [Mirowski et al., 1980]. From there, rapid development ensued, and FDA approval was obtained in 1985, at which time Cardiac Pacemakers Incorporated (CPI) took over the marketing and development of the ICD. Since then a number of competitors have arisen, and the ICD has evolved into a remarkably sophisticated medical device capable of bradycardia and antitachycardia pacing, low-energy **cardioversion**, high-energy **defibrillation** shocks, and extensive diagnostics (Fig.115.14).

Clinical Indications

Initially, ICDs were only indicated for certain patients that had survived an episode of cardiac arrest. Time of intervention is critical to survival of cardiac arrest; only 25% of people that have an episode are successfully resuscitated by first responders [Shuster and Keller, 1993]. ICDs have decreased the first-year mortality rate of these survivors from 30 to 2% [Winkle et al., 1991]. More recently, in addition to cardiac arrest survivors, patients deemed at risk for a first arrest due to sustained ventricular **tachyarrhythmias** are receiving ICDs as well [Saksena et al., 1996]. In the future, patients with more subtle predictors of sudden death may be indicated for ICDs.

Surgery

The modern ICD is now implanted similarly to a pacemaker. In the past, it was necessary to open the chest (i.e., thoracotomy) in order to suture large patch electrodes directly onto the ventricles and situate the ICD abdominally. Patch electrodes were required to achieve a low defibrillation threshold (DFT), which is a measure

Figure 115.14 The Guidant/CPI Ventak Mini IV ICD with the Endotak lead system attached (a single-pass lead). The Mini IV is a single chamber defibrillator. (Courtesy of Guidant/CPI, St. Paul, MN.)

of the amount of energy needed to reliably terminate **fibrillation** (defibrillate). Due to significant advances in the size and energy efficiency of ICD systems, it is now possible to implant the ICD pectorally and insert specially developed electrode leads into the heart intravenously without the need for a thoracotomy. This ensures greater patient comfort and significantly reduces the risk associated with surgery. There are several different lead configurations available, depending on the manufacturer, each with its own advantages. All of these systems place one electrode in the right ventricular apex, while the position of the return electrode varies between systems. Figure 115.15 shows a typical system layout in the body. The entire surgery can be performed through a single incision, using only local anesthetics and heavy sedation, and is similar to that of the pacemaker. Lead positioning is critical to obtaining low DFTs [Lang et al., 1995; Usui et al., 1995]. Once the lead(s) are in place, the ICD is tested by inducing fibrillation by artificial means and then giving a shock of known energy to halt the arrhythmia. The DFT can be determined by a number of different methods, such as by decreasing the energy of each successive shock until the **defibrillation** attempt is unsuccessful. The DFT must be well below the maximum output energy of the device before a successful implant is declared; a 10-joule safety margin is typically used [Moss et al., 1996]. If an adequate safety margin cannot be obtained through optimal electrode placement, additional electrodes may be required in order to obtain an acceptable DFT. In extreme cases, a thoracotomy may still be required. It is also necessary to thoroughly test the pacing/sensing characteristics as with pacemakers.

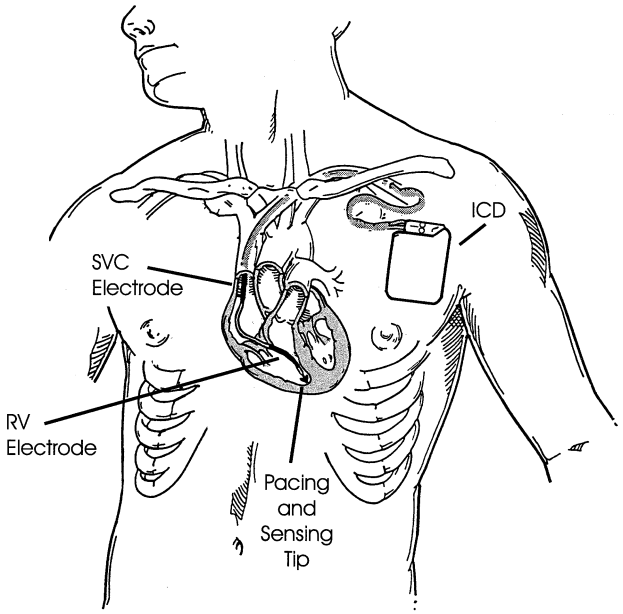

Figure 115.15 Placement of an ICD in the body and a single-pass lead system in the heart. The right ventricular (RV) and the superior vena cava (SVC) electrodes serve as the defibrillation electrodes, and there are pace/sense electrodes at the tip of the lead in the right ventricle.

Design

An ICD system consists of three main components: the programmer, the leads, and the pulse generator. The programmer provides a link to the ICD after it has been implanted and is similar to the pacemaker programmer. The leads deliver the energy from the ICD to the heart for defibrillation, as well as provide for pacing and sensing capabilities. The ICD pulse generator is an ever-evolving technology capable of delivering sophisticated cardiac rhythm management to the patient and diagnostics to the physician. As technology advances, ICDs will become smaller, more reliable, and more versatile.

Leads

The leads provide the means by which to deliver the energy of the defibrillation shock from the pulse generator to the heart, as well as pacing and sensing capabilities. They are insulated with either medical-grade silicone rubber or polyurethane, except at the electrodes. A major disadvantage of these leads is that they deliver current in a largely nonuniform manner as compared to the older patch electrodes, which results in higher energy requirements for defibrillation. Fortunately, advances in battery, capacitor, circuit, and waveform technology have compensated for this greater energy requirement while still allowing the ICDs to become smaller. Because electrode position is important, many different electrode shocking configurations have been attempted. One of the most popular is to place one electrode in the right ventricle (RV) and the return electrode in the superior vena cava (SVC). In addition to defibrillation electrodes, there must be pacing and sensing electrodes as well. Currently, three major configurations exist to accommodate these requirements. The first, known as the single pass lead, integrates two defibrillation coil electrodes (RV, SVC) and ventricular pace/sense electrodes onto a single lead. The second configuration consists of one lead, which contains the RV defibrillation electrode and the ventricular pace/sense electrodes, and a second lead, which contains the return defibrillation electrode. The third configuration consists of one lead containing both defibrillation electrodes and a separate lead containing the ventricular sense/pace electrodes. Some systems use the titanium housing of the ICD as an additional return electrode in the "active can" configuration in an attempt to distribute the current more evenly throughout the **ventricles**. Also, the most modern ICD systems utilize atrial pace/sense electrodes in addition to ventricular electrodes to achieve dual-chamber pacing and sensing capabilities. Another requirement of the defibrillation

lead is that it have very low impedance due to the large **defibrillation** currents, but can still withstand repeated flexing due to millions of heartbeats. This is achieved using a combination of high-strength, low-impedance metals. The pace/sense electrodes are similar in design to those used by pacemakers. The leads are fixed in place by either a screw-in mechanism or flexible tines.

Pulse Generator

The pulse generator is the core of the ICD system. It consists of the batteries, capacitors, and accompanying electronics enclosed in a hermetically sealed titanium can. The can may be used as a return electrode. A header, typically made of epoxy, is attached to the can and provides the link from the electronics to the leads via silicone-sealed ceramic feedthroughs. The size of the pulse generator has steadily declined since the introduction of the ICD and is currently around 40 cc. Significant efforts are underway to further reduce the size of the pulse generator in order to increase patient comfort. As research in defibrillation progresses, more efficient defibrillation strategies will no doubt be developed and allow the size to be decreased further. Currently, the major barriers to size reduction are the battery and capacitor size required to create waveforms capable of ventricular defibrillation. In addition, designing the electronics for a system that can measure cardiac signals on the order of 100 μV and produce high-energy waveforms on the order of 750 V and 40 A, all within the same small space, presents a significant engineering challenge. A problem associated with this includes high-voltage arcing among internal components. To prevent this, nitrogen gas is sealed inside the can because of its high breakdown voltage barrier.

Figure 115.16 shows a block diagram of the key components of a typical ICD pulse generator. The brain of the ICD is the microprocessor. Most ICD manufacturers use industry-standard microprocessors, such as the Z80, 6502, or 8852, to control the ICD [Warren et al., 1996]. In order to conserve energy, it is desirable to put the microprocessor into a sleep mode as often as possible and to wake it only when necessary, such as when an **arrhythmia** is suspected. To accomplish this, many of the monitoring and pacing functions are implemented using analog and digital circuits. Modern ICD designs have reduced the size of the circuitry to a small number of integrated circuits on a hybrid chip [Warren et al., 1996].

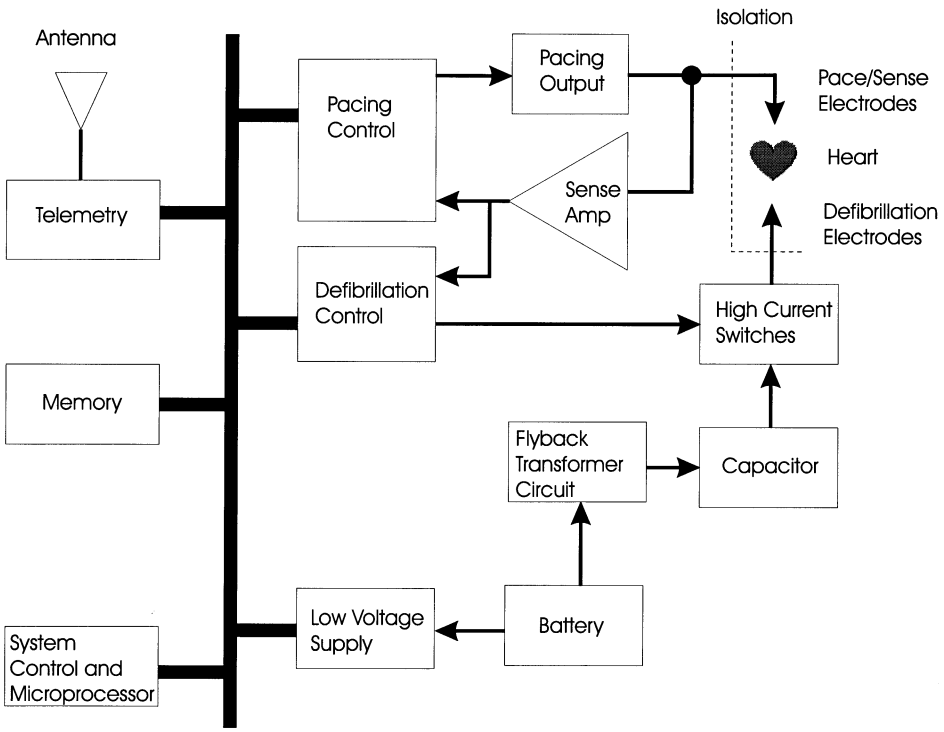

Figure 115.16 Block diagram of typical ICD components.

Memory is required to store the program and individual patient parameters for the operation of the ICD. Startup code and some of the main program is often stored in ROM, while the remaining program, parameters, patient diagnostics (e.g., electrograms), and event markers are stored in RAM. Clinicians and investigators are increasingly interested in diagnostics obtained from the ICD, which warrants future memory increases.

Additional circuitry includes support for the microprocessor, timers, the telemetry interface, low-voltage power supplies, the high-voltage system, the pacing control, the **defibrillation** control, and isolation and external protection circuits. The telemetry interface is the link to the external programmer and consists of a coil, which serves as the antenna, support circuitry, and a magnetic reed activator switch. The low-voltage supplies power the analog and digital circuitry as well as the pacing pulses. The defibrillation control determines when defibrillation is necessary and controls the process of defibrillation. The high-voltage system is used to generate the defibrillation shocks and consists of high-current batteries, capacitors, a fly-back transformer, and output switching circuits. The pacing control includes the circuitry to deliver pacing pulses, to interpret the signals from the sense amplifiers, and timers that monitor the current heart rate and wake the microprocessor if necessary. The isolation and protection circuits provide protection against external defibrillation attempts and external noise.

Amplifier

The purpose of the amplifier sense system is to reliably detect the rate of electrical activity on the heart so that the ICD can determine if there is a need for intervention. The amplifier must be immune to noise and be able to quickly respond to a large range of heart rates (30 to 360 b.p.m.) [Warren et al., 1996]. In order to obtain an accurate heart rate, it is desirable to digitally count R waves, while rejecting all other electrical activity and noise. Since the R wave is much larger in amplitude than the other waves in the electrogram, a simple method to detect them would be to use a comparator with a set threshold. Unfortunately, the amplitude of R waves is not constant; therefore, a simple comparator circuit is not reliable. For example, during tachycardias and **fibrillation**, the amplitude of the signals decreases significantly. One technique commonly used to solve this is to use a dynamically adjusting comparator threshold, in which the threshold level exponentially decreases over time until the next R wave is detected, at which time, the threshold level is reset [Brumwell et al., 1996]. This ensures that low-amplitude signals will be detected. Another technique is to use an automatic gain control to slowly increase the gain between detected R waves, while keeping the threshold constant [Brumwell et al., 1996]. To avoid double counting caused by undesired T-wave detection, there is, typically, a brief period of time after each detected R wave during which sensed signals are ignored. Detection schemes are often implemented with carefully designed analog chips, known as Application Specific Integrated Circuits (ASICs), in order to keep the current drain on the order of 10 μA [Warren et al., 1996]. An advantage of these chips is that they provide near-perfect component matching, which is critical in engineering predictable gain control and frequency response.

Battery

The design for an ICD battery has many stringent requirements and presents a unique challenge to the engineer. While the pacemaker battery is optimized for high energy density, a defibrillator battery must sacrifice some energy density for high current capability. An average defibrillator battery must be able to supply a steady background current of 10 to 20 μA for at least 5 years for monitoring and pacing functions, as well as, provide around 200, 2-A pulses for 10 to 15 seconds each in order to charge the capacitors for multiple defibrillation shocks [Holmes, 1996]. All of these criteria must be met while minimizing the size of the battery and maximizing its safety and reliability. In addition, it is necessary to be able to reliably predict the end of life of the battery. Nearly all modern ICDs use lithium silver vanadium oxide battery technology to accomplish these requirements [Liang et al., 1982]. Lithium pressed into a nickel current collector serves as the anode, and silver vanadium oxide serves as the active cathode. The electrolyte is generally a lithium salt dissolved in a mixed organic solvent. This produces approximately 3.2 V, but two cells are often connected in series to give around 6 V. Some newer systems are using single battery technology. A large electrode surface area and low internal impedance are required to achieve the high current pulses [Holmes, 1996]. This is accomplished by folding the anode in an accordion-like fashion and placing cathode plates in the folds. A disadvantage of this battery is that it exhibits a phenomenon in its mid-life known as voltage delay, in which the voltage goes low in the first second or two during a charging pulse. This can cause a prolongation of the capacitor charging time, which can be dangerous to the patient. It is due to an initial high resistance caused by a chemical buildup on the cathode in the cell

and can be alleviated by periodic pulsing of the batteries into the capacitors and internally dumping the charge. This shortens the life of the battery slightly but is not a total waste because the capacitors need this type of reforming as well. Several methods can be used to predict the end of life of a battery. Common indicators are the battery's open-circuit voltage, voltage during charging, and the time it takes to charge the capacitor [Holmes, 1996]. Future advancements in battery technology are critical in reducing defibrillator size and increasing longevity.

Charging Circuit

In order for a defibrillation shock to occur, it is necessary to convert the 6 V from the battery to an output voltage of up to 750 V to be stored across a capacitor. This is generally done with a dc/dc converter, or inverter. Unique design considerations include the large size of the conversion, a demand for high efficiency, and a minimized transformer and circuit size. The circuit includes the battery and a low-voltage, high-current switch at the input, a fly-back transformer, and a rectifying diode and storage capacitor at the output. A controlling oscillator typically operates the switch between 30 and 60 kHz for high efficiency [Warren et al., 1996]. This creates a simulated ac current, which is converted by the transformer to the higher voltage. The current in the input stage is, typically, around 2 A. The rectifier diode prevents current from flowing back into the secondary winding of the transformer. The voltage on the capacitor increases as a function of the square root of the time that the oscillator is on and typically reaches full capacity in 10 to 15 seconds [Warren et al., 1996]. It is possible for the transformer to be small because of the high-speed switching. In addition, the diameter of the core and the wire windings in the fly-back transformer can be small because the converter is only used intermittently to charge the capacitor, which allows for ease of heat dissipation compared to continuous conversion [Bach and Monroe, 1996]. There is a trade-off between the size of the converter and the efficiency. The high clock rates allow the transformer to be small, but also introduce losses in energy due to hysteresis in the coils. A typical ICD charging circuit achieves about 75% efficiency [Bach and Monroe, 1996]. This plays a major role in the charging time and, therefore, the delay before shocking therapy can be delivered.

Capacitor

The function of the capacitor is to store the energy generated from the high-voltage charging circuitry and to deliver that energy on demand to the heart over a few milliseconds. The commercially available aluminum electrolytic photoflash capacitor is currently used in the ICD. This is because of its high energy density of 1.7 J/cm^3 made possible due to special etching techniques that maximize surface area in the aluminum foil. Because the capacitors are commercially available and are not custom-designed for defibrillators, there are several shortcomings that ICD manufacturers must deal with. Since the highest energy density aluminum electrolytic capacitors are designed to operate at around 375 V, two of these capacitors must be used in series to attain the necessary 750 V used in most designs; therefore, the capacitors play a major role in determining the size of the defibrillator. Their geometry is not ideal for efficient packaging. The round shape results in wasted space in the ICD. Perhaps the greatest shortcoming is the requirement that the capacitor be reformed after periods of no use to ensure there is no leakage current during charging. This involves automatic application of the rated voltage to the capacitor for a few minutes every few weeks in order to repair damage that has occurred due to aging. The latest generation capacitors have minimized the need for reforming. As mentioned before, because the battery requires reforming as well, the energy is not completely wasted. Current research in capacitors is centered on reducing the size by increasing the energy density and eliminating the need for reforming.

Waveform and Output Switching

Optimizing the defibrillation waveform has been the subject of much investigation. Because a capacitor is used to deliver the energy, the waveform is some form of a decaying exponential. Still, there are many parameters that can be varied when creating a waveform, such as the pulse width, amplitude, decay, and the polarity and number of phases. In the past, monophasic, truncated, exponential waveforms were common. More recently, biphasic waveforms, in which the direction of current is reversed at some point during the waveform by switching the electrode polarity, have become more popular. This is due to the work of Schuder and others, who have shown that biphasic waveforms defibrillate with less energy than monophasic waveforms [Schuder et al., 1984; Feeser et al., 1990].

Output switching circuitry is needed in order to time and create these waveforms. Since the load impedance of the defibrillation system ranges from 20 to 70 Ω, it is possible to have peak currents of 40 A in the output circuit. There is, therefore, a need for high-power electronic switches to carry the current, such as Silicon Controlled Rectifiers (SCRs), Metal Oxide Semiconductor Field Effect Transistors (MOSFETs), and Insulated Gate Bipolar Transistors (IGBTs). In addition, these switches must be mounted so that there are very low junctional resistances to minimize power loss. MOSFETs and IGBTs are often used in bridge circuits to facilitate switching of biphasic waveforms. SCRs were used mostly in generating monophasic waveforms, but are still used in some biphasic waveform circuits. Because these types of switches require around 15 V for the control, it is necessary to use a low-power dc/dc converter to boost the 6 V from the battery. Timing of the switching is either controlled by timing circuitry, or by voltage monitoring circuitry that causes a polarity reversal to occur when the voltage falls to a certain threshold.

Future

In the future, ICDs will continue to evolve into increasingly sophisticated cardiac rhythm management devices. The ICD is no longer simply a safeguard against ventricular fibrillation; it is, moreover, being called to better manage bradycardias and tachycardias, and may eventually be used to predict and prevent **arrhythmias** from ever occurring. Management of atrial arrhythmias is also an important emerging frontier. To facilitate these and other demands, a number of advancements are currently being explored [Morris et al., 1999]. New lead systems will be smaller, more reliable, and better designed to manage atrial arrhythmias. Additional sensors may be incorporated, such as pressure transducers to measure hemodynamic stability. More complex rhythm discrimination algorithms will be developed to ensure that appropriate therapy is given at the appropriate time. Advances in electronics, battery, and capacitor technology will allow the ICD to continue to shrink in size. Diagnostic capabilities will be expanded due to increases in memory, and efforts will be made to dramatically decrease the complexity of programming the ICD. Finally, basic research will produce important advances in arrhythmia management, the significance of which cannot yet be imagined.

Defining Terms

Arrhythmia: A general term referring to a disorder in the electrical system of the heart.
Atria: The upper two chambers in the heart that act as primer pumps for the ventricles.
AV synchrony: The timing that must be maintained between the atria and the ventricles in order to pump blood efficiently.
Bradyarrhythmia: A class of arrhythmia that results in an abnormally slow heart rate.
Cardioversion: Termination of a tachyarrythmia, other than ventricular fibrillation, by a low-energy electrical shock.
Defibrillation: Termination of fibrillation by an electrical shock.
Fibrillation: A type of tachyarrhythmia characterized by a disorganized rhythm that can occur in either the atria or the ventricles and completely compromises their ability to pump blood.
Sinus node: Specialized cells in the top of the right atrium, which act as the heart's natural pacemaker.
Tachyarrhythmia: A class of arrhythmia that results in an abnormally fast heart rate.
Ventricles: The lower two chambers of the heart, which are responsible for pumping the blood to the body.

116.1 Tomography

M. D. Fox

The term **tomography** derives from the Greek *tomos* (cutting) and *grapho* (to write). Originally the term was applied to sectional radiography achieved by a synchronous motion of the x-ray source and detector in order to blur undesired data while creating a sharp image of the selected plane. The term *tomography* was used to distinguish between such slices and the more conventional plain film radiograph, which represents a two-dimensional shadowgraphic superposition of all x-ray absorbing structures within a volumetric body.

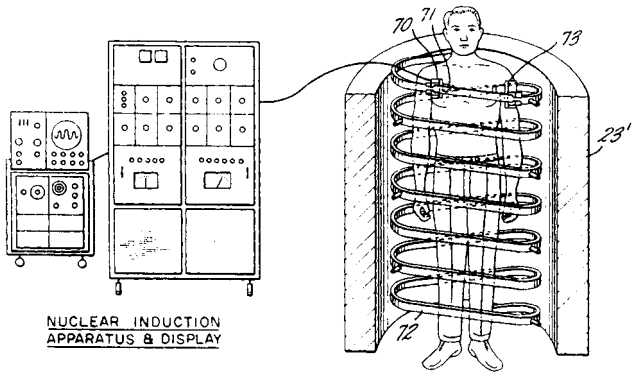
Computerized tomography, also known as **computerized axial tomography,** was introduced by EMI, Ltd. in 1973 and transformed medical imaging by obviating the superposition of intervening structures present in conventional radiographic images. Initially, the clinical application was for imaging the head, but soon the technique found wide application in body imaging.

As medical imaging has evolved into a multimodality field, the meaning of tomography has broadened to include any images of thin cross-sectional slices, regardless of the modality utilized to produce them. Thus, tomographic images can be generated by **magnetic resonance imaging** (MRI), ultrasound (US), computerized tomography (CT), or such nuclear medicine techniques as **positron emission tomography** (PET) or **single photon emission computerized tomography** (SPECT). For the purposes of this discussion we will cover all of the foregoing modalities with the exception of ultrasound, which will be treated separately.

Since the power of such computerized techniques was recognized, the practice of radiology has been revolutionized by making possible much more precise diagnosis of a wide range of conditions. In this necessarily brief discussion we will describe the basic physical principles of the major tomographic modalities as well as their key clinical applications.

Computerized Tomography

The basic concept of computerized tomography can be described by consideration of Fig. 116.1. An x-ray source is passed through an aperture to produce a fan-shaped beam that passes through the body of interest with absorption along approximately parallel lines. The natural logarithm of the detected intensity will be the integral of the linear attenuation coefficient of the object along the ray directed from the source to the detector element. If the source and the detector array are synchronously rotated about a point within the object, a number of



Apparatus and Method for Detecting Cancer in Tissue

Raymond V. Damadian
Patented February 5, 1974
#3,789,832

Excerpts from Raymond Damadian's patent application:

...It has now been found that, by measuring the degree of organization of these selected molecules in cells being studied and comparing this with the degree of organization in a known cancerous cell, cancer cells can be detected. Furthermore, it has now been found that the less the organization the greater the malignancy, therefore a scale can be made to provide a standard for basing a decision on the degree of malignancy...

