The Intel Pentium® processor, introduced at speeds of up to 300 MHz, combines the architectural advances in the Pentium Pro processor with the instruction set extensions of Intel MMX™ media enhancement technology. This combination delivers new levels of performance and the fastest Intel processor to workstations.

The Pentium II processor core, with 7.5 million transistors, is based on Intel's advanced P6 architecture and is manufactured on .35-micron process technology. First implemented in the Pentium Pro processor, the Dual Independent Bus architecture is made up of the L2 cache bus and the processor-to-main-memory system bus. The latter enables simultaneous parallel transactions instead of single, sequential transactions of previous generation processors.

The types of applications that will benefit from the speed of the Pentium II processor and the media enhancement of MMX technology include scanning, image manipulation, video conferencing, Internet browsers and plug-ins, video editing and playback, printing, faxing, compression, and encryption.

The Pentium II processor is the newest member of the P6 processor family, but certainly not the last in the line of high performance processors. (Courtesy of Intel Corporation.)

THIS SECTION PROVIDES A BRIEF REVIEW of the definitions and fundamental concepts used in the study of linear circuits and systems. We can describe a *circuit* or *system*, in a broad sense, as a collection of objects called *elements* (*components, parts,* or *subsystems*) which form an entity governed by certain laws or constraints. Thus, a physical system is an entity made up of physical objects as its elements or components. A subsystem of a given system can also be considered as a system itself.

A mathematical model describes the behavior of a physical system or device in terms of a set of equations, together with a schematic diagram of the device containing the symbols of its elements, their connections, and numerical values. As an example, a physical electrical system can be represented graphically by a network which includes resistors, inductors, and capacitors, etc. as its components. Such an illustration, together with a set of linear differential equations, is referred to as a model system.

Electrical circuits may be classified into various categories. Four of the more familiar classifications are (a) linear and nonlinear circuits, (b) time-invariant and time-varying circuits, (c) passive and active circuits, and (d) lumped and distributed circuits. A *linear* circuit can be described by a set of linear (differential) equations; otherwise it is a nonlinear circuit. A *time-invariant* circuit or system implies that none of the components of the circuit have parameters that vary with time; otherwise it is a *time-variant* system. If the total energy delivered to a given circuit is nonnegative at any instant of time, the circuit is said to be *passive*; otherwise it is *active*. Finally, if the dimensions of the components of the circuit are small compared to the wavelength of the highest of the signal frequencies applied to the circuit, it is called a *lumped* circuit; otherwise it is referred to as a *distributed* circuit.

There are, of course, other ways of classifying circuits. For example, one might wish to classify circuits according to the number of accessible terminals or terminal pairs (ports). Thus, terms such as *n-terminal circuit* and *n-port* are commonly used in circuit theory. Another method of classification is based on circuit configurations (topology),[1] which gives rise to such terms as *ladders, lattices, bridged-T circuits,* etc.

As indicated earlier, although the words *circuit* and *system* are synonymous and will be used interchangeably throughout the text, the terms *circuit theory* and *system theory* sometimes denote different points of view in the study of circuits or systems. Roughly speaking, *circuit theory* is mainly concerned with interconnections of components (circuit topology) within a given system, whereas *system theory* attempts to attain generality by means of abstraction through a generalized (input-output state) model.

One of the goals of this section is to present a unified treatment on the study of linear circuits and systems. That is, while the study of linear circuits with regard to their topological properties is treated as an important phase of the entire development of the theory, a generality can be attained from such a study.

The subject of circuit theory can be divided into two main parts, namely, analysis and synthesis. In a broad sense, *analysis* may be defined as "the separating of any material or abstract entity [system] into its constituent elements;" on the other hand, *synthesis* is "the combining of the constituent elements of separate materials or abstract entities into a single or unified entity [system]."[2]

It is worth noting that in an analysis problem, the solution is always *unique* no matter how difficult it may be, whereas in a synthesis problem there might exist an infinite number of solutions or, sometimes, *none at all!*

It should also be noted that in some network theory texts the words *synthesis* and *design* might be used interchangeably throughout the entire discussion of the subject. However, the term *synthesis* is generally used to describe *analytical* procedures that can usually be carried out step by step, whereas the term *design* includes practical (design) procedures (such as trial-and-error techniques which are based, to a great extent, on the experience of the designer) as well as analytical methods.

In analyzing the behavior of a given physical system, the first step is to establish a mathematical model. This model is usually in the form of a set of either differential or difference equations (or a combination of them),

[1]Circuit topology or graph theory deals with the way in which the circuit elements are interconnected. A detailed discussion on elementary applied graph theory is given in Chapter 3.6.

[2]The definitions of analysis and synthesis are quoted directly from *The Random House Dictionary of the English Language,* 2nd ed., Unabridged, New York: Random House, 1987.

the solution of which accurately describes the motion of the physical systems. There is, of course, no exception to this in the field of electrical engineering. A physical electrical system such as an amplifier circuit, for example, is first represented by a circuit drawn on paper. The circuit is composed of resistors, capacitors, inductors, and voltage and/or current sources,[1] and each of these circuit elements is given a symbol together with a mathematical expression (i.e., the voltage-current or simply *v-i* relation) relating its terminal voltage and current at every instant of time. Once the network and the *v-i* relation for each element is specified, Kirchhoff's voltage and current laws can be applied, possibly together with the physical principles to be introduced in Chapter 3.1, to establish the mathematical model in the form of differential equations.

In Section I, focus is on analysis only (leaving coverage of synthesis and design to Section III, "Electronics"). Specifically, the passive circuit elements—resistors, capacitors, inductors, transformers, and fuses—as well as voltage and current sources (active elements) are discussed. This is followed by a brief discussion on the elements of linear circuit analysis. Next, some popularly used passive filters and nonlinear circuits are introduced. Then, Laplace transform, state variables, *z*-transform, and T and π configurations are covered. Finally, transfer functions, frequency response, and stability analysis are discussed.

Nomenclature

Symbol	Quantity	Unit	Symbol	Quantity	Unit
A	area	m^2	ω	angular frequency	rad/s
B	magnetic flux density	Tesla	P	power	W
C	capacitance	F	PF	power factor

1.1 Resistors

Michael Pecht and Pradeep Lall

The resistor is an electrical device whose primary function is to introduce resistance to the flow of electric current. The magnitude of opposition to the flow of current is called the resistance of the resistor. A larger resistance value indicates a greater opposition to current flow.

The resistance is measured in ohms. An ohm is the resistance that arises when a current of one ampere is passed through a resistor subjected to one volt across its terminals.

The various uses of resistors include setting biases, controlling gain, fixing time constants, matching and loading circuits, voltage division, and heat generation. The following sections discuss resistor characteristics and various resistor types.

Resistor Characteristics

Voltage and Current Characteristics of Resistors

The resistance of a resistor is directly proportional to the **resistivity** of the material and the length of the resistor and inversely proportional to the cross-sectional area perpendicular to the direction of current flow. The resistance R of a resistor is given by

$$R = \frac{\rho l}{A} \tag{1.1}$$

where ρ is the resistivity of the resistor material ($\Omega \cdot$ cm), l is the length of the resistor along direction of current flow (cm), and A is the cross-sectional area perpendicular to current flow (cm^2) (Fig. 1.1). Resistivity is an inherent property of materials. Good resistor materials typically have resistivities between 2×10^{-6} and 200×10^{-6} $\Omega \cdot$ cm.

The resistance can also be defined in terms of sheet resistivity. If the sheet resistivity is used, a standard sheet thickness is assumed and factored into resistivity. Typically, resistors are rectangular in shape; therefore the length l divided by the width w gives the number of squares within the resistor (Fig. 1.2). The number of squares multiplied by the resistivity is the resistance.

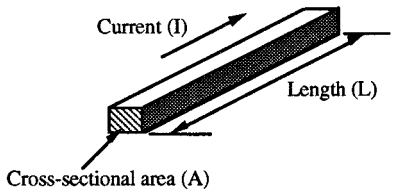

FIGURE 1.1 Resistance of a rectangular cross-section resistor with cross-sectional area A and length L.

$$R_{\text{sheet}} = \rho_{\text{sheet}} \frac{l}{w} \tag{1.2}$$

where ρ_{sheet} is the sheet resistivity (Ω/square), l is the length of resistor (cm), w is the width of the resistor (cm), and R_{sheet} is the sheet resistance (Ω).

The resistance of a resistor can be defined in terms of the **voltage drop** across the resistor and current through the resistor related by Ohm's law,

$$R = \frac{V}{I} \tag{1.3}$$

where R is the resistance (Ω), V is the voltage across the resistor (V), and I is the current through the resistor (A). Whenever a current is passed through a resistor, a voltage is dropped across the ends of the resistor. Figure 1.3 depicts the symbol of the resistor with the Ohm's law relation.

All resistors dissipate power when a voltage is applied. The power dissipated by the resistor is represented by

$$P = \frac{V^2}{R} \tag{1.4}$$

where P is the power dissipated (W), V is the voltage across the resistor (V), and R is the resistance (Ω). An ideal resistor dissipates electric energy without storing electric or magnetic energy.

Resistor Networks

Resistors may be joined to form networks. If resistors are joined in series, the effective resistance (R_T) is the sum of the individual resistances (Fig. 1.4).

$$R_T = \sum_{i=1}^{n} R_i \tag{1.5}$$

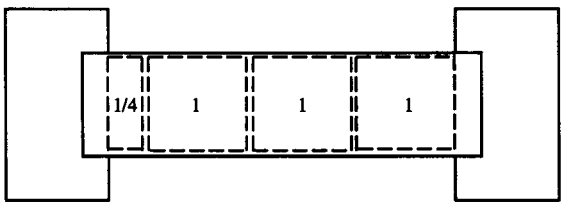

FIGURE 1.2 Number of squares in a rectangular resistor.

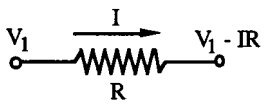

FIGURE 1.3 A resistor with resistance R having a current I flowing through it will have a voltage drop of IR across it.

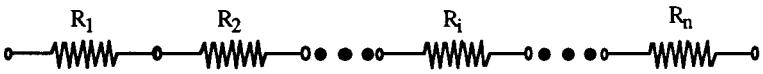

FIGURE 1.4 Resistors connected in series.

If resistors are joined in parallel, the effective resistance (R_T) is the reciprocal of the sum of the reciprocals of individual resistances (Fig. 1.5).

$$\frac{1}{R_T} = \sum_{i=1}^{n} \frac{1}{R_i} \tag{1.6}$$

Temperature Coefficient of Electrical Resistance

The resistance for most resistors changes with temperature. The temperature coefficient of electrical resistance is the change in electrical resistance of a resistor per unit change in temperature. The **temperature coefficient of resistance** is measured in Ω/°C. The temperature coefficient of resistors may be either positive or negative. A positive temperature coefficient denotes a rise in resistance with a rise in temperature; a negative temperature coefficient of resistance denotes a decrease in resistance with a rise in temperature. Pure metals typically have a positive temperature coefficient of resistance, while some metal alloys such as constantin and manganin have a zero temperature coefficient of resistance. Carbon and graphite mixed with binders usually exhibit negative temperature coefficients, although certain choices of binders and process variations may yield positive temperature coefficients. The temperature coefficient of resistance is given by

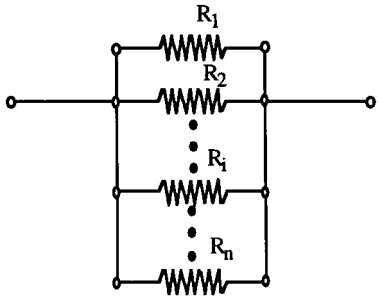

FIGURE 1.5 Resistors connected in parallel.

$$R(T_2) = R(T_1)[1 + \alpha_{T1}(T_2 - T_1)] \tag{1.7}$$

where α_{T1} is the temperature coefficient of electrical resistance at reference temperature T_1, $R(T_2)$ is the resistance at temperature T_2 (Ω), and $R(T_1)$ is the resistance at temperature T_1 (Ω). The reference temperature is usually taken to be 20°C. Because the variation in resistance between any two temperatures is usually not linear as predicted by Eq. (1.7), common practice is to apply the equation between temperature increments and then to plot the resistance change versus temperature for a number of incremental temperatures.

High-Frequency Effects

Resistors show a change in their resistance value when subjected to ac voltages. The change in resistance with voltage frequency is known as the *Boella effect*. The effect occurs because all resistors have some inductance and capacitance along with the resistive component and thus can be approximated by an equivalent circuit shown in Fig. 1.6. Even though the definition of useful frequency range is application dependent, typically, the useful range of the resistor is the highest frequency at which the impedance differs from the resistance by more than the tolerance of the resistor.

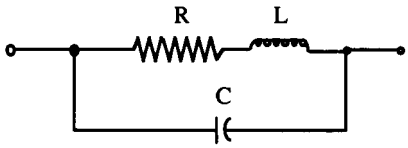

FIGURE 1.6 Equivalent circuit for a resistor.

The frequency effect on resistance varies with the resistor construction. Wire-wound resistors typically exhibit an increase in their impedance with frequency. In composition resistors the capacitances are formed by the many conducting particles which are held in contact by a dielectric binder. The ac impedance for film resistors remains constant until 100 MHz (1 MHz = 10^6 Hz) and then decreases at higher frequencies (Fig. 1.7). For film resistors, the decrease in dc resistance at higher frequencies decreases with increase in resistance. Film resistors have the most stable high-frequency performance.

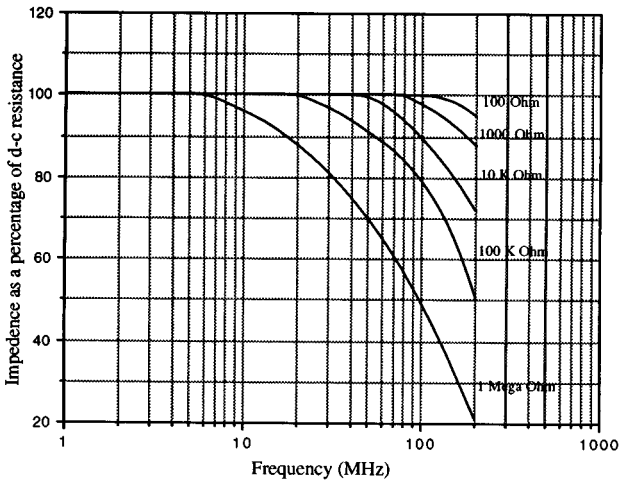

FIGURE 1.7 Typical graph of impedance as a percentage of dc resistance versus frequency for film resistors.

The smaller the diameter of the resistor the better is its frequency response. Most high-frequency resistors have a length to diameter ratio between 4:1 to 10:1. Dielectric losses are kept to a minimum by proper choice of base material.

Voltage Coefficient of Resistance

Resistance is not always independent of the applied voltage. The **voltage coefficient of resistance** is the change in resistance per unit change in voltage, expressed as a percentage of the resistance at 10% of rated voltage. The voltage coefficient is given by the relationship

$$\text{Voltage coefficient} = \frac{100(R_1 - R_2)}{R_2(V_1 - V_2)} \tag{1.8}$$

where R_1 is the resistance at the rated voltage V_1 and R_2 is the resistance at 10% of rated voltage V_2.

Noise

Resistors exhibit electrical noise in the form of small ac voltage fluctuations when dc voltage is applied. Noise in a resistor is a function of the applied voltage, physical dimensions, and materials. The total noise is a sum of Johnson noise, current flow noise, noise due to cracked bodies, and loose end caps and leads. For variable resistors the noise can also be caused by the jumping of a moving contact over turns and by an imperfect electrical path between the contact and resistance element.

The Johnson noise is temperature-dependent thermal noise (Fig. 1.8). Thermal noise is also called "white noise" because the noise level is the same at all frequencies. The magnitude of thermal noise, E_{RMS} (V), is dependent on the resistance value and the temperature of the resistance due to thermal agitation.

$$E_{RMS} = \sqrt{4kRT\Delta f} \tag{1.9}$$

where E_{RMS} is the root-mean-square value of the noise voltage (V), R is the resistance (Ω), K is the Boltzmann constant (1.38×10^{-23} J/K), T is the temperature (K), and Δf is the bandwidth (Hz) over which the noise energy is measured.

Figure 1.8 shows the variation in current noise versus voltage frequency. Current noise varies inversely with frequency and is a function of the current flowing through the resistor and the value of the resistor. The magnitude of current noise is directly proportional to the square root of current. The current noise magnitude is usually expressed by a noise index given as the ratio of the root-mean-square current noise voltage (E_{RMS})

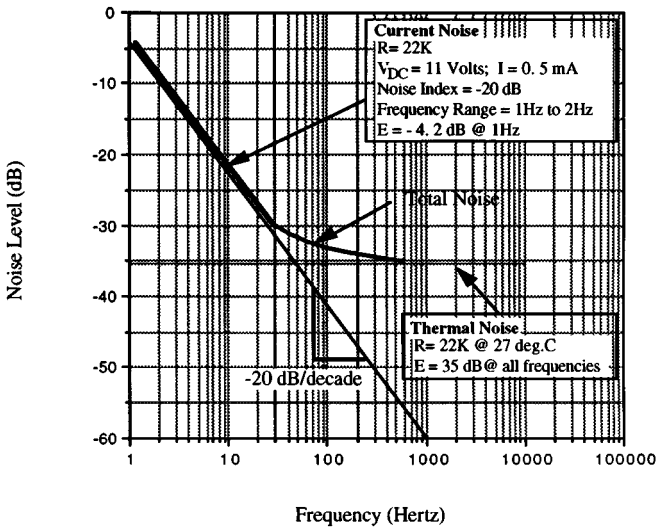

FIGURE 1.8 The total resistor noise is the sum of current noise and thermal noise. The current noise approaches the thermal noise at higher frequencies. (*Source:* Phillips Components, Discrete Products Division, *1990–91 Resistor/Capacitor Data Book,* 1991. With permission.)

over one decade bandwidth to the average voltage caused by a specified constant current passed through the resistor at a specified hot-spot temperature [Phillips, 1991].

$$\text{N.I.} = 20 \log_{10}\left(\frac{\text{Noise voltage}}{\text{dc voltage}}\right) \tag{1.10}$$

$$E_{\text{RMS}} = V_{\text{dc}} \times 10^{\text{N.I.}/20} \sqrt{\log\left(\frac{f_2}{f_1}\right)} \tag{1.11}$$

where N.I. is the noise index, V_{dc} is the dc voltage drop across the resistor, and f_1 and f_2 represent the frequency range over which the noise is being computed. Units of noise index are μV/V. At higher frequencies, the current noise becomes less dominant compared to Johnson noise.

Precision film resistors have extremely low noise. Composition resistors show some degree of noise due to internal electrical contacts between the conducting particles held together with the binder. Wire-wound resistors are essentially free of electrical noise unless resistor terminations are faulty.

Power Rating and Derating Curves

Resistors must be operated within specified temperature limits to avoid permanent damage to the materials. The temperature limit is defined in terms of the maximum power, called the *power rating,* and derating curve. The power rating of a resistor is the maximum power in watts which the resistor can dissipate. The maximum power rating is a function of resistor material, maximum voltage rating, resistor dimensions, and maximum allowable hot-spot temperature. The maximum hot-spot temperature is the temperature of the hottest part on the resistor when dissipating full-rated power at rated ambient temperature.

The maximum allowable power rating as a function of the ambient temperature is given by the derating curve. Figure 1.9 shows a typical power rating curve for a resistor. The derating curve is usually linearly drawn from the full-rated load temperature to the maximum allowable no-load temperature. A resistor may be operated at ambient temperatures above the maximum full-load ambient temperature if operating at lower than full-rated power capacity. The maximum allowable no-load temperature is also the maximum storage temperature for the resistor.

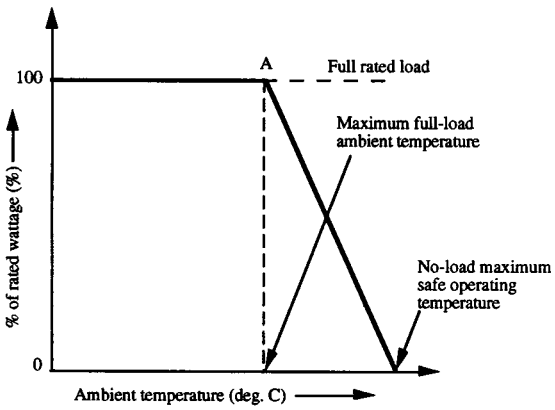

FIGURE 1.9 Typical derating curve for resistors.

Voltage Rating of Resistors

The maximum voltage that may be applied to the resistor is called the **voltage rating** and is related to the power rating by

$$V = \sqrt{PR} \tag{1.12}$$

where V is the voltage rating (V), P is the power rating (W), and R is the resistance (Ω). For a given value of voltage and power rating, a critical value of resistance can be calculated. For values of resistance below the critical value, the maximum voltage is never reached; for values of resistance above the critical value, the power dissipated is lower than the rated power (Fig. 1.10).

Color Coding of Resistors

Resistors are generally identified by color coding or direct digital marking. The color code is given in Table 1.1. The color code is commonly used in composition resistors and film resistors. The color code essentially consists of four bands of different colors. The first band is the most significant figure, the second band is the second significant figure, the third band is the multiplier or the number of zeros that have to be added after the first two significant figures, and the fourth band is the tolerance on the resistance value. If the fourth band is not present, the resistor tolerance is the standard 20% above and below the rated value. When the color code is used on fixed wire-wound resistors, the first band is applied in double width.

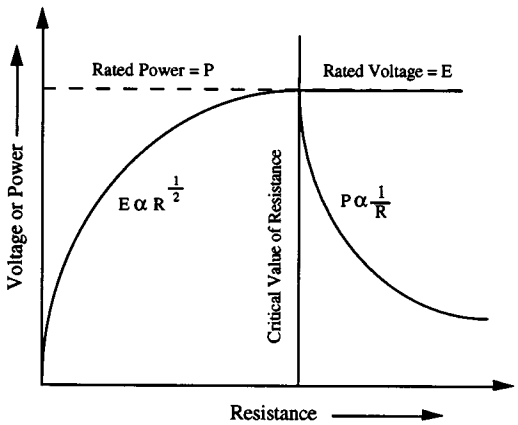

FIGURE 1.10 Relationship of applied voltage and power above and below the critical value of resistance.

TABLE 1.1 Color Code Table for Resistors

Color	First Band	Second Band	Third Band	Fourth Band Tolerance, %
Black	0	0	1	
Brown	1	1	10	
Red	2	2	100	
Orange	3	3	1,000	
Yellow	4	4	10,000	
Green	5	5	100,000	
Blue	6	6	1,000,000	
Violet	7	7	10,000,000	
Gray	8	8	100,000,000	
White	9	9	1,000,000,000	
Gold			0.1	5%
Silver			0.01	10%
No band				20%

Blanks in the table represent situations which do not exist in the color code.

Resistor Types

Resistors can be broadly categorized as fixed, variable, and special-purpose. Each of these resistor types is discussed in detail with typical ranges of their characteristics.

Fixed Resistors

The fixed resistors are those whose value cannot be varied after manufacture. Fixed resistors are classified into composition resistors, wire-wound resistors, and metal-film resistors. Table 1.2 outlines the characteristics of some typical fixed resistors.

Wire-Wound Resistors. Wire-wound resistors are made by winding wire of nickel-chromium alloy on a ceramic tube covering with a vitreous coating. The spiral winding has inductive and capacitive characteristics that make it unsuitable for operation above 50 kHz. The frequency limit can be raised by noninductive winding so that the magnetic fields produced by the two parts of the winding cancel.

Composition Resistors. Composition resistors are composed of carbon particles mixed with a binder. This mixture is molded into a cylindrical shape and hardened by baking. Leads are attached axially to each end, and the assembly is encapsulated in a protective encapsulation coating. Color bands on the outer surface indicate the resistance value and tolerance. Composition resistors are economical and exhibit low noise levels for resistances above 1 MΩ. Composition resistors are usually rated for temperatures in the neighborhood of 70°C for power ranging from 1/8 to 2 W. Composition resistors have end-to-end shunted capacitance that may be noticed at frequencies in the neighborhood of 100 kHz, especially for resistance values above 0.3 MΩ.

Metal-Film Resistors. Metal-film resistors are commonly made of nichrome, tin-oxide, or tantalum nitride, either hermetically sealed or using molded-phenolic cases. Metal-film resistors are not as stable as the

TABLE 1.2 Characteristics of Typical Fixed Resistors

Resistor Types	Resistance Range	Watt Range	Operating Temp. Range	α, ppm/°C
Wire-wound resistor				
Precision	0.1 to 1.2 MΩ	1/8 to 1/4	–55 to 145	10
Power	0.1 to 180 kΩ	1 to 210	–55 to 275	260
Metal-film resistor				
Precision	1 to 250 MΩ	1/20 to 1	–55 to 125	50–100
Power	5 to 100 kΩ	1 to 5	–55 to 155	20–100
Composition resistor				
General purpose	2.7 to 100 MΩ	1/8 to 2	–55 to 130	1500

wire-wound resistors. Depending on the application, fixed resistors are manufactured as precision resistors, semiprecision resistors, standard general-purpose resistors, or power resistors. Precision resistors have low voltage and power coefficients, excellent temperature and **time stabilities**, low noise, and very low reactance. These resistors are available in metal-film or wire constructions and are typically designed for circuits having very close resistance tolerances on values. Semiprecision resistors are smaller than precision resistors and are primarily used for current-limiting or voltage-dropping functions in circuit applications. Semiprecision resistors have long-term temperature stability. General-purpose resistors are used in circuits that do not require tight resistance tolerances or long-term stability. For general-purpose resistors, initial resistance variation may be in the neighborhood of 5% and the variation in resistance under full-rated power may approach 20%. Typically, general-purpose resistors have a high coefficient of resistance and high noise levels. Power resistors are used for power supplies, control circuits, and voltage dividers where operational stability of 5% is acceptable. Power resistors are available in wire-wound and film constructions. Film-type power resistors have the advantage of stability at high frequencies and have higher resistance values than wire-wound resistors for a given size.

Variable Resistors

Potentiometers. The potentiometer is a special form of variable resistor with three terminals. Two terminals are connected to the opposite sides of the resistive element, and the third connects to a sliding contact that can be adjusted as a voltage divider.

Potentiometers are usually circular in form with the movable contact attached to a shaft that rotates. Potentiometers are manufactured as carbon composition, metallic film, and wire-wound resistors available in single-turn or multiturn units. The movable contact does not go all the way toward the end of the resistive element, and a small resistance called the *hop-off* resistance is present to prevent accidental burning of the resistive element.

Rheostat. The rheostat is a current-setting device in which one terminal is connected to the resistive element and the second terminal is connected to a movable contact to place a selected section of the resistive element into the circuit. Typically, rheostats are wire-wound resistors used as speed controls for motors, ovens, and heater controls and in applications where adjustments on the voltage and current levels are required, such as voltage dividers and bleeder circuits.

Special-Purpose Resistors

Integrated Circuit Resistors. Integrated circuit resistors are classified into two general categories: semiconductor resistors and deposited film resistors. Semiconductor resistors use the bulk resistivity of **doped** semiconductor regions to obtain the desired resistance value. Deposited film resistors are formed by depositing resistance films on an insulating substrate which are etched and patterned to form the desired resistive network. Depending on the thickness and dimensions of the deposited films, the resistors are classified into thick-film and thin-film resistors.

Semiconductor resistors can be divided into four types: diffused, bulk, pinched, and ion-implanted. Table 1.3 shows some typical resistor properties for semiconductor resistors. Diffused semiconductor resistors use resistivity of the diffused region in the semiconductor substrate to introduce a resistance in the circuit. Both *n*-type and *p*-type diffusions are used to form the diffused resistor.

A bulk resistor uses the bulk resistivity of the semiconductor to introduce a resistance into the circuit. Mathematically the sheet resistance of a bulk resistor is given by

$$R_{\text{sheet}} = \frac{\rho_e}{d} \tag{1.13}$$

where R_{sheet} is the sheet resistance in (Ω/square), ρ_e is the sheet resistivity (Ω/square), and d is the depth of the *n*-type **epitaxial layer**.

Pinched resistors are formed by reducing the effective cross-sectional area of diffused resistors. The reduced cross section of the diffused length results in extremely high sheet resistivities from ordinary diffused resistors.

TABLE 1.3 Typical Characteristics of Integrated Circuit Resistors

Resistor Type	Sheet Resistivity (per square)	Temperature Coefficient (ppm/°C)
Semiconductor		
Diffused	0.8 to 260 Ω	1100 to 2000
Bulk	0.003 to 10 kΩ	2900 to 5000
Pinched	0.001 to 10 kΩ	3000 to 6000
Ion-implanted	0.5 to 20 kΩ	100 to 1300
Deposited resistors		
Thin-film		
Tantalum	0.01 to 1 kΩ	∓100
SnO_2	0.08 to 4 kΩ	–1500 to 0
Ni-Cr	40 to 450 Ω	∓100
Cermet (Cr-SiO)	0.03 to 2.5 kΩ	∓150
Thick-film		
Ruthenium-silver	10 Ω to 10 MΩ	∓200
Palladium-silver	0.01 to 100 kΩ	–500 to 150

Ion-implanted resistors are formed by implanting ions on the semiconductor surface by bombarding the silicon lattice with high-energy ions. The implanted ions lie in a very shallow layer along the surface (0.1 to 0.8 μm). For similar thicknesses ion-implanted resistors yield sheet resistivities 20 times greater than diffused resistors. Table 1.3 shows typical properties of diffused, bulk, pinched, and ion-implanted resistors. Typical sheet resistance values range from 80 to 250 Ω/square.

Varistors. Varistors are voltage-dependent resistors that show a high degree of nonlinearity between their resistance value and applied voltage. They are composed of a nonhomogeneous material that provides a rectifying action. Varistors are used for protection of electronic circuits, semiconductor components, collectors of motors, and relay contacts against overvoltage.

The relationship between the voltage and current of a varistor is given by

$$V = kI^{\beta} \tag{1.14}$$

where V is the voltage (V), I is the current (A), and k and β are constants that depend on the materials and manufacturing process. The electrical characteristics of a varistor are specified by its β and k values.

Varistors in Series. The resultant k value of n varistors connected in series is nk. This can be derived by considering n varistors connected in series and a voltage nV applied across the ends. The current through each varistor remains the same as for V volts over one varistor. Mathematically, the voltage and current are expressed as

$$nV = k_1 I^{\beta} \tag{1.15}$$

Equating the expressions (1.14) and (1.15), the equivalent constant k_1 for the series combination of varistors is given as

$$k_1 = nk \tag{1.16}$$

Varistors in Parallel. The equivalent k value for a parallel combination of varistors can be obtained by connecting n varistors in parallel and applying a voltage V across the terminals. The current through the varistors will still be n times the current through a single varistor with a voltage V across it. Mathematically the current and voltage are related as

$$V = k_2(nI)^{\beta} \tag{1.17}$$

From Eqs. (1.14) and (1.17) the equivalent constant k_2 for the series combination of varistors is given as

$$k_2 = \frac{k}{n^{\beta}} \tag{1.18}$$

Thermistors. Thermistors are resistors that change their resistance exponentially with changes in temperature. If the resistance decreases with increase in temperature, the resistor is called a negative temperature coefficient (NTC) resistor. If the resistance increases with temperature, the resistor is called a positive temperature coefficient (PTC) resistor.

NTC thermistors are ceramic semiconductors made by sintering mixtures of heavy metal oxides such as manganese, nickel, cobalt, copper, and iron. The resistance temperature relationship for NTC thermistors is

$$R_T = A e^{B/T} \tag{1.19}$$

where T is temperature (K), R_T is the resistance (Ω), and A, B are constants whose values are determined by conducting experiments at two temperatures and solving the equations simultaneously.

PTC thermistors are prepared from $BaTiO_3$ or solid solutions of $PbTiO_3$ or $SrTiO_3$. The resistance temperature relationship for PTC thermistors is

$$R_T = A + Ce^{BT} \tag{1.20}$$

where T is temperature (K), R_T is the resistance (Ω), and A, B are constants determined by conducting experiments at two temperatures and solving the equations simultaneously. Positive thermistors have a PTC only between certain temperature ranges. Outside this range the temperature is either zero or negative. Typically, the absolute value of the temperature coefficient of resistance for PTC resistors is much higher than for NTC resistors.

Defining Terms

Doping: The intrinsic carrier concentration of semiconductors (e.g., Si) is too low to allow controlled charge transport. For this reason some impurities called dopants are purposely added to the semiconductor. The process of adding dopants is called doping. Dopants may belong to group IIIA (e.g., boron) or group VA (e.g., phosphorus) in the periodic table. If the elements belong to the group IIIA, the resulting semiconductor is called a *p*-type semiconductor. On the other hand, if the elements belong to the group VA, the resulting semiconductor is called an *n*-type semiconductor.

Epitaxial layer: Epitaxy refers to processes used to grow a thin crystalline layer on a crystalline substrate. In the epitaxial process the wafer acts as a seed crystal. The layer grown by this process is called an epitaxial layer.

Resistivity: The resistance of a conductor with unit length and unit cross-sectional area.

Temperature coefficient of resistance: The change in electrical resistance of a resistor per unit change in temperature.

Time stability: The degree to which the initial value of resistance is maintained to a stated degree of certainty under stated conditions of use over a stated period of time. Time stability is usually expressed as a percent or parts per million change in resistance per 1000 hours of continuous use.

Voltage coefficient of resistance: The change in resistance per unit change in voltage, expressed as a percentage of the resistance at 10% of rated voltage.

Voltage drop: The difference in potential between the two ends of the resistor measured in the direction of flow of current. The voltage drop is $V = IR$, where V is the voltage across the resistor, I is the current through the resistor, and R is the resistance.

Voltage rating: The maximum voltage that may be applied to the resistor.

1.2 Capacitors and Inductors

Glen Ballou

Capacitors

If a potential difference is found between two points, an electric **field** exists that is the result of the separation of unlike charges. The strength of the field will depend on the amount the charges have been separated.

Capacitance is the concept of energy storage in an electric field and is restricted to the area, shape, and spacing of the **capacitor** plates and the property of the material separating them.

When electrical current flows into a capacitor, a force is established between two parallel plates separated by a **dielectric.** This energy is stored and remains even after the input is removed. By connecting a **conductor** (a resistor, hard wire, or even air) across the capacitor, the charged capacitor can regain electron balance, that is, discharge its stored energy.

The value of a parallel-plate capacitor can be found with the equation

$$C = \frac{x\epsilon[(N-1)A]}{d} \times 10^{-13} \tag{1.21}$$

where C = capacitance, F; ϵ = dielectric constant of insulation; d = spacing between plates; N = number of plates; A = area of plates; and $x = 0.0885$ when A and d are in centimeters, and $x = 0.225$ when A and d are in inches.

The work necessary to transport a unit charge from one plate to the other is

$$e = kg \tag{1.22}$$

where e = volts expressing energy per unit charge, g = coulombs of charge already transported, and k = proportionality factor between work necessary to carry a unit charge between the two plates and charge already transported. It is equal to $1/C$, where C is the capacitance, F.

The value of a capacitor can now be calculated from the equation

$$C = \frac{q}{e} \tag{1.23}$$

where q = charge (C) and e is found with Eq. (1.22).

The energy stored in a capacitor is

$$W = \frac{CV^2}{2} \tag{1.24}$$

where W = energy, J; C = capacitance, F; and V = applied voltage, V.

The **dielectric constant** of a material determines the electrostatic energy which may be stored in that material per unit volume for a given voltage. The value of the dielectric constant expresses the ratio of a capacitor in a vacuum to one using a given dielectric. The dielectric of air is 1, the reference unit employed for expressing the dielectric constant. As the dielectric constant is increased or decreased, the capacitance will increase or decrease, respectively. Table 1.4 lists the dielectric constants of various materials.

The dielectric constant of most materials is affected by both temperature and frequency, except for quartz, Styrofoam, and Teflon, whose dielectric constants remain essentially constant.

The equation for calculating the *force of attraction* between two plates is

$$F = \frac{AV^2}{k(1504S)^2} \tag{1.25}$$

TABLE 1.4 Comparison of Capacitor Dielectric Constants

Dielectric	K (Dielectric Constant)
Air or vacuum	1.0
Paper	2.0–6.0
Plastic	2.1–6.0
Mineral oil	2.2–2.3
Silicone oil	2.7–2.8
Quartz	3.8–4.4
Glass	4.8–8.0
Porcelain	5.1–5.9
Mica	5.4–8.7
Aluminum oxide	8.4
Tantalum pentoxide	26
Ceramic	12–400,000

where F = attraction force, dyn; A = area of one plate, cm^2; V = potential energy difference, V; k = dielectric coefficient; and S = separation between plates, cm.

The Q for a capacitor when the resistance and capacitance is in series is

$$Q = \frac{1}{2\pi fRC} \tag{1.26}$$

where Q = ratio expressing the factor of merit; f = frequency, Hz; R = resistance, Ω; and C = capacitance, F.

When capacitors are connected in *series,* the total capacitance is

$$C_T = \frac{1}{1/C_1 + 1/C_2 + \cdots + 1/C_n} \tag{1.27}$$

and is always less than the value of the smallest capacitor.

When capacitors are connected in *parallel*, the total capacitance is

$$C_T = C_1 + C_2 + \cdots + C_n \tag{1.28}$$

and is always larger than the largest capacitor.

When a voltage is applied across a group of capacitors connected in series, the voltage drop across the combination is equal to the applied voltage. The drop across each individual capacitor is inversely proportional to its capacitance.

$$V_C = \frac{V_A C_X}{C_T} \tag{1.29}$$

where V_C = voltage across the individual capacitor in the series (C_1, C_2, ...,C_n), V; V_A = applied voltage, V; C_T = total capacitance of the series combination, F; and C_X = capacitance of individual capacitor under consideration, F.

In an ac circuit, the **capacitive reactance,** or the **impedance**, of the capacitor is

$$X_C = \frac{1}{2\pi fC} \tag{1.30}$$

where X_C = capacitive reactance, Ω; f = frequency, Hz; and C = capacitance, F. The current will lead the voltage by 90° in a circuit with a pure capacitor.

When a dc voltage is connected across a capacitor, a time t is required to charge the capacitor to the applied voltage. This is called a **time constant** and is calculated with the equation

$$t = RC \tag{1.31}$$

where t = time, s; R = resistance, Ω; and C = capacitance, F.

In a circuit consisting of pure resistance and capacitance, the *time constant t* is defined as the time required to charge the capacitor to 63.2% of the applied voltage.

During the next time constant, the capacitor charges to 63.2% of the remaining difference of full value, or to 86.5% of the full value. The charge on a capacitor can never actually reach 100% but is considered to be 100% after five time constants. When the voltage is removed, the capacitor discharges to 63.2% of the full value.

Capacitance is expressed in microfarads (μF, or 10^{-6} F) or picofarads (pF, or 10^{-12} F) with a stated accuracy or tolerance. Tolerance may also be stated as GMV (guaranteed minimum value), sometimes referred to as MRV (minimum rated value).

All capacitors have a *maximum working voltage* that must not be exceeded and is a combination of the dc value plus the peak ac value which may be applied during operation.

Quality Factor (*Q*)

Quality factor is the ratio of the capacitor's **reactance** to its resistance at a specified frequency and is found by the equation

$$Q = \frac{1}{2\pi fCR} = \frac{1}{PF} \tag{1.32}$$

where Q = quality factor; f = frequency, Hz; C = value of capacitance, F; R = internal resistance, Ω; and PF = power factor

Power Factor (PF)

Power factor is the preferred measurement in describing capacitive losses in ac circuits. It is the fraction of input volt-amperes (or power) dissipated in the capacitor dielectric and is virtually independent of the capacitance, applied voltage, and frequency.

Equivalent Series Resistance (ESR)

Equivalent series resistance is expressed in ohms or milliohms (Ω, mΩ) and is derived from lead resistance, termination losses, and dissipation in the dielectric material.

Equivalent Series Inductance (ESL)

The *equivalent series inductance* can be useful or detrimental. It reduces high-frequency performance; however, it can be used in conjunction with the internal capacitance to form a resonant circuit.

Dissipation Factor (DF)

The **dissipation factor** in percentage is the ratio of the effective series resistance of a capacitor to its reactance at a specified frequency. It is the reciprocal of *quality factor* (Q) and an indication of power loss within the capacitor. It should be as low as possible.

Insulation Resistance

Insulation resistance is the resistance of the dielectric material and determines the time a capacitor, once charged, will hold its charge. A discharged capacitor has a low insulation resistance; however once charged to its rated value, it increases to megohms. The leakage in electrolytic capacitors should not exceed

$$I_L = 0.04C + 0.30 \tag{1.33}$$

where I_L = leakage current, μA, and C = capacitance, μF.

Dielectric Absorption (DA)

The *dielectric absorption* is a reluctance of the dielectric to give up stored electrons when the capacitor is discharged. This is often called "memory" because if a capacitor is discharged through a resistance and the resistance is removed, the electrons that remained in the dielectric will reconvene on the electrode, causing a voltage to appear across the capacitor. DA is tested by charging the capacitor for 5 min, discharging it for 5 s, then having an open circuit for 1 min after which the recovery voltage is read. The percentage of DA is defined as the ratio of recovery to charging voltage times 100.

Types of Capacitors

Capacitors are used to filter, couple, tune, block dc, pass ac, bypass, shift phase, compensate, feed through, isolate, store energy, suppress noise, and start motors. They must also be small, lightweight, reliable, and withstand adverse conditions.

Capacitors are grouped according to their dielectric material and mechanical configuration.

Ceramic Capacitors

Ceramic capacitors are used most often for bypass and coupling applications (Fig. 1.11). Ceramic capacitors can be produced with a variety of K values (dielectric constant). A high K value translates to small size and less stability. High-K capacitors with a dielectric constant >3000 are physically small and have values between 0.001 to several microfarads.

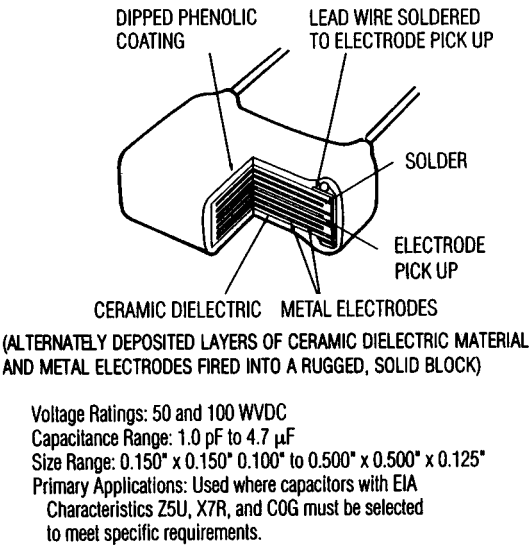

FIGURE 1.11 Monolythic® multilayer ceramic capacitors. (Courtesy of Sprague Electric Company.)

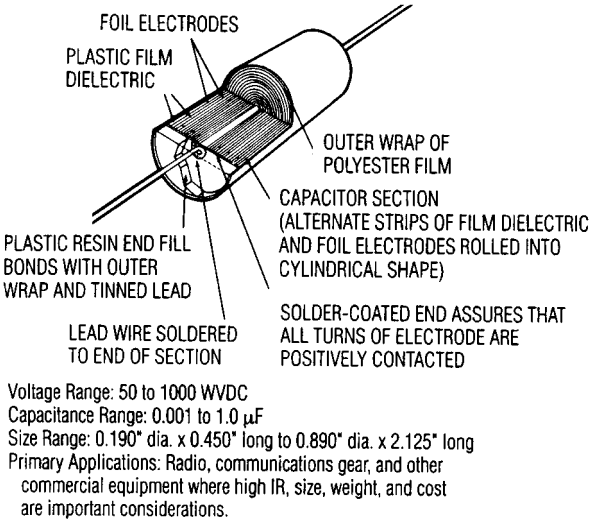

FIGURE 1.12 Film-wrapped film capacitors. (Courtesy of Sprague Electric Company.)

Good temperature stability requires capacitors to have a K value between 10 and 200. If high Q is also required, the capacitor will be physically larger. Ceramic capacitors with a zero temperature change are called **negative-positive-zero (NPO)** and come in a capacitance range of 1.0 pF to 0.033 μF.

An N750 temperature-compensated capacitor is used when accurate capacitance is required over a large temperature range. The 750 indicates a 750-ppm decrease in capacitance with a 1°C increase in temperature (750 ppm/°C). This equates to a 1.5% decrease in capacitance for a 20°C temperature increase. N750 capacitors come in values between 4.0 and 680 pF.

Film Capacitors

Film capacitors consist of alternate layers of metal foil and one or more layers of a flexible plastic insulating material (dielectric) in ribbon form rolled and encapsulated (see Fig. 1.12).

Mica Capacitors

Mica capacitors have small capacitance values and are usually used in high-frequency circuits. They are constructed as alternate layers of metal foil and mica insulation, which are stacked and encapsulated, or are silvered mica, where a silver electrode is screened on the mica insulators.

Paper-Foil-Filled Capacitors

Paper-foil-filled capacitors are often used as motor capacitors and are rated at 60 Hz. They are made of alternate layers of aluminum and paper saturated with oil that are rolled together. The assembly is mounted in an oil-filled, hermetically sealed metal case.

Electrolytic Capacitors

Electrolytic capacitors provide high capacitance in a tolerable size; however, they do have drawbacks. Low temperatures reduce performance, while high temperatures dry them out. The **electrolytes** themselves can leak and corrode the equipment. Repeated surges above the rated working voltage, excessive ripple currents, and high operating temperature reduce performance and shorten capacitor life.

Electrolytic capacitors are manufactured by an electrochemical formation of an oxide film on a metal surface. The metal on which the oxide film is formed serves as the **anode** or positive terminal of the capacitor; the oxide film is the dielectric, and the **cathode** or negative terminal is either a conducting liquid or a gel.

The equivalent circuit of an electrolytic capacitor is shown in Fig. 1.13, where A and B are the capacitor terminals, C is the effective capacitance, and L is the self-inductance of the capacitor caused by terminals, electrodes, and geometry.

The shunt resistance (insulation resistance) R_s accounts for the dc leakage current. Heat is generated in the ESR from ripple current and in the shunt resistance by voltage. The ESR is due to the spacer-electrolyte-oxide system and varies only slightly except at low temperature, where it increases greatly.

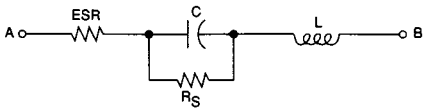

FIGURE 1.13 Simplified equivalent circuit of an electrolytic capacitor.

The *impedance* of a capacitor (Fig. 1.14) is frequency-dependent. The initial downward slope is caused by the capacitive reactance X_C. The trough (lowest impedance) is almost totally resistive, and the upward slope is due to the capacitor's self-inductance X_L. An ESR plot would show an ESR decrease to about 5–10 kHz, remaining relatively constant thereafter.

Leakage current is the direct current that passes through a capacitor when a correctly polarized dc voltage is applied to its terminals. It is proportional to temperature, becoming increasingly important at elevated **ambient temperatures**. Leakage current decreases slowly after voltage is applied, reaching steady-state conditions in about 10 min.

If a capacitor is connected with reverse polarity, the oxide film is forward-biased, offering very little resistance to current flow. This causes overheating and self-destruction of the capacitor.

The total heat generated within a capacitor is the sum of the heat created by the $I_{\text{leakage}} \times V_{\text{applied}}$ and the I^2R losses in the ESR.

The ac **ripple current** rating is very important in filter applications because excessive current produces temperature rise, shortening capacitor life. The maximum permissible rms ripple current is limited by the internal temperature and the rate of heat dissipation from the capacitor. Lower ESR and longer enclosures increase the ripple current rating.

Capacitor life expectancy is doubled for each 10°C decrease in operating temperature, so a capacitor operating at room temperature will have a life expectancy 64 times that of the same capacitor operating at 85°C (185°F).

The *surge voltage* specification of a capacitor determines its ability to withstand high transient voltages that generally occur during the starting up period of equipment. Standard tests generally specify a short on and long off period for an interval of 24 h or more, and the allowable surge voltage levels are generally 10% above the rated voltage of the capacitor.

Figure 1.15 shows how temperature, frequency, time, and applied voltage affect electrolytic capacitors.

Aluminum Electrolytic Capacitors. *Aluminum electrolytic capacitors* use aluminum as the base material (Fig. 1.16). The surface is often etched to increase the surface area as much as 100 times that of unetched foil, resulting in higher capacitance in the same volume.

Aluminum electrolytic capacitors can withstand up to 1.5 V of reverse voltage without detriment. Higher reverse voltages, when applied over extended periods, lead to loss of capacitance. Excess reverse voltages applied for short periods cause some change in capacitance but not to capacitor failure.

Large-value capacitors are often used to filter dc power supplies. After a capacitor is charged, the rectifier stops conducting and the capacitor discharges into the load, as shown in Fig. 1.17, until the next cycle. Then the capacitor recharges again to the peak voltage. The Δe is equal to the total peak-to-peak ripple voltage and is a complex wave containing many harmonics of the fundamental ripple frequency, causing the noticeable heating of the capacitor.

Tantalum Capacitors. *Tantalum electrolytics* are the preferred type where high reliability and long service life are paramount considerations.

Tantalum capacitors have as much as three times better capacitance per volume efficiency than aluminum electrolytic capacitors, because tantalum pentoxide has a dielectric constant three times greater than that of aluminum oxide (see Table 1.4).

The capacitance of any capacitor is determined by the surface area of the two conducting plates, the

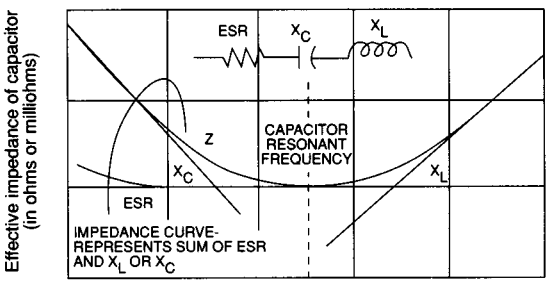

Figure 1.14 Impedance characteristics of a capacitor.

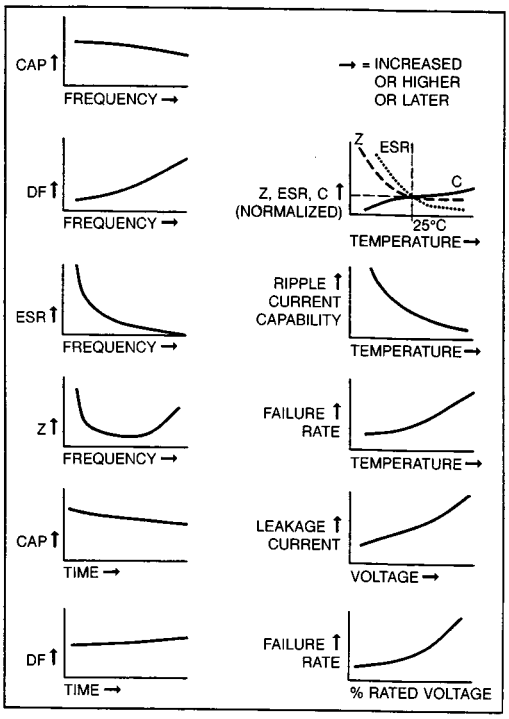

FIGURE 1.15 Variations in aluminum electrolytic characteristics caused by temperature, frequency, time, and applied voltage. (Courtesy of Sprague Electric Company.)

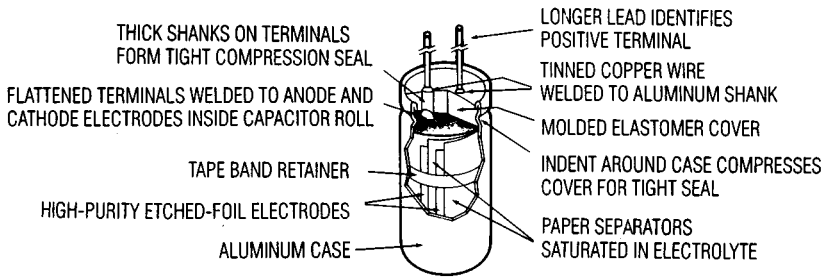

Voltage Range: 6.3 to 63 WVDC
Capacitance Range: 0.47 to 3300 μF
Size Range: 0.197" dia. x 0.433" long to 0.630" dia. x 1.614" long
Primary Applications: Coupling, decoupling, bypass, and filtering.
Vertical installation on high-density printed wiring boards in transistorized radios, portable TV sets, auto radios, tape recorders, etc.

(Courtesy

FIGURE 1.16 Verti-lytic® miniature single-ended aluminum electrolytic capacitor. (Courtesy of Sprague Electric Company.)

distance between the plates, and the dielectric constant of the insulating material between the plates [see Eq. (1.21)].

In tantalum electrolytics, the distance between the plates is the thickness of the tantalum pentoxide film, and since the dielectric constant of the tantalum pentoxide is high, the capacitance of a tantalum capacitor is high.

Tantalum capacitors contain either liquid or solid electrolytes. The liquid electrolyte in wet-slug and foil capacitors, generally sulfuric acid, forms the cathode (negative) plate. In solid-electrolyte capacitors, a dry material, manganese dioxide, forms the cathode plate.

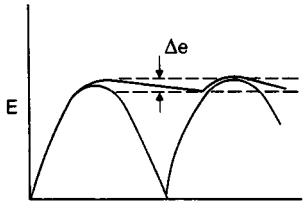

FIGURE 1.17 Full-wave capacitor charge and discharge.

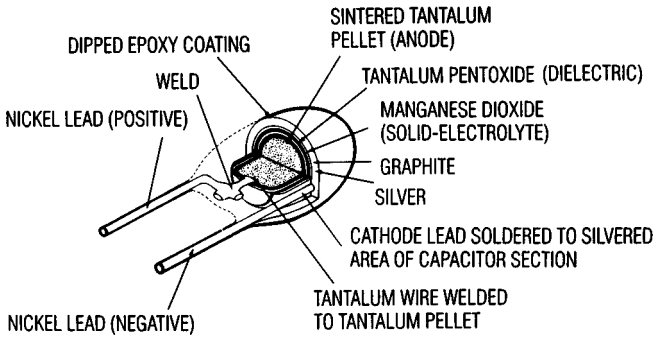
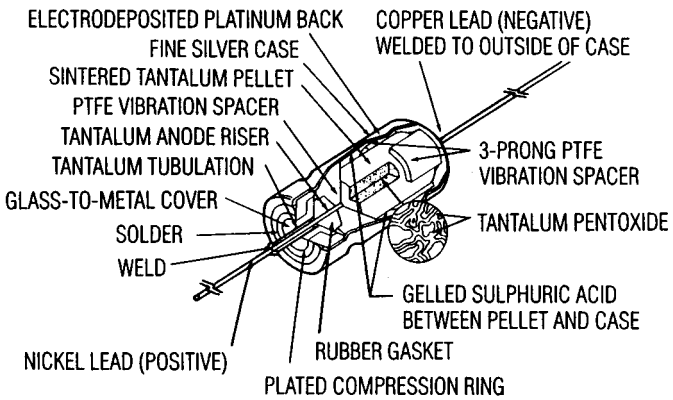
Foil Tantalum Capacitors. *Foil tantalum capacitors* can be designed to voltage values up to 300 V dc. Of the three types of tantalum electrolytic capacitors, the foil design has the lowest capacitance per unit volume and is best suited for the higher voltages primarily found in older designs of equipment. It is expensive and used only where neither a solid-electrolyte (Fig. 1.18) nor a wet-slug (Fig. 1.19) tantalum capacitor can be employed.



Voltage Range: 3 to 50 WVDC
Capacitance Range: 0.10 to 680 μF
Size Range: 0.175" dia. x 0.280" high to 0.400" dia. x 0.750" high
Primary Applications: For printed wiring boards applications where low cost, small size, high stability, low d-c leakage , and low dissipation factor are important.

FIGURE 1.18 Tantalex® solid electrolyte tantalum capacitor. (Courtesy of Sprague Electric Company.)



Voltage Range: 6 to 125 WVDC
Capacitance Range: 1.7 to 1200 μF
Size Range: 0.188" dia. x 0.453" long to 0.375" dia. x 1.062" long
Primary Applications: Industrial and military equipment where reliability and premium performance with respect to low d-c leakage current, high inrush current capability, and high volumetric efficiency.

FIGURE 1.19 Hermetically sealed sintered-anode tantalum capacitor. (Courtesy of Sprague Electric Company.)

Foil tantalum capacitors are generally designed for operation over the temperature range of –55 to +125°C (–67 to +257°F) and are found primarily in industrial and military electronics equipment.

Solid-electrolyte sintered-anode tantalum capacitors differ from the wet versions in their electrolyte, which is manganese dioxide.

Another variation of the solid-electrolyte tantalum capacitor encases the element in plastic resins, such as epoxy materials offering excellent reliability and high stability for consumer and commercial electronics with the added feature of low cost.

Still other designs of "solid tantalum" capacitors use plastic film or sleeving as the encasing material, and others use metal shells that are backfilled with an epoxy resin. Finally, there are small tubular and rectangular molded plastic encasements.

Wet-electrolyte sintered-anode tantalum capacitors, often called "wet-slug" tantalum capacitors, use a pellet of sintered tantalum powder to which a lead has been attached, as shown in Fig. 1.19. This anode has an enormous surface area for its size.

Wet-slug tantalum capacitors are manufactured in a voltage range to 125 V dc.

Use Considerations. Foil tantalum capacitors are used only where high-voltage constructions are required or where there is substantial reverse voltage applied to a capacitor during circuit operation.

Wet sintered-anode capacitors, or "wet-slug" tantalum capacitors, are used where low dc leakage is required. The conventional "silver can" design will not tolerate reverse voltage. In military or aerospace applications where utmost reliability is desired, tantalum cases are used instead of silver cases. The tantalum-cased wet-slug units withstand up to 3 V reverse voltage and operate under higher ripple currents and at temperatures up to 200°C (392°F).

Solid-electrolyte designs are the least expensive for a given rating and are used where their very small size is important. They will typically withstand a reverse voltage up to 15% of the rated dc working voltage. They also have good low-temperature performance characteristics and freedom from corrosive electrolytes.

Inductors

Inductance is used for the storage of magnetic energy. Magnetic energy is stored as long as current keeps flowing through the inductor. In a perfect **inductor**, the current of a sine wave lags the voltage by 90°.

Impedance

Inductive reactance X_L, the impedance of an inductor to an ac signal, is found by the equation

$$X_L = 2\pi fL \tag{1.34}$$

where X_L = inductive reactance, Ω; f = frequency, Hz; and L = inductance, H.

The type of wire used for its construction does not affect the inductance of a **coil**. Q of the coil will be governed by the resistance of the wire. Therefore coils wound with silver or gold wire have the highest Q for a given design.

To increase inductance, inductors are connected in series. The total inductance will always be greater than the largest inductor.

$$L_T = L_1 + L_2 + \cdots + L_n \tag{1.35}$$

To reduce inductance, inductors are connected in parallel.

$$L_T = \frac{1}{1/L_1 + 1/L_2 + \cdots + 1/L_n} \tag{1.36}$$

The total inductance will always be less than the value of the lowest inductor.

Mutual Inductance

Mutual inductance is the property that exists between two conductors carrying current when their magnetic lines of force link together.

The mutual inductance of two coils with fields interacting can be determined by the equation

$$M = \frac{L_A - L_B}{4} \tag{1.37}$$

where M = mutual inductance of L_A and L_B, H; L_A = total inductance, H, of coils L_1 and L_2 with fields aiding; and L_B = total inductance, H, of coils L_1 and L_2 with fields opposing.

The *coupled inductance* can be determined by the following equations. In parallel with fields aiding,

$$L_T = \frac{1}{\dfrac{1}{L_1 + M} + \dfrac{1}{L_2 + M}} \tag{1.38}$$

In parallel with fields opposing,

$$L_T = \frac{1}{\dfrac{1}{L_1 - M} - \dfrac{1}{L_2 - M}} \tag{1.39}$$

In series with fields aiding,

$$L_T = L_1 + L_2 + 2M \tag{1.40}$$

In series with fields opposing,

$$L_T = L_1 + L_2 - 2M \tag{1.41}$$

where L_T = total inductance, H; L_1 and L_2 = inductances of the individual coils, H; and M = mutual inductance, H.

When two coils are inductively coupled to give transformer action, the coupling coefficient is determined by

$$K = \frac{M}{\sqrt{L_1 L_2}} \tag{1.42}$$

where K = coupling coefficient; M = mutual inductance, H; and L_1 and L_2 = inductances of the two coils, H.

An inductor in a circuit has a reactance equal to $j2\pi fL\ \Omega$. Mutual inductance in a circuit has a reactance equal to $j2\pi fL\ \Omega$. The operator j denotes that the reactance dissipates no energy; however, it does oppose current flow.

The energy stored in an inductor can be determined by the equation

$$W = \frac{LI^2}{2} \tag{1.43}$$

where W = energy, J (W · s); L = inductance, H; and I = current, A.

Coil Inductance

Inductance is related to the turns in a coil as follows:

1. The inductance is proportional to the square of the turns.
2. The inductance increases as the length of the **winding** is increased.
3. A shorted turn decreases the inductance, affects the frequency response, and increases the insertion loss.
4. The inductance increases as the permeability of the core material increases.
5. The inductance increases with an increase in the cross-sectional area of the core material.
6. Inductance is increased by inserting an iron core into the coil.
7. Introducing an air gap into a choke reduces the inductance.

A conductor moving at any angle to the lines of force cuts a number of lines of force proportional to the sine of the angles. Thus,

$$V = \beta L v \sin \theta \times 10^{-8} \tag{1.44}$$

where β = flux density; L = length of the conductor, cm; and v = velocity, cm/s, of conductor moving at an angle θ.

The maximum voltage induced in a conductor moving in a magnetic field is proportional to the number of magnetic lines of force cut by that conductor. When a conductor moves parallel to the lines of force, it cuts no lines of force; therefore, no current is generated in the conductor. A conductor that moves at right angles to the lines of force cuts the maximum number of lines per inch per second, therefore creating a maximum voltage. The right-hand rule determines direction of the induced electromotive force (emf). The emf is in the direction in which the axis of a right-hand screw, when turned with the velocity vector, moves through the smallest angle toward the flux density vector.

The **magnetomotive force** (mmf) in **ampere-turns** produced by a coil is found by multiplying the number of turns of wire in the coil by the current flowing through it.

$$\begin{aligned} \text{Ampere-turns} &= T\left(\frac{V}{R}\right) \\ &= TI \end{aligned} \tag{1.45}$$

where T = number of turns; V = voltage, V; and R = resistance, Ω.

The inductance of a single layer, a spiral, and multilayer coils can be calculated by using either Wheeler's or Nagaoka's equations. The accuracy of the calculation will vary between 1 and 5%. The inductance of a single-layer coil can be calculated using Wheeler's equation:

$$L = \frac{B^2 N^2}{9B + 10A} \quad \mu\text{H} \tag{1.46}$$

For the multilayer coil,

$$L = \frac{0.8 B^2 N^2}{6B + 9A + 10C} \quad \mu\text{H} \tag{1.47}$$

For the spiral coil,

$$L = \frac{B^2 N^2}{8B + 11C} \quad \mu\text{H} \tag{1.48}$$

where B = radius of the winding, N = number of turns in the coil, A = length of the winding, and C = thickness of the winding.

Q

Q is the ratio of the inductive reactance to the internal resistance of the coil and is affected by frequency, inductance, dc resistance, inductive reactance, the type of winding, the core losses, the distributed capacity, and the permeability of the core material.

The Q for a coil where R and L are in series is

$$Q = \frac{2\pi fL}{R} \tag{1.49}$$

where f = frequency, Hz; L = inductance, H; and R = resistance, Ω.

The Q of the coil can be measured using the circuit of Fig. 1.20 for frequencies up to 1 MHz. The voltage across the inductance (L) at resonance equals $Q(V)$ (where V is the voltage developed by the oscillator); therefore, it is only necessary to measure the output voltage from the oscillator and the voltage across the inductance.

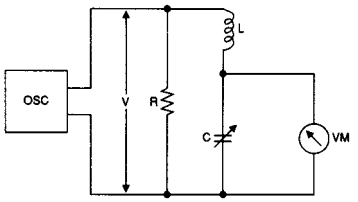


FIGURE 1.20 Circuit for measuring the Q of a coil.

The oscillator voltage is driven across a low value of resistance, R, about 1/100 of the anticipated rf resistance of the LC combination, to assure that the measurement will not be in error by more than 1%. For most measurements, R will be about 0.10 Ω and should have a voltage of 0.1 V. Most oscillators cannot be operated into this low impedance, so a step-down matching transformer must be employed. Make C as large as convenient to minimize the ratio of the impedance looking from the voltmeter to the impedance of the test circuit. The LC circuit is then tuned to resonate and the resultant voltage measured. The value of Q may then be equated

$$Q = \frac{\text{resonant voltage across } C}{\text{voltage across } R} \tag{1.50}$$

The Q of any coil may be approximated by the equation

$$\begin{aligned} Q &= \frac{2\pi fL}{R} \\ &= \frac{X_L}{R} \end{aligned} \tag{1.51}$$

where f = the frequency, Hz; L = the inductance, H; R = the dc resistance, Ω (as measured by an ohmmeter); and X_L = the inductive reactance of the coil.

Time Constant

When a dc voltage is applied to an RL circuit, a certain amount of time is required to change the circuit [see text with Eq. (1.31)]. The time constant can be determined with the equation

$$T = \frac{L}{R} \tag{1.52}$$

where R = resistance, Ω; L = inductance, H; and T = time, s.

The *right-hand rule* is used to determine the direction of a magnetic field around a conductor carrying a direct current. Grasp the conductor in the right hand with the thumb extending along the conductor pointing in the direction of the current. With the fingers partly closed, the finger tips will point in the direction of the magnetic field.

Maxwell's rule states, "If the direction of travel of a right-handed corkscrew represents the direction of the current in a straight conductor, the direction of rotation of the corkscrew will represent the direction of the magnetic lines of force."

Impedance

The total impedance created by resistors, capacitors, and inductors in circuits can be determined with the following equations.

For resistance and capacitance in series,

$$Z = \sqrt{R^2 + X_C^2} \tag{1.53}$$

$$\theta = \arctan \frac{X_C}{R} \tag{1.54}$$

For resistance and inductance in series,

$$Z = \sqrt{R^2 + X_L^2} \tag{1.55}$$

$$\theta = \arctan \frac{X_L}{R} \tag{1.56}$$

For inductance and capacitance in series,

$$Z = \begin{cases} X_L - X_C & \text{when } X_L > X_C \quad (1.57) \\ X_C - X_L & \text{when } X_C > X_L \quad (1.58) \end{cases}$$

For resistance, inductance, and capacitance in series,

$$Z = \sqrt{R^2 + (X_L - X_C)^2} \tag{1.59}$$

$$\theta = \arctan \frac{X_L - X_C}{R} \tag{1.60}$$

For capacitance and resistance in parallel,

$$Z = \frac{RX_C}{\sqrt{R^2 + X_C^2}} \tag{1.61}$$

For resistance and inductance in parallel,

$$Z = \frac{RX_L}{\sqrt{R^2 + X_L^2}} \tag{1.62}$$

For capacitance and inductance in parallel,

$$Z = \begin{cases} \dfrac{X_L X_C}{X_L - X_C} & \text{when } X_L > X_C \quad (1.63) \\ \dfrac{X_C X_L}{X_C - X_L} & \text{when } X_C > X_L \quad (1.64) \end{cases}$$

For inductance, capacitance, and resistance in parallel,

$$Z = \frac{RX_L X_C}{\sqrt{X_L^2 X_C^2 + R^2 (X_L - X_C)^2}} \quad (1.65)$$

$$\theta = \arctan \frac{R(X_L - X_C)}{X_L X_C} \quad (1.66)$$

For inductance and series resistance in parallel with resistance,

$$Z = R_2 \sqrt{\frac{R_1^2 + X_L^2}{(R_1 + R_2)^2 + X_L^2}} \quad (1.67)$$

$$\theta = \arctan \frac{X_L R_2}{R_1^2 + X_L^2 + R_1 R_2} \quad (1.68)$$

For inductance and series resistance in parallel with capacitance,

$$Z = X_C \sqrt{\frac{R^2 + X_L^2}{R^2 + (X_L - X_C)^2}} \quad (1.69)$$

$$\theta = \arctan \frac{X_L (X_C - X_L) - R^2}{RX_C} \quad (1.70)$$

For capacitance and series resistance in parallel with inductance and series resistance,

$$Z = \sqrt{\frac{(R_1^2 + X_L^2)(R_2^2 + X_C^2)}{(R_1 + R_2)^2 + (X_L - X_C)^2}} \quad (1.71)$$

$$\theta = \arctan \frac{X_L (R_2^2 + X_C^2) - X_C (R_1^2 + X_L^2)}{R_1 (R_2^2 + X_C^2) + R_2 (R_1^2 + X_L^2)} \quad (1.72)$$

where Z = impedance, Ω; R = resistance, Ω; L = inductance, H; X_L = inductive reactance, Ω; X_C = capacitive reactance, Ω; and θ = **phase** angle, degrees, by which current leads voltage in a capacitive circuit or lags voltage in an inductive circuit (0° indicates an in-phase condition).

Resonant Frequency

When an inductor and capacitor are connected in series or parallel, they form a resonant circuit. The **resonant frequency** can be determined from the equation

$$\begin{aligned} f &= \frac{1}{2\pi\sqrt{LC}} \\ &= \frac{1}{2\pi C X_C} \\ &= \frac{X_L}{2\pi L} \end{aligned} \tag{1.73}$$

where f = frequency, Hz; L = inductance, H; C = capacitance, F; and X_L, X_C = impedance, Ω.

The resonant frequency can also be determined through the use of a reactance chart developed by the Bell Telephone Laboratories (Fig. 1.21). This chart can be used for solving problems of inductance, capacitance, frequency, and impedance. If two of the values are known, the third and fourth values may be found with its use.

Defining Terms

Air capacitor: A fixed or variable capacitor in which air is the dielectric material between the capacitor's plates.

Ambient temperature: The temperature of the air or liquid surrounding any electrical part or device. Usually refers to the effect of such temperature in aiding or retarding removal of heat by radiation and convection from the part or device in question.

Ampere-turns: The magnetomotive force produced by a coil, derived by multiplying the number of turns of wire in a coil by the current (A) flowing through it.

Anode: The positive electrode of a capacitor.

Capacitive reactance: The opposition offered to the flow of an alternating or pulsating current by capacitance measured in ohms.

Capacitor: An electrical device capable of storing electrical energy and releasing it at some predetermined rate at some predetermined time. It consists essentially of two conducting surfaces (electrodes) separated by an insulating material or dielectric. A capacitor stores electrical energy, blocks the flow of direct current, and permits the flow of alternating current to a degree dependent essentially upon capacitance and frequency. The amount of energy stored, $E = 0.5\ CV^2$.

Cathode: The capacitor's negative electrode.

Coil: Anumber of turns of wire in the form of a spiral. The spiral may be wrapped around an iron core or an insulating form, or it may be self-supporting. A coil offers considerable opposition to ac current but very little to dc current.

Conductor: Abare or insulated wire or combination of wires not insulated from one another, suitable for carrying an electric current.

Dielectric: The insulating (nonconducting) medium between the two electrodes (plates) of a capacitor.

Dielectric constant: The ratio of the capacitance of a capacitor with a given dielectric to that of the same capacitor having a vacuum dielectric.

Disk capacitor: A small single-layer ceramic capacitor with a dielectric insulator consisting of conductively silvered opposing surfaces.

Dissipation factor (DF): The ratio of the effective series resistance of a capacitor to its reactance at a specified frequency measured in percent.

Electrolyte: Current-conducting solution between two electrodes or plates of a capacitor, at least one of which is covered by a dielectric.

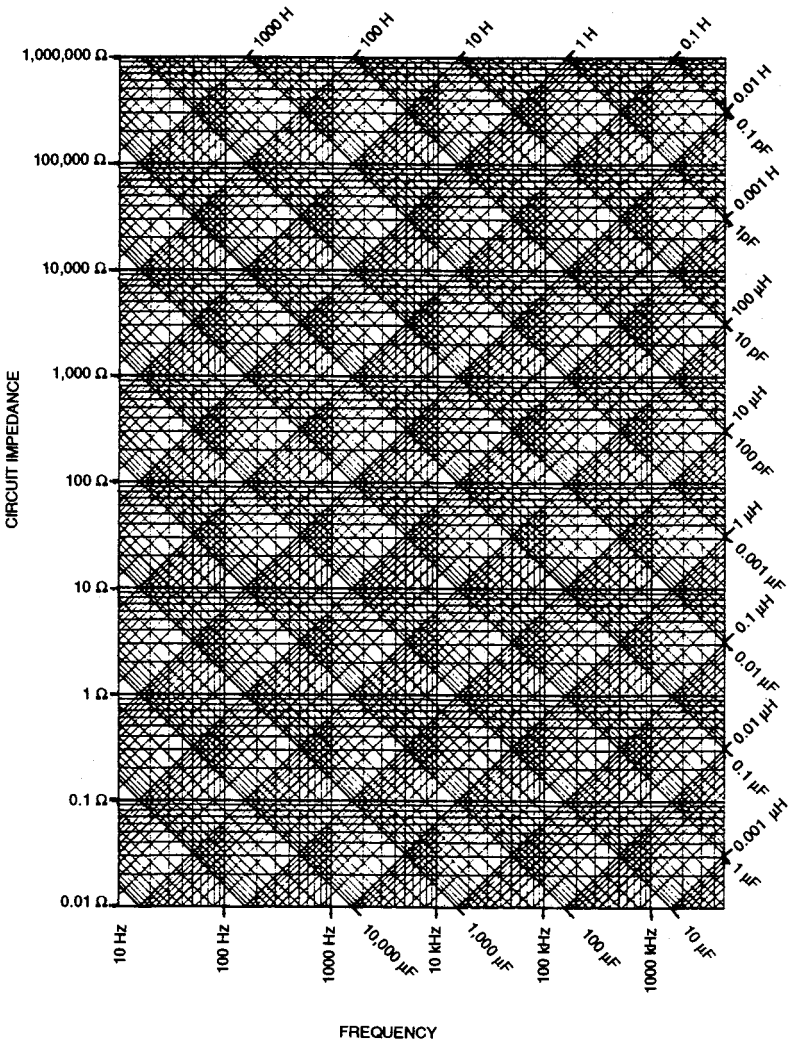

FIGURE 1.21 Reactance chart. (Courtesy AT&T Bell Laboratories.)

Electrolytic capacitor: A capacitor solution between two electrodes or plates of a capacitor, at least one of which is covered by a dielectric.

Equivalent series resistance (ESR): All internal series resistance of a capacitor concentrated or "lumped" at one point and treated as one resistance of a capacitor regardless of source, i.e., lead resistance, termination losses, or dissipation in the dielectric material.

Farad: The basic unit of measure in capacitors. Acapacitor charged to 1 volt with a charge of 1 coulomb (1 ampere flowing for 1 second) has a capacitance of 1 farad.

Field: Ageneral term referring to the region under the influence of a physical agency such as electricity, magnetism, or a combination produced by an electrical charged object.

Impedance (Z): Total opposition offered to the flow of an alternating or pulsating current measured in ohms. (Impedance is the vector sum of the resistance and the capacitive and inductive reactance, i.e., the ratio of voltage to current.)

Inductance: The property which opposes any change in the existing current. Inductance is present only when the current is changing.

Inductive reactance (X_L): The opposition to the flow of alternating or pulsating current by the inductance of a circuit.

Inductor: Aconductor used to introduce inductance into a circuit.

Leakage current: Stray direct current of relatively small value which flows through a capacitor when voltage is impressed across it.

Magnetomotive force: The force by which the magnetic field is produced, either by a current flowing through a coil of wire or by the proximity of a magnetized body. The amount of magnetism produced in the first method is proportional to the current through the coil and the number of turns in it.

Mutual inductance: The property that exists between two current-carrying conductors when the magnetic lines of force from one link with those from another.

Negative-positive-zero (NPO): An ultrastable temperature coefficient (±30 ppm/°C from –55 to 125°C) temperature-compensating capacitor.

Phase: The angular relationship between current and voltage in an ac circuit. The fraction of the period which has elapsed in a periodic function or wave measured from some fixed origin. If the time for one period is represented as 360° along a time axis, the phase position is called phase angle.

Polarized capacitor: An electrolytic capacitor in which the dielectric film is formed on only one metal electrode. The impedance to the flow of current is then greater in one direction than in the other. Reversed polarity can damage the part if excessive current flow occurs.

Power factor (PF): The ratio of effective series resistance to impedance of a capacitor, expressed as a percentage.

Quality factor (*Q*): The ratio of the reactance to its equivalent series resistance.

Reactance (*X*): Opposition to the flow of alternating current. Capacitive reactance (X_c) is the opposition offered by capacitors at a specified frequency and is measured in ohms.

Resonant frequency: The frequency at which a given system or object will respond with maximum amplitude when driven by an external sinusoidal force of constant amplitude.

Reverse leakage current: Anondestructive current flowing through a capacitor subjected to a voltage of polarity opposite to that normally specified.

Ripple current: The total amount of alternating and direct current that may be applied to an electrolytic capacitor under stated conditions.

Temperature coefficient (TC): A capacitor's change in capacitance per degree change in temperature. May be positive, negative, or zero and is usually expressed in parts per million per degree Celsius (ppm/°C) if the characteristics are linear. For nonlinear types, TC is expressed as a percentage of room temperature (25°C)capacitance.

Time constant: In a capacitor-resistor circuit, the number of seconds required for the capacitor to reach 63.2% of its full charge after a voltage is applied. The time constant of a capacitor with a capacitance (C) in farads in series with a resistance (R) in ohms is equal to $R \times C$ seconds.

Winding: Aconductive path, usually wire, inductively coupled to a magnetic core or cell.

1.3 Transformers

C. Sankaran

The electrical transformer was invented by an American electrical engineer, William Stanley, in 1885 and was used in the first ac lighting installation at Great Barrington, Massachusetts. The first transformer was used to step up the power from 500 to 3000 V and transmitted for a distance of 1219 m (4000 ft). At the receiving end the voltage was stepped down to 500 V to power street and office lighting. By comparison, present transformers are designed to transmit hundreds of megawatts of power at voltages of 700 kV and beyond for distances of several hundred miles.

Transformation of power from one voltage level to another is a vital operation in any transmission, distribution, and utilization network. Normally, power is generated at a voltage that takes into consideration the cost of generators in relation to their operating voltage. Generated power is transmitted by overhead lines many miles and undergoes several voltage transformations before it is made available to the actual user. Figure 1.22 shows a typical power flow line diagram.

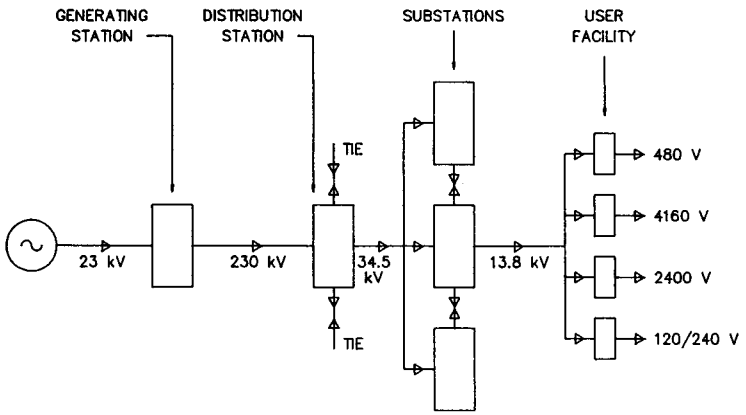

FIGURE 1.22 Power flow line diagram.

Types of Transformers

Transformers are broadly grouped into two main categories: dry-type and liquid-filled transformers. Dry-type transformers are cooled by natural or forced circulation of air or inert gas through or around the transformer enclosure. Dry-type transformers are further subdivided into ventilated, sealed, or encapsulated types depending upon the construction of the transformer. Dry transformers are extensively used in industrial power distribution for rating up to 5000 kVA and 34.5 kV.

Liquid-filled transformers are cooled by natural or forced circulation of a liquid coolant through the windings of the transformer. This liquid also serves as a **dielectric** to provide superior voltage-withstand characteristics. The most commonly used liquid in a transformer is a mineral oil known as transformer oil that has a continuous operating temperature rating of 105°C, a flash point of 150°C, and a fire point of 180°C. A good grade transformer oil has a **breakdown strength** of 86.6 kV/cm (220 kV/in.) that is far higher than the breakdown strength of air, which is 9.84 kV/cm (25 kV/in.) at atmospheric pressure.

Silicone fluid is used as an alternative to mineral oil. The breakdown strength of silicone liquid is over 118 kV/cm (300 kV/in.) and it has a flash point of 300°C and a fire point of 360°C. Silicone-fluid-filled transformers are classified as less flammable. The high dielectric strengths and superior thermal conductivities of liquid coolants make them ideally suited for large high-voltage power transformers that are used in modern power generation and distribution.

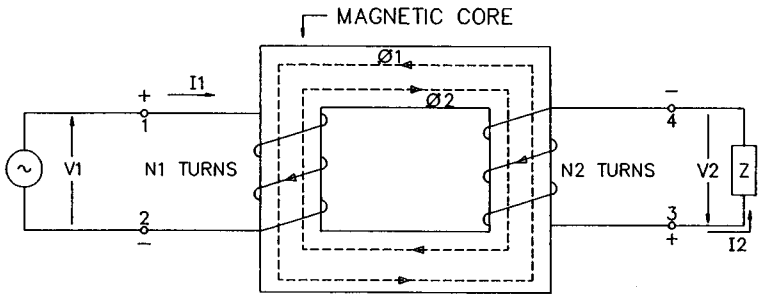

FIGURE 1.23 Electrical power transfer.

Principle of Transformation

The actual process of transfer of electrical power from a voltage of V_1 to a voltage of V_2 is explained with the aid of the simplified transformer representation shown in Fig. 1.23. Application of voltage across the primary winding of the transformer results in a **magnetic field** of ϕ_1 Wb in the magnetic core, which in turn induces a voltage of V_2 at the secondary terminals. V_1 and V_2 are related by the expression $V_1/V_2 = N_1/N_2$, where N_1 and N_2 are the number of turns in the primary and secondary windings, respectively. If a load current of I_2 A is drawn from the secondary terminals, the load current establishes a magnetic field of ϕ_2 Wb in the core and in the direction shown. Since the effect of load current is to reduce the amount of primary magnetic field, the reduction in ϕ_1 results in an increase in the primary current I_1 so that the net magnetic field is almost restored to the initial value and the slight reduction in the field is due to leakage **magnetic flux**. The currents in the two windings are related by the expression $I_1/I_2 = N_2/N_1$. Since $V_1/V_2 = N_1/N_2 = I_2/I_1$, we have the expression $V_1 \cdot I_1 = V_2 \cdot I_2$. Therefore, the voltamperes in the two windings are equal in theory. In reality, there is a slight loss of power during transformation that is due to the energy necessary to set up the magnetic field and to overcome the losses in the transformer core and windings. Transformers are static power conversion devices and are therefore highly efficient. Transformer efficiencies are about 95% for small units (15 kVA and less), and the efficiency can be higher than 99% for units rated above 5 MVA.

Electromagnetic Equation

Figure 1.24 shows a magnetic core with the area of cross section $A = W \cdot D$ m^2. The transformer primary winding that consists of N turns is excited by a sinusoidal voltage $v = V \sin(\omega t)$, where ω is the angular frequency given by the expression $\omega = 2\pi f$ and f is the frequency of the applied voltage waveform. ϕ is magnetic field in the core due to the excitation current i:

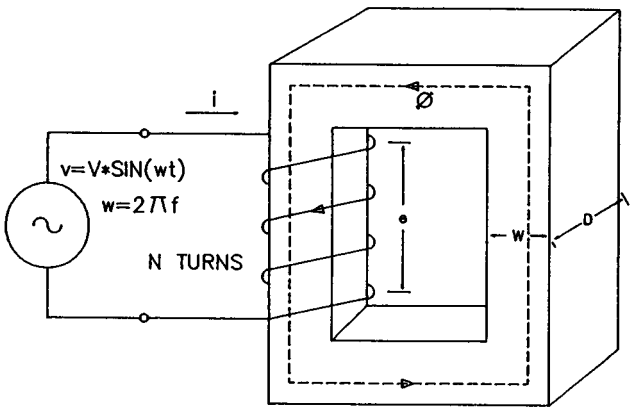

FIGURE 1.24 Electromagnetic relation.

$$\phi = \Phi \sin\left(\omega t - \frac{\pi}{2}\right) = -\Phi \cos(\omega t)$$

Induced voltage in the winding

$$e = -N\frac{d\phi}{dt} = N\frac{d[\Phi \cos(\omega t)]}{dt} = -N\omega\Phi \sin(\omega t)$$

Maximum value of the induced voltage

$$E = N\omega\Phi$$

The root-mean-square value

$$E_{\text{rms}} = \frac{E}{\sqrt{2}} = \frac{2\pi f N\Phi}{\sqrt{2}} = 4.44 f \text{ NBA}$$

where flux Φ (webers) is replaced by the product of the flux density B (teslas) and the area of cross section of the core.

This fundamental design equation determines the size of the transformer for any given voltage and frequency. Power transformers are normally operated at flux density levels of 1.5 T.

Transformer Core

The transformer core is the medium that enables the transfer of power from the primary to the secondary to occur in a transformer. In order that the transformation of power may occur with the least amount of loss, the magnetic core is made up of laminations which have the highest permeability, permeability being a measure of the ease with which the magnetic field is set up in the core.

The magnetic field reverses direction every one half cycle of the applied voltage and energy is expended in the core to accomplish the cyclic reversals of the field. This loss component is known as the hysteresis loss P_h:

$$P_h = 150.7 V_e f B^{1.6} \quad \text{W}$$

where V_e is the volume of the core in cubic meters, f is the frequency, and B is the maximum flux density in teslas.

As the magnetic field reverses direction and cuts across the core structure, it induces a voltage in the laminations known as eddy voltages. This phenomenon causes eddy currents to circulate in the laminations. The loss due to eddy currents is called the eddy current loss P_e:

$$P_e = 1.65 V_e B^2 f^2 t^2 / r$$

where V_e is the volume of the core in cubic meters, f is the frequency, B is the maximum flux density in teslas, t is thickness of the laminations in meters, and r is the resistivity of the core material in ohm-meters.

Hysteresis losses are reduced by operating the core at low flux densities and using core material of high permeability. Eddy current losses are minimized by low flux levels, reduction in thickness of the laminations, and high resistivity core material.

Cold-rolled, grain-oriented silicon steel laminations are exclusively used in large power transformers to reduce core losses. A typical silicon steel used in transformers contains 95% iron, 3% silicon, 1% manganese, 0.2% phosphor, 0.06% carbon, 0.025% sulphur, and traces of other impurities.

Transformer Losses

The heat developed in a transformer is a function of the losses that occur during transformation. Therefore, the transformer losses must be minimized and the heat due to the losses must be efficiently conducted away from the core, the windings, and the cooling medium. The losses in a transformer are grouped into two categories: (1) no-load losses and (2) load losses. The no-load losses are the losses in the core due to excitation and are mostly composed of hysteresis and eddy current losses. The load losses are grouped into three categories: (1) winding I^2R losses, (2) winding eddy current losses, and (3) other stray losses. The winding I^2R losses are the result of the flow of load current through the resistance of the primary and secondary windings. The winding eddy current losses are caused by the magnetic field set up by the winding current, due to formation of eddy voltages in the conductors. The winding eddy losses are proportional to the square of the rms value of the current and to the square of the frequency of the current. When transformers are required to supply loads that are rich in **harmonic frequency** components, the eddy loss factor must be given extra consideration. The other stray loss component is the result of induced currents in the buswork, core clamps, and tank walls by the magnetic field set up by the load current.

Transformer Connections

A single-phase transformer has one input (primary) winding and one output (secondary) winding. A conventional three-phase transformer has three input and three output windings. The three windings can be connected in one of several different configurations to obtain three-phase connections that are distinct. Each form of connection has its own merits and demerits.

Y Connection (Fig. 1.25)

In the Y connection, one end of each of the three windings is connected together to form a Y, or a neutral point. This point is normally grounded, which limits the maximum potential to ground in the transformer to the line to neutral voltage of the power system. The grounded neutral also limits transient overvoltages in the transformer when subjected to lightning or switching surges. Availability of the neutral point allows the transformer to supply line to neutral single-phase loads in addition to normal three-phase loads. Each phase of the Y-connected winding must be designed to carry the full line current, whereas the phase voltages are only 57.7% of the line voltages.

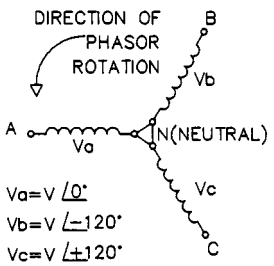

FIGURE 1.25 Y connection.

Delta Connection (Fig. 1.26)

In the delta connection, the finish point of each winding is connected to the start point of the adjacent winding to form a closed triangle, or delta. A delta winding in the transformer tends to balance out unbalanced loads that are present on the system. Each phase of the delta winding only carries 57.7% of the line current, whereas the phase voltages are equal to the line voltages.

Large power transformers are designed so that the high-voltage side is connected in Y and the low-voltage side is connected in delta. Distribution transformers that are required to supply single-phase loads are designed in the opposite configuration so that the neutral point is available at the low-voltage end.

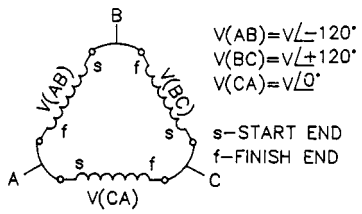

FIGURE 1.26 Delta connection.

Open-Delta Connection (Fig. 1.27)

An open-delta connection is used to deliver three-phase power if one phase of a three-phase bank of transformers fails in service. When the failed unit is removed from service, the remaining units can still supply three-phase power but at a reduced rating. An open-delta connection is also used as an economical means to deliver three-phase power using only two single-phase transformers. If P

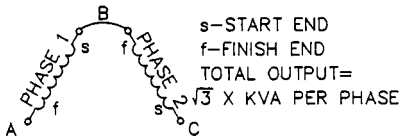

FIGURE 1.27 Open-delta connection.

is the total three-phase kVA, then each transformer of the open-delta bank must have a rating of $P/\sqrt{3}$ kVA. The disadvantage of the open-delta connection is the unequal **regulation** of the three phases of the transformer.

T Connection (Fig. 1.28)

The T connection is used for three-phase power transformation when two separate single-phase transformers with special configurations are available. If a voltage transformation from V_1 to V_2 volts is required, one of the units (main transformer) must have a voltage ratio of V_1/V_2 with the midpoint of each winding brought out. The other unit must have a ratio of $0.866V_1/0.866V_2$ with the neutral point brought out, if needed.

The Scott connection is a special type of T connection used to transform three-phase power to two-phase power for operation of electric furnaces and two-phase motors. It is shown in Fig. 1.29.

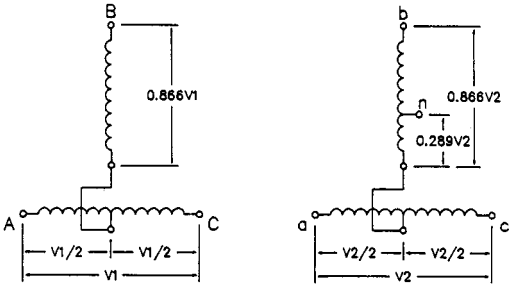

FIGURE 1.28 T connection.

Zigzag Connection (Fig. 1.30)

This connection is also called the interconnected star connection where the winding of each phase is divided into two halves and interconnected to form a zigzag configuration. The zigzag connection is mostly used to derive a neutral point for grounding purposes in three-phase, three-wire systems. The neutral point can be used to (1) supply single-phase loads, (2) provide a safety ground, and (3) sense and limit ground fault currents.

Transformer Impedance

Impedance is an inherent property in a transformer that results in a voltage drop as power is transferred from the primary to the secondary side of the power system. The impedance of a transformer consists of two parts: resistance (R) and reactance (X). The resistance component is due to the resistance of the material of the winding and the percentage value of the voltage drop due to resistance becomes less as the rating of the transformer increases. The reactive component, which is also known as leakage reactance, is the result of incomplete linkage of the magnetic field set up by the secondary winding with the turns of the primary winding, and vice versa. The net impedance of the transformer is given by $Z = \sqrt{R^2 + X^2}$. The impedance value marked on the transformer is the percentage voltage drop due to this impedance under full-load operating conditions:

$$\%\ \text{impedance}\ z = IZ\left(\frac{100}{V}\right)$$

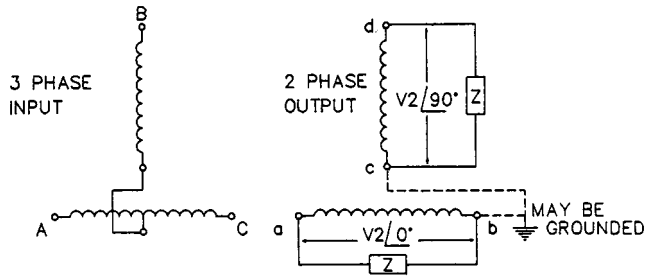

FIGURE 1.29 Three-phase–two-phase transformation.