...Further apparatus is provided for scanning throughout the entire body during which time the relaxation times are measured for selected nuclei and compared with standards. In this way a determination can be made of the existence of cancer together with the location and degree of malignancy of the cancerous cells present....

This patent describes a device that uses very powerful magnetic fields to resonate the nuclei in cells in a body. Collapsing the field and measuring the relaxation times gave a comparison to healthy cells. Later advances in digital signal processing have resulted in magnetic resonance imaging (MRI) equipment with color-coded image viewing of living tissue and its chemical composition.

lines of data can be collected, each representing the projected density of the object as a function of lateral position and angle.

A number of mathematical techniques can and have been used to recover the two-dimensional distribution of the linear attenuation coefficient from this array of measurements. These include iterative solution of a set of simultaneous linear equations, Fourier transform approaches, and techniques utilizing back-projection followed by deconvolution [Macovski, 1983]. Conceptually, the Fourier transform approach is perhaps the most straightforward, so we will describe it in some detail.

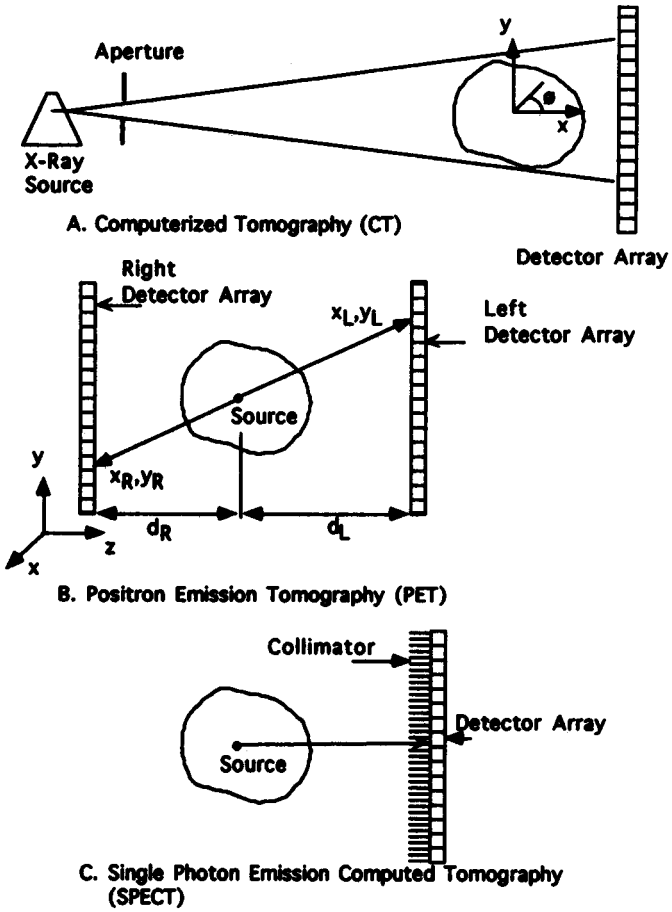


FIGURE 116.1 Comparison of three photon-based tomographic imaging modalities.

Using the coordinate system of Fig. 116.1(A) and assuming parallel rays, the intensity picked up by the detector array can be expressed as

$$I_d(y) = I_0 \exp[-\int a(x,y)\,dx]$$

where $a(x,y)$ represents the linear attenuation coefficient to x-ray photons within the body as a function of x,y position, and I_0 is the source intensity. Rearranging, we see that

$$a_p(y) = \int_{-\infty}^{\infty} a(x, y)dx = \ln[I_d(y)/I_0]$$

where $a_p(y)$ is the projected attenuation function. Taking a one-dimensional Fourier transform of this projected density function we see that

$$F[a_p(y)] = A_p(f_y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} a(x,y)dx\,e^{-j2\pi f_y y}dy$$

where $A_p(f_y)$ is the Fourier transform of a single line of detected data. But this can also be written

$$A_p(0, f_y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} a(x, y)dx\, e^{-j2\pi(0x+f_y y)}dy$$

Thus, the one-dimensional Fourier transform of the projection of the linear attenuation function, $a_p(y)$, is equal to the two-dimensional Fourier transform of the original attenuation function evaluated along a line in the frequency domain (in this case the $f_x = 0$ line).

It can readily be demonstrated that if we rotate a function $a(x,y)$ through an angle ϕ in the x,y plane, its transform will be similarly rotated through an angle ϕ [Castleman, 1979]. Thus as we rotate the source and detector around the object, each projected density function detected $a_p(\rho,\phi_i)$ can be Fourier transformed to provide one radial line of the two-dimensional Fourier transform of the desired reconstructed image, $A(\rho,\phi_i)$, where ρ is a radial spatial frequency. The set of all $A(\rho,\phi_i)$ for small angular displacements ϕ_i form a set of spokes in the transform domain which can be interpolated to estimate $A(f_x,f_y)$, the two-dimensional Fourier transform of the image in rectangular coordinates. The image can then be recovered by inverse transformation of $A(f_x,f_y)$, which can readily be carried out digitally using fast Fourier transform algorithms, i.e,

$$a(x,y) = F^{-1}[A(f_x,f_y)]$$

While the Fourier transform approach is mathematically straightforward, many commercial scanners utilize the equivalent but more easily implemented back-projection/deconvolution approach, where each ray is traced back along its propagation axis. When all rays have been back-projected and the result summed, one obtains an approximate (blurred) image of that plane. This image can then be sharpened (deblurred) through the use of an appropriate filter, which is usually implemented by convolving with an appropriate two-dimensional deblurring function. Refer to Macovski [1983] for the details of this process.

Clinically, the impact of computerized tomography was dramatic due to the vastly increased density resolution, coupled with the elimination of the superposition of overlying structures, allowing enhanced differentiation of tissues with similar x-ray transmittance, such as blood, muscle, and organ parenchyma. CT scans of the head are useful for evaluation of head injury and detection of tumor, stroke, or infection. In the body, CT is also excellent in detecting and characterizing focal lesions, such as tumors and abscesses, and for the evaluation of the skeletal system. [Axel et al., 1983]. In recent years the advent of magnetic resonance systems has provided even greater soft tissue contrast, and thus the role of CT has been constrained by this at times competing modality.

Positron Emission Tomography

Unlike computerized tomography, which relies on photons produced by an external source, in the modalities of positron emission tomography (PET) and single photon emission computed tomography (SPECT), the source of radiation is a radioisotope that is distributed within the body, and thus these modalities are sometimes referred to as forms of emission computed tomography (ECT). While conventional CT can produce images based upon anatomy of organs, emission CT techniques can quantitate the distribution of tracer materials that can potentially elucidate physiologic function.

The positron or positive electron is a positively charged particle that can be emitted from the nucleus of a radionuclide. The positron travels at most a few millimeters before being annihilated by interaction with a negative electron from the surrounding tissue. The product of this event is the emission of 511-keV gamma ray photons which travel in almost exactly opposite directions. The detectors themselves can be either discrete detectors or a modified Anger camera like those used in conventional nuclear imaging. A coincidence detector is employed to limit recorded outputs to cases in which events are detected simultaneously in both detector arrays, thus reducing the pickup of noise or scattering.

A possible detection scheme is illustrated in Fig. 116.1(B). The detector arrays shown can be made energy selective to eliminate lower energy scattered gamma rays. While the distribution of radioactivity can be reconstructed using the reconstruction from projection techniques described in the section on CT [Hurculak, 1987],

the *x,y* source position of an event can be determined directly from the detection geometry as follows [Macovski, 1983]:

$$x \approx x_L\, d_R/(d_R + d_L) + x_R\, d_L/(d_R + d_L)$$

$$y \approx y_L\, d_R/(d_R + d_L) + y_R\, d_L/(d_R + d_L)$$

Typically a single plane is studied, and no collimators are required. A drawback of PET has been that because of the short half-lives of positron-producing radioisotopes, the use of this modality has required the presence of an expensive cyclotron facility located near the hospital.

One important radionuclide commonly used in PET is oxygen 15 with a half-life of 2.07 minutes, which can be bonded to water for measurement of cerebral blood flow or to O_2/CO_2 to assess cerebral oxygen utilization. Another is carbon 11 with a half-life of 20.4 minutes, which can be bonded to glucose to trace glucose utilization. F-18 fluorodeoxyglucose (FDG) has been used to demonstrate the degree of malignancy of primary brain tumors, to distinguish necrosis from tumor, and to predict outcome [Coleman, 1991]. Perhaps the most unusual feature of this modality is the ability to quantitate the regional metabolism of the human heart [Schelbert, 1990].

Single Photon Emission Computed Tomography

In contrast to PET, SPECT can be utilized with any radioisotope that emits gamma rays, including such common radioisotopes as Tc-99m, I-125, and I-131 which have been utilized in conventional nuclear imaging for the last 30–35 years and which due to their relatively long half-lives are available at reasonable cost at nearly every modern hospital. Due to the need for direction sensitivity of the detector, a collimator must be used to eliminate gamma rays from other than the prescribed direction, thus resulting in a 1–2 order of magnitude decrease in quantum efficiency as compared with PET scanning [Knoll, 1983].

The basic concept of SPECT is illustrated in Fig. 116.1(C). A gamma ray photon from a radionuclide with energy above 100 keV will typically escape from the body without further interaction, and thus the body can be regarded as a transparent object with luminosity proportional to the concentration of the radionuclide at each point. The reconstruction mathematics are similar to those derived for absorption CT, with the exception that the variable reconstructed is a source distribution rather than an attenuation coefficient. Some errors can be introduced in the reconstruction because of the inevitable interaction of gamma rays with overlying tissue, even at energies above 100 keV, although this can be compensated for to some extent. Detection of scattered radiation can be reduced through the use of an energy acceptance window in the detector.

Technetium 99m can be used to tag red blood cells for blood pool measurements, human serum albumin for blood pool and protein distribution, or monoclonal antibodies for potential detection of individual tumors or blood cells. Emission computed tomography techniques such as PET and SPECT follow the recent trend toward imaging techniques that image physiologic processes as opposed to anatomic imaging of organ systems. The relatively low cost of SPECT systems has led to a recent resurgence of interest in this modality.

Magnetic Resonance Imaging

The basic magnetic resonance concept has been used as a tool in chemistry and physics since its discovery by Bloch in 1946, but its use expanded tremendously in the 1980s with the development of means to represent magnetic resonance signals in the form of tomographic images. Magnetic resonance imaging is based on the magnetic properties of atomic nuclei with odd numbers of protons or neutrons, which exhibit magnetic properties because of their spin. The predominant source of magnetic resonance signals in the human body is hydrogen nuclei or protons. In the presence of an external magnetic field, these hydrogen nuclei align along the axis of the field and can precess or wobble around that field direction at a definite frequency known as the Larmour frequency. This can be expressed:

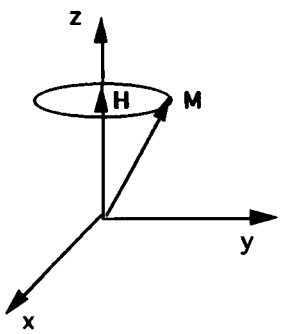

FIGURE 116.2 Geometry of precessing proton in a static magnetic field oriented in the *z* direction.

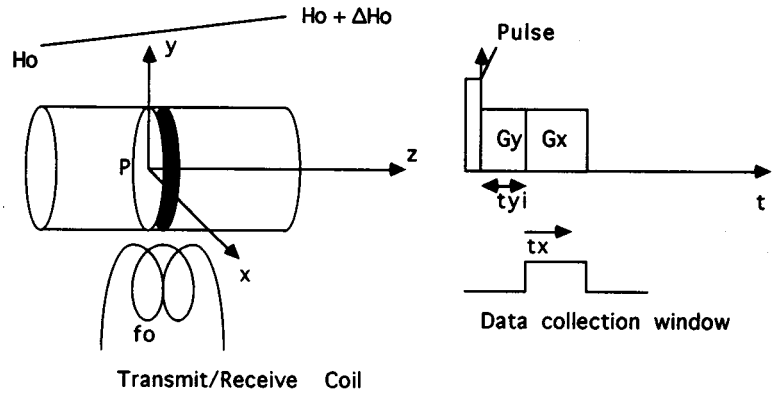

FIGURE 116.3 Concept of magnetic resonance imaging. The static magnetic field H_0 has a gradient such that excitation at frequency f_0 excites only the plane *P*. Gradient G_y in the *y* direction is applied for time t_{yi}, causing a phase shift along the *y* direction. Gradient G_x in the *x* direction is applied for time t_x, causing a frequency shift along the *x* direction. Repetition of this process for different t_{yi} allows the receive coil to pick up a signal which is the two-dimensional Fourier transform of the magnetic resonance effect within the slice.

$$f_0 = \gamma H$$

where f_0 is the Larmour frequency, γ is the gyromagnetic ratio which is a property of the atomic element, and H is the magnitude of the external magnetic field. For example, given a gyromagnetic ratio of 42.7 MHz/tesla for hydrogen and a field strength of 1 tesla (10 kilogauss), the Larmour frequency would be 42.7 MHz, which falls into the radio frequency range.

The magnetic resonance effect occurs when nuclei in a static magnetic field H are excited by a rotating magnetic field H_1 in the x,y plane, resulting in a total vector field **M** given by

$$\mathbf{M} = H\,\mathbf{z} + H_1(\mathbf{x}\cos\omega_0 t + \mathbf{y}\sin\omega_0 t)$$

Upon cessation of excitation, the magnetic field decays back to its original alignment with the static field H, emitting electromagnetic radiation at the Larmour frequency, which can be detected by the same coil that produced the excitation [Macovski, 1983].

Imaging

As shown in Fig. 116.3, one method for imaging utilizes a transmit/receive coil to emit a magnetic field at frequency f_0 which is the Larmour frequency of plane *P*. Subsequently, magnetic gradients are applied in the *y* and *x* directions. The detected signal during the data collection window can be expressed as

$$S(t_x, t_{yi}) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} s(x, y)\exp[-i\gamma(G_x x t_x + G_y y t_{yi})]\,dx\,dy$$

where $s(x,y)$ represents the magnetic resonance signal at position (x,y) (G_x,G_y) are the *x* and *y* gradients, t_x is time within the data collection window, t_{yi} is the *y* direction gradient application times, and γ is the gyromagnetic ratio. The two-dimensional spatial integration is obtained by appropriate geometry of the detection coil. Collecting a number of such signals for a range of t_{yi}, we can obtain the two-dimensional function $S(t_x,t_y)$. Comparing this to the two-dimensional Fourier transform relation

$$F(u,v) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x,y)\exp[-i2\pi(ux + vy)]\,dx\,dy$$

we see that the detected signal $S(t_x,t_y)$ is the two-dimensional Fourier transform of the magnetic resonance signal $s(x,y)$ with $u = \gamma G_x t_x/2\pi$, $v = \gamma G_y t_y/2\pi$. The magnetic resonance signal $s(x,y)$ depends on the precise sequence of pulses of magnetic energy used to perturb the nuclei. For a typical sequence known as spin-echo consisting of a 90-degree pulse followed by a 180-degree pulse spaced at time τ with the data collection at $t_e = 2\tau$, and t_r being the repetition time between 90-degree pulses, the detected magnetic resonance signal can be expressed

$$s(x,y) = \rho(1 - e^{-tr}/T_1)(e^{-te}/T_2)$$

where ρ is the proton density, and T_1 (the spin-lattice decay time) and T_2 (the spin-spin decay time) are constants of the material related to the bonding of water in cells [Wolf and Popp, 1984]. Typically T_1 ranges from 0.2 to 1.2 seconds, while T_2 ranges from 0.05 to 0.15 seconds.

By modification of the repetition and orientation of excitation pulses, an image can be made T_1, T_2, or proton density dominated. A proton density image shows static blood and fat as white and bone as black, while a T_1 weighted image shows fat as white, blood as gray, and cerebrospinal fluid as black. T_2 weighted images tend to highlight pathology since pathologic tissue tends to have longer T_2 than normal.

In general, magnetic resonance imaging has greater intrinsic ability to distinguish between soft tissues than computerized tomography. It also has some ability to visualize moving blood. As the preceding discussion indicates, magnetic resonance is a richer and more complex modality than CT. Typically MRI has been more expensive than CT. Both MRI and CT have been used primarily for anatomic imaging, but MRI has the potential through spectroscopy (visualization of other nuclei than hydrogen) to become a factor in physiologic imaging. Thus, it can be anticipated that magnetic resonance imaging will continue to increase and become an even more important modality in the next decade.

Defining Terms

Computerized axial tomography (CATscan, CT): A form of medical imaging based upon the linear attenuation coefficient of x-rays in which a tomographic image is reconstructed from computer-based analysis of a multiplicity of x-ray projections taken at different angles around the body.

Magnetic resonance imaging (MRI, NMR): Aform of medical imaging with tomographic display which represents the density and bonding of protons (primarily in water) in the tissues of the body, based upon the ability of certain atomic nuclei in a magnetic field to absorb and reemit electromagnetic radiation at specific frequencies.

Positron emission tomography (PET scan): A form of tomographic medical imaging based upon the density of positron-emitting radionuclides in an object.

Single photon emission computed tomography (SPECT): A form of tomographic medical imaging based upon the density of gamma ray-emitting radionuclides in the body.

Tomography: A method of image presentation in which the data is displayed in the form of individual slices that represent planar sections of the object.

116.2 Ultrasound

Leon A. Frizzell

Ultrasound, acoustic waves at frequencies higher than those audible by humans, has developed over the past 35 years into an indispensable clinical diagnostic tool. Currently, ultrasound is used to image most parts of the body. More than half of all pregnant women in the United States are examined with ultrasound. This widespread utilization has resulted from ultrasound's proven clinical utility for imaging soft tissues compared to more expensive imaging techniques. The development of ultrasound, particularly for fetal examinations, has also been fostered by its safety record; no case of an adverse biological effect induced by diagnostic ultrasound has ever been reported in humans [AIUM, 1988].

Diagnostic ultrasound systems are used primarily for soft tissue imaging, motion detection, and flow measurement. Except for some Doppler instruments, these systems operate in a **pulse-echo** mode. A brief summary of some of the fundamentals of acoustic wave propagation and the principles of ultrasound imaging follows.

Fundamentals of Acoustics

Unlike electromagnetic waves, acoustic waves require a medium for propagation. The acoustic wave phenomenon causes displacement of particles (consisting of many molecules), which results in pressure and density changes within the medium. For a traveling sinusoidal wave, the variation in acoustic pressure (the difference between the total and ambient pressure), excess density, particle displacement, particle velocity, and particle acceleration can all be represented by the form

$$p = P e^{-\alpha x} \cos(\omega t - kx) \tag{116.1}$$

for a wave propagating in the positive x direction, where p is the pressure (or one of the other parameters listed above), P is its amplitude, ω is the angular frequency, and $\omega = 2\pi f$ where f is the frequency in hertz, k is the propagation constant and $k = \omega/c$ where c is the propagation speed, α is the attenuation coefficient, and t is the time. The wave can experience significant attenuation, as represented by the exponential decay of amplitude with distance, during propagation in tissues. The attenuation coefficient varies greatly among tissues [Goss et al., 1978, 1980; Haney and O'Brien, 1986] but is low for most body fluids, much higher for solid tissues, and very high for bone and lung (see Table 116.1). The skin depth is the distance that the wave can propagate before being attenuated to e^{-1} of its original amplitude and is thus simply the inverse of the attenuation coefficient.

TABLE 116.1 Approximate Ultrasonic Attenuation Coefficient, Speed, and Characteristic Impedance for Water and Selected Tissues at 3.5 MHz

Tissue	Attenuation Coefficient (m^{-1})	Speed (m/s)	Characteristic Impedance (10^6 Pa s/m)
Water	0.2	1520	1.50
Amniotic fluid	0.7	1510	1.51
Blood	7	1550	1.60
Liver	35	1580	1.74
Muscle	50	1560	1.72
Bone	800	3360	5.70
Lung	1000	340	0.25

Ultrasound is typically used to image soft body tissues such as liver, but the sound beam often travels through fluids, for example, through amniotic fluid when imaging the fetus. Generally, bone and lung are not imaged with ultrasound. The attenuation processes include absorption, which is the conversion of acoustic energy to heat, and scattering, which will be addressed later. The attenuation increases roughly linearly with frequency in the 2- to 10-MHz range typically used for medical imaging. This range represents a compromise between increased penetration at lower frequencies (because of decreased attenuation) and improved resolution associated with higher frequencies as discussed below. Thus, the lower frequencies are used when greater penetration is required, such as for fetal imaging in the obese patient, and higher frequencies for lesser penetration, such as the examination of peripheral vascular flow.

When an acoustic wave impinges on an interface between two media of different specific acoustic impedance, a portion of the incident energy is reflected. For normal incidence on an infinite plane interface, the pressure reflection coefficient is given by [Kinsler et al., 1982]

$$R = \frac{z_2 - z_1}{z_2 + z_1} \tag{116.2}$$

where z_1 and z_2 are the specific acoustic impedance of the incident and transmitting media, respectively. For a plane wave the specific acoustic impedance is equal to the characteristic impedance which is the product of the density and acoustic speed in the medium (see Table 116.1). The speed is dependent upon the density and the elastic properties of the medium. Thus, at an interface between media exhibiting different densities or elastic properties, i.e., compressibility, some acoustic energy will be reflected. Although the reflection coefficient at an interface between muscle and bone is large (approximately 0.54) the reflection coefficient between two soft tissues such as liver and muscle is quite small (approximately 0.006). Reflection at oblique incidence obeys Snell's law in the same way it applies to electromagnetic waves.

In addition to the specular reflection that occurs at an interface between two media of different specific acoustic impedance as described above (where any curvature along the interface is negligible over distances comparable to a wavelength), energy may also be scattered in all directions by inhomogeneities in the medium. An acoustic image is formed by using this scattered energy as well as specular reflections. The fraction of the incident energy reflected or scattered is very small for soft tissues.

Although it is convenient to consider plane waves of infinite lateral extent, as was done above, real sources generate finite beams of ultrasound. These sources may be unfocused, but for the typical diagnostic system they are focused. Figure 116.4 shows the acoustic field from a typical focused source. The source consists of a piezoelectric transducer which converts electrical to acoustic energy and vice versa. Most transducers for medical applications are made from ceramic materials such as a lead zirconate titanate (PZT) mixture. For a circular aperture these may be circular disks with a plano-concave lens mounted in front to produce spherical focusing. Alternatively, the transducer itself may be a spherical segment that produces a focused field without a lens. Some probes utilize electronic focusing methods. Such a phased array probe consists of many individual elements which can be excited with signals having a controlled delay with respect to one another such that the

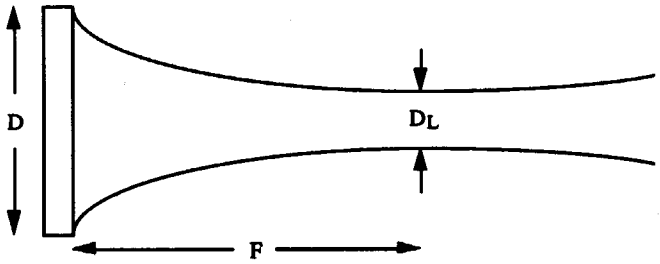

FIGURE 116.4 Cross section of a typical focused circular ultrasound source of aperture diameter D and focal length F, showing the focused beam of lateral beam width at the focus D_L.

signals constructively interfere at the desired focal region. At a receiver the signals are combined with delays associated with various elements to provide reinforcement of the signals from a receiving focal region.

The 3 db lateral beam width D_L is directly dependent upon the wavelength λ and focal length F and inversely related to the aperture diameter (diameter of the transducer) D [Kino, 1987]:

$$D_L = 1.02 \frac{F\lambda}{D} \tag{116.3}$$

Because $f\lambda = c$, the higher the frequency the smaller is λ and D_L. The smaller D_L, the better the lateral resolution near the focus, but the beam spread is greater with distance from the focus. Thus, the strength of the focusing varies among transducers so that the user may choose very good resolution over a short region or somewhat poorer resolution that is maintained over a greater depth. With phased array transducers, the focal region can be varied dynamically to optimize lateral resolution at all distances.

Principles of Pulse-Echo Ultrasound

Ultrasound imaging usually employs frequencies in the 2- to 10-MHz range, though some of the new intravascular probes use higher frequencies. Images are formed by using a transducer within a probe to generate a short pulse (typically on the order of 1 μs in duration) of ultrasound which is propagated through the tissue. A portion of the energy in this pulse is reflected back toward the transducer from specular reflectors and from scatterers in the tissue. These acoustic echoes, with amplitudes much lower than the transmitted pulse, are converted by the transducer to electrical signals which are converted to a (rectified) video signal, amplified by a time gain controlled amplifier, and displayed. The **A-mode display** is rarely used but simply involves display of the received echoes as amplitude versus time of arrival. The time of arrival is related by the wave speed to the tissue depth from which the echo returns, i.e., $d = ct/2$. Figure 116.5 provides a very simple representation of this process where the A-mode display associated with specular reflection from three different interfaces is illustrated. For clinical imaging the interfaces would not necessarily be perpendicular to the axis of the sound beam, and there would be a continuum of echoes, a continuous received signal, due to energy backscattered from within the tissues. Since the ultrasound pulse is attenuated as it propagates, all ultrasonic imaging systems use a logarithmic variation of amplifier gain with time to compensate the exponential attenuation of the tissue. Thus, echoes from structures reflecting or backscattering the same fraction of the incident signal will have the same amplitude after passing through the time gain controlled amplifier.

A **B-mode display** is typically used for ultrasound imaging. It involves display of the echoes at various brightness or gray levels corresponding to their amplitude. A **two-dimensional B-mode display** involves movement of the transducer (manually or automatically), movement of a mirror to change the direction of the field (automatically), or movement of the ultrasound beam directly (electrically) such that it scans a plane through the body. Figure 116.6 provides a simplified representation (again, echoes are shown as arising from interfaces only) of the formation of a B-mode image. The direction of the beam is monitored so that the received signals along each path are placed in their correct location on the display. Typically, the orientation information and echoes are processed by a digital scan converter for appropriate display of the two-dimensional image on

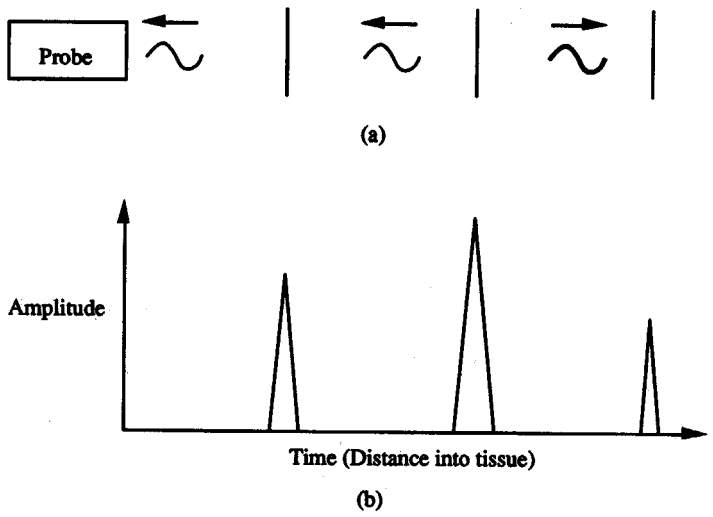

FIGURE 116.5 (a) The transmitted pulse (heavy wave) and echoes from reflecting structures; (b) the resulting A-mode display.

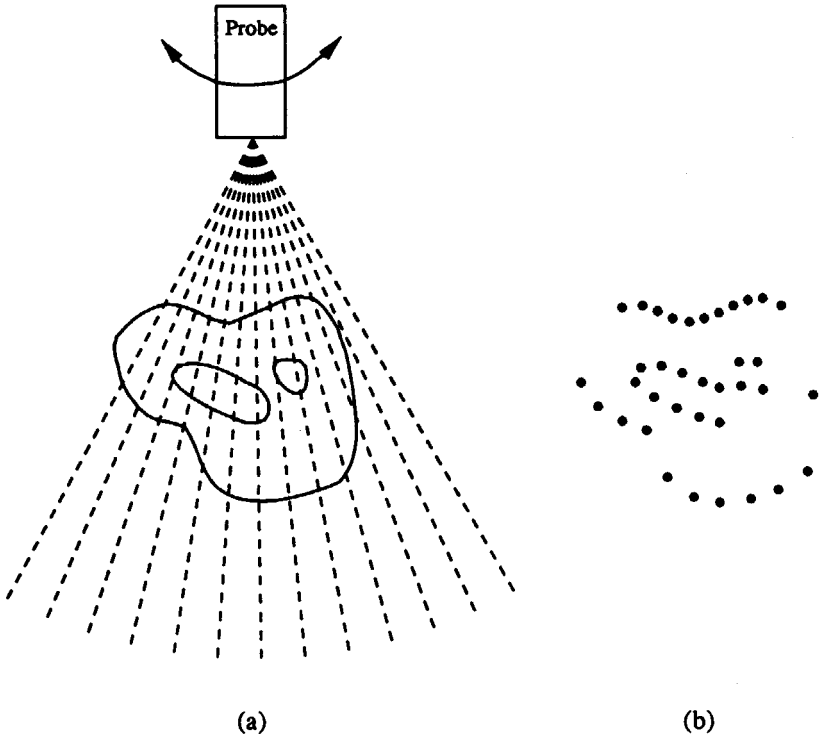

FIGURE 116.6 (a) The transmitted pulse paths for a rotating transducer probe; (b) the resulting two-dimensional B-mode display of echoes from the interfaces only.

a cathode ray tube in the standard format used for television picture display. Most B-mode systems in use today create an image in 0.1 s or less, so that the image is displayed in real-time for viewing of moving structures, such as structures in the heart or the fetus moving within the womb. This is not possible with the typical magnetic resonance or computed tomography system.

Many systems now use digital processing to enhance portions of the image. For example, it is possible to emphasize the large amplitude, small amplitude, or midrange signals. It is also possible to perform a more sophisticated analysis to enhance edges.

Many specialty probes have been designed for intracavitary examination. Examples include examination of the fetus with a vaginal probe, the prostate with a rectal probe, and blood vessel walls with intravascular probes. The intracavitary probe offers the advantage of decreasing the distance from the transducer to the tissue of interest and thus decreasing attenuation such that higher frequencies can be used for greater resolution. The lateral resolution of a focused probe is improved with frequency as discussed in the preceding subsection, but the axial (along the ultrasound beam) resolution also improves with frequency. The shorter the transmitted pulse, the better the axial resolution. Shorter pulses are generated by sources with a larger bandwidth, which corresponds to a higher center frequency when the sources have bandwidths which are approximately the same fraction of the center frequency.

The use of ultrasound for motion detection and measurement has increased tremendously in recent years. Most of these systems use the Doppler principle, but some use time domain detection. In Doppler detection, if the ultrasound is reflected from a target moving at some speed v_t toward (away from) the source at an angle θ with respect to the beam axis, the frequency of the transmitted signal f is shifted up (down) by an amount f_D, the Doppler shift, according to the following relation:

$$f_D = \frac{2 f v_t \cos\theta}{c} \tag{116.4}$$

In principle a measurement of f_D, when f, c, and θ are known, will yield the speed of the target v_t. However, it is often difficult to determine θ because the angle the transducer axis makes with a blood vessel, for example, is often unknown. Even when that angle is known, the flow is not necessarily along the direction of the vessel at every location and for all times. Time domain detection of motion, by measuring the movement of specific echoes from one pulse to another, is a recently developed alternative to Doppler detection that is not currently widely used.

For many years **duplex** systems, which provide both a two-dimensional image and a Doppler signal, showing the change of target speed with time, from a particular selected target area, have been in wide use. More recently, **color flow imaging** has been employed, which provides a two-dimensional color (typically red or blue) image of flow toward and away from the transducer superimposed on the gray scale image of stationary tissue structures. For these systems the speed, whether from Doppler or time domain detection schemes, is indicated by color saturation, hue, or luminance. These systems have proven very valuable for detecting the existence of flow in a region, detecting obstructions to flow and the turbulence associated with this, detecting reduced flow, and so on. Some other systems add to the color flow image a display of speed versus time for a region that is defined by a user-movable box.

Future Developments

It seems clear that the continuing development of intracavitary transducers, particularly for intravascular imaging, and the use of ultrasound intraoperatively will lead to more high-frequency commercially available probes that will produce better resolution images for these applications. The development of useful three-dimensional ultrasonic imaging is progressing rapidly and should immediately improve the measurement of tissue volumes [Gilja et al., 1995].

Defining Terms

A-mode display: Returned ultrasound echoes displayed as amplitude versus depth into the body.

B-mode display: Returned ultrasound echoes displayed as brightness or gray scale levels corresponding to the amplitude versus depth into the body.

Color flow imaging or color Doppler: Two-dimensional image showing color-coded flow toward and away from the transducer displayed with the two-dimensional gray scale image of stationary targets.

Duplex ultrasound: Simultaneous display of speed versus time for a chosen region and the two-dimensional B-mode image.

Pulse-echo ultrasound: Using a probe containing a transducer to generate a short ultrasound pulse and receive echoes of that pulse, associated with specular reflection from interfaces between tissues or scattering from inhomogeneities within the tissue, to form a display of the tissue backscatter properties.

Two-dimensional B-mode display: Echoes from a transducer, or beam, scanned in one plane displayed as brightness (or gray scale) versus location for the returned echo to produce a two-dimensional image.

Further Information

The American Institute of Ultrasound in Medicine publishes monthly the *Journal of Ultrasound in Medicine,* which contains largely clinically oriented articles, and many clinically oriented ultrasound texts are available covering almost any medical discipline. However, there are only a few books that provide more than a cursory treatment of the basic physics and instrumentation of ultrasound imaging.

One text that has been regularly updated since the first volume appeared in 1980 is *Diagnostic Sonography: Principles and Instruments,* 4th edition, by F.W. Kremkau (W.B. Saunders, Philadelphia, 1993). Though this text is designed primarily to train sonographers who do not have a technical background, it provides the fundamentals of ultrasound imaging in a format that is very easy to read and understand.

Other texts that provide a more technical background (though some are a bit dated) include:

Biomedical Ultrasonics, by P. N. T. Wells (Academic Press, New York, 1977).

New Techniques and Instrumentation in Ultrasonography, edited by P.N.T. Wells and M.C. Ziskin (Churchill Livingstone, New York, 1980).

Medical Physics of CT and Ultrasound, edited by G.D. Fullerton and J.A. Zagzebski (American Institute of Physics, New York, 1980).

Physical Principles of Medical Ultrasonics, edited by C. R. Hill (John Wiley, New York, 1986).

Ultrasonic Bioinstrumentation, by D.A. Christensen (John Wiley, New York, 1988).

The Physics of Medical Imaging, edited by S. Webb (IOP Publishing, New York, 1988).

Principles of Medical Imaging, by B. Tsui, M. Smith, and K.K. Shung (Academic Press, New York, 1992).

116.3 Semiconductor Detectors For Radiation Measurements

Larry A. Franks, Larry S. Darken, and Ralph B. James

Since their introduction in the early 1960s, **semiconductor radiation** detectors have become the devices of choice for numerous X-ray, gamma-ray, and charged particle measurements. They are essential in applications where maximum **energy resolution** (i.e., the ability to record the energy of the incident photon or particle) is required. In this characteristic, their performance greatly exceeds that of gaseous sensors (proportional counters, for example) or scintillator/photocell-based spectrometers. Their superior energy resolution stems, in the main, from the greater number of information carriers generated in semiconductors per unit of absorbed energy than in, for example, scintillator/photocell combinations, which are widely used as low-resolution spectrometers. In scintillator-based spectrometers, approximately 100 eV of absorbed energy is required to generate a single information carrier. In a typical semiconductor, only 3 to 5 eV are required to create one electron-hole pair — the information carrier in semiconductor detectors. The statistical variation of the number of carriers produced per ionizing event is thus substantially greater in the case of the scintillator and is reflected in reduced energy resolution. Similar arguments apply to gaseous detectors, where the relatively small number of information carriers is due to the combination of the low density of the absorbing gas and the significant energy required to produce ion-pairs (≈30 eV per ion-pair, [1]), the information carrier in the gas detector.

It is convenient to divide semiconductor detectors into two groups: those requiring cooling (normally to 77K) and those capable of room temperature (or near room temperature) operation. The former group is dominated by high-purity germanium (HPGe) and lithium drifted silicon (Si:Li) — a group characterized by particularly high energy resolution. The latter group includes detectors based on cadmium telluride, cadmium zinc telluride, and mercuric iodide, as well as a number of silicon-based devices. This group finds application in portable X-ray and gamma-ray spectrometers and counters and imaging systems where the freedom from the weight and maintenance of a cryogenic cooler is particularly valued. This chapter section is divided into sections on cryogenic detectors and room-temperature devices. Details of the physics of semiconductor detectors as well as their performance characteristics can be found in several texts [1–7].

Cryogenic Detectors

Detectors in this group are limited principally to high-purity germanium (HPGe) and lithium drifted silicon (Si:Li). HPGe detectors are available in a number of configurations for operation in the X-ray and gamma-ray regions. Si:Li detectors are primarily for the X-ray region. Cryogenic detectors provide the ultimate in energy resolution, as well as good detection efficiency. Common to the group is the requirement that they be operated in the region of 77K. In most cases, the detector temperature is maintained by liquid nitrogen (LN_2) contained in an attached cryogenic vessel (dewar). Dewars are available in capacities ranging from a few liters to several tens of liters, depending on the service interval that is acceptable and the degree of portability required. Alternatively, electromechanical coolers are also available.

Germanium Detectors

High-purity germanium (HPGe) detectors are widely used for gamma-ray spectroscopy due to their combination of efficient absorption and high energy resolution. Figure 116.7 shows the cross sections for photoelectric absorption, Compton scattering, and absorption by electron-positron pair production in several materials used for solid-state nuclear radiation detectors. Attenuation is significantly stronger in germanium than in silicon. Over much of the gamma spectrum, the dominant interaction is Compton scattering. However, it is principally the stronger photoelectric absorption in germanium that makes it more suitable than silicon for gamma-ray spectroscopy. In the typical germanium detector, a gamma-ray can be scattered several times before it is photoelectrically absorbed. Thus, the energy of the gamma-ray is primarily transmitted directly to a small number of electrons. These energetic electrons, in turn, interact with electrons in the valence bands to create mobile pairs of electrons and holes. The average number of electron-hole pairs N produced by a completely absorbed gamma-ray of energy E becomes independent of the details of the initial reaction path and varies linearly with E:

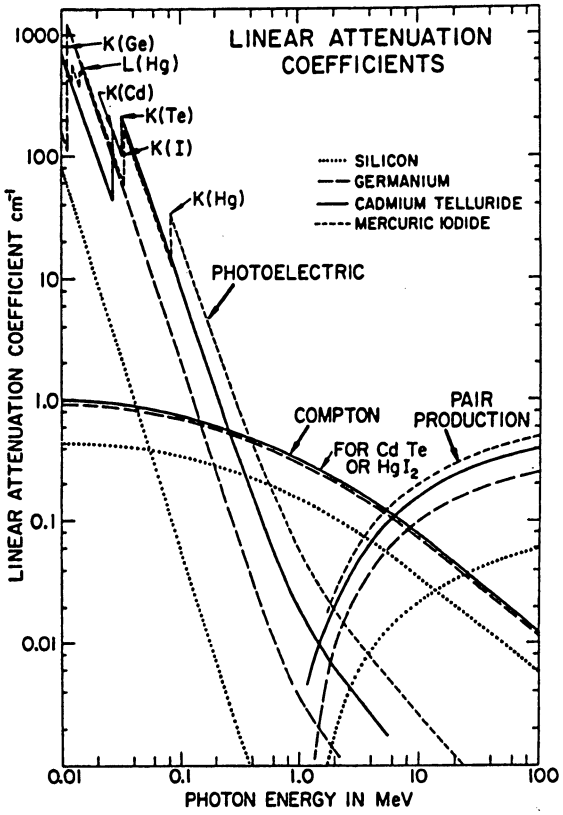

FIGURE 116.7 Attenuation coefficients vs. energy common semiconductor materials. (T. E. Schlesinger and R. B. James, *Semiconductors for Room Temperature Detector Applications.*)

$$N = E/\varepsilon \tag{116.5}$$

This relationship is more broadly valid and is the foundation of energy spectroscopy of gamma-rays using semiconductors, gases, and cryogenic liquids (ε depending on the material). While ε is independent of the gamma-ray energy (and is also virtually the same for energy deposited by charged particles), ε in germanium does increase slightly with decreasing temperature, as does the energy gap. At 77K, ε is 2.96 eV and the energy gap is 0.72 eV.

Practical exploitation of Eq. (116.5) depends on electronically detecting the motion of the ionized charge in an electric field. The signal-to-noise ratio is improved by reducing current flow in the detector from other mechanisms. In germanium, this is achieved by producing a rectifying and a blocking contact and by cooling to about 100K. For a planar detector, a slice of high-purity germanium is diffused with the donor lithium on one side, forming a strongly *n*-type layer. The opposite side is implanted with the acceptor boron, forming a p^+ layer. When voltage is properly applied, the electric field direction prevents the majority carriers in the contact regions from being injected across the device. As the voltage is applied, a region depleted of holes will advance into the slice from the n^+ contact if the slice is *p*-type. If the slice is *n*-type, the a region depleted of electrons will advance from the p^+ contact. At the depletion voltage V_d, the depletion region reaches the opposite contact. For germanium:

$$V_d = 565\ V * \left|N_A - N_D\right| \Big/ 10^{10}\ dm^{-3} * d^2 \Big/ cm^2 \tag{116.6}$$

Here, $N_A - N_D$ is the net charge density in the depleted or active region of the detector and d is the thickness of this region. This is a key relationship in high-purity germanium technology as it quantifies the effect of the residual impurity concentration on device size and depletion voltage. Techniques to grow germanium pure enough for gamma detectors were pioneered by Hall [8] and the detector group at Lawrence Berkeley Laboratory [Haller, Hansen, and Goulding [9], based on purification methods of Pfann [10] and crystal-growing techniques developed by Teal and Little [11] to produce crystals for germanium transistors.

Leakage Current

Germanium detectors need to be cooled to reduce **leakage current.** There are several potential sources of leakage current, including diffusion of minority carriers from either doped contact into the depletion region, thermal generation of carriers at either bulk or surface defects in the depletion region, and electrical breakdown at points where the electrical field is concentrated due to irregularities in the contact geometry, large-scale inhomogeneities in the bulk, or surface states. Current will also be generated if the detector is not shielded from room-temperature infrared radiation. Background nuclear radiation from materials near the detector and cosmic radiation also generate current.

Germanium detectors are typically liquid-nitrogen cooled and operated between 85K and 100K. In this temperature range, leakage current is typically less than 40 pA in "good" detectors, and is not a significant contributor to system noise (400–900 eV). Leakage current increases with temperature and eventually becomes the predominate noise component. Pehl, Haller, and Cordi [12] reported a leakage current-driven system noise of 2 KeV at 150K and 7 KeV at 170K for an 8 cm^3 planar detector. These authors also reported that above about 120K, the leakage current had an activation energy of approximately one-half the bandgap, and attributed this to generation at mid-gap surface states. Below 120K, the temperature dependence was milder.

A typical detector/cryostat configuration is shown in Fig. 116.8. The detector resides in an evacuated cryostat and is cooled by means of a copper rod inserted into a liquid nitrogen dewar. The first stage of amplification is an FET, also cooled, positioned nearby the detector. Mechanical fixturing is designed to stabilize the detector and the mechanisms for contacting it, to provide a cooling path from the detector to liquid nitrogen, and to electrically insulate the high-voltage contact.

A variety of detector geometries is shown in Fig. 116.9. These different electrode configurations allow the detectors' efficiency and **energy resolution** to be optimized for different gamma-ray energies and applications. For example, the detector in Fig. 116.9(c) minimizes noise by the lower capacitance of its electrode configuration at the expense of the reduced stopping power. Thus, this detector would be more suitable for lower-energy gamma-rays.

Coaxial Detectors

The detector type shown in Fig. 116.8 and in Fig. 116.9(e) has a closed-end coaxial geometry. Nearly all the largest volume (active volumes of 100 cm^3 to 800 cm^3) HPGe detectors are of this type. This electrode geometry reduces both capacitance and depletion voltage with respect to a planar detector of the same volume. This latter benefit relaxes the constraint on material purity. In addition, charge collection distances are shortened, and the uncontacted surface area, frequently troublesome in processing, is reduced. Also, the HPGe is grown by the Czochralski technique, and is therefore nearly cylindrical even before machining. It is important, however, to note that the reduction in depletion voltage is realized only when the device is contacted so that it depletes from the outer contact to the inner contact. Thus, *p*-type HPGe to be fabricated into a coaxial detector is lithium diffused on the outer diameter; and in the case of *n*-type HPGe, the outer diameter is boron implanted.

The boron-implanted contact (depth approximately 0.2 μ) is thinner than the lithium-diffused contact (depth approximately 750 μ), so the *n*-type coaxial detector can detect lower-energy radiation and is usually built with a beryllium window in the aluminum end-cap to take full advantage of this feature. The difference in the range of use is illustrated in Fig. 116.10. The geometric asymmetry of the contacting electrodes in the coaxial detector makes charge collection more dependent on the carriers (electrons or holes) traversing to the inner contact. As more gamma-rays are absorbed near the outer contact, the carriers traversing to the inner contact must travel on average a longer distance. Also, charge traversal near the inner contact is particularly effective in inducing current in the external circuit [13]. Thus, the *p*-type coaxial detector with positive bias on the outer electrode is more sensitive to hole collection, and the *n*-type coaxial detector with negative bias on the outer electrode is more sensitive to electron collection. This is a crucial consideration in applications where hole collection is going to be degraded during use by exposure to fast neutrons or other damaging radiation. The

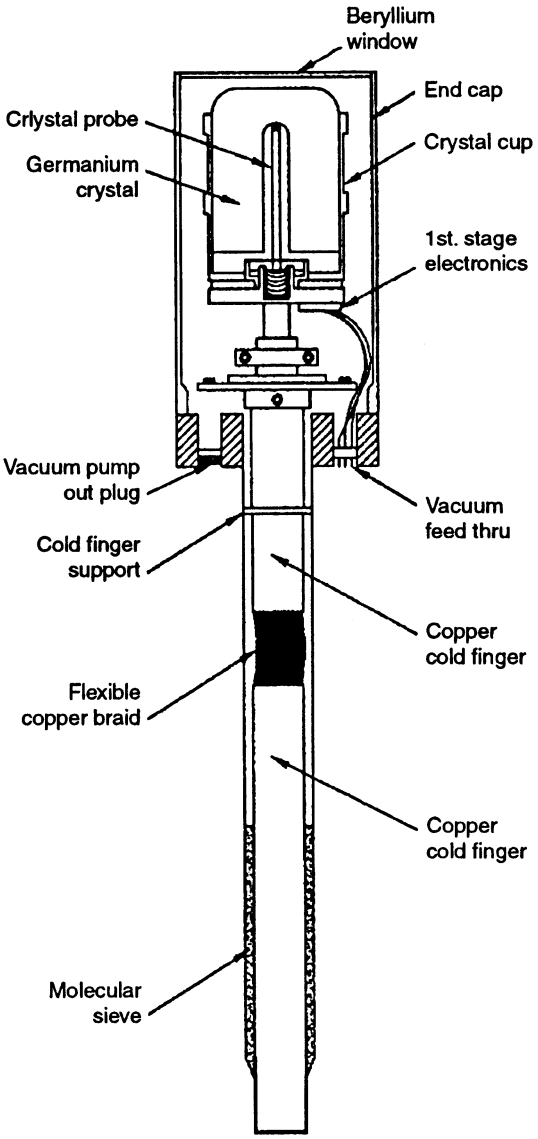

FIGURE 116.8 Schematic cross section of a dipstick cryostat. (Darken and Cox, 1993; reprinted with permission of Oxford Instruments, Inc.)

superior neutron damage resistance of the electrode biasing polarity on *n*-type coaxial detectors was demonstrated by Pehl et al. [14].