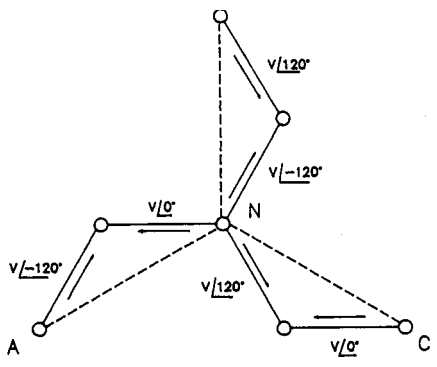

FIGURE 1.30 Zigzag connection.

where I is the full-load current of the transformer, Z is the impedance in ohms of the transformer, and V is the voltage rating of the transformer winding. It should be noted that the values of I and Z must be referred to the same side of the transformer as the voltage V.

Transformers are also major contributors of impedance to limit the fault currents in electrical power systems.

Defining Terms

Breakdown strength: Voltage gradient at which the molecules of medium break down to allow passage of damaging levels of electric current.

Dielectric: Solid, liquid, or gaseous substance that acts as an insulation to the flow of electric current.

Harmonic frequency: Integral multiples of fundamental frequency. For example, for a 60-Hz supply the harmonic frequencies are 120, 180, 240, 300, . . .

Magnetic field: Magnetic force field where lines of magnetism exist.

Magnetic flux: Term for lines of magnetism.

Regulation: The change in voltage from no-load to full-load expressed as a percentage of full-load voltage.

1.4 Electrical Fuses

Nick Angelopoulos

The fuse is a simple and reliable safety device. It is second to none in its ease of application and its ability to protect people and equipment.

The fuse is a current-sensitive device. It has a conductor with a reduced cross section (element) normally surrounded by an arc-quenching and heat-conducting material (filler). The entire unit is enclosed in a body fitted with end contacts. A basic fuse element design is illustrated in Fig. 1.32.

Ratings

Most fuses have three electrical ratings: ampere rating, voltage rating, and **interrupting rating**. The ampere rating indicates the current the fuse can carry without melting or exceeding specific temperature rise limits. The voltage rating, ac or dc, usually indicates the maximum system voltage that can be applied to the fuse. The interrupting rating (I.R.) defines the maximum short-circuit current that a fuse can safely interrupt. If a fault current higher than the interrupting rating causes the fuse to operate, the high internal pressure may cause the fuse to rupture. It is imperative, therefore, to install a fuse, or any other type of protective device, that has an interrupting rating not less than the available short-circuit current. A violent explosion may occur if the interrupting rating of any protective device is inadequate.

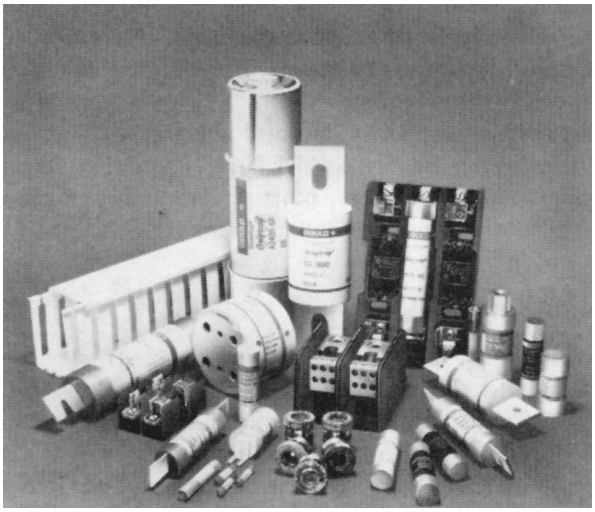

FIGURE 1.31 A variety of plug, cartridge, and blade type fuses.

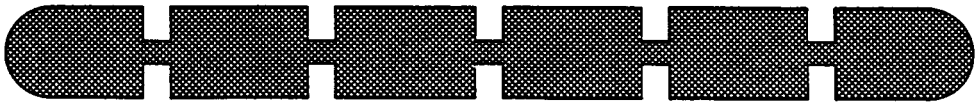

FIGURE 1.32 Basic fuse element.

A fuse must perform two functions. The first, the "passive" function, is one that tends to be taken for granted. In fact, if the fuse performs the passive function well, we tend to forget that the fuse exists at all. The passive function simply entails that the fuse can carry up to its normal load current without aging or overheating. Once the current level exceeds predetermined limits, the "active" function comes into play and the fuse operates. It is when the fuse is performing its active function that we become aware of its existence.

In most cases, the fuse will perform its active function in response to two types of circuit conditions. The first is an overload condition, for instance, when a hair dryer, teakettle, toaster, and radio are plugged into the same circuit. This overload condition will eventually cause the element to melt. The second condition is the overcurrent condition, commonly called the short circuit or the fault condition. This can produce a drastic, almost instantaneous, rise in current, causing the element to melt usually in less than a quarter of a cycle. Factors that can lead to a fault condition include rodents in the electrical system, loose connections, dirt and moisture, breakdown of insulation, foreign contaminants, and personal mistakes. Preventive maintenance and care can reduce these causes. Unfortunately, none of us are perfect and faults can occur in virtually every electrical system—we must protect against them.

Fuse Performance

Fuse performance characteristics under overload conditions are published in the form of *average melting time–current characteristic curves,* or simply *time-current curves.* Fuses are tested with a variety of currents, and the melting times are recorded. The result is a graph of time versus current coordinates that are plotted on log-log scale, as illustrated in Fig. 1.33.

Under short-circuit conditions the fuse operates and fully opens the circuit in less than 0.01 s. At 50 or 60 Hz, this represents operation within the first half cycle. The current waveform let-through by the fuse is the shaded, almost triangular, portion shown in Fig. 1.34(a). This depicts a fraction of the current that would have been let through into the circuit had a fuse not been installed.

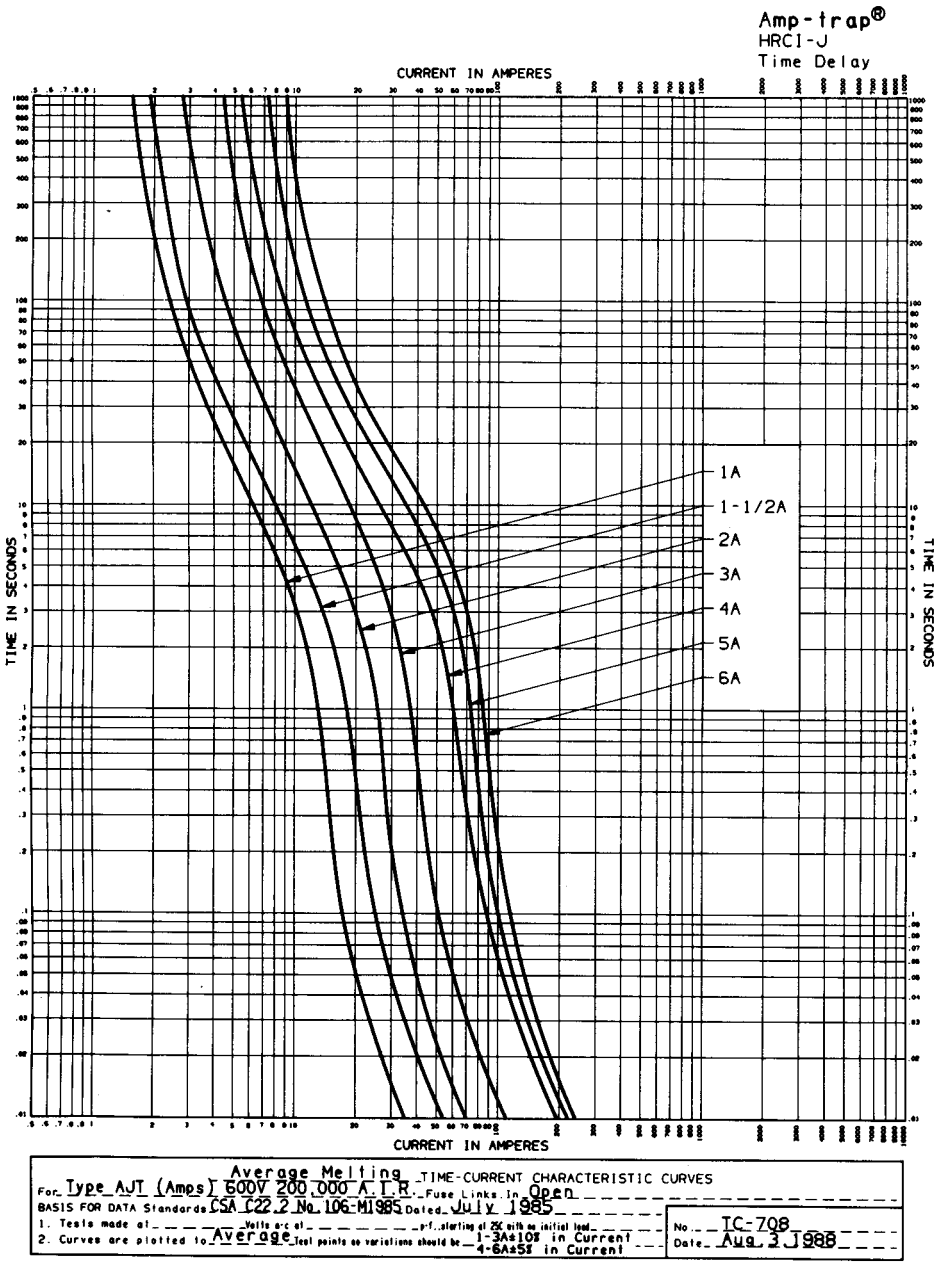

FIGURE 1.33 Time-current characteristic curves.

Fuse short-circuit performance characteristics are published in the form of peak let-through (I_p) graphs and I^2t graphs. I_p (peak current) is simply the peak of the shaded triangular waveform, which increases as the fault current increases, as shown in Fig. 1.34(b). The electromagnetic forces, which can cause mechanical damage to equipment, are proportional to I_p^2.

I^2t represents heat energy measured in units of A^2 s (ampere squared seconds) and is documented on I^2t graphs. These I^2t graphs, as illustrated in Fig. 1.34(c), provide three values of I^2t: minimum melting I^2t, arcing I^2t, and total clearing I^2t. I^2t and I_p short-circuit performance characteristics can be used to coordinate fuses and other equipment. In particular, I^2t values are often used to selectively coordinate fuses in a distribution system.

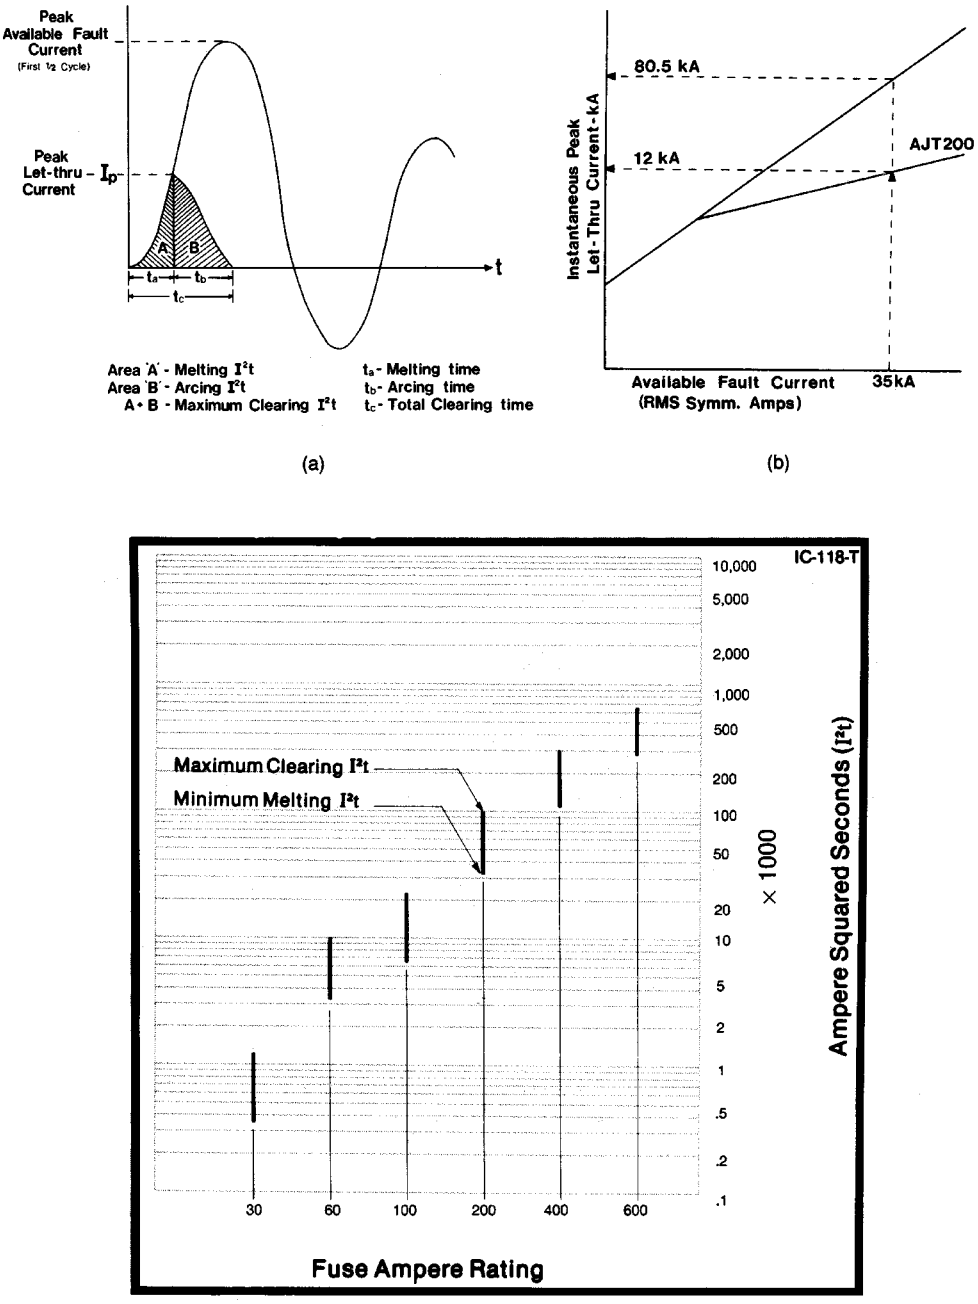

FIGURE 1.34 (a) Fuse short-circuit operation. (b) Variation of fuse peak let-through current I_p. (c) I^2t graph.

Selective Coordination

In any power distribution system, selective coordination exists when the fuse immediately upstream from a fault operates, leaving all other fuses further upstream unaffected. This increases system reliability by isolating the faulted branch while maintaining power to all other branches. Selective coordination is easily assessed by

comparing the I^2t characteristics for feeder and branch circuit fuses. The branch fuse should have a total clearing I^2t value that is less than the melting I^2t value of the feeder or upstream fuse. This ensures that the branch fuse will melt, arc, and clear the fault before the feeder fuse begins to melt.

Standards

Overload and short-circuit characteristics are well documented by fuse manufacturers. These characteristics are standardized by product standards written in most cases by safety organizations such as CSA (Canadian Standards Association) and UL (Underwriters Laboratories). CSA standards and UL specify product designations, dimensions, performance characteristics, and temperature rise limits. These standards are used in conjunction with national code regulations such as CEC (Canadian Electrical Code) and NEC (National Electrical Code) that specify how the product is applied.

IEC (International Electrotechnical Commission—Geneva, Switzerland) was founded to harmonize electrical standards to increase international trade in electrical products. Any country can become a member and participate in the standards-writing activities of IEC. Unlike CSA and UL, IEC is not a certifying body that certifies or approves products. IEC publishes consensus standards for national standards authorities such as CSA (Canada), UL (USA), BSI (UK) and DIN (Germany) to adopt as their own national standards.

Products

North American low-voltage distribution fuses can be classified under two types: Standard or Class H, as referred to in the United States, and **HRC (high rupturing capacity)** or current-limiting fuses, as referred to in Canada. It is the interrupting rating that essentially differentiates one type from the other.

Most Standard or Class H fuses have an interrupting rating of 10,000 A. They are not classified as HRC or current-limiting fuses, which usually have an interrupting rating of 200,000 A. Selection is often based on the calculated available short-circuit current.

In general, short-circuit currents in excess of 10,000 A do not exist in residential applications. In commercial and industrial installations, short-circuit currents in excess of 10,000 A are very common. Use of HRC fuses usually means that a fault current assessment is not required.

Standard—Class H

In North America, Standard or Class H fuses are available in 250- and 600-V ratings with ampere ratings up to 600 A. There are primarily three types: one-time, time-delay, and renewable. Rating for rating, they are all constructed to the same dimensions and are physically interchangeable in standard-type fusible switches and fuse blocks.

One-time fuses are not reusable once blown. They are used for general-purpose resistive loads such as lighting, feeders, and cables.

Time-delay fuses have a specified delay in their overload characteristics and are designed for motor circuits. When started, motors typically draw six times their full load current for approximately 3 to 4 seconds. This surge then decreases to a level within the motor full-load current rating. Time-delay fuse overload characteristics are designed to allow for motor starting conditions.

Renewable fuses are constructed with replaceable links or elements. This feature minimizes the cost of replacing fuses. However, the concept of replacing fuse elements in the field is not acceptable to most users today because of the potential risk of improper replacement.

HRC

HRC or current-limiting fuses have an interrupting rating of 200 kA and are recognized by a letter designation system common to North American fuses. In the United States they are known as Class J, Class L, Class R, etc., and in Canada they are known as HRCI-J, HRC-L, HRCI-R, and so forth. HRC fuses are available in ratings up to 600 V and 6000 A. The main differences among the various types are their dimensions and their short-circuit performance (I_p and I^2t) characteristics.

One type of HRC fuse found in Canada, but not in the United States, is the HRCII-C or Class C fuse. This fuse was developed originally in England and is constructed with bolt-on-type blade contacts. It is available in a voltage rating of 600 V with ampere ratings from 2 to 600 A. Some higher ampere ratings are also available but are not as common. HRCII-C fuses are primarily regarded as providing short-circuit protection only. Therefore, they should be used in conjunction with an overload device.

HRCI-R or Class R fuses were developed in the United States. Originally constructed to Standard or Class H fuse dimensions, they were classified as Class K and are available in the United States with two levels of short-circuit performance characteristics: Class K1 and Class K5. However, they are not recognized in Canadian Standards. Under fault conditions, Class K1 fuses limit the I_p and I^2t to lower levels than do Class K5 fuses. Since both Class K1 and K5 are constructed to Standard or Class H fuse dimensions, problems with interchangeability occur. As a result, a second generation of these K fuses was therefore introduced with a rejection feature incorporated in the end caps and blade contacts. This rejection feature, when used in conjunction with rejection-style fuse clips, prevents replacement of these fuses with Standard or Class H 10-kA I.R. fuses. These rejection style fuses are known as Class RK1 and Class RK5. They are available with time-delay or non-time-delay characteristics and with voltage ratings of 250 or 600 V and ampere ratings up to 600 A. In Canada, CSA has only one classification for these fuses, HRCI-R, which have the same maximum I_p and I^2t current-limiting levels as specified by UL for Class RK5 fuses.

HRCI-J or Class J fuses are a more recent development. In Canada, they have become the most popular HRC fuse specified for new installations. Both time-delay and non-time-delay characteristics are available in ratings of 600 V with ampere ratings up to 600 A. They are constructed with dimensions much smaller than HRCI-R or Class R fuses and have end caps or blade contacts which fit into 600-V Standard or Class H-type fuse clips.

However, the fuse clips must be mounted closer together to accommodate the shorter fuse length. Its shorter length, therefore, becomes an inherent rejection feature that does not allow insertion of Standard or HRCI-R fuses. The blade contacts are also drilled to allow bolt-on mounting if required. CSA and UL specify these fuses to have maximum short-circuit current-limiting I_p and I^2t limits lower than those specified for HRCI-R and HRCII-C fuses. HRCI-J fuses may be used for a wide variety of applications. The time-delay type is commonly used in motor circuits sized at approximately 125 to 150% of motor full-load current.

HRC-L or Class L fuses are unique in dimension but may be considered as an extension of the HRCI-J fuses for ampere ratings above 600 A. They are rated at 600 V with ampere ratings from 601 to 6000 A. They are physically larger and are constructed with bolt-on-type blade contacts. These fuses are generally used in low-voltage distribution systems where supply transformers are capable of delivering more than 600 A.

In addition to Standard and HRC fuses, there are many other types designed for specific applications. For example, there are medium- or high-voltage fuses to protect power distribution transformers and medium-voltage motors. There are fuses used to protect sensitive semiconductor devices such as diodes, SCRs, and triacs. These fuses are designed to be extremely fast under short-circuit conditions. There is also a wide variety of dedicated fuses designed for protection of specific equipment requirements such as electric welders, capacitors, and circuit breakers, to name a few.

Trends

Ultimately, it is the electrical equipment being protected that dictates the type of fuse needed for proper protection. This equipment is forever changing and tends to get smaller as new technology becomes available. Present trends indicate that fuses also must become smaller and faster under fault conditions, particularly as available short-circuit fault currents are tending to increase.

With free trade and the globalization of industry, a greater need for harmonizing product standards exists. The North American fuse industry is taking big steps toward harmonizing CSA and UL fuse standards, and at the same time is participating in the IEC standards process. Standardization will help the electrical industry to identify and select the best fuse for the job—anywhere in the world.

Defining Terms

HRC (high rupturing capacity): A term used to denote fuses having a high interrupting rating. Most low-voltage HRC-type fuses have an interrupting rating of 200 kA rms symmetrical.

***I*²*t* (ampere squared seconds):** A convenient way of indicating the heating effect or thermal energy which is produced during a fault condition before the circuit protective device has opened the circuit. As a protective device, the HRC or current-limiting fuse lets through far less damaging I^2t than other protective devices.

Interrupting rating (I.R.): The maximum value of short-circuit current that a fuse can safely interrupt.

2.1 Step, Impulse, Ramp, Sinusoidal, Exponential, and DC Signals

Richard C. Dorf and Zhen Wan

The important signals for circuits include the step, impulse, ramp, sinusoid, and dc signals. These signals are widely used and are described here in the time domain. All of these signals have a Laplace transform.

Step Function

The **unit-step** function $u(t)$ is defined mathematically by

$$u(t) = \begin{cases} 1, & t \geq 0 \\ 0, & t < 0 \end{cases}$$

Here *unit step* means that the amplitude of $u(t)$ is equal to 1 for $t \geq 0$. Note that we are following the convention that $u(0) = 1$. From a strict mathematical standpoint, $u(t)$ is not defined at $t = 0$. Nevertheless, we usually take $u(0) = 1$. If A is an arbitrary nonzero number, $Au(t)$ is the step function with amplitude A for $t \geq 0$. The unit step function is plotted in Fig. 2.1.

The Impulse

The **unit impulse** $\delta(t)$, also called the *delta function* or the *Dirac distribution*, is defined by

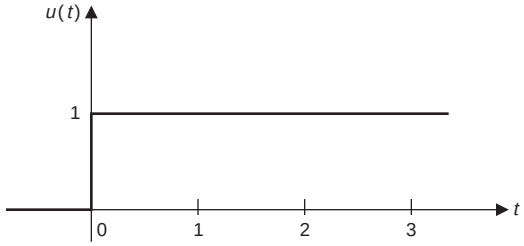

FIGURE 2.1 Unit-step function.

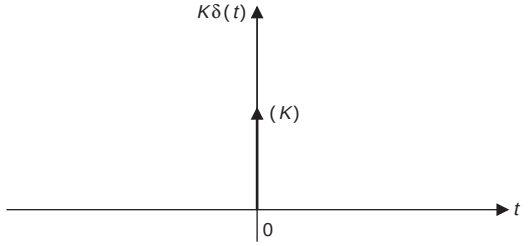

FIGURE 2.2 Graphical representation of the impulse $K\delta(t)$

$$\delta(t) = 0, \qquad t \neq 0$$
$$\int_{-\varepsilon}^{\varepsilon} \delta(\lambda)\, d\lambda = 1, \qquad \text{for any real number } \varepsilon > 0$$

The first condition states that $\delta(t)$ is zero for all nonzero values of t, while the second condition states that the area under the impulse is 1, so $\delta(t)$ has unit area. It is important to point out that the value $\delta(0)$ of $\delta(t)$ at $t = 0$ is not defined; in particular, $\delta(0)$ is not equal to infinity. For any real number K, $K\delta(t)$ is the impulse with area K. It is defined by

$$K\delta(t) = 0, \qquad t \neq 0$$
$$\int_{-\varepsilon}^{\varepsilon} K\delta(\lambda)\, d\lambda = K, \qquad \text{for any real number } \varepsilon > 0$$

The graphical representation of $K\delta(t)$ is shown in Fig. 2.2. The notation K in the figure refers to the area of the impulse $K\delta(t)$.

The unit-step function $u(t)$ is equal to the integral of the unit impulse $\delta(t)$; more precisely, we have

$$u(t) = \int_{-\infty}^{t} \delta(\lambda)\, d\lambda, \qquad \text{all } t \text{ except } t = 0$$

Conversely, the first derivative of $u(t)$, with respect to t, is equal to $\delta(t)$, except at $t = 0$, where the derivative of $u(t)$ is not defined.

Ramp Function

The *unit-ramp function* $r(t)$ is defined mathematically by

$$r(t) = \begin{cases} t, & t \geq 0 \\ 0, & t < 0 \end{cases}$$

Note that for $t \geq 0$, the slope of $r(t)$ is 1. Thus, $r(t)$ has *unit slope,* which is the reason $r(t)$ is called the unit-ramp function. If K is an arbitrary nonzero scalar (real number), the ramp function $Kr(t)$ has slope K for $t \geq 0$. The unit-ramp function is plotted in Fig. 2.3.

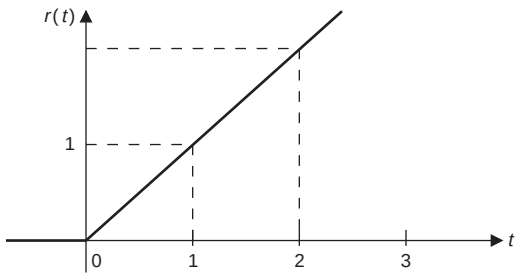

FIGURE 2.3 Unit-ramp function

The unit-ramp function $r(t)$ is equal to the integral of the unit-step function $u(t)$; that is,

$$r(t) = \int_{-\infty}^{t} u(\lambda)\, d\lambda$$

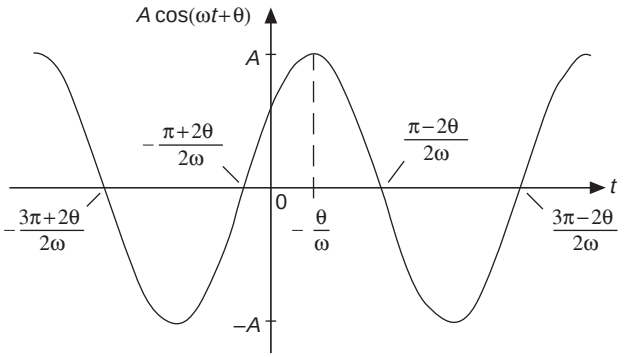

FIGURE 2.4 The sinusoid $A\cos(\omega t + \theta)$ with $-\pi/2 < \theta < 0$.

Conversely, the first derivative of $r(t)$ with respect to t is equal to $u(t)$, except at $t = 0$, where the derivative of $r(t)$ is not defined.

Sinusoidal Function

The sinusoid is a continuous-time signal: $A\cos(\omega t + \theta)$.

Here A is the amplitude, ω is the frequency in radians per second (rad/s), and θ is the phase in radians. The frequency f in cycles per second, or hertz (Hz), is $f = \omega/2\pi$. The sinusoid is a periodic signal with period $2\pi/\omega$. The sinusoid is plotted in Fig. 2.4.

Decaying Exponential

In general, an exponentially decaying quantity (Fig. 2.5) can be expressed as

$$a = A\,e^{-t/\tau}$$

where a = instantaneous value
A = amplitude or maximum value
e = base of natural logarithms = 2.718 …
τ = time constant in seconds
t = time in seconds

The current of a discharging capacitor can be approximated by a decaying exponential function of time.

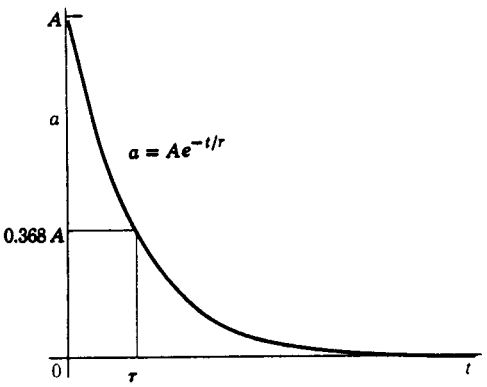

FIGURE 2.5 The decaying exponential.

Time Constant

Since the exponential factor only *approaches* zero as t increases without limit, such functions theoretically last forever. In the same sense, all radioactive disintegrations last forever. In the case of an exponentially decaying current, it is convenient to use the value of time that makes the exponent –1. When $t = \tau$ = the *time constant,* the value of the exponential factor is

$$e^{-t/\tau} = e^{-1} = \frac{1}{e} = \frac{1}{2.718} = 0.368$$

In other words, after a time equal to the time constant, the exponential factor is reduced to approximatly 37% of its initial value.

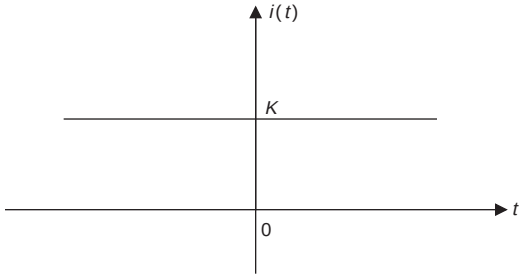

FIGURE 2.6 The dc signal with amplitude K.

DC Signal

The direct current signal (dc signal) can be defined mathematically by

$$i(t) = K \qquad -\infty < t < +\infty$$

Here, K is any nonzero number. The dc signal remains a constant value of K for any $-\infty < t < \infty$. The dc signal is plotted in Fig. 2.6.

Defining Terms

Ramp: A continually growing signal such that its value is zero for $t \leq 0$ and proportional to time t for $t > 0$.
Sinusoid: A periodic signal $x(t) = A\cos(\omega t + \theta)$ where $\omega = 2\pi f$ with frequency in hertz.
Unit impulse: A very short pulse such that its value is zero for $t \neq 0$ and the integral of the pulse is 1.
Unit step: Function of time that is zero for $t < t_0$ and unity for $t > t_0$. At $t = t_0$ the magnitude changes from zero to one. The unit step is dimensionless.

2.2 Ideal and Practical Sources

Clayton R. Paul

A *mathematical model* of an electric circuit contains *ideal models* of physical circuit elements. Some of these ideal circuit elements (e.g., the resistor, capacitor, inductor, and transformer) were discussed previously. Here we will define and examine both *ideal* and *practical voltage and current sources.* The terminal characteristics of these models will be compared to those of actual sources.

All-Plastic Battery

Researchers at the U.S. Air Force's Rome Laboratory and Johns Hopkins University have developed an all-plastic battery using polymers instead of conventional electrode materials. All-plastic power cells could be a safer, more flexible substitute for use in electronic devices and other commercial applications. In addition, all-polymer cells reduce toxic waste disposal, negate environmental concerns, and can meet EPA and FAA requirements.

Applications include powering GPS receivers, communication transceivers, remote sensors, backup power systems, cellular phones, pagers, computing products and other portable equipment. Potential larger applications include remote monitoring stations, highway communication signs and electric vehicles.

The Johns Hopkins scientists are among the first to create a potentially practical battery in which both of the electrodes and the electrolyte are made of polymers. Fluoro-substituted thiophenes polymers have been developed with potential differences of up to 2.9 volts, and with potential specific energy densities of 30 to 75 watt hours/kg.

All plastic batteries can be recharged hundreds of times and operate under extreme hot and cold temperature conditions without serious performance degradation. The finished cell can be as thin as a business card and malleable, allowing battery manufacturers to cut a cell to a specific space or make the battery the actual case of the device to be powered. (Reprinted with permission from *NASA Tech Briefs,* 20(10), 26, 1996.)

Ideal Sources

The *ideal independent voltage source* shown in Fig. 2.7 constrains the terminal voltage across the element to a prescribed function of time, $v_s(t)$, as $v(t) = v_s(t)$. The polarity of the source is denoted by ± signs within the circle which denotes this as an ideal *independent* source. Controlled or *dependent* ideal voltage sources will be discussed in Section 2.3. The current through the element will be determined by the circuit that is attached to the terminals of this source.

The *ideal independent current source* in Fig. 2.8 constrains the terminal current through the element to a prescribed function of time, $i_s(t)$, as $i(t) = i_s(t)$. The polarity of the source is denoted by an arrow within the

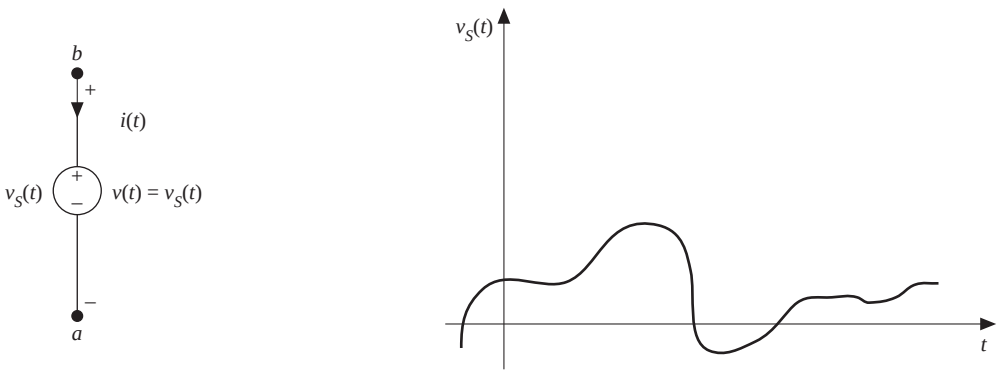

FIGURE 2.7 Ideal independent voltage source.

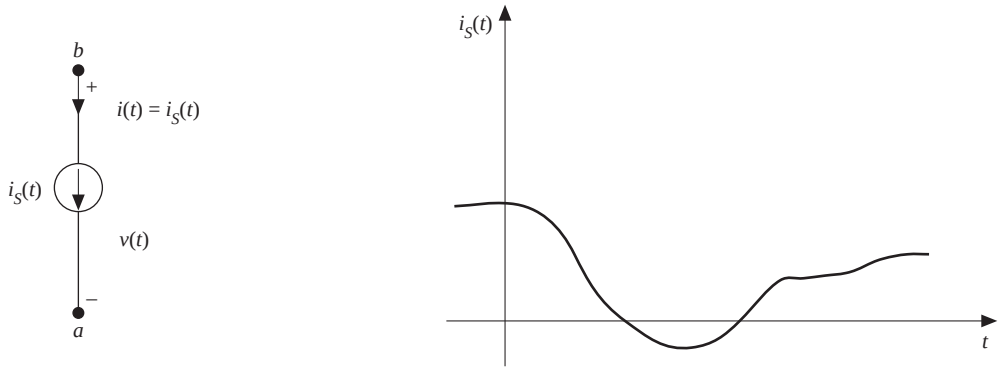

FIGURE 2.8 Ideal independent current source.

circle which also denotes this as an ideal *independent* source. The voltage across the element will be determined by the circuit that is attached to the terminals of this source.

Numerous functional forms are useful in describing the source variation with time. These were discussed in Section 2.1—the step, impulse, ramp, sinusoidal, and dc functions. For example, an ideal independent dc voltage source is described by $v_S(t) = V_S$, where V_S is a constant. An ideal independent sinusoidal current source is described by $i_S(t) = I_S\sin(\omega t + \phi)$ or $i_S(t) = I_S\cos(\omega t + \phi)$, where I_S is a constant, $\omega = 2\pi f$ with f the *frequency* in hertz and ϕ is a phase angle. Ideal sources may be used to model actual sources such as temperature transducers, phonograph cartridges, and electric power generators. Thus usually the time form of the output cannot generally be described with a simple, basic function such as dc, sinusoidal, ramp, step, or impulse waveforms. We often, however, represent the more complicated waveforms as a linear combination of more basic functions.

Practical Sources

The preceding ideal independent sources constrain the terminal voltage or current to a *known* function of time *independent of the circuit that may be placed across its terminals.* Practical sources, such as batteries, have their terminal voltage (current) dependent upon the terminal current (voltage) caused by the circuit attached to the source terminals. A simple example of this is an automobile storage battery. The battery's terminal voltage is approximately 12 V when no load is connected across its terminals. When the battery is applied across the terminals of the starter by activating the ignition switch, a large current is drawn from its terminals. During starting, its terminal voltage drops as illustrated in Fig. 2.9(a). How shall we construct a *circuit model* using the ideal elements discussed thus far to model this nonideal behavior? A model is shown in Fig. 2.9(b) and consists of the *series* connection of an ideal resistor, R_S, and an ideal independent voltage source, $V_S = 12$ V. To determine the terminal voltage–current relation, we sum Kirchhoff's voltage law around the loop to give

$$v = V_S - R_S i \tag{2.1}$$

This equation is plotted in Fig. 2.9(b) and approximates that of the actual battery. The equation gives a straight line with slope $-R_S$ that intersects the v axis ($i = 0$) at $v = V_S$. The resistance R_S is said to be the *internal resistance* of this nonideal source model. It is a fictitious resistance but the model nevertheless gives an equivalent *terminal behavior.*

Although we have derived an approximate model of an actual source, another equivalent form may be obtained. This alternative form is shown in Fig. 2.9(c) and consists of the *parallel* combination of an ideal independent current source, $I_S = V_S/R_S$, and the same resistance, R_S, used in the previous model. Although it may seem strange to model an automobile battery using a current source, the model is completely equivalent to the series voltage source–resistor model of Fig. 2.9(b) *at the output terminals a–b.* This is shown by writing Kirchhoff's current law at the upper node to give

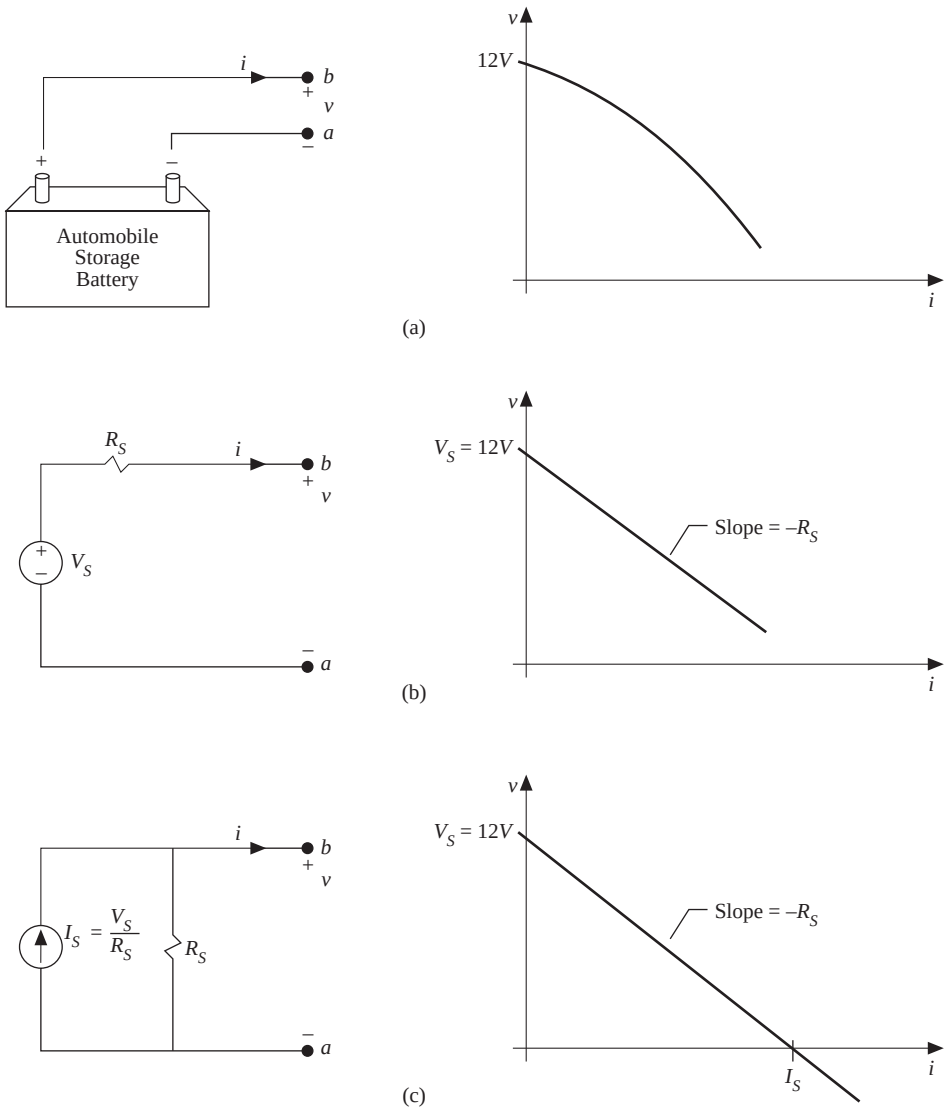

FIGURE 2.9 Practical sources. (a) Terminal *v-i* characteristic; (b) approximation by a voltage source; (c) approximation by a current source.

$$i = I_S - \frac{1}{R_S} v \tag{2.2}$$

Rewriting this equation gives

$$v = R_S I_S - R_S i \tag{2.3}$$

Comparing Eq. (2.3) to Eq. (2.1) shows that

$$V_S = R_S I_S \tag{2.4}$$

Therefore, we can convert from one form (voltage source in series with a resistor) to another form (current source in parallel with a resistor) very simply.

An ideal voltage source is represented by the model of Fig. 2.9(b) with $R_S = 0$. An actual battery therefore provides a close approximation of an ideal voltage source since the source resistance R_S is usually quite small. An ideal current source is represented by the model of Fig. 2.9(c) with $R_S = \infty$. This is very closely represented by the bipolar junction transistor (BJT).

1.1 Resistors

Defining Term

Ideal source: An ideal model of an actual source that assumes that the parameters of the source, such as its magnitude, are independent of other circuit variables.

Reference

C.R. Paul, *Analysis of Linear Circuits,* New York: McGraw-Hill, 1989.

2.3 Controlled Sources

J. R. Cogdell

When the analysis of electronic (nonreciprocal) circuits became important in circuit theory, controlled sources were added to the family of circuit elements. Table 2.1 shows the four types of controlled sources. In this section, we will address the questions: What are controlled sources? Why are controlled sources important? How do controlled sources affect methods of circuit analysis?

What Are Controlled Sources?

By *source* we mean a voltage or current source in the usual sense. By *controlled* we mean that the strength of such a source is controlled by some circuit variable(s) elsewhere in the circuit. Figure 2.10 illustrates a simple circuit containing an (independent) current source, i_s, two resistors, and a controlled voltage source, whose magnitude is controlled by the current i_1. Thus, i_1 determines two voltages in the circuit, the voltage across R_1 via Ohm's law and the controlled voltage source via some unspecified effect.

A controlled source may be controlled by more than one circuit variable, but we will discuss those having a single controlling variable since multiple controlling variables require no new ideas. Similarly, we will deal only with resistive elements, since inductors and capacitors introduce no new concepts. The controlled voltage or current source may depend on the controlling variable in a linear or nonlinear manner. When the relationship is nonlinear, however, the equations are frequently linearized to examine the effects of small variations about some dc values. When we linearize, we will use the customary notation of small letters to represent general and time-variable voltages and currents and large letters to represent constants such as the dc value or the peak value of a sinusoid. On subscripts, large letters represent the total voltage or current and small letters represent the **small-signal** component. Thus, the equation $i_B = I_B + I_b \cos \omega t$ means that the total base current is the sum of a constant and a small-signal component, which is sinusoidal with an amplitude of I_b.

To introduce the context and use of controlled sources we will consider a circuit model for the bipolar junction transistor (BJT). In Fig. 2.11 we show the standard symbol for an *npn* BJT with base (B), emitter (E), and collector (C) identified, and voltage and current variables defined. We have shown the common emitter configuration, with the emitter terminal shared to make input and output terminals. The base current, i_B, ideally depends upon the base-emitter voltage, v_{BE}, by the relationship

TABLE 2.1 Names, Circuit Symbols, and Definitions for the Four Possible Types of Controlled Sources

Name	Circuit Symbol	Definition and Units
Current-controlled voltage source (CCVS)		$v_2 = r_m i_1$ r_m = transresistance units, ohms
Current-controlled current source (CCCS)		$i_2 = \beta i_1$ β, current gain, dimensionless
Voltage-controlled voltage source (VCVS)		$v_2 = \mu v_1$ μ, voltage gain, dimensionless
Voltage-controlled current source (VCCS)		$i_2 = g_m v_1$ g_m, transconductance units, Siemans (mhos)

$$i_B = I_0\left\{\exp\left[\frac{v_{BE}}{V_T}\right] - 1\right\} \tag{2.5}$$

where I_0 and V_T are constants. We note that the base current depends on the base-emitter voltage only, but in a nonlinear manner. We can represent this current by a voltage-controlled current source, but the more common representation would be that of a nonlinear conductance, $G_{BE}(v_{BE})$, where

$$G_{BE}(v_{BE}) = \frac{i_B}{v_{BE}}$$

Let us model the effects of small changes in the base current. If the changes are small, the nonlinear nature of the conductance can be ignored and the circuit model becomes a linear conductance (or resistor). Mathematically this conductance arises from a first-order expansion of the nonlinear function. Thus, if $v_{BE} = V_{BE} + v_{be}$, where v_{BE} is the total base-emitter voltage, V_{BE} is a (large) constant voltage and v_{be} is a (small) variation in the base-emitter voltage, then the first two terms in a Taylor series expansion are

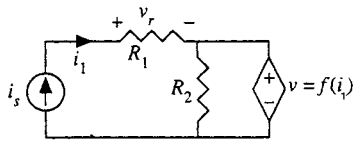

FIGURE 2.10 A simple circuit containing a controlled source.

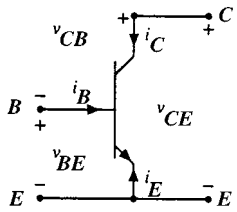

FIGURE 2.11 An *npn* BJT in the common emitter configuration.

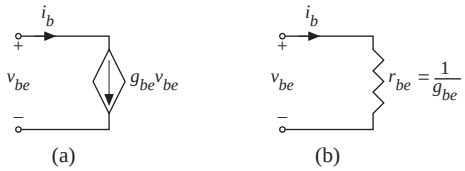

FIGURE 2.12 Equivalent circuits for the base circuit: (a) uses a controlled source and (b) uses a resistor.

$$i_B = I_0\left\{\exp\left[\frac{V_{BE} + v_{be}}{V_T}\right] - 1\right\} \cong I_0\left\{\exp\left[\frac{V_{BE}}{V_T}\right] - 1\right\} + \frac{I_0}{V_T}\exp\left[\frac{V_{BE}}{V_T}\right]v_{be} \tag{2.6}$$

We note that the base current is approximated by the sum of a constant term and a term that is first order in the small variation in base-emitter voltage, v_{be}. The multiplier of this small voltage is the linearized conductance, g_{be}. If we were interested only in small changes in currents and voltages, only this conductance would be required in the model. Thus, the input (base-emitter) circuit can be represented for the small-signal base variables, i_b and v_{be}, by either equivalent circuit in Fig. 2.12.

The voltage-controlled current source, $g_{be}v_{be}$, can be replaced by a simple resistor because the small-signal voltage and current associate with the same branch. The process of **linearization** is important to the modeling of the collector-emitter characteristic, to which we now turn.

The collector current, i_C, can be represented by one of the Eber and Moll equations

$$i_C = \beta I_0\left\{\exp\left[\frac{v_{BE}}{V_T}\right] - 1\right\} - I_0'\left\{\exp\left[\frac{v_{BC}}{V_T}\right] - 1\right\} \tag{2.7}$$

where β and I_0' are constants. If we restrict our model to the amplifying region of the transistor, the second term is negligible and we may express the collector current as

$$i_C = \beta I_0\left\{\exp\left[\frac{v_{BE}}{V_T}\right] - 1\right\} = \beta i_B \tag{2.8}$$

Thus, for the ideal transistor, the collector-emitter circuit may be modeled by a current-controlled current source, which may be combined with the results expressed in Eq. (2.5) to give the model shown in Fig. 2.13.

Using the technique of small-signal analysis, we may derive either of the small-signal equivalent circuits shown in Fig. 2.14.

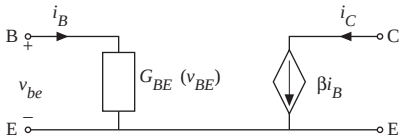

FIGURE 2.13 Equivalent circuit for BJT.

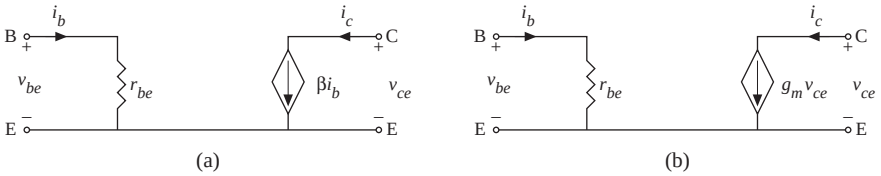

FIGURE 2.14 Two BJT small-signal equivalent circuits ($g_m = \beta/r_{be}$): (a) uses a CCCS and (b) uses a VCCS.

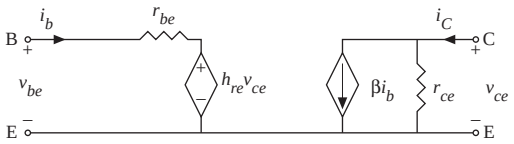

FIGURE 2.15 Full hybrid parameter model for small-signal BJT.

The small-signal characteristics of the *npn* transistor in its amplifying region is better represented by the equivalent circuit shown in Fig. 2.15. Note we have introduced a voltage-controlled voltage source to model the influence of the (output) collector-emitter voltage on the (input) base-emitter voltage, and we have placed a resistor, r_{ce}, in parallel with the collector current source to model the influence of the collector-emitter voltage on the collector current.

The four parameters in Fig. 2.15 (r_{be}, h_{re}, β, and r_{ce}) are the hybrid parameters describing the transistor properties, although our notation differs from that commonly used. The parameters in the small-signal equivalent circuit depend on the operating point of the device, which is set by the time-average voltages and currents (V_{BE}, I_C, etc.) applied to the device. All of the parameters are readily measured for a given transistor and operating point, and manufacturers commonly specify ranges for the various parameters for a type of transistor.

What Is the Significance of Controlled Sources?

Commonplace wisdom in engineering education and practice is that information and techniques that are presented visually are more useful than abstract, mathematical forms. Equivalent circuits are universally used in describing electrical engineering systems and devices because circuits portray interactions in a universal, pictorial language. This is true generally, and it is doubly necessary when circuit variables interact through the mysterious coupling modeled by controlled sources. This is the primary significance of controlled sources: that they represent unusual couplings of circuit variables in the universal, visual language of circuits.

A second significance is illustrated by our equivalent circuit of the *npn* bipolar transistor, namely, the characterization of a class of similar devices. For example, the parameter β in Eq. (2.8) gives important information about a single transistor, and similarly for the range of β for a type of transistor. In this connection, controlled sources lead to a vocabulary for discussing some property of a class of systems or devices, in this case the current gain of an *npn* BJT.

How Does the Presence of Controlled Sources Affect Circuit Analysis?

The presence of nonreciprocal elements, which are modeled by controlled sources, affects the analysis of the circuit. Simple circuits may be analyzed through the direct application of Kirchhoff's laws to branch circuit variables. Controlled sources enter this process similar to the constitutive relations defining *R*, *L*, and *C*, i.e., in defining relationships between branch circuit variables. Thus, controlled sources add no complexity to this basic technique.

The presence of controlled sources negates the advantages of the method that uses series and parallel combinations of resistors for voltage and current dividers. The problem is that the couplings between circuit variables that are expressed by controlled sources make all the familiar formulas unreliable.

When superposition is used, the controlled sources are left on in all cases as independent sources are turned on and off, thus reflecting the kinship of controlled sources to the circuit elements. In principle, little complexity is added; in practice, the repeated solutions required by superposition entail much additional work when controlled sources are involved.

The classical methods of nodal and loop (mesh) analysis incorporate controlled sources without great difficulty. For purposes of determining the number of independent variables required, that is, in establishing the topology of the circuit, the controlled sources are treated as ordinary voltage or current sources. The equations are then written according to the usual procedures. Before the equations are solved, however, the controlling variables must be expressed in terms of the unknowns of the problem. For example, let us say we

are performing a nodal analysis on a circuit containing a current-controlled current source. For purposes of counting independent nodes, the controlled current source is treated as an open circuit. After equations are written for the unknown node voltages, the current source will introduce into at least one equation its controlling current, which is not one of the nodal variables. The additional step required by the controlled source is that of expressing the controlling current in terms of the nodal variables.

The parameters introduced into the circuit equations by the controlled sources end up on the left side of the equations with the resistors rather than on the right side with the independent sources. Furthermore, the symmetries that normally exist among the coefficients are disturbed by the presence of controlled sources.

The methods of Thévenin and Norton equivalent circuits continue to be very powerful with controlled sources in the circuits, but some complications arise. The controlled sources must be left on for calculation of the Thévenin (open-circuit) voltage or Norton (short-circuit) current and also for the calculation of the output impedance of the circuit. This usually eliminates the method of combining elements in series or parallel to determine the output impedance of the circuit, and one must either determine the output impedance from the ratio of the Thévenin voltage to the Norton current or else excite the circuit with an external source and calculate the response.

Defining Terms

Controlled source (dependent source): A voltage or current source whose intensity is controlled by a circuit voltage or current elsewhere in the circuit.

Linearization: Approximating nonlinear relationships by linear relationships derived from the first-order terms in a power series expansion of the nonlinear relationships. Normally the linearized equations are useful for a limited range of the voltage and current variables.

Small-signal: Small-signal variables are those first-order variables used in a linearized circuit. A small-signal equivalent circuit is a linearized circuit picturing the relationships between the small-signal voltages and currents in a linearized circuit.

3.1 Voltage and Current Laws

Michael D. Ciletti

Analysis of linear circuits rests on two fundamental physical laws that describe how the voltages and currents in a circuit must behave. This behavior results from whatever voltage sources, current sources, and energy storage elements are connected to the circuit. A voltage source imposes a constraint on the evolution of the voltage between a pair of nodes; a current source imposes a constraint on the evolution of the current in a branch of the circuit. The energy storage elements (capacitors and inductors) impose initial conditions on currents and voltages in the circuit; they also establish a dynamic relationship between the voltage and the current at their terminals.

Regardless of how a linear circuit is stimulated, every node voltage and every branch current, at every instant of time, must be consistent with Kirchhoff's voltage and current laws. These two laws govern even the most complex linear circuits. (They also apply to a broad category of nonlinear circuits that are modeled by point models of voltage and current.)

A circuit can be considered to have a topological (or graph) view, consisting of a labeled set of nodes and a labeled set of edges. Each edge is associated with a pair of nodes. A node is drawn as a *dot* and represents a

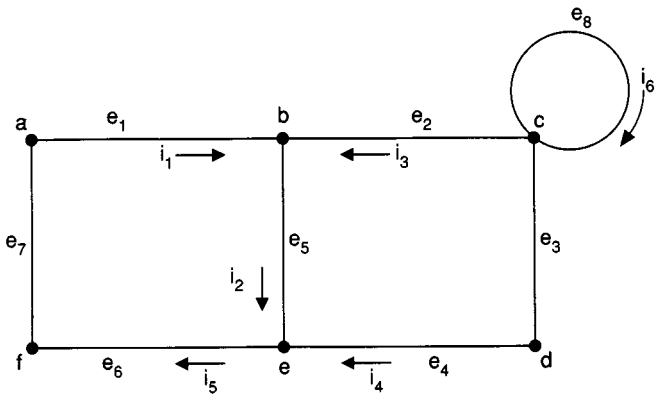

FIGURE 3.1 Graph representation of a linear circuit.

connection between two or more physical components; an edge is drawn as a *line* and represents a path, or branch, for current flow through a component (see Fig. 3.1).

The edges, or branches, of the graph are assigned current labels, $i_1, i_2, \ldots, i_m$. Each current has a designated direction, usually denoted by an *arrow* symbol. If the arrow is drawn toward a node, the associated current is said to be *entering* the node; if the arrow is drawn away from the node, the current is said to be *leaving* the node. The current i_1 is entering node b in Fig. 3.1; the current i_5 is leaving node e.

Given a branch, the pair of nodes to which the branch is attached defines the convention for measuring voltages in the circuit. Given the ordered pair of nodes (a, b), a voltage measurement is formed as follows:

$$v_{ab} = v_a - v_b$$

where v_a and v_b are the absolute electrical potentials (voltages) at the respective nodes, taken relative to some reference node. Typically, one node of the circuit is labeled as *ground,* or reference node; the remaining nodes are assigned voltage labels. The measured quantity, v_{ab}, is called the *voltage drop* from node a to node b. We note that

$$v_{ab} = -v_{ba}$$

and that

$$v_{ba} = v_b - v_a$$

is called the *voltage rise* from a to b. Each node voltage implicitly defines the voltage drop between the respective node and the ground node.

The pair of nodes to which an edge is attached may be written as (a,b) or (b,a). Given an ordered pair of nodes (a, b), a *path from a to b* is a directed sequence of edges in which the first edge in the sequence contains node label a, the last edge in the sequence contains node label b, and the node indices of any two adjacent members of the sequence have at least one node label in common. In Fig. 3.1, the edge sequence $\{e_1, e_2, e_4\}$ is not a path, because e_2 and e_4 do not share a common node label. The sequence $\{e_1, e_2\}$ is a path from node a to node c.

A path is said to be *closed* if the first node index of its first edge is identical to the second node index of its last edge. The following edge sequence forms a closed path in the graph given in Fig. 3.1: $\{e_1, e_2, e_3, e_4, e_6, e_7\}$. Note that the edge sequences $\{e_8\}$ and $\{e_1, e_1\}$ are closed paths.

Kirchhoff's Current Law

Kirchhoff's current law (KCL) imposes constraints on the currents in the branches that are attached to each node of a circuit. In simplest terms, KCL states that the sum of the currents that are entering a given node

must equal the sum of the currents that are leaving the node. Thus, the set of currents in branches attached to a given node can be partitioned into two groups whose orientation is away from (into) the node. The two groups must contain the same net current. Applying KCL at node b in Fig. 3.1 gives

$$i_1(t) + i_3(t) = i_2(t)$$

A connection of water pipes that has no leaks is a physical analogy of this situation. The net rate at which water is flowing into a joint of two or more pipes must equal the net rate at which water is flowing away from the joint. The joint itself has the property that it only connects the pipes and thereby imposes a structure on the flow of water, but it cannot store water. This is true regardless of when the flow is measured. Likewise, the nodes of a circuit are modeled as though they cannot store charge. (Physical circuits are sometimes modeled for the purpose of simulation as though they store charge, but these nodes implicitly have a capacitor that provides the physical mechanism for *storing* the charge. Thus, KCL is ultimately satisfied.)

KCL can be stated alternatively as: "the algebraic sum of the branch currents entering (or leaving) any node of a circuit at any instant of time must be zero." In this form, the label of any current whose orientation is away from the node is preceded by a minus sign. The currents *entering* node b in Fig. 3.1 must satisfy

$$i_1(t) - i_2(t) + i_3(t) = 0$$

In general, the currents entering or leaving each node m of a circuit must satisfy

$$\sum i_{km}(t) = 0$$

where $i_{km}(t)$ is understood to be the current in branch k attached to node m. The currents used in this expression are understood to be the currents that would be measured in the branches attached to the node, and their values include a magnitude and an algebraic sign. If the measurement convention is oriented for the case where currents are entering the node, then the actual current in a branch has a positive or negative sign, depending on whether the current is truly flowing toward the node in question.

Once KCL has been written for the nodes of a circuit, the equations can be rewritten by substituting into the equations the voltage-current relationships of the individual components. If a circuit is resistive, the resulting equations will be algebraic. If capacitors or inductors are included in the circuit, the substitution will produce a differential equation. For example, writing KCL at the node for v_3 in Fig. 3.2 produces

$$i_2 + i_1 - i_3 = 0$$

and

$$C_1 \frac{dv_1}{dt} + \frac{v_4 - v_3}{R_2} - C_2 \frac{dv_2}{dt} = 0$$

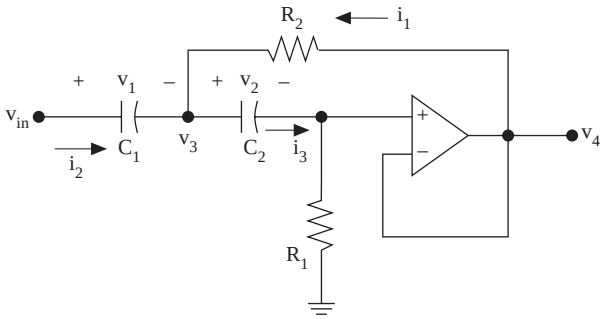

FIGURE 3.2 Example of a circuit containing energy storage elements.

KCL for the node between C_2 and R_1 can be written to eliminate variables and lead to a solution describing the capacitor voltages. The capacitor voltages, together with the applied voltage source, determine the remaining voltages and currents in the circuit. Nodal analysis (see Section 3.2) treats the systematic modeling and analysis of a circuit under the influence of its sources and energy storage elements.

Kirchhoff's Current Law in the Complex Domain

Kirchhoff's current law is ordinarily stated in terms of the real (time-domain) currents flowing in a circuit, because it actually describes physical quantities, at least in a macroscopic, statistical sense. It also applied, however, to a variety of purely mathematical models that are commonly used to analyze circuits in the so-called complex domain.

For example, if a linear circuit is in the sinusoidal steady state, all of the currents and voltages in the circuit are sinusoidal. Thus, each voltage has the form

$$v(t) = A \sin(\omega t + \phi)$$

and each current has the form

$$i(t) = B \sin(\omega t + \theta)$$

where the positive coefficients A and B are called the magnitudes of the signals, and ϕ and θ are the phase angles of the signals. These mathematical models describe the physical behavior of electrical quantities, and instrumentation, such as an oscilloscope, can display the actual waveforms represented by the mathematical model. Although methods exist for manipulating the models of circuits to obtain the magnitude and phase coefficients that uniquely determine the waveform of each voltage and current, the manipulations are cumbersome and not easily extended to address other issues in circuit analysis.

Steinmetz [Smith and Dorf, 1992] found a way to exploit complex algebra to create an elegant framework for representing signals and analyzing circuits when they are in the steady state. In this approach, a model is developed in which each physical sign is replaced by a "complex" mathematical signal. This complex signal in polar, or exponential, form is represented as

$$v_c(t) = Ae^{(j\omega t + \phi)}$$

The algebra of complex exponential signals allows us to write this as

$$v_c(t) = Ae^{j\phi}e^{j\omega t}$$

and Euler's identity gives the equivalent rectangular form:

$$v_c(t) = A[\cos(\omega t + \phi) + j \sin(\omega t + \phi)]$$

So we see that a physical signal is either the real (cosine) or the imaginary (sine) component of an abstract, complex mathematical signal. The additional mathematics required for treatment of complex numbers allows us to associate a phasor, or complex amplitude, with a sinusoidal signal. The time-invariant phasor associated with $v(t)$ is the quantity

$$\mathbf{V}_c = Ae^{j\phi}$$

Notice that the phasor $\mathbf{v}_c$ is an algebraic constant and that in incorporates the parameters A and ϕ of the corresponding time-domain sinusoidal signal.

Phasors can be thought of as being vectors in a two-dimensional plane. If the vector is allowed to rotate about the origin in the counterclockwise direction with frequency ω, the projection of its tip onto the horizontal

(real) axis defines the time-domain signal corresponding to the real part of $v_c(t)$, i.e., $A\cos[\omega t + \phi]$, and its projection onto the vertical (imaginary) axis defines the time-domain signal corresponding to the imaginary part of $v_c(t)$, i.e., $A\sin[\omega t + \phi]$.

The composite signal $v_c(t)$ is a mathematical entity; it cannot be seen with an oscilloscope. Its value lies in the fact that when a circuit is in the steady state, its voltages and currents are uniquely determined by their corresponding phasors, and these in turn satisfy Kirchhoff's voltage and current laws! Thus, we are able to write

$$\sum \mathbf{I}_{km} = 0$$

where $\boldsymbol{I_{km}}$ is the phasor of $i_{km}(t)$, the sinusoidal current in branch k attached to node m. An equation of this form can be written at each node of the circuit. For example, at node b in Fig. 3.1 KCL would have the form

$$\mathbf{I}_1 - \mathbf{I}_2 + \mathbf{I}_3 = 0$$

Consequently, a set of linear, algebraic equations describe the phasors of the currents and voltages in a circuit in the sinusoidal steady state, i.e., the notion of time is suppressed (see Section 3.2). The solution of the set of equations yields the phasor of each voltage and current in the circuit, from which the actual time-domain expressions can be extracted.

It can also be shown that KCL can be extended to apply to the Fourier transforms and the Laplace transforms of the currents in a circuit. Thus, a single relationship between the currents at the nodes of a circuit applies to all of the known mathematical representations of the currents [Ciletti, 1988].

Kirchhoff's Voltage Law

Kirchhoff's voltage law (KVL) describes a relationship among the voltages measured across the branches in any closed, connected path in a circuit. Each branch in a circuit is connected to two nodes. For the purpose of applying KVL, a path has an orientation in the sense that in "walking" along the path one would enter one of the nodes and exit the other. This establishes a direction for determining the voltage across a branch in the path: the voltage is the difference between the potential of the node entered and the potential of the node at which the path exits. Alternatively, the voltage drop along a branch is the difference of the node voltage at the entered node and the node voltage at the exit node. For example, if a path includes a branch between node "a" and node "b", the voltage drop measured along the path in the direction from node "a" to node "b" is denoted by v_{ab} and is given by $v_{ab} = v_a - v_b$. Given v_{ab}, branch voltage along the path in the direction from node "b" to node "a" is $v_{ba} = v_b - v_a = -v_{ab}$.

Kirchhoff's voltage law, like Kirchhoff's current law, is true at any time. KVL can also be stated in terms of voltage rises instead of voltage drops.

KVL can be expressed mathematically as "the algebraic sum of the voltages drops around any closed path of a circuit at any instant of time is zero." This statement can also be cast as an equation:

$$\sum v_{km}(t) = 0$$

where $v_{km}(t)$ is the instantaneous voltage drop measured across branch k of path m. By convention, the voltage drop is taken in the direction of the edge sequence that forms the path.

The edge sequence $\{e_1, e_2, e_3, e_4, e_6, e_7\}$ forms a closed path in Fig. 3.1. The sum of the voltage drops taken around the path must satisfy KVL:

$$v_{ab}(t) + v_{bc}(t) + v_{cd}(t) + v_{de}(t) + v_{ef}(t) + v_{fa}(t) = 0$$

Since $v_{af}(t) = -v_{fa}(t)$, we can also write

$$v_{af}(t) = v_{ab}(t) + v_{bc}(t) + v_{cd}(t) + v_{de}(t) + v_{ef}(t)$$

Had we chosen the path corresponding to the edge sequence $\{e_1, e_5, e_6, e_7\}$ for the path, we would have obtained

$$v_{af}(t) = v_{ab}(t) + v_{be}(t) + v_{ef}(t)$$

This demonstrates how KCL can be used to determine the voltage between a pair of nodes. It also reveals the fact that the voltage between a pair of nodes is independent of the path between the nodes on which the voltages are measured.

Kirchhoff's Voltage Law in the Complex Domain

Kirchhoff's voltage law also applies to the phasors of the voltages in a circuit in steady state and to the Fourier transforms and Laplace transforms of the voltages in a circuit.

Importance of KVL and KCL

Kirchhoff's current law is used extensively in nodal analysis because it is amenable to computer-based implementation and supports a systematic approach to circuit analysis. Nodal analysis leads to a set of algebraic equations in which the variables are the voltages at the nodes of the circuit. This formulation is popular in CAD programs because the variables correspond directly to physical quantities that can be measured easily.

Kirchhoff's voltage law can be used to completely analyze a circuit, but it is seldom used in large-scale circuit simulation programs. The basic reason is that the currents that correspond to a loop of a circuit do not necessarily correspond to the currents in the individual branches of the circuit. Nonetheless, KVL is frequently used to troubleshoot a circuit by measuring voltage drops across selected components.

Defining Terms

Branch: A symbol representing a path for current through a component in an electrical circuit.
Branch current: The current in a branch of a circuit.
Branch voltage: The voltage across a branch of a circuit.
Independent source: A voltage (current) source whose voltage (current) does not depend on any other voltage or current in the circuit.
Node: A symbol representing a physical connection between two electrical components in a circuit.
Node voltage: The voltage between a node and a reference node (usually ground).

Further Information

Kirchhoff's laws form the foundation of modern computer software for analyzing electrical circuits. The interested reader might consider the use of determining the minimum number of algebraic equations that fully characterizes the circuit. It is determined by KCL, KVL, or some mixture of the two?

3.2 Node and Mesh Analysis

J. David Irwin

In this section Kirchhoff's current law (KCL) and Kirchhoff's voltage law (KVL) will be used to determine currents and voltages throughout a network. For simplicity, we will first illustrate the basic principles of both node analysis and mesh analysis using only dc circuits. Once the fundamental concepts have been explained and illustrated, we will demonstrate the generality of both analysis techniques through an ac circuit example.

Node Analysis

In a node analysis, the node voltages are the variables in a circuit, and KCL is the vehicle used to determine them. One node in the network is selected as a reference node, and then all other node voltages are defined with respect to that particular node. This reference node is typically referred to as *ground* using the symbol (⏚), indicating that it is at ground-zero potential.

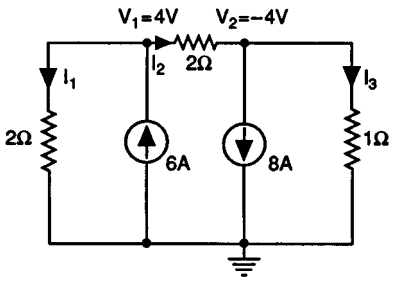

FIGURE 3.3 A three-node network.

Consider the network shown in Fig. 3.3. The network has three nodes, and the nodes at the bottom of the circuit has been selected as the reference node. Therefore the two remaining nodes, labeled V_1 and V_2, are measured with respect to this reference node.

Suppose that the node voltages V_1 and V_2 have somehow been determined, i.e., $V_1 = 4$ V and $v_2 = -4$ V. Once these node voltages are known, Ohm's law can be used to find all branch currents. For example,

$$I_1 = \frac{V_1 - 0}{2} = 2\,\text{A}$$

$$I_2 = \frac{V_1 - V_2}{2} = \frac{4 - (-4)}{2} = 4\,\text{A}$$

$$I_3 = \frac{V_2 - 0}{1} = \frac{-4}{1} = -4\,\text{A}$$

Note that KCL is satisfied at every node, i.e.,

$$I_1 - 6 + I_2 = 0$$

$$-I_2 + 8 + I_3 = 0$$

$$-I_1 + 6 - 8 - I_3 = 0$$

Therefore, as a general rule, if the node voltages are known, all branch currents in the network can be immediately determined.

In order to determine the node voltages in a network, we apply KCL to every node in the network except the reference node. Therefore, given an N-node circuit, we employ $N-1$ linearly independent simultaneous equations to determine the $N-1$ unknown node voltages. Graph theory, which is covered in Section 3.6, can be used to prove that exactly $N-1$ linearly independent KCL equations are required to find the $N-1$ unknown node voltages in a network.

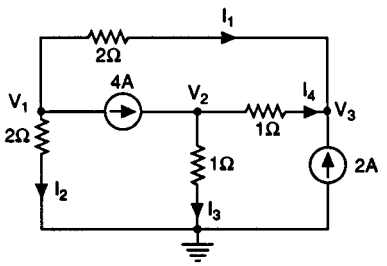

FIGURE 3.4 A four-node network.

Let us now demonstrate the use of KCL in determining the node voltages in a network. For the network shown in Fig. 3.4, the bottom

node is selected as the reference and the three remaining nodes, labeled V_1, V_2, and V_3, are measured with respect to that node. All unknown branch currents are also labeled. The KCL equations for the three nonreference nodes are

$$I_1 + 4 + I_2 = 0$$

$$-4 + I_3 + I_4 = 0$$

$$-I_1 - I_4 - 2 = 0$$

Using Ohm's law these equations can be expressed as

$$\frac{V_1 - V_3}{2} + 4 + \frac{V_1}{2} = 0$$

$$-4 + \frac{V_2}{1} + \frac{V_2 - V_3}{1} = 0$$

$$-\frac{(V_1 - V_3)}{2} - \frac{(V_2 - V_3)}{1} - 2 = 0$$

Solving these equations, using any convenient method, yields $V_1 = -8/3$ V, $V_2 = 10/3$ V, and $V_3 = 8/3$ V. Applying Ohm's law we find that the branch currents are $I_1 = -16/6$ A, $I_2 = -8/6$ A, $I_3 = 20/6$ A, and $I_4 = 4/6$ A. A quick check indicates that KCL is satisfied at every node.

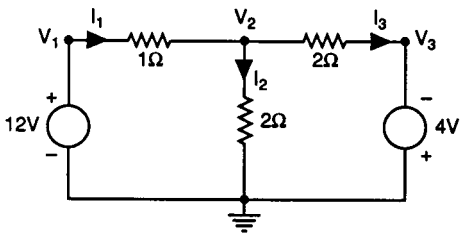

FIGURE 3.5 A four-node network containing voltage sources.

The circuits examined thus far have contained only current sources and resistors. In order to expand our capabilities, we next examine a circuit containing voltage sources. The circuit shown in Fig. 3.5 has three nonreference nodes labeled V_1, V_2, and V_3. However, we do not have three unknown node voltages. Since known voltage sources exist between the reference node and nodes V_1 and V_3, these two node voltages are known, i.e., $V_1 = 12$ V and $V_3 = -4$ V. Therefore, we have only one unknown node voltage, V_2. The equations for this network are then

$$V_1 = 12$$

$$V_3 = -4$$

and

$$-I_1 + I_2 + I_3 = 0$$

The KCL equation for node V_2 written using Ohm's law is

$$-\frac{(12 - V_2)}{1} + \frac{V_2}{2} + \frac{V_2 - (-4)}{2} = 0$$

Solving this equation yields $V_2 = 5$ V, $I_1 = 7$ A, $I_2 = 5/2$ A, and $I_3 = 9/2$ A. Therefore, KCL is satisfied at every node.

Thus, the presence of a voltage source in the network actually simplifies a node analysis. In an attempt to generalize this idea, consider the network in Fig. 3.6. Note that in this case $V_1 = 12$ V and the difference between node voltages V_3 and V_2 is constrained to be 6 V. Hence, two of the three equations needed to solve for the node voltages in the network are

$$V_1 = 12$$

$$V_3 - V_2 = 6$$

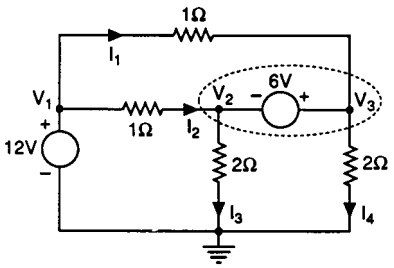

FIGURE 3.6 A four-node network used to illustrate a supernode.

To obtain the third required equation, we form what is called a supernode, indicated by the dotted enclosure in the network. Just as KCL must be satisfied at any node in the network, it must be satisfied at the supernode as well. Therefore, summing all the currents leaving the supernode yields the equation

$$\frac{V_2 - V_1}{1} + \frac{V_2}{2} + \frac{V_3 - V_1}{1} + \frac{V_3}{2} = 0$$

The three equations yield the node voltages $V_1 = 12$ V, $V_2 = 5$ V, and $V_3 = 11$ V, and therefore $I_1 = 1$ A, $I_2 = 7$ A, $I_3 = 5/2$ A, and $I_4 = 11/2$ A.

Mesh Analysis

In a mesh analysis the mesh currents in the network are the variables and KVL is the mechanism used to determine them. Once all the mesh currents have been determined, Ohm's law will yield the voltages anywhere in e circuit. If the network contains N independent meshes, then graph theory can be used to prove that N independent linear simultaneous equations will be required to determine the N mesh currents.

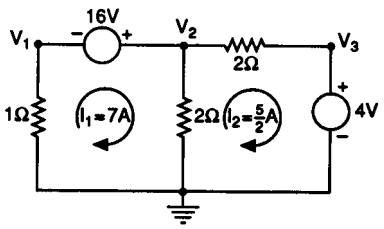

FIGURE 3.7 A network containing two independent meshes.

The network shown in Fig. 3.7 has two independent meshes. They are labeled I_1 and I_2, as shown. If the mesh currents are known to be $I_1 = 7$ A and $I_2 = 5/2$ A, then all voltages in the network can be calculated. For example, the voltage V_1, i.e., the voltage across the 1-Ω resistor, is $V_1 = -I_1R = -(7)(1) = -7$ V. Likewise $V = (I_1 - I_2)R = (7 - 5/2)(2) = 9$ V. Furthermore, we can check our analysis by showing that KVL is satisfied around every mesh. Starting at the lower left-hand corner and applying KVL to the left-hand mesh we obtain

$$-(7)(1) + 16 - (7 - 5/2)(2) = 0$$

where we have assumed that increases in energy level are positive and decreases in energy level are negative.

Consider now the network in Fig. 3.8. Once again, if we assume that an increase in energy level is positive and a decrease in energy level is negative, the three KVL equations for the three meshes defined are

$$-I_1(1) - 6 - (I_1 - I_2)(1) = 0$$

$$+12 - (I_2 - I_1)(1) - (I_2 - I_3)(2) = 0$$

$$-(I_3 - I_2)(2) + 6 - I_3(2) = 0$$

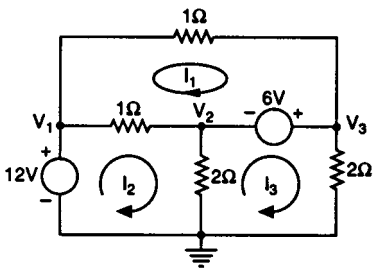

FIGURE 3.8 A three-mesh network.

These equations can be written as

$$2I_1 - I_2 = -6$$

$$-I_{12} + 3I_2 - 2I_3 = 12$$

$$-2I_2 + 4I_3 = 6$$

Solving these equations using any convenient method yields $I1 = 1$ A, $I_2 = 8$ A, and $I_3 = 11/2$ A. Any voltage in the network can now be easily calculated, e.g., $V_2 = (I_2 - I_3)(2) = 5$ V and $V_3 = I_3(2) = 11$ V.

Just as in the node analysis discussion, we now expand our capabilities by considering circuits which contain current sources. In this case, we will show that for mesh analysis, the presence of current sources makes the solution easier.

The network in Fig. 3.9 has four meshes which are labeled I_1, I_2, I_3, and I_4. However, since two of these currents, i.e., I_3 and I_4, pass directly through a current source, two of the four linearly independent equations required to solve the network are

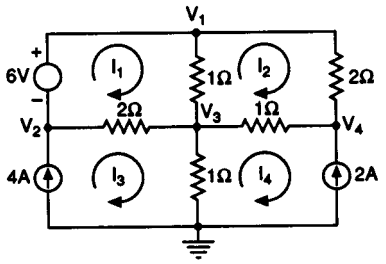

FIGURE 3.9 A four-mesh network containing current sources.

$$I_3 = 4$$

$$I_4 = -2$$

The two remaining KVL equations for the meshes defined by I_1 and I_2 are

$$+6 - (I_1 - I_2)(1) - (I_1 - I_3)(2) = 0$$

$$-(I_2 - I_1)(1) - I_2(2) - (I_2 - I_4)(1) = 0$$

Solving these equations for I_1 and I_2 yields $I_1 = 54/11$ A and $I_2 = 8/11$ A. A quick check will show that KCL is satisfied at every node. Furthermore, we can calculate any node voltage in the network. For example, $V_3 = (I_3 - I_4)(1) = 6$ V and $V_1 = V_3 + (I_1 - I_2)(1) = 112/11$ V.

Summary

Both node analysis and mesh analysis have been presented and discussed. Although the methods have been presented within the framework of dc circuits with only independent sources, the techniques are applicable to ac analysis and circuits containing dependent sources.

To illustrate the applicability of the two techniques to ac circuit analysis, consider the network in Fig. 3.10. All voltages and currents are phasors and the impedance of each passive element is known.

In the node analysis case, the voltage V_4 is known and the voltage between V_2 and V_3 is constrained. Therefore, two of the four required equations are

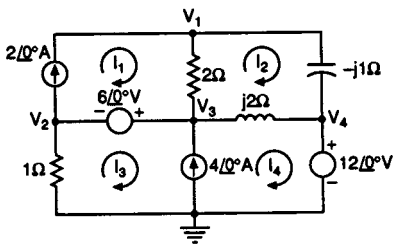

FIGURE 3.10 A network containing five nodes and four meshes.

$$V_4 = 12\ \angle 0°$$

$$V_2 + 6\ \angle 0° = V_3$$

KCL for the node labeled V_1 and the supernode containing the nodes labeled V_2 and V_3 is

$$\frac{V_1 - V_3}{2} + \frac{V_1 - V_4}{-j1} = 2\angle 0°$$

$$\frac{V_2}{1} + 2\angle 0° + \frac{V_3 - V_1}{2} + \frac{V_3 - V_4}{j2} = 4\angle 0° = 0$$

Solving these equations yields the remaining unknown node voltages.

$$\mathbf{V}_1 = 11.9 - j0.88 = 11.93\angle -4.22° \text{ V}$$

$$\mathbf{V}_2 = 3.66 - j1.07 = 3.91\angle -16.34° \text{ V}$$

$$\mathbf{V}_3 = 9.66 - j1.07 = 9.72\angle -6.34° \text{ V}$$

In the mesh analysis case, the currents I_1 and I_3 are constrained to be

$$\mathbf{I}_1 = 2\angle 0°$$

$$\mathbf{I}_4 - \mathbf{I}_3 = -4\angle 0°$$

The two remaining KVL equations are obtained from the mesh defined by mesh current I_2 and the loop which encompasses the meshes defined by mesh currents I_3 and I_4.

$$-2(I_2 - I_1) - (-j1)I_2 - j2(I_2 - I4) = 0$$

$$-(1I_3 + 6\angle 0° - j2(I_4 - I_2) - 12\angle 0° = 0$$

Solving these equations yields the remaining unknown mesh currents

$$\mathbf{I}_2 = 0.88\angle -6.34° \text{ A}$$

$$\mathbf{I}_3 = 3.91\angle 163.66° \text{ A}$$

$$\mathbf{I}_4 = 1.13\angle 72.35° \text{ A}$$

As a quick check we can use these currents to compute the node voltages. For example, if we calculate

$$\mathrm{V}_2 = -1(\mathrm{I}_3)$$

and

$$\mathrm{V}_1 = -j1(\mathrm{I}_2) + 12\angle 0°$$

we obtain the answers computed earlier.

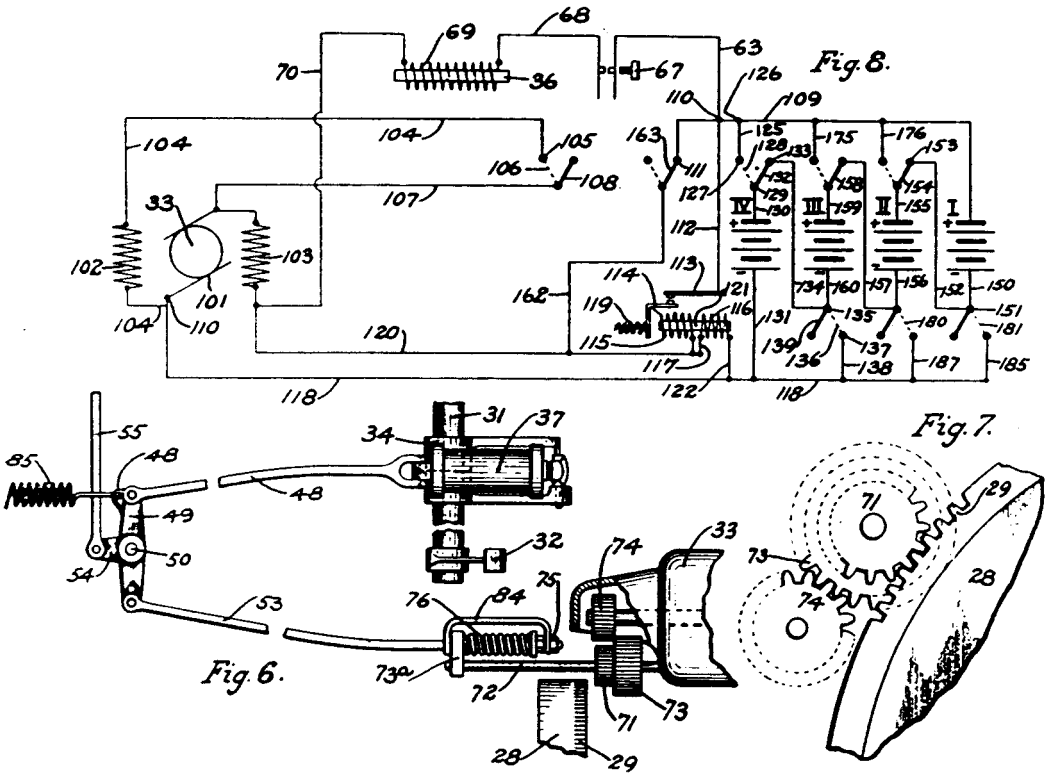
As a final point, because both node and mesh analysis will yield all currents and voltages in a network, which technique should be used? The answer to this question depends upon the network to be analyzed. If the network contains more voltage sources than current sources, node analysis might be the easier technique. If, however, the network contains more current sources than voltage sources, mesh analysis may be the easiest approach.

Engine-Starting Device

Charles F. Kettering
Patented August 17, 1915
#1,150,523

Early automobiles were all started with a crank, or arm-strong starters, as they were known. This backbreaking process was difficult for everyone, especially women. And it was dangerous. Backfires often resulted in broken wrists. Worse yet, if accidentally left in gear, the car could advance upon the person cranking. Numerous deaths and injuries were reported.

In 1910, Henry Leland, Cadillac Motors president, commissioned Charles Kettering and his Dayton Engineering Laboratories Company to develop an electric self-starter to replace the crank. Kettering had to overcome two large problems: (1) making a motor small enough to fit in a car yet powerful enough to crank the engine, and (2) finding a battery more powerful than any yet in existence. Electric Storage Battery of Philadelphia supplied an experimental 65-lb battery and Delco unveiled a working prototype electric "self-starter" system installed in a 1912 Cadillac on February 17, 1911. Leland immediately ordered 12,000 units for Cadillac. Within a few years, almost all new cars were equipped with electric starters. (Copyright © 1995, DewRay Products, Inc. Used with permission.)



Defining Terms

ac: An abbreviation for alternating current.
dc: An abbreviation for direct current.
Kirchhoff's current law (KCL): This law states that the algebraic sum of the currents either entering or leaving a node must be zero. Alternatively, the law states that the sum of the currents entering a node must be equal to the sum of the currents leaving that node.
Kirchhoff's voltage law (KVL): This law states that the algebraic sum of the voltages around any loop is zero. A loop is any closed path through the circuit in which no node is encountered more than once.
Mesh analysis: A circuit analysis technique in which KVL is used to determine the mesh currents in a network. A mesh is a loop that does not contain any loops within it.
Node analysis: A circuit analysis technique in which KCL is used to determine the node voltages in a network.
Ohm's law: A fundamental law which states that the voltage across a resistance is directly proportional to the current flowing through it.
Reference node: One node in a network that is selected to be a common point, and all other node voltages are measured with respect to that point.
Supernode: A cluster of node, interconnected with voltage sources, such that the voltage between any two nodes in the group is known.

3.3 Network Theorems

Allan D. Kraus

Linearity and Superposition

Linearity

Consider a system (which may consist of a single network element) represented by a block, as shown in Fig. 3.11, and observe that the system has an input designated by e (for excitation) and an output designated by r (for response). The system is considered to be *linear* if it satisfies the *homogeneity* and *superposition* conditions.

The homogeneity condition: If an arbitrary input to the system, e, causes a response, r, then if ce is the input, the output is cr where c is some arbitrary constant.

The superposition condition: If the input to the system, e_1, causes a response, r_1, and if an input to the system, e_2, causes a response, r_2, then a response, $r_1 + r_2$, will occur when the input is $e_1 + e_2$.

If neither the homogeneity condition nor the superposition condition is satisfied, the system is said to be *nonlinear.*

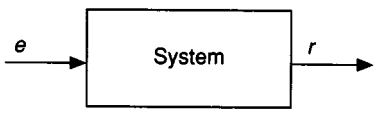

FIGURE 3.11 A simple system.

The Superposition Theorem

While both the homogeneity and superposition conditions are necessary for linearity, the superposition condition, in itself, provides the basis for the superposition theorem:

> If cause and effect are linearly related, the total effect due to several causes acting simultaneously is equal to the sum of the individual effects due to each of the causes acting one at a time.

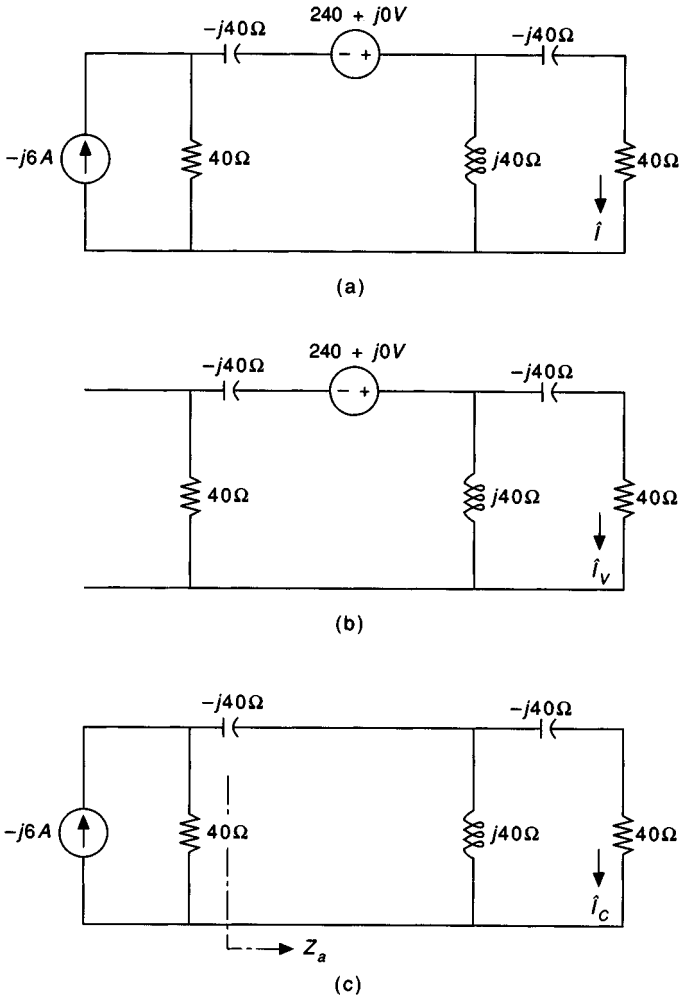

FIGURE 3.12 (a) A network to be solved by using superposition; (b) the network with the current source nulled; and (c) the network with the voltage source nulled.

Example 3.1. Consider the network driven by a current source at the left and a voltage source at the top, as shown in Fig. 3.12(a). The current phasor indicated by $\hat{I}$ is to be determined. According to the superposition theorem, the current $\hat{I}$ will be the sum of the two current components $\hat{I}_V$ due to the voltage source acting alone as shown in Fig. 3.12(b) and $\hat{I}_C$ due to the current source acting alone shown in Fig. 3.12(c).

$$\hat{I} = \hat{I}_V + \hat{I}_C$$

Figures 3.12(b) and (c) follow from the methods of removing the effects of independent voltage and current sources. Voltage sources are nulled in a network by replacing them with short circuits and current sources are nulled in a network by replacing them with open circuits.