A typical gamma-ray spectrum of a ^{60}Co source taken with a coaxial HPGe detector is shown in Fig. 116.11. The salient features are the full-energy peaks at 1.17 MeV and 1.33 MeV, and the lower-energy plateaus due to incomplete energy absorption of Compton scattered gamma-rays. The peak-to-Compton ratio [15] is generally 40 to 100, depending on the size and quality of the detector. The 1.33-MeV **peak** is shown separately in Fig. 116.12. The **energy resolution** measured as the full width at half the peak maximum (FWHM) for typical coaxial germanium detectors is between 1.6 KeV and 2.1 KeV for 1.33-MeV gamma-rays, again depending on the size and quality of the detector. The variance in the peak L^2 (FWHM = 2.35 × L, L being the standard deviation for a Gaussian distribution) can be divided into three additive components: the electronic noise component L_N^2, a component reflecting the variance in the number of electron-hole pairs created L_F^2, and a component due to incomplete charge collection L_T^2:

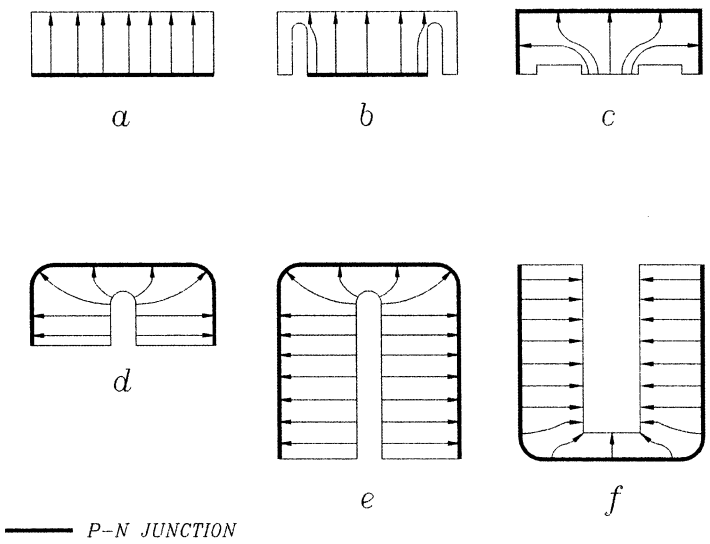

FIGURE 116.9 Schematic cross section and electrostatic field distribution in high-purity germanium detectors. The dark line represents the *p-n* **junction:** (a) true planar, (b) grooved planar, (c) low-capacity planar, (d) truncated coaxial, (e) closed end coaxial, (f) well geometry.

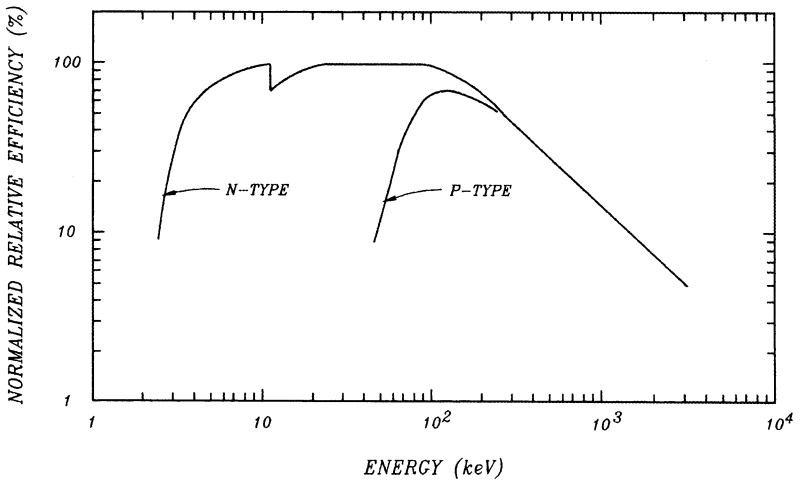

FIGURE 116.10 Relative absorption efficiencies for typical *n*- and *p*-type detectors. (Darken and Cox, 1993; reprinted with permission of Oxford Instruments, Inc.)

$$L^2 = L_N^2 + L_F^2 + L_T^2$$
$$L_F^2 = \varepsilon E F \tag{116.7}$$

F is called the Fano factor and has been experimentally determined to be no greater than 0.08 for germanium [16]. $F < 1$ implies that electron-hole pair creation events are not uncorrelated. L_T^2 is usually dominated by the trapping of electrons and holes at defect sites. However, shorter electronic shaping times, lower electric fields, and larger detectors accentuate **ballistic deficit** (loss of collected charge in the external electronics due to the finite traversal time of the electrons and holes across the detector). L_N^2 is independent of gamma-ray E and is

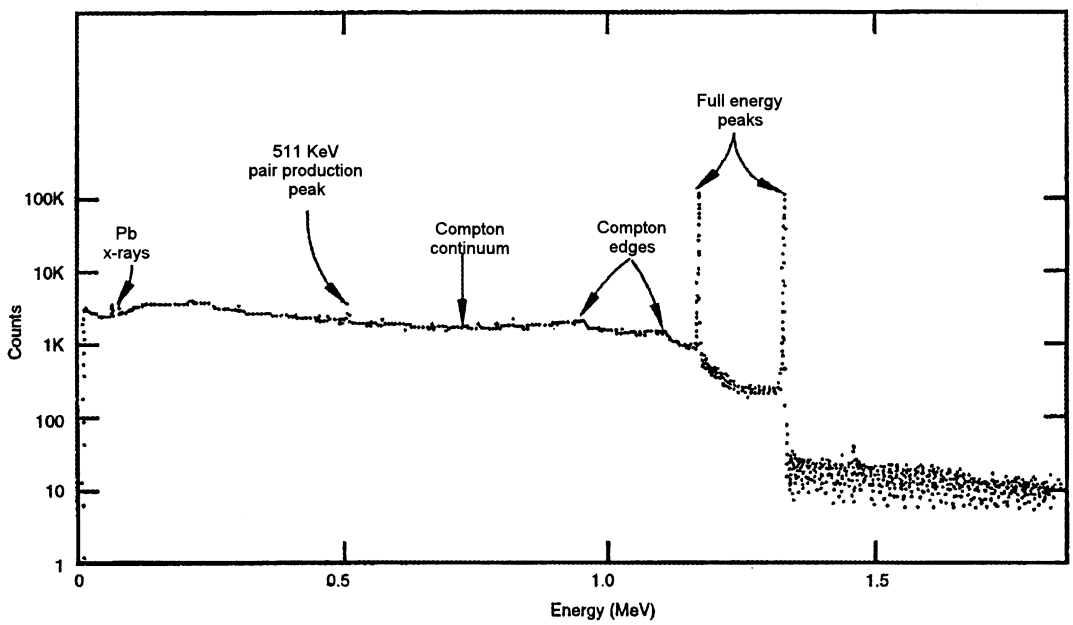

FIGURE 116.11 A ^{60}Co spectrum collected with a 15% *p*-type detector showing typical features of the germanium detector spectrum.

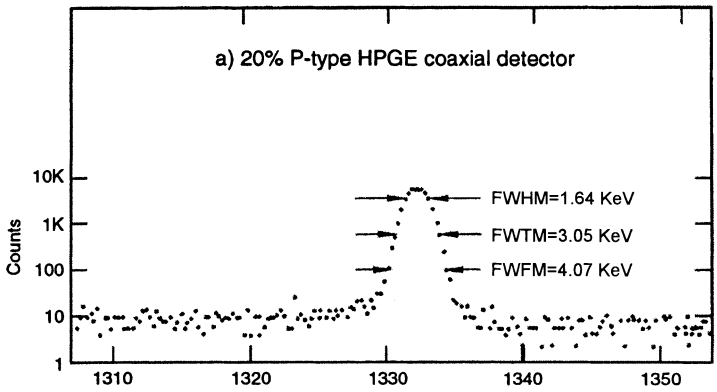

FIGURE 116.12 A ^{60}Co spectrum collected with a 22% relative efficiency *p*-type detector. (Darken and Cox, 1993; reprinted with permission of Oxford Instruments, Inc.)

the dominant resolution limiting factor at low energies. L_F^2 depends linearly on E, and for a coaxial detector usually dominates L_N^2 for E over a few hundred KeV. The energy dependence of L_T^2 is not given simply from first principles for an arbitrary trap distribution, but an E^2 dependence seems to fit under many circumstances. Thus, at high enough E, L_T^2 is expected to be the largest component. For "good" detectors at 1.33 MeV though, L_T^2 is always smaller than L_F^2. However, the magnitude of L_T^2 is variable enough between detectors that it distinguishes between acceptable, very good, and excellent detectors. L_T^2 is usually also the only component of resolution drawn from a nongaussian distribution and is thus responsible for any low-energy tailing of the peak.

X-ray Detection

Both silicon and germanium detectors are used in low noise systems for the detection of fluorescent X-rays produced by electron beams (usually in an electron microscope) or X-rays (XRF). For both materials, the detector is liquid-nitrogen cooled to reduce **leakage current,** and small volume devices (Fig. 116.9, typically

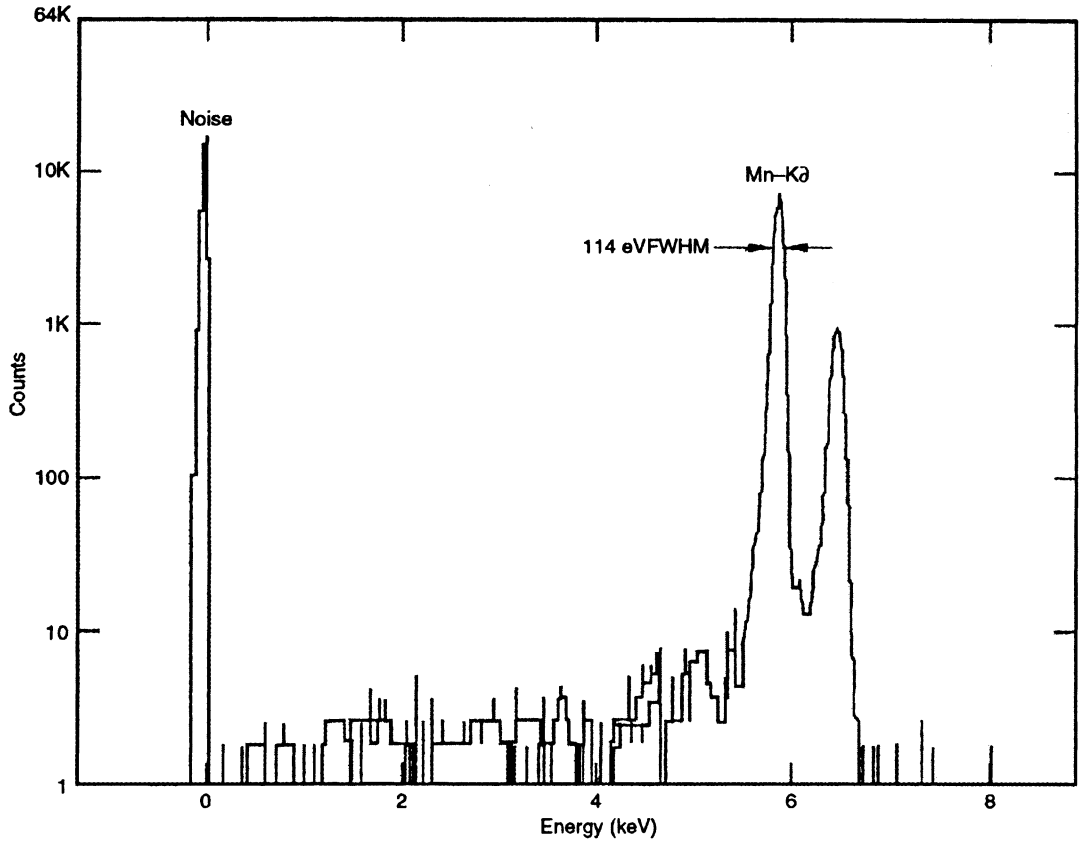

FIGURE 116.13 Manganese X-ray spectrum from an ^{55}Fe source collected with an HPGe detector. (Darken and Cox, 1993; reprinted with permission of Oxford Instruments, Inc.)

10 mm^2 active area, and 3 mm depth) are used in order to decrease capacitance and therefore further reduce electronic noise. Lithium-drifted silicon (Si:Li) detectors were used first for these applications. Early germanium detectors displayed poor peak shape for X-ray energies just above the L absorption edges (attributed to diffusion against the field to the front contact by some electrons and their resulting loss to the photopeak [17]). However, as was first demonstrated by Cox et al. [18], this is not a fundamental problem, but can be solved by the contacting technology. An X-ray spectrum taken with an HPGe detector is shown in Fig. 116.13. Germanium has the advantages with respect to silicon of a smaller ε (2.96 eV/pair vs. 3.96 eV/pair at 77K) for better **energy resolution,** and a higher Z (32 vs. 14) for better photoelectric absorption of higher-energy X-rays.

Current Status of HPGe Detector Technology

High-purity germanium detectors are a mature commercial technology. Process development in crystal growing and diode fabrication have been conducted in private industry where significant advances are proprietary. However, the results of technological advances in these areas are quite evident in the continual improvement in the size, performance, and availability of HPGe detectors. Maximum photopeak efficiency for HPGe gamma-ray detectors is doubling every 6 to 8 years. Concurrently, energy resolutions are moving toward the theoretical limits of Eq. (116.7) as the concentrations of trapping centers are reduced.

The reliability as well as the performance of germanium gamma-ray detectors has also continued to improve, although this is harder to quantify. Cryostats have been redesigned to reduce virtual and direct leaks, reduce microphonics, implement modular design, and improve ruggedness. Detector makers are also making more serious attempts to offer models with reduced backgrounds by judicious design changes and careful selection of materials.

New applications for gamma-ray spectroscopy have emerged. The HPGe detector industry has recently supplied over 100 detectors each to two different experimental facilities (GAMMASPHERE in the U.S., and EUROBALL in Europe), where they were arranged spherically in a modular fashion around the target of an ion accelerator to study the decay of nuclei from excited states of high angular momentum.

For users of single detector systems, developments in the pulse processing electronics necessary for data acquisition and in the hardware and software for data analysis have resulted in both more compact and more flexible systems. Plug-in cards for a personal computer are available now that not only contain the functions of the ADC and multichannel analyzer, but also the high voltage power supply and amplifier as well. Software developments also allow for control of many pulse processing parameters that were previously set manually.

Si:Li Type Silicon Detectors

As with germanium for gamma-ray spectroscopy, the impurity requirements on silicon for nuclear radiation detectors are also stringently low and difficult to obtain. Such silicon must be grown by the float zone technique to eliminate contamination from a crucible. Unlike germanium, little dedicated effort has been expended trying to improve silicon growth techniques to achieve superior detector characteristics. Most progress in material quality has come from technology improvements aimed at other applications. The purest silicon commercially available typically has a net electrically active impurity concentration of a few times 10^{11} cm^{-3} (compared to 10^{10} cm^{-3} for HPGe), which usually limits device thicknesses to less than a millimeter. When thicker silicon devices are required, as in X-ray spectroscopy, silicon of higher net purity can be obtained by lithium drifting [19], but such material cannot be subsequently processed above room temperature.

In X-ray spectroscopy for microanalysis, liquid-nitrogen cooled Si:Li detectors are being challenged by similarly sized HPGe detectors, but Si:Li detectors are still more widely used. Recent developments in specialized low-noise silicon drift detectors and CCD-based detector (see Room Temperature Semiconductor section) designs that have yielded promising results at room temperature may find future application in liquid nitrogen-cooled systems for microanalysis using X-ray spectroscopy.

Room-Temperature Semiconductors

Applications arise that require **energy resolution** beyond the capability of scintillator systems and where cryogenically cooled semiconductors are not suitable. Examples include detector probes for monitoring restricted areas, monitoring at remote sites where replenishing the coolant is impractical, spectral imaging, and many portable instrument applications. There is available a class of semiconductor detectors that satisfy many such needs by providing energy resolution substantially better than the best scintillators (although inferior to cryogenic semiconductors) while operating at ambient temperature. In addition to spectroscopy, these devices are also useful for counting applications where high detection efficiency per unit volume is required. In these applications, the devices are operated in **pulse mode** wherein the charge associated with single photon absorption events is recorded. They also can be operated in a **current mode** in the manner of a solid-state ion chamber. In their current stage of development, room-temperature detectors are limited in size and best suited for the energy region below 1 MeV.

There are numerous detector types in the general category of room-temperature detectors: those capable of ambient temperature operation (true room-temperature devices) and those requiring cooling to the region of –30°C. The former group includes wide bandgap materials such as cadmium zinc telluride, mercuric iodide, cadmium telluride, and a number of silicon structures. The latter group consist primarily of *p*-intrinsic-*n* (PIN) silicon devices. As a group, room-temperature detectors are employed mainly in X-ray and gamma-ray spectroscopy, although silicon surface barrier and ion-implanted devices are highly valued for charge particle spectroscopy.

True Room-Temperature Detectors

True room-temperature detectors are distinguished from cryogenic semiconductors by the magnitude of the energy gap that separates the normally vacant conduction band from the highest filled band. If this energy gap is small, as in the case of germanium (0.67 eV), electrons can be thermally stimulated across the bandgap at room temperature. The resultant current competes with the gamma-ray generated signal, precluding room-temperature operation of germanium (and many high-resolution applications of silicon). Thermally induced

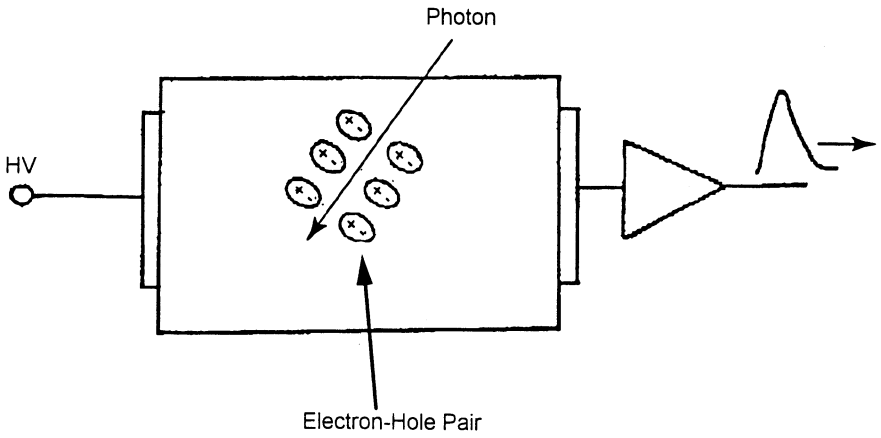

FIGURE 116.14 Schematic illustration of charge generation in a planar detector.

current is reduced to acceptable levels at bandgap energies of about 1.4 eV and above. This phenomenon has been successfully exploited in the development of room-temperature detector materials, including cadmium zinc telluride (acronym CZT), cadmium telluride (CdTe), and mercuric iodide (HgI_2).

Theory of Operation

Operating principles of room-temperature detectors are similar to those governing the more familiar cryogenic semiconductor devices. Gamma-radiation is absorbed in the material and generates electron-hole pairs that move under the influence of an applied electric field to contacts and external electronics for processing and production of the familiar pulse height spectrum. The process is shown schematically in Fig. 116.14. Fundamental to the charge-transfer process is the carrier mobility (μ) and the carrier life time (τ). The product $\mu\tau E$ defines a drift length (λ), which should be long compared to the inter-contact dimensions. Owing to the substantially higher average atomic number of the room-temperature detector materials, the probability of gamma-ray absorption is much higher than in silicon or germanium (see Fig. 116.7). As a result, room-temperature detectors provide greater detection efficiency per unit volume.

The energy required to produce an electron-hole pair (ε) is typically a few times the **energy bandgap** of the material. In silicon where the bandgap is 1.14 eV, the energy to produce an electron-hole pair (ε) is 3.62 eV. In HgI_2, where the bandgap is 2.13 eV, about 4.2 eV is required to create an electron-hole pair. The absorption of a 1 MeV photon thus produces about 276,000 e-h pairs in silicon and 240,000 e-h pairs in HgI_2. Values of ε for room-temperature materials are in the region of 4.2 to 5.0 eV/e-h pair (see Table 116.2) and consequently fewer electron-hole pairs are generated per unit of absorbed energy. Complete collection of the charge is desired although charge trapping, which may not affect the two carrier types equally, prevents this in most cases. The drift length for holes (λ_h) in these materials is often less than the inter-contact dimensions and creates a condition where the collection efficiency depends on the photon interaction depth. This phenomenon is illustrated in Fig. 116.15 where induced charge from single gamma absorption events originating at various

TABLE 116.2 Physical Parameters of Common Room-Temperature Semiconductor Materials

Material	E_g, eV	Z	ε, eV	ρ, Ω	$(\mu\tau)_e$ cm^2/V	$(\mu\tau)_h$ cm^2/V
Cadmium zinc telluride	1.65	48	5.0	10^{11}	1×10^{-3}	6×10^{-6}
Cadmium telluride	1.5	50	4.4	10^{9}	3.5×10^{-3}	2.3×10^{-4}
Mercuric iodide	2.13	62	4.2	10^{13}	1×10^{-4}	4×10^{-5}

Note: E_g = bandgap energy; Z = average atomic number; ε = energy to create an electron-hole pair; ρ = resistivity.

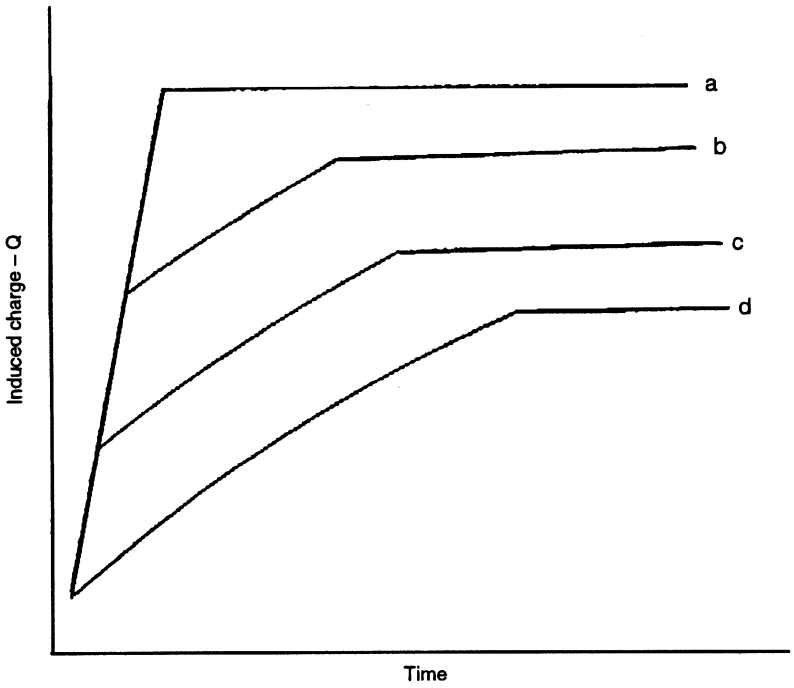

FIGURE 116.15 Charge collection in a planar detector for single-photon interaction. Curves a to d depict the charge from photon interactions at increasing depths below the cathode.

depths in the material is plotted as a function of time. The initial fast-rising segment is due to the more mobile electrons; the slower component is due to holes. In this example, hole trapping is assumed and manifests itself in the curvature of the hole segment. The charge collection efficiency (η) can be derived from the Hecht relation [20]. For a photon absorbed at a distance X from the cathode of a planar detector of thickness L operated with a uniform electric, the relationship becomes

$$\eta = \frac{\lambda_e}{L}\left[1-\exp\frac{\left(L-\mathrm{X}\right)}{\lambda_e}\right]+\frac{\lambda_h}{L}\left[1-\exp\frac{-\mathrm{X}}{\lambda_h}\right] \qquad (116.8)$$

The dependence of the collection efficiency on interaction depth reduces **energy resolution** and without mitigation would limit high resolution to thin devices. Fortunately, methods have been developed that permit high-energy resolution to be achieved in relatively thick samples. As with cooled semiconductor detectors, the energy resolution of the combined detector-electronics system is normally specified by the full width of a monoenergetic spectral peak at its half amplitude points (ΔE). The FWHM is, in turn, related to the variance in the peak L^2 (see Eq. 116.7). It is useful to note that the energy resolution is inversely related to the product $\mu\tau$.

Operational Considerations

Important physical parameters for the leading room-temperature detectors are summarized in Table 116.2. Detectors are available with surface areas of a few square centimeters and thicknesses up to about 1 cm. The performance of detectors based on the different materials varies considerably, as can the performance for detectors of the same material. The choice of specific detector material is normally dictated by the application. The exceptionally high resistivity and high photoelectric cross section in mercuric iodide permit good resolution and high efficiency in the X-ray region, particularly below 10 KeV. For example, ΔE of 5% at 5.9 KeV has been reported [21] with 1 cm^2 devices, with typical values in the region of 10%. For mercuric iodide applications in the region of 0.5 MeV, trade-offs between efficient gamma absorption and resolution may be required.

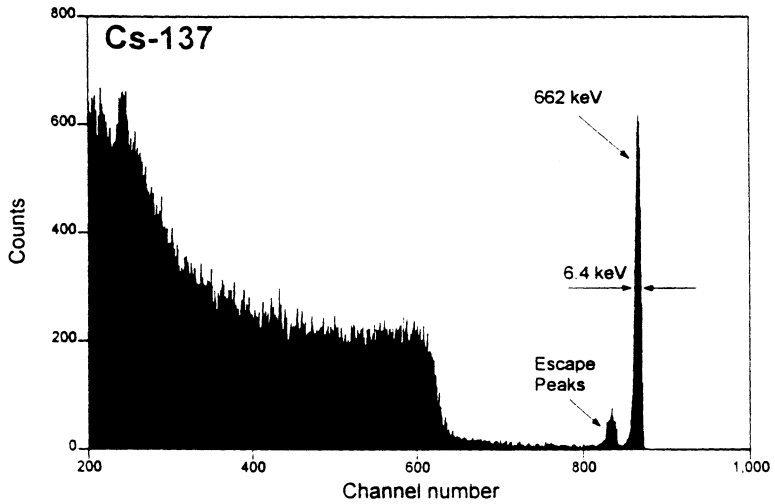

FIGURE 116.16 Energy spectrum of a ^{137}Cs source obtained with a multi-electrode CZT spectrometer. (Courtesy AMPTEK Inc. Bedford, MA.)

In gamma-ray applications where **energy resolution** is the primary concern, thinner devices that minimize charge trapping are often utilized, although procedures have been developed to mitigate many of the thickness and area limitations. Two general approaches have been developed to mitigate the effects of incomplete hole collection. Those approaches are based on electronic pulse processing via ancillary circuitry or novel electrode structures that achieve monopolar (electron transport only) operation. These methods have been particularly successful with CZT and CT devices. CZT- and CT-based devices incorporating such technology are available in commercial products. In CZT, for example, $1.5 \times 1.5 \times 0.8$ cm^3 detectors (electron only collection) are available with 3% resolution at 662 KeV. Somewhat better resolution can be obtained with smaller devices. For example, $1 \times 1 \times 0.5$ cm^3 detectors, operated in the electron-only mode, provide 2% at 662 KeV. Similarly, cylindrical detectors 6 mm in diameter and 5 mm high provide about 1% resolution at 662 KeV. An **energy spectrum** obtained with a typical CZT spectrometer obtained with a ^{137}Cs source is shown in Fig. 116.16.

Improvements in material quality can be expected to further improve the performance of thick detectors. While the area of single crystal detectors is limited currently to a few square centimeters, electronics have been developed to facilitate the operation of large arrays of single-crystal detectors and thus achieve high detection efficiency. Multiple CZT detector arrays 20×20 cm have been produced using such technology.

Further information concerning the performance of single charge collection and array structures as well as electronic processing and design details are available in the literature [2, 3, 22, 23].

Silicon Detectors

In contrast to germanium detectors, silicon detectors can be operated at room temperature in applications where some current noise can be tolerated. Compared to gas and scintillation detectors, silicon detectors have good energy resolution and are reasonably compact. They are fabricated from slices of a silicon single crystal and are available in a variety of areas (25 mm^2 to 3000 mm^2), and the active thickness is usually a few hundred microns. Specialized detectors have been developed for a wide variety of applications.

Charged Particle Detectors

Energetic heavy-charged particles lose kinetic energy continuously along a linear path in an absorbing material. Energy is transferred primarily to the electrons in the absorbing material, but to a lesser extent to the nuclei also via Rutherford scattering. Although only energy transferred directly to the electronic system generates electron-hole pairs, Eq. (116.5) (with $\varepsilon = 3.62$/pair for silicon at 300K) is still a good approximation. Energy loss is characterized by two parameters: specific ionization loss dE/dx, which depends on the incident particle, its energy, and the absorbing material, and the range R (i.e., the penetration depth of the particle), which

determines the detector thickness required for complete energy absorption. The continuous nature of energy loss leads to substantial window effects.

Diffused Junction Detector

Silicon detectors can be generically categorized by the type of rectifying contact employed. The diffused junction detector is fabricated by diffusing phosphorus from the gas phase into *p*-type silicon. This is a high-temperature (900°C to 1200°C) operation that is prone to introducing faster diffusing metals into the bulk that can act either as generation centers increasing **leakage current,** or as trapping centers degrading charge collection. The thickness of the diffused region, from 0.1 to 2.0 μ, also presents a **dead layer** to incident particles that is reduced in alternate technologies. Nonetheless, these detectors find use due to their ruggedness and economy.

Surface Barrier Detector

Surface barrier junctions are fabricated by either evaporating gold onto *n*-type silicon or aluminum onto *p*-type silicon. A typical entrance window is equivalent to 80 nm of silicon. The rectification properties depend on the charge density of surface states of the silicon and of the thin oxide layer over the silicon, as well as on the evaporated metal. The wafer is epoxied in an insulating ring before metallization. The finished detector is encapsulated in a can that has a front window for particle entry and a single contact in the back for the combined function of applying bias and for extracting the signal pulse. Devices can be operated either in the partially depleted or totally depleted mode. As fabrication is entirely at room temperature, there is no opportunity for metal contamination by diffusion. Generally, surface barrier detectors have lower leakage current, and less system noise than a diffused junction detector of comparable area and depth. However, detectors currently fabricated by ion implantation have still lower leakage current and electronic noise, together with a thinner and more rugged front contact. On the other hand, implanted detectors are not available in the same range of active thicknesses as surface barrier detectors. Below 100 μ and above 500 μ, only surface barrier detectors are currently available. Surface barrier detectors can be made in small quantities with rather simple equipment.

Ion-Implanted Detector

A simplified representation of ion-implanted detector fabrication is shown in Fig. 116.17. The first successful implementation of silicon planar processing to silicon detectors was reported by Kemmer [24]. The procedure starts with the thermal growth of an oxide film on a high-purity, *n*-type silicon wafer. Windows are then opened in the oxide by photolithographic techniques. The front contact area is implanted with boron to form the rectifying contact, and arsenic is implanted into the backside. The wafer is then annealed to activate the implant, and aluminum is evaporated on both sides to reduce sheet resistivity. Typical entrance windows are 50 nm silicon equivalent. Electrical connections are made by wire bonding to the aluminum layers. Finished detectors are canned in a manner similar to surface barrier detectors. More than one detector can be fabricated on the same wafer using the appropriate masks during photolithography. In fact, quite elaborate detector geometries can be achieved via photolithography. The detector in Fig. 116.17 is actually a strip type.

The ion implantation planar process technology is well suited for mass production of wafer sizes compatible with the rest of the silicon industry. Minimum wafer diameters are now 4 in. or 5 in. At this diameter, breakage during fabrication is an issue for thicknesses less than 150 μ. For thicknesses over 500 μ, the availability of enough sufficiently pure material to justify the cost of photolithographic masks is an issue. Ion-implanted detectors can be baked at 200°C to reduce outgassing. This is a significant improvement over surface barrier detectors, which irreversibly degrade by device processing above room temperature. This is a useful feature as most heavy charged particle spectroscopy is done in a vacuum.

Leakage currents are, at room temperature, typically 1 to 10 nA cm^{-2} active area and per 100-μ depletion depth. These values represent an order of magnitude reduction in leakage current with respect to surface barrier detectors. Two factors are relevant. Passivation of silicon surfaces by thermal oxidation is extremely effective in reducing leakage current around the rectifying contact. Also, the bulk generation current is reduced by the gettering of metal impurities during the high-temperature oxidation. Float zone silicon for radiation detectors usually has a minority carrier lifetime longer than 1 ms, and this can be increased an order of magnitude during detector fabrication [25]. Thus, not only is leakage current reduced, but potential charge collection problems are also eliminated.

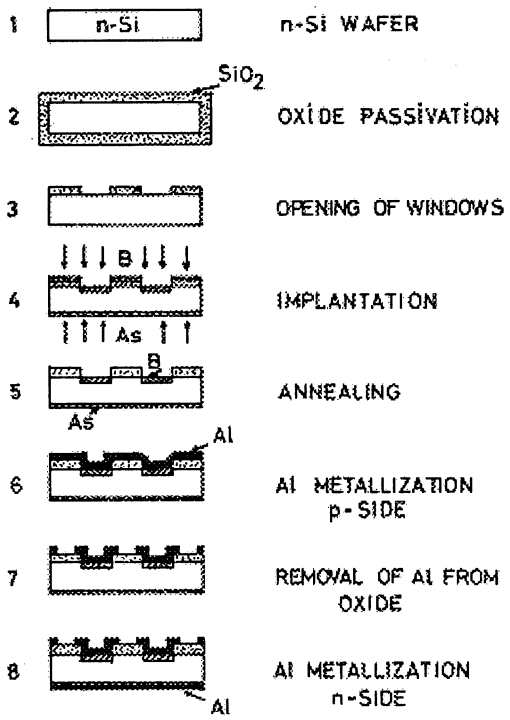

FIGURE 116.17 Steps in the fabrication of passivated planar silicon diode detectors. (Kemmer et al., 1982).

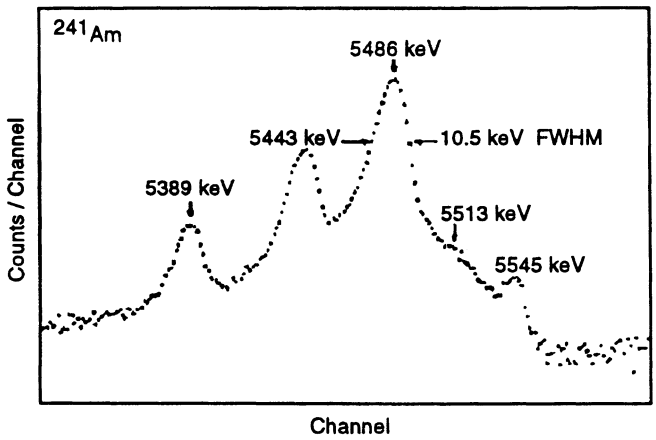

FIGURE 116.18 Spectrum of a ^{241}Am alpha-particle source (log scale) measured with an IP detector (25 mm^2 area, 300 μm thick) at room temperature. Resolution at 5.486 MeV is 10.6 KeV (FWHM). (Kemmer et al., 1982.)

Energy Resolution

A typical spectrum of an ^{241}Am alpha-particle source taken with an ion-implanted detector is shown in Fig. 116.18. While the factors considered in Eq. (116.7) for germanium gamma-ray spectrometers are still valid, additional considerations also apply. In particular, if the source is moved closer to the detector to improve collection efficiency, larger differences in the angle of incidence will produce peak broadening due to larger variation in effective window thickness. Even when the source is sufficiently distanced from the detector, there

will still be spatial variations in window thickness, as well as some variation in energy lost escaping from the source and traversing to the detector.

Another source of peak broadening is the variation in the small amount of particle energy lost during Rutherford scattering. This energy is transmitted directly to the scattering nuclei and does not generate electron-hole pairs, and a small pulse deficit results. These events are relatively few but large, and therefore contribute disproportionately to peak variance. The FWHM contribution of this effect on a 6-MeV alpha particle peak has been estimated to be 3.5 KeV [26].

Silicon Detectors for Spatial Resolution

The uninterrupted progress of the semiconductor silicon industry in achieving both larger wafers and smaller device features has allowed the development of larger and more complex silicon detectors that can provide position information in addition to (or instead of) energy information. Spatial detection can be obtained by fabricating detectors as pixels (two-dimensional) or strips (one-dimensional) on the same wafer. For penetrating radiation, two strip detectors, one behind the other but with the strip pattern rotated 90°, provide two-dimensional positioning. Frequently, such detectors are individually designed and fabricated for a particular application. Strip detectors and CCD (charge-coupled device) detectors will be discussed here.

Strip Detectors

Silicon strip detectors are currently fabricated on silicon wafers (typically approximately 300 μ thick) using photolithographic masking to implant the rectifying contact in strips [27]. The strips usually have a pitch on the order of 100 μ and a width less than half of this to minimize strip-to-strip capacitance and hence electronic noise [28]. The device is biased past depletion, and the back blocking contact is continuous. Each strip requires, in principle, its own signal processing electronics; however, charge division readout (capacitive or resistive) can reduce the number of amplifiers by a factor of 10. Detectors are fabricated in rectangular segments from a single wafer, and can be ganged together if a larger area is needed.

Strip detectors are well established in high-energy physics experiments for reconstruction on the micron scale of the tracks of ionizing particles. The particles being tracked result from the collision of accelerated particles with a target and are highly energetic ($>10^{10}$ eV). Frequently, experimental interest is focused on short-lived particles created in the collision but which decay before they can be directly detected. Spatial resolution of the decay vertex from the original collision is necessary to detect such a particle and to determine its lifetime.

The requirements of new high-energy experiments and advances in silicon technology have produced much evolution and innovation in the strip detector concept. For example, a double-sided microstrip detector with an oxide-nitride-oxide capacitor dielectric film has been reported [29]. The use of intermediate strips to improve spatial resolution has become common [30], and the biasing network has been integrated onto the detector [31].

Silicon Drift Detectors

Silicon drift detectors were first proposed by Gatti and Rehak [32] as an alternative to silicon strip detectors in high-energy physics experiments. The primary motivation was to significantly reduce the number of readout channels. Drift detectors have subsequently been adapted for X-ray spectroscopy. These detectors are usually fabricated on *n*-type silicon wafers with holes collected to either a p^+ contact on the back side of the detector, or to concentric annular p^+ contacts on the front side. The detector is depleted from both sides. The reverse bias applied to the p^+ annular rings is varied in such a way that electrons are collected radially in a potential energy trough to an n^+ anode at the center of the detector on the front side.

A cross section through a circular drift detector is shown in Fig. 116.19. The electron collecting anode ring surrounds the integrated FET used for the first stage of signal amplification. Enough negative bias is applied to the back contact (actually the entrance window) to deplete the wafer to the anode, which is near ground potential. At the same time, negative bias progressively increasing in magnitude is applied from the ring next to the anode (near ground potential) to the outermost ring, which is maintained at about two times the bias of the back contact. These applied biases deplete the detector in such a way that there is an electrostatic potential minimum for electrons that varies in depth across the detector from right under the front surface at the anode to near the back contact at the last ring. Ionized electrons will drift first to this minimum, then drift radially to the anode as shown in Fig. 116.19. A feature of this contacting arrangement is that the anode capacitance,

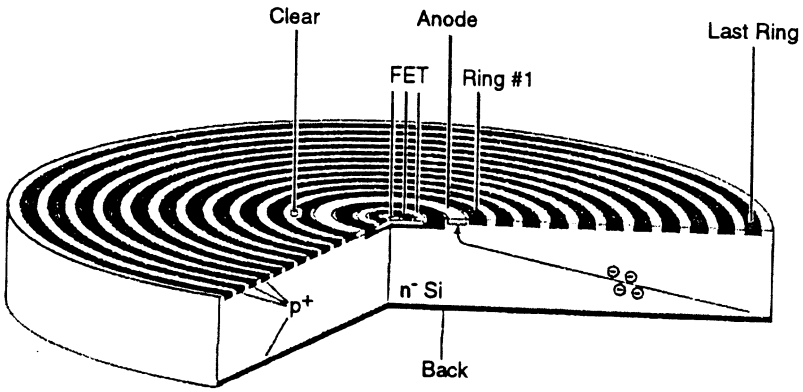

FIGURE 116.19 Cross section of a cylindrical silicon drift detector with integrated *n*-channel JFET. The gate of the transistor is connected to the collecting mode. The radiation entrance window for the ionizing radiation is the non-structured backside of the device. (P. Lechner, S. Eckbauer, R. Hartmann, S. Krisch, D. Hauff, R. Richter, H. Soltau, L. Struder, C. Fiorini, E. Gatti, A. Longoni, M. Sampietro, Nuclear Instruments and Methods in Physics Research, A377, 346–351, 1996.)

and hence amplifier series noise, is low and nearly independent of the active area of the detector. Radial position is deduced from the signal risetime.

CCD Detectors

The design of CCD (charge-coupled device) detectors has similarities to the silicon drift detector [32]. The CCD detector is normally fabricated on an *n*-type silicon wafer depleted both from the backside with a continuous p^+ contact on the back, and from p^+ CCD registers on the front. Reverse bias voltages are such that the wafer is totally depleted and the electron potential minimum is about 10 μ below the CCD registers. After an ionizing event, holes are collected to the p^+ contacts, and electrons are trapped under a nearby register, then transported down a channel of registers by properly clocked voltage pulses to the registers. Each channel has its own readout anode, which can be made small to minimize capacitance — a prerequisite for minimizing noise. The first stage of amplification is frequently integrated onto the same wafer. Spatial resolution is limited to the register (pixel) size. Brauniger et al. [33] described initial results on a 6×6 cm CCD array of 150×150 μ pixels intended for satellite X-ray imaging. The system also had an **energy resolution** of 200 eV FWHM for 5.9 KeV X-rays at room temperature.

Silicon pixel detectors have also been designed using other highly integrated device structures to optimize particular performance aspects such as timing resolution. Pixel detectors using MOS transistors [34] and using reverse biased diodes with individual readout circuitry [35] have been described.

PIN Silicon X-ray Spectrometers

Detectors based on PIN silicon structures have found considerable success as X-ray spectrometers in the region below 10 KeV. The devices consist of *n* and *p* layers on opposite sides of a high purity (10–20 K ohm-cm) silicon wafer. Particularly good performance is obtained if the devices are operated in the region of –30°C as can be provided by a thermoelectric cooler. On the order of 1 W is required to maintain a typical device at –30°C. Energy resolution (FWHM) of 186 eV at 5.9 KeV can be obtained in 7-mm^2 devices (with 20 μs shaping time). Spectrometers with areas up to about 25 mm^2 are also available, but with reduced resolution. The energy spectrum of ^{55}Fe obtained with a 7-mm^2 detector is shown in Fig. 116.20(a), together with a schematic showing construction details (Fig. 116.20(b)).

Status of Silicon Detector Technology

The simply structured silicon detectors fabricated with parallel contacts on a silicon wafer continue to serve a well established need for charged particle spectroscopy. Where economies of scale can be applied, ion implanted detectors have replaced surface barrier detectors. In projects of sufficient size to support their development, specialized low-noise silicon drift detectors and CCD-based detectors have been designed and fabricated with promising room-temperature energy resolution: 200 eV FWHM at 5.9 KeV. These highly structured detector

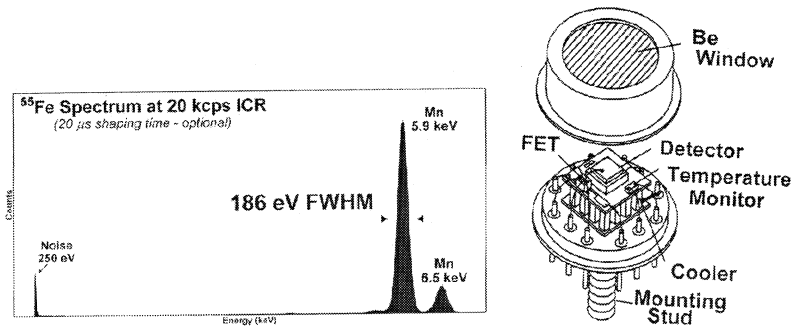

FIGURE 116.20 (a) Energy spectrum of ^{55}Fe source obtained with a 7-mm^2 PIN silicon detector using a shaping time of 20 μs. (b) Schematic diagram showing construction details of typical PIN-silicon detector with thermoelectric cooler. (Courtesy AMTEK Inc. Bedford, MA.)

technologies may find future application in liquid nitrogen-cooled or room-temperature systems for microanalysis using X-ray spectroscopy.

In high-energy physics, the use of various strip, drift, and pixellated detectors for tracking and vertex determination has flourished. These efforts will intensify as experimental requirements for spatial resolution increase. However, radiation damage to the detector is already an issue in this application, and higher luminosity beams will only increase the problem. Nevertheless, it appears that the continuing need of the high-energy physics community for a higher number and density of signal paths forecasts continued reliance on the ever-improving integration technology of the semiconductor silicon industry.

Prices and Availability

The detectors described in this section are available commercially. Their prices vary widely, depending on type, size, and performance. Room-temperature semiconductor detectors range from a few hundred dollars for small, low-resolution devices to over $1000 for large, high-resolution devices. Because of the dynamic nature of wide bandgap detector technology, buyer guides should be consulted for the latest price and availability information.

Pricing of coaxial HPGe detectors is based largely on their gamma-ray efficiency, which is specified relative to a 3 in. × 3 in. sodium iodide scintillator at 1.33 MeV. Coaxial detectors are available with relative efficiencies up to about 150% with cost in the area of several hundred dollars per percent efficiency. Planar HPGe detectors are normally less expensive than coaxial designs. In either case, the price includes the cryostat, dewar, and preamplifier. Cryogenic silicon detectors are available in areas up to several tens of square millimeters. Cost ranges to over $10,000 depending on size, performance, and complexity of design.

Defining Terms

Ballistic deficit: The loss of signal amplitude that occurs when the charge collection time in a detector is a significant fraction of the amplifier's time constant.

Current mode: Measurement mode in which the detector signal provides information on the flux X-rays, gamma-rays, or charged particles.

Dead layer: A layer (frequently associated with a contact region) in which no significant part of the energy lost by photons or particles can contribute to the resulting signal.

Electrical junction: The metallurgical transition boundary between the semiconductor regions of different electrical properties (for example, PIN or between a metal and a semiconductor).

Energy bandgap: The energy difference between the bottom of the conduction band and the top of the valence band.

Energy resolution: The full width of the half maximum of a peak in the energy spectrum, after subtraction of the background under the peak; expressed in units of energy, usually KeV or as a percentage of the energy of the peak.

Energy spectrum: A differential distribution of the intensity of the radiation as a function of the energy.

Leakage current: In the absence of external ionizing radiation and at the operating bias, the total current flowing through or across the surface of the detector element.

Line of peak (in a spectrum): A sharply peaked portion of the spectrum that represents a specific feature of the incident radiation, usually the full energy of a monoenergetic X-ray, gamma-ray, or charged particle.

Pulse mode: Measurement mode in which the detector signal provides information on a single X-ray, gamma-ray, or charged particle.

Semiconductor: Material in which the conductivity is due to charge carriers of both signs (electrons and holes) and is normally in the range between metals and insulators, and in which the charge carrier density can be changed by external means.

Semiconductor radiation detector: A semiconductor device in which the production and motion of excess free carriers is used for the detection and measurement of incident particles or photons.

117.1 Clinical Information Systems

Luis Kun

The main objective of this section is to provide the reader with a summary of areas that relate to clinical information systems. Since this field is so wide, the following topics will be covered mainly because of their importance within the field of medical informatics and the impact that these areas will have in healthcare delivery in the near future. At the end of this section there is a list of definitions that should help the reader not used to related acronyms and a list of suggested bibliographic references which should allow those interested to further increase their knowledge.