The networks displayed in Figs. 3.12(b) and (c) are simple ladder networks in the phasor domain, and the strategy is to first determine the equivalent impedances presented to the voltage and current sources. In Fig. 3.12(b), the group of three impedances to the right of the voltage source are in series-parallel and possess an impedance of

$$Z_P = \frac{(40 - j40)(j40)}{40 + j40 - j40} = 40 + j40\ \Omega$$

and the total impedance presented to the voltage source is

$$Z = Z_P + 40 - j40 = 40 + j40 + 40 - j40 = 80\ \Omega$$

Then $\hat{I}_1$, the current leaving the voltage source, is

$$\hat{I}_1 = \frac{240 + j0}{80} = 3 + j0\,\text{A}$$

and by a current division

$$\hat{I}_V = \left[\frac{j40}{40 - j40 + j40}\right](3 + j0) = j(3 + j0) = 0 + j3\,\text{A}$$

In Fig. 3.12(b), the current source delivers current to the 40-Ω resistor and to an impedance consisting of the capacitor and Z_p. Call this impedance Z_a so that

$$Z_a = -j40 + Z_P = -j40 + 40 + j40 = 40\ \Omega$$

Then, two current divisions give $\hat{I}_C$

$$\hat{I}_C = \left[\frac{40}{40 + 40}\right]\left[\frac{j40}{40 - j40 + j40}\right](0 - j6) = \frac{j}{2}(0 - j6) = 3 + j0\,\text{A}$$

The current $\hat{I}$ in the circuit of Fig. 3.12(a) is

$$\hat{I} = \hat{I}_V + \hat{I}_C = 0 + j3 + (3 + j0) = 3 + j3\ \text{A}$$

The Network Theorems of Thévenin and Norton

If interest is to be focused on the voltages and across the currents through a small portion of a network such as network *B* in Fig. 3.13(a), it is convenient to replace network *A*, which is complicated and of little interest, by a simple equivalent. The simple equivalent may contain a single, equivalent, voltage source in series with an equivalent impedance in series as displayed in Fig. 3.13(b). In this case, the equivalent is called a *Thévenin equivalent.* Alternatively, the simple equivalent may consist of an equivalent current source in parallel with an equivalent impedance. This equivalent, shown in Fig. 3.13(c), is called a *Norton equivalent.* Observe that as long as Z_T (subscript *T* for Thévenin) is equal to Z_N (subscript *N* for Norton), the two equivalents may be obtained from one another by a simple source transformation.

Conditions of Application

The Thévenin and Norton network equivalents are only valid at the terminals of network *A* in Fig. 3.13(a) and they do not extend to its interior. In addition, there are certain restrictions on networks *A* and *B*. Network *A* may contain only linear elements but may contain both independent and dependent sources. Network *B*, on the other hand, is not restricted to linear elements; it may contain nonlinear or time-varying elements and may

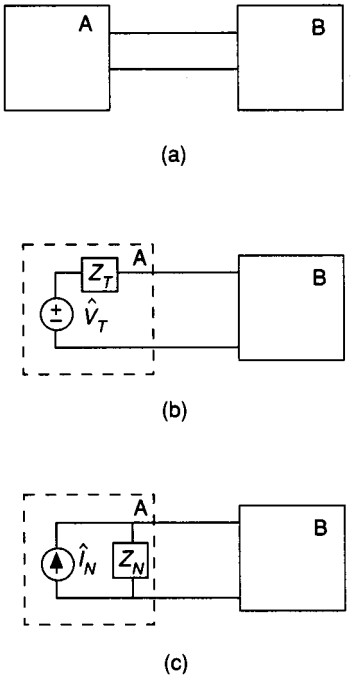

FIGURE 3.13 (a) Two one-port networks; (b) the Thévenin equivalent for network *a*; and (c) the Norton equivalent for network *a*.

also contain both independent and dependent sources. Together, there can be no controlled source coupling or magnetic coupling between networks *A* and *B*.

The Thévenin Theorem

The statement of the Thévenin theorem is based on Fig. 3.13(b):

> Insofar as a load which has no magnetic or controlled source coupling to a one-port is concerned, a network containing linear elements and both independent and controlled sources may be replaced by an ideal voltage source of strength, $\hat{V}_T$, and an equivalent impedance Z_T, in series with the source. The value of $\hat{V}_T$ is the open-circuit voltage, $\hat{V}_{OC}$, appearing across the terminals of the network and Z_T is the driving point impedance at the terminals of the network, obtained with all independent sources set equal to zero.

The Norton Theorem

The Norton theorem involves a current source equivalent. The statement of the Norton theorem is based on Fig. 3.13(c):

> Insofar as a load which has no magnetic or controlled source coupling to a one-port is concerned, the network containing linear elements and both independent and controlled sources may be replaced by an ideal current source of strength, $\hat{I}_N$, and an equivalent impedance, Z_N, in parallel with the source. The value of $\hat{I}_N$ is the short-circuit current, $\hat{I}_{SC}$, which results when the terminals of the network are shorted and Z_N is the driving point impedance at the terminals when all independent sources are set equal to zero.

The Equivalent Impedance, $Z_T = Z_N$

Three methods are available for the determination of Z_T. All of them are applicable at the analyst's discretion. When controlled sources are present, however, the first method cannot be used.

The first method involves the direct calculation of $Z_{eq} = Z_T = Z_N$ by looking into the terminals of the network after all independent sources have been nulled. Independent sources are nulled in a network by replacing all independent voltage sources with a short circuit and all independent current sources with an open circuit.

The second method, which may be used when controlled sources are present in the network, requires the computation of both the Thévenin equivalent voltage (the open-circuit voltage at the terminals of the network) and the Norton equivalent current (the current through the short-circuited terminals of the network). The equivalent impedance is the ratio of these two quantities

$$Z_T = Z_N = Z_{eq} = \frac{\hat{V}_T}{\hat{I}_N} = \frac{\hat{V}_{OC}}{\hat{I}_{SC}}$$

The third method may also be used when controlled sources are present within the network. A test voltage may be placed across the terminals with a resulting current calculated or measured. Alternatively, a test current may be injected into the terminals with a resulting voltage determined. In either case, the equivalent resistance can be obtained from the value of the ratio of the test voltage $\hat{V}_o$ to the resulting current $\hat{I}_o$

$$Z_T = \frac{\hat{V}_o}{\hat{I}_o}$$

Example 3.2. The current through the capacitor with impedance $-j35\ \Omega$ in Fig. 3.14(a) may be found using Thévenin's theorem. The first step is to remove the $-j35$-Ω capacitor and consider it as the load. When this is done, the network in Fig. 3.14(b) results.

The Thévenin equivalent voltage is the voltage across the 40–Ω resistor. The current through the 40-Ω resistor was found in Example 3.1 to be $I = 3 + j3\ \Omega$ Thus,

$$\hat{V}_T = 40(3 + j3) = 120 + j120\ \text{V}$$

The Thévenin equivalent impedance may be found by looking into the terminals of the network in Fig. 3.14(c). Observe that both sources in Fig. 3.14(a) have been nulled and that, for ease of computation, impedances Z_a and Z_b have been placed on Fig. 3.14(c). Here,

$$Z_a = \frac{(40 - j40)(j40)}{40 + j40 - j40} = 40 + j40\ \Omega$$

$$Z_b = \frac{(40)(40)}{40 + 40} = 20\ \Omega$$

and

$$Z_T = Z_b + j15 = 20 + j15\ \Omega$$

Both the Thévenin equivalent voltage and impedance are shown in Fig. 3.14(d), and when the load is attached, as in Fig. 3.14(d), the current can be computed as

$$\hat{I} = \frac{\hat{V}_T}{20 + j15 - j35} = \frac{120 + j120}{20 - j20} = 0 + j6\ \text{A}$$

The Norton equivalent circuit is obtained via a simple voltage-to-current source transformation and is shown in Fig. 3.15. Here it is observed that a single current division gives

$$\hat{I} = \left[\frac{20 + j15}{20 + j15 - j35}\right](6.72 + j0.96) = 0 + j6\ \text{A}$$

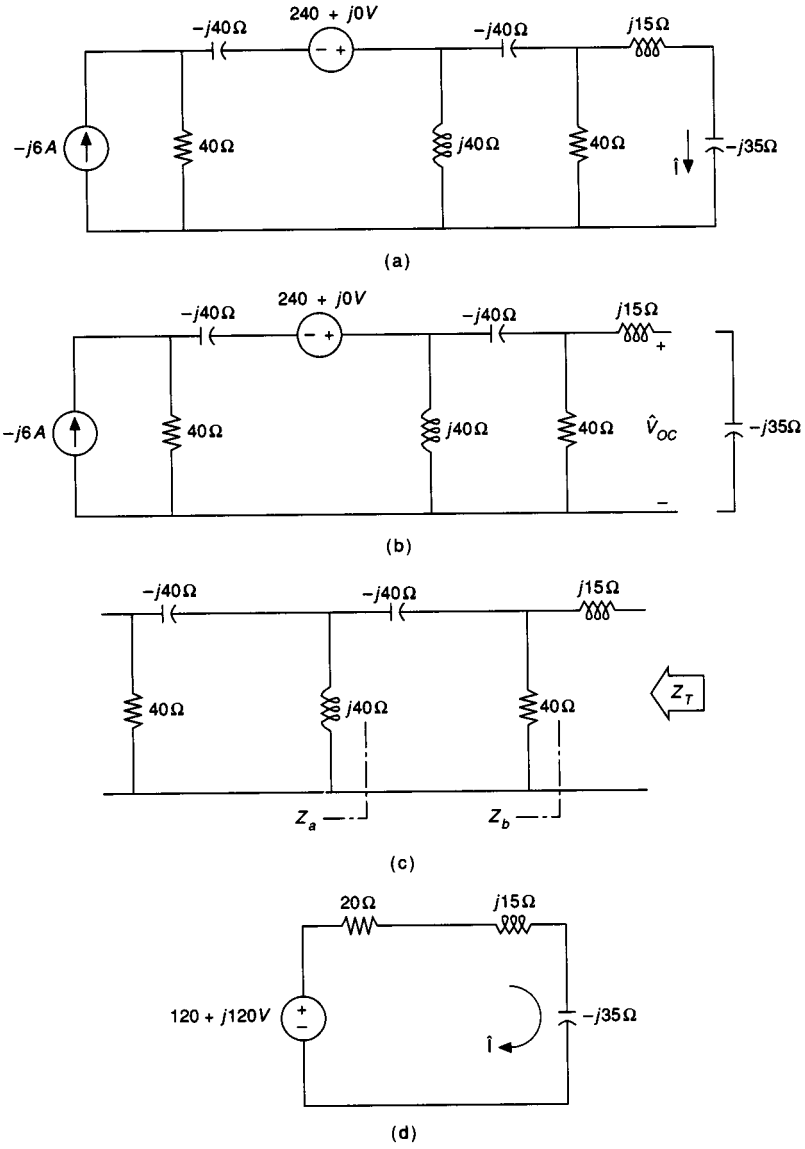

FIGURE 3.14 (a) A network in the phasor domain; (b) the network with the load removed; (c) the network for the computation of the Thévenin equivalent impedance; and (d) the Thévenin equivalent.

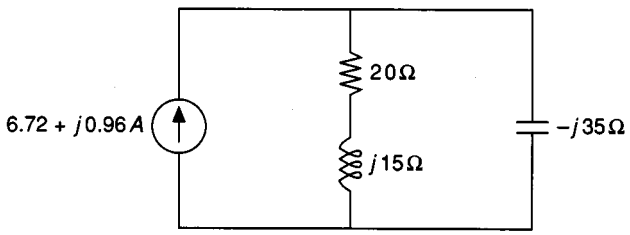

FIGURE 3.15 The Norton equivalent of Fig. 3.14(d).

Tellegen's Theorem

Tellegen's theorem states:

> In an arbitrarily lumped network subject to KVL and KCL constraints, with reference directions of the branch currents and branch voltages associated with the KVL and KCL constraints, the product of all branch currents and branch voltages must equal zero.

Tellegen's theorem may be summarized by the equation

$$\sum_{k=1}^{b} v_k j_k = 0$$

where the lower case letters v and j represent instantaneous values of the branch voltages and branch currents, respectively, and where b is the total number of branches. A matrix representation employing the branch current and branch voltage vectors also exists. Because **V** and **J** are column vectors

$$\mathbf{V} \cdot \mathbf{J} = \mathbf{V}^T\mathbf{J} = \mathbf{J}^T\mathbf{V}$$

The prerequisite concerning the KVL and KCL constraints in the statement of Tellegen's theorem is of crucial importance.

Example 3.3. Figure 3.16 displays an oriented graph of a particular network in which there are six branches labeled with numbers within parentheses and four nodes labeled by numbers within circles. Several known branch currents and branch voltages are indicated. Because the type of elements or their values is not germane to the construction of the graph, the other branch currents and branch voltages may be evaluated from repeated applications of KCL and KVL. KCL may be used first at the various nodes.

$$\text{node 3:} \quad j_2 = j_6 - j_4 = 4 - 2 = 2 \text{ A}$$

$$\text{node 1:} \quad j_3 = -j_1 - j_2 = -8 - 2 = -10 \text{ A}$$

$$\text{node 2:} \quad j_5 = j_3 - j_4 = -10 - 2 = -12 \text{ A}$$

Then KVL gives

$$v_3 = v_2 - v_4 = 8 - 6 = 2 \text{ V}$$

$$v_6 = v_5 - v_4 = -10 - 6 = -16 \text{ V}$$

$$v_1 = v_2 + v_6 = 8 - 16 = -8 \text{ V}$$

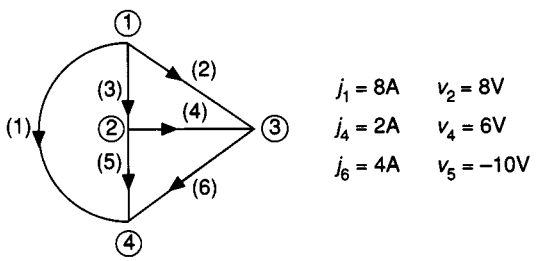

FIGURE 3.16 An oriented graph of a particular network with some known branch currents and branch voltages.

The transpose of the branch voltage and current vectors are

$$\mathbf{V}_T = [-8 \quad 8 \quad 2 \quad 6 \quad -10 \quad -16] \text{ V}$$

and

$$\mathbf{J}_T = [8 \quad 2 \quad -10 \quad 2 \quad -12 \quad 4] \text{ V}$$

The scalar product of **V** and **J** gives

$$-8(8) + 8(2) + 2(-10) + 6(2) + (-10)(-12) + (-16)(4) = -148 + 148 = 0$$

and Tellegen's theorem is confirmed.

Maximum Power Transfer

The maximum power transfer theorem pertains to the connections of a load to the Thévenin equivalent of a source network in such a manner as to transfer maximum power to the load. For a given network operating at a prescribed voltage with a Thévenin equivalent impedance

$$Z_T = |Z_T| \angle \theta_T$$

the real power drawn by any load of impedance

$$Z_o = |Z_o| \angle \theta_o$$

is a function of just two variables, $|Z_o|$ and θ_o. If the power is to be a maximum, there are three alternatives to the selection of $|Z_o|$ and θ_o:

(1) Both $|Z_o|$ and θ_o are at the designer's discretion and both are allowed to vary in any manner in order to achieve the desired result. In this case, the load should be selected to be the complex conjugate of the Thévenin equivalent impedance

$$Z_o = Z_T^*$$

(2) The angle, θ_o, is fixed but the magnitude, $|Z_o|$, is allowed to vary. For example, the analyst may select and fix $\theta_o = 0°$. This requires that the load be resistive (Z is entirely real). In this case, the value of the load resistance should be selected to be equal to the magnitude of the Thévenin equivalent impedance

$$R_o = |Z_T|$$

(3) The magnitude of the load impedance, $|Z_o|$, can be fixed, but the impedance angle, θ_o, is allowed to vary. In this case, the value of the load impedance angle should be

$$\theta_o = \arcsin\left[-\frac{2|Z_o||Z_T|\sin\theta_T}{|Z_o|^2 + |Z_T|^2}\right]$$

Example 3.4. Figure 3.17(a) is identical to Fig. 3.14(b) with the exception of a load, Z_o, substituted for the capacitive load. The Thévenin equivalent is shown in Fig. 3.17(b). The value of Z_o to transfer maximum power

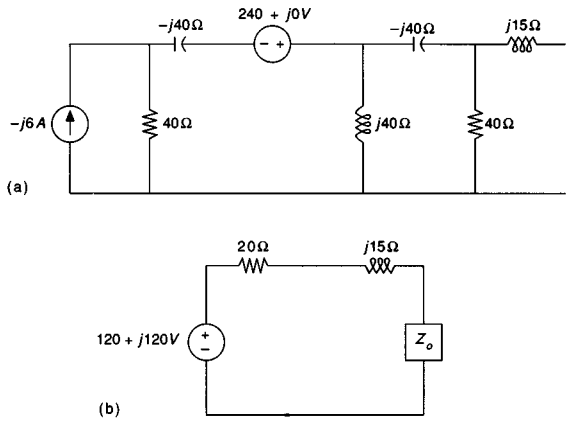

FIGURE 3.17 (a) A network for which the load, Z_o, is to be selected for maximum power transfer, and (b) the Thévenin equivalent of the network.

is to be found if its elements are unrestricted, if it is to be a single resistor, or if the magnitude of Z_o must be 20 Ω but its angle is adjustable.

For maximum power transfer to Z_o when the elements of Z_o are completely at the discretion of the network designer, Z_o must be the complex conjugate of Z_T

$$Z_o = Z_T^* = 20 - j15\ \Omega$$

If Z_o is to be a single resistor, R_o, then the magnitude of $Z_o = R_o$ must be equal to the magnitude of Z_T. Here

$$Z_T = 20 + j15 = 25\ \underline{/36.87°}$$

so that

$$R_o = |Z_o| = 25\ \Omega$$

If the magnitude of Z_o must be 20 Ω but the angle is adjustable, the required angle is calculated from

$$\begin{aligned}\theta_o &= \arcsin\left[-\frac{2|Z_o||Z_T|}{|Z_o|^2 + |Z_T|^2}\sin\theta_T\right] \\ &= \arcsin\left[-\frac{2(20)(25)}{(20)^2 + (25)^2}\sin\ \underline{/36.87°}\right] \\ &= \arcsin(-0.585) = -35.83°\end{aligned}$$

This makes Z_o

$$Z_o = 20\ \underline{/-35.83°} = 16.22 - j11.71\ \Omega$$

The Reciprocity Theorem

The reciprocity theorem is a useful general theorem that applies to all linear, passive, and bilateral networks. However, it applies only to cases where current and voltage are involved.

The ratio of a single excitation applied at one point to an observed response at another is invariant with respect to an interchange of the points of excitation and observation.

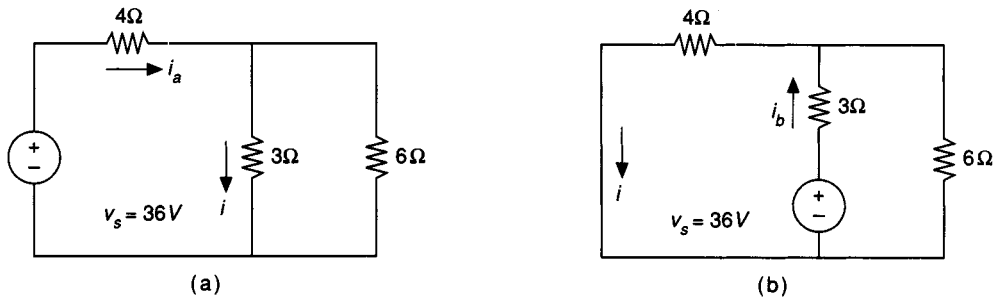

FIGURE 3.18 Two networks which can be used to illustrate the reciprocity principle.

The reciprocity principle also applies if the excitation is a current and the observed response is a voltage. It will not apply, in general, for voltage–voltage and current–current situations, and, of course, it is not applicable to network models of nonlinear devices.

Example 3.5. It is easily shown that the positions of v_s and i in Fig. 3.18(a) may be interchanged as in Fig. 3.18(b) without changing the value of the current i.

In Fig. 3.18(a), the resistance presented to the voltage source is

$$R = 4 + \frac{3(6)}{3+6} = 4 + 2 = 6\ \Omega$$

Then

$$i_a = \frac{v_s}{R} = \frac{36}{6} = 6\ \text{A}$$

and by current division

$$i_a = \frac{6}{6+3} i_a = \left(\frac{2}{3}\right) 6 = 4\ \text{A}$$

In Fig. 3.18(b), the resistance presented to the voltage source is

$$R = 3 + \frac{6(4)}{6+4} = 3 + \frac{12}{5} = \frac{27}{5}\ \Omega$$

Then

$$i_b = \frac{v_s}{R} = \frac{36}{27/5} = \frac{180}{27} = \frac{20}{3}\ \text{A}$$

and again, by current division

$$i = \frac{6}{4+6} i_b = \left(\frac{3}{5}\right)\frac{20}{3} = 4\ \text{A}$$

The network is reciprocal.

The Substitution and Compensation Theorems

The Substitution Theorem

Any branch in a network with branch voltage, v_k, and branch current, i_k, can be replaced by another branch provided it also has branch voltage, v_k, and branch current, i_k.

The Compensation Theorem

In a linear network, if the impedance of a branch carrying a current $\hat{I}$ is changed from Z to $Z + \Delta Z$, then the corresponding change of any voltage or current elsewhere in the network will be due to a compensating voltage source, $\Delta Z\hat{I}$, placed in series with $Z + \Delta Z$ with polarity such that the source, $\Delta Z\hat{I}$, is opposing the current $\hat{I}$.

Defining Terms

Linear network: A network in which the parameters of resistance, inductance, and capacitance are constant with respect to voltage or current or the rate of change of voltage or current and in which the voltage or current of sources is either independent of or proportional to other voltages or currents, or their derivatives.

Maximum power transfer theorem: In any electrical network which carries direct or alternating current, the maximum possible power transferred from one section to another occurs when the impedance of the section acting as the load is the complex conjugate of the impedance of the section that acts as the source. Here, both impedances are measured across the pair of terminals in which the power is transferred with the other part of the network disconnected.

Norton theorem: The voltage across an element that is connected to two terminals of a linear, bilateral network is equal to the short-circuit current between these terminals in the absence of the element, divided by the admittance of the network looking back from the terminals into the network, with all generators replaced by their internal admittances.

Principle of superposition: In a linear electrical network, the voltage or current in any element resulting from several sources acting together is the sum of the voltages or currents from each source acting alone.

Reciprocity theorem: In a network consisting of linear, passive impedances, the ratio of the voltage introduced into any branch to the current in any other branch is equal in magnitude and phase to the ratio that results if the positions of the voltage and current are interchanged.

Thévenin theorem: The current flowing in any impedance connected to two terminals of a linear, bilateral network containing generators is equal to the current flowing in the same impedance when it is connected to a voltage generator whose voltage is the voltage at the open-circuited terminals in question and whose series impedance is the impedance of the network looking back from the terminals into the network, with all generators replaced by their internal impedances.

3.4 Power and Energy

Norman Balabanian and Theodore A. Bickart

The concept of the voltage v between two points was introduced in Section 3.1 as the energy w expended per unit charge in moving the charge between the two points. Coupled with the definition of current i as the time rate of charge motion and that of power p as the time rate of change of energy, this leads to the following fundamental relationship between the power delivered to a two-terminal electrical component and the voltage and current of that component, with standard references (meaning that the voltage reference plus is at the tail of the current reference arrow) as shown in Fig. 3.19:

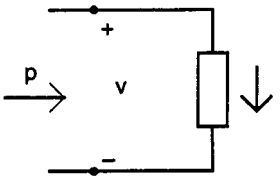

FIGURE 3.19 Power delivered to a circuit.

$$p = vi \tag{3.1}$$

Assuming that the voltage and current are in volts and amperes, respectively, the power is in *watts.* This relationship applies to any two-terminal component or network, whether linear or nonlinear.

The power delivered to the basic linear resistive, inductive, and capacitive elements is obtained by inserting the v-i relationships into this expression. Then, using the relationship between power and energy (power as the time derivative of energy and energy, therefore, as the integral of power), the energy stored in the capacitor and inductor is also obtained:

$$\begin{aligned} p_R &= v_R i_R = Ri^2 \\ p_C &= v_C i_C = Cv_C \frac{dv_C}{dt} \qquad & w_C(t) &= \int_0^t Cv_C \frac{dv_C}{dt}\,dt = \frac{1}{2}Cv_C^2(t) \\ p_L &= v_L i_L = Li_L \frac{di_L}{dt} & w_L(t) &= \int_0^t Li_L \frac{di_L}{dt}\,dt = \frac{1}{2}Li_L^2(t) \end{aligned} \tag{3.2}$$

where the origin of time ($t = 0$) is chosen as the time when the capacitor voltage (respectively, the inductor current) is zero.

Tellegen's Theorem

A result that has far-reaching consequences in electrical engineering is Tellegen's theorem. It will be stated in terms of the networks shown in Fig. 3.20. These two are said to be topologically equivalent; that is, they are represented by the same graph but the components that constitute the branches of the graph are not necessarily the same in the two networks. they can even be nonlinear, as illustrated by the diode in one of the networks. Assuming all branches have standard references, including the source branches, Tellegen's theorem states that

$$\begin{aligned} \sum_{\text{all } j} v_{bj} i_{aj} &= 0 \\ \mathbf{v}_b' \mathbf{i}_a &= 0 \end{aligned} \tag{3.3}$$

In the second line, the variables are vectors and the prime stands for the transpose. The a and b subscripts refer to the two networks.

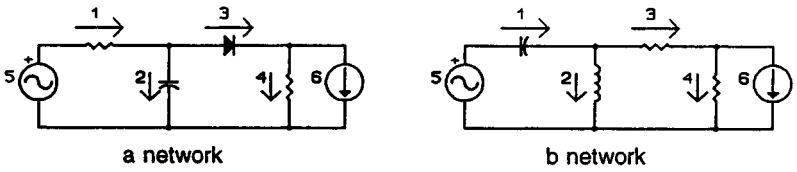

FIGURE 3.20 Topologically equivalent networks.

This is an amazing result. It can be easily proved with the use of Kirchhoff's two laws.[1] The products of v and i are reminiscent of power as in Eq. (3.1). However, the product of the voltage of a branch in one network and the current of its topologically corresponding branch (which may not even be the same type of component) in another network does not constitute power in either branch. furthermore, the variables in one network might be functions of time, while those of the other network might be steady-state phasors or Laplace transforms.

Nevertheless, some conclusions about power can be derived from Tellegen's theorem. Since a network is topologically equivalent to itself, the b network can be the same as the a network. In that case each vi product in Eq. (3.3) represents the power delivered to the corresponding branch, including the sources. The equation then says that if we add the power delivered to all the branches of a network, the result will be zero.

This result can be recast if the sources are separated from the other branches and one of the references of each source (current reference for each v-source and voltage reference for each i-source) is reversed. Then the vi product for each source, with new references, will enter Eq. (3.3) with a negative sign and will represent the power supplied by this source. When these terms are transposed to the right side of the equation, their signs are changed. The new equation will state in mathematical form that

> In any electrical network, the sum of the power supplied by the sources is equal to the sum of the power delivered to all the nonsource branches.

This is not very surprising since it is equivalent to the law of conservation of energy, a fundamental principle of science.

AC Steady-State Power

Let us now consider the ac steady-state case, where all voltages and currents are sinusoidal. Thus, in the two-terminal circuit of Fig. 3.19:

$$\begin{aligned} v(t) &= \sqrt{2}\,|V|\cos(\omega t + \alpha) \leftrightarrow V = |V|\,e^{j\alpha} \\ i(t) &= \sqrt{2}\,|I|\cos(\omega t + \beta) \leftrightarrow I = |I|\,e^{j\beta} \end{aligned} \tag{3.4}$$

The capital V and I are phasors representing the voltage and current, and their magnitudes are the corresponding rms values. The power delivered to the network at any instant of time is given by:

$$\begin{aligned} p(t) &= v(t)i(t) = 2\,|V|\,|I|\cos(\omega t + \alpha)\cos(\omega t + \beta) \\ &= \Big[|V|\,|I|\cos(\alpha - \beta)\Big] + \Big[|V|\,|I|\cos(2\omega t + \alpha + \beta)\Big] \end{aligned} \tag{3.5}$$

The last form is obtained by using trigonometric identities for the sum and difference of two angles. Whereas both the voltage and the current are sinusoidal, the instantaneous power contains a constant term (independent

[1]See, for example, N. Balabanian and T. A. Bickart, *Linear Network Theory,* Matrix Publishers, Chesterland, Ohio, 1981, chap. 9.

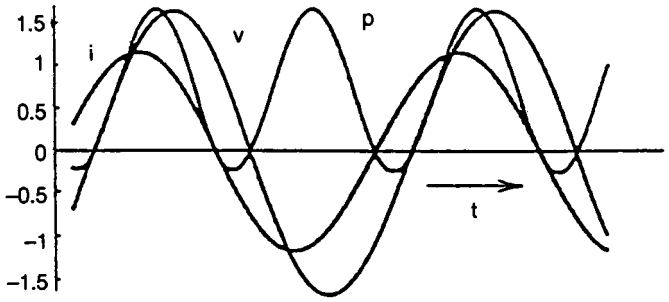

FIGURE 3.21 Instantaneous voltage, current, and power.

of time) in addition to a sinusoidal term. Furthermore, the frequency of the sinusoidal term is twice that of the voltage or current. Plots of *v*, *i*, and *p* are shown in Fig. 3.21 for specific values of α and β. The power is sometimes positive, sometimes negative. This means that power is sometimes delivered to the terminals and sometimes extracted from them.

The energy which is transmitted into the network over some interval of time is found by integrating the power over this interval. If the area under the positive part of the power curve were the same as the area under the negative part, the net energy transmitted over one cycle would be zero. For the values of α and β used in the figure, however, the positive area is greater, so there is a net transmission of energy toward the network. The energy flows back from the network to the source over part of the cycle, but on the average, more energy flows toward the network than away from it.

In Terms of RMS Values and Phase Difference

Consider the question from another point of view. The preceding equation shows the power to consist of a constant term and a sinusoid. The average value of a sinusoid is zero, so this term will contribute nothing to the net energy transmitted. Only the constant term will contribute. This constant term is the average value of the power, as can be seen either from the preceding figure or by integrating the preceding equation over one cycle. Denoting the average power by *P* and letting $\theta = \alpha - \beta$, which is the angle of the network impedance, the average power becomes:

$$\begin{aligned} P &= |V||I| \cos\theta \\ &= |V||I| \operatorname{Re}\left(e^{j\theta}\right) = \operatorname{Re}\left[|V||I| e^{j(\alpha-\beta)}\right] \\ &= \operatorname{Re}\left[\left(|V| e^{j\alpha}\right)\left(|I| e^{-j\beta}\right)\right] \\ &= \operatorname{Re}\left(VI^*\right) \end{aligned} \tag{3.6}$$

The third line is obtained by breaking up the exponential in the previous line by the law of exponents. The first factor between square brackets in this line is identified as the phasor voltage and the second factor as the conjugate of the phasor current. The last line then follows. It expresses the average power in terms of the voltage and current phasors and is sometimes more convenient to use.

Complex and Reactive Power

The average ac power is found to be the real part of a complex quantity VI^*, labeled *S*, that in rectangular form is

$$\begin{aligned} S = VI^* &= |V||I| e^{j\theta} = |V||I| \cos\theta + j|V||I| \sin\theta \\ &= P + jQ \end{aligned} \tag{3.7}$$

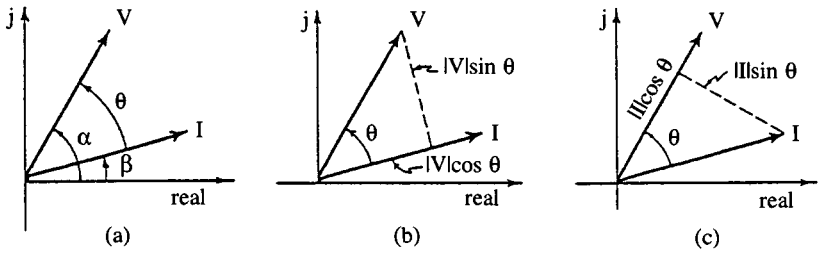

FIGURE 3.22 In-phase and quadrature components of V and I.

where

$$P = |V||I|\cos\theta \quad (a)$$
$$Q = |V||I|\sin\theta \quad (b) \qquad (3.8)$$
$$|S| = |V||I| \quad (c)$$

We already know P to be the average power. Since it is the real part of some complex quantity, it would be reasonable to call it the **real power**. The complex quantity S of which P is the real part is, therefore, called the *complex power*. Its magnitude is the product of the rms values of voltage and current: $|S| = |V|\,|I|$. It is called the *apparent power* and its unit is the volt-ampere (VA). To be consistent, then we should call Q the *imaginary power*. This is not usually done, however; instead, Q is called the **reactive power** and its unit is a VAR (volt-ampere reactive).

Phasor and Power Diagrams

An interpretation useful for clarifying and understanding the preceding relationships and for the calculation of power is a graphical approach. Figure 3.22(a) is a phasor diagram of V and I in a particular case. The phasor voltage can be resolved into two components, one parallel to the phasor current (or in phase with I) and another perpendicular to the current (or in quadrature with it). This is illustrated in Fig. 3.22(b). Hence, the average power P is the magnitude of phasor I multiplied by the in-phase component of V; the reactive power Q is the magnitude of I multiplied by the quadrature component of V.

Alternatively, one can imagine resolving phasor I into two components, one in phase with V and one in quadrature with it, as illustrated in Fig. 3.22(c). Then P is the product of the magnitude of V with the in-phase component of I, and Q is the product of the magnitude of V with the quadrature component of I. Real power is produced only by the in-phase components of V and I. The quadrature components contribute only to the reactive power.

The in-phase or quadrature components of V and I do not depend on the specific values of the angles of each, but on their phase difference. One can imagine the two phasors in the preceding diagram to be rigidly held together and rotated around the origin by any angle. As long as the angle θ is held fixed, all of the discussion of this section will still apply. It is common to take the current phasor as the reference for angle; that is, to choose $\beta = 0$ so that phasor I lies along the real axis. Then $\theta = \alpha$.

Power Factor

For any given circuit it is useful to know what part of the total complex power is real (average) power and what part is reactive power. This is usually expressed in terms of the **power factor** F_p, defined as the ratio of real power to apparent power:

$$\text{Power factor} \doteq F_p = \frac{P}{|S|} = \frac{P}{|V||I|} \qquad (3.9)$$

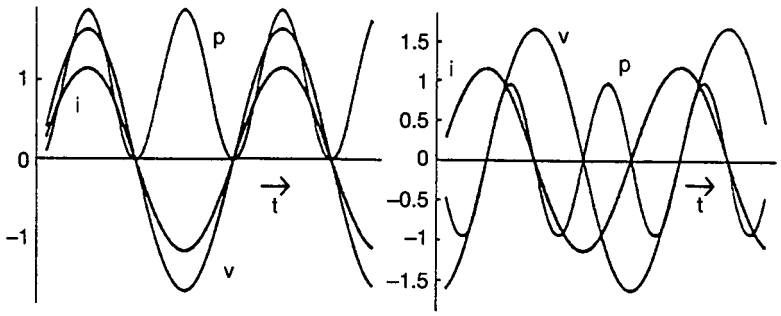

FIGURE 3.23 Power waveform for unity and zero power factors.

Not counting the right side, this is a general relationship, although we developed it here for sinusoidal excitations. With $P = |V||I|\cos\theta$, we find that the power factor is simply $\cos\theta$. Because of this, θ itself is called the power factor angle.

Since the cosine is an even function [$\cos(-\theta) = \cos\theta$], specifying the power factor does not reveal the sign of θ. Remember that θ is the angle of the impedance. If θ is positive, this means that the current lags the voltage; we say that the power factor is a *lagging* power factor. On the other hand, if θ is negative, the current leads the voltage and we say this represent a *leading* power factor.

The power factor will reach its maximum value, unity, when the voltage and current are in phase. This will happen in a purely resistive circuit, of course. It will also happen in more general circuits for specific element values and a specific frequency.

We can now obtain a physical interpretation for the reactive power. When the power factor is unity, the voltage and current are in phase and $\sin\theta = 0$. Hence, the reactive power is zero. In this case, the instantaneous power is never negative. This case is illustrated by the current, voltage, and power waveforms in Fig. 3.23; the power curve never dips below the axis, and there is no exchange of energy between the source and the circuit. At the other extreme, when the power factor is zero, the voltage and current are 90° out of phase and $\sin\theta = 1$. Now the reactive power is a maximum and the average power is zero. In this case, the instantaneous power is positive over half a cycle (of the voltage) and negative over the other half. All the energy delivered by the source over half a cycle is returned to the source by the circuit over the other half.

It is clear, then, that the reactive power is a measure of the exchange of energy between the source and the circuit without being used by the circuit. Although none of this exchanged energy is dissipated by or stored in the circuit, and it is returned unused to the source, nevertheless it is temporarily made available to the circuit by the source.[1]

Average Stored Energy

The average ac energy stored in an inductor or a capacitor can be established by using the expressions for the instantaneous stored energy for arbitrary time functions in Eq. (3.2), specifying the time function to be sinusoidal, and taking the average value of the result.

$$W_L = \frac{1}{2} L |I|^2 \qquad W_C = \frac{1}{2} C |V|^2 \tag{3.10}$$

[1]Power companies charge their industrial customers not only for the average power they use but for the reactive power they return. There is a reason for this. Suppose a given power system is to deliver a fixed amount of average power at a constant voltage amplitude. Since $P = |V||I|\cos\theta$, the current will be inversely proportional to the power factor. If the reactive power is high, the power factor will be low and a high current will be required to deliver the given power. To carry a large current, the conductors carrying it to the customer must be correspondingly larger and better insulated, which means a larger capital investment in physical plant and facilities. It may be cost effective for customers to try to reduce the reactive power they require, even if they have to buy additional equipment to do so.

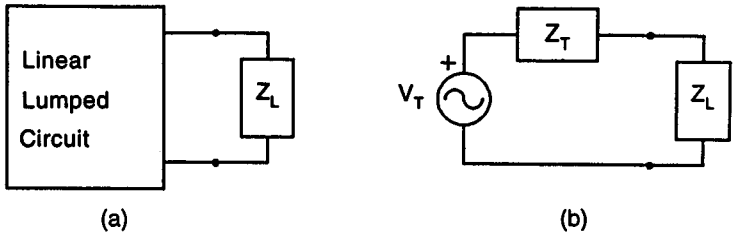

FIGURE 3.24 A linear circuit delivering power to a load in the steady state.

Application of Tellegen's Theorem to Complex Power

An example of two topologically equivalent networks was shown in Fig. 3.20. Let us now specify that two such networks are linear, all sources are same-frequency sinusoids, they are operating in the steady state, and all variables are phasors. Furthermore, suppose the two networks are the same, except that the sources of network *b* have phasors that are the complex conjugates of those of network *a*. Then, if **V** and **I** denote the vectors of branch voltages and currents of network *a*, Tellegen's theorem in Eq. (3.3) becomes:

$$\sum_{\text{all } j} \dot{V}_j^{\star} I_j = V^{\star} I = 0 \tag{3.11}$$

where $\mathbf{V}^{\star}$ is the conjugate transpose of vector **V**.

This result states that the sum of the complex power delivered to all branches of a linear circuit operating in the ac steady state is zero. Alternatively stated, the total complex power delivered to a network by its sources equals the sum of the complex power delivered to its nonsource branches. Again, this result is not surprising. Since, if a complex quantity is zero, both the real and imaginary parts must be zero, the same result can be stated for the average power and for the reactive power.

Maximum Power Transfer

The diagram in Fig. 3.24 illustrates a two-terminal linear circuit at whose terminals an impedance Z_L is connected. The circuit is assumed to be operating in the ac steady state. The problem to be addressed is this: given the two-terminal circuit, how can the impedance connected to it be adjusted so that the maximum possible average power is transferred from the circuit to the impedance?

The first step is to replace the circuit by its Thévenin equivalent, as shown in Fig. 3.24(b). The current phasor in this circuit is $I = V_T/(Z_T + Z_L)$. The average power transferred by the circuit to the impedance is:

$$\begin{aligned} P &= |I|^2 \,\text{Re}(Z_L) = \frac{|V_T|^2 \,\text{Re}(Z_L)}{|Z_T + Z_L|^2} \\ &= \frac{|V_T|^2 \, R_L}{(R_T + R_L)^2 + (X_T + X_L)^2} \end{aligned} \tag{3.12}$$

In this expression, only the load (that is, R_L and X_L) can be varied. The preceding equation, then, expresses a dependent variable (P) in terms of two independent ones (R_L and X_L).

What is required is to maximize *P*. For a function of more than one variable, this is done by setting the partial derivatives with respect to each of the independent variables equal to zero; that is, $\partial P/\partial R_L = 0$ and $\partial P/\partial X_L = 0$. Carrying out these differentiations leads to the result that maximum power will be transferred when the load impedance is the conjugate of the Thévenin impedance of the circuit: $Z_L = Z_T^{\star}$. If the Thévenin impedance is purely resistive, then the load resistance must equal the Thévenin resistance.

In some cases, both the load impedance and the Thévenin impedance of the source may be fixed. In such a case, the matching for maximum power transfer can be achieved by using a transformer, as illustrated in Fig. 3.25, where the impedances are both resistive. The transformer is assumed to be ideal, with turns ratio n. Maximum power is transferred if $n^2 = R_T/R_L$.

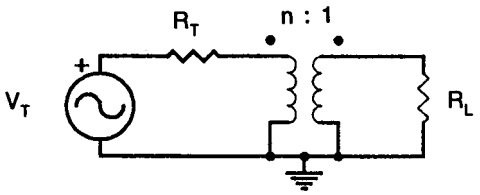

FIGURE 3.25 Matching with an ideal transformer.

Measuring AC Power and Energy

With ac steady-state average power given in the first line of Eq. (3.6), measuring the average power requires measuring the rms values of voltage and current, as well as the power factor. This is accomplished by the arrangement shown in Fig. 3.26, which includes a breakout of an electrodynamometer-type wattmeter. The current in the high-resistance pivoted coil is proportional to the voltage across the load. The current to the load and the pivoted coil together through the energizing coil of the electromagnet establishes a proportional magnetic field across the cylinder of rotation of the pivoted coil. the torque on the pivoted coil is proportional to the product of the magnetic field strength and the current in the pivoted coil. If the current in the pivoted coil is negligible compared to that in the load, then the torque becomes essentially proportional to the product of the voltage across the load (equal to that across the pivoted coil) and the current in the load (essentially equal to that through the energizing coil of the electromagnet). The dynamics of the pivoted coil together with the restraining spring, at ac power frequencies, ensures that the angular displacement of the pivoted coil becomes proportional to the average of the torque or, equivalently, the average power.

One of the most ubiquitous of electrical instruments is the induction-type watthour meter, which measures the energy delivered to a load. Every customer of an electrical utility has one, for example. In this instance the pivoted coil is replaced by a rotating conducting (usually aluminum) disk as shown in Fig. 3.27. An induced eddy current in the disk replaces the pivoted coil current interaction with the load-current-established magnetic field. After compensating for the less-than-ideal nature of the electrical elements making up the meter as just described, the result is that the disk rotates at a rate proportional to the average power to the load and the rotational count is proportional to the energy delivered to the load.

At frequencies above the ac power frequencies and, in some instances, at the ac power frequencies, electronic instruments are available to measure power and energy. They are not a cost-effective substitute for these meters in the monitoring of power and energy delivered to most of the millions upon millions of homes and businesses.

Defining Terms

AC steady-state power: Consider an ac source connected at a pair of terminals to an otherwise isolated network. Let $\sqrt{2}\cdot|V|$ and $\sqrt{2}\cdot|I|$ denote the peak values, respectively, of the ac steady-state voltage and current at the terminals. Furthermore, let θ denote the phase angle by which the voltage leads the current. Then the average power delivered by the source to the network would be expressed as $P = |V|\cdot|I|\cos(\theta)$.

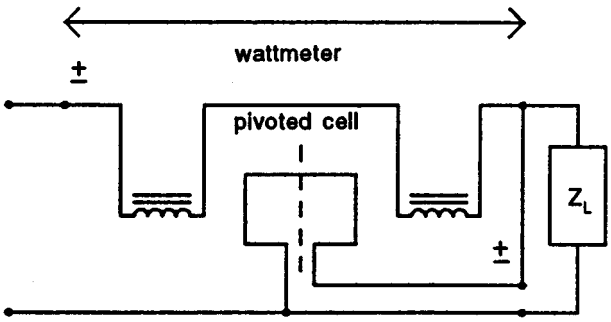

FIGURE 3.26 A wattmeter connected to a load.

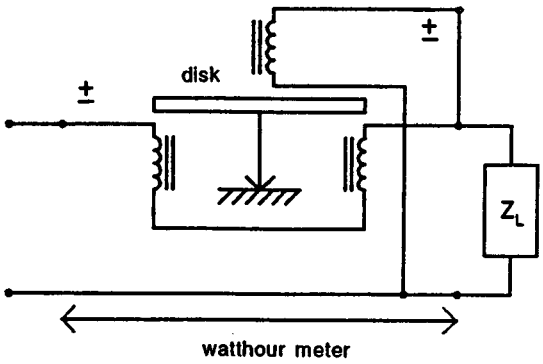

FIGURE 3.27 A watthour meter connected to a load.

Power and energy: Consider an electrical source connected at a pair of terminals to an otherwise isolated network. Power, denoted by p, is the time rate of change in the energy delivered to the network by the source. This can be expressed as $p = vi$, where v, the voltage across the terminals, is the energy expended per unit charge in moving the charge between the pair of terminals and i, the current through the terminals, is the time rate of charge motion.

Power factor: Consider an ac source connected at a pair of terminals to an otherwise isolated network. The power factor, the ratio of the real power to the apparent power $|V| \cdot |I|$, is easily established to be $\cos(\theta)$, where θ is the power factor angle.

Reactive power: Consider an ac source connected at a pair of terminals to an otherwise isolated network. The reactive power is a measure of the energy exchanged between the source and the network without being dissipated in the network. The reactive power delivered would be expressed as $Q = |V| \cdot |I| \sin(\theta)$.

Real power: Consider an ac source connected at a pair of terminals to an otherwise isolated network. The real power, equal to the average power, is the power dissipated by the source in the network.

Tellegen's theorem: Two networks, here including all sources, are topologically equivalent if they are similar structurally, component by component. Tellegen's theorem states that the sum over all products of the product of the current of a component of ne network, network a, and of the voltage of the corresponding component of the other network, network b, is zero. This would be expressed as $\Sigma_{\text{all } j}\, v_{bj}\, i_{aj} = 0$. From this general relationship it follows that in any electrical network, the sum of the power supplied by the sources is equal to the sum of the power delivered to all the nonsource components.

3.5 Three-Phase Circuits

Norman Balabanian

Figure 3.28(a) represents the basic circuit for considering the flow of power from a single sinusoidal source to a load. The power can be thought to cross an imaginary boundary surface (represented by the dotted line in the figure) separating the source from the load. Suppose that:

$$\begin{aligned} v(t) &= \sqrt{2}\,|V|\cos(\omega t + \alpha) \\ i(t) &= \sqrt{2}\,|I|\cos(\omega t + \beta) \end{aligned} \tag{3.13}$$

Then the power to the load at any instant of time is

$$p(t) = |V||I|\,[\cos(\alpha - \beta) + \cos\,(2\omega t + \alpha + \beta)] \tag{3.14}$$

The instantaneous power has a constant term and a sinusoidal term at twice the frequency. The quantity in brackets fluctuates between a minimum value of $\cos(\alpha - \beta) - 1$ and a maximum value of $\cos(\alpha - \beta) + 1$. This fluctuation of power delivered to the load has certain disadvantages in some situations where the transmission of power is the purpose of a system. An electric motor, for example, operates by receiving electric power and transmitting mechanical (rotational) power at its shaft. If the electric power is delivered to the motor in spurts, the motor is likely to vibrate. In order to run satisfactorily, a physically larger motor will be needed, with a larger shaft and flywheel, to provide inertia than would be the case if the delivered power were constant.

This problem is overcome in practice by the use of what is called a *three-phase* system. This section will provide a brief discussion of three-phase systems.

Consider the circuit in Fig. 3.28(b). This arrangement is similar to a combination of three of the simple circuits in Fig. 3.28(a) connected in such a way that each one shares the return connection from *O* to *N*. The three sources can be viewed collectively as a single source and the three loads—which are assumed to be

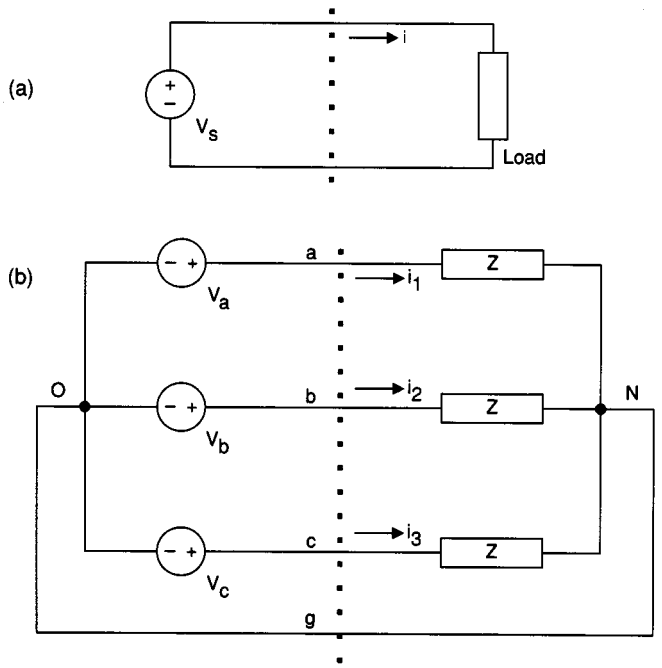

FIGURE 3.28 Flow of power from source to load.

identical—can be viewed collectively as a single load. Then, as before, the dotted line represents a surface separating the source from the load. Each of the individual sources and loads is referred to as one *phase* of the three-phase system.

The three sources are assumed to have the same frequency; they are said to be *synchronized*. It is also assumed that the three voltages have the same rms values and the phase difference between each pair of voltages is ±120° (2π/3 rad). Thus, they can be written:

$$\begin{aligned} v_a &= \sqrt{2}\,|V|\cos(\omega t + \alpha_1) \quad \leftrightarrow \quad V_a = |V|\,e^{j0^\circ} \\ v_b &= \sqrt{2}\,|V|\cos(\omega t + \alpha_2) \quad \leftrightarrow \quad V_b = |V|\,e^{-j120^\circ} \\ v_c &= \sqrt{2}\,|V|\cos(\omega t + \alpha_3) \quad \leftrightarrow \quad V_c = |V|\,e^{j120^\circ} \end{aligned} \tag{3.15}$$

The **phasors** representing the sinusoids have also been shown. For convenience, the angle of v_a has been chosen as the reference for angles; v_b *lags* v_a by 120° and v_c *leads* v_a by 120°.

Because the loads are identical, the rms values of the three currents shown in the figure will also be the same and the phase difference between each pair of them will be ±120°. Thus, the currents can be written:

$$\begin{aligned} i_1 &= \sqrt{2}\,|I|\cos(\omega t + \beta_1) \leftrightarrow I_1 = |I|\,e^{j\beta_1} \\ i_2 &= \sqrt{2}\,|I|\cos(\omega t + \beta_2) \leftrightarrow I_2 = |I|\,e^{j(\beta_1 - 120^\circ)} \\ i_3 &= \sqrt{2}\,|I|\cos(\omega t + \beta_3) \leftrightarrow I_3 = |I|\,e^{j(\beta_1 + 120^\circ)} \end{aligned} \tag{3.16}$$

Perhaps a better form for visualizing the voltages and currents is a graphical one. Phasor diagrams for the voltages separately and the currents separately are shown in Fig. 3.29. The value of angle β_1 will depend on the load. An interesting result is clear from these diagrams. First, V_2 and V_3 are each other's conjugates. So if we add them, the imaginary parts cancel and the sum will be real, as illustrated by the construction in the voltage diagram. Furthermore, the construction shows that this real part is negative and equal in size to V_1. Hence, the sum of the three voltages is zero. The same is true of the sum of the three currents, as can be established graphically by a similar construction.

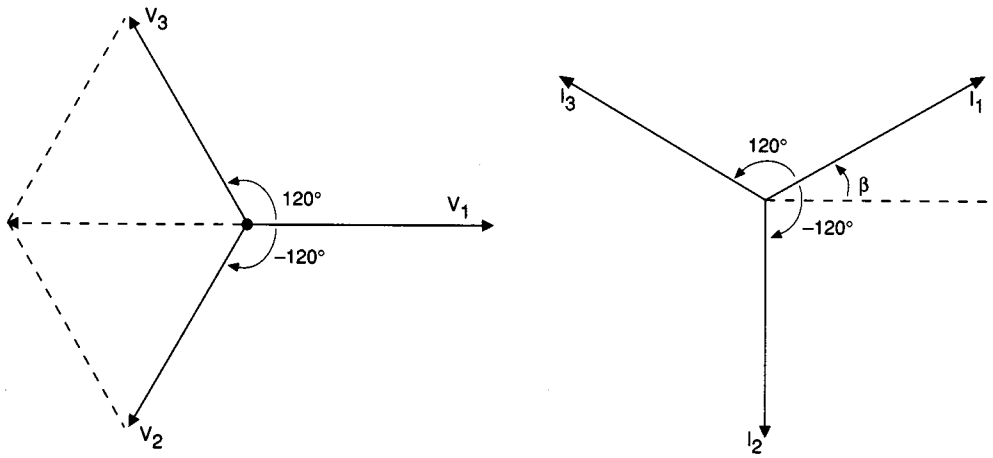

FIGURE 3.29 Voltage and current phasor diagrams.

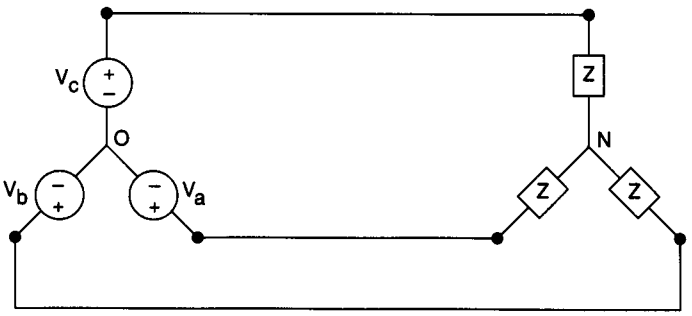

FIGURE 3.30 Wye-connected three-phase system.

By Kirchhoff's current law applied at node *N* in Fig. 3.28(b), we find that the current in the return line is the sum of the three currents in Eq. (3.16). However, since this sum was found to be zero, the return line carries no current. Hence it can be removed entirely without affecting the operation of the system. The resulting circuit is redrawn in Fig. 3.30. Because of its geometrical form, this connection of both the sources and the loads is said to be a wye (Y) connection.

The instantaneous power delivered by each of the sources has the form given in Eq. (3.14), consisting of a constant term representing the average power and a double-frequency sinusoidal term. The latter, being sinusoidal, can be represented by a phasor also. The only caution is that a different frequency is involved here, so this power phasor should not be mixed with the voltage and current phasors in the same diagram or calculations. Let $|S| = |V||I|$ be the apparent power delivered by each of the three sources and let the three power phasors be S_a, S_b, and S_c, respectively. Then:

$$\begin{aligned} S_a &= |S|\, e^{j(\alpha_1+\beta_1)} = |S|\, e^{j\beta_1} \\ S_b &= |S|\, e^{j(\alpha_2+\beta_2)} = |S|\, e^{j(-120°+\beta_1-120°)} = |S|\, e^{j(\beta_1+120°)} \\ S_c &= |S|\, e^{j(\alpha_3+\beta_3)} = |S|\, e^{j(+120°+\beta_1+120°)} = |S|\, e^{j(\beta_1-120°)} \end{aligned} \tag{3.17}$$

It is evident that the phase relationships among these three phasors are the same as the ones among the voltages and the currents. That is, the second leads the first by 120° and the third lags the first by 120°. Hence, just like the voltages and the currents, the sum of these three phasors will also be zero. This is a very significant result. Although the instantaneous power delivered by each source has a constant component and a sinusoidal component, when the three powers are added, the sinusoidal components add to zero, leaving only the constants. Thus, the total power delivered to the three loads is constant.

To determine the value of this constant power, use Eq. (3.14) as a model. The contribution of the *k*th source to the total (constant) power is $|S| \cos(\alpha_k - \beta_k)$. One can easily verify that $\alpha_k - \beta_k = \alpha_1 - \beta_1 = -\beta_1$. The first equality follows from the relationships among the α's from Eq. (3.15) and among the β's from Eq. (3.16). The choice of $\alpha_1 = 0$ leads to the last equality. Hence, the constant terms contributed to the power by each source are the same. If *P* is the total average power, then:

$$P = P_a + P_b + P_c = 3P_a = 3\,|V||I|\cos(\alpha_1 - \beta_1) \tag{3.18}$$

Although the angle α_1 has been set equal to zero, for the sake of generality we have shown it explicitly in this equation.

What has just been described is a *balanced* three-phase three-wire power system. The three sources in practice are not three independent sources but consist of three different parts of the same generator. The same is true

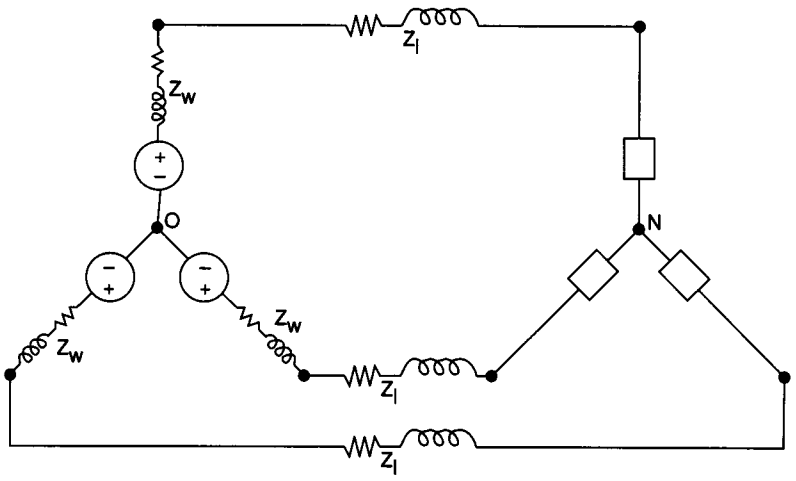

FIGURE 3.31 Three-phase circuit with nonzero winding and line impedances.

of the loads.[1] What has been described is ideal in a number of ways. First, the circuit can be *unbalanced*—for example, by the loads being somewhat unequal. Second, since the real devices whose ideal model is a voltage source are coils of wire, each source should be accompanied by a branch consisting of the coil inductance and resistance. Third, since the power station (or the distribution transformer at some intermediate point) may be at some distance from the load, the parameters of the physical line carrying the power (the line inductance and resistance) must also be inserted in series between the source and the load.

For an unbalanced system, the analysis of this section does not apply. An entirely new analytical technique is required to do full justice to such a system.[2] However, an understanding of balanced circuits is a prerequisite for tackling the unbalanced case.

The last two of the conditions that make the circuit less than ideal (line and source impedances) introduce algebraic complications, but nothing fundamental is changed in the preceding theory. If these two conditions are taken into account, the appropriate circuit takes the form shown in Fig. 3.31. Here the internal impedance of a source and the line impedance connecting that source to its load are both connected in series with the corresponding load. Thus, instead of the impedance in each phase being Z, it is $Z + Z_w + Z_l$, where w and l are subscripts standing for "winding" and "line," respectively. Hence, the rms value of each current is

$$|I| = \frac{|V|}{|Z + Z_w + Z_l|} \tag{3.19}$$

instead of $|V|/|Z|$. All other results we had arrived at remain unchanged. namely, that the sum of the phase currents is zero and that the sum of the phase powers is a constant. The detailed calculations simply become a little more complicated.

One other point, illustrated for the loads in Fig. 3.32, should be mentioned. Given wye-connected sources or loads, the wye and the **delta** can be made equivalent by proper selection of the arms of the delta. Thus,

[1]An ac power generator consists of (a) a rotor, which produces a magnetic field and which is rotated by a prime mover (say a turbine), and (b) a stator on which are wound one or more coils of wire. In three-phase systems, the number of coils is three. The rotating magnetic field induces a voltage in each of the coils. The 120° leading and lagging phase relationships among these voltages are obtained by distributing the conductors of the coils around the circumference of the stator so that they are separated geometrically by 120°. Thus, the three sources described in the text are in reality a single physical device, a single generator. Similarly, the three loads might be the three windings on a three-phase motor, again a single physical device.

[2]The technique for analyzing unbalanced circuits utilizes what are called *symmetrical components.*

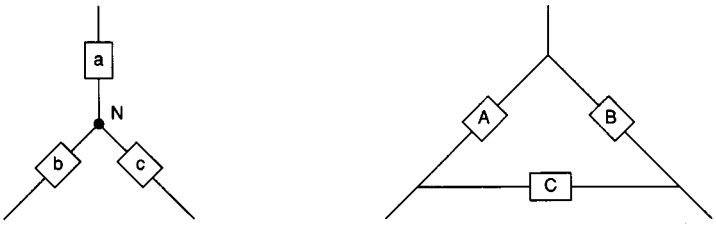

FIGURE 3.32 Wye connection and delta connection.

either the sources in Fig. 3.30 or the loads, or both, can be replaced by a delta equivalent; thus we can conceive of four different three-phase circuits; wye-wye, delta-wye, wye-delta, and delta-delta. Not only can we conceive of them, they are extensively used in practice.

It is not worthwhile to carry out detailed calculations for these four cases. Once the basic properties described here are understood, one should be able to make the calculations. Observe, however, that in the delta structure, there is no neutral connection, so the phase voltages cannot be measured. The only voltages that can be measured are the *line-to-line* or simply the *line* voltages. These are the differences of the phase voltages taken in pairs, as is evident from Fig. 3.31.

Defining Terms

Delta connection: The sources or loads in a three-phase system connected end-to-end, forming a closed path, like the Greek letter Δ.

Phasor: A complex number representing a sinusoid; its magnitude and angle are the rms value and phase of the sinusoid, respectively.

Wye connection: The three sources or loads in a three-phase system connected to have one common point, like the letter Y.

3.6 Graph Theory[1]

Shu-Park Chan

Topology is a branch of mathematics; it may be described as "the study of those properties of geometric forms that remain invariant under certain transformations, as bending, stretching, etc."[2] Network topology (or

[1]Based on S.-P. Chan, "Graph theory and some of its applications in electrical network theory," in *Mathematical Aspects of Electrical Network Analysis,* vol. 3, *SIAM/AMS Proceedings,* American Mathematical Society, Providence, R.I., 1971. With permission.

[2]This brief description of topology is quoted directly from the *Random House Dictionary of the English Language,* Random House, New York, 1967.

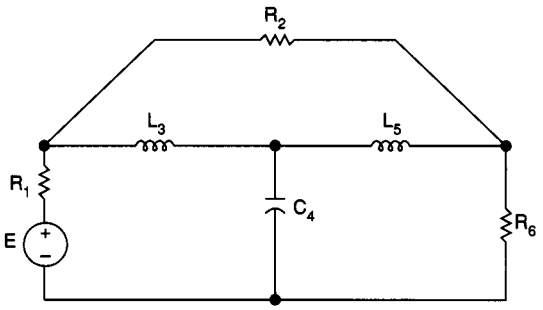

FIGURE 3.33 A passive network N with a voltage driver E.

network graph theory) is a study of (electrical) networks in connection with their nonmetric geometrical (namely topological) properties by investigating the interconnections between the branches and the nodes of the networks. Such a study will lead to important results in network theory such as algorithms for formulating network equations and the proofs of various basic network theorems [Chan, 1969; Seshu and Reed, 1961].

The following are some basic definitions in network graph theory, which will be needed in the development of topological formulas in the analysis of linear networks and systems.

A **linear graph** (or simply a *graph*) is a set of line segments called *edges* and points called *vertices*, which are the endpoints of the edges, interconnected in such a way that the edges are connected to (or *incident* with) the vertices. The *degree* of a vertex of a graph is the number of edges incident with that vertex.

A subset G_i of the edges of a given graph G is called a **subgraph** of G. If G_i does not contain all of the edges of G, it is a **proper subgraph** of G. A **path** is a subgraph having all vertices of degree 2 except for the two endpoints, which are of degree 1 and are called the *terminals* of the path. The set of all edges in a path constitutes a **path-set**. If the two terminals of a path coincide, the path is a closed path and is called a **circuit** (or **loop**). The set of all edges contained in a circuit is called a **circuit-set** (or **loop-set**).

A graph or subgraph is said to be **connected** if there is at least one path between *every* pair of its vertices. A **tree** of a connected graph G is a connected subgraph which contains all the vertices of G but no circuits. The edges contained in a tree are called the **branches of the tree**. A 2-tree of a connected graph G is a (proper) subgraph of G consisting of two unconnected circuitless subgraphs, each subgraph itself being connected, which together contain all the vertices of G. Similarly, a k-tree is a subgraph of k unconnected circuitless subgraphs, each subgraph being connected, which together include all the vertices of G. The **k-tree admittance product of a k-tree** is the product of the admittances of all the branches of the k-tree.

Example 3.5. The graph G shown in Fig. 3.34 is the graph of the network N of Fig. 3.33. The edges of G are e_1, e_2, e_4, e_5, and e_6; the vertices of G are V_1, V_2, and V_3, and V_4. A path of G is the subgraph G_1 consisting of edges e_2, e_3, and e_6 with vertices V_2 and V_4 as terminals. Thus, the set $\{e_2, e_3, e_6\}$ is a path-set. With edge e_4 added to G_1, we form another subgraph G_2, which is a circuit since as far as G_2 is concerned all its vertices are of degree 2. Hence the set $\{e_2, e_3, e_4, e_6\}$ is a circuit-set. Obviously, G is a connected graph since there exists a path between every pair of vertices of G. A tree of G may be the subgraph consisting of edges e_1, e_4, and e_6. Two other trees of G are $\{e_2, e_5, e_6\}$ and $\{e_3, e_4, e_5\}$. A 2-tree of G is $\{e_2, e_4\}$; another one is $\{e_3, e_6\}$; and still another one is $\{e_3, e_5\}$. Note that both $\{e_2, e_4\}$ and $\{e_3, e_6\}$ are subgraphs which obviously satisfy the definition of a 2-tree in the sense that each contains two disjoint circuitless connected subgraphs, both of which include all the four vertices of G. Thus, $\{e_3, e_5\}$ does not seem to be a 2-tree. However, if we agree to consider $\{e_3, e_5\}$ as a subgraph which contains edges e_3 and e_5 plus the isolated vertex V_4, we see that $\{e_3, e_5\}$ will satisfy the definition of a 2-tree since it now has two circuitless connected subgraphs with e_3 and e_5 forming one of them and the vertex V_4 alone forming the other. Moreover, both subgraphs together indeed

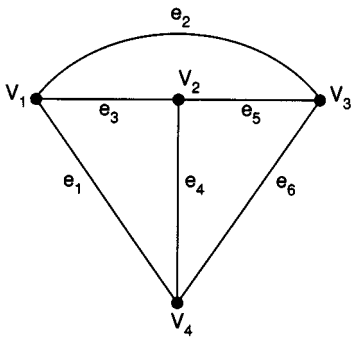

FIGURE 3.34 The graph G of the network N of Fig. 3.33.

include all the four vertices of G. It is worth noting that a 2-tree is obtained from a tree by removing *any one* of the branches from the tree; in general, a k-tree is obtained from a $(k-1)$ tree by removing from it any one of its branches. Finally, the tree admittance product of the tree $\{e_2, e_5, e_6\}$ is $\frac{1}{2}\frac{1}{5}\frac{1}{6}$; the 2-tree admittance product of the 2-tree $\{e_3, e_5\}$ is $\frac{1}{3}\frac{1}{5}$ (with the admittance of a vertex defined to be 1).

The *k*-Tree Approach

The development of the analysis of passive electrical networks using topological concepts may be dated back to 1847 when Kirchhoff formulated his set of topological formulas in terms of resistances and the branch-current system of equations. In 1892, Maxwell developed another set of topological formulas based on the k-tree concept, which are the duals of Kirchhoff's. These two sets of formulas were supported mainly by heuristic reasoning and no formal proofs were then available.

In the following we shall discuss only Maxwell's topological formulas for linear networks without mutual inductances.

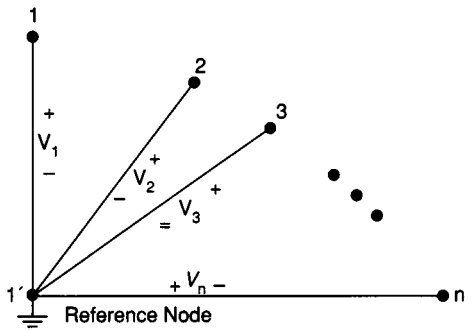

FIGURE 3.35 A network N with n independent nodes.

Consider a network N with n independent nodes as shown in Fig. 3.35. The node 1′ is taken as reference (datum) node. the voltages $V_1, V_2, \ldots, V_n$ (which are functions of s) are the transforms of the node-pair voltages (or simply node voltages) $v_1, v_2, \ldots, v_n$ (which are function s of t) between the n nodes and the reference node 1′ with the plus polarity marks at the n nodes. It can be shown [Aitken, 1956] that the matrix equation for the n independent nodes of N is given by

$$\begin{bmatrix} y_{11} & y_{12} & \cdots & y_{1n} \\ y_{21} & y_{22} & \cdots & y_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ y_{n1} & y_{n2} & \cdots & y_{nn} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ \vdots \\ V_n \end{bmatrix} = \begin{bmatrix} I_1 \\ I_2 \\ \vdots \\ I_n \end{bmatrix} \tag{3.20}$$

or, in abbreviated matrix notation,

$$Y_n V_n = I_n \tag{3.21}$$

where Y_n is the node admittance matrix, V_n the $n \times 1$ matrix of the node voltage transforms, and I_n the $n \times 1$ matrix of the transforms of the known current sources.

For a relaxed passive one-port (with zero initial conditions) shown in Fig. 3.36, the driving-point impedance function $Z_d(s)$ and its reciprocal, namely driving-point admittance function $Y_d(s)$, are given by

$$Z_d(s) = V_1/I_1 = \Delta_{11}/\Delta$$

and

$$Y_d(s) = 1/Z_d(s) = \Delta/\Delta_{11}$$

respectively, where Δ is the determinant of the node admittance matrix Y_n, and Δ_{11} is the (1,1)-cofactor of Δ.

Similarly, for a passive reciprocal *RLC* two-port (Fig. 3.37), the open-circuit impedances and the short-circuit admittances are seen to be

$$z_{11} = \Delta_{11}/\Delta \tag{3.22a}$$

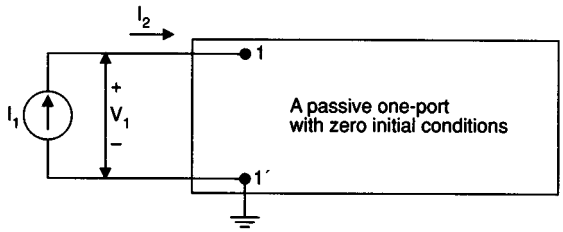

FIGURE 3.36 The network *N* driven by a single current source.

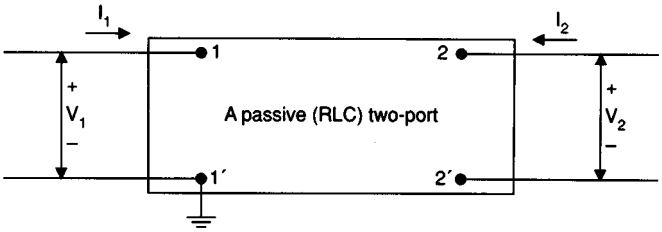

FIGURE 3.37 A passive two-port.

$$z_{12} = z_{21} = (\Delta_{12} - \Delta_{12'})/\Delta \qquad (3.22b)$$

$$z_{22} = (\Delta_{22} + \Delta_{2'2'} - 2\Delta_{22'})/\Delta \qquad (3.22c)$$

and

$$y_{11} = (\Delta_{22} + \Delta_{2'2'} - 2\Delta_{22'})/(\Delta_{1122} + \Delta_{112'2'} - 2\Delta_{1122'}) \qquad (3.23a)$$

$$y_{12} = y_{21} = \Delta_{12'} - \Delta_{12}/(\Delta_{1122} + \Delta_{112'2'} - 2\Delta_{1122'}) \qquad (3.23b)$$

$$y_{22} = \Delta_{11}/(\Delta_{1122} + \Delta_{112'2'} - 2\Delta_{1122'}) \qquad (3.23c)$$

respectively, where Δ_{ij} is the (i,j)-cofactor of Δ, and Δ_{ijkm} is the cofactor of Δ by deleting rows i and k and columns j and m from Δ [Aitken, 1956].

Expressions in terms of network determinants and cofactors for other network transfer functions are given by (Fig. 3.38):

$$z_{12} = \frac{V_2}{I_1} = \frac{\Delta_{12} - \Delta_{12'}}{\Delta} \qquad \text{(transfer impedance function)} \qquad (3.24a)$$

$$G_{12} = \frac{V_2}{V_1} = \frac{\Delta_{12} - \Delta_{12'}}{\Delta_{11}} \qquad \text{(voltage-ratio transfer function)} \qquad (3.24b)$$

$$Y_{12} = Y_L G_{12} = Y_L\left(\frac{\Delta_{12} - \Delta_{12'}}{\Delta_{11}}\right) \qquad \text{(transfer admittance function)} \qquad (3.24c)$$

$$\alpha_{12} = Y_1 Z_{12} = Y_L\left(\frac{\Delta_{12} - \Delta_{12'}}{\Delta}\right) \qquad \text{(current-ratio transfer function)} \qquad (3.24d)$$

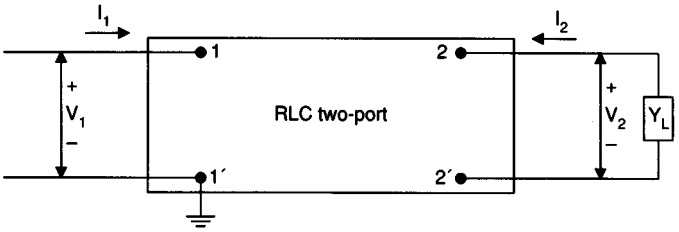

FIGURE 3.38 A loaded passive two-port.

The topological formulas for the various network functions of a passive one-port or two-port are derived from the following theorems which are stated without proof [Chan, 1969].

Theorem 3.1. Let N be a passive network without mutual inductances. The determinant Δ of the node admittance matrix Y_n is equal to the sum of all tree-admittances of N, where a tree-admittance product $t^{(i)}(y)$ is defined to be the product of the admittance of all the branches of the tree $T^{(i)}$. That is,

$$\Delta = \det Y_n = \sum_i T^{(i)}(y) \tag{3.25}$$

Theorem 3.2. Let Δ be the determinant of the node admittance matrix Y_n of a passive network N with $n + 1$ nodes and without mutual inductances. Also let the reference node be denoted by $1'$. Then the (j,j)-cofactor Δ_{jj} of Δ is equal to the sum of all the 2-tree-admittance products $T_{2j,1'}(y)$ of N, each of which contains node j in one part and node $1'$ as the reference node) and without mutual inductances is given by

$$\Delta_{jj} = \sum_k T^{(k)}_{2_{j,1'}}(y) \tag{3.26}$$

where the summation is taken over all the 2-tree-admittance products of the form $T_{2j,1'}(y)$.

Theorem 3.3. The (i,j)-cofactor Δ_{ij} of Δ of a relaxed passive network N with n independent nodes (with node $1'$ as the reference node) and without mutual inductances is given by

$$\Delta_{ij} = \sum_k T^{(k)}_{2_{ij,1'}}(y) \tag{3.27}$$

where the summation is taken over all the 2-tree-admittance products of the form $T_{2ij,1'}(y)$ with each containing nodes i and j in one connected port and the reference node $1'$ in the other.

For example, the topological formulas for the driving-point function of a passive one-port can be readily obtained from Eqs. (3.25) and (3.26) in Theorems 3.1 and 3.2 as stated in the next theorem.

Theorem 3.4. With the same notation as in Theorems 3.1 and 3.2, the driving-point admittance $Y_d(s)$ and the driving-point impedance $Z_d(s)$ of a passive one-port containing no mutual inductances at terminals 1 and $1'$ are given by

$$Y_d(s) = \frac{\Delta}{\Delta_{11}} = \frac{\sum_i T^{(i)}(y)}{\sum_k T^{(k)}_{2_{1,1}}(y)} \quad \text{and} \quad Z_d(s) = \frac{\Delta_{11}}{\Delta} = \frac{\sum_k T^{(k)}_{2_{1,1}}(y)}{\sum_i T^{(i)}(y)} \tag{3.28}$$

respectively.

For convenience we define the following shorthand notation:

$$(a)V(Y) \equiv \sum_i T^{(i)}(y) = \text{sum of all tree-admittance products, and}$$

$$(b)W_{j,r}(y) \equiv \sum_k T_{2\,j,r}(y) = \text{sum of all 2-tree-admittance products with node } j \text{ and the reference node } r \text{ contained in different parts.} \tag{3.29}$$

Thus Eq. (3.28) may be written as

$$Y_d(s) = V(Y)/W_{1,1'}(Y) \qquad \text{and} \qquad Z_d(s) = W_{1,1'}(Y)/V(Y) \tag{3.30}$$

In a two-port network N, there are four nodes to be specified, namely, 1 and 1′ at the input port (1,1′) and nodes 2 and 2′ at the output port (2,2′), as illustrated in Fig. 3.38. However, for a 2-tree of the type $T_{2\,ij,1'}$, only three nodes have been used, thus leaving the fourth one unidentified.

With very little effort, it can be shown that, in general, the following relationship holds:

$$W_{ij,1'}(Y) = W_{ijk,1'}(Y) + W_{ij,k1'}(Y)$$

or simply

$$W_{ij,1'} = W_{ijk,1'} + W_{ij,k1'} \tag{3.31}$$

where i, j, k, and 1′ are the four terminals of N with 1′ denoting the datum (reference) node. The symbol $W_{ijk,1'}$ denotes the sum of all the 2-tree-admittance products, each containing nodes i, j, and k in one connected part and the reference node, 1′, in the other.

We now state the next theorem.

Theorem 3.5. With the same hypothesis and notation as stated earlier in this section,

$$\Delta_{12} - \Delta_{12'} = W_{12,12'}(Y) - W_{12',1'2}(Y) \tag{3.32}$$

It is interesting to note that Eq. (3.32) is stated by Percival [1953] in the following descriptive fashion:

$$\Delta_{12} - \Delta_{12'} = W_{12,12'} - W_{12',1'2} = \left(\begin{array}{c} 1 \circ\!\!-\!\!-\!\!\circ\ 2 \\ \\ 1' \circ\!\!-\!\!-\!\!\circ\ 2' \end{array} \right) - \left(\begin{array}{c} 1 \circ \quad \circ\ 2 \\ \quad \times \\ 1' \circ \quad \circ\ 2' \end{array} \right)$$

which illustrates the two types of 2-trees involved in the formula. Hence, we state the topological formulas for z_{11}, z_{12}, and z_{22} in the following theorem.

Theorem 3.6. With the same hypothesis and notation as stated earlier in this section

$$z_{11} = W_{1,1'}(Y)/V(Y) \tag{3.33a}$$

$$z_{12} = z_{21} = \{W_{12,1'2'}(Y) - W_{12',1'2}(Y)\}/V(Y) \tag{3.33b}$$

$$z_{22} = W_{2,2'}(Y)/V(Y) \tag{3.33c}$$

We shall now develop the topological expressions for the short-circuit admittance functions. Let us denote by $U_{a,b,c}(Y)$ the sum of all 3-tree admittance products of the form $T_{3_{a,b,c}}(Y)$ with identical subscripts in both

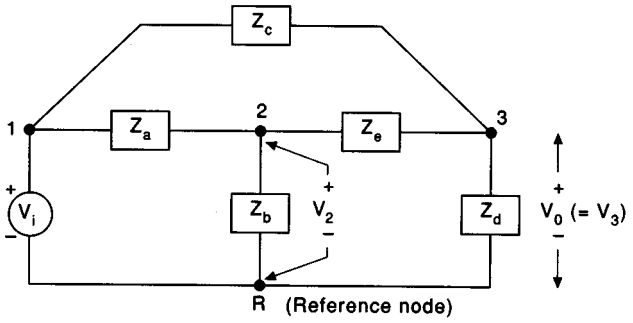

FIGURE 3.39 The network N of Example 3.7.

symbols to represent the same specified distribution of vertices. Then, following arguments similar to those of Theorem 3.5, we readily see that

$$\Delta_{1122} = \sum_i T^{(i)}_{3_{1,2,1'}}(y) \equiv U_{1,2,1'}(Y) \tag{3.34a}$$

$$\Delta_{112'2'} = \sum_j T^{(j)}_{3_{1,2',1'}}(y) \equiv U_{1,2',1'}(Y) \tag{3.34b}$$

$$\Delta_{1122'} = \sum_k T^{(k)}_{3_{1,22',1'}}(y) \equiv U_{1,22',1'}(U) \tag{3.34c}$$

where 1,1′,2,2′ are the four terminals of the two-port with 1′ denoting the reference node (Fig. 3.39). However, we note that in Eqs. (3.34a) and (3.34b) only three of the four terminals have been specified. We can therefore further expand $U_{1,2,1'}$ and $U_{1,2',1'}$ to obtain the following:

$$\Delta_{1122} + \Delta_{112'2'} - 2\Delta_{1122'} = U_{12',2,1'} + U_{1,2,1'2'} + U_{12,2',1'} + U_{1,2',1'2} \tag{3.35}$$

For convenience, we shall use the shorthand notation ΣU to denote the sum of the right of Eq. (3.35). Thus, we define

$$\sum U = U_{12',2,1'} + U_{1,2,1'2'} + U_{12,2',1'} + U_{1,2',1'2} \tag{3.36}$$

Hence, we obtain the topological formulas for the short-circuit admittances as stated in the following theorem.

Theorem 3.7. The short-circuit admittance functions y_{11}, y_{12}, and y_{22} of a passive two-port network with no mutual inductances are given by

$$y_{11} = W_{2,2'} \Big/ \sum U \tag{3.37a}$$

$$y_{12} = y_{21} = \left(W_{12,1'2} - W_{12,1'2'}\right) \Big/ \sum U \tag{3.37b}$$

$$y_{22} = W_{1,1'} \Big/ \sum U \tag{3.37c}$$

where ΣU is defined in Eq. (3.36) above.

Finally, following similar developments, other network functions are stated in Theorem 3.8.

Theorem 3.8. With the same notation as before,

$$Z_{12}(s) = \frac{W_{12,1'2'} \sqcap W_{12',1'2}}{V} \tag{3.38a}$$

$$G_{12}(s) = \frac{W_{12,1'2'} \sqcap W_{12',1'2}}{W_{1,1'}} \tag{3.38b}$$

$$Y_{12}(s) = Y_L \frac{W_{12,1'2'} \sqcap W_{12',1'2}}{W_{1,1'}} \tag{3.38c}$$

$$\alpha_{12}(s) = Y_L \frac{W_{12,1'2'} \sqcap W_{12',1'2}}{V} \tag{3.38d}$$

The Flowgraph Approach

Mathematically speaking, a linear electrical network or, more generally, a linear system can be described by a set of simultaneous linear equations. Solutions to these equations can be obtained either by the method of successive substitutions (elimination theory), by the method of determinants (Cramer's rule), or by any of the topological techniques such as Maxwell's *k*-tree approach discussed in the preceding subsection and the flowgraph techniques represented by the works of Mason [1953, 1956], and Coates [1959].

Although the methods using algebraic manipulations can be amended and executed by a computer, they do not reveal the physical situations existing in the system. The flowgraph techniques, on the other hand, show intuitively the causal relationships between the variables of the system of interest and hence enable the network analyst to have an excellent physical insight into the problem.

In the following, two of the more well-known flowgraph techniques are discussed, namely, the **signal-flowgraph** technique devised by Mason and the method based on the flowgraph of Coates and recently modified by Chan and Bapna [1967].

A *signal-flowgraph* G_m of a system S of n independent linear (algebraic) equations in n unknowns

$$\sum_{j=1}^{n} a_{ij} x_j = b_i \qquad i = 1, 2, \ldots, n \tag{3.39}$$

is a graph with junction points called *nodes* which are connected by directed line segments called *branches* with signals traveling along the branches only in the direction described by the arrows of the branches. A signal x_k traveling along a branch between x_k and x_j is multiplied by the gain of the branches g_{kj}, so that a signal of $g_{kj}x_k$ is delivered at node x_j. An *input node* (*source*) is a node which contains only outgoing branches; an *output node* (*sink*) is a node which has only incoming branches. A *path* is a continuous unidirectional succession of branches, all of which are traveling in the same direction; a *forward path* is a path from the input node to the output node along which all nodes are encountered exactly once; and a *feedback path* (*loop*) is a closed path which originates from and terminates at the same node, and along which all other nodes are encountered exactly once (the trivial case is a *self-loop* which contains exactly one node and one branch). A *path gain* is the product of all the branch gains of the path; similarly, a loop gain is the product of all the branch gains of the branches in a loop.

The procedure for obtaining the Mason graph from a system of linear algebraic equations may be described in the following steps:

a. Arrange all the equations of the system in such a way that the jth dependent (output) variable x_j in the jth equation is expressed explicitly in terms of the other variables. Thus, if the system under study is given by Eq. (3.39), namely

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2 \\ \vdots \quad\quad \vdots \quad\quad \vdots \quad\quad \vdots \quad\quad \vdots & \\ a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n &= b_n \end{aligned} \tag{3.40}$$

where $b_1, b_2, \ldots, b_n$ are inputs (sources) and $x_1, x_2, \ldots, x_n$ are outputs, the equations may be rewritten as

$$\begin{aligned} x_1 &= \frac{1}{a_{11}}b_1 - \frac{a_{12}}{a_{11}}x_2 - \frac{a_{13}}{a_{11}}x_3 - \cdots - \frac{a_{1n}}{a_{11}}x_n \\ x_2 &= \frac{1}{a_{22}}b_2 - \frac{a_{21}}{a_{22}}x_1 - \frac{a_{23}}{a_{22}}x_3 - \cdots - \frac{a_{2n}}{a_{22}}x_n \\ &\vdots \quad\quad \vdots \quad\quad \vdots \quad\quad \vdots \quad\quad \vdots \quad\quad \vdots \\ x_n &= \frac{1}{a_{nn}}b_n - \frac{a_{n1}}{a_{nn}}x_1 - \frac{a_{n2}}{a_{nn}}x_2 - \cdots - \frac{a_{n-1,n-1}}{a_{nn}}x_{n-1} \end{aligned} \tag{3.41}$$

b. The number of input nodes in the flowgraph is equal to the number of nonzero b's. That is, each of the source nodes corresponds to a nonzero b_j.
c. To each of the output nodes is associated one of the dependent variables $x_1, x_2, \ldots, x_n$.
d. The value of the variable represented by a node is equal to the sum of all the incoming signals.
e. The value of the variable represented by any node is transmitted onto all branches leaving the node.

It is a simple matter to write the equations from the flowgraph since every node, except the source nodes of the graph, represents an equation, and the equation associated with node k, for example, is obtained by equating to x_k the sum of all incoming branch gains multiplied by the values of the variables from which these branches originate.

Mason's general gain formula is now stated in the following theorem.

Theorem 3.9. Let G be the overall graph gain and G_k be the gain of the kth forward path from the source to the sink. Then

$$G = \frac{1}{\Delta}\sum_k G_k\Delta_k \tag{3.42}$$

where

$$\Delta = 1 - \sum_m p_{m1} + \sum_m p_{m2} - \sum_m p_{m3} + \cdots + (-1)^j \sum_m p_{mj}$$

p_{m1} = loop gain (the product of all the branch gains around a loop)
p_{m2} = product of the loop gains of the mth set of two nontouching loops
p_{m3} = product of the loop gains of the mth set of three nontouching loops, and in general

p_{mj} = product of the loop gains of the mth set of j nontouching loops
Δ_k = the value of Δ for that subgraph of the graph obtained by removing the kth forward path along with those branches touching the path

Mason's signal-flowgraphs constitute a very useful graphical technique for the analysis of linear systems. This technique not only retains the intuitive character of the block diagrams but at the same time allows one to obtain the gain between an input node and an output node of a signal-flowgraph by inspection. However, the derivation of the gain formula [Eq. (3.42)] is by no means simple, and, more importantly, if more than one input is present in the system, the gain cannot be obtained directly; that is, the principle of superposition must be applied to determine the gain due to the presence of more than one input. Thus, by slight modification of the conventions involved in Mason's signal-flowgraph, Coates [1959] was able to introduce the so-called "flowgraphs" which are suitable for direct calculation of gain.

Recently, Chan and Bapna [1967] further modified Coates's flowgraphs and developed a simpler gain formula based on the modified graphs. The definitions and the gain formula based on the modified Coates graphs are presented in the following discussion.

The **flowgraph G_l** (called the *modified Coates graph*) of a system S of n independent linear equations in n unknowns

$$\sum_{j=1}^{n} a_{ij}x_j = b_i \qquad i = 1, 2, \ldots, n$$

is an oriented graph such that the variable x_j in S is represented by a *node* (also denoted by x_j) in G_l, and the coefficient a_{ij} of the variable x_j in S by a *branch* with a branch gain a_{ij} connected between nodes x_i and x_j in G_l and directed from x_j to x_i. Furthermore, a *source node* is included in G_l such that for each constant b_k in S there is a node with gain b_k in G_l from node 1 to node s_k. *Graph* G_{l0} is the subgraph of G_l obtained by deleting the source node l and all the branches connected to it. Graph G_{ij} is the subgraph of G_l obtained by first removing all the outgoing branches from node x_j and then short-circuiting node l to node x_j. A *loop set* l is a subgraph of G_{l0} that contains all the nodes of G_{l0} with each node having exactly one incoming and one outgoing branch. The product p of the gains of all the branches in l is called a *loop-set product.* A 2-*loop-set* I_2 is a subgraph of G_{lj} containing all the nodes of G_{lj} with each node having exactly one incoming and one outgoing branch. The product p_2 of the gains of all the branches in l_2 is called a 2-*loop-set product.*

The modified Coates gain formula is now stated in the following theorem.

Theorem 3.10. In a system of n independent linear equations in n unknowns

$$a_{ij}x_j = b_i \qquad i = 1, 2, \ldots, n$$

the value of the variable x_j is given by

$$x_j = \sum_{(\text{all } p_2)} (-1)^{N_{l_2}} p_2 \Bigg/ \sum_{(\text{all } p_2)} (-1)^{N_l} p \tag{3.43}$$

where N_{l_2} is the number of loops in a 2-loop-set l_2 and N_l is the number of loops in a loop set l.

Since both the Mason graph G_m and the modified Coates graph G_l are topological representations of a system of equations it is logical that certain interrelationships exist between the two graphs so that one can be transformed into the other. Such interrelationships have been noted [Chan, 1969], and the transformations are briefly stated as follows:

A. *Transformation of G_m into G_l.* Graph G_m can be transformed into an equivalent Coates graph G_l (representing an equivalent system of equations) by the following steps:

a. Subtract 1 from the gain of each existing self-loop.
b. Add a self-loop with a gain of –1 to each branch devoid of self-loop.
c. Multiply by $-b_k$ the gain of the branch at the kth source node b_k ($k = 1, 2, \ldots, r$, r being the number of source nodes) and then combine all the (r) nodes into one source node (now denoted by 1).

B. *Transformation of G_l into G_m.* Graph G_l can be transformed into G_m by the following steps:
a. Add 1 to the gain of each existing self-loop.
b. Add a self-loop with a gain of 1 to each node devoid of self-loop except the source node l.
c. Break the source node l into r source nodes (r being the number of branches connected to the source node l before breaking), and identify the r new sources nodes by $b_1, b_2, \ldots, b_r$, with the gain of the corresponding r branches multiplied by $-1/b_1, -1/b_2, \ldots, -1/b_r$, respectively, so that the new gains of these branches are all equal to l, keeping the edge orientations unchanged.

The gain formulas of Mason and Coates are the classical ones in the theory of flowgraphs. From the systems viewpoint, the Mason technique provides an excellent physical insight as one can visualize the signal flow through the subgraphs (forward paths and feedback loops) of G_m. The graph reduction technique based on the Mason graph enables one to obtain the gain expression using a step-by-step approach and at the same time observe the cause-and-effect relationships in each step. However, since the Mason formula computes the ratio of a specified output over *one* particular input, the principle of superposition must be used in order to obtain the overall gain of the system if more than one input is present. The Coates formula, on the other hand, computes the output directly regardless of the number of inputs present in the system, but because of such a direct computation of a given output, the graph reduction rules of Mason cannot be applied to a Coates graph since the Coates graph is *not* based on the same cause-effect formulation of equations as Mason's.

The *k*-Tree Approach Versus the Flowgraph Approach

When a linear network is given, loop or node equations can be written from the network, and the analysis of the network can be accomplished by means of either Coates's or Mason's technique.

However, it has been shown [Chan, 1969] that if the Maxwell k-tree approach is employed in solving a linear network, the redundancy inherent either in the direct expansion of determinants or in the flowgraph techniques described above can be either completely eliminated for passive networks or greatly reduced for active networks. This point and others will be illustrated in the following example.

Example 3.7. Consider the network N as shown in Fig. 3.39. Let us determine the voltage gain, $G_{12} = V_0/V_1$, using (1) Mason's method, (2) Coates's method, and (3) the k-tree method.