Computer-Based Record

Besides improvements in patient care, enhancing the productivity of physicians, nurses, and all healthcare-related personnel is very high on the agenda of all hospitals. Hospitals, clinics, HMOs, doctors' offices, emergency care centers, group practices, laboratories, radiology clinics, and nursing homes among others have a need to share patients' records. Aside from the direction that all of these medical-related centers will have with a required connection to the insurance companies/agencies to speed up payments and their accuracy, the growing need is to have the ability to transfer patients' medical files electronically anywhere in the world. As medical centers become more competitive, they will become worldwide centers of excellence for their given specialties. In turn then, their services will be marketed to the entire world population, becoming true global resources.

The trend of converting hospitals into "paperless hospitals" is becoming one of the most important topics of the 1990s. In 1970, chartered by the National Academy of Sciences, the Institute of Medicine working under the Policy Matters for Public Health has actively pursued the creation of a computer-based record (CBR). In July of 1991 a book was published by the Institute of Medicine in regards to the CBR. The requirements to compile an all-digital medical record (ADMR)will require ways to combine data, graphics, voice, signals, and images, both clinical and document. The architecture that will accommodate all these forms of information for capturing, storing, communicating, and displaying is extremely complex. Some of the technologies involved include optical fibers, LANs, compact/optical disks, bedside terminals, medical image display stations, image diagnostic workstations, and picture archival and communications systems to name a few.

The High Performance Computing and Communications Initiative (HPCCI) was signed into law in December of 1991. Although most of the emphasis for this initiative was from a research and academic sense, some

of the true practical values of these highways of information will occur at the clinical level. While advances are taking place in different parts of the world in fighting diseases such as cancer, AIDS, heart disease, cystic fibrosis, Alzheimer's, Parkinson's, Gaucher's, and malignant hyperthermia, not sharing the knowledge learned by all the groups would be a terrible underutilization of extremely costly resources, causing duplication of effort and enormous waste of time and resources.

The four technologies that have been considered critical by the National Institutes of Health for the coming years are molecular medicine, vaccine development, structural biology, and biotechnology. The four will greatly be affected by the HPCCI. Finally, the integration of all medical-related information will be the most complex task that the healthcare arena will face this decade.

Clinical Information Standards

One of the most demanding and key areas for successfully integrating the hospital information system (HIS) with the clinical information systems (CIS) from multiple clinical departments and/or clinical areas deals with clinical information standards. Two of the driving forces behind the automation of the patient record deal with national concerns related to healthcare costs and quality of healthcare. These concerns have generated demand for managed care. The automated patient record could then be one of the vehicles to achieve managed care.

Clinical information standards are constantly evolving. They were developed (some are still in the process of development; e.g., IEEE/MIB P1073) by very different sets of requirements. What follows is a brief description and structure of most of these standards.

Communications/Storage (e.g., HL/7, IEEE/MEDIX P1157, ANSI ASC X12, ACR/NEMA, IEEE/MIB P1073)

The HL/7 standards group aimed to define vendor-independent communications standards among components of hospital information systems. The IEEE, ANSI, ACR/NEMA, and ASTM have been very active in creating standards through subcommittees from organizations within. As an example, ASTM has the following Healthcare Automation Committees (E31.XX):

- E31.10: Computer automation in the Hospital Pharmacy
- E31.11: Data exchange standards for Clinical Laboratory results
- E31.12: Medical Informatics
- E31.13: Clinical Laboratory Systems
- E31.14: Clinical Laboratory Instrument Interface
- E31.15: Health Knowledge Representation

The MEDIX mission was to establish a robust and flexible communications standard for the exchange of data between heterogeneous healthcare information systems. The MIB was created mainly to allow the exchange of data from medical instrumentation, e.g., monitoring devices and hospital information systems. Many of the manufacturers of these devices have proprietary hardware, e.g., buses and/or software, which complicates this exchange. Bedside terminals in the intensive care environment will benefit immensely from such a standard, since most hospitals' ICUs and CCUs have many vendors' equipment in their units. To effectively integrate and manage the data are major goals of the MIB.

Classification/Reimbursement (e.g., ICD, DRG, SNOMED, CPT, DSM, RCS, UMLS)

ICDs were originally used for public health morbidity statistics; now in the United States they are primarily used for reimbursement. Its structure is numbered classification of diseases grouped by anatomical areas. The DRGs facilitate the definition of case-mix for hospital reimbursement. Its structure is multi-axial: severity of illness, prognosis, treatment difficulty, need for intervention, and resource intensity. SNOMED provides description of pathological tests related to patient identification. It has four axes: function (primary symptoms), etiology (cause of disease), morphology (description of disease form), and topology (area of body). CPT is primarily used for reimbursement and utilization review. It derives codes from specialty nomenclatures divided into chapters: systemic (medicine, anesthesia, etc.), topological (cardiovascular, lymphatic, etc.), and technological

(radiology, laboratory, etc.). DSM provides consistent abbreviations for prescription and administrative use. It facilitates psychiatric education and research. Its structure is multi-axial: clinical syndromes, developmental and personality disorders, physical disorder, severity psychological stresses, and global assessment functioning. RCS is a comprehensive nomenclature and classification of medical terms for computerized records. UMLS facilitates the unification of clinical data classification systems into a single unified medical language system. It will also facilitate the creation of data into compatible automated patient record systems. Its structure reconciles clinical terminology, semantics, and formats of the major clinical coding and reference systems.

Knowledge (e.g., ARDEN SYNTAX)

The ARDEN SYNTAX is a standard for sharing medical knowledge bases in the form of medical logic modules (MLM). Its structure is derived from the HELP (LDS Hospital) and the CARE (Regenstrief MC) systems. The MLMs accommodate alerts, management critiques, therapy suggestions, diagnosis scoring, etc. Each MLM is limited to the knowledge to make a single decision.

HCFA (e.g., UCDS, WARP, UHDDS)

UCDS provides an electronic clinical data set that Medicare can use to perform clinical quality reviews. The quality evaluation is done by using algorithms related to surgical procedures, disease specific, organ specific, discharge status and disposition, etc. The UCDS permits the hospital to enter the data into a personal computer; then this information can be sent electronically to the HCFA. WARP provides an epidemiologic approach to quality assurance. It hopes to overcome about 50% of ICD miscoding and its initial focus is on ambulatory chart review rather than real-time patient care. It is not a diagnostic or procedural classification system. It basically provides a model for encoding clinical information. It is an object-oriented case tool. UHDDS was created for studies on quality of care and fraud. It is also used for auditing Medicare and Medicaid subsystems.

Bedside Terminals/Point-of-Care Systems

Patient information is generated on an ongoing basis, wherever the patient may be. Almost two decades ago with the creation of the first programmable calculators, a trend started in terms of calculating hemodynamic variables in the OR, etc. This approach was improved with the creation of personal computers, ending with the development of what are now called bedside terminals. Companies such as Clinicom, Emtek, Hewlett-Packard, Hospitronics, and Spacelabs offer systems that can go from doing simply patient monitoring, to a complete data acquisition, data management, and data analysis system that incorporates in some cases diagnosis and treatment therapy.

From the patients' point of view, it is critical to integrate their demographic information with their clinical data. Usually the HIS contains all the ADT, orders, laboratory, pharmacy, etc. while the CIS may be more of a departmental system such as ICU/CCU, which contains hemodynamic variables, i.e., blood pressure, stroke volume, heart rate, etc. Both systems need to coexist. Point-of-care systems, many times known as bedside terminals, include both general med/surgery and the ICU/CCU type. The general type include functions such as patient assessment, nursing diagnosis, patient care plans, kardex, discharge planning, discharge summary, medication administration record, I/O, vital signs, activities of daily living, patient classification/acuity, etc. The ICU/CCU systems in addition contain information regarding drug administration, fluid analysis, hemodynamic analysis (i.e., blood gas report, ECG, blood pressures, pulse oximeters, cardiac output), respiratory analysis (i.e., ventilator data, O_2/CO_2 analyzer), and real-time monitoring. Today's trends are incorporating imaging devices in both at the regular nursing stations, at the operating rooms, and at the recovery room/ICU/CCU. The motivation is to incorporate all patients' information and have it available wherever they may be. As a patient moves from a regular bed to the OR, back to an ICU, and later to a regular nursing station, the electronic record follows the patient. The one big difference with paper charts is that the electronic record can be shared simultaneously within and outside the institution.

Having the ability to look at electronic images in all of these locations not only opens the doors for consultation within the institution but also with outside institutions and/or expert individuals.

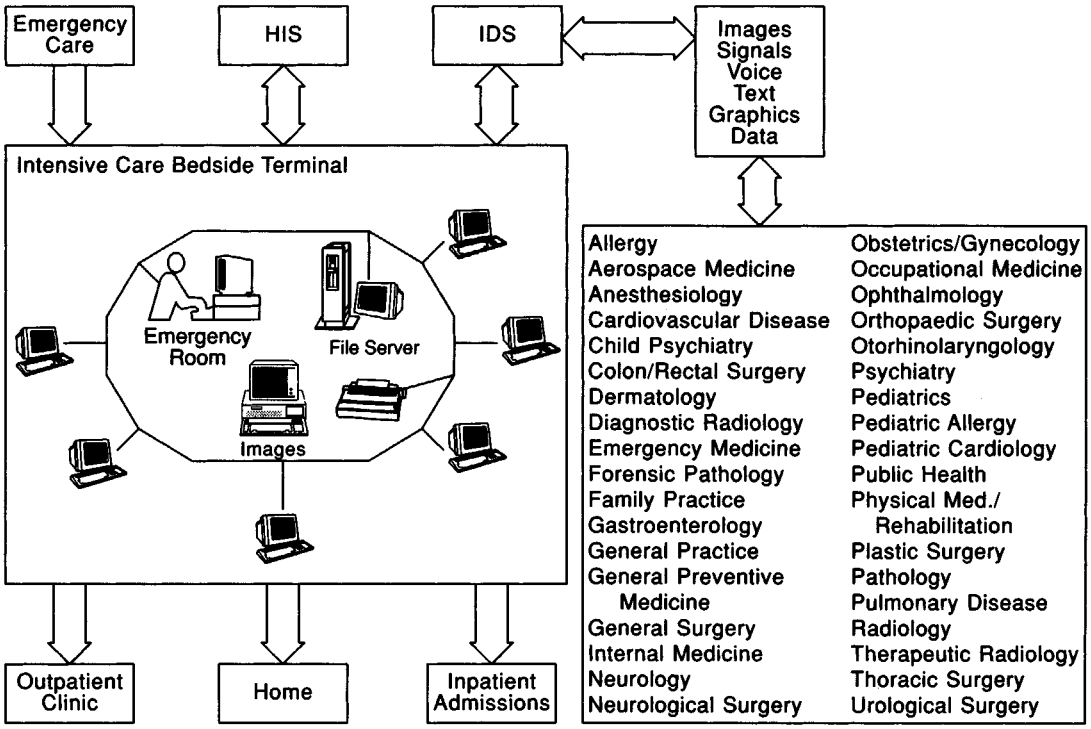

FIGURE 117.1 An example of medical systems integration.

Imaging and the CIS

Imaging plays two very important roles within the context of a computer-based record (CBR). Document imaging allows for all those records that exist today in storage for the medical records departments to be scanned and incorporated electronically with the rest of the patient's current records existing in the HIS and CIS. The second role is from the perspective of clinical images. Most imaging experts will call this PACS, which stands for picture archival and communications system and is mostly associated with the Radiology Department of the hospital. We can view clinical images as a form of data which can be generated in any department.

Some of these typical clinical departments utilizing clinical images are radiology, cardiology (e.g., echocardiography, fluoroscopic techniques, cine cameras, 3D modeling, gamma cameras), orthopedic surgery, plastic surgery, obstetrics/gynecology, laboratories (e.g., genetics, chromosome analysis, cytology, hematology, clinical chemistry, pathology, histology, electron microscope), maxillofacial clinics, sports medicine, and oncology (e.g., radiation therapy, chemotherapy), emergency rooms, intensive care units, etc.

There are five imaging modalities: x-ray, magnetic resonance imaging (MRI), computer tomography (CT), nuclear medicine (NM), and ultrasound (US). These modalities create images which are very different not only in medical terms but in their size and content. As a result, there are three main areas under PACS which are critical in succeeding with such systems: communications (i.e., network, transmission protocol, and image format), archiving (i.e., database and storage media), and image processing (i.e., display, user interface, and IP algorithms).

Systems Integration

As an example of systems integration in the emergency care environment (see Fig. 117.1), from an information-flow point of view we see the following:

1. Information coming and going to the HIS, e.g., laboratory, pharmacy, orders, etc.
2. Information going to outpatient clinics for referring services, admissions to the hospital, or even to the patient's physician at home.
3. In the emergency room, the utilization of an intensive care type of bedside terminal allowing data collection, analysis and management, and also the ability to view clinical images in the ER.
4. From a consulting point of view, the whole electronic patient record, under an integrated diagnostic system, allows for any (department) consulting physician within or outside the hospital to review the case.

Smart/Optical Cards

Smart/optical cards provide a wide range of applications in the medical field. The patient, the provider (e.g., physician, dentist, etc.), the hospital, and the insurer can all benefit from such a card. The card will eventually contain all data forms—voice, text, graphics, clinical images, document images, signals, and data values collected from medical instrumentation. Besides patient identification/demographics, medical history, medications, allergies, and insurance verification, the system could contain the patient's picture, fingerprint, digital signature, voice signature, and even genetic/blood information for security reasons.

The patient is admitted and treatment is provided more quickly, historical information is more accurate, and personal physicians and specialists can be consulted more quickly. Less testing may be a direct result, and faster diagnosis is accomplished. Since information needs to be entered only once, patients do not need to rely on their memory, particularly in emergency situations.

The hospital identifies the patient and accesses all the medical records information from multiple departments more quickly. It needs fewer staff to find records from the hospital/clinics (even from other institutions), and this could reduce the length of stay.

The provider is better informed for a quicker diagnosis by getting all the available history at admission and can consult with the patient's personal physician and specialist by having their respective phone numbers. All prior records from the same or a different set of institutions coexist in the card. It also can reduce exposure to malpractice.

The insurer reduces fraudulent claims, reduces costs for data entry, and has more complete and accurate claims data. Also, by eliminating redundant tests costs are reduced.

Most of the cards can be classified into five groups by the type of technologies used: microfilm, magnetic strip, softstrip, chip, and laser/optical. Microfilm is hard to change and can be damaged by both temperature and humidity. Magnetic strip contains little information, approximately 2K, and can be destroyed by electric and magnetic fields. The softstrip, because it is laser printed and optically read, is difficult to change information on. The chip card has only up to 10K of storage and is very expensive. Finally, the laser/optical card allows for approximately 1000 typed pages or approximately 4 Mb of memory and requires a read/write device.

Some of the complexities that are incorporated by using these types of technologies are associated with the access to the information. For someone to be able to either "read" and/or "write" in the card, it must possess technologies compatible with the ones where the information was created. It is a fundamental principle then that a set of international standards will be created so that any hospital that requires access to the card information can do so. Already the International Patient Cards Standards Council, the Health Industry Business Communications Council (HIBCC), and the Smart Card Applications and Technology (SCAT) have been created. These groups, among others, are working towards the goal of an international set of standards.

There is a large set of companies that are already marketing different types of card technologies. Some examples of projects and/or vendors include:

- Affiliated Healthcare in Princeton, New Jersey, which maintains a Health Summary Database with a Smart Card.
- CentraHealth, a Florida hospital network with about 12K users.
- Clinicard, a subscription service which provides a softstrip, 3K, PC DOS card that folds to a business card size.
- Drexler LaserCard from Mountain View, California, which has 4.1-Mb card being tested by both British Telecom with a hospital group specializing in obstetric patients and Baylor College of Medicine in Houston, Texas.

- Eltrax in St. Paul, Minnesota, which is associated with several HIS manufacturers (Spectrum, McDonald Douglas, SMS, and Meditech) and provides a magnetic strip card with about 900-character capacity.
- IMSG/INFODYNE from Englewood, Colorado, which has a medical information card on magnetic strip carrying up to 600 characters.
- IntelliScan from American Medical Data Corp. in Atlanta, Georgia, which has information stored as 350 characters of readable text printed on the top of the card and up to 850 characters of detailed medical information optically encoded at the bottom. It is being used by hospitals in both Texas and Mississippi. The cards are customized to each hospital's database.
- Lifecard, early pilot (1985) card for electronic claims provided by Blue Cross/Shield of Maryland.
- Medfirst credit card, combining both medical information and financial credit, in test by Humana and Discovery Card.
- Medi-Card, a chip card from MediData Systems in Allston, Massachusetts.
- MedKey, from Biloxi Regional Medical Center, Biloxi, Mississippi.
- Medical Information Systems, in St. Louis, Missouri, which has a microfilm card that can contain up to 18 pages of information, including signals, text, images, data, and color photos.
- Ulticard, a 64K RAM memory chip in a credit card sized pack being tested in Houston at Baylor and Methodist hospitals.

Some of the cards are being tested in different countries. Sweden, the leader for about 20 years, has been using a patient card which is issued at birth by the government together with an ID number. Sweden has a socialized medicine program and it has been in their best interest to develop uniform standards so that the information can be accessed by every institution in the country. Belgium, Canada, France, Great Britain, Spain, and Switzerland all have several systems on trial.

Acronyms

ACR/NEMA: American College of Radiology/National Equipment Manufacturers Association
ANSI ASC X12: American National Standards Institute Accredited Standards Committee
ARDEN SYNTAX: Syntax for Medical Logic Modules
ASTM: American Society for Testing and Materials
CIS: Clinical Information System
CPT: Current Procedural Terminology
DRG: Diagnostic Related Group
DSM: Diagnostic and Statistical Manual of Mental Disorders
EDI: Electronic Data Interchange
HCFA: Healthcare Financing Administration
HIS: Hospital Information System
HL/7: Health Level/7
ICD: International Classification of Diseases
IDS: Integrated Diagnostic System
IEEE: Institute of Electrical and Electronics Engineers
IEEE/MEDIX P1157: Medical Data Interchange
IEEE/MIB P1073: Medical Information Bus
OSI: Open Systems Interconnection
RCS: Read Classification System
SNOMED: Systemized Nomenclature of Medicine
UCDS: Uniform Clinical Data Set
UHDDS: Uniform Hospital Discharge Data Set
UMLS: Unified Medical Language System
WARP: Wisconsin Ambulatory Review Project

117.2 Hospital Information Systems

Matthew F. Baretich

What does an electrical engineer need to know to be part of a team designing and implementing a hospital information system? For the most part, the necessary skills are those required to design and implement any comprehensive information system in a complex organization. Hospitals do, however, have unique characteristics that must be taken into account. These characteristics are described in the following pages.

The Clinical Environment

Hospitals are, indeed, complex organizations. They perform a vital function (patient care) but are subject to strict regulation and operate under severe financial constraints. Quality of patient care is the highest value, but a competitive marketplace demands efficient operation. Hospital information systems range from nonexistent to antique to state-of-the-art.

Hospitals are highly professionalized. Each professional group has a particular area of expertise and a unique perspective regarding the healthcare delivery system. Hospital administrators are much like administrators of other organizations. Recent graduates essentially have standard MBA (Master of Business Administration) degrees with some extent of healthcare specialization. However, many administrators in positions of authority received MHA (Master of Hospital Administration) degrees from programs more closely affiliated with medical schools than with business schools.

Hospitals also have large clinical staffs which include nurses and technologists (who are hospital employees) and medical doctors (who are usually not hospital employees). Clinicians are educated in the biological and medical sciences, and their preparation generally includes a large component of practical experience in the hospital as well as theoretical study in the classroom. As hospital employees, nurses and technologists (respiratory, laboratory, etc.) are part of the administrative structure of the hospital. Medical doctors (physicians and surgeons), on the other hand, are part of a separate medical staff structure that is largely independent of the hospital's administrative structure. However, medical doctors control the admission and discharge of the hospital's patients, and many hospital activities are the result of medical orders for patient services.

The number of hospital employees with an engineering background is limited. For the electrical engineer who is involved in the implementation of a hospital information system, hospital-based technical support may include an information systems department and a clinical engineering (or biomedical engineering) department.

The following aspects of the healthcare delivery system are worthy of study by an electrical engineer working in the clinical environment:

- The healthcare delivery system in the United States [Williams and Torrens, 1984]
- The organizational structure of hospitals [Goldberg and Buttaro, 1990]
- The characteristics of hospital information systems [Austin, 1988; Minard, 1991]

With this background information the electrical engineer will be better prepared to translate the concerns of hospital administrators and clinicians into the technical specifications of the hospital information system.

Healthcare Codes and Standards

The healthcare delivery system is a highly regulated industry. Numerous governmental and nongovernmental organizations have established codes and standards intended to promote safe and effective patient care. Although there can be significant differences in the regulatory environment from one hospital to another, the major codes and standards are relatively uniform.

The **National Electrical Code** (NFPA 70), promulgated by the National Fire Protection Association (NFPA: Quincy, Massachusetts) applies to hospitals. Specifically, Article 517 deals with "Health Care Facilities." A more focused document, however, is the *Standard for Health Care Facilities* (NFPA 99). The most accessible format for this information is the NFPA's *Health Care Facilities Handbook* [Klein, 1990] which includes the full text of NFPA 99 as well as interpretive and explanatory material.

Many of the healthcare-related provisions of the electrical code are based on two concerns. First, many patients in surgery and intensive care depend on electrical equipment for life support. Such equipment ranges from heart-lung bypass devices to mechanical ventilators. Therefore, much attention is devoted to ensuring the availability of electrical power in the event that the primary power distribution system fails. A hospital information system that provides life-support functions may be subject to these provisions.

Second, because of the use of invasive medical procedures, many patients are considered to be "electrically susceptible." Under certain conditions, electrical currents on the order of microamperes can cause ventricular fibrillation, a potentially fatal disruption of normal cardiac function. Therefore, the NFPA and other organizations have established strict standards for grounding, "leakage" current, and other electrical parameters. These standards apply to devices and cabling in patient-care locations of the hospital.

The **Joint Commission on Accreditation of Healthcare Organizations** (Chicago, Illinois) is another major source of standards affecting hospitals. The JCAHO's *Accreditation Manual for Hospitals* [JCAHO, 1993] covers the entire spectrum of hospital activities. Pursuit of JCAHO accreditation is voluntary but, in practice, essentially all hospitals seek accreditation to ensure eligibility for reimbursement under certain governmental programs. At present, JCAHO standards include little reference to information systems. However, this is expected to change and, therefore, familiarity with the latest edition of the *Accreditation Manual for Hospitals* is advisable.

Another standard unique to the healthcare system is **Health Level 7** (HL7) which is a data communications protocol intended to facilitate the interfacing of various components in a hospital information system [Walker, 1989]. These components range from accounting systems (financial data) to clinical laboratory information systems (laboratory test results) to medical records systems (documentation of patient care services) to patient data management systems (physiological data). In the recent past, each such component was independent and generally incompatible with other components. However, to achieve high quality in patient care at the lowest cost, both administrators and clinicians need integrated, comprehensive access to a wide variety of information.

HL7 is an attempt to specify the types of data (and their formats) to be shared within a hospital information system. For example, if all components of the system use a common format for a patient's name, then it is possible for a single database query to gather all data regarding that patient. This also allows automation of certain activities such as billing (through the accounting system) for laboratory tests ordered by clinicians (through the clinical laboratory system). Unfortunately, HL7 has not achieved its promise but it does represent a significant step away from the chaotic past [Bond et al., 1990].

Summary

The electrical engineer will be only one of many professionals involved in the implementation of a hospital information system. Successful participation in this team will depend on more than the electrical engineering skills that are applicable to any information system project. The critical success factor is an understanding of the hospital—the people (clinicians and administrators), their objectives (low cost and high quality), and the environment within which they work.

Defining Terms

HL7: A data communications protocol for interfacing components of a hospital information system.

JCAHO: The Joint Commission on Accreditation of Healthcare Organizations, an organization that promulgates standards affecting hospital operations.

NEC: The National Electrical Code, an NFPA standard that is commonly adopted by governmental units and, therefore, having the force of law.

Computer Design for Biomedical Applications

Raymond Luebbers
Pennsylvania State University

The Finite Difference Time Domain (FDTD) [Yee, 1966; Kunz and Luebbers, 1993; Taflove, 1995] is a numerical method for the solution of electromagnetic field interaction problems. It utilizes a geometry mesh, usually of rectangular box-shaped cells. The constitutive parameters for each cell edge may be set independently, so that objects having irregular geometries and inhomogeneous dielectric composition can be analyzed.

The FDTD method solves Maxwell's differential equations at each cell edge at discrete time steps. Since no matrix solution is involved, electrically large geometries can be analyzed. FDTD solutions for three dimensional complex biological geometries involving millions of cells have become routine. FDTD may be used for both open region calculations, such as a human body in free space, or closed regions, such as within a TEM cell. Commercial FDTD software is available from several sources (CST, EMA, and Remcom), with some of these also offering FDTD meshes for human heads and bodies. These commercial packages provide a graphical user interface for viewing the FDTD mesh. Some provide interactive mesh editing (Remcom), while others allow for import of objects from CAD programs (CST and EMA).

The choice of cell size is critical in applying FDTD. It must be small enough to permit accurate results at the highest frequency of interest, and yet be large enough to keep resource requirements manageable. Cell size is directly affected by the materials present. The greater the permittivity and/or conductivity, the shorter the wavelength at a given frequency and the smaller the cell size required. Once the cell size is selected, the maximum time step is determined by the Courant stability condition. After the user determines the cell size, a problem space large enough to encompass the scattering object, plus space between the object and the absorbing outer boundary, is determined. From the number of Yee cells needed and the number of time steps required, resource requirements can be estimated.

The fundamental constraint is that the cell size must be much less than the smallest wavelength for which accurate results are desired. An often quoted constraint is "10 cells per wavelength", meaning that the side of each cell should be 1/10 of the wavelength at the highest frequency (shortest wavelength) of interest. Since FDTD is a volumetric computational method, if some portion of the computational space is filled with penetrable material, one must use the wavelength *in the material* to determine the maximum cell size. For problems containing biological materials, this results in cells in the material that are much smaller than if only free space and perfect conductors were being considered.

Another cell size consideration is that the important characteristics of the problem geometry must be accurately modeled. This will normally be met automatically by making the cells smaller than 1/10 λ unless some special geometry features smaller than this are factors in determining the response of interest.

In some situations there is a specific region of the object where smaller FDTD cells are needed, for example, a region of high dielectric material, or of fine geometry features such as eyes. But if uniform FDTD cells are used throughout the computation, then these small cells must be used even in regions where they are not needed. One approach to reduce the total number of FDTD cells for these situations is to mesh local regions with smaller cells than in the main mesh [Kim and Hoefer, 1990; Zivanovic et al., 1991]. All of the commercial FDTD software referenced above has this local grid capability.

The other basic constraint on FDTD calculations is the time step size. For a three-dimensional grid with cell edges of length Δx, Δy, Δz, with v the maximum velocity of propagation in any medium in the problem, usually the speed of light in free space, the time step size Δt is limited by

$$v\,\Delta t \;\le\; 1 \Big/ \sqrt{\frac{1}{(\Delta x)^2} + \frac{1}{(\Delta y)^2} + \frac{1}{(\Delta z)^2}}$$

Now let us consider how to estimate the computer resources required. Given the shortest wavelength of interest, the cell dimensions are determined as 1/10 of this wavelength (or less if greater accuracy is required). From this and the physical size of the problem geometry the total number of cells in the problem space (here denoted as NC) can be determined. We assume that the material information for each cell edge is stored in 1 byte (INTEGER*1) arrays with only dielectric materials considered. Then, to estimate the computer storage in bytes required, and assuming single-precision FORTRAN field variables, we can use the relationship

$$storage \;=\; NC * \left(6\,\frac{components}{cell} \times 4\,\frac{bytes}{component} + 3\,\frac{edges}{cell} \times 1\,\frac{byte}{edge} \right)$$

where components indicate the vector electric and magnetic field components. If magnetic materials are included, then six edges must also be considered for the material arrays. In this equation, we have neglected the relatively small number of auxiliary variables needed for the computation process.

One can estimate the computational cost in terms of the number of floating point operations required using

$$Operations \;=\; NC \times 6\ components/cell \times 15\ operations/component \times N$$

where 15 operations is an approximation based on experience and where N is the total number of time steps. The number of time steps N is typically on the order of five to ten times the number of cells on one side of the problem space. It will be larger for resonant objects and smaller for lossy objects.

As an example, consider a human body meshed with 5-mm cubical cells. At 10 cells per free space wavelength, this would correspond to a maximum frequency of 6 GHZ. But, since the biological materials in the body have relatively high dielectric constants, the wavelength inside the body is reduced. If the maximum dielectric constant of body materials is 49, then the maximum frequency would be reduced by 7 to about 857 MHz. If results at higher frequencies are needed, then the cell size must be reduced.

For a human body that fits into a box of $63 \times 36 \times 183$ cm, with a 15-cell border around the body to separate it from the outer boundary, the problem space is about $160 \times 100 \times 400$ or 6.4 millions cells. Using the above formula, the computer RAM necessary to make this calculation is approximately 172 MBytes. Since this does not allow for storage of instructions and other arrays, and since the operating system will take some computer memory, a machine with about 256 MBytes of random access memory (RAM) should be sufficient to make this calculation.

A conservative estimate of the number of time steps needed is 10 times the longest dimension in cells, or 4000 time steps. Using the above equation, an estimate of 2.3×10^{12} operations results. Typical MFLOPS (Million Floating Point Operations per Second) ratings for computers are 15 for a Pentium PC or low end work station, 60 for a fast work station, and several hundred for a super computer. If we use 200 MFLOPS for the super computer, then the calculation times for the human body are 42 h for the PC or low end work station, 10.5 h for the fast work station, and 3.1 h for the super computer.

The preceding discussion primarily considers the high frequency limitations of FDTD calculations, which are based on the size of the object in wavelengths. The low frequency limitation is usually determined by a combination of the geometry features and time step. For example, consider applying FDTD for a 60-Hz calculation for a human body. Based on the wavelength, the FDTD cells could be huge, but then the body shape would be unrecognizable. Suppose that we pick FDTD cells of 10 cm to at least make a crude body shape. Then the maximum time step would be 19.2×10^{-10} s. If we further assume that we need to make FDTD calculations for at least one period of the sine wave in order to read some semblance of steady state, this would require about 86 million time steps, which is not feasible on current computers. This illustrates the difficulty of using FDTD for extremely low frequencies. For these very low frequencies other methods, such as finite elements, are preferred.

Depending on the application, human body models may be crude approximations or detailed meshes based on actual anatomy. A popular source of anatomical data suitable as the basis for an FDTD biological mesh is the Visible Human Project of the National Library of Medicine. Various types of data are available, with the most useful perhaps being the cross-sections. These are 1-mm slices for the male and 0.33-mm slices for the female. Both have a cross-sectional resolution of 0.33 mm. The FDTD meshing of this data still requires considerable effort, especially in assigning the colors of the slices to particular tissue types.

The actual FDTD calculations may be excited in different ways. Most commonly the electric fields on one or more mesh edges are determined by an analytical function of time, such as a Gaussian pulse or sine wave. This then acts as a driven voltage source. This may be used to excite an antenna. For example, a short monopole antenna on a rectangular box may approximate a portable telephone. This monopole antenna could be driven by a drive voltage source located on the mesh edge at the monopole base next to the top of the box. Both Kunz and Luebbers [1993] and Taflove [1995] describe methods for modeling RF sources. A variety of FDTD sources, including current sources, are described in Piket-May et al. [1994]. Alternatively a plane wave may be incident on the object as the excitation source.

The time variation of the excitation may be either pulsed or sine wave. The advantage of the pulse is that response for a wide frequency range can be obtained. But, for accurate results, the frequency-dependent behavior of biological materials must be included in the calculations. Methods for doing this are well known [Kunz and Luebbers, 1993; Taflove, 1995] so that transient electromagnetic field amplitudes for pulse excitation can be calculated using FDTD [Furse et al., 1994]. When results at a single frequency or at a few specific frequencies are desired, then sine wave excitation is preferred. This is especially true if results for the entire body, such as SAR, are needed, since storing the transient results for the entire body mesh and then applying fast Fourier transformation to calculate the SAR vs. frequency requires extremely large amounts of computer storage.

119.6 The Future of Engineering in Rehabilitation

Charles J. Robinson
Louisiana Tech University
Overton Brooks VA Medical Center

Rehabilitation engineering requires a multidisciplinary effort. To put rehabilitation engineering into its proper context, we need to review some of the other disciplines with which rehabilitation engineers must be familiar. Robinson [1993] has reviewed or put forth the following working definitions and discussions.

Rehabilitation: The (Re)integration of an individual with a **disability** into society. This can be done either by enhancing existing capabilities or by providing alternative means to perform various functions or to substitute for specific sensations.

Rehabilitation engineering: The *application* of science and technology to ameliorate the handicaps of individuals with disabilities [Reswick, 1982]. In actual practice, many individuals who say that they practice rehabilitation engineering are not engineers by training. While this leads to controversies from practitioners with traditional engineering degrees, it also has the *de facto* benefit of greatly widening the scope of what is encompassed by the term "rehabilitation engineering."

Rehabilitation medicine: A clinical *practice* that focuses on the physical aspects of **functional** recovery, but that also considers medical, neurological and psychological factors. Physical therapy, occupational therapy, and rehabilitation counseling are professions in their own right. On the sensory-motor side, other medical and therapeutical specialties practice rehabilitation in vision, audition, and speech.

Rehabilitation technology (or Assistive technology): Narrowly defined, the *selection*, *design*, or *manufacture* of *augmentative* or *assistive devices* that are appropriate for the individual with a disability. Such devices are selected based on the specific disability, the function to be augmented or restored, the user's wishes, the clinician's preferences, cost, and the environment in which the device will be used.

Rehabilitation science: The *development* of a body of knowledge, gleaned from rigorous basic and clinical research, that describes how a disability alters specific physiological functions or anatomical structures, and that details the underlying principles by which **residual function** or capacity can be measured and used to restore function of individuals with disabilities.

119.1 Rehabilitation Concepts

Effective rehabilitation engineers must be well versed in all of the areas described above because they generally work in a team setting, in collaboration with physical and occupational therapists, orthopedic surgeons, physical medicine specialists, and/or neurologists. Some rehabilitation engineers are interested in certain activities that we do in the course of a normal day that could be summarized as *activities of daily living* (**ADL**). These include eating, toileting, combing hair, brushing teeth, reading, etc. Other engineers focus on *mobility* and the limitations to mobility. Mobility can be personal (e.g., within a home or office) or public (automobile, public transportation, accessibility questions in buildings). Mobility also includes the ability to move functionally through the environment. Thus, the question of mobility is not limited to that of getting from place to place, but also includes such questions as whether one can reach an object in a particular setting or whether a paralyzed urinary bladder can be made functional again. Barriers that limit mobility are also studied. For example, an ill-fitted wheelchair cushion or support system will most assuredly limit mobility by reducing the time that an individual can spend in a wheelchair before he or she must vacate it to avoid serious and difficult-to-heal pressure sores. Other groups of rehabilitation engineers deal with *sensory disabilities*, such as sight or hearing, or with *communications disorders*, both on the production side (e.g., the nonvocal) or on the comprehension side. For any given client, a rehabilitation engineer might have all of these concerns to consider (i.e., ADLs, mobility, sensory, and communication dysfunctions).

A key concept in physical or sensory rehabilitation is that of *residual function* or *residual capacity*. Such a concept implies that the function or sense can be quantified, that the performance range of that function or sense is known in a nonimpaired population, and that the use of residual capacity by a disabled individual should be encouraged. These measures of human performance can be made subjectively by clinicians or objectively by some rather clever computerized test devices.

A rehabilitation engineer asks three key questions: Can a diminished function or sense be successfully augmented? Is there a substitute way to return the function or to restore a sense? And is the solution appropriate and cost-effective? These questions give rise to two important rehabilitation concepts: orthotics and prosthetics. An ***orthosis***is an appliance that aids an existing function. A ***prosthesis***provides a substitute.

An artificial limb is a *prosthesis*, as is a wheelchair. An ankle brace is an *orthosis*; so are eyeglasses. In fact, eyeglasses might well be the penultimate rehabilitation device. They are inexpensive, have little social stigma, and are almost completely unobtrusive to the user. They have let many millions of individuals with correctable vision problems lead productive lives. But in essence, a pair of eyeglasses is an optical device, governed by traditional equations of physical optics. Eyeglasses can be made out of simple glass (from a raw material as abundant as the sands of the earth) or complex plastics such as those that are ultraviolet sensitive. They can be ground by hand or by sophisticated computer-controlled optical grinders. Thus, crude technology can restore functional vision. Increasing the technical content of the eyeglasses (either by material or manufacturing method) in most cases will not increase the amount of function restored, but it might make the glasses cheaper, lighter, and more prone to be used.

119.2 Engineering Concepts in Sensory Rehabilitation

Of the five traditional senses, vision and hearing best define the interactions that permit us to be human. These two senses are the main input channels through which data with high information content can flow. We read; we listen to speech or music; we view art. A loss of one or the other of these senses (or both) can have a devastating impact on the individual affected. Rehabilitation engineers attempt to restore the functions of these senses, either through augmentation or via sensory substitution systems. Eyeglasses and hearing aids are examples of augmentative devices that can be used if some residual capacity remains. A major area of rehabilitation engineering research deals with *sensory substitution systems* [Kaczmarek et al., 1991].

The visual system has the capability to detect a single photon of light, yet also has a dynamic range that can respond to intensities many orders of magnitude greater. It can work with high contrast items and with those of almost no contrast, and across the visible spectrum of colors. Millions of parallel data channels form the optic nerve that comes from an eye; each channel transmits an asynchronous and quasi-random (in time) stream of binary pulses. While the temporal coding on any one of these channels is not fast (on the order of

200 bits per second or less), the capacity of the human brain to parallel process the entire image is faster than any supercomputer yet built.

If sight is lost, how can it be replaced? A simple pair of eyeglasses will not work, because either the sensor (the retina), the communication channel (the optic nerve and all of its relays to the brain), or one or more essential central processors (the occipital part of the cerebral cortex for initial processing; the parietal and other cortical areas for information extraction) has been damaged. For replacement within the system, one must determine where the visual system has failed and whether a stage of the system can be artificially bypassed. If one uses another sensory modality (e.g., touch or hearing) as an alternate input channel, one must determine whether there is sufficient bandwidth in that channel and whether the higher-order processing hierarchy is plastic enough to process information coming via a different route.

While the above discussion might seem just philosophical, it is more than that. We normally read printed text with our eyes. We recognize words from their (visual) letter combinations. We comprehend what we read via a mysterious processing in the parietal and temporal parts of the cerebral cortex. Could we perhaps read and comprehend this text or other forms of writing through our fingertips with an appropriate interface? The answer, surprisingly, is yes! And, the adaptation actually goes back to one of the earliest applications of coding theory — that of the development of Braille. Braille condenses all text characters to a raised matrix of 2 by 3 dots (2^6 combinations), with certain combinations reserved as indicators for the next character (such as a number indicator) or for special contractions. Trained readers of Braille can read over 250 words per minute of grade 2 Braille (as fast as most sighted readers can read printed text). Thus, the Braille code is in essence a rehabilitation engineering concept where an alternate sensory channel is used as a substitute and where a recoding scheme has been employed.

Rehabilitation engineers and their colleagues have designed other ways to read text. To replace the retina as a sensor element, a modern high-resolution, high-sensitivity, fast-imaging sensor (CCD, etc.) is employed to capture a visual image of the text. One method, used by various page scanning devices, converts the scanned image to text by using optical character recognition schemes, and then outputs the text as speech via text-to-speech algorithms. This machine essentially recites the text, much as a sighted helper might do when reading aloud to the blind individual. The user of the device is thus freed of the absolute need for a helper. Such *independence* is often the goal of rehabilitation.

Perhaps the most interesting method presents an image of the scanned data directly to the visual cortex or retina via an array of implantable electrodes that are used to electrically activate nearby cortical or retinal structures. The visual cortex and retina are laid out in topographic fashion such that there is an orderly mapping of the signal from different parts of the visual field to the retina, and from the retina to corresponding parts of the occipital cortex. The goal of stimulation is to mimic the neural activity that would have been evoked had the signal come through normal channels. And, such stimulation does produce the sensation of light. Since the "image" stays within the visual system, the rehabilitation solution is said to be ***modality specific***. However, substantial problems dealing with biocompatibility and image processing and reduction remain in the design of the electrode arrays and processors that serve to interface the electronics and neurological tissue.

Deafness is another manifestation of a loss of a communication channel, this time for the sense of hearing. Totally deaf individuals use vision as a substitute input channel when communicating via sign language (also a substitute code), and can sign at information rates that match or exceed that of verbal communication. Hearing aids are now commercially available that can adaptively filter out background noise (a predictable signal) while amplifying speech (unpredictable) using autoregressive, moving average (ARMA) signal processing. With the recent advent of powerful digital signal processing chips, true digital hearing aids are now available. Previous analog aids, or digitally programmable analog aids, provided a set of tunable filters and amplifiers to cover the low-, mid-, and high-frequency ranges of the hearing spectrum. But the digital aids can be specifically and easily tailored (i.e., programmed) to compensate for the specific losses of each individual client across the frequency continuum of hearing, and still provide automatic gain control and one or more user-selectable settings that have been adjusted to perform optimally in differing noise environments.

An exciting development is occurring outside the field of rehabilitation that will have a profound impact on the ability of the deaf to comprehend speech. Electronics companies are now beginning to market universal translation aids for travelers, where a phrase spoken in one language is captured, parsed, translated, and restated

(either spoken or displayed) in another language. The deaf would simply require that the visual display be in the language that they use for writing.

Deafness is often brought on (or occurs congenitally) by damage to the cochlea. The cochlea normally transduces variations in sound pressure intensity at a given frequency into patterns of neural discharge. This neural code is then carried by the auditory (eighth cranial) nerve to the brainstem, where it is preprocessed and relayed to the auditory cortex for initial processing and on to the parietal and other cortical areas for information extraction. Similar to the case for the visual system, the cochlea, auditory nerve, auditory cortex, and all relays in between maintain a topological map, this time based on tone frequency (tonotopic). If deafness is solely due to cochlear damage (as is often the case) and if the auditory nerve is still intact, a cochlear implant can often be substituted for the regular transducer array (the cochlea) while still sending the signal through the normal auditory channel (to maintain modality specificity).

At first glance, the design of a cochlear prosthesis to restore hearing appears daunting. The hearing range of a healthy young individual is 20 to 16,000 Hz. The transducing structure, the cochlea, has 3500 inner and 12,000 outer hair cells, each best activated by a specific frequency that causes a localized mechanical resonance in the basilar membrane of the cochlea. Deflection of a hair cell causes the cell to fire an all-or-none (i.e., pulsatile) neuronal discharge, whose rate of repetition depends to a first approximation on the amplitude of the stimulus. The outputs of these hair cells have an orderly convergence on the 30,000 to 40,000 fibers that make up the auditory portion of the eighth cranial nerve. These afferent fibers, in turn, go to brainstem neurons that process and relay the signals on to higher brain centers [Klinke, 1983]. For many causes of deafness, the hair cells are destroyed, but the eighth nerve remains intact. Thus, if one could elicit activity in a specific output fiber by means other than the hair cell motion, perhaps some sense of hearing could be restored. The geometry of the cochlea helps in this regard as different portions of the nerve are closer to different parts of the cochlea.

Electrical stimulation is now used in the cochlear implant to bypass hair cell transduction mechanisms [Loeb, 1985; Clark et al., 1990]. These sophisticated devices have required that complex signal processing, electronic, and packaging problems be solved. One current cochlear implant has 22 stimulus sites along the scala tympani of the cochlea. Those sites provide excitation to the peripheral processes of the cells of the eighth cranial nerve, which are splayed out along the length of the scala. The electrode assembly itself has 22 ring electrodes spaced along its length and some additional guard rings between the active electrodes and the receiver to aid in securing the very flexible electrode assembly after it is snaked into the cochlea's very small (a few millimeters) round window (a surgeon related to me that positioning the electrode was akin to pushing a piece of cooked spaghetti through a small hole at the end of a long tunnel). The electrode is attached to a receiver that is inlaid into a slot milled out of the temporal bone. The receiver contains circuitry that can select any electrode ring to be a source and any other electrode to be a sink for the stimulating current, and that can rapidly sequence between various pairs of electrodes. The receiver is powered and controlled by a radiofrequency link with an external transmitter, whose alignment is maintained by means of a permanent magnet imbedded in the receiver.

A digital signal processor stores information about a specific user and his or her optimal electrode locations for specific frequency bands. The object is to determine what pair of electrodes best produces the subjective perception of a certain pitch *in the implanted individual himself or herself*, and then to associate a particular filter with that pair via the controller. An enormous amount of compression occurs in taking the frequency range necessary for speech comprehension and reducing it to a few discrete channels. At present, the optimum compression algorithm is unknown, and much fundamental research is being carried out in speech processing, compression, and recognition. But, what is amazing is that a number of totally deaf individuals can relearn to comprehend speech exceptionally well without speech-reading through the use of these implants. Other individuals find that the implant aids in speech-reading. For some, only an awareness of environmental sounds is apparent; and for another group, the implant appears to have little effect. But, if you could (as I have been able to) finally converse in unaided speech with an individual who had been rendered totally blind and deaf by a traumatic brain injury, you would certainly begin to appreciate the power of rehabilitation engineering.

119.3 Engineering Concepts in Motor Rehabilitation

Limitations in mobility can severely restrict the quality of life of an individual so affected. A wheelchair is a prime example of a prosthesis that can restore personal mobility to those who cannot walk. Given the proper

environment (fairly level floors, roads, etc.), modern wheelchairs can be highly efficient. In fact, the fastest times in one of man's greatest tests of endurance, the Boston Marathon, are achieved by the wheelchair racers. Although they do gain the advantage of being able to roll, they still must climb the same hills, and do so with only one fifth of the muscle power available to an able-bodied marathoner.

While a wheelchair user could certainly go down a set of steps (not recommended), climbing steps in a normal manual or electric wheelchair is a virtual impossibility. Ramps or lifts are engineered to provide accessibility in these cases, or special climbing wheelchairs can be purchased. Wheelchairs also do not work well on surfaces with high rolling resistance or viscous coefficients (e.g., mud, rough terrain, etc.), so alternate mobility aids must be found if access to these areas is to be provided to the physically disabled. Hand-controlled cars, vans, tractors, and even airplanes are now driven by wheelchair users. The design of appropriate control modifications falls to the rehabilitation engineer.

Loss of a limb can greatly impair functional activity. The engineering aspects of artificial limb design increase in complexity as the amount of residual limb decreases, especially if one or more joints are lost. As an example, a person with a mid-calf amputation could use a simple wooden stump to extend the leg, and could ambulate reasonably well. But such a leg is not cosmetically appealing and completely ignores any substitution for ankle function.

Immediately following World War II, the U.S. government began the first concerted effort to foster better engineering design for artificial limbs. Dynamically lockable knee joints were designed for artificial limbs for above-knee amputees. In the ensuing years, energy-storing artificial ankles have been designed, some with prosthetic feet so realistic that beach thongs could be worn with them. Artificial hands, wrists, and elbows were designed for upper-limb amputees. Careful design of the actuating cable system also provided for a sense of hand grip force, so that the user had some feedback and did not need to rely on vision alone for guidance.

Perhaps the most transparent (to the user) artificial arms are the ones that use electrical activity generated by the muscles remaining in the stump to control the actions of the elbow, wrist, and hand [Stein et al., 1988]. This electrical activity is known as myoelectricity, and is produced as the muscle contraction spreads through the muscle. Note that these muscles, if intact, would have controlled at least one of these joints (e.g., the biceps and triceps for the elbow). Thus, a high level of modality specificity is maintained because the functional element is substituted only at the last stage. All of the batteries, sensor electrodes, amplifiers, motor actuators, and controllers (generally analog) reside entirely within these myoelectric arms. An individual trained in the use of a myoelectric arm can perform some impressive tasks with this arm. Current engineering research efforts involve the control of simultaneous multi-joint movements (rather than the single joint movement now available) and the provision for sensory feedback from the end effector of the artificial arm to the skin of the stump via electrical means.