The two node equations for the network are given by

$$\begin{aligned} \text{for node 2:} \quad & (Y_a + Y_b + Y_e)V_2 + (-Y_3)V_0 = Y_a V_i \\ \text{for node 3:} \quad & (-Y_e)V_2 + (Y_c + Y_d + Y_e)V_0 = Y_c V_i \end{aligned} \tag{3.44}$$

where

$$Y_a = 1/Z_a,\ Y_b = 1/Z_b,\ Y_c = 1/Z_c,\ Y_d = 1/Z_d \text{ and } Y_e = 1/Z_e$$

(1) *Mason's approach.* Rewrite the system of two equations (3.44) as follows:

$$\begin{aligned} V_2 &= \left(\frac{Y_a}{Y_a + Y_b + Y_e}\right)V_i + \left(\frac{Y_e}{Y_a + Y_b + Y_e}\right)V_0 \\ V_0 &= \left(\frac{Y_c}{Y_c + Y_d + Y_e}\right)V_i + \left(\frac{Y_e}{Y_c + Y_d + Y_e}\right)V_2 \end{aligned} \tag{3.45}$$

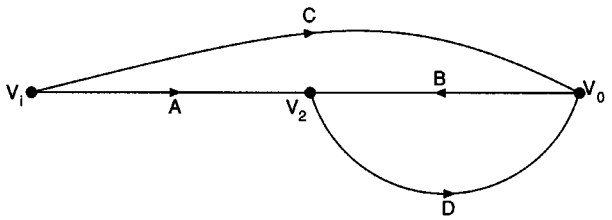

FIGURE 3.40 The Mason graph of *N*.

or

$$V_2 = AV_i + BV_0 \quad V_0 = CV_i + DV_2 \tag{3.46}$$

where

$$A = \frac{Y_a}{Y_a + Y_b + Y_e} \qquad B = \frac{Y_e}{Y_a + Y_b + Y_e}$$
$$C = \frac{Y_c}{Y_c + Y_d + Y_e} \qquad D = \frac{Y_e}{Y_c + Y_d + Y_e}$$

The Mason graph of system (3.46) is shown in Fig. 3.40, and according to the Mason graph formula (3.42), we have

$$\Delta = 1 - BD$$
$$G_C = C \quad \Delta_C = 1$$
$$G_{AD} = AD \quad \Delta_{AD} = 1$$

and hence

$$G_{12} = \frac{V_0}{V_1} = \frac{1}{\Delta}\sum_k G_k\Delta_k = \frac{1}{1 - BD}(C + AD)$$
$$= \frac{Y_c/(Y_c + Y_d + Y_e) + Y_a/(Y_a + Y_b + Y_e)(Y_c + Y_d + Y_e)}{1 - Y_e^2/(Y_a + Y_b + Y_e)(Y_c + Y_d + Y_e)}$$

Upon cancellation and rearrangement of terms

$$G_{12} = \frac{Y_aY_c + Y_aY_e + Y_bY_c + Y_cY_e}{Y_aY_c + Y_aY_d + Y_aY_e + Y_bY_c + Y_bY_d + Y_bY_e + Y_cY_e + Y_dY_e} \tag{3.47}$$

(2) *Coates's approach.* From (3.44) we obtain the Coates graphs G_l, G_{l0}, and G_{l3} as shown in Fig. 3.41(a), (b), and (c), respectively. The set of all loop-sets of G_{l0} is shown in Fig. 3.42, and the set of all 2-loop-sets of G_{l3} is shown in Fig. 3.43. Thus, by Eq. (3.43),

$$V_0 = \frac{\sum_{(\text{all } p_2)}(-1)^{N_{l_2}}p_2}{\sum_{(\text{all } p)}(-1)^{N_l}p} = \frac{(-1)^1(-Y_e)(Y_aV_i) + (-1)^2(Y_a + Y_b + Y_e)(Y_cV_i)}{(-1)^1(-Y_e)(-Y_e) + (-1)^2(Y_a + Y_b + Y_e)(Y_c + Y_d + Y_e)}$$

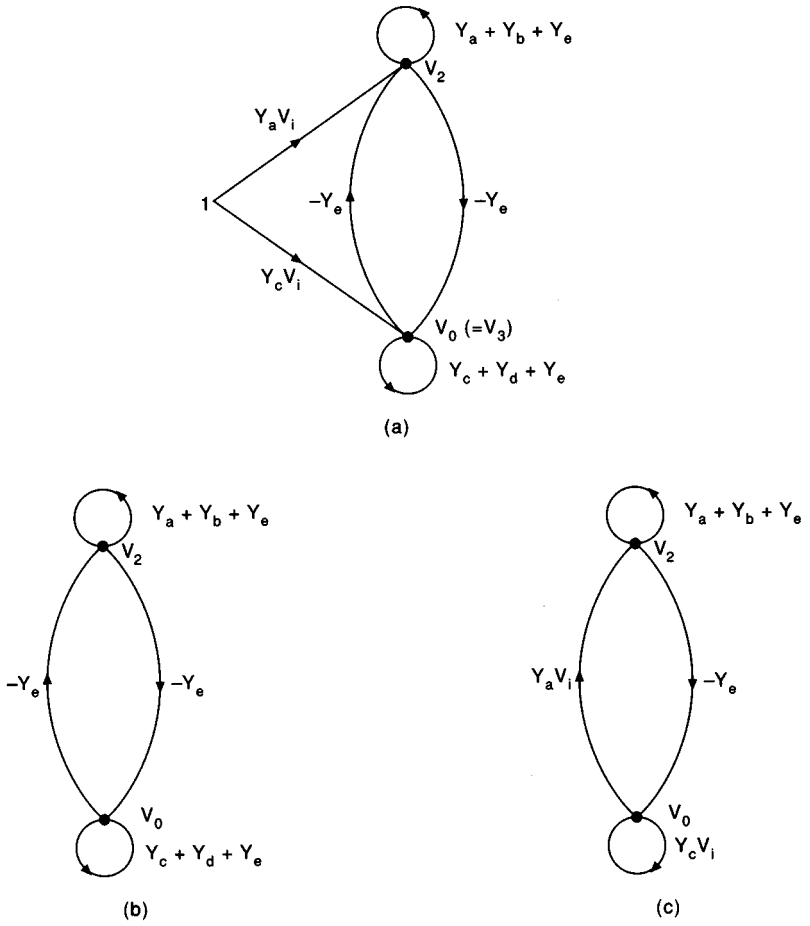

FIGURE 3.41 The Coates graphs: (a) G_l, (b) G_{l0}, and (c) G_{l3}.

Or, after simplification, we find

$$V_0 = \frac{(Y_aY_c + Y_aY_e + Y_bY_c + Y_cY_e)V_i}{Y_aY_c + Y_aY_d + Y_aY_e + Y_bY_c + Y_bY_d + Y_bY_e + Y_cY_e + Y_dY_e} \tag{3.48}$$

which gives the same ratio V_0/V_i as Eq. (3.47).

(3) *The k-tree approach.* Recall that the gain formula for V_0/V_i using the k-tree approach is given [Chan, 1969] by

$$\frac{V_0}{V_i} = \frac{\Delta_{13}}{\Delta_{11}} = \frac{W_{13,R}}{W_{1,R}} = \frac{\sum\left(\begin{array}{l}\text{all 2-tree admittance products with nodes 1 and 3 in one part}\\ \text{and the reference node } R \text{ in the other part of each of such 2-tree}\end{array}\right)}{\sum\left(\begin{array}{l}\text{all 2-tree admittance products with node 1 in one part and}\\ \text{the reference node } R \text{ in the other part of each of such 2-tree}\end{array}\right)} \tag{3.49}$$

where Δ_{13} and Δ_{11} are cofactors of the determinant Δ of the node admittance matrix of the network. Furthermore, it is noted that the 2-trees corresponding to Δ_{ii} may be obtained by finding all the trees of the modified graph G_i, which is obtained from the graph G of the network by short-circuiting node i (i being any node other than

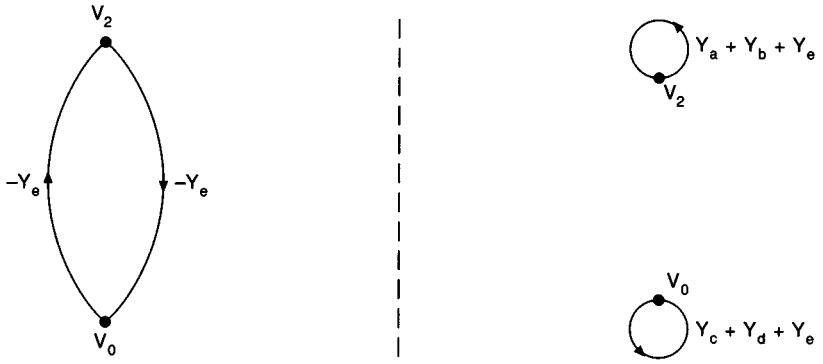

FIGURE 3.42 The set of all loop-sets of G_{l0}.

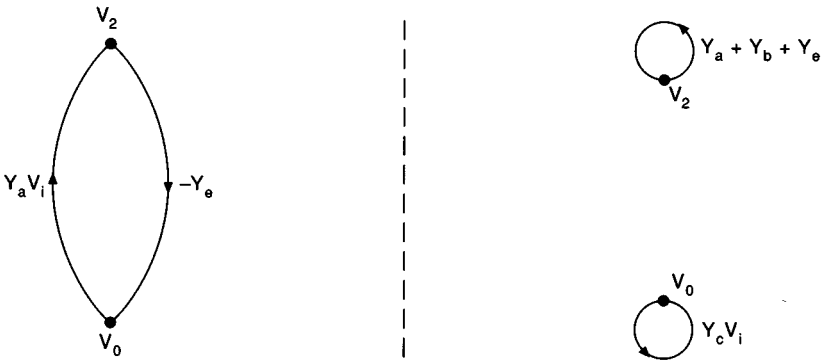

FIGURE 3.43 The set of all 2-loop-sets of G_{l3}.

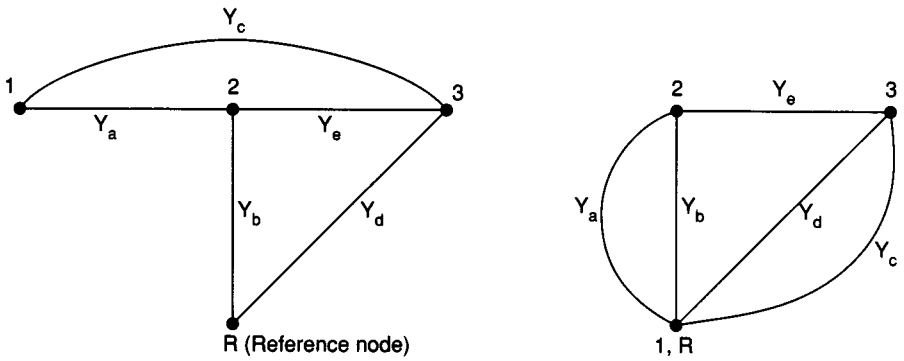

FIGURE 3.44 (a) Graph G, and (b) the modified graph G_l of G.

R) to the reference node R, and that the 2-trees corresponding to Δ_{ij} can be found by taking all those 2-trees each of which is a tree of both G_i and G_j [Chan, 1969]. Thus, for Δ_{11}, we first find G and G_1 (Fig. 3.44), and then find the set S_1 of all trees of G_1 (Fig. 3.45); then for Δ_{13}, we find G_3 (Fig. 3.46) and the set S_3 of all trees of G_3 (Fig. 3.47) and then from S_1 and S_3 we find all the terms common to both sets (which correspond to the

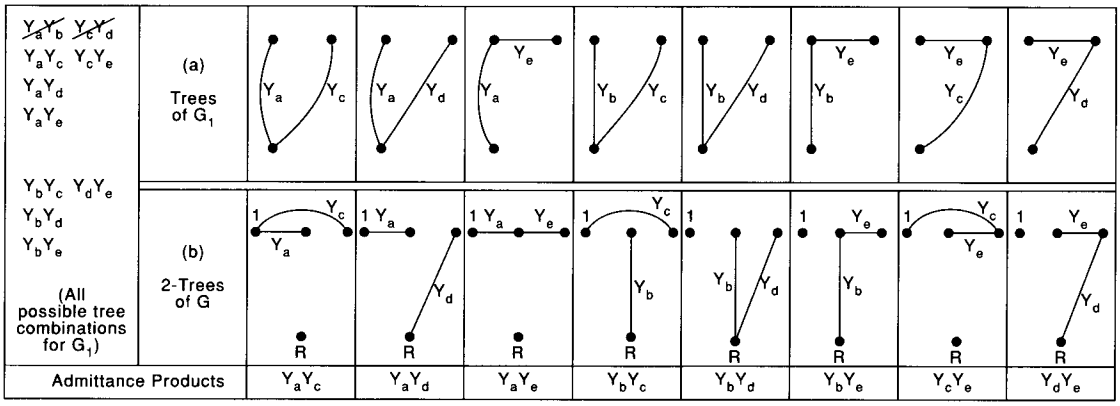

FIGURE 3.45 (a) The set of all trees of the modified graph G_1 which corresponds to (b) the set of all 2-trees of G (with nodes l and R in separate parts in each of such 2-tree).

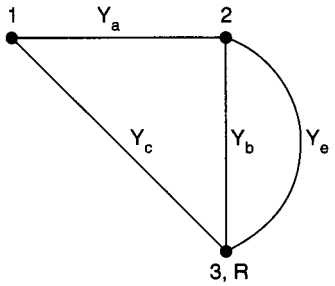

FIGURE 3.46 The modified graph G_3 of G.

set of all trees common to G_1 and G_3) as shown in Fig. 3.48. Finally we form the ratio of 2-tree admittance products according to Eq. (3.49). Thus from Figs. 3.45 and 3.48, we find

$$\frac{V_0}{V_i} = \frac{Y_aY_c + Y_aY_e + Y_bY_c + Y_cY_e}{Y_aY_c + Y_aY_d + Y_aY_e + Y_bY_c + Y_bY_d + Y_bY_e + Y_cY_e + Y_dY_e}$$

which is identical to the results obtained by the flowgraph techniques.

From the above discussions and Example 3.7 we see that the Mason approach is the best from the systems viewpoint, especially when a single source is involved. It gives an excellent physical insight to the system and reveals the cause-effect relationships at various stages when graph reduction technique is employed. While the Coates approach enables one to compute the output directly regardless of the number of inputs involved in the system, thus overcoming one of the difficulties associated with Mason's approach, it does not allow one to reduce the graph step-by-step toward the final solution as Mason's does. However, it is interesting to note that in the modified Coates technique the introduction of the loop-sets (analogous to trees) and the 2-loop-sets (analogous to 2-trees) brings together the two different concepts—the flowgraph approach and the k-tree approach.

From the networks point of view, the Maxwell k-tree approach not only enables one to express the solution in terms of the topology (namely the trees and 2-trees in Example 3.7) of the network but also avoids the cancellation problem inherent in all the flowgraph techniques since, as evident from Example 3.7, the trees and

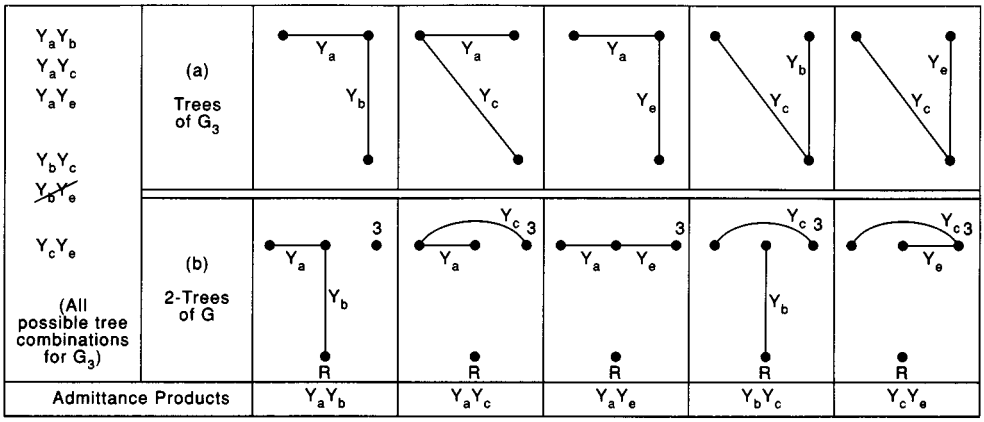

FIGURE 3.47 (a) The set of all trees of the modified graph G_3, which corresponds to (b) the set of all 2-trees of G (with nodes 3 and R in separate parts in each of such 2-tree).

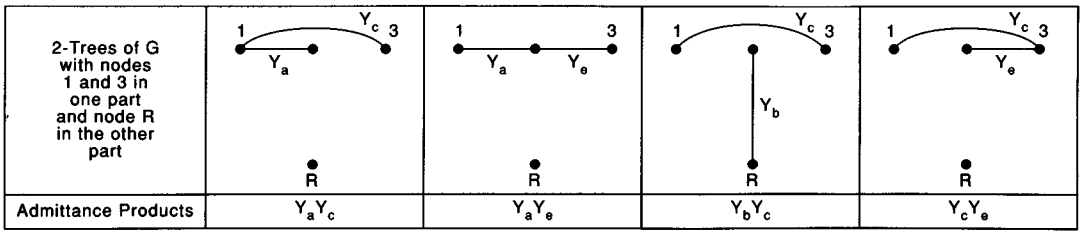

FIGURE 3.48 The set of all 2-trees of G (with nodes l and 3 in one part of the reference node R in the other part of each of such 2-tree).

the 2-trees in the gain expression by the k-tree approach correspond (one-to-one) to the *uncanceled terms* in the final expressions of the gain by the flowgraph techniques. Finally, it should be obvious that the k-tree approach depends upon the knowledge of the graph of a given network. Thus, if in a network problem only the system of (loop or node) equations is given and the network is not known, or more generally, if a system is characterized by a block diagram or a system of equations, the k-tree approach cannot be applied and one must resort to the flowgraph techniques between the two approaches.

Some Topological Applications in Network Analysis and Design

In practice a circuit designer often has to make approximations and analyze the same network structure many times with different sets of component values before the final network realization is obtained. Conventional analysis techniques which require the evaluation of high-order determinants are undesirable even on a digital computer because of the large amount of redundancy inherent in the determinant expansion process. The extra calculation in the evaluation (expansion of determinants) and simplification (cancellation of terms) is time consuming and costly and thereby contributes much to the undesirability of such methods.

The k-tree topological formulas presented in this section, on the other hand, eliminate completely the cancellation of terms. Also, they are particularly suited for digital computation when the size of the network is not exceedingly large. All of the terms involved in the formulas can be computed by means of a digital compute using a single "tree-finding" program [Chan, 1969]. Thus, the application of topological formulas in analyzing a network with the aid of a digital computer can mean a saving of a considerable amount of time and cost to the circuit designer, especially true when it is necessary to repeat the same analysis procedure a large number of times.

In a preliminary system design, the designer usually seeks one or more concepts which will meet the specifications, and in engineering practice each concept is generally subjected to some form of analysis. For linear systems, the signal flowgraph of Mason is widely used in this activity. The flowgraph analysis is popular because it depicts the relationships existing between system variables, and the graphical structure may be manipulated using Mason's formulas to obtain system transfer functions in symbolic or symbolic/numerical form.

Although the preliminary design problems are usually of limited size (several variables), hand derivation of transfer functions is nonetheless difficult and often prone to error arising from the omission of terms. The recent introduction of remote, time-shared computers into modern design areas offers a means to handle such problems swiftly and effectively.

An efficient algorithm suitable for digital compution of transfer functions from the signal flowgraph description of a linear system has been developed (Dunn and Chan, 1969] which provides a powerful analytical tool in the conceptual phases of linear system design.

In the past several decades, graph theory has been widely used in electrical engineering, computer science, social science, and in the solution of economic problems [Swamy and Thulasiraman, 1981; Chen, 1990]. finally, the application of graph theory in conjunction with symbolic network analysis and computer-aided simulation of electronic circuits has been well recognized in recent years [Lin, 1991].

Defining Terms

Branches of a tree: The edges contained in a tree.

Circuit (or loop): A closed path where all vertices are of degree 2, thus having *no* endpoints in the path.

Circuit-set (or loop-set): The set of all edges contained in a circuit (loop).

Connectedness: A graph or subgraph is said to be connected if there is at least one path between *every* pair of its vertices.

Flowgraph G_l (or modified Coates graph G_l): The flowgraph G_l (called *the modified Coates graph*) of a system S of n independent linear equations in n unknowns

$$\sum_{j=1}^{n} a_{ij}x_j = b_i \qquad i = 1, 2, \ldots, n$$

is an oriented graph such that the variable x_j in S is represented by a *node* (also denoted by x_j) in G_l, and the coefficient a_{ij} of the variable x_j in S by a *branch* with a branch gain a_{ij} connected between nodes x_i and x_j in G_l and directed from x_j to x_i. Furthermore, a *source node* l is included in G_l such that for each constant b_k in S there is a node with gain b_k in G_l from node l to node s_k. Graph G_{ij} is the subgraph of G_l obtained by first removing all the outgoing branches from node x_j and then short-circuiting node l to node x_j. A *loop set l* is a subgraph of G_{l0} that contains all the nodes of G_{l0} with each node having exactly one incoming and one outgoing branch. The product p of the gains of all the branches in l is called a *loop-set product.* A 2-*loop-set* l_2 is a subgraph of G_{lj} containing all the nodes of G_{lj} with each node having exactly one incoming and one outgoing branch. The product p_2 of the gains of all the branches in l_2 is called a 2-*loop-set product.*

***k*-tree admittance product of a *k*-tree:** The product of the admittances of all the branches of the *k*-tree.

***k*-tree of a connected graph *G*:** A proper subgraph of G consisting of k unconnected circuitless subgraphs, each subgraph itself being connected, which together contain all the vertices of G.

Linear graph: A set of line segments called edges and points called vertices, which are the endpoints of the edges, interconnected in such a way that the edges are connected to (or incident with) the vertices. The degree of a vertex of a graph is the number of edges incident with that vertex.

Path: A subgraph having all vertices of degree 2 except for the two endpoints which are of degree 1 and are called the terminals of the path, where the degree of a vertex is the number of edges connected to the vertex in the subgraph.

Path-set: The set of all edges in a path.

Proper subgraph: A subgraph which does not contain all of the edges of the given graph.

Signal-flowgraph G_m (or Mason's graph G_m): A signal-flowgraph G_m of a system S of n independent linear (algebraic) equations in n unknowns

$$\sum_{j=1}^{n} a_{ij}x_j = b_i \qquad i = 1, 2, \ldots, n$$

is a graph with junction points called *nodes* which are connected by directed line segments called *branches* with signals traveling along the branches only in the direction described by the arrows of the branches. A signal x_k traveling along a branch between x_k and x_j is multiplied by the gain of the branches g_{kj}, so that a signal $g_{kj}\,x_k$ is delivered at node x_j. An *input node* (*source*) is a node which contains only outgoing branches; an *output node* (*sink*) is a node which has only incoming branches. A *path* is a continuous unidirectional succession of branches, all of which are traveling in the same direction; a *forward path* is a path from the input node to the output node along which all nodes are encountered exactly once; and a *feedback path* (*loop*) is a closed path which originates from and terminates at the same node, and along with all other nodes are encountered exactly once (the trivial case is a *self-loop* which contains exactly one node and one branch). A *path* gain is the product of all the branch gains of the branches in a loop.

Subgraph: A subset of the edges of a given graph.

Tree: A connected subgraph of a given connected graph G which contains all the vertices of G but no circuits.

3.7 Two-Port Parameters and Transformations

Norman S. Nise

Introduction

Many times we want to model the behavior of an electric network at only two terminals as shown in Fig. 3.49. Here, only V_1 and I_1, not voltages and currents internal to the circuit, need to be described. To produce the model for a linear circuit, we use **Thévenin's** or **Norton's theorem** to simplify the network as viewed from the selected terminals. We define the pair of terminals shown in Fig. 3.49 as a **port**, where the current, I_1, entering one terminal equals the current leaving the other terminal.

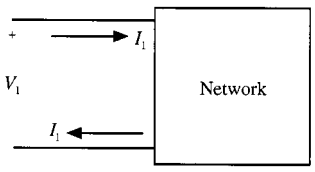

FIGURE 3.49 An electrical network port.

If we further restrict the network by stating that (1) all external connections to the circuit, such as sources and impedances, are made at the port and (2) the network can have internal **dependent sources**, but not **independent sources**, we can mathematically model the network at the port as

$$V_1 = ZI_1 \tag{3.50}$$

or

$$I_1 = YV_1 \tag{3.51}$$

where Z is the Thévenin impedance and Y is the Norton admittance at the terminals. Z and Y can be constant resistive terms, Laplace transforms $Z(s)$ or $Y(s)$, or sinusoidal steady-state functions $Z(j\omega)$ or $Y(j\omega)$.

Defining Two-Port Networks

Electrical networks can also be used to transfer signals from one port to another. Under this requirement, connections to the network are made in two places, the input and the output. For example, a transistor has an input between the base and emitter and an output between the collector and emitter. We can model such circuits as **two-port networks** as shown in Fig. 3.50. Here we see the input port, represented by V_1 and I_1, and the output port, represented by V_2 and I_2. Currents are assumed positive if they flow as shown in Fig. 3.50. The same restrictions about external connections and internal sources mentioned above for the single port also apply.

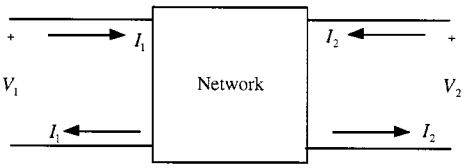

FIGURE 3.50 A two-port network.

Now that we have defined two-port networks, let us discuss how to create a mathematical model of the network by establishing relationships among all of the input and output voltages and currents. Many possibilities exist for modeling. In the next section we arbitrarily begin by introducing the z-parameter model to establish the technique. In subsequent sections we present alternative models and draw relationships among them.

Mathematical Modeling of Two-Port Networks via *z* Parameters

In order to produce a mathematical model of circuits represented by Fig. 3.50, we must find relationships among V_1, I_1, V_2, and I_2. Let us visualize placing a current source at the input and a current source at the output. Thus, we have selected two of the variables, I_1 and I_2. We call these variables the independent variables. The remaining variables, V_1 and V_2, are dependent upon the selected applied currents. We call V_1 and V_2 the dependent variables. Using **superposition** we can write each dependent variable as a function of the independent variables as follows:

$$V_1 = z_{11}I_1 + z_{12}I_2 \tag{3.52a}$$

$$V_2 = z_{21}I_1 + z_{22}I_2 \tag{3.52b}$$

We call the coefficients, z_{ij}, in Eqs. (3.52) parameters of the two-port network or, simply, **two-port parameters**.

From Eqs. (3.52), the two-port parameters are evaluated as

$$\begin{aligned} z_{11} &= \left.\frac{V_1}{I_1}\right|_{I_2=0}; \quad z_{12} = \left.\frac{V_1}{I_2}\right|_{I_1=0} \\ z_{21} &= \left.\frac{V_2}{I_1}\right|_{I_2=0}; \quad z_{22} = \left.\frac{V_2}{I_2}\right|_{I_1=0} \end{aligned} \tag{3.53}$$

Notice that each parameter can be measured by setting a port current, I_1 or I_2, equal to zero. Since the parameters are found by setting these currents equal to zero, this set of parameters is called **open-circuit parameters**. Also, since the definitions of the parameters as shown in Eqs. (3.53) are the ratio of voltages to currents, we alternatively refer to them as **impedance parameters**, or ***z* parameters**. The parameters themselves can be impedances represented as Laplace transforms, $Z(s)$, sinusoidal steady-state impedance functions, $Z(j\omega)$, or simply pure resistance values, R.

Evaluating Two-Port Network Characteristics in Terms of *z* Parameters

The two-port parameter model can be used to find the following characteristics of a two-port network when used in some cases with a source and load as shown in Fig. 3.51:

$$\text{Input impedance} = Z_{\text{in}} = V_1/I_1 \tag{3.54a}$$

$$\text{Output impedance} = Z_{\text{out}} = V_2/I_2 \mid V_S = 0 \tag{3.54b}$$

$$\text{Network voltage gain} = V_g = V_2/V_1 \tag{3.54c}$$

$$\text{Total voltage gain} = V_{gt} = V_2/V_S \tag{3.54d}$$

$$\text{Network current gain} = I_g = I_2/I_1 \tag{3.54e}$$

To find Z_{in} of Fig. 3.51, determine V_1/I_1. From Fig. 3.51, $V_2 = -I_2 Z_L$. Substituting this value in Eq. 3.52(b) and simplifying, Eqs. (3.52) become

$$V_1 = z_{11}I_1 + z_{12}I_2 \tag{3.55a}$$

$$0 = z_{21}I_1 + (z_{22} + Z_L)I_2 \tag{3.55b}$$

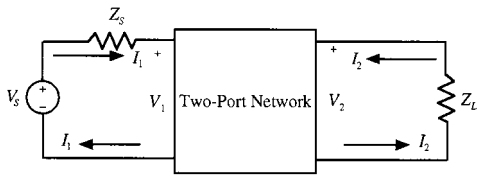

FIGURE 3.51 Terminated two-port network for finding two-port network characteristics.

Solving simultaneously for I_1 and then forming $V_1/I_1 = Z_{in}$, we obtain

$$Z_{in} = \frac{V_1}{I_1} = z_{11} - \frac{z_{12}z_{21}}{(z_{22} + Z_L)} \tag{3.56}$$

To find Z_{out}, set $V_S = 0$ in Fig. 3.51. This step terminates the input with Z_S. Next, determine V_2/I_2. From Fig. 3.51 with V_S shorted, $V_1 = -I_1 Z_S$. By substituting this value into Eq. 3.52(a) and simplifying, Eqs. (3.52) become

$$0 = (z_{11} + Z_S)I_1 + z_{12}I_2 \tag{3.57a}$$

$$V_2 = z_{21}I_1 + z_{22}I_2 \tag{3.57b}$$

By solving simultaneously for I_2 and then forming $V_2/I_2 = Z_{out}$,

$$Z_{out} = \left.\frac{V_2}{I_2}\right|_{V_S=0} = z_{22} - \frac{z_{12}z_{21}}{(z_{11} + Z_S)} \tag{3.58}$$

To find V_g, we see from Fig. 3.51 that $I_2 = -V_2/Z_L$. Substituting this value in Eqs. (3.52) and simplifying, we obtain

$$V_1 = z_{11}I_1 - \frac{z_{12}}{Z_L}V_2 \tag{3.59a}$$

$$0 = z_{21}I_1 - \left(\frac{z_{22} + Z_L}{Z_L}\right)V_2 \tag{3.59b}$$

By solving simultaneously for V_2 and then forming $V_2/V_1 = V_g$,

$$V_g = \frac{V_2}{V_1} = \frac{z_{21}Z_L}{z_{11}(z_{22} + Z_L) - z_{12}z_{21}} \tag{3.60}$$

Similarly, other characteristics, such as current gain and the total voltage gain from the source voltage to the load voltage can be found. Table 3.1 summarizes many of the network characteristics that can be found using z parameters as well as the process to arrive at the result.

TABLE 3.1 Network Characteristics Developed from *z*-Parameter Defining Eqs. (3.52)

Network Characteristic Definition	From Fig. 3.51	Substitute in Defining Eqs. (3.52) and Obtain	Solve for Network Characteristic
Input impedance $z_{in} = \dfrac{V_1}{I_1}$	$V_2 = -I_2 Z_L$	$V_1 = z_{11} I_1 + z_{12} I_2$ $0 = z_{21} I_1 + (z_{22} + Z_L) I_2$	$Z_{in} = z_{11} - \dfrac{z_{12} z_{21}}{z_{22} + Z_L}$
Output impedance $Z_{out} = \left.\dfrac{V_2}{I_2}\right\|_{V_S = 0}$	$V_1 = V_S - I_1 Z_S$ $V_S = 0$	$0 = (z_{11} + Z_S) I_1 + z_{12} I_2$ $V_2 = z_{21} I_1 + z_{22} I_2$	$Z_{out} = z_{22} - \dfrac{z_{12} z_{21}}{z_{11} + Z_S}$
Network voltage gain $V_g = \dfrac{V_2}{V_1}$	$I_2 = -\dfrac{V_2}{Z_L}$	$V_1 = z_{11} I_1 - \dfrac{z_{12} V_2}{Z_L}$ $0 = z_{21} I_1 - \dfrac{(z_{22} + Z_L) V_2}{Z_L}$	$V_g = \dfrac{z_{21} Z_L}{z_{11}(z_{22} + Z_L) - z_{12} z_{21}}$
Total voltage gain $V_{gt} = \dfrac{V_2}{V_S}$	$V_1 = V_S - I_1 Z_S$ $I_2 = -\dfrac{V_2}{Z_L}$	$V_S = (z_{11} + Z_S) I_1 - \dfrac{z_{12} V_2}{Z_L}$ $0 = z_{21} I_1 - \dfrac{(z_{22} + Z_L) V_2}{Z_L}$	$V_{gt} = \dfrac{z_{21} Z_L}{(z_{11} + Z_S)(z_{22} + Z_L) - z_{12} z_{21}}$
Network current gain $I_g = \dfrac{I_2}{I_1}$	$V_2 = -I_2 Z_L$	$V_1 = z_{11} I_1 + z_{12} I_2$ $0 = z_{21} I_1 + (z_{22} + Z_L) I_2$	$I_g = -\dfrac{z_{21}}{z_{22} + Z_L}$

To summarize the process of finding network characteristics:

1. Define the network characteristic.
2. Use approproate relationships from Fig. 3.51.
3. Substitute the relationships from Step 2 into Eqs. (3.52).
4. Solve the modified equations for the network characteristic.

An Example Finding *z* Parameters and Network Characteristics

To solve for two-port network characteristics we can first represent the network with its two-port parameters and then use these parameters to find the characteristics summarized in Table 3.1. To find the parameters, we terminate the network adhering to the definition of the parameter we are evaluating. Then, we can use mesh or nodal analysis, current or voltage division, or equivalent impedance to solve for the parameters. The following example demonstates the technique.

Consider the network of Fig. 3.52(a). The first step is to evaluate the *z* parameters. From their definition, z_{11} and z_{21} are found by open-circuiting the output and applying a voltage at the input as shown in Fig. 3.52(b). Thus, with $I_2 = 0$

$$6 I_1 - 4 I_a = V_1 \tag{3.61a}$$

$$-4 I_1 + 18 I_a = 0 \tag{3.61b}$$

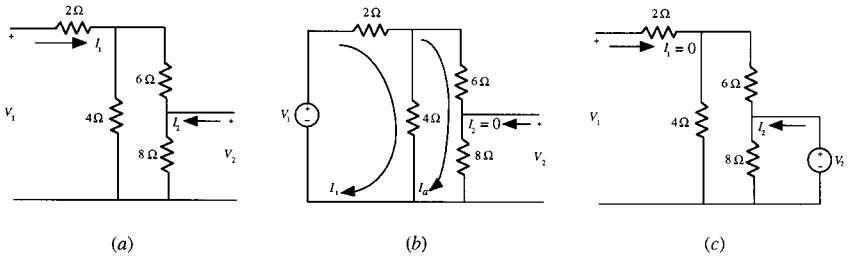

FIGURE 3.52 (a) Two-port network example; (b) two-port network modified to find z_{11} and z_{21}; (c) two-port network modified to find z_{22} and z_{12}.

Solving for I_1 yields

$$I_1 = \frac{\begin{vmatrix} V_1 & -4 \\ 0 & 18 \end{vmatrix}}{\begin{vmatrix} 6 & -4 \\ -4 & 18 \end{vmatrix}} = \frac{18V_1}{92} \tag{3.62}$$

from which

$$z_{11} = \left.\frac{V_1}{I_1}\right|_{I_2=0} = \frac{46}{9} \tag{3.63}$$

We now find z_{21}. From Eq. (3.61b)

$$\frac{I_a}{I_1} = \frac{2}{9} \tag{3.64}$$

But, from Fig. 3.52(b), $I_a = V_2/8$. Thus,

$$z_{21} = \left.\frac{V_2}{I_1}\right|_{I_2=0} = \frac{16}{9} \tag{3.65}$$

Based on their definitions, z_{22} and z_{12} are found by placing a source at the output and open-circuiting the input as shown in Fig. 3.52(c). The equivalent resistance, R_{2eq}, as seen at the output with $I_1 = 0$ is

$$R_{2eq} = \frac{8 \times 10}{8 + 10} = \frac{40}{9} \tag{3.66}$$

Therefore,

$$z_{22} = \left.\frac{V_2}{I_2}\right|_{I_1=0} = \frac{40}{9} \tag{3.67}$$

From Fig. 3.52(c), using voltage division

$$V_1 = (4/10)\,V_2 \tag{3.68}$$

But

$$V_2 = \mathrm{I}_2 \mathrm{R}_{2\,\mathrm{eq}} = \mathrm{I}_2(40/9) \tag{3.69}$$

Substituting Eq. (3.69) into Eq. (3.68) and simplifying yields

$$z_{12} = \left.\frac{V_1}{I_2}\right|_{I_1=0} = \frac{16}{9} \tag{3.70}$$

Using the z-parameter values found in Eqs. (3.63), (3.65), (3.67), and (3.70) and substituting into the network characteristic relationships shown in the last column of Table 3.1, assuming $Z_S = 20\ \Omega$ and $Z_L = 10\ \Omega$, we obtain $Z_{\mathrm{in}} = 4.89\ \Omega$, $Z_{\mathrm{out}} = 4.32\ \Omega$, $V_g = 0.252$, $V_{gt} = 0.0494$, and $I_g = -0.123$.

Additional Two-Port Parameters and Conversions

We defined the *z* parameters by establishing I_1 and I_2 as the independent variables and V_1 and V_2 as the dependent variables. Other choices of independent and dependent variables lead to definitions of alternative two-port parameters. The total number of combinations one can make with the four variables, taking two at a time as independent variables, is six. Table 3.2 defines the six possibilities as well as the names and symbols given to the parameters.

The table also presents the expressions used to calculate directly the parameters of each set based upon their definition as we did with *z* parameters. For example, consider the *y*, or **admittance, parameters**. These parameters are seen to be **short-circuit parameters**, since their evaluation requires V_1 or V_2 to be zero. Thus, to find y_{22} we short-circuit the input and find the admittance looking back from the output. For Fig. 3.52(a), $y_{22} = 23/88$. Any parameter in Table 3.2 is found either by open-circuiting or short-circuiting a terminal and then performing circuit analysis to find the defining ratio.

Another method of finding the parameters is to convert from one set to another. Using the "Definition" row in Table 3.2, we can convert the defining equations of one set to the defining equations of another set. For example, we have already found the *z* parameters. We can find the ***h* parameters** as follows:

Solve for I_2 using the second *z*-parameter equation, Eq. (3.52b), and obtain the second *h*-parameter equation as

$$I_2 = -\frac{z_{21}}{z_{22}}\,I_1 + \frac{1}{z_{22}}\,V_2 \tag{3.71}$$

which is of the form, $I_2 = h_{21}I_1 + h_{22}V_2$, the second *h*-parameter equation. Now, substitute Eq. (3.71) into the first *z*-parameter equation, Eq. (3.52a), rearrange, and obtain

$$V_1 = \frac{z_{11}z_{22} - z_{12}z_{21}}{z_{22}}\,I_1 + \frac{z_{12}}{z_{22}}\,V_2 \tag{3.72}$$

which is of the form, $V_1 = h_{11}I_1 + h_{12}V_2$, the first *h*-parameter equation. Thus, for example, $h_{21} = -z_{21}/z_{22}$ from Eq. (3.71). Other transformations are found through similar manipulations and are summarized in Table 3.2.

Finally, there are other parameter sets that are defined differently from the standard sets covered here. Specifically, they are scattering parameters used for microwave networks and image parameters used for filter design. A detailed discussion of these parameters is beyond the scope of this section. The interested reader should consult the bibliography in the "Further Information" section below, or Section 39.1 of this handbook.

TABLE 3.2 Two-Port Parameter Definitions and Conversions

	Impedance Parameters (Open-Circuit Parameters) z	Admittance Parameters (Short-Circuit Parameters) y	Hybrid Parameters h
Definition	$V_1 = z_{11}I_1 + z_{12}I_2$ $V_2 = z_{21}I_1 + z_{22}I_2$	$I_1 = y_{11}V_1 + y_{12}V_2$ $I_2 = y_{21}V_1 + y_{22}V_2$	$V_1 = h_{11}I_1 + h_{12}V_2$ $I_2 = h_{21}I_1 + h_{22}V_2$

Two-Port Parameter Selection

The choice of parameters to use for a particular analysis or design problem is based on analytical convenience or the physics of the device or network at hand. For example, an ideal transformer cannot be represented with z parameters. I_1 and I_2 are not linearly independent variables, since they are related through the turns ratio. A similar argument applies to the ***y*-parameter** representation of a transformer. Here V_1 and V_2 are not independent, since they too are related via the turns ratio. A possible choice for the transformer is the **transmission parameters**. For an ideal transformer, B and C would be zero. For a BJT transistor, there is effectively linear independence between the input current and the output voltage. Thus, the hybrid parameters are the parameters of choice for the transistor.

The choice of parameters can be based also upon the ease of analysis. For example, Table 3.3 shows that "T" networks lend themselves to easy evaluation of the z parameters, while y parameters can be easily evaluated for "Π" networks. Table 3.3 summarizes other suggested uses and selections of network parameters for a few specific cases. When electric circuits are interconnected, a judicious choice of parameters can simplify the calculations to find the overall parameter description for the interconnected networks. For example, Table 3.3 shows that the z parameters for series-connected networks are simply the sum of the z parameters of the individual circuits (see Ruston et al., [1966] for derivations of the parameters for some of the interconnected networks). The bold entries imply 2×2 matrices containing the four parameters. For example,

$$\mathbf{h} = \begin{bmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{bmatrix} \tag{3.73}$$

Summary

In this section, we developed two-port parameter models for two-port electrical networks. The models define interrelationships among the input and output voltages and currents. A total of six models exists, depending upon which two variables are selected as independent variables. Any model can be used to find such network characteristics as input and output impedance, and voltage and current gains. Once one model is found, other models can be obtained from transformation equations. The choice of parameter set is based upon physical reality and analytical convenience.

Defining Terms

Admittance parameters: That set of two-port parameters, such as y parameters, where all the parameters are defined to be the ratio of current to voltage. See Table 3.2 for the specific definition.

Dependent source: A voltage or current source whose value is related to another voltage or current in the network.

***g* Parameters:** See hybrid parameters.

***h* Parameters:** See hybrid parameters.

Hybrid (inverse hybrid) parameters: That set of two-port parameters, such as $h(g)$ parameters, where input current (voltage) and output voltage (current) are the independent variables. The parenthetical expressions refer to the inverse hybrid parameters. See Table 3.2 for specific definitions.

Impedance parameters: That set of two-port parameters, such as z parameters, where all the parameters are defined to be the ratio of voltage to current. See Table 3.2 for the specific definition.

Independent source: A voltage or current source whose value is not related to any other voltage or current in the network.

Norton's theorem: At a pair of terminals a linear electrical network can be replaced with a current source in parallel with an admittance. The current source is equal to the current that flows through the terminals when the terminals are short-circuited. The admittance is equal to the admittance at the terminals with all independent sources set equal to zero.

Open-circuit parameters: Two-port parameters, such as z parameters, evaluated by open-circuiting a port.

TABLE 3.3 Two-Port Parameter Set Selection

	Common Circuit Applications	Interconnected Network Applications
Impedance parameters z	• T networks  $z_{11} = Z_a + Z_c$; $z_{12} = z_{21} = Z_c$ $z_{22} = Z_b + Z_c$	• Series connected  $\mathbf{z = z_A + z_B}$
Admittance parameters y	• Π networks  $y_{11} = Y_a + Y_c$; $y_{12} = y_{21} = -Y_c$ $y_{22} = Y_b + Y_c$ • Field effect transistor equivalent circuit  where typically: $1/y_{11} = \infty$, $y_{12} = 0$, $y_{21} = g_m$, $1/y_{22} = r_d$	• Parallel connected  $\mathbf{y = y_A + y_B}$
Hybrid parameters h	• Transistor equivalent circuit  where typically for common emitter: $h_{11} = h_{ie}$, $h_{12} = h_{re}$, $h_{21} = h_{fe}$, $h_{22} = h_{oe}$	• Series–parallel connected  $\mathbf{h = h_A + h_B}$
Inverse hybrid parameters g		• Parallel-series connected  $\mathbf{g = g_A + g_B}$
Transmission parameters T	• Ideal transformer circuits	• Cascade connected  $\mathbf{T = T_A T_B}$
Inverse transmission parameters T'		• Cascade connected  $\mathbf{T' = T'_B T'_A}$

Port: Two terminals of a network where the current entering one terminal equals the current leaving the other terminal.

Short-circuit parameters: Two-port parameters, such as *y* parameters, evaluated by short-circuiting a port.

Superposition: In linear networks, a method of calculating the value of a dependent variable. First, the value of the dependent variable produced by each independent variable acting alone is calculated. Then, these values are summed to obtain the total value of the dependent variable.

Thévenin's theorem: At a pair of terminals a linear electrical network can be replaced with a voltage source in series with an impedance. The voltage source is equal to the voltage at the terminals when the terminals are open-circuited. The impedance is equal to the impedance at the terminals with all independent sources set equal to zero.

***T* parameters:** See transmission parameters.

***T′* parameters:** See transmission parameters.

Transmission (inverse transmission) parameters: That set of two-port parameters, such as the $T(T')$ parameters, where the dependent variables are the input (output) variables of the network and the independent variables are the output (input) variables. The parenthetical expressions refer to the inverse transmission parameters. See Table 3.2 for specific definitions.

Two-port networks: Networks that are modeled by specifying two ports, typically input and output ports.

Two-port parameters: A set of four constants, Laplace transforms, or sinusoidal steady-state functions used in the equations that describe a linear two-port network. Some examples are *z, y, h, g, T,* and T' parameters.

***y* Parameters:** See admittance parameters.

***z* Parameters:** See impedance parameters.

4.1 Introduction

This chapter will include detailed design information for passive RLC filters; including Butterworth, Thomson, and Chebyshev, both singly and doubly terminated. As the filter slope is increased in order to obtain greater rejection of frequencies beyond cut-off, the complexity and cost are increased and the response to a step input is worsened. In particular, the overshoot and the settling time are increased. The element values given are for normalized low pass configurations to 5th order. All higher order doubly-terminated Butterworth filter element values can be obtained using Takahasi's equation, and an example is included. In order to use this information in a practical filter these element values must be scaled. Scaling rules to denormalize in frequency and impedance are given with examples. Since all data is for low-pass filters the transformation rules to change from low-pass to high-pass and to band-pass filters are included with examples.

Laplace Transform

We will use the Laplace operator, $s = \sigma + j\omega$. Steady-state impedance is thus Ls and $1/Cs$, respectively, for an inductor (L) and a capacitor (C), and admittance is $1/Ls$ and Cs. In steady state $\sigma = 0$ and therefore $s = j\omega$.

Transfer Functions

We will consider only lumped, linear, constant, bilateral elements, and we will define the **transfer function** $T(s)$ as response over excitation.

$$T(s) = \frac{\text{signal output}}{\text{signal input}} = \frac{N(s)}{D(s)}$$

Adapted from *Instrumentation and Control: Fundamentals and Applications,* edited by Chester L. Nachtigal, pp. 487–497, copyright 1990, John Wiley and Sons, Inc. Reproduced by permission of John Wiley and Sons, Inc.

The roots of the numerator polynomial $N(s)$ are the zeros of the system, and the roots of the denominator $D(s)$ are the poles of the system (the points of infinite response). If we substitute $s = j\omega$ into $T(s)$ and separate the result into real and imaginary parts (numerator and denominator) we obtain

$$T(j\omega) = \frac{A_1 + jB_1}{A_2 + jB_2} \tag{4.1}$$

Then the magnitude of the function, $|T(j\omega)|$, is

$$|T(j\omega)| = \left(\frac{A_1^2 + B_1^2}{A_2^2 + B_2^2}\right)^{\frac{1}{2}} \tag{4.2}$$

and the phase $\underline{\overline{T(j\omega)}}$ is

$$\underline{\overline{T(j\omega)}} = \tan^{-1}\frac{B_1}{A_1} - \tan^{-1}\frac{B_2}{A_2} \tag{4.3}$$

Analysis

Although mesh or nodal analysis can always be used, since we will consider only ladder networks we will use a method commonly called *linearity*, or *working your way through*. The method starts at the output and assumes either 1 volt or 1 ampere as appropriate and uses Ohm's law and Kirchhoff's current law only.

Example 4.1. Analysis of the circuit of Fig. 4.1 for $V_o = 1$ Volt.

$$I_3 = \tfrac{3}{2}s;\quad V_1 = 1 + \left(\tfrac{3}{2}s\right)\left(\tfrac{4}{3}s\right) = 1 + 2s^2$$

$$I_2 = V_1\left(\tfrac{1}{2}s\right) = \tfrac{1}{2}s + s^3;\quad I_1 = I_2 + I_3$$

$$V_i = V_1 + I_1 = s^3 + 2s^2 + 2s + 1$$

$$T(s) = \frac{V_o}{V_i} = \frac{1}{s^3 + 2s^2 + 2s + 1}$$

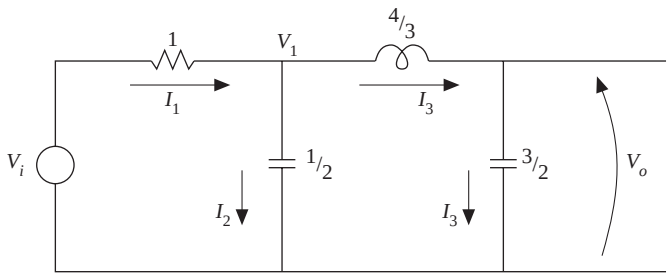

FIGURE 4.1 Singly terminated 3rd order low pass filter (Ω, H, F).

Example 4.2 Determine the magnitude and phase of T(s) in Example 4.1.

$$|T(s)| = \left| \frac{1}{s^3 + 2s^2 + 2s + 1} \right|_{s=j\omega}$$

$$|T(s)| = \sqrt{\frac{1}{\left(1 - 2\omega^2\right)^2 + \left(2\omega - \omega^3\right)^2}} = \frac{1}{\sqrt{\omega^6 + 1}}$$

$$\underline{T(s)} = \tan^{-1} 0 - \tan^{-1} \frac{2\omega - \omega^3}{1 - 2\omega^2} = -\tan^{-1} \frac{2\omega - \omega^3}{1 - 2\omega^2}$$

The values used for the circuit of Fig. 4.1 were normalized; that is, they are all near unity in ohms, henrys, and farads. These values simplify computation and, as we will see later, can easily be scaled to any desired set of actual element values. In addition, this circuit is low-pass because of the shunt capacitors and the series inductor. By low-pass we mean a circuit that passes the lower frequencies and attenuates higher frequencies. The cut-off frequency is the point at which the magnitude is 0.707 (–3 dB) of the dc level and is the dividing line between the **passband** and the **stopband**. In the above example we see that the magnitude of V_o/V_i at ω = 0 (dc) is 1.00 and that at ω = 1 rad/s we have

$$\left| T(j\omega) \right| = \left| \frac{1}{\sqrt{(\omega^6 + 1)}} \right|_{\omega=1\ rad/s} = 0.707 \tag{4.4}$$

and therefore this circuit has a cut-off frequency of 1 rad/s.

Thus, we see that the normalized element values used here give us a cut-off frequency of 1 rad/s.

4.2 Low-Pass Filter Functions[1]

The most common function in signal processing is the Butterworth. It is a function that has only poles (i.e., no finite zeros) and has the flattest magnitude possible in the passband. This function is also called **maximally flat magnitude (MFM)**. The derivation of this function is illustrated by taking a general all-pole function of third-order with a dc gain of 1 as follows:

$$T(s) = \frac{1}{as^3 + bs^2 + cs + 1} \tag{4.5}$$

The squared magnitude is

$$|T(j\omega)|^2 = \frac{1}{(1 - b\omega^2)^2 + (c\omega - a\omega^3)^2} \tag{4.6}$$

[1]Adapted from *Handbook of Measurement Science,* edited by Peter Sydenham, copyright 1982, John Wiley and Sons Limited. Reproduced by permission of John Wiley and Sons Limited.

or

$$|T(j\omega)|^2 = \frac{1}{a^2\omega^6 + (b^2 - 2ac)\omega^4 + (c^2 - 2b)\omega^2 + 1} \tag{4.7}$$

MFM requires that the coefficients of the numerator and the denominator match term by term (or be in the same ratio) except for the highest power.

Therefore

$$c^2 - 2b = 0; \qquad b^2 - 2ac = 0 \tag{4.8}$$

We will also impose a normalized cut-off (–3 dB) at $\omega = 1$ rad/s; that is,

$$|T(j\omega)|_{\omega=1} = \frac{1}{\sqrt{(a^2 + 1)}} = 0.707 \tag{4.9}$$

Thus, we find $a = 1$, then $b = 2$, $c = 2$ are solutions to the flat magnitude conditions of Eq. 4.8 and our third-order Butterworth function is

$$T(s) = \frac{1}{s^3 + 2s^2 + 2s + 1} \tag{4.10}$$

Table 4.1 gives the Butterworth denominator polynomials up to $n = 5$.

In general, for all Butterworth functions the normalized magnitude is

$$|T(j\omega)| = \frac{1}{\sqrt{(\omega^{2n} + 1)}} \tag{4.11}$$

Note that this is down 3 dB at $\omega = 1$ rad/s for all n.

This may, of course, be multiplied by any constant less than one for circuits whose dc gain is deliberately set to be less than one.

Example 4.3. A low-pass Butterworth filter is required whose cut-off frequency (–3 dB) is 3 kHz and in which the response must be down 40 dB at 12 kHz. Normalizing to a cut-off frequency of 1 rad/s, the –40-dB frequency is

$$\frac{12\text{ kHz}}{3\text{ kHz}} = 4\text{ rad/s}$$

thus

$$-40 = 20\log\frac{1}{\sqrt{4^{2n} + 1}}$$

therefore $n = 3.32$. Since n must be an integer, a fourth-order filter is required for this specification.

There is an extremely important difference between the singly terminated (dc gain = 1) and the doubly terminated filters (dc gain = 0.5). As was shown by John Orchard, the sensitivity in the passband (ideally at maximum output) to all *L, C* components in an *L, C* filter with *equal* terminations is *zero.* This is true regardless of the circuit.

This, of course, means component tolerances and temperature coefficients are of much less importance in the equally terminated case. For this type of Butterworth low-pass filter (normalized to equal 1-Ω terminations), Takahasi has shown that the normalized element values are exactly given by

$$L,\ C = 2\ \sin\left(\frac{(2k-1)\pi}{2n}\right) \tag{4.12}$$

for any order *n,* where *k* is the *L* or *C* element from 1 to *n.*

Example 4.4. Design a normalized (ω_{-3dB} =1 rad/s) doubly terminated (i.e., source and load = 1 Ω) Butterworth low-pass filter of order 6; that is, $n = 6$.

The element values from Eq. (4.12) are

$$L_1 = 2\ \sin\frac{(2-1)\pi}{12} = 0.5176\ \text{H}$$
$$C_2 = 2\ \sin\frac{(4-1)\pi}{12} = 1.4141\ \text{F}$$
$$L_3 = 2\ \sin\frac{(6-1)\pi}{12} = 1.9319\ \text{H}$$

The values repeat for C_4, L_5, C_6 so that

$$C_4 = L_3,\ L_5 = C_2,\ C_6 = L_1$$

Thomson Functions

The Thomson function is one in which the time delay of the network is made maximally flat. This implies a linear phase characteristic since the steady-state time delay is the negative of the derivative of the phase. This function has excellent time domain characteristics and is used wherever excellent step response is required. These functions have very little overshoot to a step input and have far superior settling times compared to the Butterworth functions. The slope near cut-off is more gradual than the Butterworth. Table 4.2 gives the Thomson denominator polynomials. The numerator is a constant equal to the dc gain of the circuit multiplied by the denominator constant. The cut-off frequencies are *not* all 1 rad/s. They are given in Table 4.2.

TABLE 4.2 Thomson Polynomials

	ω_{-3dB} (rad/s)
$s + 1$	1.0000
$s^2 + 3s + 3$	1.3617
$s^3 + 6s^2 + 15s + 15$	1.7557
$s^4 + 10s^3 + 45s^2 + 105s + 105$	2.1139
$s^5 + 15s^4 + 105s^3 + 420s^2 + 945s + 945$	2.4274

Chebyshev Functions

A second function defined in terms of magnitude, the Chebyshev, has an **equal ripple** character within the passband. The ripple is determined by **ϵ.**

TABLE 4.3 Chebyshev Polynomials

$s + \sinh \nu$
$s^2 + \left(\sqrt{2} \sinh \nu\right)s + \sinh^2 \nu + 1/2$
$\left(s + \sinh \nu\right)\left[s^2 + \left(\sinh \nu\right)s + \sinh^2 \nu + 3/4\right]$
$\left[s^2 + \left(0.75637 \sinh \nu\right)s + \sinh^2 \nu + 0.85355\right] \times \left[s^2 + \left(1.84776 \sinh \nu\right)s + \sinh^2 \nu + 0.14645\right]$
$\left(s + \sinh \nu\right)\left[s^2 + \left(0.61803 \sinh \nu\right)s + \sinh^2 \nu + 0.90451\right] \times \left[s^2 + \left(1.61803 \sinh \nu\right)s + \sinh^2 \nu + 0.34549\right]$

Source: Handbook of Measurement Science, edited by Peter Sydenham, copyright 1982, John Wiley and Sons Limited. Reproduced by permission of John Wiley and Sons Limited.

$$\epsilon = \sqrt{(10^{A/10} - 1)} \tag{4.13}$$

where A = decibels of ripple; then for a given order n, we define v.

$$v = \frac{1}{n} \sinh^{-1}\left(\frac{1}{\epsilon}\right) \tag{4.14}$$

Table 4.3 gives denominator polynomials for the Chebyshev functions. In all cases, the cut-off frequency (defined as the end of the ripple) is 1 rad/s. The –3-dB frequency for the Chebyshev function is

$$\omega_{-3\text{dB}} = \cosh\left[\frac{\cosh^{-1}(1/\epsilon)}{n}\right] \tag{4.15}$$

The magnitude in the *stopband* ($\omega > 1$ rad/s) for the normalized filter is

$$\left|T(j\omega)\right|^2 = \frac{1}{1 + \epsilon^2 \cosh^2(n \cosh^{-1} \omega)} \tag{4.16}$$

for the singly terminated filter. For equal terminations the above magnitude is multiplied by one-half [1/4 in Eq. (4.16)].

Example 4.5. What order of singly terminated Chebyshev filter having 0.25-dB ripple (A) is required if the magnitude must be –60 dB at 15 kHz and the cut-off frequency (–0.25 dB) is to be 3 kHz? The normalized frequency for a magnitude of –60 dB is

$$\frac{15 \text{ kHz}}{3 \text{ kHz}} = 5 \text{ rad/s}$$

Thus, for a ripple of A = 0.25 dB, we have from Eq. (4.13)

$$\epsilon = \sqrt{(10^{A/10} - 1)} = 0.2434$$

and solving Eq. (4.16) for n with $\omega = 5$ rad/s and $\left|T(j\omega)\right|$ = –60 dB, we obtain n = 3.93. Therefore we must use n = 4 to meet these specifications.

4.3 Low-Pass Filters[1]

Introduction

Normalized element values are given here for both singly and doubly terminated filters. The source and load resistors are normalized to 1 Ω. Scaling rules will be given in Section 4.4 that will allow these values to be modified to any specified impedance value and to any cut-off frequency desired. In addition, we will cover the **transformation** of these **low-pass filters** to **high-pass** or **bandpass filters**.

Butterworth Filters

For n = 2, 3, 4, or 5, Fig. 4.2 gives the element values for the singly terminated filters and Fig. 4.3 gives the element values for the doubly terminated filters. All cut-off frequencies (–3 dB) are 1 rad/s.

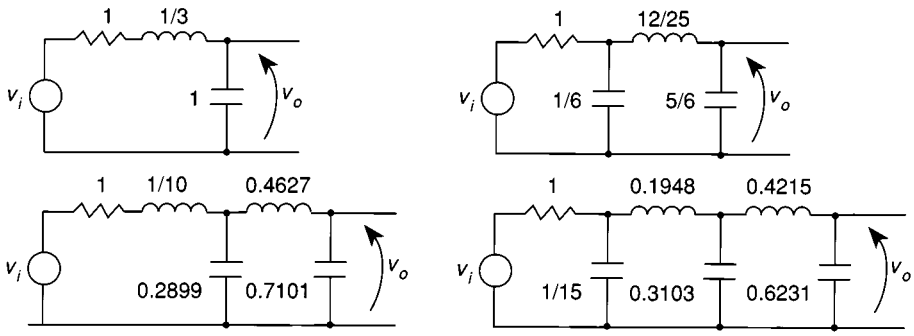

FIGURE 4.4 Singly terminated Thomson filter element values (in Ω, H, F). *(Source: Handbook of Measurement Science,* edited by Peter Sydenham, copyright 1982, John Wiley and Sons Limited. Reproduced by permission of John Wiley and Sons Limited.)

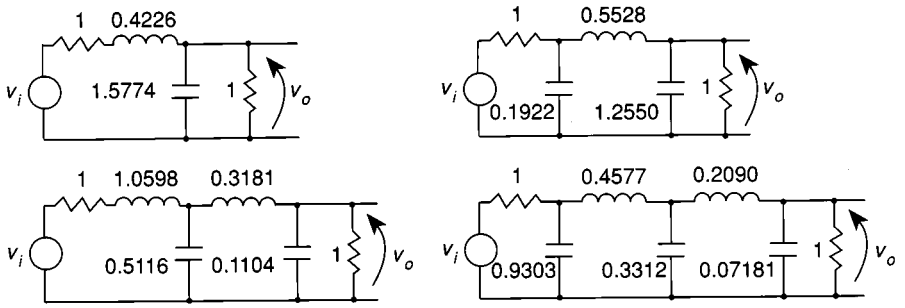

FIGURE 4.5 Doubly terminated Thomson filter element values (in Ω, H, F). (*Source: Handbook of Measurement Science,* edited by Peter Sydenham, copyright 1982, John Wiley and Sons Limited. Reproduced by permission of John Wiley and Sons Limited.)

Thomson Filters

Singly and doubly terminated Thomson filters of order $n = 2, 3, 4, 5$ are shown in Figs. 4.4 and 4.5. All time delays are 1 s. The cut-off frequencies are given in Table 4.2.

Chebyshev Filters

The amount of ripple can be specified as desired, so that only a selective sample can be given here. We will use 0.1 dB, 0.25 dB, and 0.5 dB. All cut-off frequencies (end of ripple for the Chebyshev function) are at 1 rad/s. Since the maximum power transfer condition precludes the existence of an equally terminated even-order filter, only odd orders are given for the doubly terminated case. Figure 4.6 gives the singly terminated Chebyshev filters for $n = 2, 3, 4,$ and 5 and Fig. 4.7 gives the doubly terminated Chebyshev filters for $n = 3$ and $n = 5$.

4.4 Filter Design

We now consider the steps necessary to convert normalized filters into actual filters by scaling both in frequency and in impedance. In addition, we will cover the transformation laws that convert low-pass filters to high-pass filters and low-pass to bandpass filters.

Scaling Laws and a Design Example

Since all data previously given are for normalized filters, it is necessary to use the scaling rules to design a low-pass filter for a specific signal processing application.

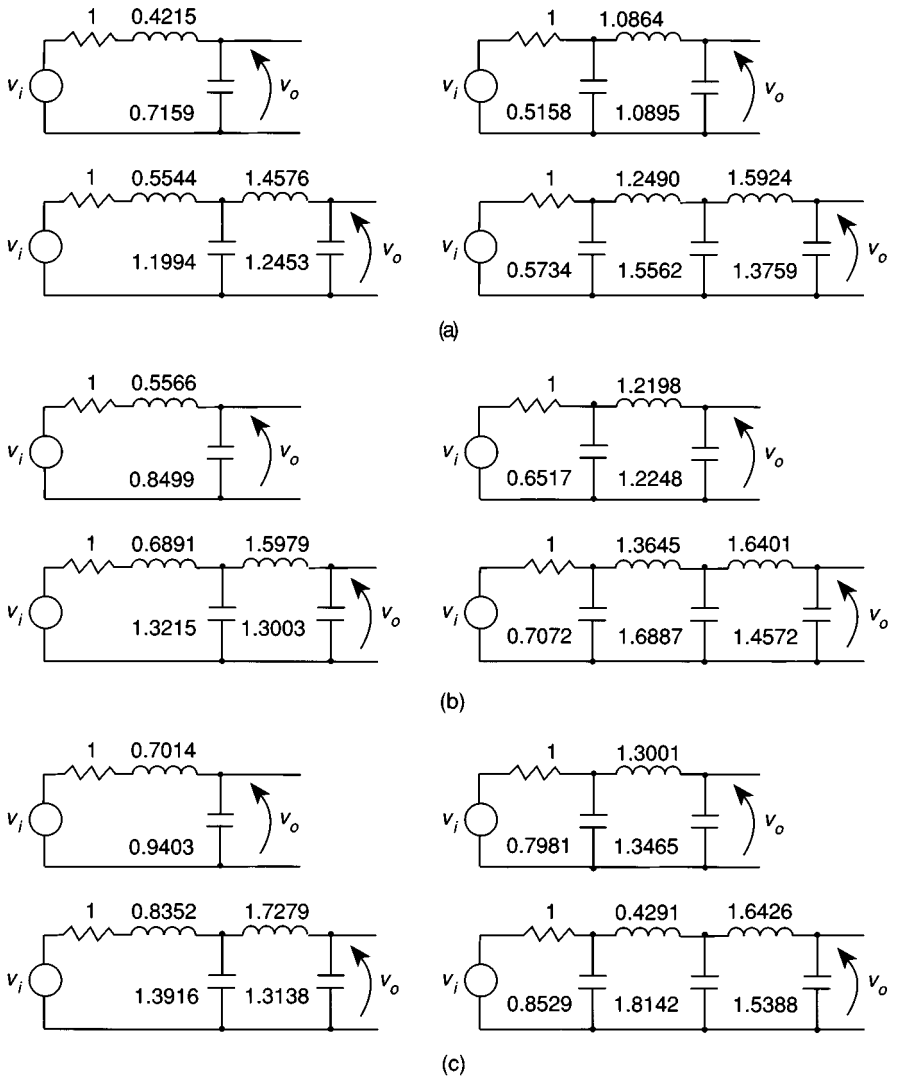

FIGURE 4.6 Singly terminated Chebyshev filter element values (in Ω, H, F): (a) 0.1-dB ripple; (b) 0.25-dB ripple; (c) 0.50-dB ripple. (*Source: Handbook of Measurement Science,* edited by Peter Sydenham, copyright 1982, John Wiley and Sons Limited. Reproduced by permission of John Wiley and Sons Limited.)

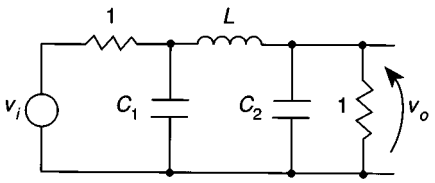
Rule 1. All impedances may be multiplied by any constant without affecting the transfer voltage ratio.

Rule 2. To modify the cut-off frequency, divide all inductors and capacitors by the ratio of the desired frequency to the normalized frequency.

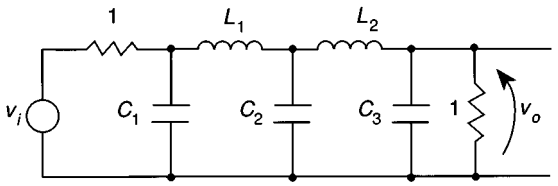
Example 4.6. Design a low-pass filter of MFMtype (Butterworth) to operate from a 600-Ω source into a 600-Ω load, with a cut-off frequency of 500 Hz. The filter must be at least 36 dB below the dc level at 2 kHz, that is, –42 dB (dc level is –6 dB).

Since 2 kHz is four times 500 Hz, it corresponds to $\omega = 4$ rad/s in the normalized filter. Thus at $\omega = 4$ rad/s we have

$$-42 \text{ dB} = 20 \log \frac{1}{2}\left[\frac{1}{\sqrt{4^{2n} + 1}}\right]$$



Ripple (dB)	C_1	L	C_2
0.10	1.0316	1.1474	1.0316
0.25	1.3034	1.1463	1.3034
0.50	1.5963	1.0967	1.5963



Ripple (dB)	C_1	L_1	C_2	L_2	C_3
0.10	1.1468	1.3712	1.9750	1.3712	1.1468
0.25	1.3824	1.3264	2.2091	1.3264	1.3824
0.50	1.7058	1.2296	2.5408	1.2296	1.7058

FIGURE 4.7 Doubly terminated Chebyshev filter element values (in Ω, H, F).

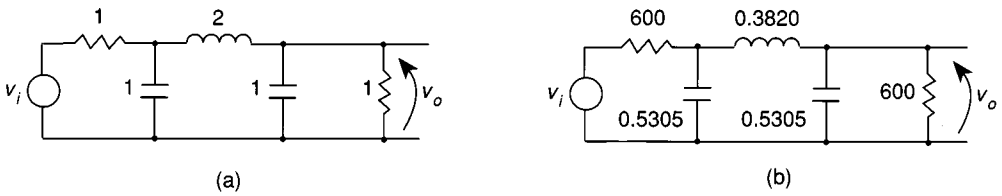


FIGURE 4.8 Third-order Butterworth low-pass filter: (a) normalized (in Ω, H, F); (b) scaled (in Ω, H, μF).

therefore, $n = 2.99$, so $n = 3$ must be chosen. The 1/2 is present because this is a doubly terminated (equal values) filter so that the dc gain is 1/2.

Thus a third-order, doubly terminated Butterworth filter is required. From Fig. 4.3 we obtain the normalized network shown in Fig. 4.8(a).

The **impedance scaling** factor is 600/1 = 600 and the **frequency scaling** factor is $2\pi 500/1 = 2\pi 500$: that is, the ratio of the desired radian cut-off frequency to the normalized cut-off frequency (1 rad/s). Note that the impedance scaling factor increases the size of the resistors and inductors, but reduces the size of the capacitors. The result is shown in Fig. 4.8(b).

Transformation Rules, Passive Circuits

All information given so far applies only to low-pass filters, yet we frequently need high-pass or bandpass filters in signal processing.

Low-Pass to High-Pass Transformation

To transform a low-pass filter to high-pass, we first scale it to a cut-off frequency of 1 rad/s if it is not already at 1 rad/s. This allows a simple frequency rotation about 1 rad/s of $s \rightarrow 1/s$. All L's become C's, all C's become L's, and all values reciprocate. The cut-off frequency does not change.

Example 4.7. Design a third-order, high-pass Butterworth filter to operate from a 600-Ω source to a 600-Ω load with a cut-off frequency of 500 Hz.

Starting with the normalized third-order low-pass filter of Fig. 4.3 for which $\omega_{-3} = 1$ rad/s, we reciprocate all elements and all values to obtain the filter shown in Fig. 4.9(a) for which $\omega_{-3} = 1$ rad/s.

Now we apply the scaling rules to raise all impedances to 600 Ω and the radian cut-off frequency to $2\pi 500$ rad/s as shown in Fig. 4.9(b).

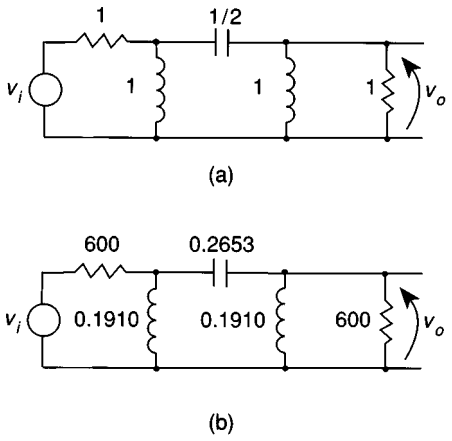

FIGURE 4.9 Third-order Butterworth high-pass filter: (a) normalized (in Ω, H, F); (b) scaled (in Ω, H, μF).

Low-Pass to Bandpass Transformation

To transform a low-pass filter to a bandpass filter we must first scale the low-pass filter so that the cut-off frequency is equal to the bandwidth of the normalized bandpass filter. The normalized center frequency of the bandpass filter is $\omega_0 = 1$ rad/s. Then we apply the transformation $s \rightarrow s + 1/s$. For an inductor

$$Z = Ls \text{ transforms to } Z = L\left(s + \frac{1}{s}\right)$$

For a capacitor

$$Y = Cs \text{ transforms to } Y = C\left(s + \frac{1}{s}\right)$$

The first step is then to determine the Q of the bandpass filter where

$$Q = \frac{f_0}{B} = \frac{\omega_0}{B_r}$$

(f_0 is the center frequency in Hz and B is the 3-dB bandwidth in Hz). Now we scale the low-pass filter to a cut-off frequency of $1/Q$ rad/s, then series tune every inductor, L, with a capacitor of value $1/L$ and parallel tune every capacitor, C, with an inductor of value $1/C$.

Example 4.8. Design a bandpass filter centered at 100 kHz having a 3-dB bandwidth of 10 kHz starting with a third-order Butterworth low-pass filter. The source and load resistors are each to be 600 Ω.

The Q required is

$$Q = \frac{100 \text{ kHz}}{10 \text{ kHz}} = 10, \text{ or } \frac{1}{Q} = 0.1$$

Scaling the normalized third-order low-pass filter of Fig. 4.10(a) to $\omega_{-3\text{dB}} = 1/Q = 0.1$ rad/s, we obtain the filter of Fig. 4.10(b).

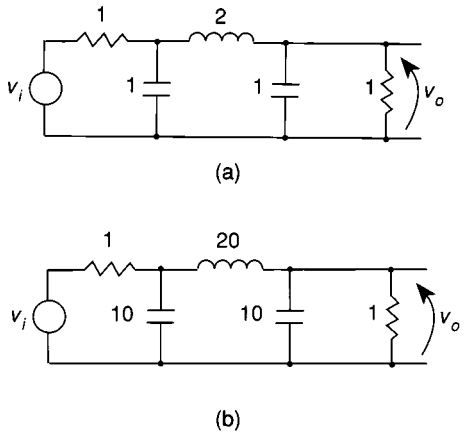

FIGURE 4.10 Third-order Butterworth low-pass filter: (a) normalized (in Ω, H, F); (b) scaled in (in Ω, H, F).

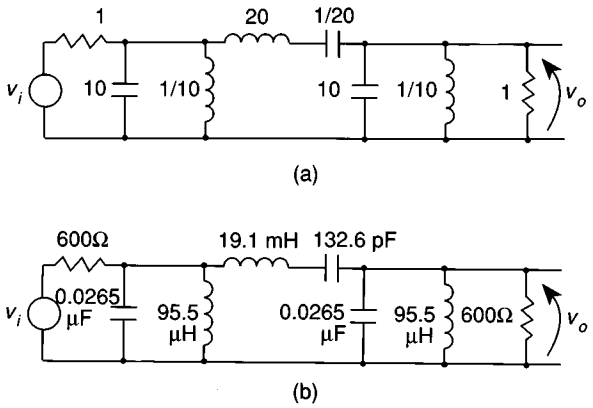

FIGURE 4.11 Sixth-order Butterworth bandpass filter ($Q = 10$): (a) normalized, $\omega_0 = 1$ rad/s (in Ω, H, F); (b) scaled.

Now converting to bandpass with $\omega_0 = 1$ rad/s, we obtain the normalized bandpass filter of Fig. 4.11(a). Next, scaling to an impedance of 600 Ω and to a center frequency of $f_0 = 100$ kHz ($\omega_0 = 2\pi 100$ k rad/s), we obtain the filter of Fig. 4.11(b).

Defining Terms

Bandpass filter: A filter whose passband extends from a finite lower cut-off frequency to a finite upper cut-off frequency.

Equal ripple: A frequency response function whose magnitude has equal maxima and equal minima in the passband.

Frequency scaling: The process of modifying a filter to change from a normalized set of element values to other usually more practical values by dividing all L, C elements by a constant equal to the ratio of the scaled (cut-off) frequency desired to the normalized cut-off frequency.

High-pass filter: A filter whose band extends from some finite cut-off frequency to infinity.

Impedance scaling: Modifying a filter circuit to change from a normalized set of element values to other usually more practical element values by multiplying all impedances by a constant equal to the ratio of the desired (scaled) impedance to the normalized impedance.

Low-pass filter: A filter whose passband extends from dc to some finite cut-off frequency.

Maximally flat magnitude (MFM) filter: A filter having a magnitude that is as flat as possible versus frequency while maintaining a monotonic characteristic.

Passband: A frequency region of signal transmission usually within 3 dB of the maximum transmission.

Stopband: The frequency response region in which the signal is attenuated, usually by more than 3 dB from the maximum transmission.

Transfer function: The Laplace transform of the response (output voltage) divided by the Laplace transform of the excitation (input voltage).

Transformation: The modification of a low-pass filter to convert it to an equivalent high-pass or bandpass filter.

5.1 Diodes and Rectifiers

Jerry L. Hudgins

A **diode** generally refers to a two-terminal solid-state semiconductor device that presents a low impedance to current flow in one direction and a high impedance to current flow in the opposite direction. These properties allow the diode to be used as a one-way current valve in electronic circuits. *Rectifiers* are a class of circuits whose purpose is to convert ac waveforms (usually sinusoidal and with zero average value) into a waveform that has a significant non-zero average value (dc component). Simply stated, rectifiers are ac-to-dc energy converter circuits. Most rectifier circuits employ diodes as the principal elements in the energy conversion process; thus the almost inseparable notions of diodes and rectifiers. The general electrical characteristics of common diodes and some simple rectifier topologies incorporating diodes are discussed.

Diodes

Most diodes are made from a host crystal of silicon (Si) with appropriate impurity elements introduced to modify, in a controlled manner, the electrical characteristics of the device. These diodes are the typical ***pn*-junction** (or **bipolar**) devices used in electronic circuits. Another type is the **Schottky diode** (unipolar), produced by placing a metal layer directly onto the semiconductor [Schottky, 1938; Mott, 1938]. The metal-semiconductor interface serves the same function as the *pn*-junction in the common diode structure. Other semiconductor materials such as gallium-arsenide (GaAs) and silicon-carbide (SiC) are also in use for new and specialized applications of diodes. Detailed discussion of diode structures and the physics of their operation can be found in later paragraphs of this section.

The electrical circuit symbol for a bipolar diode is shown in Fig. 5.1. The polarities associated with the forward voltage drop for forward current flow are also included. Current or voltage opposite to the polarities indicated in Fig. 5.1 are considered to be negative values with respect to the diode conventions shown.

The characteristic curve shown in Fig. 5.2 is representative of the current-voltage dependencies of typical diodes. The diode conducts forward current with a small forward voltage drop across the device, simulating a closed switch. The relationship between the forward current and forward voltage is approximately given by the Shockley diode equation [Shockley, 1949]:

$$i_D = I_s\left[\exp\left(\frac{qV_D}{nkT}\right) - 1\right] \qquad (5.1)$$

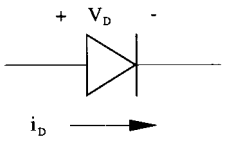

FIGURE 5.1 Circuit symbol for a bipolar diode indicating the polarity associated with the forward voltage and current directions.

where I_s is the leakage current through the diode, q is the electronic charge, n is a correction factor, k is Boltzmann's constant, and T is the temperature of the semiconductor. Around the knee of the curve in Fig. 5.2 is a positive voltage that is termed the turn-on or sometimes the threshold voltage for the diode. This value is an approximate voltage above which the diode is considered turned "on" and can be modeled to first degree as a closed switch with constant forward drop. Below the threshold voltage value the diode is considered weakly conducting and approximated as an open switch. The exponential relationship shown in Eq. (5.1) means that the diode forward current can change by orders of magnitude before there is a large change in diode voltage, thus providing the simple circuit model during conduction. The nonlinear relationship of Eq. (5.1) also provides a means of frequency mixing for applications in modulation circuits.

Reverse voltage applied to the diode causes a small leakage current (negative according to the sign convention) to flow that is typically orders of magnitude lower than current in the forward direction. The diode can withstand reverse voltages up to a limit determined by its physical construction and the semiconductor material used. Beyond this value the reverse voltage imparts enough energy to the charge carriers to cause large increases in current. The mechanisms by which this current increase occurs are impact ionization (avalanche) [McKay, 1954] and a tunneling phenomenon (Zener breakdown) [Moll, 1964]. Avalanche breakdown results in large power dissipation in the diode, is generally destructive, and should be avoided at all times. Both breakdown regions are superimposed in Fig. 5.2 for comparison of their effects on the shape of the diode characteristic curve. Avalanche breakdown occurs for reverse applied voltages in the range of volts to kilovolts depending on the exact design of the diode. Zener breakdown occurs at much lower voltages than the avalanche mechanism. Diodes specifically designed to operate in the Zener breakdown mode are used extensively as voltage regulators in regulator integrated circuits and as discrete components in large regulated power supplies.

During forward conduction the power loss in the diode can become excessive for large current flow. Schottky diodes have an inherently lower turn-on voltage than *pn*-junction diodes and are therefore more desirable in applications where the energy losses in the diodes are significant (such as output rectifiers in switching power supplies). Other considerations such as recovery characteristics from forward conduction to reverse blocking

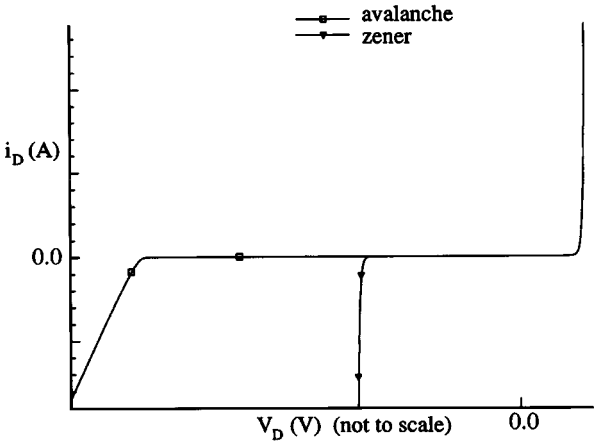

FIGURE 5.2 A typical diode dc characteristic curve showing the current dependence on voltage.

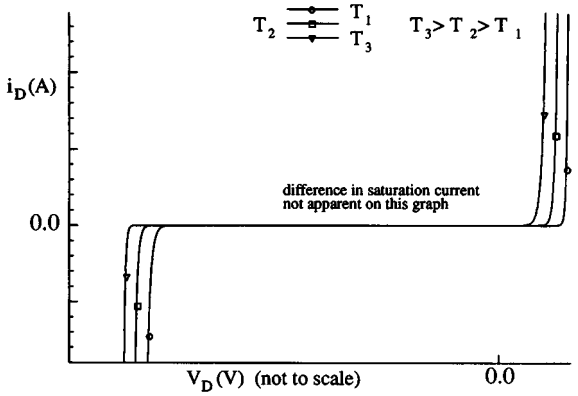

FIGURE 5.3 The effects of temperature variations on the forward voltage drop and the avalanche breakdown voltage in a bipolar diode.

may also make one diode type more desirable than another. Schottky diodes conduct current with one type of charge carrier and are therefore inherently faster to turn off than bipolar diodes. However, one of the limitations of Schottky diodes is their excessive forward voltage drop when designed to support reverse biases above about 200 V. Therefore, high-voltage diodes are the *pn*-junction type.

The effects due to an increase in the temperature in a bipolar diode are many. The forward voltage drop during conduction will decrease over a large current range, the reverse leakage current will increase, and the reverse avalanche breakdown voltage (V_{BD}) will increase as the device temperature climbs. A family of static characteristic curves highlighting these effects is shown in Fig. 5.3 where $T_3 > T_2 > T_1$. In addition, a major effect on the switching characteristic is the increase in the reverse recovery time during turn-off. Some of the key parameters to be aware of when choosing a diode are its repetitive peak inverse voltage rating, V_{RRM} (relates to the avalanche breakdown value), the peak forward surge current rating, I_{FSM} (relates to the maximum allowable transient heating in the device), the average or rms current rating, I_O (relates to the steady-state heating in the device), and the reverse recovery time, t_{rr} (relates to the switching speed of the device).

Rectifiers

This section discusses some simple **uncontrolled rectifier** circuits that are commonly encountered. The term *uncontrolled* refers to the absence of any control signal necessary to operate the primary switching elements (diodes) in the rectifier circuit. The discussion of controlled rectifier circuits, and the controlled switches themselves, is more appropriate in the context of power electronics applications [Hoft, 1986]. Rectifiers are the fundamental building block in dc power supplies of all types and in dc power transmission used by some electric utilities.

A single-phase full-wave rectifier circuit with the accompanying input and output voltage waveforms is shown in Fig. 5.4. This topology makes use of a center-tapped transformer with each diode conducting on opposite half-cycles of the input voltage. The forward drop across the diodes is ignored on the output graph, which is a valid approximation if the peak voltages of the input and output are large compared to 1 V. The circuit changes a sinusoidal waveform with no dc component (zero average value) to one with a dc component of $2V_{peak}/\pi$. The rms value of the output is $0.707V_{peak}$.

The dc value can be increased further by adding a low-pass filter in cascade with the output. The usual form of this filter is a shunt capacitor or an LC filter as shown in Fig. 5.5. The resonant frequency of the LC filter should be lower than the fundamental frequency of the rectifier output for effective performance. The ac portion of the output signal is reduced while the dc and rms values are increased by adding the filter. The remaining ac portion of the output is called the **ripple.** Though somewhat confusing, the transformer, diodes, and filter are often collectively called the rectifier circuit.

Another circuit topology commonly encountered is the bridge rectifier. Figure 5.6 illustrates single- and three-phase versions of the circuit. In the single-phase circuit diodes D1 and D4 conduct on the positive half-cycle of the input while D2 and D3 conduct on the negative half-cycle of the input. Alternate pairs of diodes conduct in the three-phase circuit depending on the relative amplitude of the source signals.

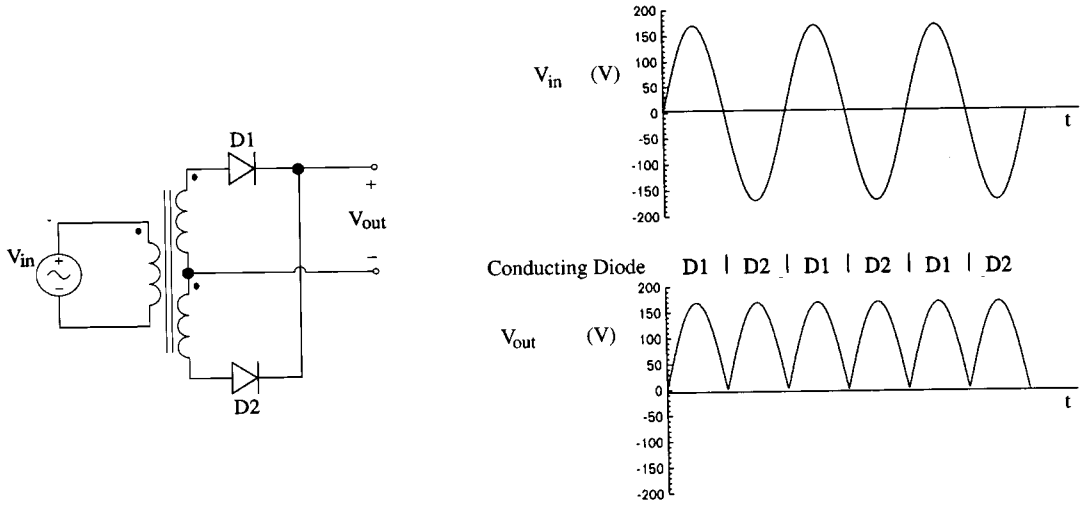

FIGURE 5.4 A single-phase full-wave rectifier circuit using a center-tapped transformer with the associated input and output waveforms.

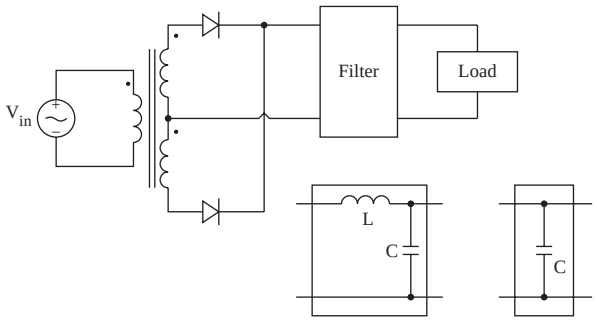

FIGURE 5.5 A single-phase full-wave rectifier with the addition of an output filter.

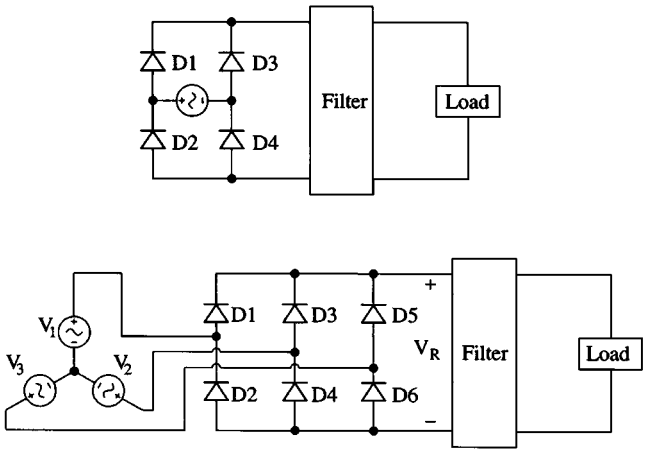

FIGURE 5.6 Single- and three-phase bridge rectifier circuits.

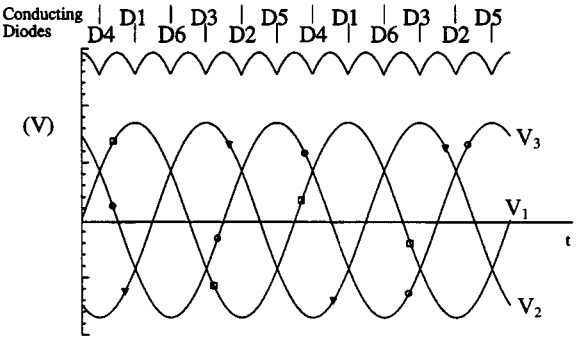

FIGURE 5.7 Three-phase rectifier output compared to the input signals. The input signals as well as the conducting diode labels are those referenced to Fig. 5.6.

The three-phase inputs with the associated rectifier output voltage are shown in Fig. 5.7 as they would appear without the low-pass filter section. The three-phase bridge rectifier has a reduced ripple content of 4% as compared to a ripple content of 47% in the single-phase bridge rectifier [Milnes, 1980]. The corresponding diodes that conduct are also shown at the top of the figure. This output waveform assumes a purely resistive load connected as shown in Fig. 5.6. Most loads (motors, transformers, etc.) and many sources (power grid) include some inductance, and in fact may be dominated by inductive properties. This causes phase shifts between the input and output waveforms. The rectifier output may thus vary in shape and phase considerably from that shown in Fig. 5.7 [Kassakian et al., 1991]. When other types of switches are used in these circuits the inductive elements can induce large voltages that may damage sensitive or expensive components. Diodes are used regularly in such circuits to shunt current and clamp induced voltages at low levels to protect expensive components such as electronic switches.

One variation of the typical rectifier is the Cockroft-Walton circuit used to obtain high voltages without the necessity of providing a high-voltage transformer. The circuit in Fig. 5.8 multiplies the peak secondary voltage by a factor of six. The steady-state voltage level at each filter capacitor node is shown in the figure. Adding additional stages increases the load voltage further. As in other rectifier circuits, the value of the capacitors will determine the amount of ripple in the output waveform for given load resistance values. In general, the capacitors in a lower voltage stage should be larger than in the next highest voltage stage.

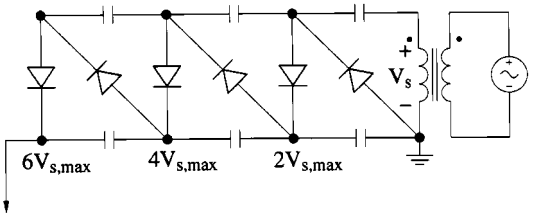

FIGURE 5.8 Cockroft-Walton circuit used for voltage multiplication.

Defining Terms

Bipolar device: Semiconductor electronic device that uses positive and negative charge carriers to conduct electric current.

Diode: Two-terminal solid-state semiconductor device that presents a low impedance to current flow in one direction and a high impedance to current flow in the opposite direction.

***pn*-junction:** Metallurgical interface of two regions in a semiconductor where one region contains impurity elements that create equivalent positive charge carriers (*p*-type) and the other semiconductor region contains impurities that create negative charge carriers (*n*-type).

Ripple: The ac (time-varying) portion of the output signal from a rectifier circuit.

Schottky diode: A diode formed by placing a metal layer directly onto a unipolar semiconductor substrate.

Uncontrolled rectifier: A rectifier circuit employing switches that do not require control signals to operate them in their "on" or "off" states.

Further Information

A good introduction to solid-state electronic devices with a minimum of mathematics and physics is *Solid State Electronic Devices,* 3rd edition, by B.G. Streetman, Prentice-Hall, 1989. A rigorous and more detailed discussion is provided in *Physics of Semiconductor Devices,* 2nd edition, by S.M. Sze, John Wiley & Sons, 1981. Both of these books discuss many specialized diode structures as well as other semiconductor devices. Advanced material on the most recent developments in semiconductor devices, including diodes, can be found in technical journals such as the *IEEE Transactions on Electron Devices, Solid State Electronics,* and *Journal of Applied Physics.* A good summary of advanced rectifier topologies and characteristics is given in *Basic Principles of Power Electronics* by K. Heumann, Springer-Verlag, 1986. Advanced material on rectifier designs as well as other power electronics circuits can be found in *IEEE Transactions on Power Electronics, IEEE Transactions on Industry Applications,* and the *EPE Journal.* Two good industry magazines that cover power devices such as diodes and power converter circuitry are *Power Control and Intelligent Motion* (PCIM) and *Power Technics.*

5.2 Limiters[1]

Theodore F. Bogart, Jr.

Limiters are named for their ability to limit voltage excursions at the output of a circuit whose input may undergo unrestricted variations. They are also called *clipping circuits* because waveforms having rounded peaks that exceed the limit(s) imposed by such circuits appear, after limiting, to have their peaks flattened, or "clipped" off. **Limiters** may be designed to clip positive voltages at a certain level, negative voltages at a different level, or to do both. The simplest types consist simply of diodes and dc voltage sources, while more elaborate designs incorporate operational amplifiers.

Limiting Circuits

Figure 5.9 shows how the transfer characteristics of limiting circuits reflect the fact that outputs are clipped at certain levels. In each of the examples shown, note that the characteristic becomes horizontal at the output level where clipping occurs. The horizontal line means that the output remains constant regardless of the input level in that region. Outside of the clipping region, the transfer characteristic is simply a line whose slope equals

[1]Excerpted from T.F. Bogart, Jr., *Electronic Devices and Circuits,* 3rd ed., Columbus, Ohio:Macmillan/Merrill, 1993, pp. 689–697. With permission.

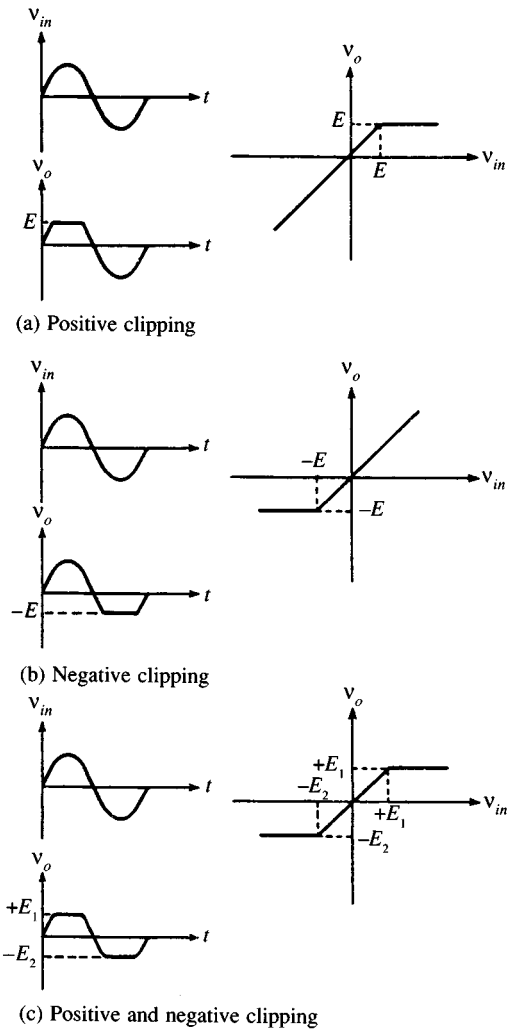

FIGURE 5.9 Waveforms and transfer characteristics of limiting circuits. (*Source:* T.F. Bogart, Jr., *Electronic Devices and Circuits,* 3rd ed., Columbus, Ohio: Macmillan/Merrill, 1993, p. 676. With permission.)

the gain of the device. This is the region of linear operation. In these examples, the devices are assumed to have unity gain, so the slope of each line in the linear region is 1.

Figure 5.10 illustrates a somewhat different kind of limiting action. Instead of the positive or negative peaks being clipped, the output follows the input when the signal is above or below a certain level. The transfer characteristics show that linear operation occurs only when certain signal levels are reached and that the output remains constant below those levels. This form of limiting can also be thought of as a special case of that shown in Fig. 5.9. Imagine, for example, that the clipping level in Fig. 5.9(b) is raised to a positive value; then the result is the same as Fig. 5.10(a).

Limiting can be accomplished using **biased diodes.** Such circuits rely on the fact that diodes have very low impedances when they are forward biased and are essentially open circuits when reverse biased. If a certain point in a circuit, such as the output of an amplifier, is connected through a very small impedance to a *constant* voltage, then the voltage at the circuit point cannot differ significantly from the constant voltage. We say in this case that the point is *clamped* to the fixed voltage. An ideal, forward-biased diode is like a closed switch, so if it is connected between a point in a circuit and a fixed voltage source, the diode very effectively holds the point to the fixed voltage. Diodes can be connected in operational amplifier circuits, as well as other circuits,

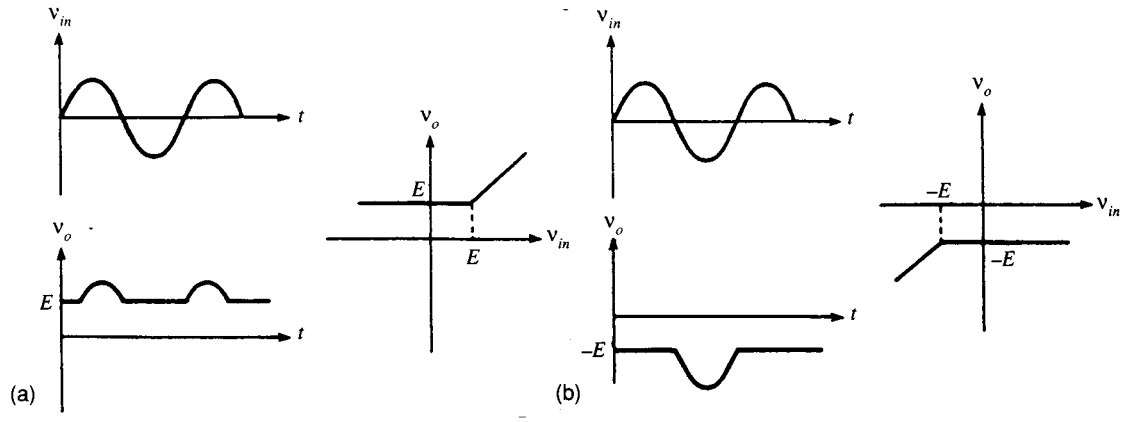

FIGURE 5.10 Another form of clipping. Compare with Fig. 5.9. (*Source:* T.F. Bogart, Jr., *Electronic Devices and Circuits,* 3rd ed., Columbus, Ohio: Macmillan/Merrill, 1993, p. 690. With permission.)

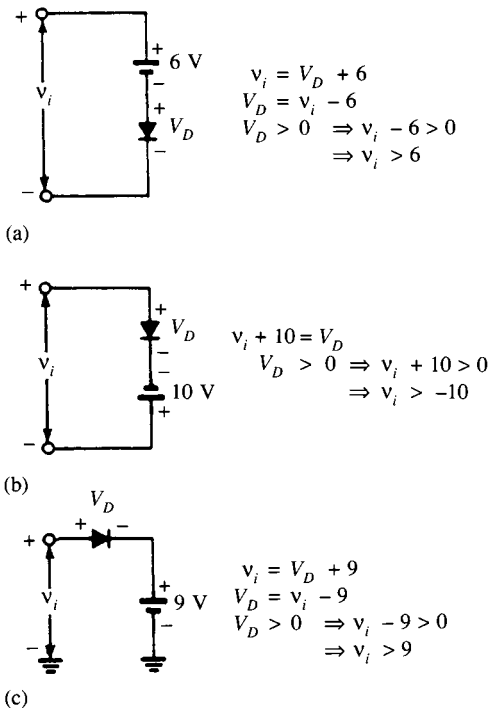

FIGURE 5.11 Examples of biased diodes and the signal voltages v_i required to forward bias them. (Ideal diodes are assumed.) In each case, we solve for the value of v_i that is necessary to make $V_D > 0$. (*Source:* T.F. Bogart, Jr., *Electronic Devices and Circuits,* 3rd ed., Columbus, Ohio: Macmillan/Merrill, 1993, p. 691. With permission.)

in such a way that they become forward biased when a signal reaches a certain voltage. When the forward-biasing level is reached, the diode serves to hold the output to a fixed voltage and thereby establishes a clipping level.

A biased diode is simply a diode connected to a fixed voltage source. The value and polarity of the voltage source determine what value of total voltage across the combination is necessary to forward bias the diode. Figure 5.11 shows several examples. (In practice, a series resistor would be connected in each circuit to limit current flow when the diode is forward biased.) In each part of the figure, we can write Kirchhoff's voltage law

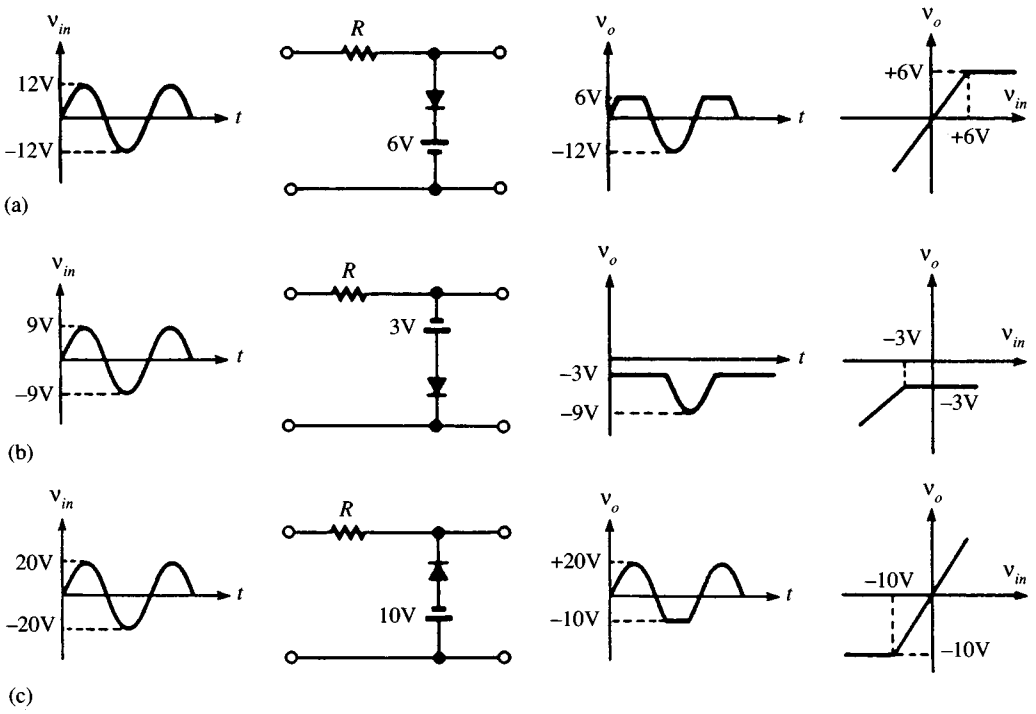

FIGURE 5.12 Examples of parallel clipping circuits. (*Source:* T.F. Bogart, Jr., *Electronic Devices and Circuits,* 3rd ed., Columbus, Ohio: Macmillan/Merrill, 1993, p. 692. With permission.)

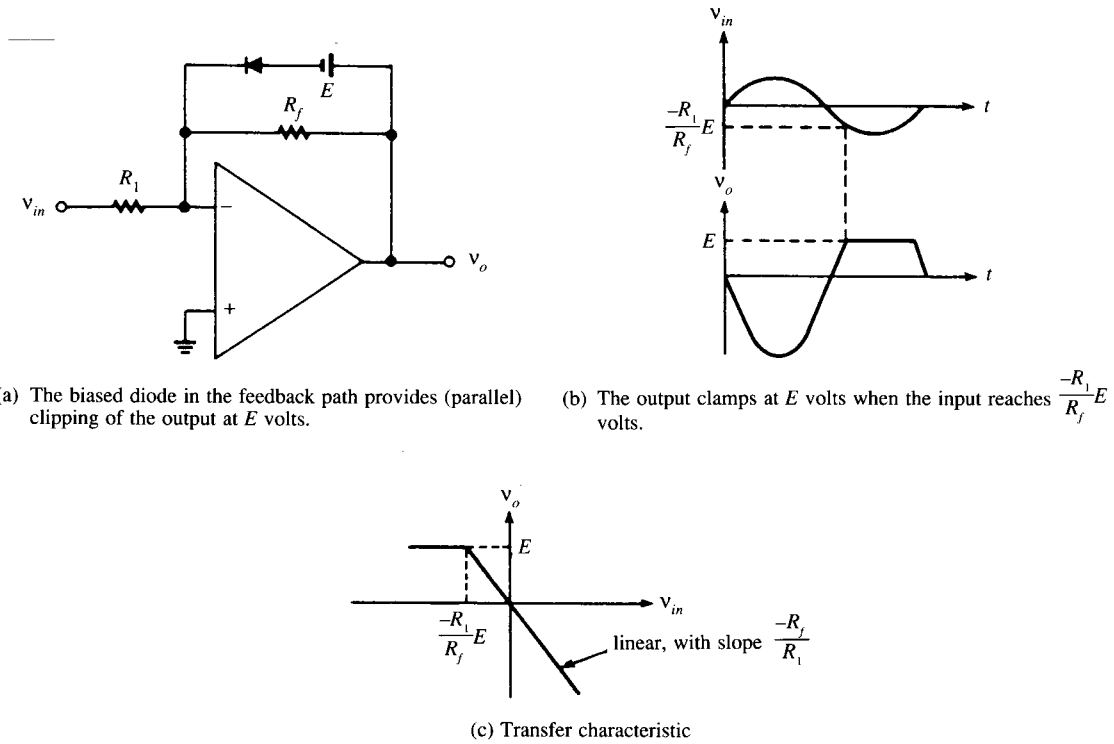
around the loop to determine the value of input voltage v_i that is necessary to forward bias the diode. Assuming that the diodes are ideal (neglecting their forward voltage drops), we determine the value v_i necessary to forward bias each diode by determining the value v_i necessary to make $v_D > 0$. When v_i reaches the voltage necessary to make $V_D > 0$, the diode becomes forward biased and the signal source is forced to, or held at, the dc source voltage. If the forward voltage drop across the diode is not neglected, the clipping level is found by determining the value of v_i necessary to make V_D greater than that forward drop (e.g., $V_D > 0.7$ V for a silicon diode).

Figure 5.12 shows three examples of clipping circuits using ideal biased diodes and the waveforms that result when each is driven by a sine-wave input. In each case, note that the output equals the dc source voltage when the input reaches the value necessary to forward bias the diode. Note also that the type of clipping we showed in Fig. 5.9 occurs when the fixed bias voltage tends to *reverse* bias the diode, and the type shown in Fig. 5.10 occurs when the fixed voltage tends to *forward* bias the diode. When the diode is reverse biased by the input signal, it is like an open circuit that disconnects the dc source, and the output follows the input. These circuits are called *parallel* clippers because the biased diode is in parallel with the output. Although the circuits behave the same way whether or not one side of the dc voltage source is connected to the common (low) side of the input and output, the connections shown in Fig. 5.12(a) and (c) are preferred to that in (b), because the latter uses a floating source.

Figure 5.13 shows a biased diode connected in the feedback path of an inverting operational amplifier. The diode is in parallel with the feedback resistor and forms a parallel clipping circuit like that shown in Fig. 5.12. In an operational amplifier circuit, $v^- \approx v^+$, and since $v^+ = 0$ V in this circuit, v^- is approximately 0 V (virtual ground). Thus, the voltage across R_f is the same as the output voltage v_o. Therefore, when the output voltage reaches the bias voltage E, the output is held at E volts. Figure 5.13(b) illustrates this fact for a sinusoidal input. So long as the diode is reverse biased, it acts like an open circuit and the amplifier behaves like a conventional inverting amplifier. Notice that output clipping occurs at *input* voltage $-(R_1/R_f)E$, since the amplifier inverts and has closed-loop gain magnitude R_f/R_1. The resulting transfer characteristic is shown in Fig. 5.13(c).

In practice, the biased diode shown in the feedback of Fig. 5.13(a) is often replaced by a *Zener* diode in series with a conventional diode. This arrangement eliminates the need for a floating voltage source. Zener diodes



(a) The biased diode in the feedback path provides (parallel) clipping of the output at E volts.

(b) The output clamps at E volts when the input reaches $\frac{-R_1}{R_f}E$ volts.

(c) Transfer characteristic

FIGURE 5.13 An operational amplifier limiting circuit. (*Source:* T.F. Bogart, Jr., *Electronic Devices and Circuits,* 3rd ed., Columbus, Ohio:Macmillan/Merrill, 1993, p. 693. With permission.)

are in many respects functionally equivalent to biased diodes. Figure 5.14 shows two operational amplifier clipping circuits using Zener diodes. The Zener diode conducts like a conventional diode when it is forward biased, so it is necessary to connect a reversed diode in series with it to prevent shorting of R_f. When the reverse voltage across the Zener diode reaches V_Z, the diode breaks down and conducts heavily, while maintaining an essentially constant voltage, V_Z, across it. Under those conditions, the total voltage across R_f, i.e., v_o, equals V_Z plus the forward drop, V_D, across the conventional diode.

Figure 5.15 shows *double-ended* limiting circuits, in which both positive and negative peaks of the output waveform are clipped. Figure 5.15(a) shows the conventional parallel clipping circuit and (b) shows how double-ended limiting is accomplished in an operational amplifier circuit. In each circuit, note that no more than one diode is forward biased at any given time and that both diodes are reverse biased for $-E_1 < v_o < E_2$, the linear region.

Figure 5.16 shows a double-ended limiting circuit using back-to-back Zener diodes. Operation is similar to that shown in Fig. 5.14, but no conventional diode is required. Note that diode D_1 is conducting in a forward direction when D_2 conducts in its reverse breakdown (Zener) region, while D_2 is forward biased when D_1 is conducting in its reverse breakdown region. Neither diode conducts when $-(V_{Z2} + 0.7) < v_o < (V_{Z1} + 0.7)$, which is the region of linear amplifier operation.

Precision Rectifying Circuits

A *rectifier* is a device that allows current to pass through it in one direction only. A diode can serve as a rectifier because it permits generous current flow in only one direction—the direction of forward bias. Rectification is the same as limiting at the 0-V level: all of the waveform below (or above) the zero-axis is eliminated. However, a diode rectifier has certain intervals of nonconduction and produces resulting "gaps" at the zero-crossing points of the output voltage, due to the fact that the input must overcome the diode drop (0.7 V for silicon) before

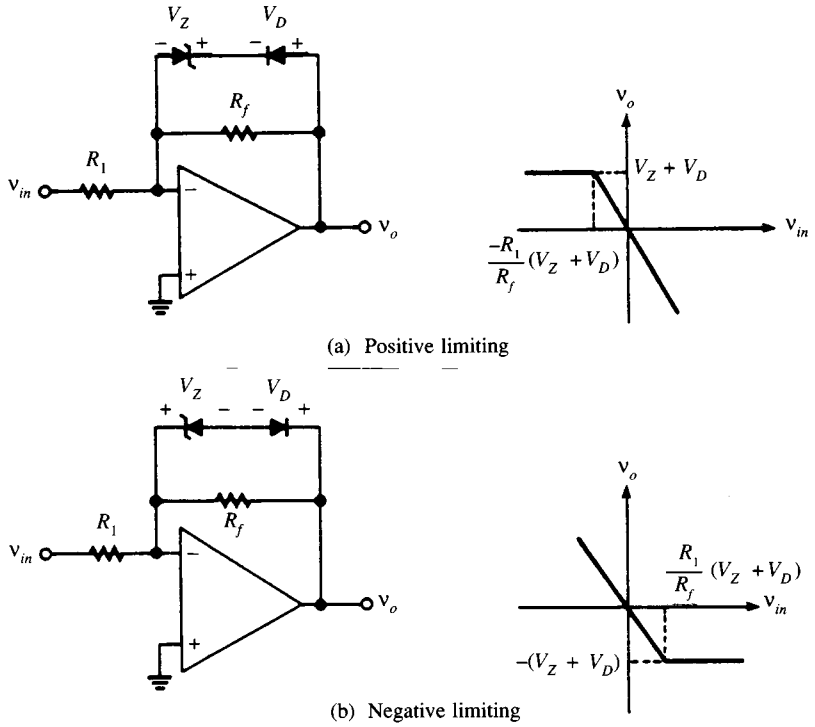


FIGURE 5.14 Operational amplifier limiting circuits using Zener diodes. (*Source:* T.F. Bogart, Jr., *Electronic Devices and Circuits,* 3rd ed., Columbus, Ohio: Macmillan/Merrill, 1993, p. 694. With permission.)

conduction begins. In power-supply applications, where input voltages are quite large, these gaps are of no concern. However, in many other applications, especially in instrumentation, the 0.7-V drop can be a significant portion of the total input voltage swing and can seriously affect circuit performance. For example, most ac instruments rectify ac inputs so they can be measured by a device that responds to dc levels. It is obvious that small ac signals could not be measured if it were always necessary for them to reach 0.7 V before rectification could begin. For these applications, *precision* rectifiers are necessary.

Figure 5.17 shows one way to obtain precision rectification using an operational amplifier and a diode. The circuit is essentially a noninverting voltage follower (whose output follows, or duplicates, its input) when the diode is forward biased. When v_{in} is positive, the output of the amplifier, v_o, is positive, the diode is forward biased, and a low-resistance path is established between v_o and v^-, as necessary for a voltage follower. The load voltage, v_L, then follows the positive variations of $v_{in} = v^+$. Note that even a very small positive value of v_{in} will cause this result, because of the large differential gain of the amplifier. That is, the large gain and the action of the feedback cause the usual result that $v^+ \approx v^-$. Note also that the drop across the diode does not appear in v_L.

When the input goes negative, v_o becomes negative, and the diode is reverse biased. This effectively opens the feedback loop, so v_L no longer follows v_{in}. The amplifier itself, now operating open-loop, is quickly driven to its maximum negative output, thus holding the diode well into reverse bias.

Another precision rectifier circuit is shown in Fig. 5.18. In this circuit, the load voltage is an amplified and inverted version of the *negative* variations in the input signal, and is 0 when the input is positive. Also in contrast with the previous circuit, the amplifier in this rectifier is not driven to one of its output extremes. When v_{in} is negative, the amplifier output, v_o, is positive, so diode D_1 is reverse biased and diode D_2 is forward biased. D_1 is open and D_2 connects the amplifier output through R_f to v^-. Thus, the circuit behaves like an ordinary inverting amplifier with gain $-R_f/R_1$. The load voltage is an amplified and inverted (positive) version of the negative variations in v_{in}. When v_{in} becomes positive, v_o is negative, D_1 is forward biased, and D_2 is reverse biased. D_1 shorts the output v_o to v^-, which is held at virtual ground, so v_L is 0.

Defining Terms

Biased diode: A diode connected in series with a dc voltage source in order to establish a clipping level. Clipping occurs when the voltage across the combination is sufficient to forward bias the diode.

Limiter: A device or circuit that restricts voltage excursions to prescribed level(s). Also called a clipping circuit.

5.3 Distortion

Kartikeya Mayaram

The diode was introduced in the previous sections as a nonlinear device that is used in rectifiers and limiters. These are applications that depend on the nonlinear nature of the diode. Typical electronic systems are composed not only of diodes but also of other nonlinear devices such as transistors (Section III). In analog applications transistors are used to amplify weak signals (amplifiers) and to drive large loads (output stages). For such situations it is desirable that the output be an amplified true reproduction of the input signal; therefore, the transistors must operate as linear devices. However, the inherent nonlinearity of transistors results in an output which is a "distorted" version of the input.

The distortion due to a nonlinear device is illustrated in Fig. 5.19. For an input X the output is $Y = F(X)$ where F denotes the nonlinear transfer characteristics of the device; the dc operating point is given by X_0. Sinusoidal input signals of two different amplitudes are applied and the output responses corresponding to these inputs are also shown.

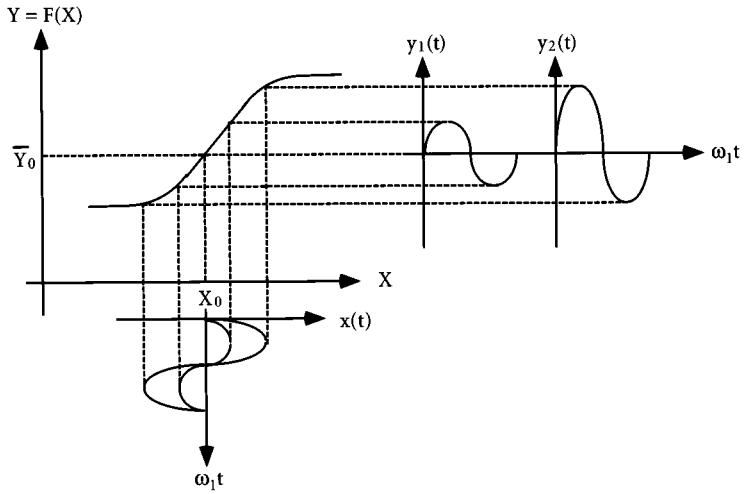

FIGURE 5.19 DC transfer characteristics of a nonlinear circuit and the input and output waveforms. For a large input amplitude the output is distorted.

For an input signal of small amplitude the output faithfully follows the input, whereas for large-amplitude signals the output is distorted; a flattening occurs at the negative peak value. The distortion in amplitude results in the output having frequency components that are integer multiples of the input frequency, *harmonics*, and this type of distortion is referred to as **harmonic distortion.**

The distortion level places a restriction on the amplitude of the input signal that can be applied to an electronic system. Therefore, it is essential to characterize the distortion in a circuit. In this section different types of distortion are defined and techniques for distortion calculation are presented. These techniques are applicable to simple circuit configurations. For larger circuits a circuit simulation program is invaluable.

Harmonic Distortion

When a sinusoidal signal of a single frequency is applied at the input of a nonlinear device or circuit, the resulting output contains frequency components that are integer multiples of the input signal. These harmonics are generated by the nonlinearity of the circuit and the *harmonic distortion* is measured by comparing the magnitudes of the harmonics with the fundamental component (input frequency) of the output.

Consider the input signal to be of the form:

$$x(t) = X_1 \cos \omega_1 t \tag{5.2}$$

where $f_1 = \omega_1/2\pi$ is the frequency and X_1 is the amplitude of the input signal. Let the output of the nonlinear circuit be

$$y(t) = Y_0 + Y_1 \cos \omega_1 t + Y_2 \cos 2\omega_1 t + Y_3 \cos 3\omega_1 t + \ldots \tag{5.3}$$

where Y_0 is the dc component of the output, Y_1 is the amplitude of the fundamental component, and Y_2, Y_3 are the amplitudes of the second and third harmonic components. The *second harmonic distortion factor* (HD_2), the *third harmonic distortion factor* (HD_3), and the *n*th *harmonic distortion factor* (HD_n) are defined as

$$HD_2 = \frac{|Y_2|}{|Y_1|} \tag{5.4}$$

$$\mathrm{HD}_3 = \frac{|Y_3|}{|Y_1|} \tag{5.5}$$

$$\mathrm{HD}_n = \frac{|Y_n|}{|Y_1|} \tag{5.6}$$

The **total harmonic distortion** (THD) of a waveform is defined to be the ratio of the rms (root-mean-square) value of the harmonics to the amplitude of the fundamental component.

$$\mathrm{THD} = \frac{\sqrt{Y_2^2 + Y_3^2 + \cdots + Y_n^2}}{|Y_1|} \tag{5.7}$$

THD can be expressed in terms of the individual **harmonic distortion factors**

$$\mathrm{THD} = \sqrt{\mathrm{HD}_2^2 + \mathrm{HD}_3^2 + \cdots + \mathrm{HD}_n^2} \tag{5.8}$$

Various methods for computing the harmonic distortion factors are described next.

Power-Series Method

In this method a truncated power-series expansion of the dc transfer characteristics of a nonlinear circuit is used. Therefore, the method is suitable only when energy storage effects in the nonlinear circuit are negligible and the input signal is small. In general, the input and output signals comprise both dc and time-varying components. For distortion calculation we are interested in the time-varying or incremental components around a quiescent[1] operating point. For the transfer characteristic of Fig. 5.19, denote the quiescent operating conditions by X_0 and $\bar{Y}_0$ and the incremental variables by $x(t)$ and $y(t)$, at the input and output, respectively. The output can be expressed as a function of the input using a series expansion

$$\bar{Y}_0 + y = F(X_0 + x) = a_0 + a_1 x + a_2 x^2 + a_3 x^3 + \ldots \tag{5.9}$$

where $a_0 = \bar{Y}_0 = F(X_0)$ is the output at the dc operating point. The incremental output is

$$y = a_1 x + a_2 x^2 + a_3 x^3 + \ldots \tag{5.10}$$

Depending on the amplitude of the input signal, the series can be truncated at an appropriate term. Typically only the first few terms are used, which makes this technique applicable only to small input signals. For a pure sinusoidal input [Eq. (5.2)], the distortion in the output can be estimated by substituting for x in Eq. (5.10) and by use of trigonometric identities one can arrive at the form given by Eq. (5.3). For a series expansion that is truncated after the cubic term

[1]Defined as the operating condition when the input has no time-varying component.

$$
\begin{aligned}
Y_0 &= \frac{a_2 X_1^2}{2} \\
Y_1 &= a_1 X_1 + \frac{3a_3 X_1^3}{4} \cong a_1 X_1 \\
Y_2 &= \frac{a_2 X_1^2}{2} \\
Y_3 &= \frac{a_3 X_1^3}{4}
\end{aligned}
\tag{5.11}
$$

Notice that a dc term Y_0 is present in the output (produced by the even-powered terms) which results in a shift of the operating point of the circuit due to distortion. In addition, depending on the sign of a_3 there can be an *expansion* or *compression* of the fundamental component. The harmonic distortion factors (assuming $Y_1 = a_1 X_1$) are

$$
\begin{aligned}
\mathrm{HD}_2 &= \frac{|Y_2|}{|Y_1|} = \frac{1}{2}\left|\frac{a_2}{a_1} X_1\right| \\
\mathrm{HD}_3 &= \frac{|Y_3|}{|Y_1|} = \frac{1}{4}\left|\frac{a_3}{a_1} X_1^2\right|
\end{aligned}
\tag{5.12}
$$

As an example, choose as the transfer function $Y = F(X) = \exp(X)$; then, $a_1 = 1$, $a_2 = 1/2$, $a_3 = 1/6$. For an input signal amplitude of 0.1, $\mathrm{HD}_2 = 2.5\%$ and $\mathrm{HD}_3 = 0.04\%$.

Differential-Error Method

This technique is also applicable to nonlinear circuits in which energy storage effects can be neglected. The method is valuable for circuits that have small distortion levels and relies on one's ability to calculate the small-signal gain of the nonlinear function at the quiescent operating point and at the maximum and minimum excursions of the input signal. Again the power-series expansion provides the basis for developing this technique. The small-signal gain[1] at the quiescent state ($x = 0$) is a_1. At the extreme values of the input signal X_1 (positive peak) and $-X_1$ (negative peak) let the small-signal gains be a^+ and a^-, respectively. By defining two new parameters, the differential errors, E^+ and E^-, as

$$
E^+ = \frac{a^+ - a_1}{a_1} \qquad E^- = \frac{a^- - a_1}{a_1} \tag{5.13}
$$

the distortion factors are given by

$$
\begin{aligned}
\mathrm{HD}_2 &= \frac{E^+ - E^-}{8} \\
\mathrm{HD}_3 &= \frac{E^+ + E^-}{24}
\end{aligned}
\tag{5.14}
$$

[1]Small-signal gain $= dy/dx = a_1 + 2a_2 x + 3a_3 x^2 + \ldots$

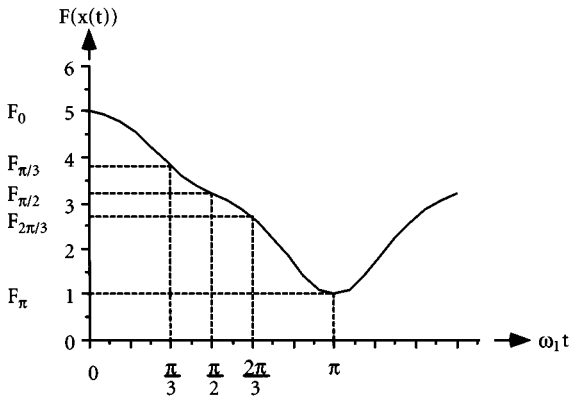

FIGURE 5.20 Output waveform from a nonlinear circuit.

The advantage of this method is that the transfer characteristics of a nonlinear circuit can be directly used; an explicit power-series expansion is not required. Both the power-series and the differential-error techniques cannot be applied when only the output waveform is known. In such a situation the distortion factors are calculated from the output signal waveform by a simplified Fourier analysis as described in the next section.

Three-Point Method

The three-point method is a simplified analysis applicable to small levels of distortion and can only be used to calculate HD_2. The output is written directly as a Fourier cosine series as in Eq. (5.3) where only terms up to the second harmonic are retained. The dc component includes the quiescent state and the contribution due to distortion that results in a shift of the dc operating point. The output waveform values at $\omega_1 t = 0$ (F_0), $\omega_1 t = \pi/2$ $(F_{\pi/2})$, $\omega_1 t = \pi$ (F_π), as shown in Fig. 5.20, are used to calculate Y_0, Y_1, and Y_2.

$$
\begin{aligned}
Y_0 &= \frac{F_0 + 2F_{\pi/2} + F_\pi}{4} \\
Y_1 &= \frac{F_0 - F_\pi}{2} \\
Y_2 &= \frac{F_0 - 2F_{\pi/2} + F_\pi}{4}
\end{aligned}
\tag{5.15}
$$

The second harmonic distortion is calculated from the definition. From Fig. 5.20, $F_0 = 5$, $F_{\pi/2} = 3.2$, $F_\pi = 1$, $Y_0 = 3.1$, $Y_1 = 2.0$, $Y_2 = -0.1$, and $HD_2 = 5.0\%$.

Five-Point Method

The five-point method is an extension of the above technique and allows calculation of third and fourth harmonic distortion factors. For distortion calculation the output is expressed as a Fourier cosine series with terms up to the fourth harmonic where the dc component includes the quiescent state and the shift due to distortion. The output waveform values at $\omega_1 t = 0$ (F_0), $\omega_1 t = \pi/3$ $(F_{\pi/3})$, $\omega_1 t = \pi/2$ $(F_{\pi/2})$, $\omega_1 t = 2\pi/3$ $(F_{2\pi/3})$, $\omega_1 t = \pi$ (F_π), as shown in Fig. 5.20, are used to calculate Y_0, Y_1, Y_2, Y_3, and Y_4.

$$
\begin{aligned}
Y_0 &= \frac{F_0 + 2F_{\pi/3} + 2F_{2\pi/3} + F_\pi}{6} \\
Y_1 &= \frac{F_0 + F_{\pi/3} - F_{2\pi/3} - F_\pi}{3} \\
Y_2 &= \frac{F_0 - 2F_{\pi/2} + F_\pi}{4} \\
Y_3 &= \frac{F_0 - 2F_{\pi/3} + 2F_{2\pi/3} - F_\pi}{6} \\
Y_4 &= \frac{F_0 - 4F_{\pi/3} + 6F_{\pi/2} - 4F_{2\pi/3} + F_\pi}{12}
\end{aligned} \tag{5.16}
$$

For $F_0 = 5$, $F_{\pi/3} = 3.8$, $F_{\pi/2} = 3.2$, $F_{2\pi/3} = 2.7$, $F_\pi = 1$, $Y_0 = 3.17$, $Y_1 = 1.7$, $Y_2 = -0.1$, $Y_3 = 0.3$, $Y_4 = -0.07$, and $HD_2 = 5.9\%$, $HD_3 = 17.6\%$. This particular method allows calculation of HD_3 and also gives a better estimate of HD_2. To obtain higher-order harmonics a detailed Fourier series analysis is required and for such applications a circuit simulator, such as SPICE, should be used.

Intermodulation Distortion

The previous sections have examined the effect of nonlinear device characteristics when a single-frequency sinusoidal signal is applied at the input. However, if there are two or more sinusoidal inputs, then the nonlinearity results in not only the fundamental and harmonics but also additional frequencies called the *beat frequencies* at the output. The distortion due to the components at the beat frequencies is called **intermodulation distortion.** To characterize this type of distortion consider the incremental output given by Eq. (5.10) and the input signal to be

$$x(t) = X_1 \cos \omega_1 t + X_2 \cos \omega_2 t \tag{5.17}$$

where $f_1 = \omega_1/2\pi$ and $f_2 = \omega_2/2\pi$ are the two input frequencies. The output frequency spectrum due to the quadratic term is shown in Table 5.1.

In addition to the dc term and the second harmonics of the two frequencies, there are additional terms at the sum and difference frequencies, $f_1 + f_2$, $f_1 - f_2$, which are the beat frequencies. The *second-order intermodulation distortion* (IM_2) is defined as the ratio of the amplitude at a beat frequency to the amplitude of the fundamental component.

$$IM_2 = \left| \frac{a_2 X_1 X_2}{a_1 X_1} \right| = \left| \frac{a_2 X_2}{a_1} \right| \tag{5.18}$$

where it has been assumed that the contribution to second-order intermodulation by higher-order terms is negligible. In defining IM_2 the input signals are assumed to be of equal amplitude and for this particular condition $IM_2 = 2\ HD_2$ [Eq. (5.12)].

TABLE 5.1 Output Frequency Spectrum Due to the Quadratic Term

Frequency	0	$2f_1$	$2f_2$	$f_1 \pm f_2$
Amplitude	$\frac{a_2}{2}[X_1^2 + X_2^2]$	$\frac{a_2}{2}X_1^2$	$\frac{a_2}{2}X_2^2$	$a_2 X_1 X_2$

TABLE 5.2 Output Frequency Spectrum Due to the Cubic Term

Frequency	f_1	f_2	$2f_1 \pm f_2$	$2f_2 \pm f_1$	$3f_1$	$3f_2$
Amplitude	$\frac{3a_3}{4}[X_1^3 + X_1X_2^2]$	$\frac{3a_3}{4}[X_2^3 + X_1^2X_2]$	$\frac{3}{4}a_3X_1^2X_2$	$\frac{3}{4}a_3X_1X_2^2$	$\frac{1}{4}a_3X_1^3$	$\frac{1}{4}a_3X_2^3$

The cubic term of the series expansion for the nonlinear circuit gives rise to components at frequencies $2f_1 + f_2$, $2f_2 + f_1$, $2f_1 - f_2$, $2f_2 - f_1$, and these terms result in *third-order intermodulation distortion* (IM_3). The frequency spectrum obtained from the cubic term is shown in Table 5.2.

For definition purposes the two input signals are assumed to be of equal amplitude and IM_3 is given by (assuming negligible contribution to the fundamental by the cubic term)

$$IM_3 = \frac{3}{4}\left|\frac{a_3X_1^3}{a_1X_1}\right| = \frac{3}{4}\left|\frac{a_3X_1^2}{a_1}\right| \tag{5.19}$$

Under these conditions $IM_3 = 3\ HD_3$ [Eq. (5.12)]. When f_1 and f_2 are close to one another, then the third-order intermodulation components, $2f_1 - f_2$, $2f_2 - f_1$, are close to the fundamental and are difficult to filter out.

Triple-Beat Distortion

When three sinusoidal signals are applied at the input then the output consists of components at the triple-beat frequencies. The cubic term in the nonlinearity results in the triple-beat terms

$$\frac{3}{2}a_3X_1X_2X_2\ \cos[\omega_1 \pm \omega_2 \pm \omega_3]t \tag{5.20}$$

and the *triple-beat distortion factor* (TB) is defined for equal amplitude input signals.

$$TB = \frac{3}{2}\left|\frac{a_3X_1^2}{a_1}\right| \tag{5.21}$$

From the above definition $TB = 2\ IM_3$. If all of the frequencies are close to one another, the triple beats will be close to the fundamental and cannot be easily removed.

Cross Modulation

Another form of distortion that occurs in amplitude-modulated (AM) systems (Chapter 63) due to the circuit nonlinearity is **cross modulation**. The modulation from an unwanted AM signal is transferred to the signal of interest and results in distortion. Consider an AM signal

$$x(t) = X_1\cos\omega_1t + X_2[1 + m\cos\omega_mt]\cos\omega_2t \tag{5.22}$$

where $m < 1$ is the modulation index. Due to the cubic term of the nonlinearity the modulation from the second signal is transferred to the first and the modulated component corresponding to the fundamental is

$$a_1X_1\left[1 + \frac{3a_3X_2^2m}{a_1}\cos\omega_mt\right]\cos\omega_1t \tag{5.23}$$

The *cross-modulation factor* (CM) is defined as the ratio of the transferred modulation index to the original modulation.

$$\mathrm{CM} = 3\left|\frac{a_3 X_2^2}{a_1}\right| \tag{5.24}$$

The cross modulation is a factor of four larger than IM_3 and twelve times as large as HD_3.

Compression and Intercept Points

For high-frequency circuits distortion is specified in terms of **compression and intercept points**. These quantities are derived from extrapolated small-signal output power levels. The 1 *dB compression point* is defined as the value of the fundamental output power for which the power is 1 dB below the extrapolated small-signal value.

The *nth-order intercept point* (IP_n), $n \geq 2$, is the output power at which the extrapolated small-signal powers of the fundamental and the nth harmonic intersect. Let P_{in} be an input power that is small enough to ensure small-signal operation. If P_1 is the output power of the fundamental, and P_n the output power of the nth harmonic, then the nth-order intercept point is given by $IP_n = \frac{nP_1 - P_n}{n-1}$, where power is measured in dB.

Crossover Distortion

This type of distortion occurs in circuits that use devices operating in a "push-pull" manner. The devices are used in pairs and each device operates only for half a cycle of the input signal (Class AB operation). One advantage of such an arrangement is the cancellation of even harmonic terms resulting in smaller total harmonic distortion. However, if the circuit is not designed to achieve a smooth crossover or transition from one device to another, then there is a region of the transfer characteristics when the output is zero. The resulting distortion is called **crossover distortion**.

Failure-to-Follow Distortion

When a properly designed peak detector circuit is used for AM demodulation the output follows the envelope of the input signal whereby the original modulation signal is recovered. A simple peak detector is a diode in series with a low-pass RC filter. The critical component of such a circuit is a linear element, the filter capacitance C. If C is large, then the output fails to follow the envelope of the input signal, resulting in **failure-to-follow distortion.**

Frequency Distortion

Ideally an amplifier circuit should provide the same amplification for all input frequencies. However, due to the presence of energy storage elements the gain of the amplifier is frequency dependent. Consequently different frequency components have different amplifications resulting in **frequency distortion.** The distortion is specified by a frequency response curve in which the amplifier output is plotted as a function of frequency. An ideal amplifier has a flat frequency response over the frequency range of interest.

Phase Distortion

When the phase shift (θ) in the output signal of an amplifier is not proportional to the frequency, the output does not preserve the form of the input signal, resulting in **phase distortion.** If the phase shift is proportional to frequency, different frequency components have a constant delay time (θ/ω) and no distortion is observed. In TV applications phase distortion can result in a smeared picture.

Computer Simulation of Distortion Components

Distortion characterization is important for nonlinear circuits. However, the techniques presented for distortion calculation can only be used for simple circuit configurations and at best to determine the second and third

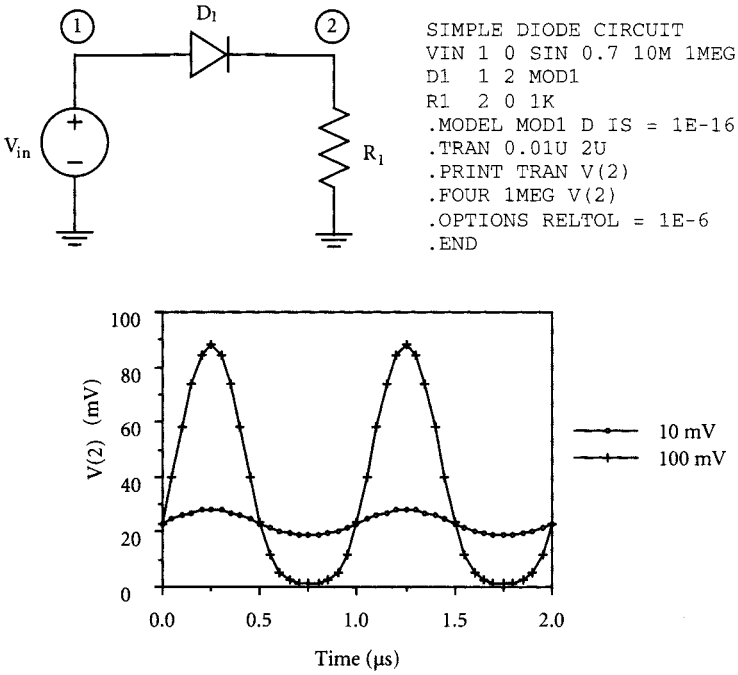

FIGURE 5.21 Simple diode circuit, SPICE input file, and output voltage waveforms.

harmonic distortion factors. In order to determine the distortion generation in actual circuits one must fabricate the circuit and then use a harmonic analyzer for sine curve inputs to determine the harmonics present in the output. An attractive alternative is the use of circuit simulation programs that allow one to investigate circuit performance before fabricating the circuit. In this section a brief overview of the techniques used in circuit simulators for distortion characterization is provided.

The simplest approach is to simulate the time-domain output for a circuit with a specified sinusoidal input signal and then perform a Fourier analysis of the output waveform. The simulation program SPICE2 provides a capability for computing the Fourier components of any waveform using a *.FOUR* command and specifying the voltage or current for which the analysis has to be performed. A simple diode circuit, the SPICE input file, and transient voltage waveforms for an input signal frequency of 1 MHz and amplitudes of 10 and 100 mV are shown in Fig. 5.21. The Fourier components of the resistor voltage are shown in Fig. 5.22; only the fundamental and first two significant harmonics are shown (SPICE provides information to the ninth harmonic).

In this particular example the input signal frequency is 1 MHz, and this is the frequency at which the Fourier analysis is requested. Since there are no energy storage elements in the circuit another frequency would have given identical results. To determine the Fourier components accurately a small value of the parameter RELTOL is used and a sufficient number of points for transient analysis are specified. From the output voltage waveforms and the Fourier analysis it is seen that the harmonic distortion increases significantly when the input voltage amplitude is increased from 10 mV to 100 mV.

The transient approach can be computationally expensive for circuits that reach their periodic steady state after a long simulation time. Results from the Fourier analysis are meaningful only in the periodic steady state, and although this approach works well for large levels of distortion it is inaccurate for small distortion levels.

For small distortion levels accurate distortion analysis can be performed by use of the Volterra series method. This technique is a generalization of the power-series method and is useful for analyzing harmonic and intermodulation distortion due to frequency-dependent nonlinearities. The SPICE3 program supports this analysis technique (in addition to the Fourier analysis of SPICE2) whereby the second and third harmonic and intermodulation components can be efficiently obtained by three small-signal analyses of the circuit.

FIGURE 5.22 Fourier components of the resistor voltage for input amplitudes of 10 and 100 mV, respectively.

An approach based on the *harmonic balance* technique available in the simulation program SPECTRE is applicable to both large and small levels of distortion. The program determines the periodic steady state of a circuit with a sinusoidal input. The unknowns are the magnitudes of the circuit variables at the fundamental frequency and at all the significant harmonics of the fundamental. The distortion levels can be simply calculated by taking the ratios of the magnitudes of the appropriate harmonics to the fundamental.

Defining Terms

Compression and Intercept Points: Characterize distortion in high-frequency circuits. These quantities are derived from extrapolated small-signal output power levels.

Cross modulation: Occurs in amplitude-modulated systems when the modulation of one signal is transferred to another by the nonlinearity of the system.

Crossover distortion: Present in circuits that use devices operating in a push-pull arrangement such that one device conducts when the other is off. Crossover distortion results if the transition or crossover from one device to the other is not smooth.

Failure-to-follow distortion: Can occur during demodulation of an amplitude-modulated signal by a peak detector circuit. If the capacitance of the low-pass RC filter of the peak detector is large, then the output fails to follow the envelope of the input signal, resulting in failure-to-follow distortion.

Frequency distortion: Caused by the presence of energy storage elements in an amplifier circuit. Different frequency components have different amplifications, resulting in frequency distortion and the distortion is specified by a frequency response curve.

Harmonic distortion: Caused by the nonlinear transfer characteristics of a device or circuit. When a sinusoidal signal of a single frequency (the *fundamental* frequency) is applied at the input of a nonlinear circuit, the output contains frequency components that are integer multiples of the fundamental frequency (*harmonics*). The resulting distortion is called harmonic distortion.

Harmonic distortion factors: A measure of the harmonic content of the output. The *n*th *harmonic distortion factor* is the ratio of the amplitude of the *n*th harmonic to the amplitude of the fundamental component of the output.

Intermodulation distortion: Distortion caused by the mixing or beating of two or more sinusoidal inputs due to the nonlinearity of a device. The output contains terms at the sum and difference frequencies called the *beat frequencies*.

Phase distortion: Occurs when the phase shift in the output signal of an amplifier is not proportional to the frequency.

Total harmonic distortion: The ratio of the root-mean-square value of the harmonics to the amplitude of the fundamental component of a waveform.

Further Information

Characterization and simulation of distortion in a wide variety of electronic circuits (with and without feedback) is presented in detail in Pederson and Mayaram [1991]. Also derivations for the simple analysis techniques are provided and verified using SPICE2 simulations. Algorithms for computer-aided analysis of distortion are available in Weiner and Spina [1980], Nagel [1975], Roychowdhury [1989], and Kundert [1987]. Chapter 5 of Kundert [1995] gives valuable information on use of Fourier analysis in SPICE for distortion calculation in circuits. The software packages SPICE2, SPICE3 and SPECTRE are available from EECS Industrial Liaison Program Office, University of California, Berkeley, CA 94720.

5.4 Communicating with Chaos

Michael Peter Kennedy and Géza Kolumbán

The goal of a digital communications system is to deliver information represented by a sequence of binary symbols from a transmitter, through a physical channel, to a receiver. The mapping of these symbols into analog signals is called digital modulation.

In a conventional digital modulation scheme, the modulator represents each symbol to be transmitted as a weighted sum of a number of *periodic* basis functions. For example, two orthogonal signals, such as a sine and a cosine, can be used. Each symbol represents a certain bit sequence and is mapped to a corresponding set of weights. The objective of the receiver is to recover the weights associated with the received signal and thereby

to decide which symbol was transmitted [1]. The receiver's estimate of the transmitted symbol is mapped back to a bit sequence by a decoder.

When sinusoidal basis functions are used, the modulated signal consists of segments of periodic waveforms corresponding to the individual symbols. A unique segment of analog waveform corresponds to each symbol. If the spread spectrum technique is not used, the transmitted signal is narrow-band. Consequently, multipath propagation can cause high attenuation or even dropout of the transmitted narrow-band signal.

Chaotic signals are *nonperiodic* waveforms, generated by deterministic systems, which are characterized by a continuous "noise-like" broad power spectrum [2]. In the time domain, chaotic signals appear "random." Chaotic systems are characterized by "sensitive dependence on initial conditions"; an arbitrarily small perturbation eventually causes a large change in the state of the system. Equivalently, chaotic signals decorrelate rapidly with themselves. The autocorrelation function of a chaotic signal has a large peak at zero and decays rapidly.

Thus, while chaotic signals share many of the properties of stochastic processes, they also possess a deterministic structure that makes it possible to generate noise-like chaotic signals in a theoretically reproducible manner. In particular, a continuous-time chaotic system can be used to generate a wideband noise-like signal with robust and reproducible statistical properties [2].

Due to its wide-band nature, a signal comprising chaotic basis functions is potentially more resistant to multipath propagation than one constructed of sinusoids. Thus, **chaotic digital modulation,** where the digital information signal to be transmitted is mapped to chaotic waveforms, is potentially useful in propagation environments where multipath effects dominate.

In this chapter section, four chaotic digital modulation techniques are described in detail: Chaos Shift Keying (CSK), **Chaotic On-Off Keying** (COOK), **Differential Chaos Shift Keying** (DCSK), and FM-DCSK.

Elements of Chaotic Digital Communications Systems

In a digital communications system, the symbol to be transmitted is mapped by the modulator to an analog sample function and this analog signal passes through an analog channel. The analog signal in the channel is subject to a number of disturbing influences, including attenuation, bandpass filtering, and additive noise. The role of the demodulator is to decide, on the basis of the received corrupted sample function, which symbol was transmitted.

Transmitter

The sample function of duration T representing a symbol i is a weighted sum of analog basis functions $g_j(t)$:

$$s_i(t) = \sum_{j=1}^{N} s_{ij} g_j(t) \tag{5.25}$$

In a conventional digital modulation scheme, the analog sample function of duration T that represents a symbol is a linear combination of *periodic, orthogonal* basis functions (e.g., a sine and a cosine, or sinusoids at different frequencies), and the symbol duration T is an integer multiple of the period of the basis functions.

In a *chaotic* digital communications system, shown schematically in Fig. 5.23, the analog sample function of duration T that represents a symbol is a weighted sum of inherently nonperiodic *chaotic* basis function(s).

Channel Model

In any practical communications system, the signal $r_i(t)$ that is present at the input to the demodulator differs from that which was transmitted, due to the effects of the channel.

The simplest realistic model of the channel is a linear bandpass channel with additive white Gaussian noise (AWGN). A block diagram of the bandpass AWGN channel model that is considered throughout this section and the next is shown in Fig. 5.24. The additive noise is characterized by its power spectral density No.

Receiver

The role of the receiver in a digital communications system is to decide, on the basis of the received signal $r_i(t)$, which symbol was transmitted. This decision is made by estimating some property of the received sample

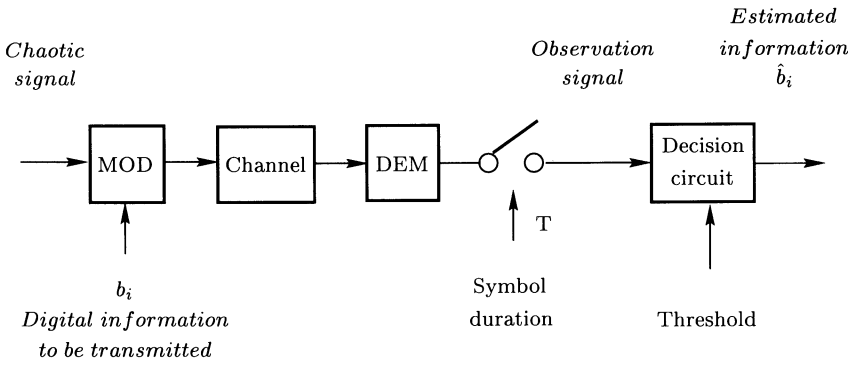

FIGURE 5.23 Block diagram of a chaotic communications scheme. The modulator and demodulator are labeled MOD and DEM, respectively.

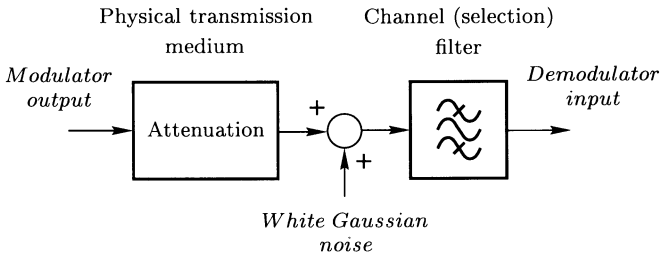

FIGURE 5.24 Model of an additive white Gaussian noise channel including the frequency selectivity of the receiver.

function. The property, for example, could be the weights of the coefficients of the basis functions, the energy of the received signal, or the correlation measured between different parts of the transmitted signal.

If the basis functions $g_j(t)$ are chosen such that they are periodic and orthogonal — that is:

$$\int_T g_i(t)\, g_j(t)\, dt = \begin{cases} K & \text{if } i = j \\ 0 & \text{otherwise} \end{cases} \tag{5.26}$$

then the coefficients s_{ij} for symbol s_i can be recovered in the receiver by evaluating the observation signals

$$z_{ij} = \frac{1}{K} \int_T r_i(t)\, g_j(t)\, dt \tag{5.27}$$

Clearly, if $r_i(t) = s_i(t)$, then $z_{ij} = s_{ij}$ for every j, and the transmitted symbol can be identified.

In every physical implementation of a digital communications system, the received signal is corrupted by noise and the observation signal becomes a random process. The decision rule is very simple: decide in favor of the symbol to which the observation signal is closest.

Unlike periodic waveforms, chaotic basis functions are *inherently nonperiodic* and are different in each interval of duration T. Chaotic basis functions have the advantage that each transmitted symbol is represented by a unique analog sample function, and the correlation between chaotic sample functions is extremely low. However, it also produces a problem associated with estimating long-term statistics of a chaotic process from sample functions of finite duration.

This is the so-called *estimation problem*, discussed next [3]. It arises in all chaotic digital modulation schemes where the energy associated with a transmitted symbol is different every time that symbol is transmitted.

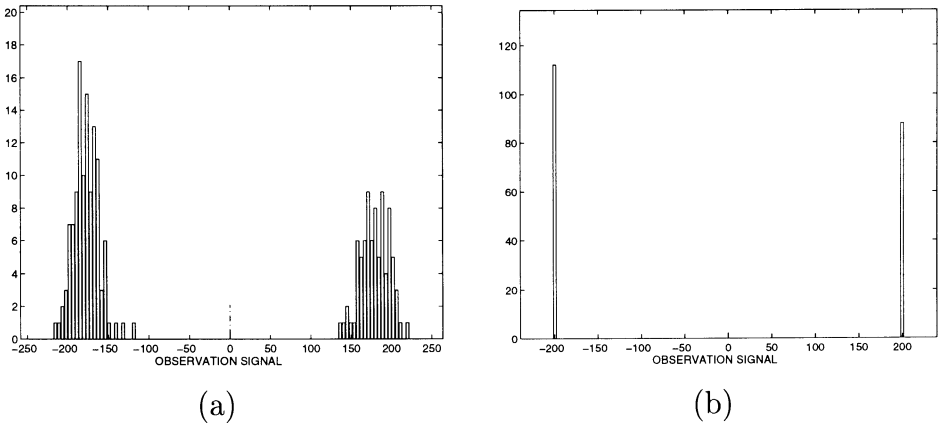

FIGURE 5.25 Histograms of the observation signal z_i for (a) non-constant and (b) constant energy per symbol.

The Estimation Problem

In modulation schemes that use periodic basis functions, $s_i(t)$ is periodic and the bit duration T is an integer multiple of the period of the basis function(s); hence, $\int_T s_i^2(t)dt$ is constant. By contrast, chaotic signals are inherently nonperiodic, so $\int_T s_i^2(t)dt$ varies from one sample function of length T to the next.

This effect is illustrated in Fig. 5.25(a), which shows a histogram of the observation signal in a noise-free binary **chaotic digital modulation** scheme where $s_{i1}(t) = g(t)$ and $s_{i2}(t) = -g(t)$. The observation signal is given by

$$z_i = \begin{cases} +\int_T g^2(t)dt & \text{when symbol } i \text{ is "1"} \\ -\int_T g^2(t)dt & \text{when symbol } i \text{ is "0"} \end{cases} \tag{5.28}$$

Because the basis function $g(\cdot)$ is *not periodic*, the value $\int_T g^2(t)dt$ varies from one symbol period of length T to the next. Consequently, the samples of the observation signal z_i corresponding to symbols "0" and "1" are clustered *with non-zero variance* about –180 and +180, respectively. Thus, the nonperiodic nature of the chaotic signal itself produces an effect that is indistinguishable at the receiver from the effect of additive channel noise.

By increasing the bit duration T, the variance of estimation can be reduced, but it also imposes a constraint on the maximum symbol rate. The estimation problem can be solved completely by keeping the energy per symbol constant. In this case, the variance of the samples of the observation signal is zero, as shown in Fig. 5.25(b).

Chaotic Digital Modulation Schemes

Chaos Shift Keying CSK

In Chaos Shift Keying (CSK), each symbol is represented by a weighted sum of chaotic basis functions $g_j(t)$. A binary CSK transmitter is shown in Fig. 5.26. The sample function $s_i(t)$ is $g_1(t)$ or $g_2(t)$, depending on whether symbol "1" or "0" is to be transmitted.

The required chaotic basis functions can be generated by different chaotic circuits (as shown in Fig. 5.26) or they can be produced by a single chaotic generator whose output is multiplied by two different constants. In both cases, the binary information to be transmitted is mapped to the bit energies of chaotic sample functions.

In chaotic digital communications systems, as in conventional communications schemes, the transmitted symbols can be recovered using either coherent or noncoherent demodulation techniques.

Coherent Demodulation of CSK

Coherent demodulation is accomplished by reproducing copies of the basis functions in the receiver, typically by means of a synchronization scheme [4]. When synchronization is exploited, the synchronization scheme must be able to recover the basis function(s) from the corrupted received signal.

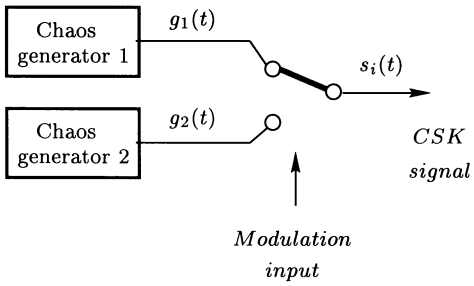

FIGURE 5.26 Block diagram of a CSK modulator.

If a single sinusoidal basis function is used, then a *narrow-band* phase-locked loop (PLL) can be used to recover it [1]. Noise corrupting the transmitted signal is suppressed because of the low-pass property of the PLL. When an inherently wideband chaotic basis function is used, the synchronized circuit must also be *wideband* in nature. Typically, both the "amplitude" and "phase" of the chaotic basis function must be recovered from the received signal. Because of the wideband property of the chaotic basis function, narrow-band linear filtering cannot be used to suppress the additive channel noise.

Figure 5.27 shows a coherent (synchronization-based) receiver using binary CSK modulation with two basis functions $g_1(t)$ and $g_2(t)$. Synchronization circuits at the receiver attempt to reproduce the basis functions, given the received noisy sample function $r_i(t) = s_i(t) + n(t)$.

An acquisition time T_S is allowed for the synchronization circuits to lock to the incoming signal. The recovered basis functions $\hat{g}_1(t)$ and $\hat{g}_2(t)$ are then correlated with $r_i(t)$ for the remainder of the bit duration T. A decision is made on the basis of the relative closeness of $r_i(t)$ to $\hat{g}_1(t)$ and $\hat{g}_2(t)$, as quantified by the observation variables z_{i1} and z_{i2}, respectively.

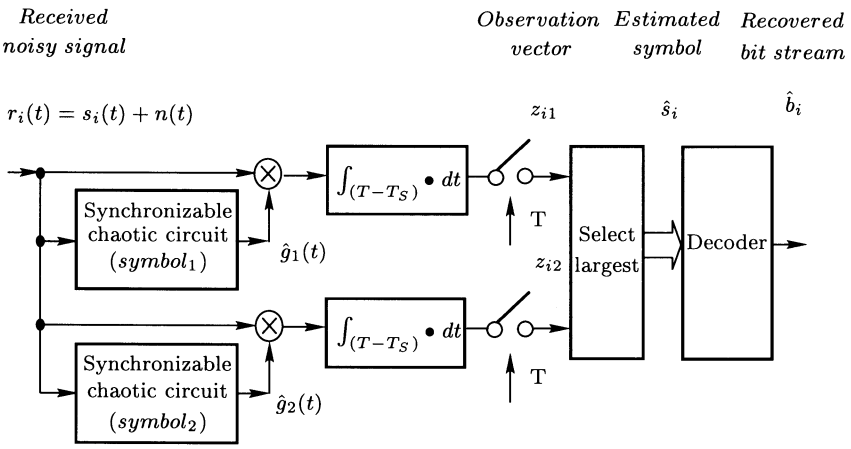

FIGURE 5.27 Block diagram of a coherent CSK receiver.

Studies of **chaotic synchronization,** where significant noise and filtering have been introduced in the channel, suggest that the performance of chaotic synchronization schemes is significantly worse at low *signal-to-noise ratio* (SNR) than that of the best synchronization schemes for sinusoids [4–6].

Noncoherent Demodulation of CSK

Synchronization (in the sense of carrier recovery) is not a necessary requirement for digital communications; demodulation can also be performed without synchronization. This is true for both periodic and chaotic sample functions.

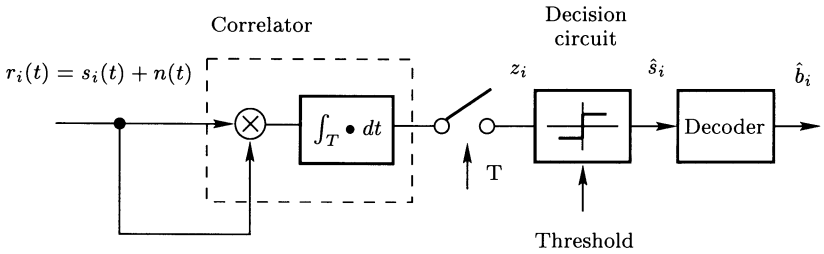

FIGURE 5.28 Block diagram of a non-coherent CSK receiver.

Due to the nonperiodic property of chaotic signals, the energy of chaotic sample functions varies from one sample function to the next, even if the same symbol is transmitted. If the mean bit energies $\int_T g_1^2(t)dt$ and $\int_T g_2^2(t)dt$ associated with symbols "1" and "0," respectively, are sufficiently different, then a CSK transmission can be demodulated without synchronization. In this case, the bit energy can be estimated by a correlator at the receiver, as shown in Fig. 5.28, without recovering the basis functions. The decision as to which symbol was transmitted is made by comparing this estimate against a threshold.

The observation signal z_i that is used by the decision circuit is defined by

$$z_i = \int_T r_i^2(t)dt \tag{5.29}$$

where $\int_T$ denotes integration over one bit period.

For a given noise level and chaotic signal, the best noise performance of CSK can be achieved if the distance between the mean bit energies of the two symbols is maximized; this requirement can be satisfied by the Chaotic On-Off Keying technique, described next.

Chaotic On-Off Keying (COOK)

In the Chaotic On-Off Keying (COOK) scheme, the chaotic signal is switched on and off to transmit symbols "1" and "0," respectively, as shown in Fig. 5.29.

If the average bit energy is E_b and both symbols are equiprobable, then the distance between the elements of the signal set is $2E_b$. It is well-known from the theory of communications systems that the greater the distance between the elements of the signal set, the better the noise performance of a modulation scheme [1]. The noise

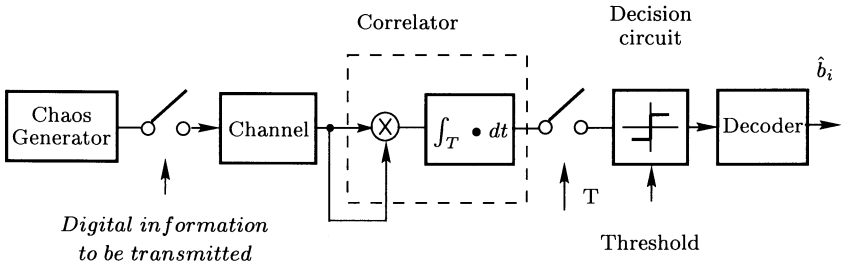

FIGURE 5.29 Block diagram of COOK modulation scheme with non-coherent demodulation.

performance of COOK represents the upper bound for CSK because the distance between the elements of the signal set is maximized.

Notice that the observation signal is determined by the energy per bit of the noisy received signal $r_i(t) = s_i(t) + n(t)$. This is why a significant drawback of the CSK system — namely that the threshold value of the decision circuit depends on the noise level — also applies to COOK. This means that using COOK, one can maximize the distance between the elements of the signal set, but the threshold level required by the decision

circuit depends on the SNR. The threshold can be kept constant by applying the Differential Chaos Shift Keying method.

Differential Chaos Shift Keying (DCSK)

In Differential Chaos Shift Keying (DCSK), every symbol to be transmitted is represented by two chaotic sample functions. The first sample function serves as a *reference*, while the second one carries the information. symbol "1" is sent by transmitting a reference signal provided by a chaos generator twice in succession; while for symbol "0," the reference chaotic signal is transmitted, followed by an inverted copy of the same integral. Thus,

$$s(t)=\begin{cases} x(t), & t_i \le t < t_i + T/2 \\ +x(t-T/2), & t_i + T/2 \le t < t_i + T \end{cases} \tag{5.30}$$

if symbol "1" is transmitted in $(t_i, t_i + T)$ and

$$s(t)=\begin{cases} x(t), & t_i \le t < t_i + T/2 \\ -x(t-T/2), & t_i + T/2 \le t < t_i + T \end{cases} \tag{5.31}$$

if symbol "0" is transmitted in $(t_i, t_i + T)$.

Figures 5.30 and 5.31 show a block diagram of a DCSK modulator and a typical DCSK signal corresponding to the binary sequence 1100. In this example, the chaotic signal is produced by an analog phase-locked loop (APLL) and the bit duration is 20 ms.

Since each bit is mapped to the correlation between successive segments of the transmitted signal of length $T/2$, the information signal can be recovered by a correlator. A block diagram of a DCSK demodulator is shown in Fig. 5.32.

The received noisy signal is delayed by half of the bit duration ($T/2$), and the correlation between the received signal and the delayed copy of itself is determined. The decision is made by a level comparator [7].

In contrast to the CSK and COOK schemes discussed above, DCSK is an antipodal modulation scheme. In addition to superior noise performance, the decision threshold is zero independently of the SNR [7].

A further advantage results from the fact that the reference- and information-bearing sample functions pass through the same channel, thereby rendering the modulation scheme insensitive to channel distortion. DCSK can also operate over a time-varying channel if the parameters of the channel remain constant for half the bit duration T.

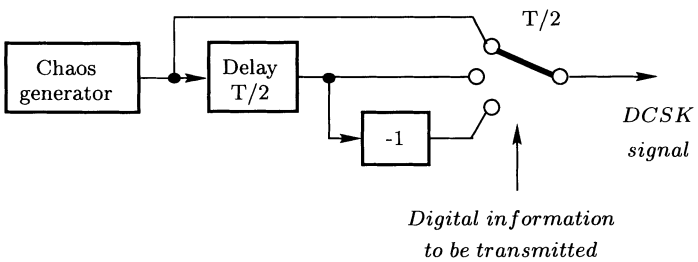

FIGURE 5.30 Block diagram of a DCSK modulator.

The principal drawback of DCSK arises from the fact that the correlation is performed over half the bit duration. Compared to conventional techniques where the elements of the signal set are available at the receiver, DCSK has half of the data rate, and only half the bit energy contributes to its noise performance [4,6].

In the CSK, COOK, and DCSK modulation schemes, the information signal to be transmitted is mapped to chaotic sample functions of finite length. The property required by the decision circuit at the receiver to

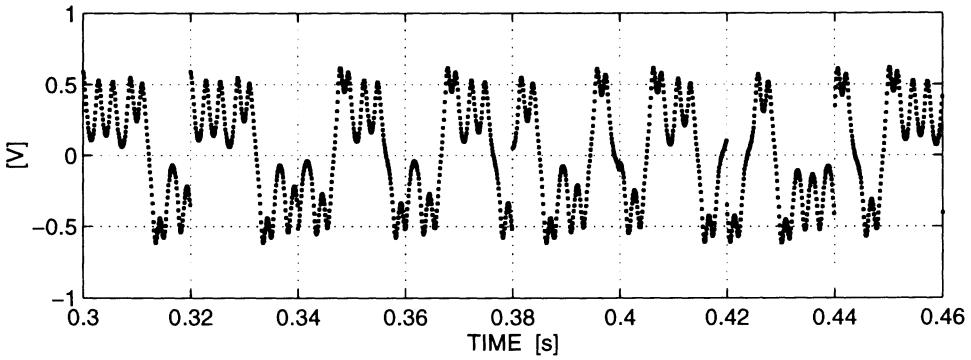

FIGURE 5.31 DCSK signal corresponding to binary sequence 1100.

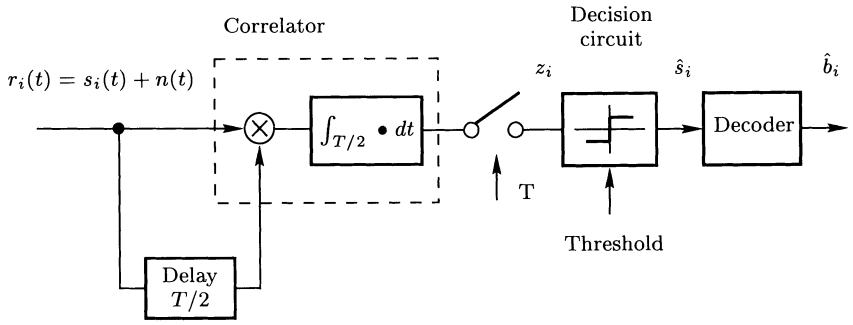

FIGURE 5.32 Block diagram of a DCSK receiver.

perform the demodulation can only be *estimated* because of the nonperiodic nature of chaotic signals. The estimation has a non-zero variance even in the noise-free case; this puts a lower bound on the bit duration and thereby limits the data rate.

One way to improve the data rate is to use a multilevel modulation scheme such as those described in [8]. Alternatively, one can solve the estimation problem directly by modifying the modulation scheme such that the transmitted energy for each symbol is kept constant. FM-DCSK is an example of the latter approach.

FM-DCSK

The power of a **frequency-modulated** (FM) signal is independent of the modulation. Therefore, if a chaotic signal is applied to the input of an FM modulator, and the output of the FM modulator is applied to the input of a DCSK modulator, then the resulting output of the DCSK modulator has constant energy per symbol. If this signal is applied directly to a DCSK correlation receiver, then the observation signal in the receiver has zero variance in the noise-free case and the estimation problem is solved.

As in the DCSK technique, every information bit is transmitted in two pieces: the first sample function serves as a reference, while the second one carries the information. The operation of the modulator shown in Fig. 5.33 is similar to DCSK, the difference being that the FM signal, rather than the chaotic signal itself, is applied to the input of the DCSK modulator. In this example, the chaotic signal is generated by an appropriately designed analog phase-locked loop (APLL).

The demodulator of an FM-DCSK system is a DCSK receiver. The only difference is that, instead of low-frequency chaotic signals, the noisy FM signals are correlated directly in the receiver, as shown in Fig. 5.34.

The noise performance of the FM-DCSK system is an attainable upper bound to that of DCSK. The main advantage of FM-DCSK modulation over CSK, COOK, and DCSK is that the data rate is not limited by the properties of the chaotic signal.

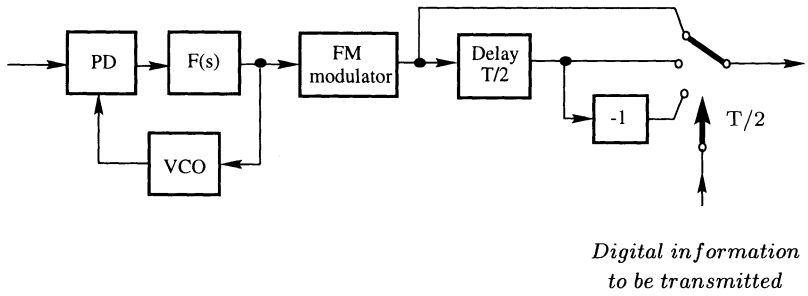

FIGURE 5.33 Block diagram of an FM-DCSK modulator.

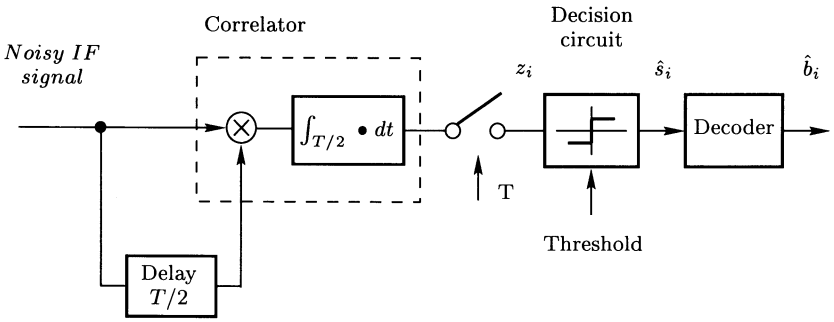

FIGURE 5.34 Block diagram of an FM-DCSK demodulator.

Performance Evaluation

The noise performance of a digital modulation scheme is characterized by plotting the *bit error rate* (BER) as a function of the ratio of the energy per bit to the noise spectial density. (E_b/N_0). The simulated noise performance of noncoherent CSK, COOK, and DCSK/FM-DCSK is summarized graphically in Fig. 5.35.

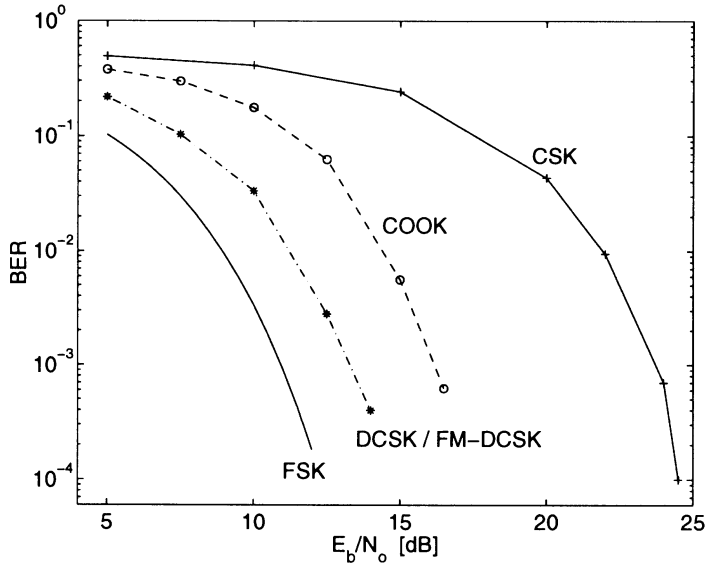

FIGURE 5.35 Noise performance of the CSK, COOK, and DCSK/FM-DCSK techniques. Non-coherent FSK is shown for comparison.

The upper bound on the data rate of DCSK can be increased by using multilevel modulation schemes or by keeping the transmitted energy constant for each symbol. The FM-DCSK technique, which is an antipodal modulation scheme with constant bit energy, represents an optimal solution in the sense that its noise performance is equal to that of DCSK but the data rate is not limited by the properties of the underlying chaotic signal.

Low-Pass Equivalent Models for Chaotic Communications Systems

The previous sections have described **chaotic digital modulation** schemes. The output of these modulations is generally a low-pass signal. Many telecommunications channels, such as a radio channel, can transmit only bandpass signals, so a second modulation scheme must be used to produce an RF output in these cases. An exception is the FM-DCSK modulation scheme, where the output of the FM modulator is already a bandpass RF signal and the DCSK modulation is applied directly to this signal.

The performance evaluation of communications systems can be done analytically only in the simplest cases; usually, computer simulation is required. However, if computer simulations of RF communications systems are performed directly in the RF domain, then the sampling frequency for the simulation depends on both the carrier frequency and the bandwidth of the transmitted signal. The high carrier frequency results in a high sampling frequency and consequently a long simulation time. On the other hand, the parameters of a bandpass system do not depend on the actual value of the carrier frequency.

It is well-known that a low-pass equivalent model can be developed for every bandpass system [1]. As a result, the carrier frequency can be removed from the model of an RF communications system and the sampling frequency is then determined solely by the bandwidth of the RF signal. This reduces significantly the computational effort required to characterize the performance of a chaotic communications system. This section illustrates the development of a low-pass equivalent model for the RF FM-DCSK system. For further details and models of other chaotic communications systems, see [9].

Theoretical Background

Representation of Bandpass Signals

A signal $x(t)$ is referred to as a bandpass signal if its energy is nonnegligible only in a frequency band of total extent $2BW$ centered about a carrier frequency f_c. Every bandpass signal can be expressed in terms of a slowly varying signal $\tilde{x}(t)$ and a complex exponential

$$x(t) = Re\left[\tilde{x}(t)e^{j\omega_c t}\right] \tag{5.32}$$

where $\tilde{x}(t)$ is called the complex envelope, and $\omega_c = 2\pi f_c$. In general, $\tilde{x}(t)$ is a complex-valued quantity; it can be expressed in terms of its *in-phase* and *quadrature* components, $x_I(t)$ and $x_Q(t)$, as follows:

$$\tilde{x}(t) = x_I(t) + jx_Q(t) \tag{5.33}$$

Both $x_I(t)$ and $x_Q(t)$ are low-pass signals limited to the frequency band $-BW \le f \le BW$.

The complex envelope $\tilde{x}(t)$ carries all of the information, except the carrier frequency, of the original bandpass signal $x(t)$. This means that if the complex envelope of a signal is given, then that signal is completely characterized. Knowing the carrier frequency, in addition, means that the original bandpass signal can be reconstructed.

The in-phase and quadrature components of the complex envelope can be generated from the bandpass signal $x(t)$ using the scheme shown in Fig. 5.36, where the ideal low-pass filters have bandwidth BW.

The original bandpass signal $x(t)$ can be reconstructed from the in-phase and quadrature components of $\tilde{x}(t)$ as shown in Fig. 5.37.

Representation of Bandpass Systems

Let the bandpass input signal $x(t)$ be applied to a linear time-invariant bandpass system with impulse response $h(t)$, and let the bandwidth of the bandpass system be equal to $2B$ and centered about the carrier frequency f_c. Then, by analogy with the representation of bandpass signals, the impulse response of the bandpass system can also be expressed in terms of a slowly varying complex impulse response $\tilde{h}(t)$ and a complex exponential:

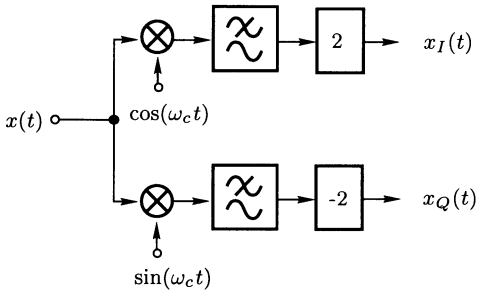

FIGURE 5.36 Generation of the in-phase and quadrature components of a bandpass signal.

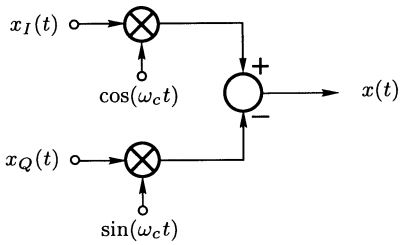

FIGURE 5.37 Reconstruction of the original bandpass signal from its in-phase and quadrature components.

$$h(t) = Re\left[\tilde{h}(t)e^{j\omega_c t}\right] \tag{5.34}$$

In general, the complex impulse response is a complex-valued quantity that can be expressed in terms of its in-phase and quadrature components

$$\tilde{h}(t) = h_I(t) + jh_Q(t) \tag{5.35}$$

where $\tilde{h}(t)$, $h_I(t)$, and $h_Q(t)$ are all low-pass functions limited to the frequency band $-B \le f \le B$.

Representation of Bandpass Gaussian Noise

If the channel noise $n(t)$ is a bandpass Gaussian random process and its spectrum is symmetric about the carrier frequency f_c, then $n(t)$ can also be represented by its complex envelope

$$\tilde{n}(t) = n_I(t) + jn_Q(t) \tag{5.36}$$

Low-Pass Equivalent of FM-DCSK System

The block diagram of a general chaotic communications system is given in Fig. 5.23. As shown in Fig. 5.34, the demodulator of an FM-DCSK system is a correlator, and the observation signal z_i is the correlator output sampled at the decision time instants. To derive the low-pass equivalent model of a chaotic communications scheme, the relationship between the analog input and output signals must be found; that is, the correlator output $z(t)$ must be determined for a given analog input signal.

The block diagram of the RF FM-DCSK system to be transformed is shown in Fig. 5.38, where $h(t)$ denotes

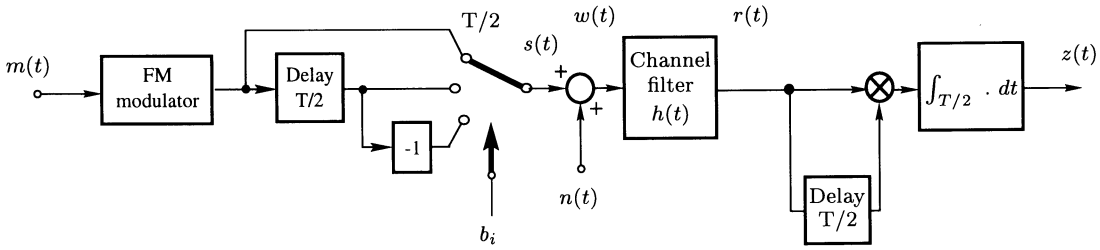

FIGURE 5.38 Block diagram of an RF FM-DCSK system.

the impulse response of channel filter, $n(t)$ is the channel noise, and $w(t)$ is the input to the channel filter.

Applying the theorems of the analytic signal approach [1], assuming a zero-phase channel filter and that half of the bit duration is equal to an entire multiple of the RF carrier period, the low-pass equivalent model of the RF FM-DCSK system can be developed as shown in Fig. 5.39 (for further details, see [9]).

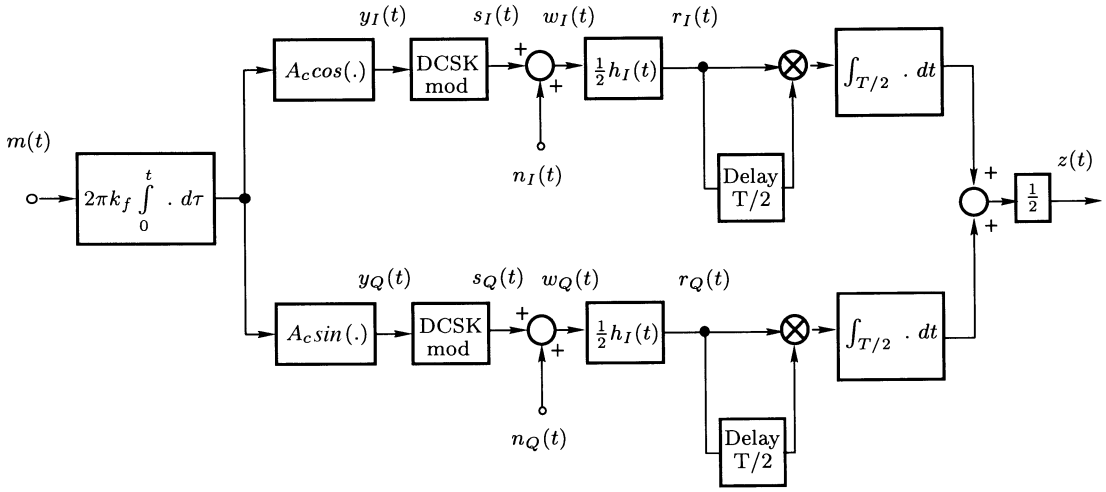

FIGURE 5.39 Low-pass equivalent model of the RF FM-DCSK chaotic communications system shown in Fig. 5.38.

Note that all RF signals and the carrier frequency have been removed from Fig. 5.39. Consequently, the sampling frequency required for computer simulations is determined exclusively by the slowly-varying low-pass signals. All noise performance curves shown in this chapter section have been determined using low-pass equivalent models derived in this way.

Multipath Performance of FM-DCSK

In many applications, such as mobile communications or indoor radio, the transmitted signal arrives at the receiver via multiple propagation paths with different delays, thus giving rise to multipath propagation. The components arriving via different propagation paths may add destructively, resulting in deep frequency-selective fading. Conventional narrow-band systems completely fail to operate if a *multipath-related null* (defined below) resulting from deep frequency-selective fading coincides with the carrier frequency. Because of the inherently broad-band nature of chaotic signals, chaotic modulation schemes have potentially better performance in multipath environments than narrow-band ones. In this section, the performance degradation of the FM-DCSK scheme resulting from multipath propagation is determined by computer simulation.

Multipath Model

A time-invariant multipath radio channel having two propagation paths can be modeled as shown in Fig. 5.40.

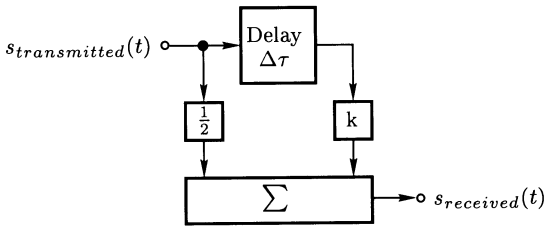

FIGURE 5.40 Tapped delay line model of a multipath radio channel.

In the worst case, the two received signals cancel each other completely at the carrier frequency ω_c; that is, $\Delta\tau\omega_c = (2n + 1)\,\pi$, $n = 0, \pm1, \pm2,\ldots$, and $k = -1/2$, where $\Delta\tau$ denotes the additional delay of the second path.

Let the multipath channel be characterized by its frequency response shown in Fig. 5.41. Note that the

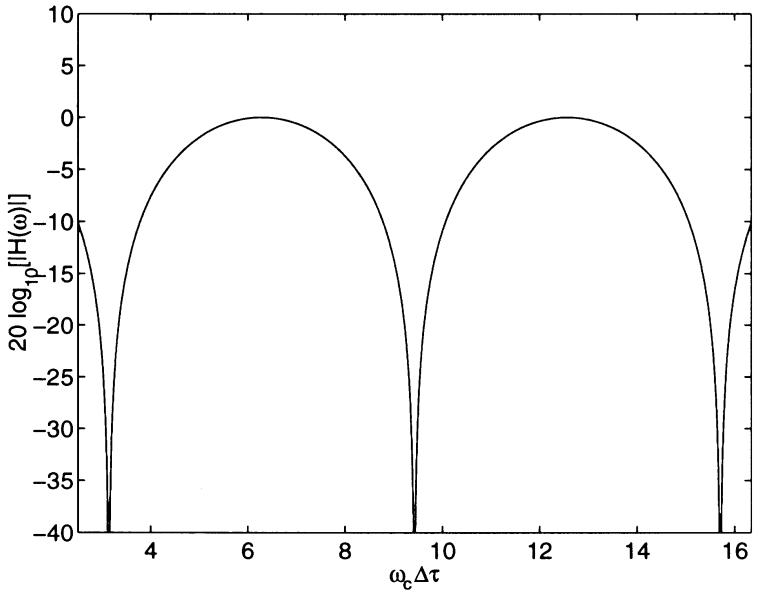

FIGURE 5.41 Magnitude of the frequency response of a multipath channel.

multipath-related nulls, where the attenuation becomes infinitely large, appear at

$$f_{\text{null}} = \frac{2n+1}{2\Delta\tau}, \quad n = 0, \pm1, \pm2, \ldots \tag{5.37}$$

Let the bandwidth of fading be defined as the frequency range over which the attenuation of the multipath channel is greater than 10 dB. Then the bandwidth of fading can be expressed as

$$\Delta f_{\text{null}} \approx \frac{0.1}{\Delta\tau} \tag{5.38}$$

Performance of FM-DCSK Modulation Scheme

Figure 5.41 shows why conventional narrow-band systems can fail to operate over a multipath channel. Due to high attenuation appearing about the multipath-related nulls, the SNR becomes extremely low at the input of the receiver. Consequently, the demodulator and the carrier recovery circuit, if used, cannot operate.

In a chaotic communications system, the power of the radiated signal is spread over a wide frequency range. The appearance of a multipath-related null means that part of the transmitted power is lost, but the system still operates. Of course, the lower SNR at the demodulator input results in a worse bit error rate.

The performance degradation of the FM-DCSK system due to multipath propagation is shown in Fig. 5.42,

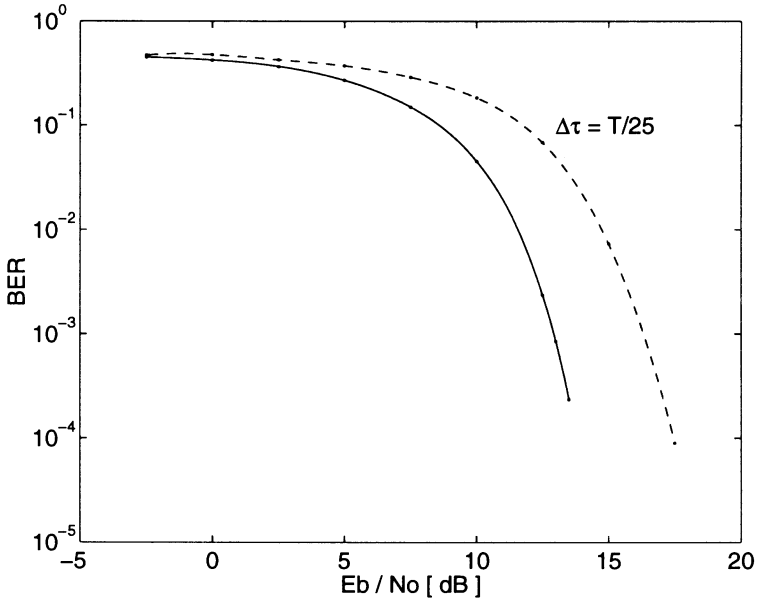

FIGURE 5.42 Noise performance of FM-DCSK with (dashed curve) and without (solid curve) multipath effects.

where $\Delta\tau = T/25$. The solid line shows the noise performance if multipath propagation is not present, while the system performance for $k = -1/2$ is given by the dashed curve. Note that FM-DCSK performs extremely well over a radio channel suffering from multipath effects; the performance degradation even in the worst case is less than a few dB. Note that conventional narrow-band systems cannot operate over this channel.