119.4 Engineering Concepts in Communications Disorders

Speech is a uniquely human means of interpersonal communication. Problems that affect speech can occur at the initial transducer (the larynx) or at other areas of the vocal tract. They can be of neurological (due to cortical, brainstem, or peripheral nerve damage), structural, and/or cognitive origin. A person might only be able to make a halting attempt at talking, or might not have sufficient control of other motor skills to type or write.

If only the larynx is involved, an externally applied artificial larynx can be used to generate a resonant column of air that can be modulated by other elements in the vocal tract. If other motor skills are intact, typing can be used to generate text, which in turn can be spoken via text-to-speech devices described above. And the rate of typing (either whole words or via coding) might be fast enough so that reasonable speech rates could be achieved.

The rehabilitation engineer often becomes involved in the design or specification of *augmentative communication aids* for individuals who do not have good muscle control, either for speech or for limb movement. An entire industry has developed around the design of symbol or letter boards, where the user can point out (often painstakingly) letters, words, or concepts. Some of these boards now have speech output. Linguistics and information theory have been combined in the invention of acceleration techniques intended to speed up

the communication process. These include alternative language representation systems based on semantic (iconic), alphanumeric, or other codes; and prediction systems, which provide choices based on previously selected letters or words.

Some individuals can produce speech, but it is dysarthric and very difficult to understand. Yet the utterance does contain information. Can this limited information be used to figure out what the individual wanted to say, and then voice it by artificial means? Research labs are now employing neural network theory to determine which pauses in an utterance are due to content (i.e., between a word or sentence) and which are due to unwanted halts in speech production.

119.5 Appropriate Technology

Rehabilitation engineering lies at the interface of a wide variety of technical, biological, and other concerns. A user might (and often does) put aside a technically sophisticated rehabilitation device in favor of a simpler device that is cheaper and easier to use and maintain. The cosmetic appearance of the device (or cosmesis) sometimes becomes the overriding factor in acceptance or rejection of a device. A key design factor often lies in the use of the ***appropriate technology*** to accomplish the task adequately, given the extent of the resources available to solve the problem and the residual capacity of the client. Adequacy can be verified by determining that increasing the technical content of the solution results in disproportionately diminishing gains or escalating costs. Thus, a rehabilitation engineer must be able to distinguish applications where high technology is required from those where such technology results in an incremental gain in cost, durability, acceptance, and other factors. Further, appropriateness very much depends on location. What is appropriate to a client near a major medical center in a highly developed country might not be appropriate to one in a rural setting or in a developing country.

This is not to say that rehabilitation engineers should shun advances in technology. In fact, a fair proportion of rehabilitation engineers work in a research setting where state-of-the-art technology is being applied to the needs of the disabled. However, it is often difficult to transfer complex technology from a laboratory to disabled consumers not directly associated with that laboratory. Such devices are often designed for use only in a structured environment, are difficult to repair properly in the field, and often require a high level of user interaction or sophistication.

Technology transfer in the rehabilitation arena is difficult, due to the limited and fragmented market. Advances in rehabilitation engineering are often piggybacked onto advances in commercial electronics. For example, the exciting developments in text-to-speech and speech-to-text devices mentioned above are being driven by the commercial marketplace, and not by the rehabilitation arena. But such developments will be welcomed by rehabilitation engineers no less.

119.6 The Future of Engineering in Rehabilitation

The traditional engineering disciplines permeate many aspects of rehabilitation. Signal processing, control and information theory, materials design, and computers are all in widespread use from an electrical engineering perspective. Neural networks, microfabrication, fuzzy logic, virtual reality, image processing, and other emerging electrical and computer engineering tools are increasingly being applied. Mechanical engineering principles are used in biomechanical studies, gait and motion analysis, prosthetic fitting, seat cushion and back support design, and the design of artificial joints. Materials and metallurgical engineers provide input on newer biocompatible materials. Chemical engineers are developing implantable sensors. Industrial engineers are increasingly studying rehabilitative ergonomics.

The challenge to rehabilitation engineers is to find advances in *any* field — engineering or otherwise — that will aid their clients who have a disability.

Defining Terms

[*Note:* the first five terms below have been proposed by the National Center for Medical Rehabilitation and Research (NCMRR) of the U.S. National Institutes of Health (NIH).]

Activities of daily living (ADL): Personal activities that are done by almost everyone in the course of a normal day, including eating, toileting, combing hair, brushing teeth, reading, etc. ADLs are distinguished from hobbies and from work-related activities (e.g., typing).

Appropriate technology: The technology that will accomplish a task adequately, given the resources available. Adequacy can be verified by determining that increasing the technological content of the solution results in diminishing gains or increasing costs.

Disability: Inability or limitation in performing tasks, activities, and roles to levels expected within physical and social contexts.

Functional limitation: Restriction or lack of ability to perform an action in the manner or within the range consistent with the purpose of an organ or organ system.

Impairment: Loss or abnormality of cognitive, emotional, physiological, or anatomical structure or function, including all losses or abnormalities, not just those attributed to the initial **pathophysiology.**

Modality-specific: A task that is specific to a single sense or movement pattern.

Orthosis: A modality-specific appliance that aids the performance of a function or movement by augmenting or assisting the residual capabilities of that function or movement. An orthopedic brace is an orthosis.

Pathophysiology: Interruption or interference with normal physiological and developmental processes or structures.

Prosthesis: An appliance that substitutes for the loss of a particular function, generally by involving a different modality as an input and/or output channel. An artificial limb, a sensory substitution system, or an augmentative communication aid are prosthetic devices.

Residual function or **residual capacity:** *Residual function* is a measure of the ability to carry out one of more general tasks using the methods normally used. *Residual capacity* is a measure of the ability to to carry out these tasks using any means of performance. These residual measures are generally more subjective than other more quantifiable measures such as residual strength.

Societal limitation: Restriction, attributable to social policy or barriers (structural or attitudinal), that limits fulfillment of roles, or denies access to services or opportunities that are associated with full participation in society.

The mathematical equation used to generate this three-dimensional figure is worth a thousand words. It represents a single-solitron surface for the sine-Gordon equation $w_{uv} = \sin w$. Among the areas in which the sine-Gordon equation arises is that of wave propagation on nonlinear transmission lines and in semi-conductors. The equation is famous because it is known to have a nonlinear superposition principle obtainable by means of a Bäcklund Transformation. The sine-Gordon equation is an example of an evolution equation which has an infinite sequence of non-trivial conservation laws so important in the fields of engineering and physics. For further information on the Bäcklund Transformation see *Bäcklund Transformations and their Application,* Rogers and Shadwick, Academic Press, 1982.

This three-dimensional projection was generated using the MAPLE® software package. MAPLE® is one of three important mathematical computer packages that offer a variety of analytical and numerical software for use by scientists, engineers, and mathematicians.

This figure was developed by W.K. Schief and C. Rogers and the Center for Dynamical Systems and Nonlinear Studies at Georgia Institute of Technology and the University of New South Wales in Sydney, Australia. (Figure courtesy of Schief and Rogers.)

THE GREAT ACHIEVEMENTS in engineering deeply affect the lives of all of us and also serve to remind us of the importance of mathematics. Interest in mathematics has grown steadily with these engineering achievements and with concomitant advances in pure physical science. Whereas scholars in nonscientific fields, and even in such fields as botany, medicine, geology, etc., can communicate most of the problems and results in nonmathematical language, this is virtually impossible in present-day engineering and physics. Yet it is interesting to note that until the beginning of the twentieth century engineers regarded calculus as something of a mystery. Modern students of engineering now study calculus, as well as differential equations, complex variables, vector analysis, orthogonal functions, and a variety of other topics in applied analysis. The study of systems has ushered in matrix algebra and, indeed, most engineering students now take linear algebra as a core topic early in their mathematical education.

This section contains concise summaries of relevant topics in applied engineering mathematics and certain key formulas, that is, those formulas that are most often needed in the formulation and solution of engineering problems. Whereas even inexpensive electronic calculators contain tabular material (e.g., tables of trigonometric and logarithmic functions) that used to be needed in this kind of handbook, most calculators do not give symbolic results. Hence, we have included formulas along with brief summaries that guide their use. In many cases we have added numerical examples, as in the discussions of matrices, their inverses, and their use in the solutions of linear systems. A table of derivatives is included, as well as key applications of the derivative in the solution of problems in maxima and minima, related rates, analysis of curvature, and finding approximate

roots by numerical methods. A list of infinite series, along with the interval of convergence of each, is also included.

Of the two branches of calculus, integral calculus is richer in its applications, as well as in its theoretical content. Though the theory is not emphasized here, important applications such as finding areas, lengths, volumes, centroids, and the work done by a nonconstant force are included. Both cylindrical and spherical polar coordinates are discussed, and a table of integrals is included. Vector analysis is summarized in a separate section and includes a summary of the algebraic formulas involving dot and cross multiplication, frequently needed in the study of fields, as well as the important theorems of Stokes and Gauss. The part on special functions includes the gamma function, hyperbolic functions, Fourier series, orthogonal functions, and both Laplace and *z*-transforms. The Laplace transform provides a basis for the solution of differential equations and is fundamental to all concepts and definitions underlying analytical tools for describing feedback control systems. The *z*-transform, not discussed in most applied mathematics books, is most useful in the analysis of discrete signals as, for example, when a computer receives data sampled at some prespecified time interval. The Bessel functions, also called cylindrical functions, arise in many physical applications, such as the heat transfer in a "long" cylinder, whereas the other orthogonal functions discussed—Legendre, Hermite, and Laguerre polynomials—are needed in quantum mechanics and many other subjects (e.g., solid-state electronics) that use concepts of modern physics.

The world of mathematics, even applied mathematics, is vast. Even the best mathematicians cannot keep up with more than a small piece of this world. The topics included in this section, however, have withstood the test of time and, thus, are truly *core* for the modern engineer.

This section also incorporates tables of physical constants and symbols widely used by engineers. While not exhaustive, the constants, conversion factors, and symbols provided will enable the reader to accommodate a majority of the needs that arise in design, test, and manufacturing functions.

International System of Units (SI)

The International System of units (SI) was adopted by the 11th General Conference on Weights and Measures (CGPM) in 1960. It is a coherent system of units built form seven *SI base units,* one for each of the seven dimensionally independent base quantities: they are the meter, kilogram, second, ampere, kelvin, mole, and candela, for the dimensions length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity, respectively. The definitions of the SI base units are given below. The *SI derived units* are expressed as products of powers of the base units, analogous to the corresponding relations between physical quantities but with numerical factors equal to unity.

In the International System there is only one SI unit for each physical quantity. This is either the appropriate SI base unit itself or the appropriate SI derived unit. However, any of the approved decimal prefixes, called *SI prefixes,* may be used to construct decimal multiples or submultiples of SI units.

It is recommended that only SI units be used in science and technology (with SI prefixes where appropriate). Where there are special reasons for making an exception to this rule, it is recommended always to define the units used in terms of SI units. This section is based on information supplied by IUPAC.

Definitions of SI Base Units

Meter—The meter is the length of path traveled by light in vacuum during a time interval of 1/299 792 458 of a second (17th CGPM, 1983).

Kilogram—The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram (3rd CGPM, 1901).

Second—The second is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom (13th CGPM, 1967).

Ampere—The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length (9th CGPM, 1948).

Kelvin—The kelvin, unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water (13th CGPM, 1967).

Mole—The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, or other particles, or specified groups of such particles (14th CGPM, 1971).

Examples of the use of the mole:

1 mol of H_2 contains about 6.022×10^{23} H_2 molecules, or 12.044×10^{23} H atoms
1 mol of HgCl has a mass of 236.04 g
1 mol of Hg_2Cl_2 has a mass of 472.08 g
1 mol of Hg_2^{2+} has a mass of 401.18 g and a charge of 192.97 kC
1 mol of $Fe_{0.91}S$ has a mass of 82.88 g
1 mol of e^- has a mass of 548.60 μg and a charge of –96.49 kC
1 mol of photons whose frequency is 10^{14} Hz has energy of about 39.90 kJ

Candela—The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of (1/683) watt per steradian (16th CGPM, 1979).

Names and Symbols for the SI Base Units

Physical quantity	Name of SI unit	Symbol for SI unit
length	meter	m
mass	kilogram	kg
time	second	s
electric current	ampere	A
thermodynamic temperature	kelvin	K
amount of substance	mole	mol
luminous intensity	candela	cd

SI Derived Units with Special Names and Symbols

Physical quantity	Name of SI unit	Symbol for SI unit	Expression in terms of SI base units	
frequency[1]	hertz	Hz	s^{-1}	
force	newton	N	m kg s^{-2}	
pressure, stress	pascal	Pa	N m^{-2}	$=m^{-1}$ kg s^{-2}
energy, work, heat	joule	J	N m	$= m^2$ kg s^{-2}
power, radiant flux	watt	W	J s^{-1}	$= m^2$ kg s^{-3}
electric charge	coulomb	C	A s	
electric potential, electromotive force	volt	V	J C^{-1}	$= m^2$ kg s^{-3} A^{-1}
electric resistance	ohm	Ω	V A^{-1}	$= m^2$ kg s^{-3} A^{-2}
electric conductance	siemens	S	$Ω^{-1}$	$= m^{-2}$ kg^{-1} s^3 A^2
electric capacitance	farad	F	C V^{-1}	$= m^{-2}$ kg^{-1} s^4 A^2
magnetic flux density	tesla	T	V s m^{-2}	= kg s^{-2} A^{-1}
magnetic flux	weber	Wb	V s	$= m^2$ kg s^{-2} A^{-1}
inductance	henry	H	V A^{-1} s	$= m^2$ kg s^{-2} A^{-2}
Celsius temperature[2]	degree Celsius	°C	K	
luminous flux	lumen	lm	cd sr	
illuminance	lux	lx	cd sr m^{-2}	
activity (radioactive)	becquerel	Bq	s^{-1}	
absorbed dose (of radiation)	gray	Gy	J kg^{-1}	$= m^2$ s^{-2}
dose equivalent (dose equivalent index)	sievert	Sv	J kg^{-1}	$= m^2$ s^{-2}

Physical quantity	Name of SI unit	Symbol for SI unit	Expression in terms of SI base units	
plane angle	radian	rad	1	$= \mathrm{m\ m^{-1}}$
solid angle	steradian	sr	1	$= \mathrm{m^2\ m^{-2}}$

[1]For radial (circular) frequency and for angular velocity the unit rad s^{-1}, or simply s^{-1}, should be used, and this may not be simplified to Hz. The unit Hz should be used only for frequency in the sense of cycles per second.

[2]The Celsius temperature θ is defined by the equation:

$$\theta/°\mathrm{C} = T/\mathrm{K} - 273.15$$

The SI unit of Celsius temperature interval is the degree Celsius, °C, which is equal to the kelvin, K. °C should be treated as a single symbol, with no space between the ° sign and the letter C. (The symbol °K, and the symbol °, should no longer be used.)

Units in Use Together with the SI

These units are not part of the SI, but it is recognized that they will continue to be used in appropriate contexts. SI prefixes may be attached to some of these units, such as milliliter, ml; millibar, mbar; megaelectronvolt, MeV; kilotonne, ktonne.

Physical quantity	Name of unit	Symbol for unit	Value in SI units
time	minute	min	60 s
time	hour	h	3600 s
time	day	d	86 400 s
plane angle	degree	°	$(\pi/180)$ rad
plane angle	minute	′	$(\pi/10\ 800)$ rad
plane angle	second	″	$(\pi/648\ 000)$ rad
length	ångstrom[1]	Å	10^{-10} m
area	barn	b	$10^{-28}\ \mathrm{m^2}$
volume	litre	l, L	$\mathrm{dm^3} = 10^{-3}\ \mathrm{m^3}$
mass	tonne	t	$\mathrm{Mg} = 10^3$ kg
pressure	bar[1]	bar	10^5 Pa $= 10^5\ \mathrm{N\ m^{-2}}$
energy	electronvolt[2]	eV $(= e \times \mathrm{V})$	$\approx 1.60218 \times 10^{-19}$ J
mass	unified atomic mass unit[2,3]	u $(= m_a(^{12}\mathrm{C})/12)$	$\approx 1.66054 \times 10^{-27}$ kg

[1]The ångstrom and the bar are approved by CIPM for "temporary use with SI units," until CIPM makes a further recommendation. However, they should not be introduced where they are not used at present.

[2]The values of these units in terms of the corresponding SI units are not exact, since they depend on the values of the physical constants e (for the electronvolt) and N_a (for the unified atomic mass unit), which are determined by experiment.

[3]The unified atomic mass unit is also sometimes called the dalton, with symbol Da, although the name and symbol have not been approved by CGPM.

Conversion Constants and Multipliers

Recommended Decimal Multiples and Submultiples

°Fahrenheit	°Celsius	$t_C = \frac{t_F - 32}{1.8}$
	Kelvin	$T_k = \frac{t_F - 32}{1.8} + 273.15$
	°Rankine	$T_R = t_F + 459.67$
Kelvin	°Celsius	$t_C = T_K - 273.15$
	°Rankine	$T_R = T_K \times 1.8$
°Rankine	Kelvin	$T_K = \frac{T_R}{1.8}$
	°Farenheit	$t_F = T_R - 459.67$

Physical Constants

General

Equatorial radius of the earth = 6378.388 km = 3963.34 miles (statute).
Polar radius of the earth, 6356.912 km = 3949.99 miles (statute).
1 degree of latitude at 40° = 69 miles.
1 international nautical mile = 1.15078 miles (statute) = 1852 m = 6076.115 ft.
Mean density of the earth = 5.522 g/cm^3 = 344.7 lb/ft^3
Constant of gravitation $(6.673 \pm 0.003) \times 10^{-8}$ cm^3 gm^{-1} s^{-2}.

Acceleration due to gravity at sea level, latitude 45° = 980.6194 cm/s^2 = 32.1726 ft/s^2.
Length of seconds pendulum at sea level, latitude 45° = 99.3575 cm = 39.1171 in.
1 knot (international) = 101.269 ft/min = 1.6878 ft/s = 1.1508 miles (statute)/h.
1 micron = 10^{-4} cm.
1 ångstrom = 10^{-8} cm.
Mass of hydrogen atom = $(1.67339 \pm 0.0031) \times 10^{-24}$ g.
Density of mercury at 0°C = 13.5955 g/ml.
Density of water at 3.98°C = 1.000000 g/ml.
Density, maximum, of water, at 3.98°C = 0.999973 g/cm^3.
Density of dry air at 0°C, 760 mm = 1.2929 g/l.
Velocity of sound in dry air at 0°C = 331.36 m/s – 1087.1 ft/s.
Velocity of light in vacuum = $(2.997925 \pm 0.000002) \times 10^{10}$ cm/s.
Heat of fusion of water 0°C = 79.71 cal/g.
Heat of vaporization of water 100°C = 539.55 cal/g.
Electrochemical equivalent of silver 0.001118 g/s international amp.
Absolute wavelength of red cadmium light in air at 15°C, 760 mm pressure = 6438.4696 Å.
Wavelength of orange-red line of krypton 86 = 6057.802 Å.

Symbols and Terminology for Physical and Chemical Quantities

Name	*Symbol*	*Definition*	*SI unit*
	Classical Mechanics		
mass	m		kg
reduced mass	μ	$\mu = m_1 m_2/(m_1 + m_2)$	kg
density, mass density	ρ	$\rho = M/V$	kg m^{-3}
relative density	d	$d = \rho/\rho^{\theta}$	l
surface density	ρ_A, ρ_S	$\rho_A = m/A$	kg m^{-2}

Symbols and Terminology for Physical and Chemical Quantities (continued)

Name	*Symbol*	*Definition*	*SI unit*
		Classical Mechanics (continued)	
momentum	$\boldsymbol{p}$	$\boldsymbol{p} = m\boldsymbol{v}$	kg m s^{-1}
angular momentum, action	$\boldsymbol{L}$	$\boldsymbol{l} = \boldsymbol{r} ¥ \boldsymbol{p}$	J s
moment of inertia	I, J	$I = \Sigma m_i r_i^2$	kg m^2
force	$\boldsymbol{F}$	$\boldsymbol{F} = \mathrm{d}\boldsymbol{p}/\mathrm{d}t = m\boldsymbol{a}$	N
torque, moment of a force	$\boldsymbol{T}$, ($\boldsymbol{M}$)	$\boldsymbol{T} = \boldsymbol{r} \times \boldsymbol{F}$	N m
energy	E		J
potential energy	E_p, V, Φ	$E_p = -\int \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{s}$	J
kinetic energy	E_k, T, K	$e_k = (1/2)mv^2$	J
work	W, w	$w = \int \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{s}$	J
Hamilton function	H	$H(q, p) = T(q, p) + V(q)$	J
Lagrange function	L	$L(q, \dot{q})$ T$(q, \dot{q}) - V(q)$	J
pressure	p, P	$p = F/A$	Pa, N m^{-2}
surface tension	γ, σ	$\gamma = \mathrm{d}W/\mathrm{d}A$	N m^{-1}, J m^{-2}
weight	G, (W, P)	$G = mg$	N
gravitational constant	G	$F = Gm_1m_2/r^2$	N m^2 kg^{-2}
normal stress	σ	$\sigma = F/A$	Pa
shear stress	τ	$\tau = F/A$	Pa
linear strain, relative elongation	ε, e	$\varepsilon = \Delta l/l$	l
modulus of elasticity, Young's modulus	E	$E = \sigma/\varepsilon$	Pa
shear strain	γ	$\gamma = \Delta x/d$	l
shear modulus	G	$G = \tau/\gamma$	Pa
volume strain, bulk strain	θ	$\theta = \Delta V/V_0$	l
bulk modulus, compression modulus	K	$K = -V_0(\mathrm{d}p/\mathrm{d}V)$	Pa
viscosity, dynamic viscosity	η, μ	$\tau_{x,z} = \eta(\mathrm{d}v_x/\mathrm{d}z)$	Pa s
fluidity	ϕ	$\phi = 1/\eta$	m kg^{-1} s
kinematic viscosity	ν	$\nu = \eta/\rho$	m^2 s^{-1}
friction coefficient	μ, (f)	$F_{\mathrm{frict}} = \mu F_{\mathrm{norm}}$	l
power	P	$P = \mathrm{d}W/\mathrm{d}t$	W
sound energy flux	P, P_a	$P = \mathrm{d}E/\mathrm{d}t$	W
acoustic factors			
reflection factor	ρ	$\rho = P_r/P_0$	l
acoustic absorption factor	α_a, (α)	$\alpha_a = 1 - \rho$	l
transmission factor	τ	$\tau = P_{tr}/P_0$	l
dissipation factor	δ	$\delta = \alpha_a - \tau$	l
		Electricity and Magnetism	
quantity of electricity, electric charge	Q		C
charge density	ρ	$\rho = Q/V$	C m^{-3}
surface charge density	σ	$\sigma = Q/A$	C m^{-2}
electric potential	V, ϕ	$V = \mathrm{d}W/\mathrm{d}Q$	V, J C^{-1}
electric potential difference	U, ΔV, $\Delta\phi$	$U = V_2 - V_1$	V
electromotive force	E	$E = \int(\boldsymbol{F}/Q) \cdot \mathrm{d}\boldsymbol{s}$	V
electric field strength	$\boldsymbol{E}$	$\boldsymbol{E} = \boldsymbol{F}/Q = -\mathrm{grad}\ V$	V m^{-1}
electric flux	Ψ	$\Psi = \int \boldsymbol{D} \cdot \mathrm{d}\boldsymbol{A}$	C
electric displacement	$\boldsymbol{D}$	$\boldsymbol{D} = \varepsilon\boldsymbol{E}$	C m^{-2}
capacitance	C	$C = Q/U$	F, C V^{-1}
permittivity	ε	$D = \varepsilon E$	F m^{-1}
permittivity of vacuum	ε_0	$\varepsilon_0 = \mu_0^{-1} c_0^{-2}$	F m^{-1}
relative permittivity	ε_r	$\varepsilon_r = \varepsilon/\varepsilon_0$	l
dielectric polarization	$\boldsymbol{P}$	$\boldsymbol{P} = \boldsymbol{D} - \varepsilon_0\boldsymbol{E}$	C m^{-2}