Defining Terms

Chaotic synchronization: The process by which a dynamical system is synchronized with a chaotic reference signal. In chaotic digital communications, chaotic (rather than periodic) basis functions must be recovered without distortion from the noisy received (reference) signal at the receiver. Noise corrupting the reference signal must be suppressed as much as possible.

Chaotic digital modulation: The mapping of information-source symbols into chaotic signals, which is performed to carry information through the analog transmission channel.

Chaos shift keying: A digital modulation scheme in which the source information is carried by the coefficients of a weighted sum of chaotic waveforms.

Chaotic on-off keying: A binary digital modulation scheme in which the chaotic carrier is switched on or off, depending on the binary information to be transmitted.

Differential chaos shift keying: A digital modulation scheme in which the source information is carried by the correlation between segments of a chaotic waveform that are separated in time.

Frequency-modulated differential chaos shift keying: A digital modulation scheme in which the source information is carried by the correlation between chaotic frequency-modulated waveforms.

Further Information

An introduction to chaos for electrical engineers can be found in [2].

Digital modulation theory and low-pass equivalent circuits of bandpass communications systems are described at an introductory level in [1]. The theory of spread spectrum communications can be found in [10].

The field of communicating with chaos has developed rapidly since the experiments by Pecora, Carroll, and others in the 1990s on chaotic synchronization [11]. Hasler [12] has written an overview of early work in this field.

The role of synchronization in chaotic digital modulation is explored in [4,6]. These papers also describe the state of the art in noncoherent receivers for chaotic digital communications. FM-DCSK is developed in [13].

Advances in the theory and practice of chaotic communications in electrical engineering are reported in *Electronics Letters*, the *IEEE Transactions on Circuits and Systems*, and the *IEEE Transactions on Communications*.

This section has focused exclusively on chaotic modulation techniques. Other applications of chaotic signals and synchronization schemes have been proposed but they are less close to practice: discrete-time chaotic sequences for spread spectrum systems were introduced in [14]; synchronization techniques for chaotic systems,

such as [15] and methods for transmitting or hiding information (e.g., [16]), are frequently reported in physics journals such as *Physical Review Letters* and the *Physical Review E*.

6.1 Definitions and Properties

Richard C. Dorf and Zhen Wan

The **Laplace transform** is a useful analytical tool for converting time-domain signal descriptions into functions of a complex variable. This *complex domain* description of a signal provides new insight into the analysis of signals and systems. In addition, the Laplace transform method often simplifies the calculations involved in obtaining system response signals.

Laplace Transform Integral

The Laplace transform completely characterizes the exponential response of a time-invariant linear function. This transformation is formally generated through the process of multiplying the linear characteristic signal $x(t)$ by the signal e^{-st} and then integrating that product over the time interval $(-\infty, +\infty)$. This systematic procedure is more generally known as *taking the Laplace transform* of the signal $x(t)$.

Definition: The Laplace transform of the continuous-time signal $x(t)$ is

$$X(s) = \int_{-\infty}^{+\infty} x(t)e^{-st}dt$$

The variable s that appears in this integrand exponential is generally complex valued and is therefore often expressed in terms of its rectangular coordinates

$$s = \sigma + j\omega$$

where $\sigma = \mathrm{Re}(s)$ and $\omega = \mathrm{Im}(s)$ are referred to as the *real* and *imaginary* components of s, respectively.

The signal $x(t)$ and its associated Laplace transform $X(s)$ are said to form a *Laplace transform pair*. This reflects a form of equivalency between the two apparently different entities $x(t)$ and $X(s)$. We may symbolize this interrelationship in the following suggestive manner:

$$X(s) = \mathcal{L}[x(t)]$$

where the operator notation $\mathcal{L}$ means to multiply the signal $x(t)$ being operated upon by the complex exponential e^{-st} and then to integrate that product over the time interval $(-\infty, +\infty)$.

Region of Absolute Convergence

In evaluating the Laplace transform integral that corresponds to a given signal, it is generally found that this integral will exist (that is, the integral has finite magnitude) for only a restricted set of s values.

The definition of **region of absolute convergence** is as follows. The set of complex numbers s for which the magnitude of the Laplace transform integral is finite is said to constitute the region of absolute convergence for that integral transform. This region of convergence is always expressible as

$$\sigma_+ < \mathrm{Re}(s) < \sigma_-$$

where σ_+ and σ_- denote real parameters that are related to the causal and anticausal components, respectively, of the signal whose Laplace transform is being sought.

Laplace Transform Pair Tables

It is convenient to display the Laplace transforms of standard signals in one table. Table 6.1 displays the time signal $x(t)$ and its corresponding Laplace transform and region of absolute convergence and is sufficient for our needs.

Example. To find the Laplace transform of the first-order causal exponential signal

$$x_1(t) = e^{-at}u(t)$$

where the constant a can in general be a complex number.

The Laplace transform of this general exponential signal is determined upon evaluating the associated Laplace transform integral

$$\begin{aligned} X_1(s) &= \int_{-\infty}^{+\infty} e^{-at}u(t)e^{-st}dt = \int_0^{+\infty} e^{-(s+a)t}dt \\ &= \left.\frac{e^{-(s+a)t}}{-(s+a)}\right|_0^{+\infty} \end{aligned} \tag{6.1}$$

In order for $X_1(s)$ to exist, it must follow that the real part of the exponential argument be positive, that is,

$$\mathrm{Re}(s+a) = \mathrm{Re}(s) + \mathrm{Re}(a) > 0$$

If this were not the case, the evaluation of expression (6.1) at the upper limit $t = +\infty$ would either be unbounded if $\mathrm{Re}(s) + \mathrm{Re}(a) < 0$ or undefined when $\mathrm{Re}(s) + \mathrm{Re}(a) = 0$. On the other hand, the upper limit evaluation is zero when $\mathrm{Re}(s) + \mathrm{Re}(a) > 0$, as is already apparent. The lower limit evaluation at $t = 0$ is equal to $1/(s + a)$ for all choices of the variable s.

The Laplace transform of exponential signal $e^{-at}\,u(t)$ has therefore been found and is given by

$$\mathcal{L}\ [e^{-at}u(t)] = \frac{1}{s+a} \quad \text{for } \mathrm{Re}(s) > -\mathrm{Re}(a)$$

TABLE 6.1 Laplace Transform Pairs

	Time Signal $x(t)$	Laplace Transform $X(s)$	Region of Absolute Convergence
1.	$e^{-at}u(t)$	$\frac{1}{s+a}$	$\mathrm{Re}(s) > -\mathrm{Re}(a)$
2.	$t^k e^{-at}u(-t)$	$\frac{k!}{(s+a)^{k+1}}$	$\mathrm{Re}(s) > -\mathrm{Re}(a)$
3.	$-e^{-at}u(-t)$	$\frac{1}{(s+a)}$	$\mathrm{Re}(s) < -\mathrm{Re}(a)$
4.	$(-t)^k e^{-at}u(-t)$	$\frac{k!}{(s+a)^{k+1}}$	$\mathrm{Re}(s) < -\mathrm{Re}(a)$
5.	$u(t)$	$\frac{1}{s}$	$\mathrm{Re}(s) > 0$
6.	$\delta(t)$	1	all s
7.	$\frac{d^k\delta(t)}{dt^k}$	s^k	all s
8.	$t^k u(t)$	$\frac{k!}{s^{k+1}}$	$\mathrm{Re}(s) > 0$
9.	$\mathrm{sgn}\, t = \begin{cases} 1, t \geq 0 \\ -1, t < 0 \end{cases}$	$\frac{2}{s}$	$\mathrm{Re}(s) = 0$
10.	$\sin \omega_0 t\ u(t)$	$\frac{\omega_0}{s^2+\omega_0^2}$	$\mathrm{Re}(s) > 0$
11.	$\cos \omega_0 t\ u(t)$	$\frac{s}{s^2+\omega_0^2}$	$\mathrm{Re}(s) > 0$
12.	$e^{-at} \sin \omega_0 t\ u(t)$	$\frac{\omega}{(s+a)^2+\omega_0^2}$	$\mathrm{Re}(s) > -\mathrm{Re}(a)$
13.	$e^{-at} \cos \omega_0 t\ u(t)$	$\frac{s+a}{(s+a)^2+\omega_0^2}$	$\mathrm{Re}(s) > -\mathrm{Re}(a)$

Properties of Laplace Transform

Linearity

Let us obtain the Laplace transform of a signal, $x(t)$, that is composed of a linear combination of two other signals,

$$x(t) = \alpha_1 x_1(t) + \alpha_2 x_2(t)$$

where α_1 and α_2 are constants.

The linearity property indicates that

$$\mathcal{L}[\alpha_1 x_1(t) + \alpha_2 x_2(t)] = \alpha_1 X_1(s) + \alpha_2 X_2(s)$$

and the region of absolute convergence is *at least as large* as that given by the expression

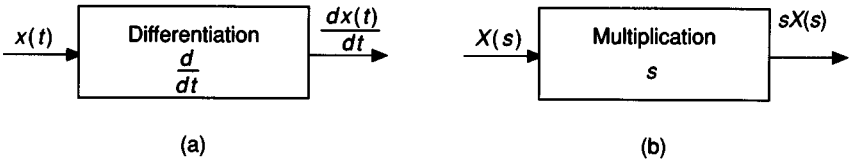

FIGURE 6.1 Equivalent operations in the (a) time-domain operation and (b) Laplace transform-domain operation. (*Source:* J.A. Cadzow and H.F. Van Landingham, *Signals, Systems, and Transforms,* Englewood Cliffs, N.J.: Prentice-Hall, 1985, p. 138. With permission.)

$$\max(\sigma_+^1; \sigma_+^2) < \mathrm{Re}(s) < \min(\sigma_-^1; \sigma_-^2)$$

where the pairs $(\sigma_+^1; \sigma_+^2) < \mathrm{Re}(s) < \min(\sigma_-^1; \sigma_-^2)$ identify the regions of convergence for the Laplace transforms $X_1(s)$ and $X_2(s)$, respectively.

Time-Domain Differentiation

The operation of time-domain differentiation has then been found to correspond to a multiplication by s in the Laplace variable s domain.

The Laplace transform of differentiated signal $dx(t)/dt$ is

$$\mathcal{L}\left[\frac{dx(t)}{dt}\right] = sX(s)$$

Furthermore, it is clear that the region of absolute convergence of $dx(t)/dt$ is at least as large as that of $x(t)$. This property may be envisioned as shown in Fig. 6.1.

Time Shift

The signal $x(t - t_0)$ is said to be a version of the signal $x(t)$ right shifted (or delayed) by t_0 seconds. Right shifting (delaying) a signal by a t_0 second duration in the time domain is seen to correspond to a multiplication by e^{-st0} in the Laplace transform domain. The desired Laplace transform relationship is

$$\mathcal{L}[x(t - t_0)] = e^{-st_0}X(s)$$

where $X(s)$ denotes the Laplace transform of the unshifted signal $x(t)$. As a general rule, any time a term of the form e^{-st0} appears in $X(s)$, this implies some form of time shift in the time domain. This most important property is depicted in Fig. 6.2. It should be further noted that the regions of absolute convergence for the signals $x(t)$ and $x(t - t_0)$ are identical.

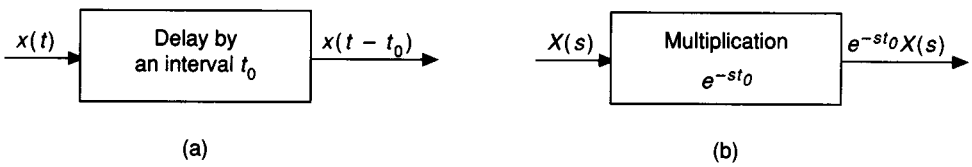

FIGURE 6.2 Equivalent operations in (a) the time domain and (b) the Laplace transform domain. (*Source:* J.A. Cadzow and H.F. Van Landingham, *Signals, Systems, and Transforms,* Englewood Cliffs, N.J.: Prentice-Hall, 1985, p. 140. With permission.)

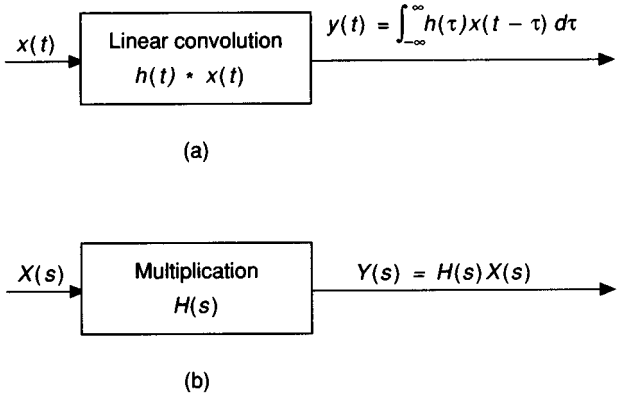

FIGURE 6.3 Representation of a time-invariant linear operator in (a) the time domain and (b) the *s*-domain. *(Source:* J. A. Cadzow and H. F. Van Landingham, *Signals, Systems, and Transforms,* Englewood Cliffs, N.J.: Prentice-Hall, 1985, p. 144. With permission.)

Time-Convolution Property

The convolution integral signal $y(t)$ can be expressed as

$$y(t) = \int_{-\infty}^{\infty} h(\tau)x(t - \tau)d\tau$$

where $x(t)$ denotes the input signal, the $h(t)$ characteristic signal identifying the operation process.

The Laplace transform of the response signal is simply given by

$$Y(s) = H(s)X(s)$$

where $H(s) = \mathcal{L}[h(t)]$ and $X(s) = \mathcal{L}[x(t)]$. Thus, the convolution of two time-domain signals is seen to correspond to the multiplication of their respective Laplace transforms in the *s*-domain. This property may be envisioned as shown in Fig. 6.3.

Time-Correlation Property

The operation of correlating two signals $x(t)$ and $y(t)$ is formally defined by the integral relationship

$$\phi_{xy}(\tau) = \int_{-\infty}^{\infty} x(t)y(t + \tau)dt$$

The Laplace transform property of the correlation function $\phi_{xy}(\tau)$ is

$$\Phi_{xy}(s) = X(-s)Y(s)$$

in which the region of absolute convergence is given by

$$\max(-\sigma_{x^-}, \sigma_{y^+}) < \mathrm{Re}(s) < \min(-\sigma_{x^+}, \sigma_{y^-})$$

Autocorrelation Function

The autocorrelation function of the signal $x(t)$ is formally defined by

$$\phi_{xx}(\tau) = \int_{-\infty}^{\infty} x(t)x(t+\tau)dt$$

The Laplace transform of the autocorrelation function is

$$\Phi_{xx}(s) = X(-s)X(s)$$

and the corresponding region of absolute convergence is

$$\max(-\sigma_{x^-}, \sigma_{y^+}) < \mathrm{Re}(s) < \min(-\sigma_{x^+}, \sigma_{y^-})$$

Other Properties

A number of properties that characterize the Laplace transform are listed in Table 6.2. Application of these properties often enables one to efficiently determine the Laplace transform of seemingly complex time functions.

TABLE 6.2 Laplace Transform Properties

Property	Signal $x(t)$ Time Domain	Laplace Transform $X(s)$ s Domain	Region of Convergence of $X(s)$ $\sigma_+ < \mathrm{Re}(s) < \sigma_-$
Linearity	$\alpha_1 x_1(t) + \alpha_2 x_2(t)$	$\alpha_1 X_1(s) + \alpha_2 X_2(s)$	At least the intersection of the region of convergence of $X_1(s)$ and $X_2(s)$
Time differentiation	$\frac{dx(t)}{dt}$	sX(s)	At least $\sigma_+ < \mathrm{Re(s)}$ and $\mathrm{X_2(s)}$
Time shift	$x(t-t_0)$	$e^{-st0}X(s)$	$\sigma_+ < \mathrm{Re}(s) < \sigma_-$
Time convolution	$\int_{-\infty}^{\infty} h(\tau)\,x(t-\tau)\,dt$	$H(s)X(s)$	At least the intersection of the region of convergence of $H(s)$ and $X(s)$
Time scaling	$x(at)$	$\frac{1}{\lvert a\rvert} X\left(\frac{s}{a}\right)$	$\sigma_+ < \mathrm{Re}\left(\frac{s}{a}\right) < \sigma_-$
Frequency shift	$e^{-at}x(t)$	$X(s+a)$	$\sigma_+ - \mathrm{Re}(a) < \mathrm{Re}(s) < \sigma_- - \mathrm{Re}(a)$
Multiplication (frequency convolution)	$x_1(t)x_2(t)$	$\frac{1}{2\pi j}\int_{c-j\infty}^{c+j\infty} X_1(u)X_2(s-u)\,d$	$\sigma_+^{(1)} + \sigma_+^{(2)} < \mathrm{Re}(s) < \sigma_-^{(1)} + \sigma_-^{(2)}$ $\sigma_+^{(1)} + \sigma_+^{(2)} < c < \sigma_-^{(1)} + \sigma_-^{(2)}$
Time integration	$\int_{-\infty}^{t} x(\tau)\,d\tau$	$\frac{1}{s}X(s)$ for $X(0) =$	At least $\sigma_+ < \mathrm{Re}(s) < \sigma_-$

Inverse Laplace Transform

Given a transform function $X(s)$ and its region of convergence, the procedure for finding the signal $x(t)$ that generated that transform is called *finding the inverse Laplace transform* and is symbolically denoted as

$$x(t) = \mathcal{L}^{\pm 1}[X(s)]$$

The signal $x(t)$ can be recovered by means of the relationship

$$x(t) = \frac{1}{2\pi j}\int_{c-j\infty}^{c+j\infty} X(s)e^{st}ds$$

In this integral, the real number c is to be selected so that the complex number $c + j\omega$ lies entirely within the region of convergence of $X(s)$ for all values of the imaginary component ω. For the important class of rational Laplace transform functions, there exists an effective alternate procedure that does not necessitate directly evaluating this integral. This procedure is generally known as the *partial-fraction expansion method.*

Partial Fraction Expansion Method

As just indicated, the partial fraction expansion method provides a convenient technique for reacquiring the signal that generates a given rational Laplace transform. Recall that a transform function is said to be rational if it is expressible as a ratio of polynomial in s, that is,

$$X(s) = \frac{B(s)}{A(s)} = \frac{b_m s^m + b_{m-1}s^{m-1} + \cdots + b_1 s + b_0}{s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0}$$

The partial fraction expansion method is based on the appealing notion of equivalently expressing this rational transform as a sum of n elementary transforms whose corresponding inverse Laplace transforms (i.e., generating signals) are readily found in standard Laplace transform pair tables. This method entails the simple five-step process as outlined in Table 6.3. A description of each of these steps and their implementation is now given.

I. Proper Form for Rational Transform. This division process yields an expression in the proper form as given by

$$\begin{aligned} X(s) &= \frac{B(s)}{A(s)} \\ &= Q(s) + \frac{R(s)}{A(s)} \end{aligned}$$

TABLE 6.3 Partial Fraction Expansion Method for Determining the Inverse Laplace Transform

I.	Put rational transform into proper form whereby the degree of the numerator polynomial is less than or equal to that of the denominator polynomial.
II.	Factor the denominator polynomial.
III.	Perform a partial fraction expansion.
IV.	Separate partial fraction expansion terms into causal and anticausal components using the associated region of absolute convergence for this purpose.
V.	Using a Laplace transform pair table, obtain the inverse Laplace transform.

Source: J. A. Cadzow and H.F. Van Landingham, *Signals, Systems, and Transforms,* Englewood Cliffs, N.J.: Prentice-Hall, 1985, p. 153. With permission.

in which $Q(s)$ and $R(s)$ are the quotient and remainder polynomials, respectively, with the division made so that the degree of $R(s)$ is less than or equal to that of $A(s)$.

II. Factorization of Denominator Polynomial. The next step of the partial fraction expansion method entails the factorizing of the nth-order denominator polynomial $A(s)$ into a product of n first-order factors. This factorization is always possible and results in the equivalent representation of $A(s)$ as given by

$$A(s) = (s - p_1)(s - p_2)\ldots(s - p_n)$$

The terms $p_1, p_2, \ldots, p_n$ constituting this factorization are called the *roots of polynomial* $A(s)$, or the *poles of* $X(s)$.

III. Partial Fraction Expansion. With this factorization of the denominator polynomial accomplished, the rational Laplace transform $X(s)$ can be expressed as

$$X(s) = \frac{B(s)}{A(s)} = \frac{b_n s^n + b_{n-1}s^{n-1} + \cdots + b_0}{(s - p_1)(s - p_2)\cdots(s - p_n)} \tag{6.2}$$

We shall now *equivalently represent* this transform function as a linear combination of elementary transform functions.

Case 1: $A(s)$ Has Distinct Roots.

$$X(s) = \alpha_0 + \frac{\alpha_1}{s - p_1} + \frac{\alpha_2}{s - p_2} + \cdots + \frac{\alpha_n}{s - p_n}$$

where the α_k are constants that identify the expansion and must be properly chosen for a valid representation.

$$\alpha_k = (s - p_k)X(s)\Big|_{s=p_k} \quad \text{for } k = 1, 2, \ldots, n$$

and

$$\alpha_0 = b_n$$

The expression for parameter α_0 is obtained by letting s become unbounded (i.e., $s = +\infty$) in expansion (6.2).

Case 2: $A(s)$ Has Multiple Roots.

$$X(s) = \frac{B(s)}{A(s)} = \frac{B(s)}{(s - p_1)^q A_1(s)}$$

The appropriate partial fraction expansion of this rational function is then given by

$$X(s) = \alpha_0 + \frac{\alpha_1}{(s - p_1)^1} + \cdots + \frac{\alpha_q}{(s - p_1)^q} + (n - q)\ \text{other elementary terms due to the roots of } A_1(s)$$

The coefficient α_0 may be expediently evaluated by letting s approach infinity, whereby each term on the right side goes to zero except α_0. Thus,

$$\alpha_0 = \lim_{s \to +\infty} X(s) = 0$$

The α_q coefficient is given by the convenient expression

$$\begin{aligned} \alpha_q &= (s - p_1)^q X(s) \Big|_{s=p_1} \\ &= \frac{B(p_1)}{A_1(p_1)} \end{aligned} \tag{6.3}$$

The remaining coefficients $\alpha_1, \alpha_2, \ldots, \alpha_{q-1}$ associated with the multiple root p_1 may be evaluated by solving Eq. (6.3) by setting s to a specific value.

IV. Causal and Anticausal Components. In a partial fraction expansion of a rational Laplace transform $X(s)$ whose region of absolute convergence is given by

$$\sigma_+ < \mathrm{Re}(s) < \sigma_-$$

it is possible to decompose the expansion's elementary transform functions into causal and anticausal functions (and possibly impulse-generated terms). Any elementary function is interpreted as being (1) *causal* if the real component of its pole is less than or equal to σ_+ and (2) *anticausal* if the real component of its pole is greater than or equal to σ_-.

The poles of the rational transform that lie to the left (right) of the associated region of absolute convergence correspond to the causal (anticausal) component of that transform. Figure 6.4 shows the location of causal and anticausal poles of rational transform.

V. Table Look-Up of Inverse Laplace Transform. To complete the inverse Laplace transform procedure, one need simply refer to a standard Laplace transform function table to determine the time signals that generate each of the elementary transform functions. The required time signal is then equal to the same linear combination of the inverse Laplace transforms of these elementary transform functions.

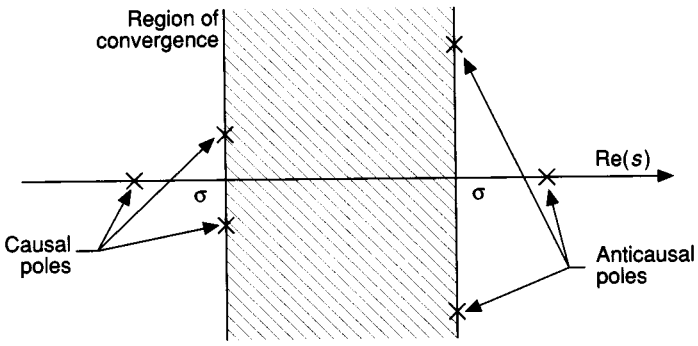

FIGURE 6.4 Location of causal and anticausal poles of a rational transform. (*Source:* J.A. Cadzow and H.F. Van Landingham, *Signals, Systems, and Transforms,* Englewood Cliffs, N.J.: Prentice-Hall, 1985, p. 161. With permission.)

Defining Terms

Laplace transform: A transformation of a function $f(t)$ from the time domain into the complex frequency domain yielding $F(s)$.

$$F(s) = \int_{-\infty}^{\infty} f(t)e^{-st}dt$$

where $s = \sigma + j\omega$.

Region of absolute convergence: The set of complex numbers s for which the magnitude of the Laplace transform integral is finite. The region can be expressed as

$$\sigma_+ < \mathrm{Re}(s) < \sigma_-$$

where σ_+ and σ_- denote real parameters that are related to the causal and anticausal components, respectively, of the signal whose Laplace transform is being sought.

6.2 Applications[1]

David E. Johnson

In applications such as electric circuits, we start counting time at $t = 0$, so that a typical function $f(t)$ has the property $f(t) = 0$, $t < 0$. Its transform is given therefore by

$$F(s) = \int_{0}^{\infty} f(t)e^{-st}\ dt$$

which is sometimes called the *one-sided Laplace transform.* Since $f(t)$ is like $x(t)u(t)$ we may still use Table 6.1 of the previous section to look up the transforms, but for simplicity we will omit the factor $u(t)$, which is understood to be present.

Differentiation Theorems

Time-Domain Differentiation

If we replace $f(t)$ in the one-sided transform by its derivative $f'(t)$ and integrate by parts, we have the transform of the derivative,

[1]Based on D.E. Johnson, J.R. Johnson, and J.L. Hilburn, *Electric Circuit Analysis,* 2nd ed., Englewood Cliffs, N.J.: Prentice-Hall, 1992, chapters 19 and 20. With permission.

$$\mathcal{L}[f'(t)] = sF(s) - f(0) \tag{6.4}$$

We may formally replace f by f' to obtain

$$\mathcal{L}[f''(t)] = s\,\mathcal{L}\,[f'(t)] - f'(0)$$

or by (6.4),

$$\mathcal{L}[f''(t)] = s^2F(s) - sf(0) - f'(0) \tag{6.5}$$

We may replace f by f' again in (6.5) to obtain $\mathcal{L}\,[f'''(t)]$, and so forth, obtaining the general result,

$$\mathcal{L}[f^{(n)}(t)] = s^nF(s) - s^{n-1}f(0) - s^{n-2}f'(0) - \cdots - f^{(n-1)}(0) \tag{6.6}$$

where $f^{(n)}$ is the nth derivative. The functions $f, f', \ldots, f^{(n-1)}$ are assumed to be continuous on $(0,\infty)$, and $f^{(n)}$ is continuous except possibly for a finite number of finite discontinuities.

Example 6.2.1 As an example, let $f(t) = t^n$, for n a nonnegative integer. Then $f^{(n)}(t) = n!$ and $f(0) = f'(0) = \ldots = f^{(n-1)}(0) = 0$. Therefore, we have

$$\mathcal{L}[n!\,] = s^n\mathcal{L}\,[t^n]$$

or

$$\mathcal{L}[t^n] = \frac{1}{s^n}\,\mathcal{L}\,[n!\,] = \frac{n!}{s^{n+1}}; \quad n = 0, 1, 2, \ldots \tag{6.7}$$

■

Example 6.2.2 As another example, let us invert the transform

$$F(s) = \frac{8}{s^3(s+2)}$$

which has the partial fraction expansion

$$F(s) = \frac{A}{s^3} + \frac{B}{s^2} + \frac{C}{s} + \frac{D}{s+2}$$

where

$$A = s^3F(s)\Big|_{s=0} = 4$$

and

$$D = (s+2)F(s)\Big|_{s=-2} = -1$$

To obtain B and C, we clear $F(s)$ of fractions, resulting in

$$8 = 4(s + 2) + Bs(s + 2) + Cs^2(s + 2) - s^3$$

Equating coefficients of s^3 yields $C = 1$, and equating those of s^2 yields $B = -2$. The transform is therefore

$$F(s) = 2\frac{2!}{s^3} - 2\frac{1!}{s^2} + \frac{1}{s} - \frac{1}{s + 2}$$

so that

$$f(t) = 2t^2 - 2t + 1 - e^{-2t}$$ ■

Frequency-Domain Differentiation

Frequency-domain differentiation formulas may be obtained by differentiating the Laplace transform with respect to s. That is, if $F(s) = \mathcal{L}[f(t)]$,

$$\frac{dF(s)}{ds} = \frac{d}{ds}\int_0^\infty f(t)e^{-st}dt$$

Assuming that the operations of differentiation and integration may be interchanged, we have

$$\frac{dF(s)}{ds} = \int_0^\infty \frac{d}{ds}[f(t)e^{-st}]\,dt$$

$$= \int_0^\infty [-tf(t)]\,e^{-st}dt$$

From the last integral it follows by definition of the transform that

$$\mathcal{L}[tf(t)] = -\frac{dF(s)}{ds} \tag{6.8}$$

Example 6.2.3 As an example, if $f(t) = \cos kt$, then $F(s) = s/(s^2 + k^2)$, and we have

$$\mathcal{L}[t\cos kt] = -\frac{d}{ds}\left(\frac{s}{s^2 + k^2}\right) = \frac{s^2 - k^2}{(s^2 + k^2)^2}$$ ■

We may repeatedly differentiate the transform to obtain the general case

$$\frac{d^nF(s)}{ds^n} = \int_0^\infty [(-t)^n f(t)]\,e^{-st}dt$$

from which we conclude that

TABLE 6.4 One-Sided Laplace Transform Properties

	$f(t)$	$F(s)$
1.	$cf(t)$	$cF(s)$
2.	$f_1(t) + f_2(t)$	$F_1(s) + F_2(s)$
3.	$\dfrac{df(t)}{dt}$	$sF(s) - f(0)$
4.	$\dfrac{d^n f(t)}{dt^n}$	$s^n F(s) - s^{n-1} f(0) - s^{n-2} f'(0) - s^{n-1} f''(0) - \cdots - f^{(n-1)}(0)$
5.	$\displaystyle\int_0^t f(\tau)\, d\tau$	$\dfrac{F(s)}{s}$
6.	$e^{-at} f(t)$	$F(s + a)$
7.	$f(t - \tau)u(t - \tau)$	$e^{-s\tau} F(s)$
8.	$f * g = \displaystyle\int_0^t f(\tau) g(t - \tau)\, d\tau$	$F(s)G(s)$
9.	$f(ct), c > 0$	$\dfrac{1}{c} F\left(\dfrac{s}{c}\right)$
10.	$t^n f(t), n = 0,1,2, \ldots$	$(-1)^n F^{(n)}(s)$

$$\mathcal{L}[t^n f(t)] = (-1)^n \frac{d^n F(s)}{ds^n}; \quad n = 0, 1, 2, \ldots \tag{6.9}$$

Properties of the Laplace transform obtained in this and the previous section are listed in Table 6.4.

Applications to Integrodifferential Equations

If we transform both members of a linear differential equation with constant coefficients, the result will be an algebraic equation in the transform of the unknown variable. This follows from Eq. (6.6), which also shows that the initial conditions are automatically taken into account. The transformed equation may then be solved for the transform of the unknown and inverted to obtain the time-domain answer.

Thus, if the differential equation is

$$a_n x^{(n)} + a_{n-1} x^{(n-1)} + \ldots + a_0 x = f(t)$$

the transformed equation is

$$\begin{aligned} &a_n\left[s^n X(s) - s^{n-1} x(0) - \ldots - x^{(n-1)}(0)\right] \\ &+ a_{n-1}\left[s^{n-1} X(s) - s^{n-2} x(0) - \ldots - x^{(n-2)}(0)\right] \\ &+ \ldots + a_0 X(s) = F(s) \end{aligned}$$

The transform $X(s)$ may then be found and inverted to give $x(t)$.

Example 6.2.4 As an example, let us find the solution $x(t)$, for $t > 0$, of the system of equations

$$x'' + 4x' + 3x = e^{-2t}$$
$$x(0) = 1, \quad x'(0) = 2$$

Transforming, we have

$$s^2X(s) - s - 2 + 4[sX(s) - 1] + 3X(s) = \frac{1}{s+2}$$

from which

$$X(s) = \frac{s^2 + 8s + 13}{(s+1)(s+2)(s+3)}$$

The partial fraction expansion is

$$X(s) = \frac{3}{s+1} - \frac{1}{s+2} - \frac{1}{s+3}$$

from which

$$x(t) = 3e^{-t} - e^{-2t} - e^{-3t}$$

■

Integration Property

Certain integrodifferential equations may be transformed directly without first differentiating to remove the integrals. We need only transform the integrals by means of

$$\mathcal{L}\left[\int_0^t f(\tau)\, d\tau\right] = \frac{F(s)}{s}$$

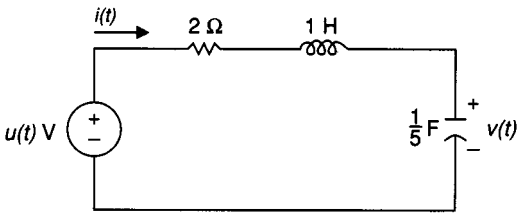

FIGURE 6.5 An *RLC* circuit.

Example 6.2.5 As an example, the current $i(t)$ in Fig. 6.5, with no initial stored energy, satisfies the system of equations,

$$\frac{di}{dt} + 2i + 5\int_0^t i\, dt = u(t)$$
$$i(0) = 0$$

Transforming yields

$$sI(s) + 2I(s) + \frac{5}{s} I(s) = \frac{1}{s}$$

or

$$I(s) = \frac{1}{s^2 + 2s + 5} = \frac{1}{2}\left[\frac{2}{(s+1)^2 + 4}\right]$$

Therefore the current is

$$i(t) = 0.5e^{-t} \sin 2t \quad \text{A}$$ ■

Applications to Electric Circuits

As the foregoing example shows, the Laplace transform method is an elegant procedure than can be used for solving electric circuits by transforming their describing integrodifferential equations into algebraic equations and applying the rules of algebra. If there is more than one loop or nodal equation, their transformed equations are solved simultaneously for the desired circuit current or voltage transforms, which are then inverted to obtain the time-domain answers. Superposition is not necessary because the various source functions appearing in the equations are simply transformed into algebraic quantities.

The Transformed Circuit

Instead of writing the describing circuit equations, transforming the results, and solving for the transform of the circuit current or voltage, we may go directly to a **transformed circuit**, which is the original circuit with the currents, voltages, sources, and passive elements replaced by transformed equivalents. The current or voltage transforms are then found using ordinary circuit theory and the results inverted to the time-domain answers.

Voltage Law Transformation

First, let us note that if we transform Kirchhoff's voltage law,

$$v_1(t) + v_2(t) + \cdots + v_n(t) = 0$$

we have

$$V_1(s) + V_2(s) + \cdots + V_n(s) = 0$$

where $V_i(s)$ is the transform of $v_i(t)$.The transformed voltages thus satisfy Kirchhoff's voltage law. A similar procedure will show that transformed currents satisfy Kirchhoff's current law, as well. Next, let us consider the passive elements. For a resistance R, with current i_R and voltage v_R, for which

$$v_R = Ri_R$$

the transformed equation is

$$V_R(s) = RI_R(s) \tag{6.10}$$

This result may be represented by the transformed resistor element of Fig. 6.6(a).

Inductor Transformation

For an inductance L, the voltage is

$$v_L = L\, di_L/dt$$

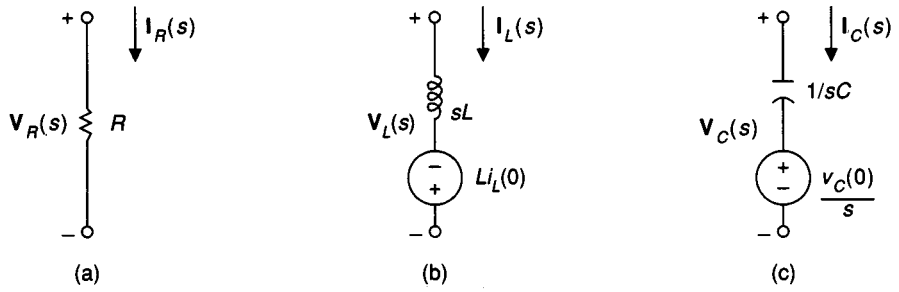

FIGURE 6.6 Transformed circuit elements.

Transforming, we have

$$V_L(s) = sLI_L(s) - Li_L(0) \tag{6.11}$$

which may be represented by an inductor with impedance sL in series with a source, $Li_L(0)$, with the proper polarity, as shown in Fig. 6.6(b). The included voltage source takes into account the initial condition $i_L(0)$.

Capacitor Transformation

In the case of a capacitance C we have

$$v_C = \frac{1}{C}\int_0^t i_C \, dt + v_C(0)$$

which transforms to

$$V_C(s) = \frac{1}{sC} I_C(s) + \frac{1}{s} v_C(0) \tag{6.12}$$

This is represented in Fig. 6.6(c) as a capacitor with impedance $1/sC$ in series with a source, $v_C(0)/s$, accounting for the initial condition.

We may solve Eqs. (6.10), (6.11), and (6.12) for the transformed currents and use the results to obtain alternate transformed elements useful for nodal analysis, as opposed to those of Fig. 6.6, which are ideal for loop analysis. The alternate elements are shown in Fig. 6.7.

Source Transformation

Independent sources are simply labeled with their transforms in the transformed circuit. Dependent sources are transformed in the same way as passive elements. For example, a controlled voltage source defined by

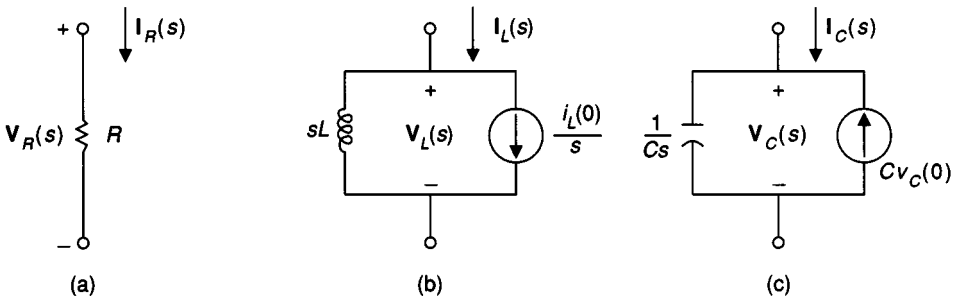

FIGURE 6.7 Transformed elements useful for nodal analysis.

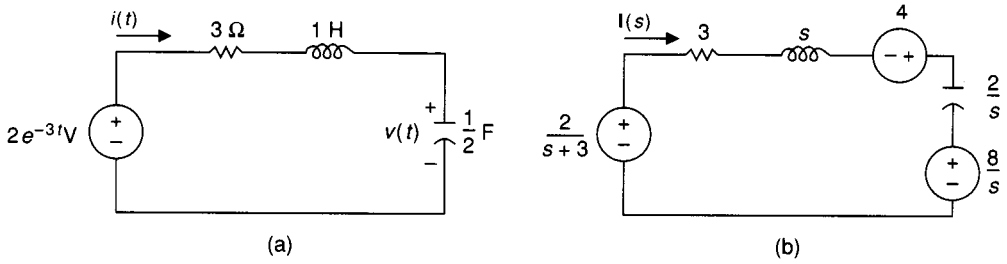

FIGURE 6.8 (a) A circuit and (b) its transformed counterpart.

$$v_1(t) = Kv_2(t)$$

transforms to

$$V_1(s) = KV_2(s)$$

which in the transformed circuit is the transformed source controlled by a transformed variable. Since Kirchhoff's laws hold and the rules for impedance hold, the transformed circuit may be analyzed exactly as we would an ordinary resistive circuit.

Example 6.2.6 To illustrate, let us find $i(t)$ in Fig. 6.8(a), given that $i(0) = 4$ A and $v(0) = 8$ V. The transformed circuit is shown in Fig. 6.8(b), from which we have

$$I(s) = \frac{[2/(s+3)] + 4 - (8/s)}{3 + s + (2/s)}$$

This may be written

$$I(s) = -\frac{13}{s+1} + \frac{20}{s+2} - \frac{3}{s+3}$$

so that

$$i(t) = -13e^{-t} + 20e^{-2t} - 3e^{-3t} \quad \text{A}$$ ■

Thévenin's and Norton's Theorems

Since the procedure using transformed circuits is identical to that using the phasor equivalent circuits in the ac steady-state case, we may obtain transformed Thévenin and Norton equivalent circuits exactly as in the phasor case. That is, the Thévenin impedance will be $Z_{th}(s)$ seen at the terminals of the transformed circuit with the sources made zero, and the open-circuit voltage and the short-circuit current will be $V_{oc}(s)$ and $I_{sc}(s)$, respectively, at the circuit terminals. The procedure is exactly like that for resistive circuits, except that in the transformed circuit the quantities involved are functions of s. Also, as in the resistor and phasor cases, the open-circuit voltage and short-circuit current are related by

$$V_{oc}(s) = Z_{th}(s)I_{sc}(s) \tag{6.13}$$

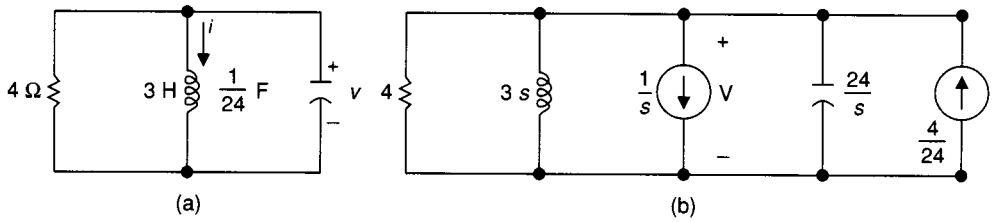

FIGURE 6.9 (a) An *RLC* parallel circuit and (b) its transformed circuit.

Example 6.2.7 As an example, let us consider the circuit of Fig. 6.9(a) with the transformed circuit shown in Fig. 6.9(b). The initial conditions are $i(0) = 1$ A and $v(0) = 4$ V. Let us find $v(t)$ for $t > 0$ by replacing everything to the right of the 4-Ω resistor in Fig. 6.9(b) by its Thévenin equivalent circuit. We may find $Z_{th}(s)$ directly from Fig. 6.9(b) as the impedance to the right of the resistor with the two current sources made zero (open circuited). For illustrative purposes we choose, however, to find the open-circuit voltage and short-circuit current shown in Figs. 6.10(a) and (b), respectively, and use Eq. (6.13) to get the Thévenin impedance.

The nodal equation in Fig. 6.10(a) is

$$\frac{V_{oc}(s)}{3s} + \frac{1}{s} + \frac{s}{24} V_{oc}(s) = \frac{1}{6}$$

from which we have

$$V_{oc}(s) = \frac{4(s-6)}{s^2 + 8}$$

From Fig. 6.10(b)

$$I_{sc}(s) = \frac{s-6}{6s}$$

The Thévenin impedance is therefore

$$Z_{th}(s) = \frac{V_{oc}(s)}{I_{sc}(s)} = \frac{\left[\dfrac{4(s-6)}{s^2+8}\right]}{\left[\dfrac{s-6}{6s}\right]} = \frac{24s}{s^2+8}$$

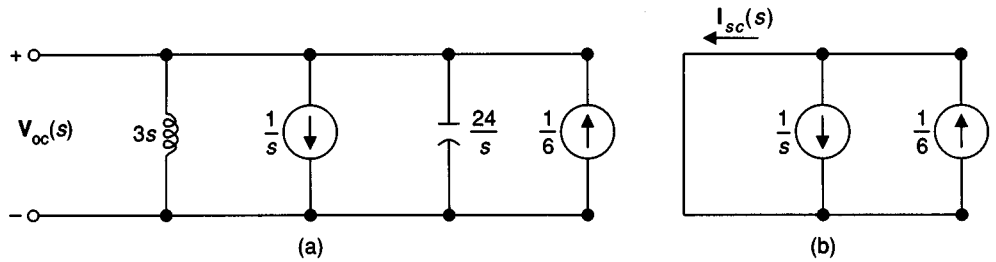

FIGURE 6.10 Circuit for obtaining (a) $V_{oc}(s)$ and (b) $I_{sc}(s)$.

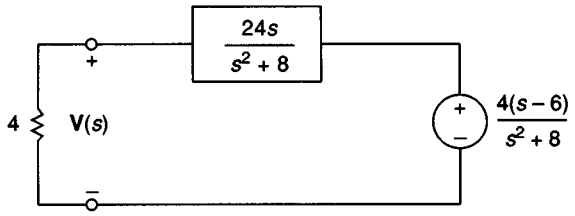

FIGURE 6.11 Thévenin equivalent circuit terminated in a resistor.

and the Thévenin equivalent circuit, with the 4 Ω connected, is shown in Fig. 6.11. From this circuit we find the transform

$$V(s) = \frac{4(s-6)}{(s+2)(s+4)} = \frac{-16}{s+2} + \frac{20}{s+4}$$

from which

$$v(t) = -16e^{-2t} + 20e^{-4t} \quad \text{V}$$ ■

Network Functions

A **network function** or **transfer function** is the ratio $H(s)$ of the Laplace transform of the output function, say $v_o(t)$, to the Laplace transform of the input, say $v_i(t)$, assuming that there is only one input. (If there are multiple inputs, the transfer function is based on one of them with the others made zero.) Suppose that in the general case the input and output are related by the differential equation

$$a_n \frac{d^n v_o}{dt^n} + a_{n-1} \frac{d^{n-1} v_o}{dt^{n-1}} + \cdots + a_1 \frac{dv_o}{dt} + a_o v_o = b_m \frac{d^m v_i}{dt^m} + b_{m-1} \frac{d^{m-1} v_i}{dt^{m-1}} + \cdots + b_1 \frac{dv_i}{dt} + b_o v_i$$

and that the initial conditions are all zero; that is,

$$v_o(0) = \frac{dv_o(0)}{dt} = \cdots = \frac{d^{n-1} v_o(0)}{dt^{n-1}} = v_i(0) = \frac{dv_i(0)}{dt} = \cdots = \frac{d^{m-1} v_i(0)}{dt^{m-1}} = 0$$

Then, transforming the differential equation results in

$$(a_n s^n + a_{n-1} s^{n-1} + \cdots + a_1 s + a_0) V_o(s) = (b_m s^m + b_{m-1} s^{m-1} + \cdots + b_1 s + b_0) V_i(s)$$

from which the network function, or transfer function, is given by

$$H(s) = \frac{V_o(s)}{V_i(s)} = \frac{b_m s^m + b_{m-1} s^{m-1} + \cdots + b_1 s + b_0}{a_n s^n + a_{n-1} s^{n-1} + \cdots + a_1 s + a_0} \tag{6.14}$$

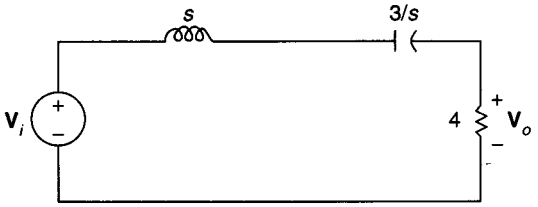

FIGURE 6.12 An *RLC* circuit.

Example 6.2.8 As an example, let us find the transfer function for the transformed circuit of Fig. 6.12, where the transfer function is $V_o(s)/V_i(s)$. By voltage division we have

$$H(s) = \frac{V_o(s)}{V_i(s)} = \frac{4}{s + 4 + (3/s)} = \frac{4s}{(s + 1)(s + 3)} \tag{6.15}$$

■

Step and Impulse Responses

In general, if $Y(s)$ and $X(s)$ are the transformed output and input, respectively, then the network function is $H(s) = Y(s)/X(s)$ and the output is

$$Y(s) = H(s)X(s) \tag{6.16}$$

The **step response** $r(t)$ is the output of a circuit when the input is the unit step function $u(t)$, with transform $1/s$. Therefore, the transform of the step response $R(s)$ is given by

$$R(s) = H(s)/s \tag{6.17}$$

The **impulse response** $h(t)$ is the output when the input is the unit impulse $\delta(t)$. Since $\mathcal{L}[\delta(t)] = 1$, we have from Eq. (6.16),

$$h(t) = \mathcal{L}^{-1}[H(s)/1] = \mathcal{L}^{-1}[H(s)] \tag{6.18}$$

Example 6.2.9 As an example, for the circuit of Fig. 6.12, $H(s)$, given in Eq. (6.15), has the partial fraction expansion,

$$H(s) = \frac{-2}{s + 1} + \frac{6}{s + 3}$$

so that

$$h(t) = -2e^{-t} + 6e^{-3t} \quad \text{V}$$

■

If we know the impulse response, we can find the transfer function,

$$H(s) = \mathcal{L}[h(t)]$$

from which we can find the response to *any* input. In the case of the step and impulse responses, it is understood that there are no other inputs except the step or the impulse. Otherwise, the transfer function would not be defined.

Stability

An important concern in circuit theory is whether the output signal remains bounded or increases indefinitely following the application of an input signal. An unbounded output could damage or even destroy the circuit, and thus it is important to know before applying the input if the circuit can accommodate the expected output. This question can be answered by determining the *stability* of the circuit.

A circuit is defined to have **bounded input–bounded output** (BIBO) stability if any bounded input results in a bounded output. The circuit in this case is said to be **absolutely stable** or *unconditionally stable*. BIBO stability can be determined by examining the *poles* of the network function (6.14).

If the denominator of $H(s)$ in Eq. (6.14) contains a factor $(s - p)^n$, then p is said to be a pole of $H(s)$ of *order n*. The output $V_o(s)$ would also contain this factor, and its partial fraction expansion would contain the term $K/(s - p)^n$. Thus, the inverse transform $v_o(t)$ is of the form

$$v_o(t) = A_n t^{n-1} e^{pt} + A_{n-1} t^{n-2} e^{pt} + \cdots + A_1 e^{pt} + v_1(t) \tag{6.19}$$

where $v_1(t)$ results from other poles of $V_o(s)$. If p is a real positive number or a complex number with a positive real part, $v_o(t)$ is unbounded because e^{pt} is a growing exponential. Therefore, for absolute stability there can be no pole of $V_o(s)$ that is positive or has a positive real part. This is equivalent to saying that $V_o(s)$ has no poles in the right half of the s-plane. Since $v_i(t)$ is bounded, $V_i(s)$ has no poles in the right half-plane. Therefore, since the only poles of $V_o(s)$ are those of $H(s)$ and $V_i(s)$, no pole of $H(s)$ for an absolutely stable circuit can be in the right-half of the s-plane.

From Eq. (6.19) we see that $v_i(t)$ is bounded, as far as pole p is concerned, if p is a *simple* pole (of order 1) and is purely imaginary. That is, $p = j\omega$, for which

$$e^{pt} = \cos \omega t + j \sin \omega t$$

which has a bounded magnitude. Unless $V_i(s)$ contributes an identical pole $j\omega$, $v_o(t)$ is bounded. Thus, $v_o(t)$ is bounded on the *condition* that any $j\omega$ pole of $H(s)$ is simple.

In summary, a network is *absolutely stable* if its network function $H(s)$ has only left half-plane poles. It is **conditionally stable** if $H(s)$ has only simple $j\omega$-axis poles and possibly left half-plane poles. It is *unstable* otherwise (right half-plane or multiple $j\omega$-axis poles).

Example 6.2.10 As an example, the circuit of Fig. 6.12 is absolutely stable, since from Eq. (6.15) the only poles of its transfer function are $s = -1, -3$, which are both in the left half-plane. There are countless examples of conditionally stable circuits that are extremely useful, for example, a network consisting of a single capacitor with $C = 1$ F with input current $I(s)$ and output voltage $V(s)$. The transfer function is $H(s) = Z(s) = 1/Cs = 1/s$, which has the simple pole $s = 0$ on the $j\omega$-axis. Figure 6.13 illustrates a circuit which is unstable. The transfer function is

$$H(s) = I(s)/V_i(s) = 1/(s - 2)$$

which has the right half-plane pole $s = 2$. ■

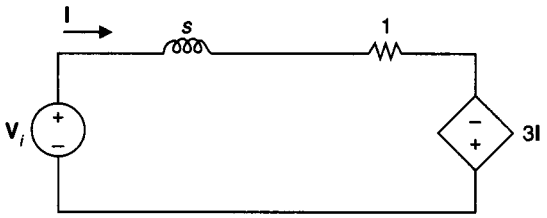

FIGURE 6.13 Unstable circuit.

Defining Terms

Absolute stability: When the network function $H(s)$ has only left half-plane poles.
Bounded input–bounded output stability: When any bounded input results in a bounded output.
Conditional stability: When the network function $H(s)$ has only simple $j\omega$-axis poles and possibly left half-plane poles.
Impulse response, $h(t)$: The output when the input is the unit impulse $\delta(t)$.
Network or transfer function: The ratio $H(s)$ of the Laplace transform of the output function to the Laplace transform of the input function.
Step response, $r(t)$: The output of a circuit when the input is the unit step function $u(t)$, with transform $1/s$.
Transformed circuit: An original circuit with the currents, voltages, sources, and passive elements replaced by transformed equivalents.

7.1 Introduction

An electrical network is describable by a system of algebraic and differential equations known as the primary system of equations obtained by applying the Kirchhoff's current and voltage laws and the element *v-i* relations. In the case of linear networks, these equations can be transformed into a system of linear algebraic equations by means of the Laplace transformation, which is relatively simple to manipulate. The main drawback is that it contains a large number equations. To reduce this number, three secondary systems of equations are available: the nodal system, the cutset system, and the loop system. If a network has n nodes, b branches, and c components, there are $n - c$ linearly independent equations in nodal or cutset analysis and $b - n + c$ linearly independent equations in loop analysis. These equations can then be solved to yield the Laplace transformed solution. To obtain the final time-domain solution, we must take the inverse Laplace transformation. For most practical networks, the procedure is usually long and complicated and requires an excessive amount of computer time.

As an alternative we can formulate the network equations in the time domain as a system of first-order differential equations, which describe the dynamic behavior of the network. Some advantages of representing the network equations in this form are the following. First, such a system has been widely studied in mathematics, and its solution, both analytic and numerical, is known and readily available. Second, the representation can easily and naturally be extended to time-varying and nonlinear networks. In fact, computer-aided solution of time-varying, nonlinear network problems is almost always accomplished using the state-variable approach. Finally, the first-order differential equations can easily be programmed for a digital computer or simulated on an analog computer. Even if it were not for the above reasons, the approach provides an alternative view of the physical behavior of the network.

The term **state** is an abstract concept that may be represented in many ways. If we call the set of instantaneous values of all the branch currents and voltages as the *state* of the network, then the knowledge of the instantaneous values of all these variables determines this instantaneous state. Not all of these instantaneous values are required in order to determine the instantaneous state, however, because some can be calculated from the others. A set of data qualifies to be called the *state* of a system if it fulfills the following two requirements:

1. The state of any time, say, t_0, and the input to the system from t_0 on determine uniquely the state at any time $t > t_0$.

2. The state at time t and the inputs together with some of their derivatives at time t determine uniquely the value of any system variable at the time t.

The state may be regarded as a vector, the components of which are *state variables*. Network variables that are candidates for the state variables are the branch currents and voltages. Our problem is to choose state variables in order to formulate the *state equations*. Like the nodal, cutset, or loop system of equations, the state equations are formulated from the primary system of equations. For our purposes, we shall focus our attention on how to obtain state equations for linear systems.

7.2 State Equations in Normal Form

For a linear network containing k energy storage elements and h independent sources, our objective is to write a system of k first-order differential equations from the primary system of equations, as follows:

$$\dot{x}_i(t) = \sum_{j=1}^{k} a_{ij}x_j(t) + \sum_{j=1}^{h} b_{ij}u_j(t), \qquad (i = 1, 2, \ldots, k) \tag{7.1}$$

In matrix notation, Eq. (7.1) becomes

$$\begin{bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \\ \cdot \\ \cdot \\ \cdot \\ \dot{x}_k(t) \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1k} \\ a_{21} & a_{22} & \cdots & a_{2k} \\ \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdots & \cdot \\ a_{k1} & a_{k2} & \cdots & a_{kk} \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \\ \cdot \\ \cdot \\ \cdot \\ x_k(t) \end{bmatrix} + \begin{bmatrix} b_{11} & b_{12} & \cdots & b_{1h} \\ b_{21} & b_{22} & \cdots & b_{2h} \\ \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdots & \cdot \\ b_{k1} & b_{k2} & \cdots & b_{kh} \end{bmatrix} \begin{bmatrix} u_1(t) \\ u_2(t) \\ \cdot \\ \cdot \\ \cdot \\ u_h(t) \end{bmatrix} \tag{7.2}$$

or, more compactly,

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t) \tag{7.3}$$

The real functions $x_1(t)$, $x_2(t)$, ..., $x_k(t)$ of the time t are called the **state variables**, and the k-vector $\mathbf{x}(t)$ formed by the state variables is known as the **state vector**. The h-vector $\mathbf{u}(t)$ formed by the h known forcing functions or excitations $u_j(t)$ is referred to as the **input vector**. The coefficient matrices $\mathbf{A}$ and $\mathbf{B}$, depending only upon the network parameters, are of orders $k \times k$ and $k \times h$, respectively. Equation (7.3) is usually called the **state equation in normal form**.

The state variables x_j may or may not be the desired output variables. We therefore must express the desired output variables in terms of the state variables and excitations. In general, if there are q output variables $y_j(t)$ ($j = 1, 2, \ldots, q$) and h input excitations, the **output vector** $\mathbf{y}(t)$ formed by the q output variables $y_j(t)$ can be expressed in terms of the state vector $\mathbf{x}(t)$ and the input vector $\mathbf{u}(t)$ by the matrix equation

$$\mathbf{y}(t) = \mathbf{C}\mathbf{x}(t) + \mathbf{D}\mathbf{u}(t) \tag{7.4}$$

where the known coefficient matrices **C** and **D**, depending only on the network parameters, are of orders $q \times k$ and $q \times h$, respectively. Equation (7.4) is called the **output equation**. The state equation, Eq. (7.3), and the output equation, Eq. (7.4), together are known as the **state equations**.

7.3 The Concept of State and State Variables and Normal Tree

Our immediate problem is to choose the network variables as the state variables in order to formulate the state equations. If we call the set of instantaneous values of all the branch currents and voltages the *state* of the network, then the knowledge of the instantaneous values of all these variables determines this instantaneous state. Not all of these instantaneous values are required in order to determine the instantaneous state, however, because some can be calculated from the others. For example, the instantaneous voltage of a resistor can be obtained from its instantaneous current through Ohm's law. The question arises as to the minimum number of instantaneous values of branch voltages and currents that are sufficient to determine completely the instantaneous state of the network.

In a given network, a minimal set of its branch variables is said to be a **complete set of state variables** if their instantaneous values are sufficient to determine completely the instantaneous values of all the branch variables. For a linear time-invariant nondegenerate network, it is convenient to choose the capacitor voltages and inductor currents as the state variables. A **nondegenerate network** is one that contains neither a circuit composed only of capacitors and/or independent or dependent voltage sources nor a cutset composed only of inductors and/or independent or dependent current sources, where a cutset is a minimal subnetwork the removal of which cuts the original network into two connected pieces. Thus, not all the capacitor voltages and inductor currents of a degenerate network can be state variables. To help systematically select the state variables, we introduce the notion of normal tree.

A **tree** of a connected network is a connected subnetwork that contains all the nodes but does not contain any circuit. A **normal tree** of a connected network is a tree that contains all the independent voltage sources, the maximum number of capacitors, the minimum number of inductors, and none of the independent current sources. This definition excludes the possibility of having unconnected networks. In the case of unconnected networks, we can consider the normal trees of the individual components. We remark that the representation of the state of a network is generally not unique, but the state of a network itself is.

7.4 Systematic Procedure in Writing State Equations

In the following we present a systematic step-by-step procedure for writing the state equation for a network. They are a systematic way to eliminate the unwanted variables in the primary system of equations.

1. In a given network N, assign the voltage and current references of its branches.
2. In N select a normal tree T and choose as the state variables the capacitor voltages of T and the inductor currents of the **cotree** $\bar{T}$, the complement of T in N.
3. Assign each branch of T a voltage symbol, and assign each element of $\bar{T}$, called the **link**, a current symbol.
4. Using Kirchhoff's current law, express each tree-branch current as a sum of cotree-link currents, and indicate it in N if necessary.
5. Using Kirchhoff's voltage law, express each cotree-link voltage as a sum of tree-branch voltages, and indicate it in N if necessary.
6. Write the element v-i equations for the passive elements and separate these equations into two groups:
   a. Those element v-i equations for the tree-branch capacitors and the cotree-link inductors
   b. Those element v-i equations for all other passive elements
7. Eliminate the nonstate variables among the equations obtained in the preceding step. **Nonstate variables** are defined as those variables that are neither state variables nor known independent sources.
8. Rearrange the terms and write the resulting equations in normal form.

We illustrate the preceding steps by the following examples.

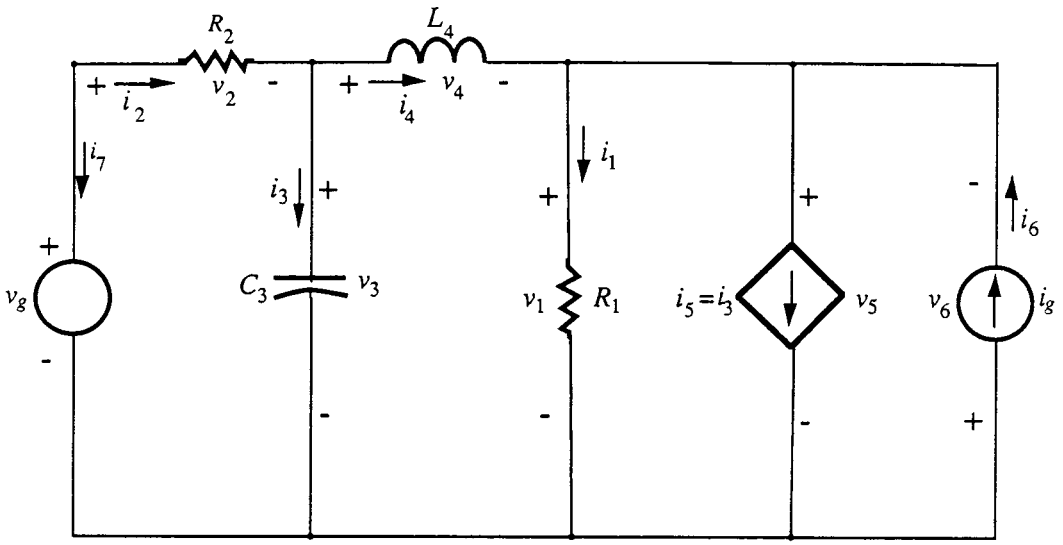

FIGURE 7.1 An active network used to illustrate the procedure for writing the state equations in normal form.

Example 1

We write the state equations for the network N of Fig. 7.1 by following the eight steps outlined above.

Step 1

The voltage and current references of the branches of the active network N are as indicated in Fig. 7.1.

Step 2

Select a normal tree T consisting of the branches R_1, C_3, and v_g. The subnetwork $C_3 i_5 v_g$ is another example of a normal tree.

Step 3

The tree branches R_1, C_3, and v_g are assigned the voltage symbols v_1, v_3, and v_g; and the cotree-links R_2, L_4, i_5, and i_g are assigned the current symbols i_2, i_4, i_3, and i_g, respectively. The controlled current source i_5 is given the current symbol i_3 because its current is controlled by the current of the branch C_3, which is i_3.

Step 4

Applying Kirchhoff's current law, the branch currents i_1, i_3, and i_7 can each be expressed as the sums of cotree-link currents:

$$i_1 = i_4 + i_g - i_3 \tag{7.5a}$$

$$i_3 = i_2 - i_4 \tag{7.5b}$$

$$i_7 = -i_2 \tag{7.5c}$$

Step 5

Applying Kirchhoff's voltage law, the cotree-link voltages v_2, v_4, v_5, and v_6 can each be expressed as the sums of tree-branch voltages:

$$v_2 = v_g - v_3 \tag{7.6a}$$

$$v_4 = v_3 - v_1 \tag{7.6b}$$

$$v_5 = v_1 \tag{7.6c}$$

$$v_6 = -v_1 \tag{7.6d}$$

Step 6

The element *v-i* equations for the tree-branch capacitor and the cotree-link inductor are found to be

$$C_3\dot{v}_3 = i_3 = i_2 - i_4 \tag{7.7a}$$

$$L_4\dot{i}_4 = v_4 = v_3 - v_1 \tag{7.7b}$$

Likewise, the element *v-i* equations for other passive elements are obtained as

$$v_1 = R_1 i_1 = R_1(i_4 + i_g - i_3) \tag{7.8a}$$

$$i_2 = \frac{v_2}{R_2} = \frac{v_g - v_3}{R_2} \tag{7.8b}$$

Step 7

The state variables are the capacitor voltage v_3 and inductor current i_4, and the known independent sources are i_g and v_g. To obtain the state equation, we must eliminate the nonstate variables v_1 and i_2 in Eq. (7.7). From Eqs. (7.5b) and (7.8) we express v_1 and i_2 in terms of the state variables and obtain

$$v_1 = R_1\left(2i_4 + i_g + \frac{v_3}{R_2} - \frac{v_g}{R_2}\right) \tag{7.9a}$$

$$i_2 = \frac{v_g - v_3}{R_2} \tag{7.9b}$$

Substituting these in Eq. (7.7) yields

$$C_3\dot{v}_3 = \frac{v_g - v_3}{R_2} - i_4 \tag{7.10a}$$

$$L_4\dot{i}_4 = \left(1 - \frac{R_1}{R_2}\right)v_3 - 2R_1 i_4 - R_1 i_g + \frac{R_1 v_g}{R_2} \tag{7.10b}$$

Step 8

Equations (7.10a) and (7.10b) are written in matrix form as

$$\begin{bmatrix} \dot{v}_3 \\ \dot{i}_4 \end{bmatrix} = \begin{bmatrix} -\dfrac{1}{R_2 C_3} & -\dfrac{1}{C_3} \\ \dfrac{1}{L_4} & -\dfrac{R_1}{R_2 L_4} & -\dfrac{2R_1}{L_4} \end{bmatrix} \begin{bmatrix} v_3 \\ i_4 \end{bmatrix} + \begin{bmatrix} \dfrac{1}{R_2 C_3} & 0 \\ \dfrac{R_1}{R_2 L_4} & -\dfrac{R_1}{L_4} \end{bmatrix} \begin{bmatrix} v_g \\ i_g \end{bmatrix} \tag{7.11}$$

This is the state equation in normal form for the active network N of Fig. 7.1.

Suppose that resistor voltage v_1 and capacitor current i_3 are the output variables. Then from Eqs. (7.5b) and (7.9) we obtain

$$v_1 = \frac{R_1}{R_2} v_3 + 2R_1 i_4 + R_1 \left(i_g - \frac{v_g}{R_2} \right) \tag{7.12a}$$

$$i_3 = -\frac{v_3}{R_2} - i_4 + \frac{v_g}{R_2} \tag{7.12b}$$

In matrix form, the output equation of the network becomes

$$\begin{bmatrix} v_1 \\ i_3 \end{bmatrix} = \begin{bmatrix} \dfrac{R_1}{R_2} & 2R_1 \\ -\dfrac{1}{R_2} & -1 \end{bmatrix} \begin{bmatrix} v_3 \\ i_4 \end{bmatrix} + \begin{bmatrix} -\dfrac{R_1}{R_2} & R_1 \\ \dfrac{1}{R_2} & 0 \end{bmatrix} \begin{bmatrix} v_g \\ i_g \end{bmatrix} \tag{7.13}$$

Equations (7.11) and (7.13) together are the state equations of the active network of Fig. 7.1.

7.5 State Equations for Networks Described by Scalar Differential Equations

In many situations we are faced with networks that are described by scalar differential equations of order higher than one. Our purpose here is to show that these networks can also be represented by the state equations in normal.

Consider a network that can be described by the nth-order linear differential equation

$$\frac{d^n y}{dt^n} + a_1 \frac{d^{n-1} y}{dt^{n-1}} + a_2 \frac{d^{n-2} y}{dt^{n-2}} + \cdots + a_{n-1} \frac{dy}{dt} + a_n y = bu \tag{7.14}$$

Then its state equation can be obtained by defining

$$\begin{aligned} x_1 &= y \\ x_2 &= \dot{x}_1 \\ &\cdot \\ &\cdot \\ &\cdot \\ x_n &= \dot{x}_{n-1} \end{aligned} \tag{7.15}$$

showing that the nth-order linear differential Eq. (7.14) is equivalent to

$$\begin{aligned}
\dot{x}_1 &= x_2 \\
\dot{x}_2 &= x_3 \\
&\cdot \\
&\cdot \\
&\cdot \\
\dot{x}_{n-1} &= x_n \\
\dot{x}_n &= -a_n x_1 - a_{n-1} x_2 - \quad . \quad . \quad . - a_2 x_{n-1} - a_1 x_n + bu
\end{aligned} \tag{7.16}$$

or, in matrix form,

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \cdot \\ \cdot \\ \cdot \\ \dot{x}_{n-1} \\ \dot{x}_n \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ 0 & 0 & 0 & \cdots & 1 \\ -a_n & -a_{n-1} & -a_{n-2} & \cdots & -a_1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \cdot \\ \cdot \\ \cdot \\ x_{n-1} \\ x_n \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \cdot \\ \cdot \\ \cdot \\ 0 \\ b \end{bmatrix} \begin{bmatrix} u \end{bmatrix} \tag{7.17}$$

More compactly, Eq. (7.17) can be written as

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t) \tag{7.18}$$

The coefficient matrix **A** is called the **companion matrix** of Eq. (7.14), and Eq. (7.17) is the state-equation representation of the network describable by the linear differential equation (7.14).

Let us now consider the more general situation where the right-hand side of (7.14) includes derivatives of the input excitation u. In this case, the different equation takes the general form

$$\begin{aligned}
&\frac{d^n y}{dt^n} + a_1 \frac{d^{n-1} y}{dt^{n-1}} + a_2 \frac{d^{n-2} y}{dt^{n-2}} + \ldots + a_{n-1} \frac{dy}{dt} + a_n y \\
&\qquad = b_0 \frac{d^n u}{dt^n} + b_1 \frac{d^{n-1} u}{dt^{n-1}} + \ldots + b_{n-1} \frac{du}{dt} + b_n u
\end{aligned} \tag{7.19}$$

Its state equation can be obtained by defining

$$\begin{aligned}
x_1 &= y - c_0 u \\
x_2 &= \dot{x}_1 - c_1 u \\
&\vdots \\
x_n &= \dot{x}_{n-1} - c_{n-1} u
\end{aligned} \tag{7.20}$$

The general state equation becomes

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \vdots \\ \dot{x}_{n-1} \\ \dot{x}_n \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -a_n & -a_{n-1} & -a_{n-2} & \cdots & -a_1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_{n-1} \\ x_n \end{bmatrix} + \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_{n-1} \\ c_n \end{bmatrix} \begin{bmatrix} u \end{bmatrix} \tag{7.21}$$

where $n > 1$,

$$\begin{aligned} c_1 &= b_1 - a_1 b_0 \\ c_2 &= \left(b_2 - a_2 b_0\right) - a_1 c_1 \\ c_3 &= \left(b_3 - a_3 b_0\right) - a_2 c_1 - a_1 c_2 \\ &\vdots \\ c_n &= \left(b_n - a_3 b_0\right) - a_{n-1} c_1 - a_{n-2} c_2 - \cdots - a_2 c_{n-2} - a_1 c_{n-1} \end{aligned} \tag{7.22}$$

and

$$x_1 = y - b_0 u \tag{7.23}$$

Finally, if y is the output variable, the output equation becomes

$$y(t) = \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} + \begin{bmatrix} b_0 \end{bmatrix} \begin{bmatrix} u \end{bmatrix} \tag{7.24}$$

7.6 Extension to Time-Varying and Nonlinear Networks

A great advantage in the state-variable approach to network analysis is that it can easily be extended to time-varying and nonlinear networks, which are often not readily amenable to the conventional methods of analysis. In these cases, it is more convenient to choose the capacitor charges and inductor flux as the the state variables instead of capacitor voltages and inductor currents.

In the case of a linear time-varying network, its state equations can be written the same as before except that now the coefficient matrices are time-dependent:

$$\dot{\mathbf{x}}(t) = \mathbf{A}(t)\mathbf{x}(t) + \mathbf{B}(t)\mathbf{u}(t) \tag{7.25a}$$

$$\mathbf{y}(t) = \mathbf{C}(t)\mathbf{x}(t) + \mathbf{D}(t)\mathbf{u}(t) \tag{7.25b}$$

Thus, with the state-variable approach, it is no more difficult to write the governing equations for a linear time-varying network than it is for a linear time-invariant network. Their solutions are, of course, a different matter.

For a nonlinear network, its state equation in normal form is describable by a coupled set of first-order differential equations:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}, t) \tag{7.26}$$

If the function **f** satisfies the familiar Lipshitz condition with respect to **x** in a given domain, then for every set of initial conditions $\mathbf{x}_0(t_0)$ and every input **u** there exists a unique solution $\mathbf{x}(t)$, the components of which are the state variables of the network.

Defining Terms

Companion matrix: The coefficient matrix in the state-equation representation of the network describable by a linear differential equation.

Complete set of state variables: A minimal set of network variables, the instantaneous values of which are sufficient to determine completely the instantaneous values of all the network variables.

Cotree: The complement of a tree in a network.

Cutset: A minimal subnetwork, the removal of which cuts the original network into two connected pieces.

Cutset system: A secondary system of equations using cutset voltages as variables.

Input vector: A vector formed by the input variables to a network.

Link: An element of a cotree.

Loop system: A secondary system of equations using loop currents as variables.

Nodal system: A secondary system of equations using nodal voltages as variables.

Nondegenerate network: A network that contains neither a circuit composed only of capacitors and/or independent or dependent voltage sources nor a cutset composed only of inductors and/or independent or dependent current sources.

Nonstate variables: Network variables that are neither state variables nor known independent sources.

Normal tree: A tree that contains all the independent voltage sources, the maximum number of capacitors, the minimum number of inductors, and none of the independent current sources.

Output equation: An equation expressing the output vector in terms of the state vector and the input vector.

Output vector: A vector formed by the output variables of a network.

Primary system of equations: A system of algebraic and differential equations obtained by applying the Kirchhoff's current and voltage laws and the element *v-i* relations.

Secondary system of equations: A system of algebraic and differential equations obtained from the primary system of equations by transformation of network variables.

State: A set of data, the values of which at any time *t*, together with the input to the system at the time, determine uniquely the value of any network variable at the time *t*.

State equation in normal form: A system of first-order differential equations that describes the dynamic behavior of a network and that is put into a standard form.

State equations: Equations formed by the state equation and the output equation.

State variables: Network variables used to describe the state.

State vector: A vector formed by the state variables.

Tree: A connected subnetwork that contains all the nodes of the original network but does not contain any circuit.

8.1 Introduction

Discrete-time signals can be represented as sequences of numbers. Thus, if x is a discrete-time signal, its values can, in general, be indexed by n as follows:

$$x = \{\ldots, x(-2), x(-1), x(0), x(1), x(2), \ldots, x(n), \ldots\}$$

In order to work within a transform domain for discrete-time signals, we define the z-transform as follows. The z-transform of the sequence x in the previous equation is

$$\mathcal{Z}\{x(n)\} = X(z) = \sum_{n=-\infty}^{\infty} x(n)z^{-n}$$

in which the variable z can be interpreted as being either a time-position marker or a complex-valued variable, and the script $\mathcal{Z}$ is the z-transform operator. If the former interpretation is employed, the number multiplying the marker z^{-n} is identified as being the nth element of the x sequence, i.e., $x(n)$. It will be generally beneficial to take z to be a complex-valued variable.

The z-transforms of some useful sequences are listed in Table 8.1.

8.2 Properties of the *z*-Transform

Linearity

Both the direct and inverse z-transform obey the property of linearity. Thus, if $\mathcal{Z}\{f(n)\}$ and $\mathcal{Z}\{g(n)\}$ are denoted by $F(z)$ and $G(z)$, respectively, then

$$\mathcal{Z}\{af(n) + bg(n)\} = aF(z) + bG(z)$$

where a and b are constant multipliers.

Translation

An important property when transforming terms of a difference equation is the *z-transform* of a sequence shifted in time. For a constant shift, we have

$$\mathcal{Z}\{f(n+k)\} = z^k F(z)$$

for positive or negative integer k. The region of convergence of $z^k F(z)$ is the same as for $F(z)$ for positive k; only the point $z = 0$ need be eliminated from the convergence region of $F(z)$ for negative k.

Convolution

In the z-domain, the time-domain convolution operation becomes a simple product of the corresponding transforms, that is,

$$\mathcal{Z}\{f(n) * g(n)\} = F(z)G(z)$$

Multiplication by a^n

This operation corresponds to a rescaling of the z-plane. For $a > 0$,

$$\mathcal{Z}\{a^n f(n)\} = F\left(\frac{z}{a}\right) \quad \text{for } aR_1 < |z| < aR_2$$

where $F(z)$ is defined for $R_1 < |z| < R_2$.

Time Reversal

$$\mathcal{Z}\{f(\pm n)\} = F(z^{-1}) \quad \text{for } R_2^{-1} < |z| < R_1^{-1}$$

where $F(z)$ is defined for $R_1 < |z| < R_2$.

8.3 Unilateral z-Transform

The unilateral z-transform is defined as

$$\mathcal{Z}_+\{x(n)\} = X(z) = \sum_{n=0}^{\infty} x(n)z^{-n} \quad \text{for } |z| > R$$

where it is called single-sided since $n \geq 0$, just as if the sequence $x(n)$ was in fact single-sided. If there is no ambiguity in the sequel, the subscript plus is omitted and we use the expression *z-transform* to mean either the double- or the single-sided transform. It is usually clear from the context which is meant. By restricting signals to be single-sided, the following useful properties can be proved.

Time Advance

For a single-sided signal $f(n)$,

$$\mathcal{Z}_+\{f(n+1)\} = zF(z) - zf(0)$$

More generally,

$$\mathcal{Z}_+\{f(n+k)\} = z^k F(z) - z^k f(0) - z^{k-1} f(1) - \cdots - zf(k-1)$$

This result can be used to solve linear constant-coefficient difference equations. Occasionally, it is desirable to calculate the initial or final value of a single-sided sequence without a complete inversion. The following two properties present these results.

Initial Signal Value

If $f(n) = 0$ for $n < 0$,

$$f(0) = \lim_{z \Rightarrow \infty} F(z)$$

where $F(z) = Z\{f(n)\}$ for $|z| > R$.

Final Value

If $f(n) = 0$ for $n < 0$ and $Z\{f(n)\} = F(z)$ is a rational function with all its denominator roots (poles) strictly inside the unit circle except possibly for a first-order pole at $z = 1$,

$$f(\infty) = \lim_{n \Rightarrow \infty} f(n) = \lim_{z \Rightarrow \infty} (1 - z^{-1}) F(z)$$

8.4 *z*-Transform Inversion

We operationally denote the inverse transform of $F(z)$ in the form

$$f(n) = Z^{-1}\{F(z)\}$$

There are three useful methods for inverting a transformed signal. They are:

1. Expansion into a series of terms in the variables z and z^{-1}
2. Complex integration by the method of residues
3. Partial-fraction expansion and table look-up

We discuss two of these methods in turn.

Method 1

For the expansion of $F(z)$ into a series, the theory of functions of a complex variable provides a practical basis for developing our inverse transform techniques. As we have seen, the general region of convergence for a transform function $F(z)$ is of the form $a < |z| < b$, i.e., an annulus centered at the origin of the z-plane. This first method is to obtain a series expression of the form

$$F(z) = \sum_{n=-\infty}^{\infty} c_n z^{-n}$$

which is valid in the annulus of convergence. When $F(z)$ has been expanded as in the previous equation, that is, when the coefficients c_n, $n = 0, \pm 1, \pm 2, \ldots$ have been found, the corresponding sequence is specified by $f(n) = c_n$ by uniqueness of the transform.

Method 2

We evaluate the inverse transform of $F(z)$ by the method of residues. The method involves the calculation of residues of a function both inside and outside of a simple closed path that lies inside the region of convergence. A number of key concepts are necessary in order to describe the required procedure.

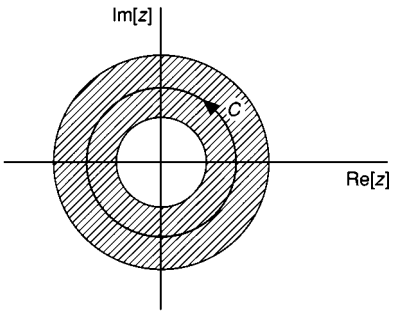

FIGURE 8.1 Typical convergence region for a transformed discrete-time signal (*Source:* J. A. Cadzow and H. F. Van Landingham, *Signals, Systems and Transforms*, Englewood Cliffs, N.J.: Prentice-Hall, 1985, p. 191. With permission.)

A complex-valued function $G(z)$ has a pole of order k at $z = z_0$ if it can be expressed as

$$G(z) = \frac{G_1(z_0)}{(z - z_0)^k}$$

where $G_1(z_0)$ is finite.

The residue of a complex function $G(z)$ at a pole of order k at $z = z_0$ is defined by

$$\text{Res}[G(z)]\Big|_{z=z_0} = \frac{1}{(k-1)!}\frac{d^{k-1}}{dz^{k-1}}[(z - z_0)^k G(z)]\Big|_{z=z_0}$$

Inverse Transform Formula (Method 2)

If $F(z)$ is convergent in the annulus $0 < a < |z| < b$ as shown in Fig. 8.1 and C is the closed path shown (the path C must lie entirely within the annulus of convergence), then

$$f(n)\begin{cases}\text{sum of residues of } F(z)z^{n-1} \text{ at poles of } F(z) \text{ inside } C, & m \geq 0\\ -(\text{sum of residues of } F(z)z^{n-1} \text{ at poles of } F(z) \text{ outside } C), & m < 0\end{cases}$$

where m is the least power of z in the numerator of $F(z)z^{n-1}$, e.g., m might equal $n - 1$. Figure 8.1 illustrates the previous equation.

8.5 Sampled Data

Data obtained for a signal only at discrete intervals (sampling period) is called sampled data. One advantage of working with sampled data is the ability to represent sequences as combinations of sampled time signals. Table 8.2 provides some key z-transform pairs. So that the table can serve a multiple purpose, there are three items per line: the first is an indicated sampled continuous-time signal, the second is the Laplace transform of the continuous-time signal, and the third is the z-transform of the uniformly sampled continous-time signal. To illustrate the interrelation of these entries, consider Fig. 8.2. For simplicity, only single-sided signals have been used in Table 8.2. Consequently, the convergence regions are understood in this context to be $\text{Re}[s] < \sigma_0$

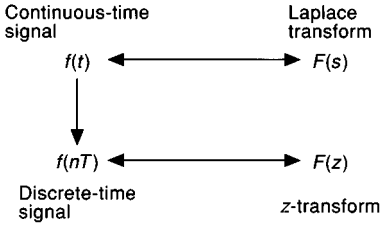

FIGURE 8.2 Signal and transform relationships for Table 8.2.

9.1 Introduction
9.2 Three-Phase Connections
9.3 Wye ⇔ Delta Transformations

9.1 Introduction

Two very important two-ports are the T and Π networks shown in Fig. 9.1. Because we encounter these two geometrical forms often in two-port analyses, it is useful to determine the conditions under which these two networks are equivalent. In order to determine the equivalence relationship, we will examine *Z*-parameter equations for the T network and the *Y*-parameter equations for the Π network.

For the T network the equations are

$$\mathbf{V}_1 = (\mathbf{Z}_1 + \mathbf{Z}_3)\mathbf{I}_1 + \mathbf{Z}_3\mathbf{I}_2$$

$$\mathbf{V}_2 = \mathbf{Z}_3\mathbf{I}_1 + (\mathbf{Z}_2 + \mathbf{Z}_3)\mathbf{I}_2$$

and for the Π network the equations are

$$\mathbf{I}_1 = (\mathbf{Y}_a + \mathbf{Y}_b)\mathbf{V}_1 - \mathbf{Y}_b\mathbf{V}_2$$

$$\mathbf{I}_2 = -\mathbf{Y}_b\mathbf{V}_1 + (\mathbf{Y}_b + \mathbf{Y}_c)\mathbf{V}_2$$

Solving the equations for the T network in terms of $\mathbf{I}_1$ and $\mathbf{I}_2$, we obtain

$$\mathbf{I}_1 = \left(\frac{\mathbf{Z}_2 + \mathbf{Z}_3}{\mathbf{D}_1}\right)\mathbf{V}_1 - \frac{\mathbf{Z}_3\mathbf{V}_2}{\mathbf{D}_1}$$

$$\mathbf{I}_2 = -\frac{\mathbf{Z}_3\mathbf{V}_1}{\mathbf{D}_1} + \left(\frac{\mathbf{Z}_1 + \mathbf{Z}_3}{\mathbf{D}_1}\right)\mathbf{V}_2$$

where $\mathbf{D}_1 = \mathbf{Z}_1\mathbf{Z}_2 + \mathbf{Z}_2\mathbf{Z}_3 + \mathbf{Z}_1\mathbf{Z}_3$. Comparing these equations with those for the Π network, we find that

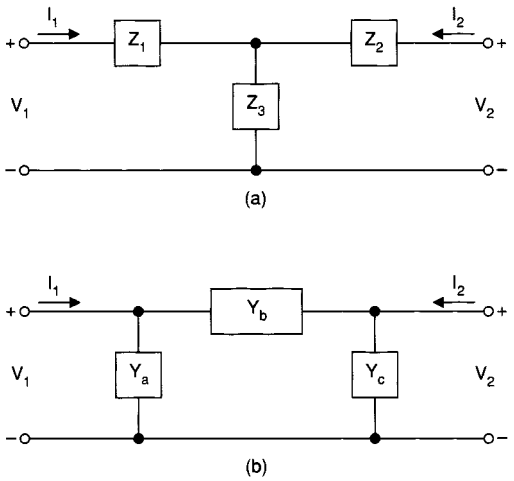

FIGURE 9.1 T and Π two-port networks.

$$\mathbf{Y}_a = \frac{\mathbf{Z}_2}{\mathbf{D}_1}$$
$$\mathbf{Y}_b = \frac{\mathbf{Z}_3}{\mathbf{D}_1}$$
$$\mathbf{Y}_c = \frac{\mathbf{Z}_1}{\mathbf{D}_1}$$

or in terms of the impedances of the Π network

$$\mathbf{Z}_a = \frac{\mathbf{D}_1}{\mathbf{Z}_2}$$
$$\mathbf{Z}_b = \frac{\mathbf{D}_1}{\mathbf{Z}_3}$$
$$\mathbf{Z}_c = \frac{\mathbf{D}_1}{\mathbf{Z}_1}$$

If we reverse this procedure and solve the equations for the Π network in terms of $\mathbf{V}_1$ and $\mathbf{V}_2$ and then compare the resultant equations with those for the T network, we find that

$$\mathbf{Z}_1 = \frac{\mathbf{Y}_c}{\mathbf{D}_2}$$
$$\mathbf{Z}_2 = \frac{\mathbf{Y}_a}{\mathbf{D}_2} \tag{9.1}$$
$$\mathbf{Z}_3 = \frac{\mathbf{Y}_b}{\mathbf{D}_2}$$

where $\mathbf{D}_2 = \mathbf{Y}_a\mathbf{Y}_b + \mathbf{Y}_b\mathbf{Y}_c + \mathbf{Y}_a\mathbf{Y}_c$. Equation (9.1) can also be written in the form

$$\mathbf{Z}_1 = \frac{\mathbf{Z}_a\mathbf{Z}_b}{\mathbf{Z}_a + \mathbf{Z}_b + \mathbf{Z}_c}$$

$$\mathbf{Z}_2 = \frac{\mathbf{Z}_b\mathbf{Z}_c}{\mathbf{Z}_a + \mathbf{Z}_b + \mathbf{Z}_c}$$

$$\mathbf{Z}_3 = \frac{\mathbf{Z}_a\mathbf{Z}_c}{\mathbf{Z}_a + \mathbf{Z}_b + \mathbf{Z}_c}$$

The T is a wye-connected network and the Π is a delta-connected network, as we discuss in the next section.

9.2 Three-Phase Connections

By far the most important polyphase voltage source is the balanced three-phase source. This source, as illustrated by Fig. 9.2, has the following properties. The phase voltages, that is, the voltage from each line *a*, *b*, and *c* to the neutral *n*, are given by

$$\mathbf{V}_{an} = \mathbf{V}_p \angle 0°$$

$$\mathbf{V}_{bn} = \mathbf{V}_p \angle -120° \qquad (9.2)$$

$$\mathbf{V}_{cn} = \mathbf{V}_p \angle +120°$$

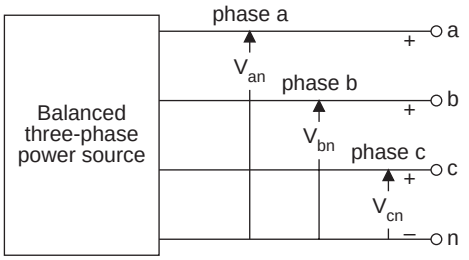

FIGURE 9.2 Balanced three-phase voltage source.

An important property of the balanced voltage set is that

$$\mathbf{V}_{an} + \mathbf{V}_{bn} + \mathbf{V}_{cn} = 0 \qquad (9.3)$$

From the standpoint of the user who connects a load to the balanced three-phase voltage source, it is not important how the voltages are generated. It is important to note, however, that if the load currents generated by connecting a load to the power source shown in Fig. 9.2 are also *balanced*, there are two possible equivalent configurations for the load. The equivalent load can be considered as being connected in either a *wye* (*Y*) or a *delta* (Δ) configuration. The balanced wye configuration is shown in Fig. 9.3. The delta configuration is shown in Fig. 9.4. Note that in the case of the delta connection, there is no neutral line. The actual function of the

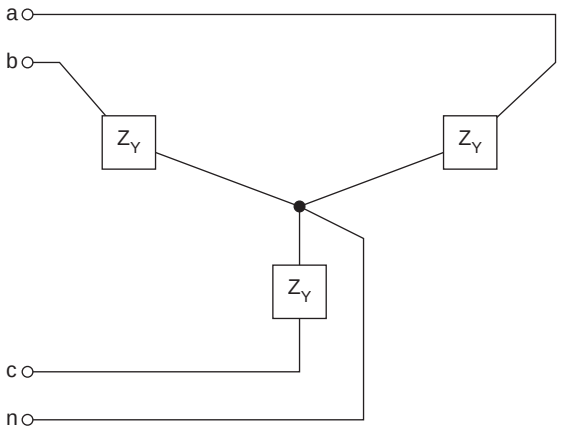

FIGURE 9.3 Wye (*Y*)-connected loads.

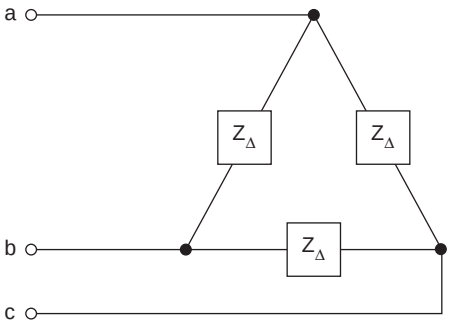

FIGURE 9.4 Delta (Δ)-connected loads.

neutral line in the wye connection will be examined and it will be shown that in a balanced system the neutral line carries no current and therefore may be omitted.

9.3 Wye ⇔ Delta Transformations

For a balanced system, the equivalent load configuration may be either wye or delta. If both of these configurations are connected at only three terminals, it would be very advantageous if an equivalence could be established between them. It is, in fact, possible characteristics are the same. Consider, for example, the two networks shown in Fig. 9.5. For these two networks to be equivalent at each corresponding pair of terminals it is necessary that the input impedances at the corresponding terminals be equal, for example, if at terminals *a* and *b*, with *c* open-circuited, the impedance is the same for both configurations. Equating the impedances at each port yields

TABLE 9.1 Current-Voltage Relationships for the Wye and Delta Load Configurations

Parameter	Wye Configuration	Delta Configuration
Voltage	$\mathbf{V}_{\text{line to line}} = \sqrt{3}\mathbf{V}_Y$	$\mathbf{V}_{\text{line to line}} = \mathbf{V}_\Delta$
Current	$\mathbf{I}_{\text{line}} = \mathbf{I}_Y$	$\mathbf{I}_{\text{line}} = \sqrt{3}\mathbf{I}_\Delta$

$$\begin{aligned}
\mathbf{Z}_{ab} &= \mathbf{Z}_a + \mathbf{Z}_b = \frac{\mathbf{Z}_1(\mathbf{Z}_2 + \mathbf{Z}_3)}{\mathbf{Z}_1 + \mathbf{Z}_2 + \mathbf{Z}_3} \\
\mathbf{Z}_{bc} &= \mathbf{Z}_b + \mathbf{Z}_c = \frac{\mathbf{Z}_3(\mathbf{Z}_1 + \mathbf{Z}_2)}{\mathbf{Z}_1 + \mathbf{Z}_2 + \mathbf{Z}_3} \\
\mathbf{Z}_{ca} &= \mathbf{Z}_c + \mathbf{Z}_a = \frac{\mathbf{Z}_2(\mathbf{Z}_1 + \mathbf{Z}_3)}{\mathbf{Z}_1 + \mathbf{Z}_2 + \mathbf{Z}_3}
\end{aligned} \tag{9.4}$$

Solving this set of equations for $\mathbf{Z}_a$, $\mathbf{Z}_b$, and $\mathbf{Z}_c$ yields

$$\begin{aligned}
\mathbf{Z}_a &= \frac{\mathbf{Z}_1\mathbf{Z}_2}{\mathbf{Z}_1 + \mathbf{Z}_2 + \mathbf{Z}_3} \\
\mathbf{Z}_b &= \frac{\mathbf{Z}_1\mathbf{Z}_3}{\mathbf{Z}_1 + \mathbf{Z}_2 + \mathbf{Z}_3} \\
\mathbf{Z}_c &= \frac{\mathbf{Z}_2\mathbf{Z}_3}{\mathbf{Z}_1 + \mathbf{Z}_2 + \mathbf{Z}_3}
\end{aligned} \tag{9.5}$$

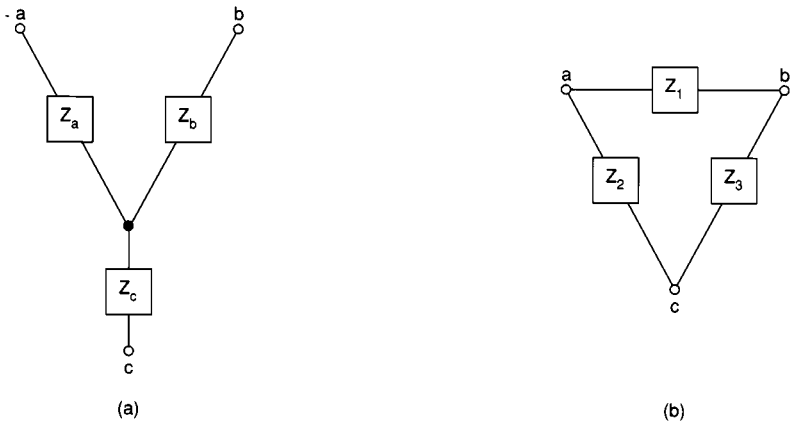

FIGURE 9.5 General wye- and delta-connected loads.

Similary, if we solve Eq. (9.4) for $\mathbf{Z}_1$, $\mathbf{Z}_2$, and $\mathbf{Z}_3$, we obtain

$$\begin{aligned}\mathbf{Z}_1 &= \frac{\mathbf{Z}_a\mathbf{Z}_b + \mathbf{Z}_b\mathbf{Z}_c + \mathbf{Z}_c\mathbf{Z}_a}{\mathbf{Z}_c}\\ \mathbf{Z}_2 &= \frac{\mathbf{Z}_a\mathbf{Z}_b + \mathbf{Z}_b\mathbf{Z}_c + \mathbf{Z}_c\mathbf{Z}_a}{\mathbf{Z}_b}\\ \mathbf{Z}_3 &= \frac{\mathbf{Z}_a\mathbf{Z}_b + \mathbf{Z}_b\mathbf{Z}_c + \mathbf{Z}_c\mathbf{Z}_a}{\mathbf{Z}_a}\end{aligned} \tag{9.6}$$

Equations (9.5) and (9.6) are general relationships and apply to any set of impedances connected in a wye or delta configuration. For the balanced case where $\mathbf{Z}_a = \mathbf{Z}_b = \mathbf{Z}_c$ and $\mathbf{Z}_1 = \mathbf{Z}_2 = \mathbf{Z}_3$, the equations above reduce to

$$\mathbf{Z}_Y = \frac{1}{3}\mathbf{Z} \tag{9.7}$$

and

$$\mathbf{Z}_\Delta = 3\mathbf{Z}_Y \tag{9.8}$$

Defining Terms

Balanced voltages of the three-phase connection: The three voltages satisfy

$$\mathbf{V}_{an} + \mathbf{V}_{bn} + \mathbf{V}_{cn} = 0$$

where

$$\mathbf{V}_{an} = \mathbf{V}_p \angle 0°$$

$$\mathbf{V}_{bn} = \mathbf{V}_p \angle -120°$$

$$\mathbf{V}_{cn} = \mathbf{V}_p \angle +120°$$

T network: The equations of the T network are

$$\mathbf{V}_1 = (\mathbf{Z}_1 + \mathbf{Z}_3)\mathbf{I}_1 + \mathbf{Z}_3\mathbf{I}_2$$

$$\mathbf{V}_2 = \mathbf{Z}_3\mathbf{I}_1 + (\mathbf{Z}_2 + \mathbf{Z}_3)\mathbf{I}_2$$

Π network: The equations of Π network are

$$\mathbf{I}_1 = (\mathbf{Y}_a + \mathbf{Y}_b)\mathbf{V}_1 - \mathbf{Y}_b\mathbf{V}_2$$

$$\mathbf{I}_2 = -\mathbf{Y}_b\mathbf{V}_1 + (\mathbf{Y}_b + \mathbf{Y}_c)\mathbf{V}_2$$

T and Π can be transferred to each other.

10.7 Chebyshev Filters

10.1 Introduction

Filters are widely used to pass signals at selected frequencies and reject signals at other frequencies. An *electrical filter* is a circuit that is designed to introduce gain or loss over a prescribed range of frequencies. In this section, we will describe ideal filters and then a selected set of practical filters.

10.2 Ideal Filters

An **ideal filter** is a system that completely rejects sinusoidal inputs of the form $x(t) = A \cos \omega t$, $-\infty < t < \infty$, for ω in certain frequency ranges and does not attenuate sinusoidal inputs whose frequencies are outside these ranges. There are four basic types of ideal filters: low-pass, high-pass, bandpass, and bandstop. The magnitude functions of these four types of filters are displayed in Fig. 10.1. Mathematical expressions for these magnitude functions are as follows:

$$\text{Ideal low-pass:} \quad |H(\omega)| = \begin{cases} 1, & -B \le \omega \le B \\ 0, & |\omega| > B \end{cases} \tag{10.1}$$

$$\text{Ideal high-pass:} \quad |H(\omega)| = \begin{cases} 0, & -B < \omega < B \\ 1, & |\omega| \ge B \end{cases} \tag{10.2}$$

$$\text{Ideal bandpass:} \quad |H(\omega)| = \begin{cases} 1, & B_1 \le |\omega| \le B_2 \\ 0, & \text{all other } \omega \end{cases} \tag{10.3}$$

$$\text{Ideal bandstop:} \quad |H(\omega)| = \begin{cases} 0, & B_1 \le |\omega| \le B_2 \\ 1, & \text{all other } \omega \end{cases} \tag{10.4}$$

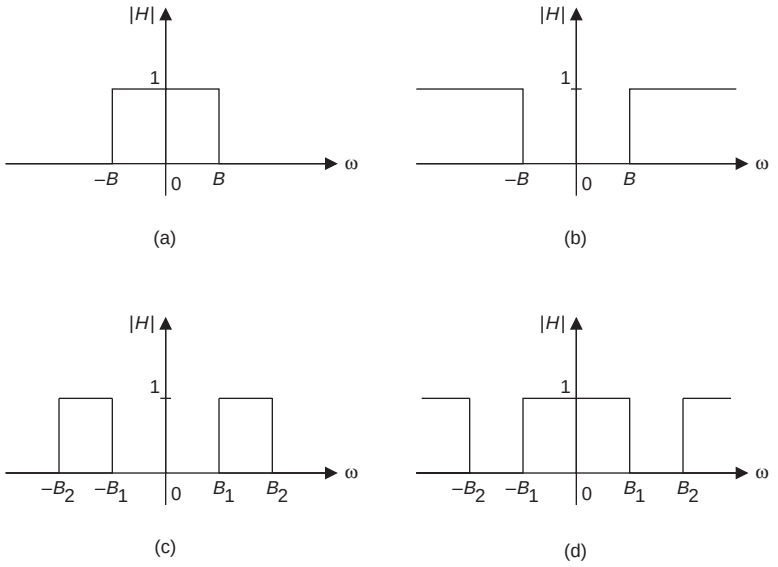

FIGURE 10.1 Magnitude functions of ideal filters:(a) low-pass; (b) high-pass; (c) bandpass; (d) bandstop.

The **stopband** of an ideal filter is defined to be the set of all frequencies ω for which the filter completely stops the sinusoidal input $x(t) = A\cos\omega t$, $-\infty < t < \infty$. The **passband** of the filter is the set of all frequencies ω for which the input $x(t)$ is passed without attenuation.

More complicated examples of ideal filters can be constructed by cascading ideal low-pass, high-pass, bandpass, and bandstop filters. For instance, by cascading bandstop filters with different values of B_1 and B_2, we can construct an ideal comb filter, whose magnitude function is illustrated in Fig. 10.2.

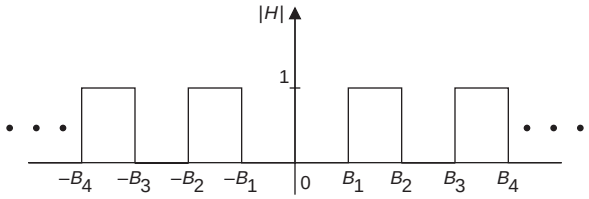

FIGURE 10.2 Magnitude function of an ideal comb filter.

10.3 The Ideal Linear-Phase Low-Pass Filter

Consider the ideal low-pass filter with the frequency function

$$H(\omega) = \begin{cases} e^{-j\omega t_d}, & -B \le \omega \le B \\ 0, & \omega < -B, \quad \omega > B \end{cases} \tag{10.5}$$

where t_d is a positive real number. Equation (10.5) is the polar-form representation of $H(\omega)$. From Eq. (10.5) we have

$$|H(\omega)| = \begin{cases} 1, & -B \le \omega \le B \\ 0, & \omega < -B, \quad \omega > B \end{cases}$$

and

$$\underline{/H(\omega)} = \begin{cases} -\omega t_d, & -B \le \omega \le B \\ 0, & \omega < -B, \quad \omega > B \end{cases}$$

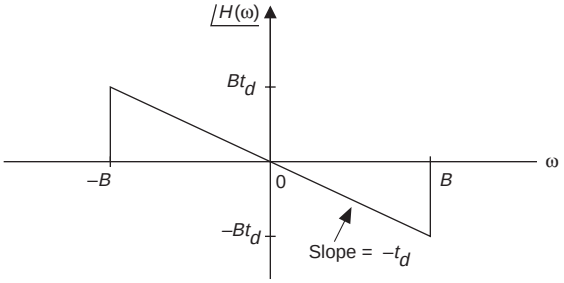

FIGURE 10.3 Phase function of ideal low-pass filter defined by Eq. (10.5).

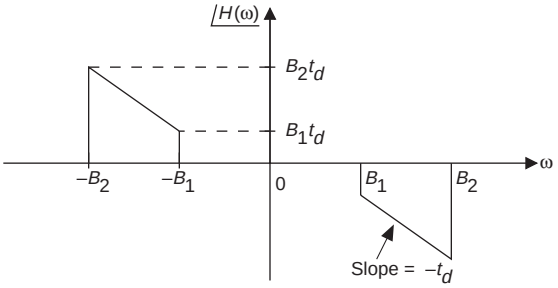

FIGURE 10.4 Phase function of ideal linear-phase bandpass filter.

The phase function $\underline{/H(\omega)}$ of the filter is plotted in Fig. 10.3. Note that over the frequency range 0 to B, the phase function of the system is linear with slope equal to $-t_d$.

The impulse response of the low-pass filter defined by Eq. (10.5) can be computed by taking the inverse Fourier transform of the frequency function $H(\omega)$. The impulse response of the ideal lowpass filter is

$$h(t) = \frac{B}{\pi} Sa[B(t - t_d)], \qquad -\infty < t < \infty \tag{10.6}$$

where $Sa(x) = (\sin x)/x$. The impulse response $h(t)$ of the ideal low-pass filter is not zero for $t < 0$. Thus, the filter has a response before the impulse at $t = 0$ and is said to be noncausal. As a result, it is not possible to build an ideal low-pass filter.

10.4 Ideal Linear-Phase Bandpass Filters

One can extend the analysis to ideal linear-phase bandpass filters. The frequency function of an ideal linear-phase bandpass filter is given by

$$H(\omega) = \begin{cases} e^{-j\omega t_d}, & B_1 \le |\omega| \le B_2 \\ 0, & \text{all other } \omega \end{cases}$$

where t_d, B_1, and B_2 are positive real numbers. The magnitude function is plotted in Fig. 10.1(c) and the phase function is plotted in Fig. 10.4. The passband of the filter is from B_1 to B_2. The filter will pass the signal within the band with no distortion, although there will be a time delay of t_d seconds.

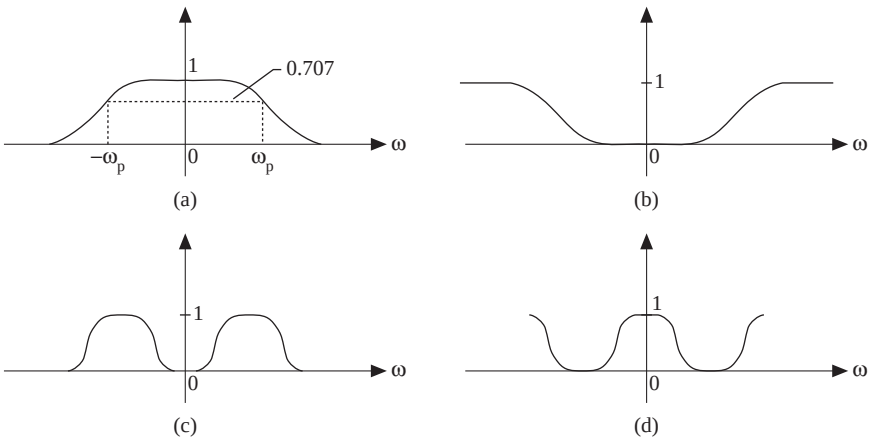

FIGURE 10.5 Causal filter magnitude functions: (a) low-pass; (b) high-pass; (c) bandpass; (d) bandstop.

10.5 Causal Filters

As observed in the preceding section, ideal filters cannot be utilized in real-time filtering applications, since they are noncausal. In such applications, one must use **causal filters**, which are necessarily nonideal; that is, the transition from the passband to the stopband (and vice versa) is gradual. In particular, the magnitude functions of causal versions of low-pass, high-pass, bandpass, and bandstop filters have gradual transitions from the passband to the stopband. Examples of magnitude functions for the basic filter types are shown in Fig. 10.5.

For a causal filter with frequency function $H(\omega)$, the passband is defined as the set of all frequencies ω for which

$$|H(\omega)| \geq \frac{1}{\sqrt{2}} |H(\omega_p)| \simeq 0.707 |H(\omega_p)| \tag{10.7}$$

where ω_p is the value of ω for which $|H(\omega)|$ is maximum. Note that Eq. (10.7) is equivalent to the condition that $|H(\omega)|_{dB}$ is less than 3 dB down from the peak value $|H(\omega_p)|_{dB}$. For low-pass or bandpass filters, the width of the passband is called the **3-dB bandwidth**.

A stopband in a causal filter is a set of frequencies ω for which $|H(\omega)|_{dB}$ is down some desired amount (e.g., 40 or 50 dB) from the peak value $|H(\omega_p)|_{dB}$. The range of frequencies between a passband and a stopband is called a **transition region**. In causal filter design, a key objective is to have the transition regions be suitably small in extent.

10.6 Butterworth Filters

The transfer function of the two-pole Butterworth filter is

$$H(s) = \frac{\omega_n^2}{s^2 + \sqrt{2}\ \omega_n s + \omega_n^2}$$

Factoring the denominator of $H(s)$, we see that the poles are located at

$$s = -\frac{\omega_n}{\sqrt{2}} \pm j\frac{\omega_n}{\sqrt{2}}$$

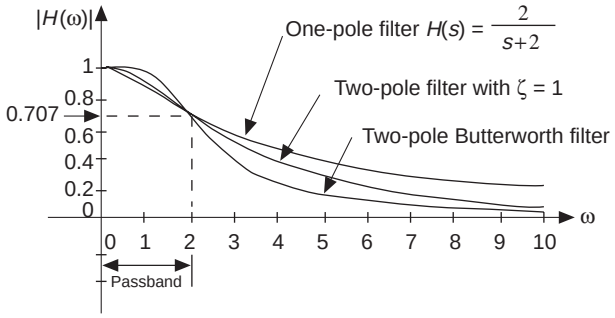

FIGURE 10.6 Magnitude curves of one- and two-pole low-pass filters.

Note that the magnitude of each of the poles is equal to ω_n.

Setting $s = j\omega$ in $H(s)$, we have that the magnitude function of the two-pole Butterworth filter is

$$|H(\omega)| = \frac{1}{\sqrt{1 + (\omega / \omega_n)^4}} \tag{10.8}$$

From Eq. (10.8) we see that the 3-dB bandwidth of the Butterworth filter is equal to ω_n. For the case $\omega_n = 2$ rad/s, the frequency response curves of the Butterworth filter are plotted in Fig. 10.6. Also displayed are the frequency response curves for the one-pole low-pass filter with transfer function $H(s) = 2/(s + 2)$, and the two-pole low-pass filter with $\zeta = 1$ and with 3-dB bandwidth equal to 2 rad/s. Note that the Butterworth filter has the sharpest cutoff of all three filters.

10.7 Chebyshev Filters

The magnitude function of the n-pole Butterworth filter has a monotone characteristic in both the passband and stopband of the filter. Here *monotone* means that the magnitude curve is gradually decreasing over the passband and stopband. In contrast to the Butterworth filter, the magnitude function of a type 1 Chebyshev filter has ripple in the passband and is monotone decreasing in the stopband (a type 2 Chebyshev filter has the opposite characteristic). By allowing ripple in the passband or stopband, we are able to achieve a sharper transition between the passband and stopband in comparison with the Butterworth filter.

The n-pole type 1 Chebyshev filter is given by the frequency function

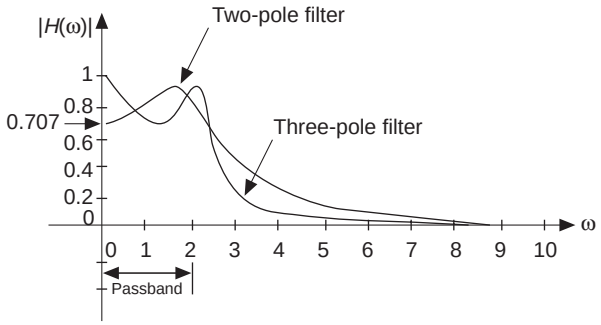
$$|H(\omega)| = \frac{1}{\sqrt{1 + \epsilon^2 T_n^2 (\omega/\omega_1)}} \tag{10.9}$$

where $T_n(\omega/\omega_1)$ is the nth-order Chebyshev polynomial. Note that ϵ is a numerical parameter related to the level of ripple in the passband. The Chebyshev polynomials can be generated from the recursion

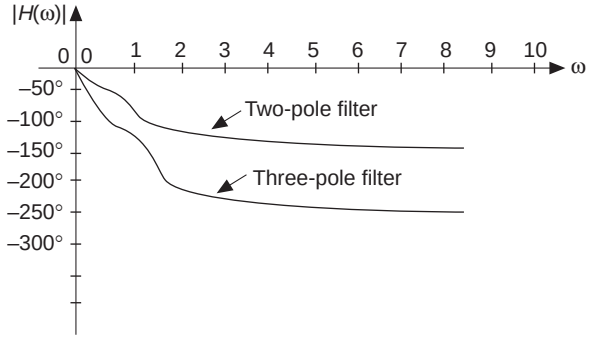
$$T_n(x) = 2xT_{n-1}(x) - T_{n-2}(x)$$

where $T_0(x) = 1$ and $T_1(x) = x$. The polynomials for $n = 2, 3, 4, 5$ are

$$\begin{aligned} T_2(x) &= 2x(x) - 1 = 2x^2 - 1 \\ T_3(x) &= 2x(2x^2 - 1) - x = 4x^3 - 3x \\ T_4(x) &= 2x(4x^3 - 3x) - (2x^2 - 1) = 8x^4 - 8x^2 + 1 \\ T_5(x) &= 2x(8x^4 - 8x^2 + 1) - (4x^3 - 3x) = 16x^5 - 20x^3 + 5x \end{aligned} \tag{10.10}$$



(a)



(b)

FIGURE 10.7 Frequency curves of two- and three-pole Chebyshev filters with ω_c = 2.5 rad/s: (a) magnitude curves; (b) phase curves.

Using Eq. (10.10), the two-pole type 1 Chebyshev filter has the following frequency function

$$|H(\omega)| = \frac{1}{\sqrt{1 + \epsilon^2[2(\omega / \omega_1)^2 - 1]^2}}$$

For the case of a 3-dB ripple (ϵ = 1), the transfer functions of the two-pole and three-pole type 1 Chebyshev filters are

$$H(s) = \frac{0.50\omega_c^2}{s^2 + 0.645\omega_c s + 0.708\omega_c^2}$$

$$H(s) = \frac{0.251\omega_c^3}{s^3 + 0.597\omega_c s^2 + 0.928\omega_c^2 s + 0.251\omega_c^3}$$

where ω_c = 3-dB bandwidth. The frequency curves for these two filters are plotted in Fig. 10.7 for the case ω_c = 2.5 rad.

The magnitude response functions of the three-pole Butterworth filter and the three-pole type 1 Chebyshev filter are compared in Fig. 10.8 with the 3-dB bandwidth of both filters equal to 2 rad. Note that the transition from passband to stopband is sharper in the Chebyshev filter; however, the Chebyshev filter does have the 3-dB ripple over the passband.

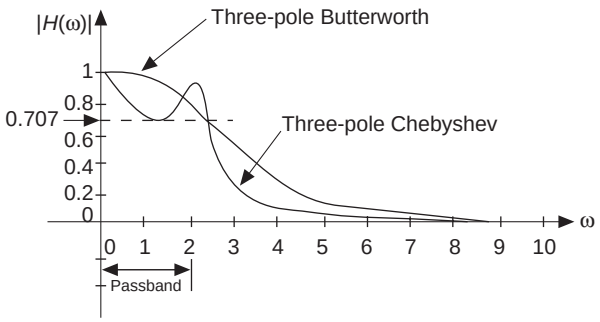


FIGURE 10.8 Magnitude curves of three-pole Butterworth and three-pole Chebyshev filters with 3-dB bandwidth equal to 2.5 rad/s.

Defining Terms

Causal filter: A filter of which the transition from the passband to the stopband is gradual, not ideal. This filter is realizable.

3-dB bandwidth: For a causal low-pass or bandpass filter with a frequency function $H(j\omega)$: the frequency at which $|H(\omega)|_{\text{dB}}$ is less than 3 dB down from the peak value $|H(\omega_p)|_{\text{dB}}$.

Ideal filter: An ideal filter is a system that completely rejects sinusoidal inputs of the form $x(t) = A \cos \omega t$, $-\infty < t < \infty$, for ω within a certain frequency range, and does not attenuate sinusoidal inputs whose frequencies are outside this range. There are four basic types of ideal filters:low-pass, high-pass, bandpass, and bandstop.

Passband: Range of frequencies ω for which the input is passed without attenuation.

Stopband: Range of frequencies ω for which the filter completely stops the input signal.

Transition region: The range of frequencies of a filter between a passband and a stopband.

Frequency Response

11.1 Introduction
11.2 Linear Frequency Response Plotting
11.3 Bode Diagrams
11.4 A Comparison of Methods

Paul Neudorfer
Seattle University

11.1 Introduction

The IEEE Standard Dictionary of Electrical and Electronics Terms defines **frequency response** in stable, linear systems to be "the frequency-dependent relation in both gain and phase difference between steady-state sinusoidal inputs and the resultant steady-state sinusoidal outputs" [IEEE, 1988]. In certain specialized applications, the term *frequency response* may be used with more restrictive meanings. However, all such uses can be related back to the fundamental definition. The frequency response characteristics of a system can be found directly from its transfer function. A single-input/single-output linear time-invariant system is shown in Fig. 11.1.

For dynamic linear systems with no time delay, the transfer function $H(s)$ is in the form of a ratio of polynomials in the complex frequency s,

$$H(s) = K\frac{N(s)}{D(s)}$$

where K is a frequency-independent constant. For a system in the sinusoidal steady state, s is replaced by the sinusoidal frequency $j\omega$ ($j = \sqrt{-1}$) and the system function becomes

$$H(j\omega) = K\frac{N(j\omega)}{D(j\omega)} = |H(j\omega)|e^{j\arg H(j\omega)}$$

$H(j\omega)$ is a complex quantity. Its magnitude, $|H(j\omega)|$, and its argument or phase angle, $\arg H(j\omega)$, relate, respectively, the amplitudes and phase angles of sinusoidal steady-state input and output signals. Using the terminology of Fig. 11.1, if the input and output signals are

$$x(t) = X\cos(\omega t + \Theta_x)$$

$$y(t) = Y\cos(\omega t + \Theta_y)$$

then the output's amplitude Y and phase angle Θ_y are related to those of the input by the two equations

$$Y = |H(j\omega)|X$$

$$\Theta_y = \arg H(j\omega) + \Theta_x$$

The phrase *frequency response characteristics* usually implies a complete description of a system's sinusoidal steady-state behavior as a function of frequency. Because $H(j\omega)$ is complex and, therefore, two dimensional in nature, frequency response characteristics cannot be graphically displayed as a single curve plotted with respect to frequency. Instead, the magnitude and argument of $H(j\omega)$ can be separately plotted as functions of frequency. Often, only the magnitude curve is presented as a concise way of characterizing the system's behavior, but this must be viewed as an incomplete description. The most common form for such plots is the **Bode diagram** (developed by H.W. Bode of Bell Laboratories), which uses a logarithmic scale for frequency. Other forms of frequency response plots have also been developed. In the **Nyquist plot** (Harry Nyquist, also of Bell Labs), $H(j\omega)$ is displayed on the complex plane, $\mathrm{Re}[H(j\omega)]$ on the horizontal axis, and $\mathrm{Im}[H(j\omega)]$ on the vertical. Frequency is a parameter of such curves. It is sometimes numerically identified at selected points of the curve and sometimes omitted. The **Nichols chart** (N.B. Nichols) graphs magnitude versus phase for the system function. Frequency again is a parameter of the resultant curve, sometimes shown and sometimes not.

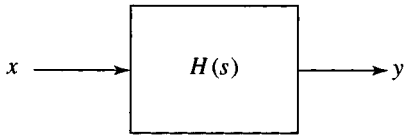

FIGURE 11.1 A single-input/single-output linear system.

Frequency response techniques are used in many areas of engineering. They are most obviously applicable to such topics as communications and filters, where the frequency response behaviors of systems are central to an understanding of their operations. It is, however, in the area of control systems where frequency response techniques are most fully developed as analytical and design tools. The Nichols chart, for instance, is used exclusively in the analysis and design of feedback control systems.

The remaining sections of this chapter describe several frequency response plotting methods. Applications of the methods can be found in other chapters throughout the *Handbook*.

11.2 Linear Frequency Response Plotting

Linear frequency response plots are prepared most directly by computing the magnitude and phase of $H(j\omega)$ and graphing each as a function of frequency (either f or ω), the frequency axis being scaled linearly. As an example, consider the transfer function

$$H(s) = \frac{160{,}000}{s^2 + 220s + 160{,}000}$$

Formally, the complex frequency variable s is replaced by the sinusoidal frequency $j\omega$ and the magnitude and phase found.

$$H(j\omega) = \frac{160{,}000}{(j\omega)^2 + 220(j\omega) + 160{,}000}$$

$$|H(j\omega)| = \frac{160{,}000}{\sqrt{(160{,}000 - \omega^2)^2 + (220\omega)^2}}$$

$$\arg H(j\omega) = -\tan^{-1}\frac{220\omega}{160{,}000 - \omega^2}$$

The plots of magnitude and phase are shown in Fig. 11.2.

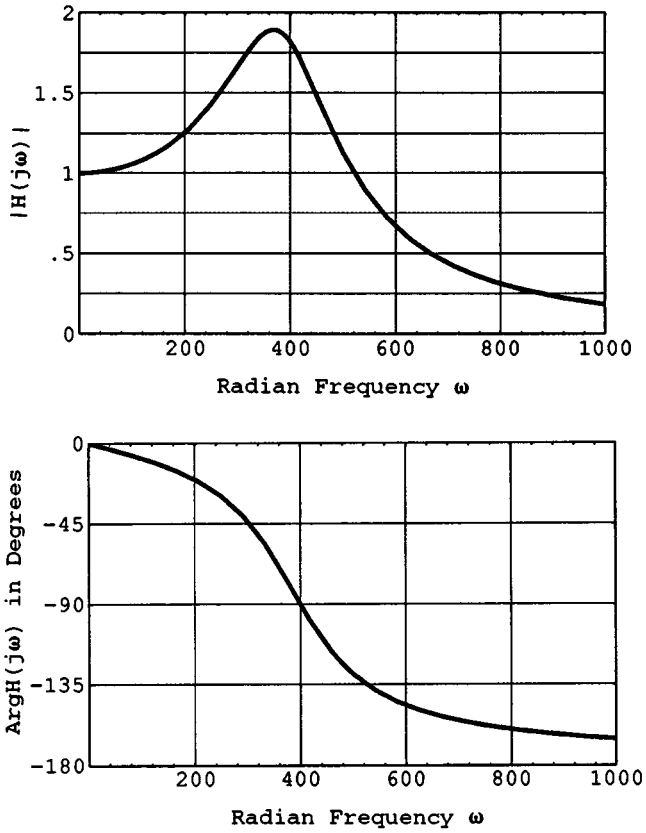

Figure 11.2 Linear frequency response curves of $H(j\omega)$.

11.3 Bode Diagrams

A Bode diagram consists of plots of the gain and phase of a transfer function, each with respect to logarithmically scaled frequency axes. In addition, the gain of the transfer function is scaled in **decibels** according to the definition

$$|H|_{\text{dB}} = H_{\text{dB}} = 20 \log_{10} |H(j\omega)|$$

This definition relates to transfer functions which are ratios of voltages and/or currents. The decibel gain between two *powers* has a multiplying factor of 10 rather than 20. This method of plotting frequency response information was popularized by H.W. Bode in the 1930s. There are two main advantages of the Bode approach. The first is that, with it, the gain and phase curves can be easily and accurately drawn. Second, once drawn, features of the curves can be identified both qualitatively and quantitatively with relative ease, even when those features occur over a wide dynamic range. Digital computers have rendered the first advantage obsolete. Ease of interpretation, however, remains a powerful advantage, and the Bode diagram is today the most common method chosen for the display of frequency response data.

A Bode diagram is drawn by applying a set of simple rules or procedures to a transfer function. The rules relate directly to the set of poles and zeros and/or time constants of the function. Before constructing a Bode diagram, the transfer function is normalized so that each pole or zero term (except those at $s = 0$) has a dc gain of one. For instance:

$$H(s) = K \frac{s + \omega_z}{s(s + \omega_p)} = \frac{K\omega_z}{\omega_p} \frac{s/\omega_z + 1}{s(s/\omega_p + 1)} = K' \frac{s\tau_z + 1}{s(s\tau_p + 1)}$$

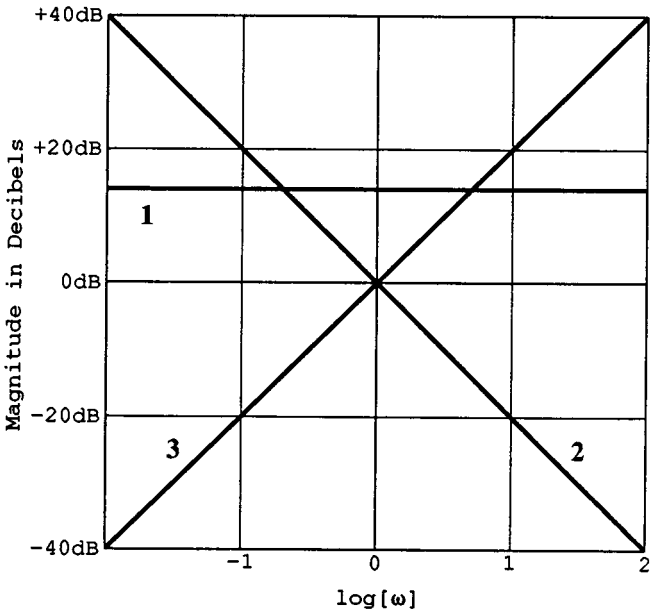

Figure 11.3 Bode magnitude functions for (1) $K = 5$, (2) $1/s$, and (3) s.

In the last form of the expression, $\tau_z = 1/\omega_z$ and $\tau_p = 1/\omega_p$. τ_p is a time constant of the system and $s = -\omega_p$ is the corresponding natural frequency. Because it is understood that Bode diagrams are limited to sinusoidal steady-state frequency response analysis, one can work directly from the transfer function $H(s)$ rather than resorting to the formalism of making the substitution $s = j\omega$.

Bode frequency response curves (gain and phase) for $H(s)$ are generated from the individual contributions of the four terms K', $s\tau_z + 1$, $1/s$, and $1/(s\tau_p + 1)$. As described in the following paragraph, the frequency response effects of these individual terms are easily drawn. To obtain the overall frequency response curves for the transfer function, the curves for the individual terms are added together.

The terms used as the basis for drawing Bode diagrams are found from factoring $N(s)$ and $D(s)$, the numerator and denominator polynomials of the transfer function. The factorization results in four standard forms. These are (1) a constant K; (2) a simple s term corresponding to either a zero (if in the numerator) or a pole (if in the denominator) at the origin; (3) a term such as $(s\tau + 1)$ corresponding to a real valued (nonzero) pole or zero; and (4) a quadratic term with a possible standard form of $[(s/\omega_n)^2 + (2\zeta/\omega_n)s + 1]$ corresponding to a pair of complex conjugate poles or zeros. The Bode magnitude and phase curves for these possibilities are displayed in Figs. 11.3–11.5. Note that both decibel magnitude and phase are plotted semilogarithmically. The frequency axis is logarithmically scaled so that every tenfold, or **decade**, change in frequency occurs over an equal distance. The magnitude axis is given in decibels. Customarily, this axis is marked in 20-dB increments. Positive decibel magnitudes correspond to amplifications between input and output that are greater than one (output amplitude larger than input). Negative decibel gains correspond to attenuation between input and output.

Figure 11.3 shows three separate magnitude functions. Curve 1 is trivial; the Bode magnitude of a constant K is simply the decibel-scaled constant $20 \log_{10} K$, shown for an arbitrary value of $K = 5$ ($20 \log_{10} 5 = 13.98$). Phase is not shown. However, a constant of $K > 0$ has a phase contribution of 0° for all frequencies. For $K < 0$, the contribution would be ±180° (Recall that $-\cos\theta = \cos(\theta \pm 180°)$. Curve 2 shows the magnitude frequency response curve for a pole at the origin ($1/s$). It is a straight line with a slope of –20 dB/decade. The line passes through 0 dB at $\omega = 0$ rad/s. The phase contribution of a simple pole at the origin is a constant –90°, independent of frequency. The effect of a zero at the origin (s) is shown in Curve 3. It is again a straight line that passes through 0 dB at $\omega = 0$ rad/s; however, the slope is +20 dB/decade. The phase contribution of a simple zero at $s = 0$ is +90°, independent of frequency.

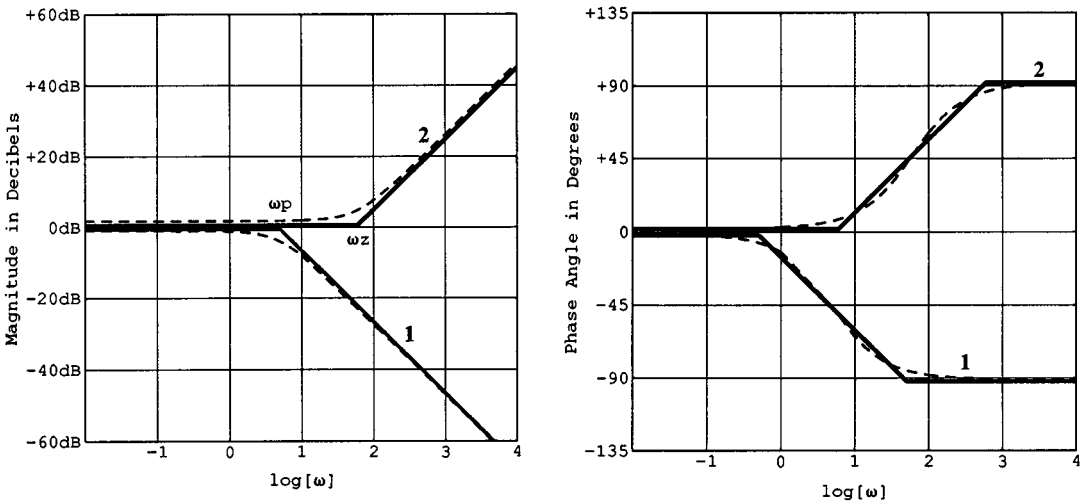

Figure 11.4 Bode curves for (1) a simple pole at $s = -\omega_p$ and (2) a simple zero at $s = -\omega_z$.

Note from Fig. 11.3 and the foregoing discussion that in Bode diagrams the effect of a pole term at a given location is simply the negative of that of a zero term at the same location. This is true for both magnitude and phase curves.

Figure 11.4 shows the magnitude and phase curves for a zero term of the form $(s/\omega_z + 1)$ and a pole term of the form $1/(s/\omega_p + 1)$. Exact plots of the magnitude and phase curves are shown as dashed lines. *Straight line approximations* to these curves are shown as solid lines. Note that the straight line approximations are so good that they obscure the exact curves at most frequencies. For this reason, some of the curves in this and later figures have been displaced slightly to enhance clarity. The greatest error between the exact and approximate magnitude curves is ±3 dB. The approximation for phase is always within 7° of the exact curve and usually much closer. The approximations for magnitude consist of two straight lines. The points of intersection between these two lines ($\omega = \omega_z$ for the zero term and $\omega = \omega_p$ for the pole) are **breakpoints** of the curves. Breakpoints of Bode gain curves always correspond to locations of poles or zeros in the transfer function.

In Bode analysis complex conjugate poles or zeros are always treated as pairs in the corresponding quadratic form $[(s/\omega_n)^2 + (2\zeta/\omega_n)s + 1]$.[1] For quadratic terms in stable, minimum phase systems, the **damping ratio** ζ (Greek letter zeta) is within the range $0 < \zeta < 1$. Quadratic terms cannot always be adequately represented by straight line approximations. This is especially true for lightly damped systems (small ζ). The traditional approach was to draw a preliminary representation of the contribution. This consists of a straight line of 0 dB from dc up to the breakpoint at ω_n followed by a straight line of slope ±40 dB/decade beyond the breakpoint, depending on whether the plot refers to a pair of poles or a pair of zeros. Then, referring to a family of curves as shown in Fig. 11.5, the preliminary representation was improved based on the value of ζ. The phase contribution of the quadratic term was similarly constructed. Note that Fig. 11.5 presents frequency response contributions for a quadratic pair of poles. For zeros in the corresponding locations, both the magnitude and phase curves would be negated. Digital computer applications programs render this procedure unnecessary for purposes of constructing frequency response curves. Knowledge of the technique is still valuable, however, in the qualitative and quantitative interpretation of frequency response curves. Localized peaking in the gain curve is a reflection of the existence of **resonance** in a system. The height of such a peak (and the corresponding value of ζ) is a direct indication of the degree of resonance.

Bode diagrams are easily constructed because, with the exception of lightly damped quadratic terms, each contribution can be reasonably approximated with straight lines. Also, the overall frequency response curve is found by adding the individual contributions. Two examples follow.

[1]Several such standard forms are used. This is the one most commonly encountered in controls applications.

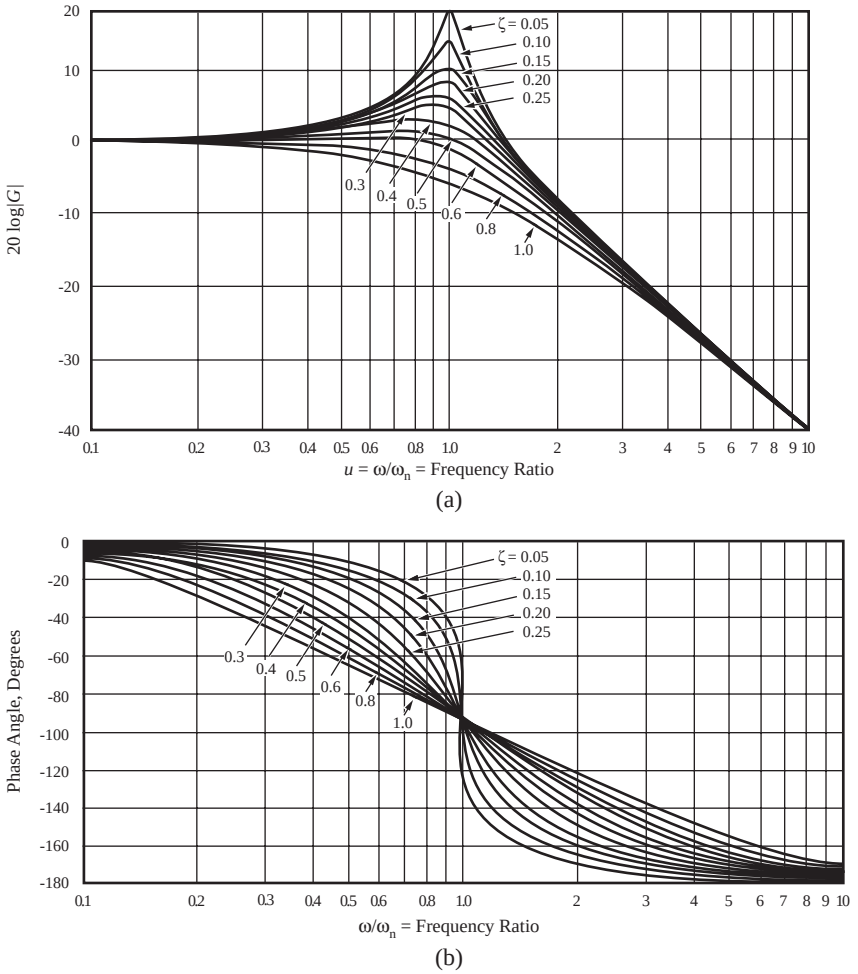

Figure 11.5 Bode diagram of $1/[(s/\omega_n)^2 + (2\zeta/\omega_n)s + 1]$.

Example 1

$$A(s) = \frac{10^4 s}{s^2 + 1100s + 10^5} = \frac{10^4 s}{(s + 100)(s + 1000)} = 10^{-1}\,\frac{s}{(s/100 + 1)(s/1000 + 1)}$$

In Fig. 11.6, the individual contributions of the four factored terms of $A(s)$ are shown as long dashed lines. The straight line approximations for gain and phase are shown with solid lines. The exact curves are presented with short dashed lines.

Example 2

$$G(s) = \frac{1000(s + 500)}{s^2 + 70s + 10{,}000} = \frac{50(s/500 + 1)}{(s/100)^2 + 2(0.35)(s/100) + 1}$$

Note that the damping factor for the quadratic term in the denominator is $\zeta = 0.35$. If drawing the response curves by hand, the resonance peak near the breakpoint at $\omega = 100$ would be estimated from Fig. 11.5. Figure 11.7 shows the exact gain and phase frequency response curves for $G(s)$.

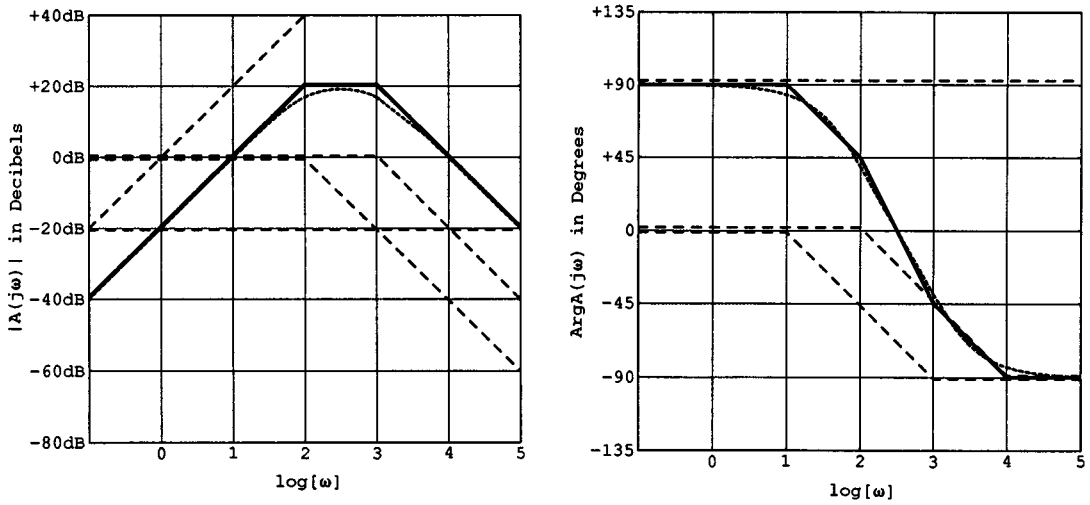

Figure 11.6 Bode diagram of $A(s)$.

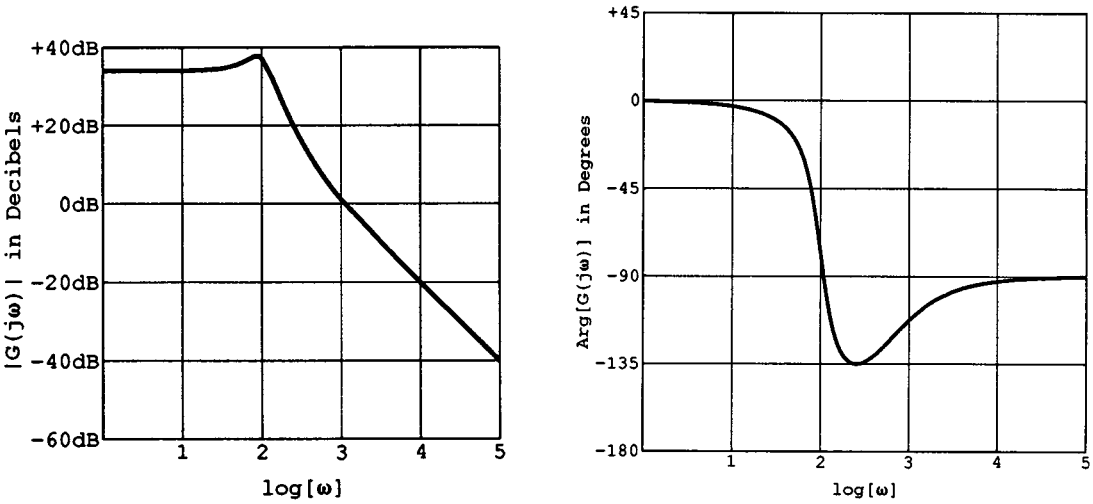

Figure 11.7 Bode diagram of $G(s)$.

11.4 A Comparison of Methods

This chapter concludes with the frequency response of a simple system function plotted in three different ways.

Example 3

$$T(s) = \frac{10^7}{(s + 100)(s + 200)(s + 300)}$$

Figure 11.8 shows the direct, linear frequency response curves for $T(s)$. Corresponding Bode and Nyquist diagrams are shown, respectively, in Figs. 11.9 and 11.10.

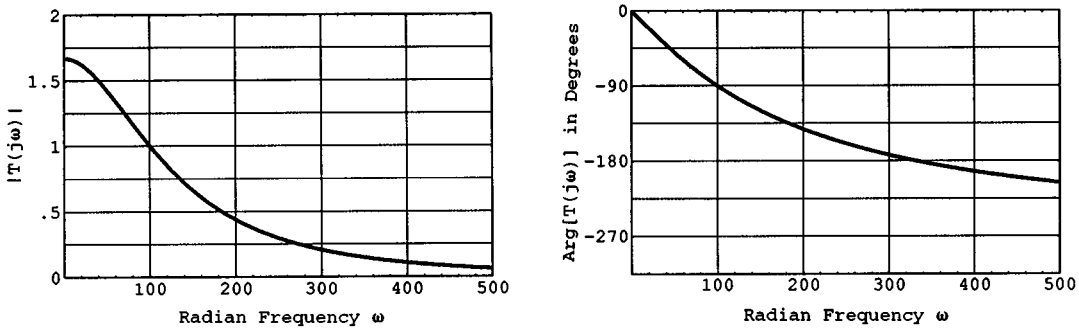

Figure 11.8 Linear frequency response plot of $T(s)$.

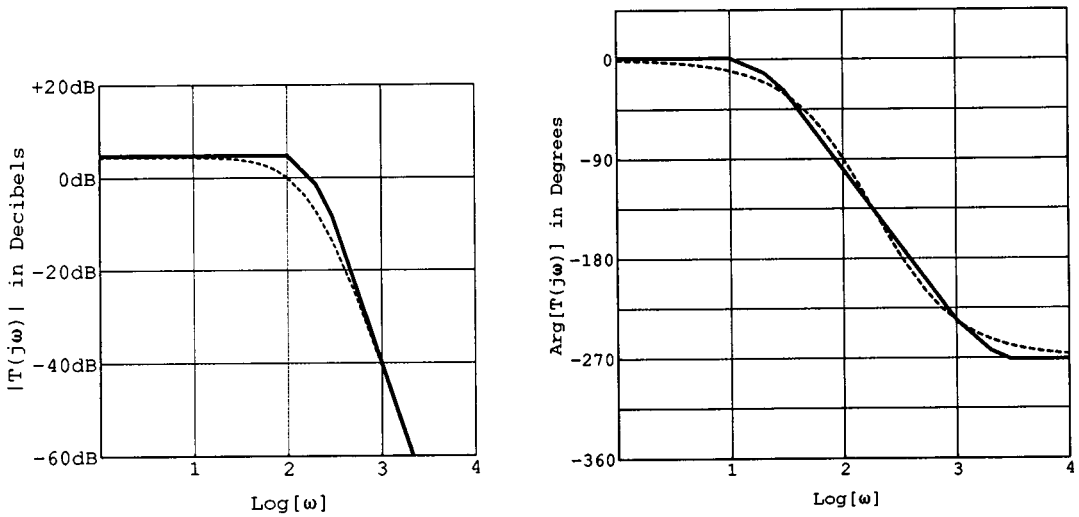

Figure 11.9 Bode diagram of $T(s)$.

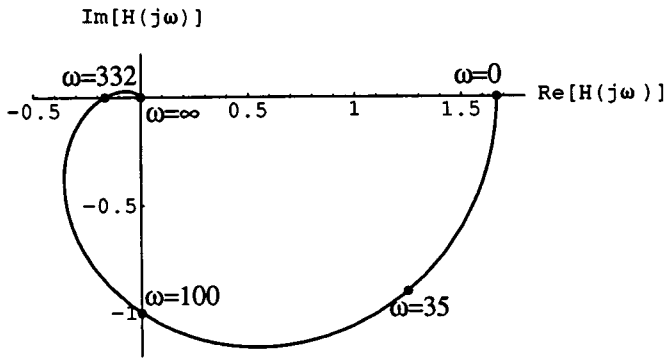

Figure 11.10 Nyquist plot of $T(s)$.

Defining Terms

Bode diagram: A frequency response plot of 20 log gain and phase angle on a log-frequency base.

Breakpoint: A point of abrupt change in slope in the straight line approximation of a Bode magnitude curve.

Damping ratio: The ratio between a system's damping factor (measure of rate of decay of response) and the damping factor when the system is critically damped.

Decade: Synonymous with power of ten. In context, a tenfold change in frequency.

Decibel: A measure of relative size. The decibel gain between voltages V_1 and V_2 is $20 \log_{10}(V_1/V_2)$. The decibel ratio of two powers is $10 \log_{10}(P_1/P_2)$.

Frequency response: The frequency-dependent relation in both gain and phase difference between steady-state sinusoidal inputs and the resultant steady-state sinusoidal outputs.

Nichols chart: Control systems — a plot showing magnitude contours and phase contours of the return transfer function referred to as ordinates of logarithmic loop gain and abscissae of loop phase angle.

Nyquist plot: A parametric frequency response plot with the real part of the transfer function on the abscissa and the imaginary part of the transfer function on the ordinate.

Resonance: The enhancement of the response of a physical system to a steady-state sinusoidal input when the excitation frequency is near a natural frequency of the system.

12.1 Introduction

In this chapter, which is based on Szidarovszky and Bahill [1992], we first discuss stability in general and then present four techniques for assessing the stability of a system: (1) Lyapunov functions, (2) finding the eigenvalues for state-space notation, (3) finding the location in the complex frequency plane of the poles of the closed-loop transfer function, and (4) proving bounded outputs for all bounded inputs. Proving stability with Lyapunov functions is very general: it works for nonlinear and time-varying systems. It is also good for doing proofs. Proving the stability of a system with Lyapunov functions is difficult, however, and failure to find a Lyapunov function that proves a system is stable does not prove that the system is unstable. The next techniques we present, finding the eigenvalues or the poles of the transfer function, are sometimes difficult, because they require factoring high-degree polynomials. Many commercial software packages are now available for this task, however. We think most engineers would benefit by having one of these computer programs. Jamshidi et al. [1992] and advertisements in technical publications such as the *IEEE Control Systems Magazine* and *IEEE Spectrum* describe many appropriate software packages. The last technique we present, bounded-input, bounded-output stability, is also quite general.

Let us begin our discussion of **stability** and **instability** of systems informally. In an *unstable system* the state can have large variations, and small inputs or small changes in the initial state may produce large variations in the output. A common example of an unstable system is illustrated by someone pointing the microphone of a public address (PA) system at a speaker; a loud high-pitched tone results. Often instabilities are caused by too much gain, so to quiet the PA system, decrease the gain by pointing the microphone away from the speaker. Discrete systems can also be unstable. A friend of ours once provided an example. She was sitting in a chair reading and she got cold. So she went over and turned up the thermostat on the heater. The house warmed up. She got hot, so she got up and turned down the thermostat. The house cooled off. She got cold and turned up the thermostat. This process continued until someone finally suggested that she put on a sweater (reducing the gain of her heat loss system). She did, and was much more comfortable. We modeled this as a discrete system, because she seemed to sample the environment and produce outputs at discrete intervals about 15 minutes apart.

12.2 Using the State of the System to Determine Stability

The stability of a system is defined with respect to a given equilibrium point in state space. If the initial state $\mathbf{x}_0$ is selected at an equilibrium state $\bar{\mathbf{x}}$ of the system, then the state will remain at $\bar{\mathbf{x}}$ for all future time. When the initial state is selected close to an equilibrium state, the system might remain close to the equilibrium state or it might move away. In this section we introduce conditions that guarantee that whenever the system starts near an equilibrium state, it remains near it, perhaps even converging to the equilibrium state as time increases. For simplicity, only time-invariant systems are considered in this section. Time-variant systems are discussed in Section 12.5.

Continuous, time-invariant systems have the form

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t)) \tag{12.1}$$

and discrete, time-invariant systems are modeled by the difference equation

$$\mathbf{x}(t+1) = \mathbf{f}(\mathbf{x}(t)) \tag{12.2}$$

Here we assume that $\mathbf{f}$: $X \to \mathbf{R}^n$, where $X \subseteq \mathbf{R}^n$ is the state space. We also assume that function $\mathbf{f}$ is continuous; furthermore, for arbitrary initial state $\mathbf{x}_0 \in X$, there is a unique solution of the corresponding initial value problem $\mathbf{x}(t_0) = \mathbf{x}_0$, and the entire trajectory $\mathbf{x}(t)$ is in X. Assume furthermore that t_0 denotes the initial time period of the system.

It is also known that a vector $\bar{\mathbf{x}} \in X$ is an equilibrium state of the continuous system, Eq. (12.1), if and only if $\mathbf{f}(\bar{\mathbf{x}}) = \mathbf{0}$, and it is an equilibrium state of the discrete system, Eq. (12.2), if and only if $\bar{\mathbf{x}} = \mathbf{f}(\bar{\mathbf{x}})$. In this chapter the equilibrium of a system will always mean the equilibrium *state*, if it is not specified otherwise. In analyzing the dependence of the state trajectory $\mathbf{x}(t)$ on the selection of the initial state $\mathbf{x}_0$ nearby the equilibrium, the following stability types are considered.

Definition 12.1

1. An equilibrium state $\bar{\mathbf{x}}$ is stable if there is an $\varepsilon_0 > 0$ with the following property: For all ε_1, $0 < \varepsilon_1 < \varepsilon_0$, there is an $\varepsilon > 0$ such that if $\| \bar{\mathbf{x}} - \mathbf{x}_0 \| < \varepsilon$, then $\| \bar{\mathbf{x}} - \mathbf{x}(t) \| < \varepsilon_1$, for all $t > t_0$.
2. An equilibrium state $\bar{\mathbf{x}}$ is **asymptotically stable** if it is stable and there is an $\varepsilon > 0$ such that whenever $\| \bar{\mathbf{x}} - \mathbf{x}_0 \| < \varepsilon$, then $\mathbf{x}(t) \to \bar{\mathbf{x}}$ as $t \to \infty$.
3. An equilibrium state $\bar{\mathbf{x}}$ is **globally asymptotically stable** if it is stable and with arbitrary initial state $\mathbf{x}_0 \in X$, $\mathbf{x}(t) \to \bar{\mathbf{x}}$ as $t \to \infty$.

The first definition says an equilibrium state $\bar{\mathbf{x}}$ is stable if the entire trajectory $\mathbf{x}(t)$ is closer to the equilibrium state than any small ε_1, if the initial state $\mathbf{x}_0$ is selected close enough to the equilibrium state. For asymptotic stability, in addition, $\mathbf{x}(t)$ has to converge to the equilibrium state as $t \to \infty$. If an equilibrium state is globally asymptotically stable, then $\mathbf{x}(t)$ converges to the equilibrium state regardless of how the initial state $\mathbf{x}_0$ is selected.

These stability concepts are called **internal**, because they represent properties of the state of the system. They are illustrated in Fig. 12.1.

In the electrical engineering literature, sometimes our stability definition is called marginal stability, and our asymptotic stability is called stability.

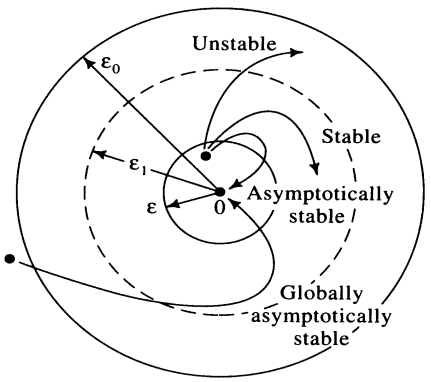

FIGURE 12.1 Stability concepts. (*Source:* F. Szidarovszky and A.T. Bahill, *Linear Systems Theory*, Boca Raton, Fla.: CRC Press, 1992, p. 168. With permission.)

12.3 Lyapunov Stability Theory

Assume that $\bar{\mathbf{x}}$ is an equilibrium state of a continuous or discrete system, and let Ω denote a subset of the state space X such that $\bar{\mathbf{x}} \in \Omega$.

Definition 12.2

A real-valued function V defined on Ω is called a Lyapunov function, if

1. V is continuous;
2. V has a unique global minimum at $\bar{\mathbf{x}}$ with respect to all other points in Ω;
3. for any state trajectory $\mathbf{x}(t)$ contained in Ω, $V(\mathbf{x}(t))$ is nonincreasing in t.

The Lyapunov function can be interpreted as the generalization of the energy function in electrical systems. The first requirement simply means that the graph of V has no discontinuities. The second requirement means that the graph of V has its lowest point at the equilibrium, and the third requirement generalizes the well-known fact of electrical systems, that the energy in a free electrical system with resistance always decreases, unless the system is at rest.

Theorem 12.1

Assume that there exists a Lyapunov function V on the spherical region

$$\Omega = \{\mathbf{x} \mid \| \mathbf{x} - \bar{\mathbf{x}} \| < \varepsilon_0\} \tag{12.3}$$

where $\varepsilon_0 > 0$ is given; furthermore $\Omega \subseteq X$. Then the equilibrium state is stable.

Theorem 12.2

Assume that in addition to the conditions of Theorem 12.1, the Lyapunov function $V(\mathbf{x}(t))$ is strictly decreasing in t, unless $\mathbf{x}(t) = \bar{\mathbf{x}}$. Then the equilibrium state is asymptotically stable.

Theorem 12.3

Assume that the Lyapunov function is defined on the entire state space X, $V(\mathbf{x}(t))$ is strictly decreasing in t unless $\mathbf{x}(t) = \bar{\mathbf{x}}$; furthermore, $V(\mathbf{x})$ tends to infinity as any component of $\mathbf{x}$ gets arbitrarily large in magnitude. Then the equilibrium state is globally asymptotically stable.

Example 12.1

Consider the differential equation

$$\dot{\mathbf{x}} = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix} \mathbf{x} + \begin{pmatrix} 0 \\ 1 \end{pmatrix}$$

The stability of the equilibrium state $(1/\omega, 0)^T$ can be verified directly by using Theorem 12.1 without computing the solution. Select the Lyapunov function

$$V(\mathbf{x}) = (\mathbf{x} - \bar{\mathbf{x}})^T (\mathbf{x} - \bar{\mathbf{x}}) = \| \mathbf{x} - \bar{\mathbf{x}} \|_2^2$$

where the Euclidian norm is used.

This is continuous in $\mathbf{x}$; furthermore, it has its minimal (zero) value at $\mathbf{x} = \bar{\mathbf{x}}$. Therefore, to establish the stability of the equilibrium state we have to show only that $V(\mathbf{x}(t))$ is decreasing. Simple differentiation shows that

$$\frac{d}{dt} V(\mathbf{x}(t)) = 2(\mathbf{x} - \bar{\mathbf{x}})^T \cdot \dot{\mathbf{x}} = 2(\mathbf{x} - \bar{\mathbf{x}})^T (\mathbf{A}\mathbf{x} + \mathbf{b})$$

with

$$\mathbf{A} = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix} \quad \text{and} \quad \mathbf{b} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$$

That is, with $\mathbf{x} = (x_1, x_2)^T$,

$$\begin{aligned} \frac{d}{dt} V(\mathbf{x}(t)) &= 2\left(x_1 - \frac{1}{\omega}, \quad x_2 \right)\begin{pmatrix} \omega x_2 \\ -\omega x_1 + 1 \end{pmatrix} \\ &= 2(\omega x_1 x_2 - x_2 - \omega x_1 x_2 + x_2) = 0 \end{aligned}$$

Therefore, function $V(\mathbf{x}(t))$ is a constant, which is a (not strictly) decreasing function. That is, all conditions of Theorem 12.1 are satisfied, which implies the stability of the equilibrium state.

Theorems 12.1, 12.2, and 12.3 guarantee, respectively, the stability, asymptotic stability, and global asymptotic stability of the equilibrium state, if a Lyapunov function is found. Failure to find such a Lyapunov function does not mean that the system is unstable or that the stability is not asymptotic or globally asymptotic. It only means that you were not clever enough to find a Lyapunov function that proved stability.

12.4 Stability of Time-Invariant Linear Systems

This section is divided into two subsections. In the first subsection the stability of linear time-invariant systems given in state-space notation is analyzed. In the second subsection, methods based on transfer functions are discussed.

Stability Analysis with State-Space Notation

Consider the time-invariant continuous linear system

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{b} \tag{12.4}$$

and the time-invariant discrete linear system

$$\mathbf{x}(t+1) = \mathbf{A}\mathbf{x}(t) + \mathbf{b} \tag{12.5}$$

Assume that $\bar{\mathbf{x}}$ is an equilibrium state, and let $\phi(t,t_0)$ denote the fundamental matrix.

Theorem 12.4

1. The equilibrium state $\bar{\mathbf{x}}$ is stable if and only if $\phi(t,t_0)$ is bounded for $t \geq t_0$.
2. The equilibrium state $\bar{\mathbf{x}}$ is asymptotically stable if and only if $\phi(t,t_0)$ is bounded and tends to zero as $t \to \infty$.

We use the symbol s to denote complex frequency, i.e., $s = \sigma + j\omega$. For specific values of s, such as eigenvalues and poles, we use the symbol λ.

Theorem 12.5

1. If for at least one eigenvalue of A, Re $\lambda_i > 0$ (or $|\lambda_i| > 1$ for discrete systems), then the system is unstable.
2. Assume that for all eigenvalues λ_i of $\mathbf{A}$, Re $\lambda_i \leq 0$ in the continuous case (or $|\lambda_i| \leq 1$ in the discrete case), and all eigenvalues with the property Re $\lambda_i = 0$ (or $|\lambda_i| = 1$) have single multiplicity; then the equilibrium state is stable.
3. The stability is asymptotic if and only if for all i, Re $\lambda_i < 0$ (or $|\lambda_i| < 1$).

Remark 1. Note that Part 2 gives only sufficient conditions for the stability of the equilibrium state. As the following example shows, these conditions are not necessary.

Example 12.2

Consider first the continuous system $\dot{\mathbf{x}} = \mathbf{O}\mathbf{x}$, where $\mathbf{O}$ is the zero matrix. Note that all constant functions $\mathbf{x}(t) \equiv \bar{\mathbf{x}}$ are solutions and also equilibrium states. Since

$$\phi(t, t_0) = e^{\mathbf{O}(t-t_0)} = \mathbf{I}$$

is bounded (being independent of t), all equilibrium states are stable, but $\mathbf{O}$ has only one eigenvalue $\lambda_1 = 0$ with zero real part and multiplicity n, where n is the order of the system.

Consider next the discrete systems $\mathbf{x}(t+1) = \mathbf{I}\mathbf{x}(t)$, when all constant functions $\mathbf{x}(t) \equiv \bar{\mathbf{x}}$ are also solutions and equilibrium states. Furthermore,

$$\phi(t, t_0) = \mathbf{A}^{t-t_0} = \mathbf{I}^{t-t_0} = \mathbf{I}$$

which is obviously bounded. Therefore, all equilibrium states are stable, but the condition of Part 2 of the theorem is violated again, since $\lambda_1 = 1$ with unit absolute value having a multiplicity n.

Remark 2. The following extension of Theorem 12.5 can be proven. The equilibrium state is stable if and only if for all eigenvalues of $\mathbf{A}$, $\text{Re}\,\lambda_i \le 0$ (or $|\lambda_i| \le 1$), and if λ_i is a repeated eigenvalue of A such that $\text{Re}\,\lambda_i = 0$ (or $|\lambda_i| = 1$), then the size of each block containing λ_i in the Jordan canonical form of A is 1×1.

Remark 3. The equilibrium states of inhomogeneous equations are stable or asymptotically stable if and only if the same holds for the equilibrium states of the corresponding homogeneous equations.

Example 12.3

Consider again the continuous system

$$\dot{\mathbf{x}} = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix} \mathbf{x} + \begin{pmatrix} 0 \\ 1 \end{pmatrix}$$

the stability of which was analyzed earlier in Example 12.1 by using the Lyapunov function method. The characteristic polynomial of the coefficient matrix is

$$\varphi(s) = \det \begin{pmatrix} -s & \omega \\ -\omega & -s \end{pmatrix} = s^2 + \omega^2$$

therefore, the eigenvalues are $\lambda_1 = j\omega$ and $\lambda_2 = -j\omega$. Both eigenvalues have single multiplicities, and $\text{Re}\,\lambda_1 = \text{Re}\,\lambda_2 = 0$. Hence, the conditions of Part 2 are satisfied, and therefore the equilibrium state is stable. The conditions of Part 3 do not hold. Consequently, the system is not asymptotically stable.

If a time-invariant system is nonlinear, then the Lyapunov method is the most popular choice for stability analysis. If the system is linear, then the direct application of Theorem 12.5 is more attractive, since the eigenvalues of the coefficient matrix $\mathbf{A}$ can be obtained by standard methods. In addition, several conditions are known from the literature that guarantee the asymptotic stability of time-invariant discrete and continuous systems even without computing the eigenvalues. For examining asymptotic stability, linearization is an alternative approach to the Lyapunov method as is shown here. Consider the time-invariant continuous and discrete systems

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t))$$

and

$$\mathbf{x}(t+1) = \mathbf{f}(\mathbf{x}(t))$$

Let $\mathbf{J}(\mathbf{x})$ denote the Jacobian of $\mathbf{f}(\mathbf{x})$, and let $\bar{\mathbf{x}}$ be an equilibrium state of the system. It is known that the method of linearization around the equilibrium state results in the time-invariant linear systems

$$\dot{\mathbf{x}}_\delta(t) = \mathbf{J}(\bar{\mathbf{x}})\mathbf{x}_\delta(t)$$

and

$$\mathbf{x}_\delta(t+1) = \mathbf{J}(\bar{\mathbf{x}})\mathbf{x}_\delta(t)$$

where $\mathbf{x}_\delta(t) = \mathbf{x}(t) - \bar{\mathbf{x}}$. It is also known from the theory of ordinary differential equations that the asymptotic stability of the zero vector in the linearized system implies the asymptotic stability of the equilibrium state $\bar{\mathbf{x}}$ in the original nonlinear system.

For continuous systems the following result has a special importance.

Theorem 12.6

The equilibrium state of a continuous system [Eq. (12.4)] is asymptotically stable if and only if equation

$$\mathbf{A}^T\mathbf{Q} + \mathbf{QA} = -\mathbf{M} \tag{12.6}$$

has positive definite solution $\mathbf{Q}$ with some positive definite matrix $\mathbf{M}$.

We note that in practical applications the identity matrix is almost always selected for $\mathbf{M}$. An initial stability check is provided by the following result.

Theorem 12.7

Let $\varphi(\lambda)=\lambda^n + p_{n-1}\lambda^{n-1} + \ldots + p_1\lambda + p_0$ be the characteristic polynomial of matrix $\mathbf{A}$. Assume that all eigenvalues of matrix $\mathbf{A}$ have negative real parts. Then $p_i > 0$ $(i = 0, 1,..., n-1)$.

Corollary. If any of the coefficients p_i is negative or zero, the equilibrium state of the system with coefficient matrix $\mathbf{A}$ cannot be asymptotically stable. However, the conditions of the theorem do not imply that the eigenvalues of $\mathbf{A}$ have negative real parts.

Example 12.4

For matrix

$$\mathbf{A} = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix}$$

the characteristic polynominal is $\varphi(s) = s^2 + \omega^2$. Since the coefficient of s^1 is zero, the system of Example 12.3 is not asymptotically stable.

The Transfer Function Approach

The transfer function of the time invariant linear continuous system

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{Ax} + \mathbf{Bu} \\ \mathbf{y} &= \mathbf{Cx} \end{aligned} \tag{12.7}$$

and that of the time invariant linear discrete system

$$\begin{aligned} \mathbf{x}(t+1) &= \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t) \\ \mathbf{y}(t) &= \mathbf{C}\mathbf{x}(t) \end{aligned} \tag{12.8}$$

have the common form

$$\mathbf{TF}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B}$$

If both the input and output are single, then

$$\mathbf{TF}(s) = \frac{\mathbf{Y}(s)}{\mathbf{U}(s)}$$

or in the familiar electrical engineering notation

$$\mathbf{TF}(s) = \frac{K\mathbf{G}(s)}{1 + K\mathbf{G}(s)\mathbf{H}(s)} \tag{12.9}$$

where K is the gain term in the forward loop, $\mathbf{G}(s)$ represents the dynamics of the forward loop, or the plant, and $\mathbf{H}(s)$ models the dynamics in the feedback loop. We note that in the case of continuous systems s is the variable of the transfer function, and for discrete systems the variable is denoted by z.

After the Second World War systems and control theory flourished. The transfer function representation was the most popular representation for systems. To determine the stability of a system we merely had to factor the denominator of the transfer function (12.9) and see if all of the poles were in the left half of the complex frequency plane. However, with manual techniques, factoring polynomials of large order is difficult. So engineers, being naturally lazy people, developed several ways to determine the stability of a system without factoring the polynomials [Dorf, 1992]. First, we have the methods of Routh and Hurwitz, developed a century ago, that looked at the coefficients of the characteristic polynomial. These methods showed whether the system was stable or not, but they did not show how close the system was to being stable.

What we want to know is for what value of gain, K, and at what frequency, ω, will the denominator of the transfer function (12.9) become zero. Or, when will $K\mathbf{GH} = -1$, meaning, when will the magnitude of $K\mathbf{GH}$ equal 1 with a phase angle of –180 degrees? These parameters can be determined easily with a Bode diagram. Construct a Bode diagram for $K\mathbf{GH}$ of the system, look at the frequency where the phase angle equals –180 degrees, and look up at the magnitude plot. If it is smaller than 1.0, then the system is stable. If it is larger than 1.0, then the system is unstable. Bode diagram techniques are discussed in Chapter 11.

The quantity $K\mathbf{G}(s)\mathbf{H}(s)$ is called the open-loop transfer function of the system, because it is the effect that would be encountered by a signal in one loop around the system if the feedback loop were artificially opened [Bahill, 1981].

To gain some intuition, think of a closed-loop negative feedback system. Apply a small sinusoid at frequency ω to the input. Assume that the gain around the loop, $K\mathbf{GH}$, is 1 or more, and that the phase lag is 180 degrees. The summing junction will flip over the fed back signal and add it to the original signal. The result is a signal that is bigger than what came in. This signal will circulate around this loop, getting bigger and bigger until the real system no longer matches the model. This is what we call instability.

The question of stability can also be answered with Nyquist diagrams. They are related to Bode diagrams, but they give more information. A simple way to construct a Nyquist diagram is to make a polar plot on the complex frequency plane of the Bode diagram. Simply stated, if this contour encircles the –1 point in the complex frequency plane, then the system is unstable. The two advantages of the Nyquist technique are (1) in

addition to the information on Bode diagrams, there are about a dozen rules that can be used to help construct Nyquist diagrams, and (2) Nyquist diagrams handle bizarre systems better, as is shown in the following rigorous statement of the Nyquist stability criterion. The number of clockwise encirclements minus the number of counterclockwise encirclements of the point $s = -1 + j0$ by the Nyquist plot of $K\mathbf{G}(s)\mathbf{H}(s)$ is equal to the number of poles of $\mathbf{Y}(s)/\mathbf{U}(s)$ minus the number of poles of $K\mathbf{G}(s)\mathbf{H}(s)$ in the right half of the s-plane.

The root-locus technique was another popular technique for assessing stability. It furthermore allowed the engineer to see the effects of small changes in the gain, K, on the stability of the system. The root-locus diagram shows the location in the s-plane of the poles of the closed-loop transfer function, $\mathbf{Y}(s)/\mathbf{U}(s)$. All branches of the root-locus diagram start on poles of the open-loop transfer function, $K\mathbf{GH}$, and end either on zeros of the open-loop transfer function, $K\mathbf{GH}$, or at infinity. There are about a dozen rules to help draw these trajectories. The root-locus technique is discussed in Chapter 93.4.

We consider all these techniques to be old fashioned. They were developed to help answer the question of stability without factoring the characteristic polynomial. However, many computer programs are currently available that factor polynomials. We recommend that engineers merely buy one of these computer packages and find the roots of the closed-loop transfer function to assess the stability of a system.

The poles of a system are defined as all values of s such that $s\mathbf{I} - \mathbf{A}$ is singular. The poles of a closed-loop transfer function are exactly the same as the eigenvalues of the system: engineers prefer the term *poles* and the symbol s, and mathematicians prefer the term *eigenvalues* and the symbol λ. We will use s for complex frequency and λ for specific values of s.

Sometimes, some poles could be canceled in the rational function form of $\mathbf{TF}(s)$ so that they would not be explicitly shown. However, even if some poles could be canceled by zeros, we still have to consider all poles in the following criteria which is the statement of Theorem 12.5. The equilibrium state of the continuous system [Eq. (12.7)] with constant input is unstable if at least one pole has a positive real part, and is stable if all poles of $\mathbf{TF}(s)$ have nonpositive real parts and all poles with zero real parts are single. The equilibrium state is asymptotically stable if and only if all poles of $\mathbf{TF}(s)$ have negative real parts; that is, all poles are in the left half of the s-plane. Similarly, the equilibrium state of the discrete system [Eq. (12.8)] with constant input is unstable if the absolute value of at least one pole is greater than one, and is stable if all poles of $\mathbf{TF}(z)$ have absolute values less than or equal to one and all poles with unit absolute values are single. The equilibrium state is asymptotically stable if and only if all poles of $\mathbf{TF}(z)$ have absolute values less than one; that is, the poles are all inside the unit circle of the z-plane.

Example 12.5

Consider again the system

$$\dot{\mathbf{x}} = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix} \mathbf{x} + \begin{pmatrix} 0 \\ 1 \end{pmatrix}$$

which was discussed earlier. Assume that the output equation has the form

$$y = (1, 1)\mathbf{x}$$

Then

$$\mathbf{TF}(s) = \frac{s + \omega}{s^2 + \omega^2}$$

The poles are $j\omega$ and $-j\omega$, which have zero real parts; that is, they are on the imaginary axis of the s-plane. Since they are single poles, the equilibrium state is stable but not asymptotically stable. A system such as this would produce constant amplitude sinusoids at frequency ω. So it seems natural to assume that such systems would be used to build sinusoidal signal generators and to model oscillating systems. However, this is not the case, because (1) zero resistance circuits are hard to make; therefore, most function generators use other

techniques to produce sinusoids; and (2) such systems are not good models for oscillating systems, because most real-world oscillating systems (i.e., biological systems) have energy dissipation elements in them.

More generally, real-world function generators are seldom made from closed-loop feedback control systems with 180 degrees of phase shift, because (1) it would be difficult to get a broad range of frequencies and several waveforms from such systems, (2) precise frequency selection would require expensive high-precision components, and (3) it would be difficult to maintain a constant frequency in such circuits in the face of changing temperatures and power supply variations. Likewise, closed-loop feedback control systems with 180 degrees of phase shift are not good models for oscillating biological systems, because most biological systems oscillate because of nonlinear network properties.

A special stability criterion for single-input, single-output time-invariant continuous systems will be introduced next. Consider the system

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{b}u \quad \text{and} \quad y = \mathbf{c}^{\mathrm{T}}\mathbf{x} \tag{12.10}$$

where $\mathbf{A}$ is an $n \times n$ constant matrix, and $\mathbf{b}$ and $\mathbf{c}$ are constant n-dimensional vectors. The transfer function of this system is

$$TF_1(s) = \mathbf{c}^{\mathrm{T}}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{b}$$

which is obviously a rational function of s. Now let us add negative feedback around this system so that $u = ky$, where k is a constant. The resulting system can be described by the differential equation

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + k\mathbf{b}\mathbf{c}^{\mathrm{T}}\mathbf{x} = (\mathbf{A} + k\mathbf{b}\mathbf{c}^{\mathrm{T}})\mathbf{x} \tag{12.11}$$

The transfer function of this feedback system is

$$\mathrm{TF}(s) = \frac{\mathrm{TF}_1(s)}{1 - k\mathrm{TF}_1(s)} \tag{12.12}$$

To help show the connection between the asymptotic stability of systems (12.10) and (12.11), we introduce the following definition.

Definition 12.3

Let $r(s)$ be a rational function of s. Then the locus of points

$$L(r) = \{a + jb \,|\, a = Re(r(jv)), \quad b = Im(r(jv)), \quad v \in \mathrm{R}\}$$

is called the *response diagram of r*. Note that $L(r)$ is the image of the imaginary line $\mathrm{Re}(s) = 0$ under the mapping r. We shall assume that $L(r)$ is bounded, which is the case if and only if the degree of the denominator is not less than that of the numerator and r has no poles on the line $\mathrm{Re}(s) = 0$.

Theorem 12.8

The Nyquist stability criterion. Assume that TF_1 has a bounded response diagram $L(TF_1)$. If TF_1 has ν poles in the right half of the s-plane, where $\mathrm{Re}(s) > 0$, then H has $\rho + \nu$ poles in the right half of the s-plane where $\mathrm{Re}(s) > 0$ if the point $1/k + j \cdot 0$ is not on $L(TF_1)$, and $L(TF_1)$ encircles $1/k + j \cdot 0$ ρ times in the clockwise sense.

Corollary. Assume that system (12.10) is asymptotically stable with constant input and that $L(TF_1)$ is bounded and traversed in the direction of increasing ν and has the point $1/k + j \cdot 0$ on its left. Then the feedback system (12.11) is also asymptotically stable.

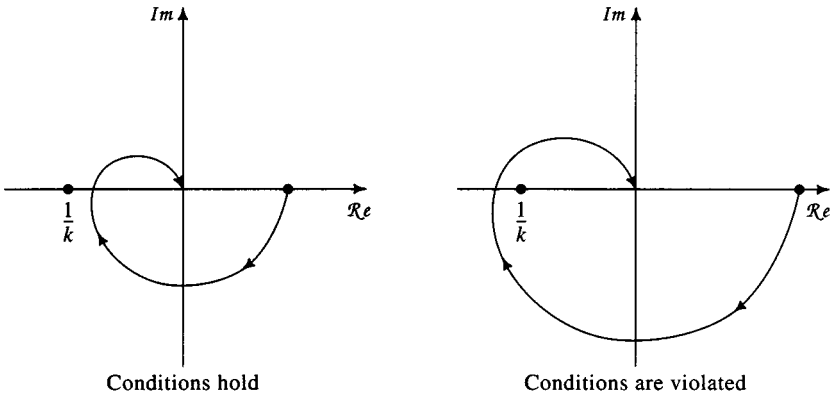

FIGURE 12.2 Illustration of Nyquist stability criteria. (*Source:* F. Szidarovszky and A. T. Bahill, *Linear Systems Theory*, Boca Raton, Fla.: CRC Press, 1992, p.184. With permission.)

This result has many applications, since feedback systems have a crucial role in constructing stabilizers, observers, and filters for given systems. Fig. 12.2 illustrates the conditions of the corollary. The application of this result is especially convenient, if system (12.10) is given and only appropriate values k of the feedback are to be determined. In such cases the locus $L(TF_1)$ has to be computed first, and then the region of all appropriate k values can be determined easily from the graph of $L(TF_1)$.

This analysis has dealt with the closed-loop transfer function, whereas the techniques of Bode, root-locus, etc. use the open-loop transfer function. This should cause little confusion as long as the distinction is kept in mind.

12.5 BIBO Stability

In the previous sections, internal stability of time-invariant systems was examined, i.e., the stability of the state was investigated. In this section the **external stability** of systems is discussed; this is usually called the **BIBO** (*b*ounded-*i*nput, *b*ounded-*o*utput) **stability**. Here we drop the simplifying assumption of the previous section that the system is time-invariant: we will examine time-variant systems.

Definition 12.4

A system is called BIBO stable if for zero initial conditions, a bounded input always evokes a bounded output.

For continuous systems a necessary and sufficient condition for BIBO stability can be formulated as follows.

Theorem 12.9

Let $\mathbf{T}(t,\tau) = (t_{ij}(t,\tau))$ be the weighting pattern, $\mathbf{C}(t)\phi(t,\tau)\mathbf{B}(\tau)$, of the system. Then the continuous time-variant linear system is BIBO stable if and only if the integral

$$\int_{t_0}^{t} \left| t_{ij}(t,\tau) \right| d\tau \tag{12.13}$$

is bounded for all $t > t_0$, i and j.

Corollary. Integrals (12.13) are all bounded if and only if

$$I(t) = \int_{t_0}^{t} \sum_i \sum_j \left| t_{ij}(t,\tau) \right| d\tau \tag{12.14}$$

is bounded for $t \geq t_0$. Therefore, it is sufficient to show the boundedness of only one integral in order to establish BIBO stability.
The discrete counterpart of this theorem can be given in the following way.

Theorem 12.10

Let $\mathbf{T}(t,\tau) = (t_{ij}(t,\tau))$ be the weighting pattern of the discrete linear system. Then it is BIBO stable if and only if the sum

$$I(t) = \sum_{\tau=t_0}^{t-1} \left| t_{ij}(t,\tau) \right| \tag{12.15}$$

is bounded for all $t > t_0$, i and j.
Corollary. The sums (12.15) are all bounded if and only if

$$\sum_{\tau=t_0}^{t-1} \sum_{i} \sum_{j} \left| t_{ij}(t,\tau) \right| \tag{12.16}$$

is bounded. Therefore it is sufficient to verify the boundedness of only one sum in order to establish BIBO stability.

Consider next the time-invariant case, when $\mathbf{A}(t) \equiv \mathbf{A}$, $\mathbf{B}(t) \equiv \mathbf{B}$ and $\mathbf{C}(t) \equiv \mathbf{C}$. From the foregoing theorems and the definition of $\mathbf{T}(t,\tau)$ we have immediately the following sufficient condition.

Theorem 12.11

Assume that for all eigenvalues λ_i of $\mathbf{A}$, $\operatorname{Re}\lambda_i < 0$ (or $|\lambda_i| < 1$). Then the time-invariant linear continuous (or discrete) system is BIBO stable.

Finally, we note that BIBO stability is not implied by an observation that a certain bounded input generates bounded output. All bounded inputs must generate bounded outputs in order to guarantee BIBO stability.

Adaptive-control systems are time-varying systems. Therefore, it is usually difficult to prove that they are stable. Szidarovszky et al. [1990], however, show a technique for doing this. This new result gives a necessary and sufficient condition for the existence of an asymptotically stable model-following adaptive-control system based on the solvability of a system of nonlinear algebraic equations, and in the case of the existence of such systems they present an algorithm for finding the appropriate feedback parameters.

12.6 Physical Examples

In this section we show some examples of stability analysis of physical systems.

1. Consider a simple *harmonic oscillator* constructed of a mass and an ideal spring. Its dynamic response is summarized with

$$\dot{\mathbf{x}} = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix} \mathbf{x} + \begin{pmatrix} 0 \\ 1 \end{pmatrix} u$$

In Example 12.3 we showed that this system is stable but not asymptotically stable. This means that if we leave it alone in its equilibrium state, it will remain stationary, but if we jerk on the mass it will oscillate forever. There is no damping term to remove the energy, so the energy will be transferred back and forth between potential energy in the spring and kinetic energy in the moving mass. A good approximation of such a harmonic oscillator is a pendulum clock. The more expensive it is (i.e., the smaller the damping), the less often we have to wind it (i.e., add energy).

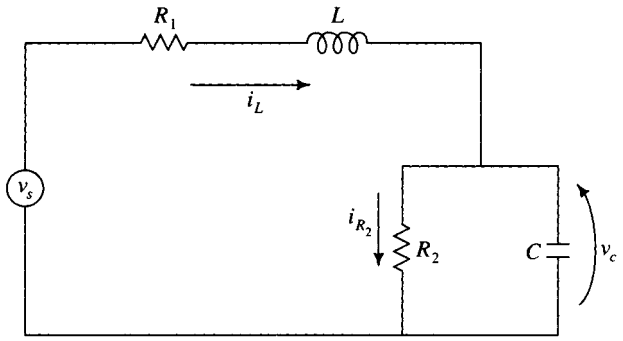

FIGURE 12.3 A simple electrical system. (*Source:* F. Szidarovszky and A. T. Bahill, *Linear Systems Theory*, Boca Raton, Fla.: CRC Press, 1992, p. 125. With permission.)

2. A *linear second-order electrical system* composed of a series connection of an input voltage source, an inductor, a resistor, and a capacitor, with the output defined as the voltage across the capacitor, can be characterized by the second-order equation

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{1}{LCs^2 + RCs + 1}$$

For convenience, let us define

$$\omega_n = \sqrt{\frac{1}{LC}} \quad \text{and} \quad \zeta = \frac{R}{2}\sqrt{\frac{C}{L}}$$

and assume that $\zeta < 1$. With these parameters the transfer function becomes

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n + \omega_n^2}$$

Is this system stable? The roots of the characteristic equation are

$$\lambda_{1,2} = -\zeta\omega_n \pm j\omega_n\sqrt{1-\zeta^2}$$

If $\zeta > 0$, the poles are in the left half of the s-plane, and therefore the system is asymptotically stable. If $\zeta = 0$, as in the previous example, the poles are on the imaginary axis; therefore, the system is stable but not asymptotically stable. If $\zeta < 0$, the poles are in the right half of the s-plane and the system is unstable.

3. An *electrical system* is shown in Fig. 12.3. Simple calculation shows that by defining the state variables

$$x_1 = i_L, \quad x_2 = v_c, \quad \text{and} \quad u = v_s$$

the system can be described by the differential equations

$$\dot{x}_1 = -\frac{R_1}{L}x_1 - \frac{1}{L}x_2 + \frac{1}{L}u$$

$$\dot{x}_2 = \frac{1}{C}x_1 - \frac{1}{CR_2}x_2$$

The characteristic equation has the form

$$\left(-s - \frac{R_1}{L}\right)\left(-s - \frac{1}{CR_2}\right) + \frac{1}{LC} = 0$$

which simplifies as

$$s^2 + s\left(\frac{R_1}{L} + \frac{1}{CR_2}\right) + \left(\frac{R_1}{LCR_2} + \frac{1}{LC}\right) = 0$$

Since R_1, R_2, L, and C are positive numbers, the coefficients of this equation are all positive. The constant term equals $\lambda_1\lambda_2$, and the coefficient of s^1 is $-(\lambda_1 + \lambda_2)$. Therefore

$$\lambda_1 + \lambda_2 < 0 \quad \text{and} \quad \lambda_1\lambda_2 > 0$$

If the eigenvalues are real, then these relations hold if and only if both eigenvalues are negative. If they were positive, then $\lambda_1 + \lambda_2 > 0$. If they had different signs, then $\lambda_1\lambda_2 < 0$. Furthermore, if at least one eigenvalue is zero, then $\lambda_1\lambda_2 = 0$. Assume next that the eigenvalues are complex:

$$\lambda_{1,2} = Re\, s \pm j\, Im\, s$$

Then

$$\lambda_1 + \lambda_2 = 2Re\, s$$

and

$$\lambda_1\lambda_2 = (Re\, s)^2 + (Im\, s)^2$$

Hence $\lambda_1 + \lambda_2 < 0$ if and only if $\text{Re}\, s < 0$.

In summary, the system is asymptotically stable, since in both the real and complex cases the eigenvalues have negative values and negative real parts, respectively.

4. The classical *stick balancing* problem is shown in Fig. 12.4. Simple analysis shows that $y(t)$ satisfies the second-order equation

$$\ddot{y} = \frac{g}{L}(y - u)$$

If one selects $L = 1$, then the characteristic equation has the form

$$s^2 - g = 0$$

So, the eigenvalues are

$$\lambda_{1,2} = \pm\sqrt{g}$$

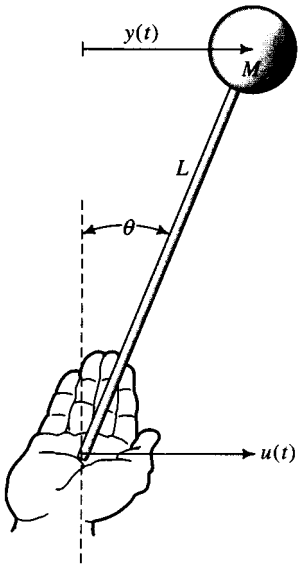

FIGURE 12.4 Stick balancing. (*Source:* F. Szidarovszky and A. T. Bahill, *Linear Systems Theory*, Boca Raton, Fla.: CRC Press, 1992, p. 127. With permission.)

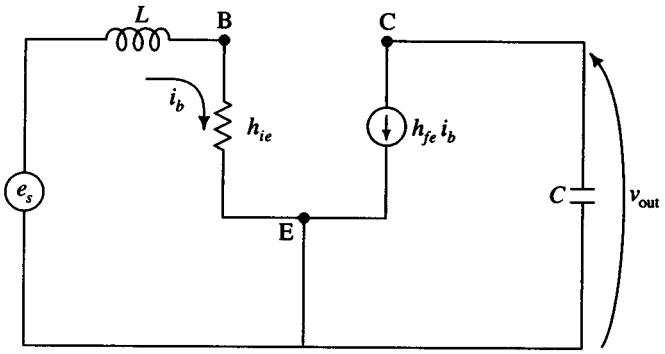

FIGURE 12.5 A model for a simple transistor circuit. (*Source:* F. Szidarovszky and A. T. Bahill, *Linear Systems Theory*, Boca Raton, Fla.: CRC Press 1992, p. 127. With permission.)

One is in the right half of the *s*-plane and the other is in the left half of the *s*-plane, so the system is unstable. This instability is understandable, since without an intelligent input to control the system, if the stick is not upright with zero velocity, it will fall over.

5. A simple *transistor circuit* can be modeled as shown in Fig. 12.5. The state variables are related to the input and output of the circuit: the base current, i_b, is x_1 and the output voltage, v_{out}, is x_2. Therefore,

$$\dot{\mathbf{x}} = \begin{pmatrix} -\dfrac{h_{ie}}{L} & 0 \\ \dfrac{h_{fe}}{C} & 0 \end{pmatrix} \mathbf{x} + \begin{pmatrix} \dfrac{1}{L} \\ 0 \end{pmatrix} e_s \text{ and } \mathbf{c}^T = (0, 1)$$

The **A** matrix looks strange with a column of all zeros, and indeed the circuit does exhibit odd behavior. For example, as we will show, there is no equilibrium state for a unit step input of e_s. This is reasonable, however,

because the model is for mid-frequencies, and a unit step does not qualify. In response to a unit step the output voltage will increase linearly until the model is no longer valid. If e_s is considered to be the input, then the system is

$$\dot{\mathbf{x}} = \begin{pmatrix} -\dfrac{h_{ie}}{L} & 0 \\ \dfrac{h_{fe}}{C} & 0 \end{pmatrix} \mathbf{x} + \begin{pmatrix} \dfrac{1}{L} \\ 0 \end{pmatrix} u$$

If $u(t) \equiv 1$, then at the equilibrium state:

$$\begin{pmatrix} -\dfrac{h_{ie}}{L} & 0 \\ \dfrac{h_{fe}}{C} & 0 \end{pmatrix} \begin{pmatrix} \bar{x}_1 \\ \bar{x}_2 \end{pmatrix} + \begin{pmatrix} \dfrac{1}{L} \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}$$

That is,

$$-\frac{h_{ie}}{L}\,\bar{x}_1 + \frac{1}{L} = 0$$

$$\frac{h_{fe}}{C}\,\bar{x}_1 = 0$$

Since $h_{fe}/C \neq 0$, the second equation implies that $\bar{x}_1 = 0$, and by substituting this value into the first equation we get the obvious contradiction $1/L = 0$. Hence, with nonzero constant input *no* equilibrium state exists.

Let us now investigate the stability of this system. First let $\tilde{\mathbf{x}}(t)$ denote a fixed trajectory of this system, and let $\mathbf{x}(t)$ be an arbitrary solution. Then the difference $\mathrm{x}_\delta(t) = \mathbf{x}(t) - \tilde{\mathbf{x}}(t)$ satisfies the homogeneous equation

$$\dot{\mathrm{x}}_\delta = \begin{pmatrix} -\dfrac{h_{ie}}{L} & 0 \\ \dfrac{h_{fe}}{C} & 0 \end{pmatrix} \mathrm{x}_\delta$$

This system has an equilibrium $\mathbf{x}_\delta(t) = 0$. Next, the stability of this equilibrium is examined by solving for the poles of the closed-loop transfer function. The characteristic equation is

$$\det \begin{pmatrix} -\dfrac{h_{ie}}{L} - s & 0 \\ \dfrac{h_{fe}}{C} & -s \end{pmatrix} = 0$$

which can be simplified as

$$s^2 + s\,\frac{h_{ie}}{L} + 0 = 0$$

The roots are

$$\lambda_1 = 0 \quad \text{and} \quad \lambda_2 = -\frac{h_{ie}}{L}$$

Therefore, the system is stable but not asymptotically stable. This stability means that for small changes in the initial state the entire trajectory $\mathbf{x}(t)$ remains close to $\tilde{\mathbf{x}}(t)$.

Defining Terms

Asymptotic stability: An equilibrium state $\bar{\mathbf{x}}$ of a system is asymptotically stable if, in addition to being stable, there is an $\varepsilon > 0$ such that whenever $\|\bar{\mathbf{x}} - \mathbf{x}_0\| < \varepsilon$, then $\mathbf{x}(t) \to \bar{\mathbf{x}}$ as $t \to \infty$. A system is asymptotically stable if all the poles of the closed-loop transfer function are in the left half of the *s*-plane (inside the unit circle of the *z*-plane for discrete systems). This is sometimes called *stability.*

BIBO stability: A system is BIBO stable if for zero initial conditions a bounded input always evokes a bounded output.

External stability: Stability concepts related to the input-output behavior of the system.

Global asymptotic stability: An equilibrium state $\bar{\mathbf{x}}$ of a system is globally asymptotically stable if it is stable and with arbitrary initial state $\mathbf{x}_0 \in X$, $\mathbf{x}(t) \to \bar{\mathbf{x}}$ as $t \to \infty$.

Internal stability: Stability concepts related to the state of the system.

Instability: An equilibrium state of a system is unstable if it is not stable. A system is unstable if at least one pole of the closed-loop transfer function is in the right half of the *s*-plane (outside the unit circle of the *z*-plane for discrete systems).

Stability: An equilibrium state $\bar{\mathbf{x}}$ of a system is stable if there is an $\varepsilon_0 > 0$ with the following property: for all ε_1, $0 < \varepsilon_1 < \varepsilon_0$, there is an $\varepsilon > 0$ such that if $\|\bar{\mathbf{x}} - \mathbf{x}_0\| < \varepsilon$, then $\|\bar{\mathbf{x}} - \mathbf{x}(t)\| < \varepsilon_1$ for all $t > t_0$. A system is stable if the poles of its closed-loop transfer function are (1) in the left half of the complex frequency plane, called the *s*-plane (inside the unit circle of the *z*-plane for discrete systems), or (2) on the imaginary axis, and all of the poles on the imaginary axis are single (on the unit circle and all such poles are single for discrete systems). Stability for a system with repeated poles on the $j\omega$ axis (the unit circle) is complicated and is examined in the discussion after Theorem 12.5. In the electrical engineering literature, this definition of stability is sometimes called *marginal stability* and sometimes *stability in the sense of Lyapunov.*

13.1 Analog Circuit Simulation

J. Gregory Rollins

Introduction

Computer-aided simulation is a powerful aid during the design or analysis of electronic circuits and semiconductor devices. The first part of this chapter focuses on analog circuit simulation. The second part covers simulations of semiconductor processing and devices. While the main emphasis is on analog circuits, the same simulation techniques may, of course, be applied to digital circuits (which are, after all, composed of analog circuits). The main limitation will be the size of these circuits because the techniques presented here provide a very detailed analysis of the circuit in question and, therefore, would be too costly in terms of computer resources to analyze a large digital system.

The most widely known and used circuit simulation program is SPICE (simulation program with integrated circuit emphasis). This program was first written at the University of California at Berkeley by Laurence Nagel in 1975. Research in the area of circuit simulation is ongoing at many universities and industrial sites. Commercial versions of SPICE or related programs are available on a wide variety of computing platforms, from small personal computers to large mainframes. A list of some commercial simulator vendors can be found in the Appendix.

It is possible to simulate virtually any type of circuit using a program like SPICE. The programs have built-in elements for resistors, capacitors, inductors, dependent and independent voltage and current sources, diodes, MOSFETs, JFETs, BJTs, transmission lines, transformers, and even transformers with saturating cores in some versions. Found in commercial versions are libraries of standard components which have all necessary

[1]The material in this chapter was previously published by CRC Press in *The Circuits and Filters Handbook,* Wai-Kai Chen, Ed., 1995.

parameters prefitted to typical specifications. These libraries include items such as discrete transistors, op amps, phase-locked loops, voltage regulators, logic integrated circuits (ICs) and saturating transformer cores.

Computer-aided circuit simulation is now considered an essential step in the design of integrated circuits, because without simulation the number of "trial runs" necessary to produce a working IC would greatly increase the cost of the IC. Simulation provides other advantages, however:

- The ability to measure "inaccessible" voltages and currents. Because a mathematical model is used all voltages and currents are available. No loading problems are associated with placing a voltmeter or oscilloscope in the middle of the circuit, with measuring difficult one-shot wave forms, or probing a microscopic die.
- Mathematically ideal elements are available. Creating an ideal voltage or current source is trivial with a simulator, but impossible in the laboratory. In addition, all component values are exact and no parasitic elements exist.
- It is easy to change the values of components or the configuration of the circuit. Unsoldering leads or redesigning IC masks are unnecessary.

Unfortunately, computer-aided simulation has its own problems:

- Real circuits are distributed systems, not the "lumped element models" which are assumed by simulators. Real circuits, therefore, have resistive, capacitive, and inductive parasitic elements present besides the intended components. In high-speed circuits these parasitic elements are often the dominant performance-limiting elements in the circuit, and must be painstakingly modeled.
- Suitable predefined numerical models have not yet been developed for certain types of devices or electrical phenomena. The software user may be required, therefore, to create his or her own models out of other models which are available in the simulator. (An example is the solid-state thyristor which may be created from a NPN and PNP bipolar transistor.)
- The numerical methods used may place constraints on the form of the model equations used.

The following sections consider the three primary simulation modes: DC, AC, and transient analysis. In each section an overview is given of the numerical techniques used. Some examples are then given, followed by a brief discussion of common pitfalls.

DC (Steady-State) Analysis

DC analysis calculates the state of a circuit with fixed (non-time varying) inputs after an infinite period of time. DC analysis is useful to determine the operating point (Q-point) of a circuit, power consumption, regulation and output voltage of power supplies, transfer functions, noise margin and fanout in logic gates, and many other types of analysis. In addition DC analysis is used to find the starting point for AC and transient analysis. To perform the analysis the simulator performs the following steps:

1. All capacitors are removed from the circuit (replaced with opens).
2. All inductors are replaced with shorts.
3. Modified nodal analysis is used to construct the nonlinear circuit equations. This results in one equation for each circuit node plus one equation for each voltage source. Modified nodal analysis is used rather than standard nodal analysis because an ideal voltage source or inductance cannot be represented using normal nodal analysis. To represent the voltage sources, loop equations (one for each voltage source or inductor), are included as well as the standard node equations. The node voltages and voltage source currents, then, represent the quantities which are solved for. These form a vector $\mathbf{x}$. The circuit equations can also be represented as a vector $\mathbf{F}(\mathbf{x}) = \mathbf{0}$.
4. Because the equations are nonlinear, Newton's method (or a variant thereof) is then used to solve the equations.

Example 13.1. **Simulation Voltage Regulator:** We shall now consider simulation of the type 723 voltage regulator IC, shown in Fig. 13.1. We wish to simulate the IC and calculate the sensitivity of the output IV

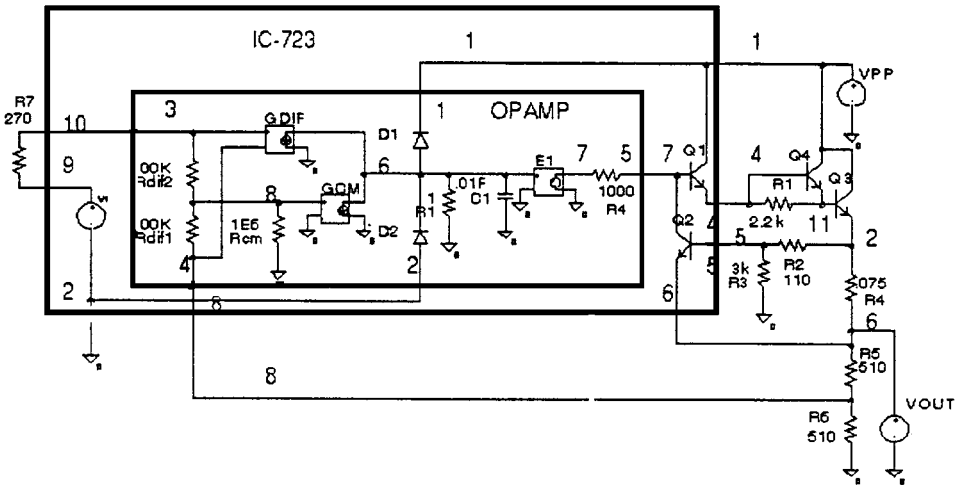

FIGURE 13.1 Regulator circuit to be used for DC analysis, created using PSPICE.

characteristic and verify that the output current follows a "fold-back" type characteristic under overload conditions.

The IC itself contains a voltage reference source and operational amplifier. Simple models for these elements are used here rather than representing them in their full form, using transistors, to illustrate model development. The use of simplified models can also greatly reduce the simulation effort. (For example, the simple op amp used here requires only eight nodes and ten components, yet realizes many advanced features.)

Note in Fig. 13.1 that the numbers next to the wires represent the circuit nodes. These numbers are used to describe the circuit to the simulator. In most SPICE-type simulators the nodes are represented by numbers, with the ground node being node zero. Referring to Fig. 13.2, the 723 regulator and its internal op amp are represented by subcircuits. Each subcircuit has its own set of nodes and components. Subcircuits are useful for encapsulating sections of a circuit or when a certain section needs to be used repeatedly (see next section).

The following properties are modeled in the op amp:

1. Common mode gain
2. Differential mode gain
3. Input impedance
4. Output impedance
5. Dominant pole
6. Output voltage clipping

The input terminals of the op amp connect to a "T" resistance network, which sets the common and differential mode input resistance. Therefore, the common mode resistance is RCM + RDIF = 1.1E6 and the differential mode resistance is RDIF1 + RDIF2 = 2.0E5.

Dependent current sources are used to create the main gain elements. Because these sources force current into a 1-Ω resistor, the voltage gain is Gm*R at low frequency. In the differential mode this gives (GDIF*R1 = 100). In the common mode this gives (GCM*R1*(RCM/(RDIF1 + RCM = 0.0909). The two diodes D1 and D2 implement clipping by preventing the voltage at node 6 from exceeding VCC or going below VEE. The diodes are made "ideal" by reducing the ideality factor n. Note that the diode current is $I_d = I_s[\exp(V_d/(nV_t)) - 1]$, where V_t is the thermal voltage (0.026 V). Thus, reducing n makes the diode turn on at a lower voltage.

A single pole is created by placing a capacitor (C1) in parallel with resistor R1. The pole frequency is therefore given by 1.0/(2*π*R1*C1). Finally, the output is driven by the voltage-controlled voltage source E1 (which has a voltage gain of unity), through the output resistor R4. The output resistance of the op amp is therefore equal to R4.

To observe the output voltage as a function of resistance, the regulator is loaded with a voltage source (VOUT) and the voltage source is swept from 0.05 to 6.0 V. A plot of output voltage vs. resistance can then be obtained

FIGURE 13.2 SPICE input listing of regulator circuit shown in Fig. 13.1.

by plotting VOUT vs. VOUT/I(VOUT) (using PROBE in this case; see Fig. 13.3). Note that for this circuit, eventhough a current source would seem a more natural choice, a voltage source must be used as a load rather than a current source because the output characteristic curve is multivalued in current. If a current source were used it would not be possible to easily simulate the entire curve. Of course, many other interesting quantities can be plotted; for example, the power dissipated in the pass transistor can be approximated by plotting IC(Q3)*VC(Q3).

For these simulations PSPICE was used running on an IBM PC. The simulation took < 1 min of CPU time.

Pitfalls. Convergence problems are sometimes experienced if "difficult" bias conditions are created. An example of such a condition is if a diode is placed in the circuit backwards, resulting in a large forward bias voltage, SPICE will have trouble resolving the current. Another difficult case is if a current source were used instead of

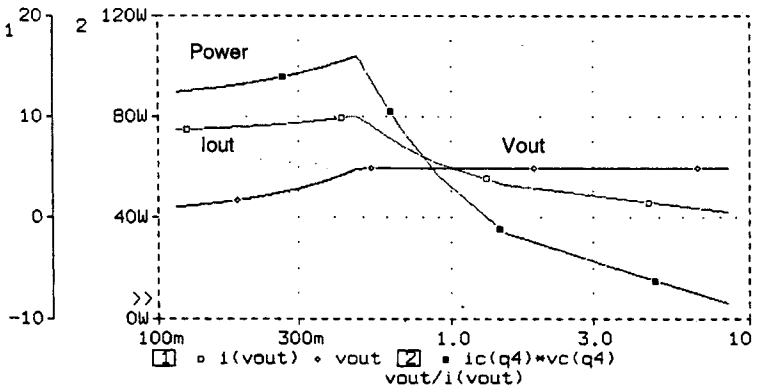

FIGURE 13.3 Output characteristics of regulator circuit using PSPICE.

a voltage to bias the output in the previous example. If the user then tried to increase the output current above 10 A, SPICE would not be able to converge because the regulator will not allow such a large current.

AC Analysis

Ac analysis uses phasor analysis to calculate the frequency response of a circuit. The analysis is useful for calculating the gain. 3 dB frequency input and output impedance, and noise of a circuit as a function of frequency, bias conditions, temperature, etc.

Numerical Method

1. A DC solution is performed to calculate the Q-point for the circuit.
2. A linearized circuit is constructed at the Q point. To do this, all nonlinear elements are replaced by their linearized equivalents. For example, a nonlinear current source $I = aV_1^2 + bV_2^3$ would be replaced by a linear voltage controlled current source $I = V_1(2aV_{1q}) + V_2(3bV_{2q}^2)$.
3. All inductors and capacitors are replaced by complex impedances, and conductances evaluated at the frequency of interest.
4. Nodal analysis is now used to reduce the circuit to a linear algebraic complex matrix. The AC node voltages may now be found by applying an excitation vector (which represents the independent voltage and current sources) and using Gaussian elimination (with complex arithmetic) to calculate the node voltages.

AC analysis does have limitations and the following types of nonlinear or large signal problems cannot be modeled:

1. Distortion due to nonlinearities such as clipping, etc.
2. Slew rate-limiting effects
3. Analog mixers
4. Oscillators

Noise analysis is performed by including noise sources in the models. Typical noise sources include thermal noise in resistors $I_n^2 = 4kT\,\Delta f/R$, and shot $I_n^2 = 2qI_d\,\Delta f$, and flicker noise in semiconductor devices. Here, T is temperature in Kelvins, k is Boltzmann's constant, and Δf is the bandwidth of the circuit. These noise sources are inserted as independent current sources, $\mathrm{In}_j(f)$ into the AC model. The resulting current due to the noise source is then calculated at a user-specified summation node(s) by multiplying by the gain function between the noise source and the summation node $A_{js}(f)$. This procedure is repeated for each noise source and then the contributions at the reference node are root mean squared (RMS) summed to give the total noise at the reference node. The equivalent input noise is then easily calculated from the transfer function between the circuit input and the reference node $A_{is}(f)$. The equation describing the input noise is therefore:

$$I_i = \frac{1}{A_{is}(f)} \sqrt{\sum_j \left[A_{js}(f)\,In_j(f)\right]^2}$$

Example 13.2. **Cascode Amplifier with Macro Models:** Here, we find the gain, bandwidth, input impedance, and output noise of a cascode amplifier. The circuit for the amplifier is shown in Fig. 13.5. The circuit is assumed to be fabricated in a monolithic IC process, so it will be necessary to consider some of the parasitics of the IC process. A cross-section of a typical IC bipolar transistor is shown in Fig. 13.4 along with some of the parasitic elements. These parasitic elements are easily included in the amplifier by creating a "macro model" for each transistor. The macro model is then implemented in SPICE form using subcircuits.

The input to the circuit is a voltage source (VIN), applied differentially to the amplifier. The output will be taken differentially across the collectors of the two upper transistors at nodes 2 and 3. The input impedance of the amplifier can be calculated as VIN/I(VIN) or because VIN = 1.0 just as 1/I(VIN). These quantities are shown plotted using PROBE in Fig. 13.6. It can be seen that the gain of the amplifier falls off at high frequency

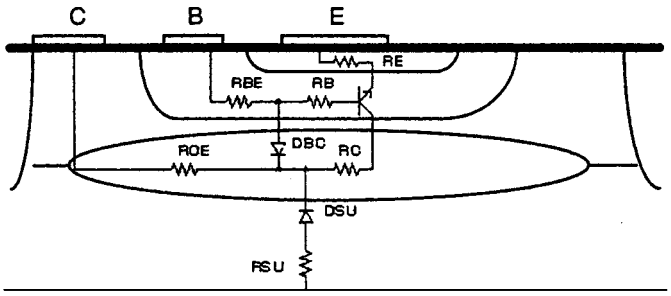

FIGURE 13.4 BJT cross-section with macro model elements.

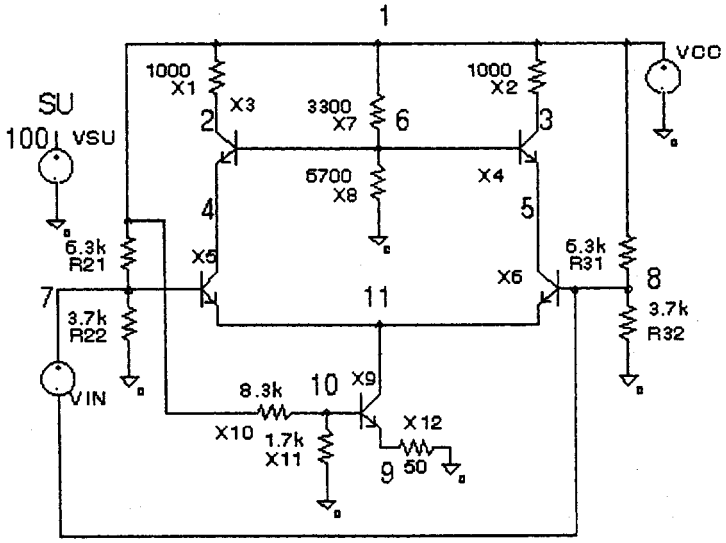

FIGURE 13.5 Cascode amplifier for AC analysis, created using PSPICE.

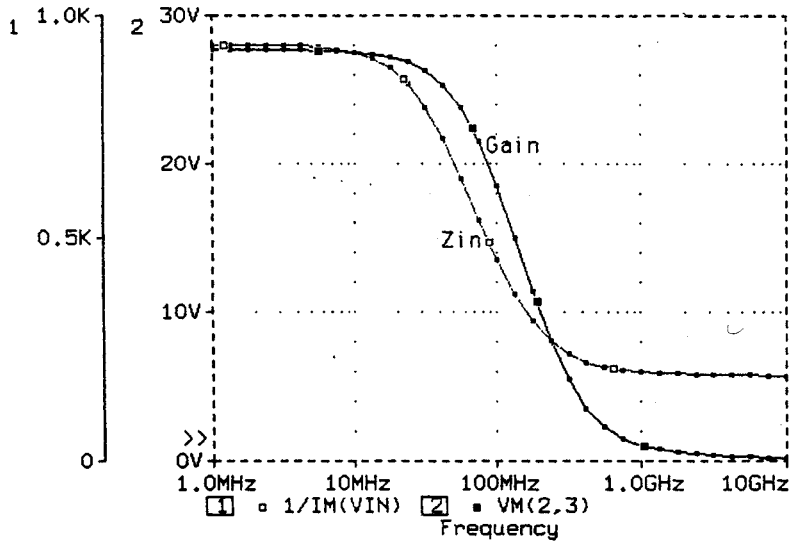

FIGURE 13.6 Gain and input impedance of cascode amplifier.

as expected. The input impedance also drops because parasitic capacitances shunt the input. This example took <1 min on an IBM PC.

Pitfalls. Many novice users will forget that AC analysis is a linear analysis. They will, for example, apply a 1-V signal to an amplifier with 5-V power supplies and a gain of 1000 and be surprised when SPICE tells them that the output voltage is 1000 V. Of course, the voltage generated in a simple amplifier must be less than the power supply voltage, but to examine such clipping effects, transient analysis must be used. Likewise, selection of a proper Q point is important. If the amplifier is biased in a saturated portion of its response and AC analysis is performed, the gain reported will be much smaller than the actual large signal gain.

Transient Analysis

Transient analysis is the most powerful analysis capability of a simulator because the transient response is so hard to calculate analytically. Transient analysis can be used for many types of analysis, such as switching speed, distortion, basic operation of certain circuits like switching power supplies. Transient analysis is also the most CPU intensive and can require 100 or 1000 times the CPU time as a DC or AC analysis.

Numerical Method

In a transient analysis time is discretized into intervals called time steps. Typically the time steps are of unequal length, with the smallest steps being taken during portions of the analysis when the circuit voltages and currents are changing most rapidly. The capacitors and inductors in the circuit are then replaced by voltage and current sources based on the following procedure.

The current in a capacitor is given by $I_c = CdV_c/dt$. The time derivative can be approximated by a difference equation:

$$I_c^k + I_c^{k-1} = 2C\frac{V_c^k - V_c^{k-1}}{t^k - t^{k-1}}$$

In this equation the superscript k represents the number of the time step. Here, k is the time step we are presently solving for and $(k-1)$ is the previous time step. This equation can be solved to give the capacitor current at the present time step.

$$I_c^k = V_c^k\left(2C/\Delta t\right) - V_c^{k-1}\left(2C/\Delta t\right) - I_c^{k-1}.$$

Here, $\Delta t = t^k - t^{k-1}$, or the length of the time step. As time steps are advanced, $V_c^{k-1} \rightarrow V_c^k$; $I_c^{k-1} \rightarrow I_c^k$. Note that the second two terms on the right hand side of the above equation are dependent only on the capacitor voltage and current from the previous time step, and are therefore fixed constants as far as the present step is concerned. The first term is effectively a conductance ($g = 2C/\Delta t$) multiplied by the capacitor voltage, and the second two terms could be represented by an independent current source. The entire transient model for the capacitor therefore consists of a conductance in parallel with two current sources (the numerical values of these are, of course, different at each time step). Once the capacitors and inductors have been replaced as indicated, the normal method of DC analysis is used. One complete DC analysis must be performed for each time point. This is the reason that transient analysis is so CPU intensive. The method outlined here is the trapezoidal time integration method and is used as the default in SPICE.

Example 13.3. **Phase-Locked Loop Circuit:** Figure 13.7 shows the phase-locked loop circuit. The phase detector and voltage-controlled oscillator are modeled in separate subcircuits. Examine the VCO subcircuit and note the PULSE-type current source ISTART connected across the capacitor. The source gives a current pulse 03.E-6 s wide at the start of the simulation to start the VCO running. To start a transient simulation SPICE first computes a DC operating point (to find the initial voltages V_c^{k-1} on the capacitors). As this DC point is a valid, although not necessarily stable, solution, an oscillator will remain at this point indefinitely unless some perturbation is applied to start the oscillations. Remember, this is an ideal mathematical model and no noise

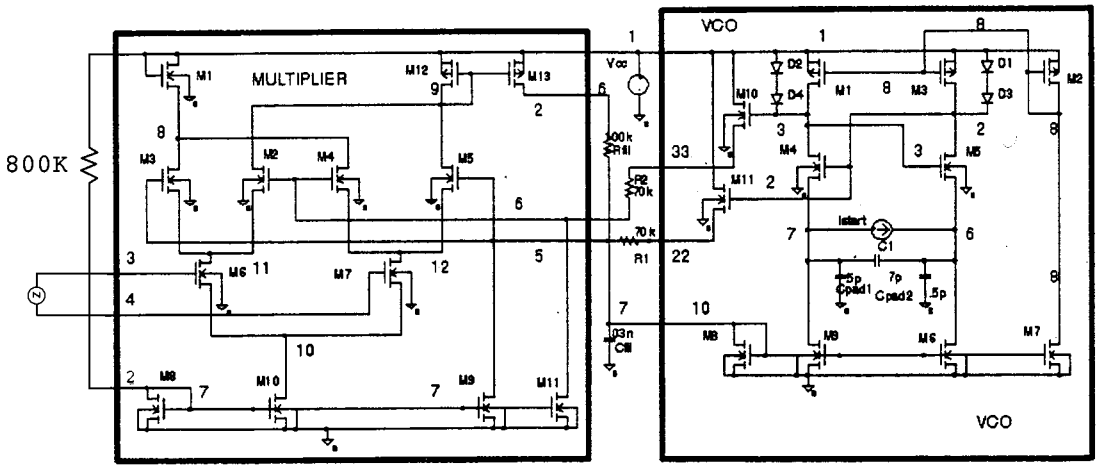

FIGURE 13.7 Phase-locked loop circuit for transient analysis, created with PSPICE.

sources or asymmetries exist that would start a real oscillator—it must be done manually. The capacitor C1 would have to be placed off-chip, and bond pad capacitance (CPAD1 and CPAD2) have been included at the capacitor nodes. Including the pad capacitances is very important if a small capacitor C1 is used for high-frequency operation.

In this example, the PLL is to be used as a FM detector circuit and the FM signal is applied to the input using a single frequency FM voltage source. The carrier frequency is 600 kHz and the modulation frequency is 60 kHz. Figure 13.8 shows the input voltage and the output voltage of the PLL at the VCO output and at the phase detector output. It can be seen that after a brief starting transient, the PLL locks onto the input signal

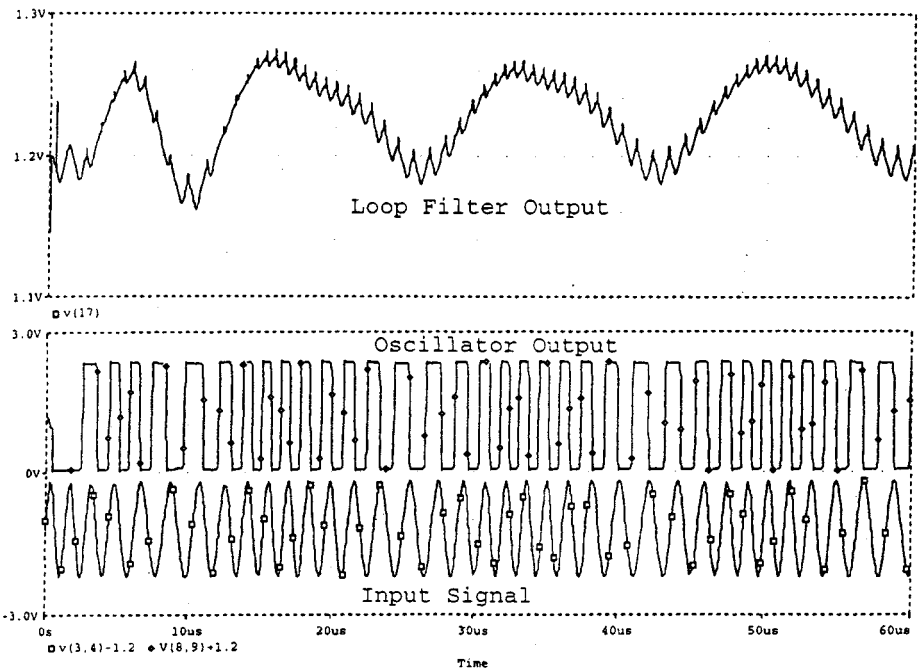

FIGURE 13.8 Transient analysis results of PLL circuit, created using PSPICE.

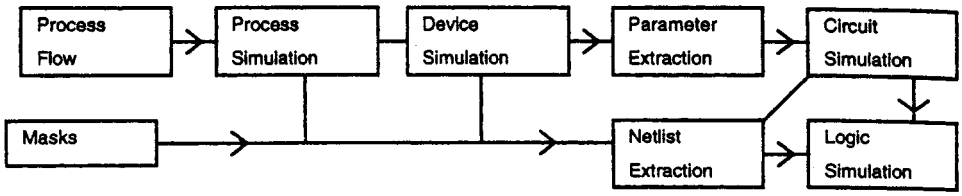

FIGURE 13.9 Data flow for complete process-device-circuit modeling.

and that the phase detector output has a strong 60-kHz component. This example took 251 s on a Sun SPARC-2 workstation (3046 time steps, with an average of 5 Newton iterations per time step).

Pitfalls. Occasionally SPICE will fail and give the message "Timestep too small in transient analysis", which means that the process of Newton iterations at certain time steps could not be made to converge. One of the most common causes of this is the specification of a capacitor with a value that is much too large, for example, specifying a 1-F capacitor instead of a 1 pF capacitor (an easy mistake to make by not adding the "p" in the value specification). Unfortunately, we usually have no way to tell which capacitor is at fault from the type of failure generated other than to manually search the input deck.

Other transient failures are caused by MOSFET models. Some models contain discontinuous capacitances (with respect to voltage) and others do not conserve charge. These models can vary from version to version so it is best to check the user's guide.

Process and Device Simulation

Process and devices simulation are the steps that precede analog circuit simulation in the overall simulation flow (see Fig. 13.9). The simulators are also different in that they are not measurement driven as are analog circuit simulators. The input to a process simulator is the sequence of process steps performed (times, temperatures, gas concentrations) as well as the mask dimensions. The output from the process simulator is a detailed description of the solid-state device (doping profiles, oxide thickness, junction depths, etc.). The input to the device simulator is the detailed description generated by the process simulator (or via measurement). The output of the device simulator is the electrical characteristics of the device (IV curves, capacitances, switching transient curves).

Process and device simulation are becoming increasingly important and widely used during the integrated circuit design process. A number of reasons exist for this:

- As device dimensions shrink, second-order effects can become dominant. Modeling of these effects is difficult using analytical models.
- Computers have greatly improved, allowing time-consuming calculations to be performed in a reasonable amount of time.
- Simulation allows access to impossible to measure physical characteristics.
- Analytic models are not available for certain devices, for example, thyristors, heterojunction devices and IGBTS.
- Analytic models have not been developed for certain physical phenomena, for example, single event upset, hot electron aging effects, latchup, and snap-back.
- Simulation runs can be used to replace split lot runs. As the cost to fabricate test devices increases, this advantage becomes more important.
- Simulation can be used to help device, process, and circuit designers understand how their devices and processes work.

Clearly, process and device simulation is a topic which can be and has been the topic of entire texts. The following sections attempt to provide an introduction to this type of simulation, give several examples showing what the simulations can accomplish, and provide references to additional sources of information.

Process Simulation

Integrated circuit processing involves a number of steps which are designed to deposit (deposition, ion implantation), remove (etching), redistribute (diffusion), or transform (oxidation) the material of which the IC is made. Most process simulation work has been in the areas of diffusion, oxidation, and ion implantation; however, programs are available that can simulate the exposure and development of photo-resist, the associated optical systems, as well as gas and liquid phase deposition and etch.

In the following section a very brief discussion of the governing equations used in SUPREM (from Stanford University, California) will be given along with the results of an example simulation showing the power of the simulator.

Diffusion

The main equation governing the movement of electrically charged impurities (acceptors in this case) in the crystal is the diffusion equation:

$$\frac{\partial C}{\partial t} = \nabla \cdot \left(D\nabla C - \frac{DqC_a}{kT} \mathbf{E} \right)$$

Here, C is the concentration (#/cm^3) of impurities, C_a is the number of electrically active impurities (#/cm^3), q is the electron charge, k is Boltzmann's constant, T is temperature in degrees Kelvin, D is the diffusion constant, and E is the built-in electric field. The built-in electric field E in (V/cm) can be found from:

$$\mathbf{E} = -\frac{kT}{q}\frac{1}{n}\nabla n$$

In this equation n is the electron concentration (#/cm^3), which in turn can be calculated from the number of electrically active impurities (C_a). The diffusion constant (D) is dependent on many factors. In silicon the following expression is commonly used:

$$D = F_{IV}\left(D_x + D_+ \frac{n_i}{n} + D_- \frac{n}{n_i} + D_= \left(\frac{n}{n_i} \right)^2 \right)$$

The four D components represent the different possible charge states for the impurity: (x) neutral, (+) positive, (–) negative, (=) doubly negatively charged. n_i is the intrinsic carrier concentration, which depends only on temperature. Each D component is in turn given by an expression of the type

$$D = A \exp\left(-\frac{B}{kT} \right)$$

Here, A and B are experimentally determined constants, different for each type of impurity (x, +, –, =). B is the activation energy for the process. This expression derives from the Maxwellian distribution of particle energies and will be seen many times in process simulation. It is easily seen that the diffusion process is strongly influenced by temperature. The term F_{IV} is an enhancement factor which is dependent on the concentration of interstitials and vacancies within the crystal lattice (an interstitial is an extra silicon atom which is not located on a regular lattice site; a vacancy is a missing silicon atom which results in an empty lattice site) $F_{IV} \propto C_I + C_v$. The concentration of vacancies, C_v, and interstitials, C_I, are in turn determined by their own diffusion equation:

$$\frac{\partial C_v}{\partial t} = +\nabla \cdot D_V \cdot \nabla C_V - R + G$$

In this equation D_V is another diffusion constant of the form $A \exp(-B/kT)$. R and G represent the recombination and generation of vacancies and interstitials. Note that an interstitial and a vacancy may recombine and in the process destroy each other, or an interstitial and a vacancy pair may be simultaneously generated by knocking a silicon atom off its lattice site. Recombination can occur anywhere in the device via a bulk recombination process $R = A(C_V C_1)\exp(-B/kT)$. Generation occurs where there is damage to the crystal structure, in particular at interfaces where oxide is being grown or in regions where ion implantation has occurred, as the high-energy ions can knock silicon atoms off their lattice sites.

Oxidation

Oxidation is a process whereby silicon reacts with oxygen (or with water) to form new silicon dioxide. Conservation of the oxidant requires the following equation:

$$\frac{dy}{dt} = \frac{\mathbf{F}}{N}$$

Here, F is the flux of oxidant (#/cm^2/s), N is the number of oxidant atoms required to make up a cubic centimeter of oxide, and dy/dt is the velocity with which the Si-SiO_2 interface moves into the silicon. In general the greater the concentration of oxidant (C_0), the faster the growth of the oxide and the greater the flux of oxidant needed at the Si-SiO_2 interface. Thus, $F = k_s C_0$. The flux of oxidant into the oxide from the gaseous environment is given by:

$$F = h(HP_{ox} - C_0)$$

Here H is a constant, P is the partial pressure of oxygen in the gas, and C_0 is the concentration of oxidant in the oxide at the surface and h is of the form $A \exp(-B/kT)$. Finally, the movement of the oxidant within the already existing oxide is governed by diffusion: $\mathbf{F} = D_0 \nabla C$. When all these equations are combined, it is found that (in the one-dimensional case) oxides grow linearly $dy/dt \propto t$ when the oxide is thin and the oxidant can move easily through the existing oxide. As the oxide grows thicker $dy/dt \propto \sqrt{t}$ because the movement of the oxidant through the existing oxide becomes the rate-limiting step.

Modeling two-dimensional oxidation is a challenging task. The newly created oxide must "flow" away from the interface where it is begin generated. This flow of oxide is similar to the flow of a very thick or viscous liquid and can be modeled by a creeping flow equation:

$$\nabla_2 V \propto \nabla P$$

$$\nabla \cdot V = 0$$

V is the velocity at which the oxide is moving and P is the hydrostatic pressure. The second equation results form the incompressibility of the oxide. The varying pressure P within the oxide leads to mechanical stress, and the oxidant diffusion constant D_0 and the oxide growth rate constant k_s are both dependent on this stress. The oxidant flow and the oxide flow are therefore coupled because the oxide flow depends on the rate at which oxide is generated at the interface and the rate at which the new oxide is generated depends on the availability of oxidant, which is controlled by the mechanical stress.

Ion Implantation

Ion implantation is normally modeled in one of two ways. The first involves tables of moments of the final distribution of the ions which are typically generated by experiment. These tables are dependent on the energy and the type of ion being implanted. The second method involves Monte-Carlo simulation of the implantation process. In Monte-Carlo simulation the trajectories of individual ions are followed as they interact with (bounce off) the silicon atoms in the lattice. The trajectories of the ions, and the recoiling Si atoms (which can strike more Si atoms) are followed until all come to rest within the lattice. Typically several thousand trajectories are

simulated (each will be different due to the random probabilities used in the Monte-Carlo method) to build up the final distribution of implanted ions.

Process simulation is always done in the transient mode using time steps as was done with transient circuit simulation. Because partial differential equations are involved, rather than ordinary differential equations, spatial discretization is needed as well. To numerically solve the problem, the differential equations are discretized on a grid. Either rectangular or triangular grids in one, two, or three dimensions are commonly used. This discretization process results in the conversion of the partial differential equations into a set of nonlinear algebraic equations. The nonlinear equations are then solved using a Newton method in a way very similar to the method used for the circuit equations in SPICE.

Example 13.4. **NMOS Transistor:** In this example the process steps used to fabricate a typical NMOS transistor will be simulated using SUPREM-4. These steps are

1. Grow initial oxide (30 min at 1000 K)
2. Deposit nitride layer (a nitride layer will prevent oxidation of the underlying silicon)
3. Etch holes in nitride layer
4. Implant P+ channel stop (boron dose = 5e12, energy = 50 keV)
5. Grow the field oxide (180 min at 1000 K wet O_2)
6. Remove all nitride
7. Perform P channel implant (boron dose = 1e11, energy = 40 keV)
8. Deposit and etch polysilicon for gate
9. Oxidize the polysilicon (30 min at 1000 K, dry O_2)
10. Implant the light doped drain (arsenic dose = 5e13 energy = 50 keV)
11. Deposit sidewall space oxide
12. Implant source and drain (arsenic, dose = 1e15, energy = 200 keV)
13. Deposit oxide layer and etch contact holes
14. Deposit and etch metal

The top 4 μm of the completed structure, as generated by SUPREM-4, is shown in Fig. 13.10. The actual simulation structure used is 200 μm deep to allow correct modeling of the diffusion of the vacancies and interstitials. The gate is at the center of the device. Notice how the edges of the gate have lifted up due to the diffusion of oxidant under the edges of the polysilicon (the polysilicon, as deposited in step 8, is flat). The dashed contours show the concentration of dopants in both the oxide and silicon layers. The short dashes

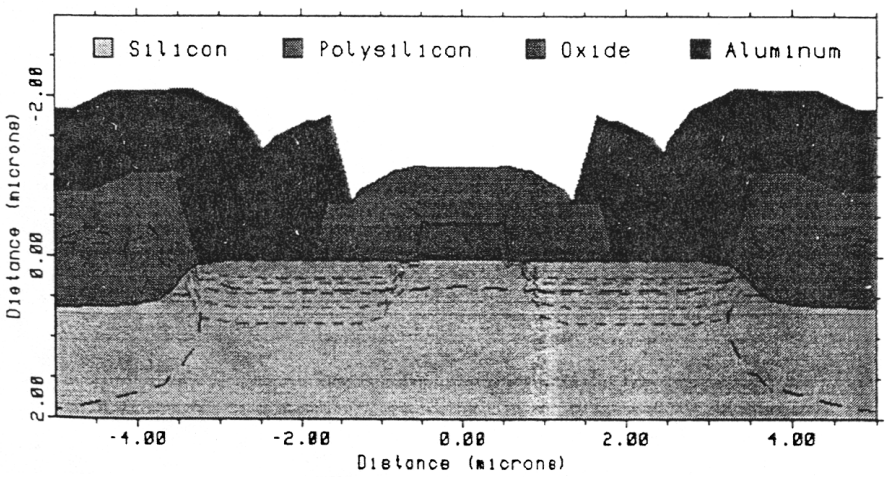

FIGURE 13.10 Complete NMOS transistor cross section generated by process simulation, created with TMA SUPREM-4.

indicate N-type material, while the longer dashes indicate P-type material. This entire simulation requires about 30 min on a Sun SPARC-2 workstation.

Device Simulation

Device simulation uses a different approach from that of conventional lumped circuit models to determine the electrical device characteristics. Whereas with analytic or empirical models all characteristics are determined by fitting a set of adjustable parameters to measured data, device simulators determine the electrical behavior by numerically solving the underlying set of differential equations. The first is the Poisson equation, which describes the electrostatic potential within the device

$$\nabla \cdot \varepsilon \cdot \nabla \Psi = q\left(N_a^- - N_d^+ - p + n - Q_f\right)$$

N_d and N_a are the concentration of donors and acceptors, i.e., the N- and P-type dopants. Q_f is the concentration of fixed charge due, for example, to traps or interface charge. The electron and hole concentrations are given by n and p, respectively, and Ψ is the electrostatic potential.

A set of continuity equations describes the conservation of electrons and holes:

$$\frac{\partial n}{\partial t} = \left(\frac{1}{q}\nabla \cdot \mathbf{J}_n - R + G\right)$$

$$\frac{\partial p}{\partial t} = \left(-\frac{1}{q}\nabla \cdot \mathbf{J}_p - R + G\right)$$

In these equations R and G describe the recombination and generation rates for the electrons and holes. The recombination process is influenced by factors such as the number of electrons and holes present as well as the doping and temperature. The generation rate is also dependent upon the carrier concentrations, but is most strongly influenced by the electric field, with increasing electric fields giving larger generation rates. Because this generation process is included, device simulators are capable of modeling the breakdown of devices at high voltage. $\mathbf{J}_n$ and $\mathbf{J}_p$ are the electron and hole current densities (in amperes per square centimeter). These current densities are given by another set of equations

$$\mathbf{J}_n = q\mu\left(-n\nabla\Psi + \frac{kT_n}{q}\nabla n\right)$$

$$\mathbf{J}_p = q\mu\left(-p\nabla\Psi - \frac{kT_p}{q}\nabla p\right)$$

In this equation k is Boltzmann's constant, μ is the carrier mobility, which is actually a complex function of the doping, n, p, electric field, temperature, and other factors. In silicon the electron mobility will range between 50 and 1000 and the hole mobility will normally be a factor of 2 smaller. In other semiconductors such as gallium arsenide the electron mobility can be as high as 5000. T_n and T_p are the electron and hole mean temperatures, which describe the average carrier energy. In many models these default to the device temperature (300 K). In the first term the current is proportional to the electric field ($\nabla\Psi$), and this term represents the drift of carriers with the electric field. In the second term the current is proportional to the gradient of the carrier concentration (∇n), so this term represents the diffusion of carriers from regions of high concentration to those of low concentration. The model is therefore called the drift-diffusion model.

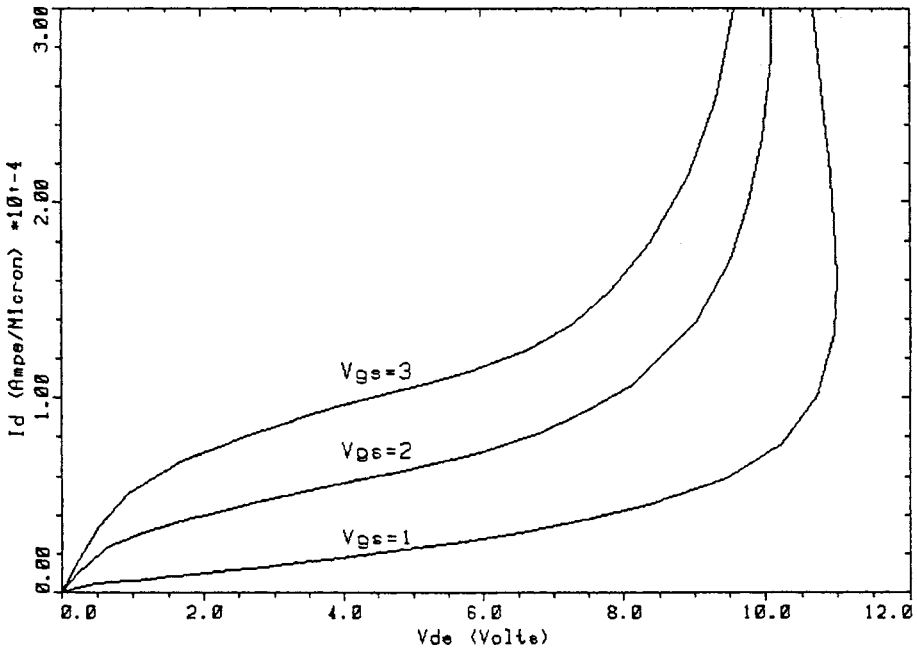

FIGURE 13.11 I_d vs. V_{ds} curves generated by device simulation, created with TMA MEDICI.

In devices in which self-heating effects are important, a lattice heat equation can also be solved to give the internal device temperature:

$$\sigma(T)\frac{\partial T}{\partial t} = H + \nabla \cdot \lambda(T) \cdot \nabla T$$

$$H = -(\mathbf{J}_n + \mathbf{J}_p) \cdot \nabla \Psi + H_R$$

where H is the heat generation term, which includes resistive (Joule) heating as well as recombination heating, H_u. The terms $\sigma(T)$, $\lambda(T)$ represent the specific heat and the thermal conductivity of the material (both temperature dependent). Inclusion of the heat equation is essential in many power device problems.

As with process simulation partial differential equations are involved, therefore, a spatial discretization is required. As with circuit simulation problems, various types of analysis are available:

- Steady state (DC), used to calculate characteristic curves of MOSFETs, BJTs diodes, etc.
- AC analysis, used to calculate capacitances, *Y*-parameters, small signal gains, and *S*-parameters.
- Transient analysis used for calculation of switching and large signal behavior, and special types of analysis such as radiation effects.

Example 13.5. **NMOS IV Curves:** The structure generated in the previous SUPREM-IV simulation is now passed into the device simulator and bias voltages are applied to the gate and drain. Models were included with account for Auger and Shockley Reed Hall recombination, doping and electric field-dependent mobility, and impact ionization. The set of drain characteristics obtained is shown in Fig. 13.11. Observe how the curves bend upward at high V_{ds} as the device breaks down. The V_g, = 1 curve has a negative slope at I_d = 1.5e-4A as the device enters snap-back. It is possible to model this type of behavior because impact ionization is included in the model.

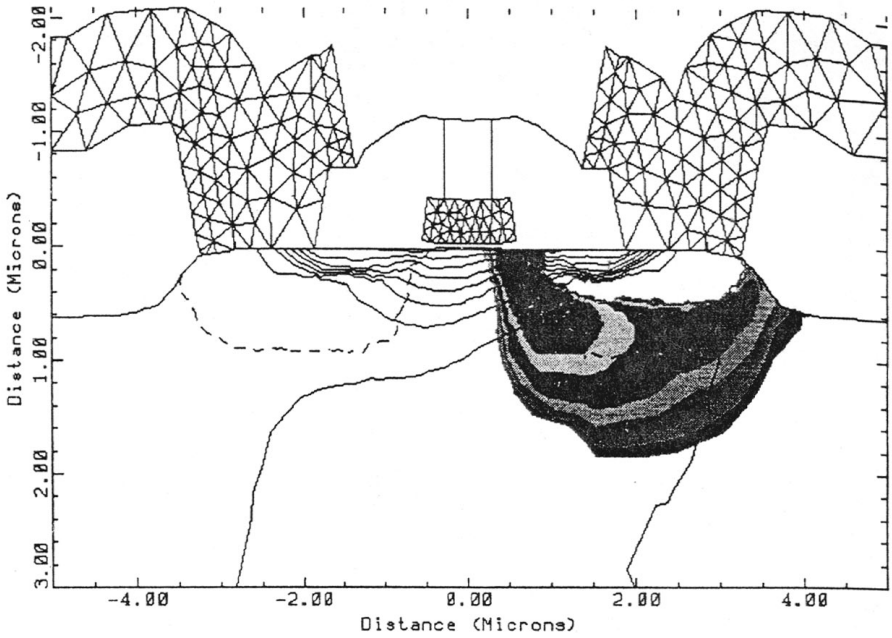

FIGURE 13.12 Internal behavior of MOSFET under bias, created with TMA MEDICI.

Figure 13.12 shows the internal behavior of the device with V_{gs} = 3 V and I_d = 3e-4A. The filled contours indicate impact ionization, with the highest rate being near the edge of the drain right beneath the gate. This is to be expected because this is the region in which the electric field is largest due to the drain depletion region. The dark lines indicate current flow from the source to the drain. Some current also flows from the drain to the substrate. This substrate current consists of holes generated by the impact ionization. The triangular grid used in the simulation can be seen in the source, drain, and gate electrodes. A similar grid was used in the oxide and silicon regions.

13.2 Parameter Extraction for Analog Circuit Simulation

Peter Bendix

Introduction

Definition of Device Modeling

We use various terms such as device characterization, parameter extraction, optimization, and model fitting to address an important engineering task. In all of these, we start with a mathematical model that describes the transistor behavior. The model has a number of parameters which are varied or adjusted to match the IV (current-voltage) characteristics of a particular transistor or set of transistors. The act of determining the appropriate set of model parameters is what we call device modeling. We then use the model with the particular set of parameters that represent our transistors in a circuit simulator such as SPICE[1] to simulate how circuits with our kinds of transistors will behave. Usually the models are supplied by the circuit simulator we chose. Occasionally we may want to modify these models or construct our own models. In this case we need access to the circuit simulator model subroutines as well as the program that performs the device characterization.

Steps Involved in Device Characterization

Device characterization begins with a test chip. Without the proper test chip structures, proper device modeling cannot be done from measured data. A good test chip for MOS technology would include transistors of varying geometries, gate oxide capacitance structures, junction diode capacitance structures, and overlap capacitance structures. This would be a minimal test chip. Additional structures might include ring oscillators and other circuits for checking the AC performance of the models obtained. It is very important that the transistors be well designed and their geometries be chosen appropriate for the technology as well as the desired device model. Although a complete test chip description is beyond the scope of this book, be aware that even perfect device models cannot correct for a poor test chip.

Next we need data that represent the behavior of a transistor or set of transistors of different sizes. these data can come from direct measurement or they can be produced by a device simulator such as PISCES.[2]

It is also possible to use a combination of a process simulator like SUPREM-IV[3] coupled to a device simulator, to provide the simulated results. The benefits of using simulation over measurement are that no expensive measurement equipment or fabricated wafers are necessary. This can be very helpful when trying to predict the device characteristics of a new fabrication process before any wafers have been produced.

Once the measured (or simulated) data are available, parameter extraction software is used to find the best set of model parameter values to fit the data.

[1]SPICE is a circuit simulation program from the Department of Electrical Engineering and Computer Science at the University of California at Berkeley.

[2]PISCES is a process simulation program from the Department of Electrical Engineering at Stanford University, Stanford, CA.

[3]SUPREM-IV is a process simulation program from the Department of Electrical Engineering at Stanford University, Stanford, CA.

Least-Squares Curve Fitting (Analytical)

We begin this section by showing how to do least-squares curve fitting by analytical solutions, using a simple example to illustrate the method. We then mention least-squares curve fitting using numerical solutions in the next section. We can only find analytical solutions to simple problems. The more complex ones must rely on numerical techniques.

Assume a collection of measured data, $m_1, \ldots, m_n$. For simplicity, let these measured data values be functions of a single variable, v, which was varied from v_1 through v_n, measuring each m_i data point at each variable value v_i, i running from 1 to n. For example, the m_i data points might be drain current of an MOS transistor, and the v_i might be the corresponding values of gate voltage. Assume that we have a model for calculating simulated values of the measured data points, and let these simulated values be denoted by $s_1, \ldots, s_n$. We define the least-squares, root mean square (RMS) error as

$$\text{Error}_{\text{rms}} = \left[\frac{\sum_{i=1}^{n} \left\{ \text{weight}_i \left(s_i - m_i \right) \right\}^2}{\sum_{i=1}^{n} \left\{ \text{weight}_i m_i \right\}^2} \right]^{1/2} \tag{13.1}$$

where a weighting term is included for each data point. The goal is to have the simulated data match the measured data as closely as possible, which means we want to minimize the RMS error. Actually, what we have called the RMS error is really the relative RMS error, but the two terms are used synonymously. There is another way of expressing the error, called the absolute RMS error, defined as follows:

$$\text{Error}_{\text{rms}} = \left[\frac{\sum_{i=1}^{n} \left\{ \text{weight}_i \left(s_i - m_i \right) \right\}^2}{\sum_{i=1}^{n} \left\{ \text{weight}_i m_{\min} \right\}^2} \right]^{1/2} \tag{13.2}$$

where we have used the term $m_{\min}$ in the denominator to represent some minimum value of the measured data. The absolute RMS error is usually used when the measured values approach zero to avoid problems with small or zero denominators in (13.1). For everything that follows, we consider only the relative RMS error. The best result is obtained by combining the relative RMS formula with the absolute RMS formula by taking the maximum of the denominator from (13.1) or (13.2).

We have a simple expression for calculating the simulated data points, s_i, in terms of the input variable, v, and a number of model parameters, $p_1, \ldots, p_m$. That is,

$$s_i = f\left(v_i, p_1, \ldots, p_m \right) \tag{13.3}$$

where f is some function. Minimizing the RMS error function is equivalent to minimizing its square. Also, we can ignore the term in the denominator of (13.1) as concerns minimizing, because it is a normalization term. In this spirit, we can define a new error term,

$$\text{Error} = \left(\text{Error}_{\text{rms}} \right)^2 \left[\sum_{i=1}^{n} \left\{ \text{weight}_i m_i \right\}^2 \right] \tag{13.4}$$

and claim that minimizing Error is equivalent to minimizing Error_{rms}. To minimize Error, we set all partial derivatives of it with respect to each model parameter equal to zero; that is, write

$$\frac{\partial(\text{Error})}{\partial p_j} = 0, \qquad \text{for } j = 1, \ldots, m \tag{13.5}$$

Then solve the above equations for the value of p_j.

Least-Square Curve Fitting (Numerical)

For almost all practical applications we are forced to do least-squares curve fitting numerically, because the analytic solutions as previously discussed are not obtainable in closed form. What we are calling least-squares curve fitting is more generally known as nonlinear optimization. Many fine references on this topic are available. We refer the reader to [Gill et al., 1981] for details.

Extraction (as Opposed to Optimization)

The terms "extraction" and "optimization" are, unfortunately, used interchangeably in the semiconductor industry; however, strictly speaking, they are not the same. By optimization, we mean using generalized least-squares curve fitting methods such as the Levenberg-Marquardt algorithm [Gill et al., 1981] to find a set of model parameters. By extraction, we mean any technique that does not use general least-squares fitting methods. This is a somewhat loose interpretation of the term extraction. The main point is that we write the equations we want and then solve them by whatever approximations we choose, as long as these approximations allow us to get the extracted results in closed form. This is parameter extraction.

Extraction vs. Optimization

Extraction has the advantage of being much faster than optimization, but it is not always as accurate. It is also much harder to supply extraction routines for models that are being developed. Each time you make a change in the model, you must make suitable changes in the corresponding extraction routine. For optimization, however, no changes are necessary other than the change in the model itself, because least-squares curve fitting routines are completely general. Also, if anything goes wrong in the extraction algorithm (and no access to the source code is available), almost nothing can be done to correct the problem. With optimization, one can always change the range of data, weighting, upper and lower bounds, etc. A least-squares curve fitting program can be steered toward a correct solution.

Novices at device characterization find least-squares curve fitting somewhat frustrating because a certain amount of user intervention and intuition is necessary to obtain the correct results. These beginners prefer extraction methods because they do not have to do anything. However, after being burned by extraction routines that do not work, a more experienced user will usually prefer the flexibility, control, and accuracy that optimization provides.

Commercial software is available that provides both extraction and optimization together. The idea here is to first use extraction techniques to make reasonable initial guesses and then use these results as a starting point for optimization, because optimization can give very poor results if poor initial guesses for the parameters are used. Nothing is wrong with using extraction techniques to provide initial guesses for optimization, but for an experienced user this is rarely necessary, assuming that the least-squares curve fitting routine is robust (converges well) and the experienced user has some knowledge of the process under characterization. Software that relies heavily on extraction may do so because of the nonrobustness of its optimizer.

These comments apply when an experienced user is doing optimization locally, not globally. For global optimization (a technique we do not recommend), the above comparisons between extraction and optimization are not valid. The following section contains more detail about local vs. global optimization.

Strategies: General Discussion

The most naive way of using an optimization program would be to take all the measured data for all devices, put them into one big file, and fit to all these data with all model parameters simultaneously. Even for a very high quality, robust optimization program the chances of this method converging are slight. Even if the program does converge, it is almost certain that the values of the parameters will be very unphysical. This kind of approach is an extreme case of global optimization. We call any optimization technique that tries to fit with parameters to data outside their region of applicability a global approach. That is, if we try to fit to saturation

region data with linear region parameters such as threshold voltage, mobility, etc., we are using a global approach. In general, we advise avoiding global approaches, although in the strategies described later, sometimes the rules are bent a little.

Our recommended approach is to fit subsets of relevant parameters to corresponding subsets of relevant data in a way that makes physical sense. For example, in the MOS level 3 model, VT0 is defined as the threshold voltage of a long, wide transistor at zero back-bias. It does not make sense to use this parameter to fit to a short channel transistor, or to fit at nonzero back-bias values, or to fit to anywhere outside the linear region. In addition, subsets of parameters should be obtained in the proper order so that those obtained at a later step do not affect those obtained at earlier steps. That is, we would not obtain saturation region parameters before we have obtained linear region parameters because the values of the linear region parameters would influence the saturation region fits; we would have to go back and reoptimize on the saturation region parameters after obtaining the linear region parameters. Finally, never use optimization to obtain a parameter value when the parameter can be measured directly. For example, the MOS oxide thickness, TOX, is a model parameter, but we would never use optimization to find it. Always measure its value directly on a large oxide capacitor provided on the test chip. The recommended procedure for proper device characterization follows:

1. Have all the appropriate structures necessary on your test chip. Without this, the job cannot be performed properly.
2. Always measure whatever parameters are directly measurable. Never use otpimization for these.
3. Fit the subset of parameters to corresponding subsets of data, and do so in physically meaningful ways.
4. Fit parameters in the proper order so that those obtained later do not affect those obtained previously. If this is not possible, iteration may be necessary.

Naturally, a good strategy cannot be mounted if one is not intimately familiar with the model used. There is no substitute for learning as much about the model as possible. Without this knowledge, one must rely on strategies provided by software vendors, and these vary widely in quality.

Finally, no one can provide a completely general strategy applicable to all models and all process technologies. At some point the strategy must be tailored to suit the available technology and circuit performance requirements. This not only requires familiarity with the available device models, but also information from the circuit designers and process architects.

MOS DC Models

Available MOS Models

A number of MOS models have been provided over time with the original circuit simulation program, SPICE. In addition, some commercially available circuit simulation programs have introduced their own proprietary models, most notably HSPICE.[1] This section is concentrated on the standard MOS models provided by UC Berkeley's SPICE, not only because they have become the standard models used by all circuit simulation programs, but also because the proprietary models provided by commercial vendors are not well documented and no source code is available for these models to investigate them thoroughly.

MOS Levels 1, 2, and 3. Originally, SPICE came with three MOS models known as level 1, level 2, and level 3. The level 1 MOS model is a very crude first-order model that is rarely used. The level 2 and level 3 MOS models are extensions of the level 1 model and have been used extensively in the past and present [Vladimirescu and Liu, 1980]. These two models contain about 15 DC parameters each and are usually considered useful for digital circuit simulation down to 1 μm channel length technologies. They can fit the drain current for wide transistors of varying length with reasonable accuracy (about 5% RMS error), but have very little advanced fitting capability for analog application. They have only one parameter for fitting the subthreshold region, and no parameters for fitting the derivative of drain current with respect to drain voltage, G_{ds} (usually considered critical for analog applications). They also have no ability to vary the mobility degradation with back-bias, so the fits to I_{ds} in the saturation region at high back-bias are not very good. Finally, these models do not interpolate well over device

[1]HSPICE is a commercially available, SPICE-like circuit simulation program from Meta Software, Campbell, CA.

geometry; e.g., if a fit it made to a wide-long device and a wide-short device, and then one observes how the models track for lengths between these two extremes, they usually do not perform well. For narrow devices they can be quite poor as well. Level 3 has very little practical advantage over level 2, although the level 2 model is proclaimed to be more physically based, whereas the level 3 model is called semiempirical. If only one can be used, perhaps level 3 is slightly better because it runs somewhat faster and does not have quite such an annoying kink in the transition region from linear to saturation as does level 2.

Berkeley Short-Channel Igfet Model (BSIM). To overcome the many short-comings of level 2 and level 3, the BSIM and BSIM2 models were introduced. The most fundamental difference between these and the level 2 and 3 models is that BSIM and BSIM2 use a different approach to incorporating the geometry dependence [Ouster et al., 1988; Jeng et al., 1987]. In level 2 and 3 the geometry dependence is built directly into the model equations. In BSIM and BSIM2 each parameter (except for a very few) is written as a sum of three terms

$$\text{Parameter} \;-\; \text{Par}_0 + \frac{\text{Par}_L}{L_{\text{eff}}} + \frac{\text{Par}_W}{W_{\text{eff}}}, \tag{13.6}$$

where Par_0 is the zero-order term, Par_L accounts for the length dependence of the parameter, Par_W accounts for the width dependence, and L_{eff} and W_{eff} are the effective channel width and length, respectively. This approach has a large influence on the device characterization strategy, as discussed later. Because of this tripling of the number of parameters and for other reasons as well, the BSIM model has about 54 DC parameters and the BSIM2 model has over 100.

The original goal of the BSIM model was to fit better than the level 2 and 3 models for submicron channel lengths, over a wider range of geometries, in the subthreshold region, and for nonzero back-bias. Without question, BSIM can fit individual devices better than level 2 and level 3. It also fits the subthreshold region better and it fits better for nonzero back-biases. However, its greatest shortcoming is its inability to fit over a large geometry variation. This occurs because (13.6) is a truncated Taylor series in $1/L_{\text{eff}}$ and $1/W_{\text{eff}}$ terms, and in order to fit better over varying geometries, higher power terms in $1/L_{\text{eff}}$ and $1/W_{\text{eff}}$ are needed. In addition, no provision was put into the BSIM model for fitting G_{ds}, so its usefulness for analog applications is questionable. Many of the BSIM model parameters are unphysical, so it is very hard to understand the significance of these model parameters. This has profound implications for generating skew models (fast and slow models to represent the process corners) and for incorporating temperature dependence. Another flaw of the BSIM model is its wild behavior for certain values of the model parameters. If model parameters are not specified for level 2 or 3, they will default to values that will at least force the model to behave well. For BSIM, not specifying certain model parameters, setting them to zero, or various combinations of values can cause the model to become very ill-behaved.

BSIM2. The BSIM2 model was developed to address the shortcomings of the BSIM model. This was basically an extension of the BSIM model, removing certain parameters that had very little effect, fixing fundamental problems such as currents varying the wrong way as a function of certain parameters, adding more unphysical fitting parameters, and adding parameters to allow fitting G_{ds}. BSIM2 does fit better than BSIM, but with more than twice as many parameters as BSIM, it should. However, it does not address the crucial problem of fitting large geometry variations. Its major strengths over BSIM are fitting the subthreshold region better, and fitting G_{ds} better. Most of the other shortcomings of BSIM are also present in BSIM2, and the large number of parameters in BSIM2 makes it a real chore to use in device characterization.

BSIM3. Realizing the shortcomings of BSIM2, UC Berkeley recently introduced the BSIM3 model. This is an unfortunate choice of name because it implies BSIM3 is related to BSIM and BSIM2. In reality, BSIM3 is an entirely new model that in some sense is related more to level 2 and 3 than BSIM or BSIM2. The BSIM3 model abandons the length and width dependence approach of BSIM and BSIM2, preferring to go back to incorporating the geometry dependence directly into the model equations, as do level 2 and 3. In addition, BSIM3 is a more physically based model, with about 30 fitting parameters (the model has many more parameters, but

the majority of these can be left untouched for fitting), making it more manageable, and it has abundant parameters for fitting G_{ds}, making it a strong candidate for analog applications.

It is an evolving model, so perhaps it is unfair to criticize it at this early stage. Its greatest shortcoming is, again, the inability to fit well over a wide range of geometries. It is hoped that future modifications will address this problem. In all fairness, however, it is a large order to ask a model to be physically based, have not too many parameters, be well behaved for all default values of the parameters, fit well over temperature, fit G_{ds}, fit over a wide range of geometries, and still fit individual geometries as well as a model with over 100 parameters, such as BSIM2. Some of these features were compromised in developing BSIM3.

Proprietary Models. A number of other models are available from commercial circuit simulator vendors, the literature, etc. Some circuit simulators also offer the ability to add a researcher's own models. In general, we caution against using proprietary models, especially those which are supplied without source code and complete documentation. Without an intimate knowledge of the model equations, it is very difficult to develop a good device characterization strategy. Also, incorporating such models into device characterization software is almost impossible. To circumvent this problem, many characterization programs have the ability to call the entire circuit simulator as a subroutine in order to exercise the proprietary model subroutines. This can slow program execution by a factor of 20 or more, seriously impacting the time required to characterize a technology. Also, if proprietary models are used without source code, the circuit simulator results can never be checked against other circuit simulators. Therefore, we want to stress the importance of using standard models. If these do not meet the individual requirements, the next best approach is to incorporate a proprietary model whose source code one has access to. This requires being able to add the individual model not only to circuit simulators, but also to device characterization programs; it can become a very large task.

MOS Level 3 Extraction Strategy in Detail

The strategy discussed here is one that we consider to be a good one, in the spirit of our earlier comments. Note, however, that this is not the only possible strategy for the level 3 model. The idea here is to illustrate basic concepts so that this strategy can be refined to meet particular individual requirements.

In order to do a DC characterization, the minimum requirement is one each of the wide-long, wide-short, and narrow-long devices. We list the steps of the procedure and then discuss them in more detail.

STEP 1. Fit the wide-long device in the linear region at zero back-bias at V_{gs} values above the subthreshold region, with parameters VT0 (threshold voltage), U0 (mobility), and THETA (mobility degradation with V_{gs}).

STEP 2. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VT0, LD (length encroachment), and THETA. When finished with this step, replace VT0 and THETA with the values from step 1, but keep the value of LD.

STEP 3. Fit the narrow-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VT0, DW (width encroachment), and THETA. When finished with this step, replace VT0 and THETA with the values from step 1, but keep the value of DW.

STEP 4. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters RS and RD (source and drain series resistance).

STEP 5. Fit the wide-long device in the linear region at all back-biases, at V_{gs} values above the subthreshold region, with parameter NSUB (channel doping affects long channel variation of threshold voltage with back-bias).

STEP 6. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameter XJ (erroneously called the junction depth; affects short-channel variation of threshold voltage with back-bias).

STEP 7. Fit the narrow-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameter DELTA (narrow channel correction to threshold voltage).

STEP 8. Fit the wide-short device in the saturation region at zero back-bias (or all back-biases) with parameters VMAX (velocity saturation), KAPPA (saturation region slope fitting parameter), and ETA (V_{ds} dependence of threshold voltage).

STEP 9. Fit the wide-short device in the subthreshold region at whatever back-bias and drain voltage is appropriate (usually zero back-bias and low V_{ds}) with parameter NES (subthreshold slope fitting parameter). One may need to fit with VT0 also and then VT0 is replaced after this step with the value of VT0 obtained from step 1.

This completes the DC characterization steps for the MOS level 3 model. One would then go on to do the junction and overlap capacitance terms (discussed later). Note that this model has no parameters for fitting over temperature, although temperature dependence is built into the model that the user cannot control.

In Step 1 VT0, U0, and THETA are defined in the model for a wide-long device at zero back-bias. They are zero-order fundamental parameters without any short or narrow channel corrections. We therefore fit them to a wide-long device. It is absolutely necessary that such a device be on the test chip. Without it, one cannot obtain these parameters properly. The subthreshold region must be avoided also because these parameters do not control the model behavior in subthreshold.

In Step 2 we use LD to fit the slope of the linear region curve, holding U0 fixed from step 1. We also fit with VT0 and THETA because without them the fitting will not work. However, we want only the value of LD that fits the slope, so we throw away VT0 and THETA, replacing them with the values from step 1.

Step 3 is the same as step 2, except that we are getting the width encroachment instead of the length.

In Step 1 the value of THETA that fits the high V_{gs} portion of the wide-long device linear region curve was found. Because the channel length of a long transistor is very large, the source and drain series resistances have almost no effect here, but for a short-channel device, the series resistance will also affect the high V_{gs} portion of the linear region curve. Therefore, in step 4 we fix THETA from step 1 and use RS and RD to fit the wide-short device in the linear region, high V_{gs} portion of the curve.

In Step 5 we fit with NSUB to get the variation of threshold voltage with back-bias. We will get better results if we restrict ourselves to lower values of V_{gs} (but still above subthreshold) because no mobility degradation adjustment exists with back-bias, and therefore the fit may not be very good at higher V_{gs} values for the nonzero back-bias curves.

Step 6 is just like step 5, except we are fitting the short-channel device. Some people think that the value of XJ should be the true junction depth. This is not true. The parameter XJ is loosely related to the junction depth, but XJ is really the short-channel correction to NSUB. Do not be surprised if XJ is not equal to the true junction depth.

Step 7 uses DELTA to make the narrow channel correction to the threshold voltage. This step is quite straightforward.

Step 8 is the only step that fits in the saturation region. The use of parameters VMAX and KAPPA is obvious, but one may question using ETA to fit in the saturation region. The parameter ETA adjusts the threshold voltage with respect to V_{ds}, and as such one could argue that ETA should be used to fit measurements of I_{ds} sweeping V_{gs} and stepping V_{ds} to high values. In doing so, one will corrupt the fit in the saturation region, and usually we want to fit the saturation region better at the expense of the linear region.

Step 9 uses NFS to fit the slope of the $\log(I_{ds})$ vs. V_{gs} curve. Often the value of VT0 obtained from step 1 will prevent one from obtaining a good fit in the subthreshold region. If this happens, try fitting with VT0 and NFS, but replacing the final value of VT0 with that from step 1 at the end, keeping only NFS from this final step.

The above steps illustrate the concepts of fitting relevant subsets of parameters to relevant subsets of data to obtain physical values of the parameters, as well as fitting parameters in the proper order so that those obtained in the later steps will affect those obtained in earlier steps minimally. Please refer to Figs. 13.13 and 13.14 for how the resulting fits typically appear (all graphs showing model fits are provided by the device modeling software package Aurora, from Technology Modeling Associates, Inc., Palo Alto, CA).

An experienced person may notice that we have neglected some parameters. For example, we did not use parameters KP and GAMMA. This means KP will be calculated from U0, and GAMMA will be calculated from NSUB. In a sense U0 and NSUB are more fundamental parameters than KP and GAMMA. For example, KP

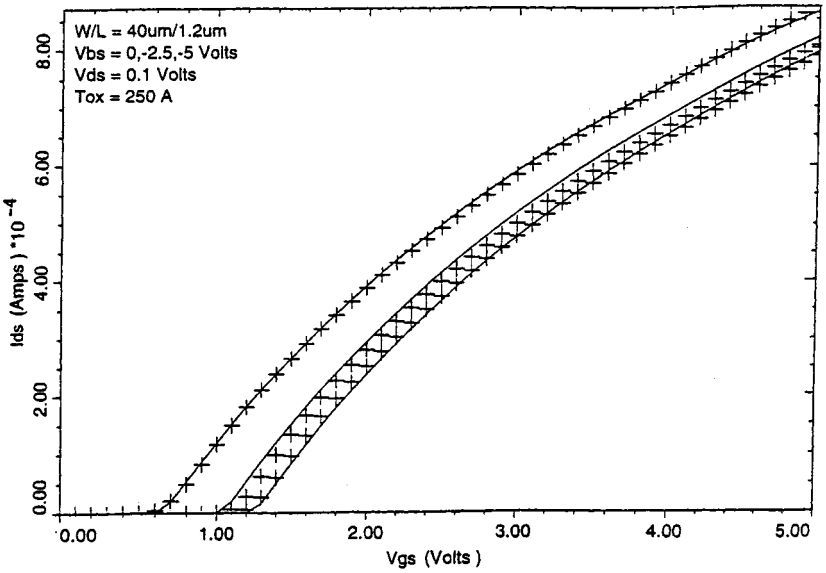

FIGURE 13.13 Typical MOS level 3 linear region measured and simulated plots at various V_{bs} values for a wide-short device.

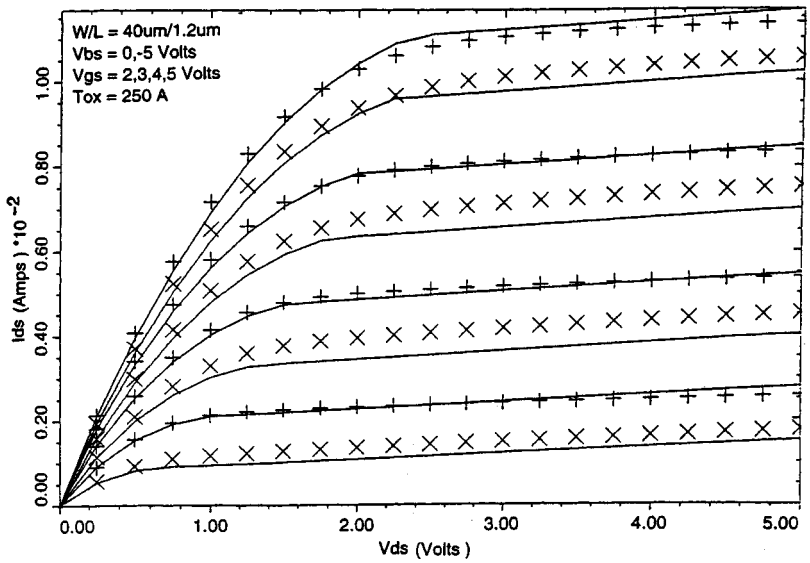

FIGURE 13.14 Typical MOS level 3 saturation region measured and simulated plots at various V_{gs} and V_{bs} values for a wide-short device.

depends on U0 and TOX; GAMMA depends on NSUB and TOX. If one is trying to obtain skew models, it is much more advantageous to analyze statistical distributions of parameters that depend on a single effect than those that depend on multiple effects. KP will depend on mobility and oxide thickness; U0 is therefore a more fundamental parameter. We also did not obtain parameter PHI, so it will be calculated from NSUB. The level 3 model is very insensitive to PHI, so using it for curve fitting is pointless. This illustrates the importance of being very familiar with the model equations. The kind of judgments described here cannot be made without such knowledge.

Test Chip Warnings. The following hints will greatly assist in properly performing device characterization.

1. Include a wide-long device; without this, the results will not be physically correct.
2. All MOS transistors with the same width should be drawn with their sources and drains identical. No difference should be seen in the number of source/drain contacts, contact spacing, source/drain contact overlap, poly gate to contact spacing, etc.
3. Draw devices in pairs. That is, if the wide-long device is W/L = 20/20, make the wide-short device the same width as the wide-long device; e.g., make the short device 20/1, not 19/1. If the narrow-long device is 2/20, make the narrow-short device of the same width; i.e., make is 2/1, not 3/1, and similarly for the lengths. (Make the wide-short and the narrow-short devices have the same length.)

BSIM Extraction Strategy in Detail

All MOS model strategies have basic features in common; namely, fit the linear region at zero back-bias to get the basic zero-order parameters, fit the linear region at nonzero back-bias, fit the saturation region at zero back-bias, fit the saturation region at nonzero back-bias, and then fit the subthreshold region. It is possible to extend the type of strategy we covered for level 3 to the BSIM model, but that is not the way BSIM was intended to be used.

The triplet sets of parameters for incorporating geometry dependence into the BSIM model, (13.6), allow an alternate strategy. We obtain sets of parameters without geometry dependence by fitting to individual devices without using the Par_L and Par_W terms. We do this for each device size individually. This produces sets of parameters relevant to each individual device. So, for device number 1 of width W(1) and length L(1) we would have a value for the parameter VFB which we will call VFB(1); for device number n of width W(n) and length L(n) we will have VFB(n). To get the Par_0, Par_L, and VFB_W we fit to the "data points" VFB(1), . . .,VFB(n) with parameters VFB_0, VFB_L, and VFB_W using (13.6) where L_{eff} and W_{eff} are different for each index, 1 through n.

Note that as L and W become very large, the parameters must approach Par_0. This suggests that we use the parameter values for the wide-long device as the Par_0 terms and only fit the other geometry sizes to get the Par_L and Par_W terms. For example, if we have obtained VFB(1) for our first device which is our wide-long device, we would set VFB_0 = VFB(1), and then fit to VFB(2), . . .,VBF(n) with parameters VFB_L and VFB_W, and similarly for all the other triplets of parameters. In order to use a general least-squares optimization program in this way the software must be capable of specifying parameters as targets, as well as measured data points.

We now list a basic strategy for the BSIM model:

STEP 1. Fit the wide-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB (flatband voltage), MUZ (mobility), and U0 (mobility degradation), with DL (length encroachment) and DW (width encroachment) set to zero.

STEP 2. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB, U0, and DL.

STEP 3. Fit the narrow-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB, U0, and DW.

STEP 4. Refit the wide-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB, MUZ, and U0, now that DL and DW are known.

STEP 5. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB, RS, and RD. When finished, replace the value of VFB with the value found in step 4.

STEP 6. Fit the wide-long device in the linear region at all back-biases, at V_{gs} values above the subthreshold region, with parameters K1 (first-order body effect), K2 (second-order body effect), U0, and X2U0 (V_{bs} dependence of U0).

STEP 7. Fit the wide-long device in the saturation region at zero back-bias with parameters U0, ETA (V_{ds} dependence of threshold voltage), MUS (mobility in saturation), U1 (V_{ds} dependence of mobility), and X3MS (V_{ds} dependence of MUS).

STEP 8. Fit the wide-long device in the saturation region at all back-biases with parameter X2MS (V_{bs} dependence of MUS).

STEP 9. Fit the wide-long device in the subthreshold region at zero back-bias and low V_{ds} value with parameter N0; then fit the subthreshold region nonzero back-bias low V_{ds} data with parameter NB; and finally fit the subthreshold region data at higher V_{ds} values with parameter ND. Or, fit all the subthreshold data simultaneously with parameters N0, NB, and ND.

Repeat Steps 6 through 10 for all the other geometries, with the result of sets of geometry-independent parameters for each different size device. Then follow the procedure described previously for obtaining the geometry-dependent terms Par_0, Par_L, and Par_W.

In the above strategy we have omitted various parameters either because they have minimal effect or because they have the wrong effect and were modified in the BSIM2 model. Because of the higher complexity of the BSIM model over the level 3 model, many more strategies are possible than the one just listed. One may be able to find variations of the above strategy that suit the individual technology better. Whatever modifications are made, the general spirit of the above strategy probably will remain.

Some prefer to use a more global approach with BSIM, fitting to measured data with Par_L and Par_W terms directly. Although this is certainly possible, it is definitely not a recommended approach. It represents the worst form of blind curve fitting, with no regard for physical correctness or understanding. The BSIM model was originally developed with the idea of obtaining the model parameters via extraction as opposed to optimization. In fact, UC Berkeley provides software for obtaining BSIM parameters using extraction algorithms, with no optimization at all. As stated previously, this has the advantage of being relatively fast and easy. Unfortunately, it does not always work. One of the major drawbacks of the BSIM model is that certain values of the parameters can cause the model to produce negative values of G_{ds} in saturation. This is highly undesirable, not only from a modeling standpoint, but also because of the convergence problems it can cause in circuit simulators. If an extraction strategy is used that does not guarantee non-negative G_{ds}, very little can be done to fix the problem when G_{ds} becomes negative. Of course, the extraction algorithms can be modified, but this is difficult and time consuming. With optimization strategies, one can weight the fitting for G_{ds} more heavily and thus force the model to produce non-negative G_{ds}. We, therefore, do not favor extraction strategies for BSIM, or anything else. As with most things in life, minimal effort provides minimal rewards.

BSIM2 Extraction Strategy

We do not cover the BSIM2 strategy in complete detail because it is very similar to the BSIM strategy, except more parameters are involved. The major difference in the two models is the inclusion of extra terms in BSIM2 for fitting G_{ds} (refer to Fig. 13.15, which shows how badly BSIM typically fits $1/G_{ds}$ vs. V_{ds}). Basically, the BSIM2 strategy follows the BSIM strategy for the extraction of parameters not related to G_{ds}. Once these have been obtained, the last part of the strategy includes steps for fitting to G_{ds} with parameters that account for channel length modulation and hot electron effects. The way this proceeds in BSIM2 is to fit I_{ds} first, and then parameters MU2, MU3, and MU4 are used to fit to $1/G_{ds}$ vs. V_{ds} curves for families of V_{gs} and V_{bs}. This can be a very time consuming and frustrating experience, because fitting to $1/G_{ds}$ is quite difficult. Also, the equations describing how G_{ds} is modeled with MU2, MU3, and MU4 are very unphysical and the interplay between the parameters makes fitting awkward. The reader is referred to Fig. 13.16, which shows how BSIM2 typically fits $1/G_{ds}$ vs. V_{ds}. BSIM2 is certainly better than BSIM but it has its own problems fitting $1/G_{ds}$.

BSIM3 Comments

The BSIM3 model is very new and will undoubtedly change in the future [Huang et al., 1993]. We will not list a BSIM3 strategy here, but focus instead on the features of the model that make it appealing for analog modeling.

BSIM3 has terms for fitting G_{ds} that relate to channel length modulation, drain-induced barrier lowering, and hot electron effects. They are incorporated completely differently from the G_{ds} fitting parameters of BSIM2. In BSIM3 these parameters enter through a generalized Early voltage relation, with the drain current in saturation written as

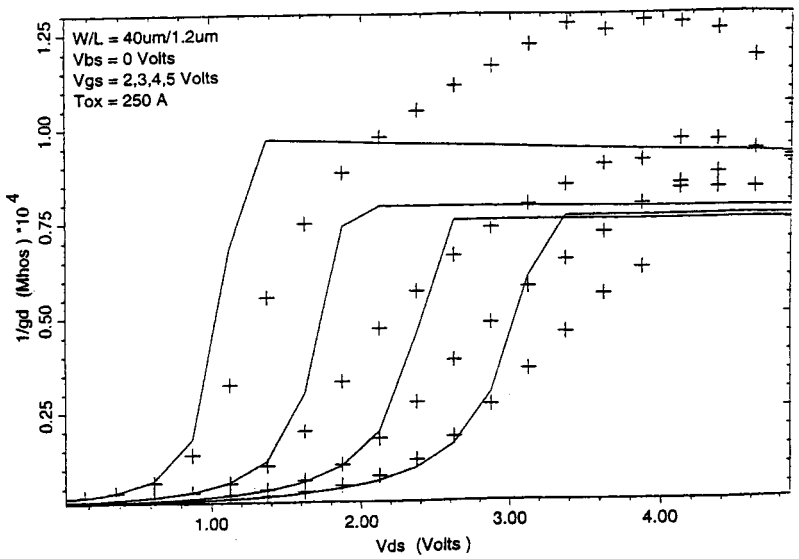

FIGURE 13.15 Typical BSIM $1/G_d$ vs. V_{ds} measured and simulated plots at various V_{gs} values for a wide-short device.

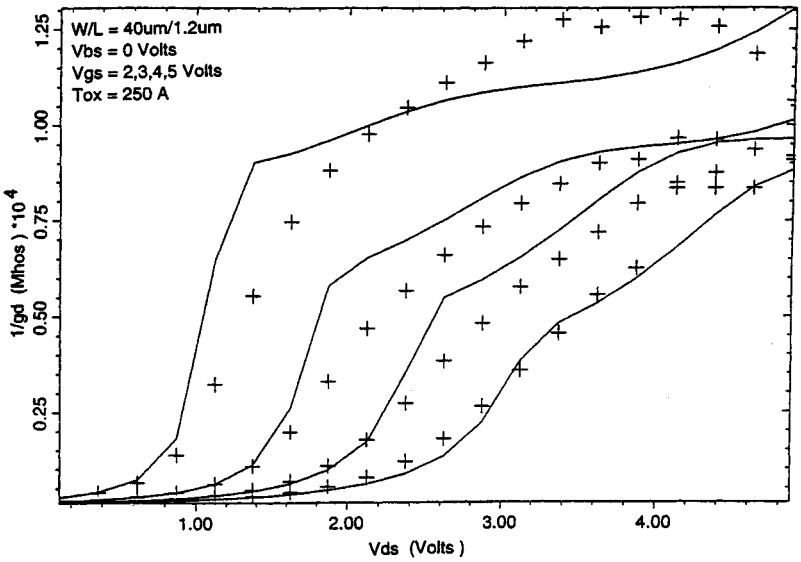

FIGURE 13.16 Typical BSIM2 $1/G_d$ vs. V_{ds} measured and simulated plots at various V_{gs} values for a wide-short device.

$$I_{ds} = I_{d\,\mathrm{sat}}\left[1 + \frac{\left(V_{ds} - V_{d\,\mathrm{sat}}\right)}{V_A}\right] \tag{13.7}$$

where V_A is a generalized Early voltage made up of three terms as

$$\frac{1}{V_A} = \frac{1}{V_{\mathrm{ACLM}}} + \frac{1}{V_{\mathrm{ADIBL}}} + \frac{1}{V_{\mathrm{AHCE}}} \tag{13.8}$$

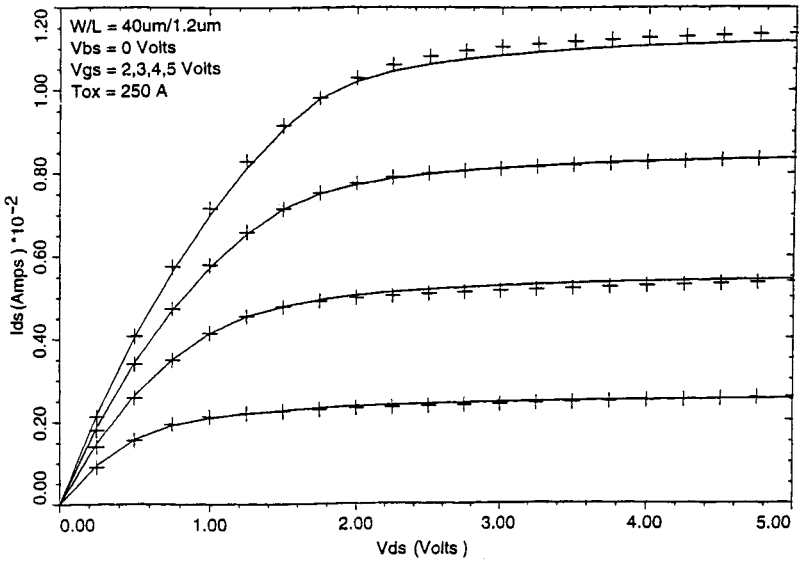

FIGURE 13.17 Typical BSIM3 saturation region measured and simulated plots at various V_{gs} values for a wide-short device.

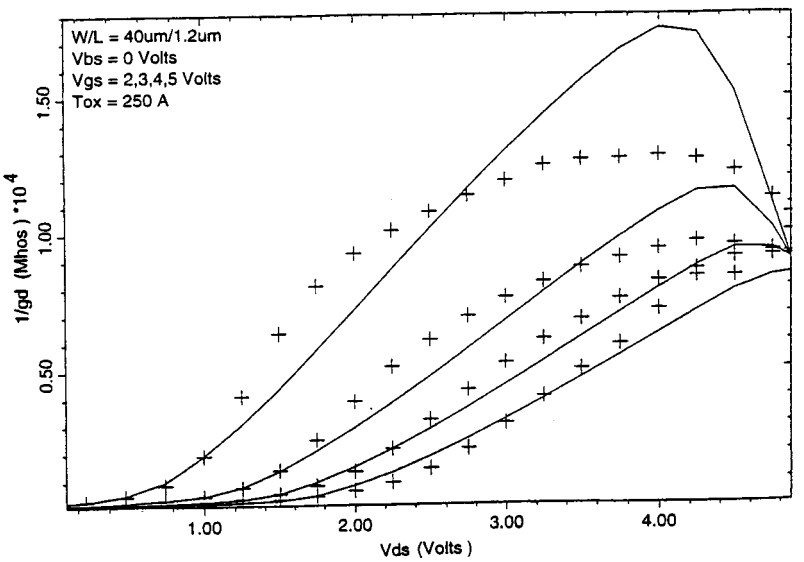

FIGURE 13.18 Typical BSIM3 $1/G_d$ vs. V_{ds} measured and simulated plots at various V_{gs} values for a wide-short device.

with the terms in (13.8) representing generalized Early voltages for channel length modulation (CLM), drain-induced barrier lowering (DIBL), and hot carrier effects (HCE). This formulation is more physically appealing than the one used in BSIM2, making it easier to fit $1/G_{ds}$ vs. V_{ds} curves with BSIM2. Figures 13.17 and 13.18 show how BSIM3 typically fits I_{ds} vs. V_{ds} and $1/G_{ds}$ vs. V_{ds}.

Most of the model parameters for BSIM3 have physical significance so they are obtained in the spirit of the parameters for the level 2 and 3 models. The incorporation of temperature dependence is also easier in BSIM3 because the parameters are more physical. All this, coupled with the fact that about 30 parameters exist for BSIM3 as compared to over 100 for BSIM2, makes BSIM3 a logical choice for analog design. However, BSIM3 is evolving, and shortcomings to the model may still exist that may be corrected in later revisions.

Which MOS Model To Use?

Many MOS models are available in circuit simulators, and the novice is bewildered as to which model is appropriate. No single answer exists, but some questions must be asked before making a choice:

1. What kind of technology am I characterizing?
2. How accurate a model do I need?
3. Do I want to understand the technology?
4. How important are the skew model files (fast and slow parameter files)?
5. How experienced am I? Do I have the expertise to handle a more complicated model?
6. How much time can I spend doing device characterization?
7. Do I need to use this model in more than one circuit simulator?
8. Is the subthreshold region important?
9. Is fitting G_{ds} important?

Let us approach each question with regard to the models available. If the technology is not submicron, perhaps a simpler model such as level 3 is capable of doing everything needed. If the technology is deep submicron, then use a more complicated model such as BSIM, BSIM2, or BSIM3. If high accuracy is required, then the best choice is BSIM3, mainly because it is more physical than all the other models and is capable of fitting better.

For a good physical understanding of the process being characterized. BSIM and BSIM2 are not good choices. These are the least physically based of all the models. The level 2 and 3 models have good physical interpretation for most of the parameters, although they are relatively simple models. BSIM3 is also more physically based, with many more parameters than level 2 or 3, so it is probably the best choice.

If meaningful skew models need to be generated, then BSIM and BSIM2 are very difficult to use, again, because of their unphysical parameter sets. Usually, the simplest physically based model is the best for skew model generation. A more complicated physically based model such as BSIM3 may also be difficult to use for skew model generation.

If the user is inexperienced, none of the BSIM models should be used until the user's expertise improves. Our advice is to practice using simpler models before tackling the harder ones.

If time is critical, the simpler models will definitely be much faster for use in characterization. The more complicated models require more measurements over wider ranges of voltages as well as wider ranges of geometries. This, coupled with the larger number of parameters, means they will take some time with which to work. The BSIM2 model will take longer than all the rest, especially if the G_{ds} fitting parameters are to be used.

The characterization results may need to be used in more than one circuit simulator. For example, if a foundry must supply models to various customers, they may be using different circuit simulators. In this case proprietary models applicable to a single circuit simulator should not be used. Also, circuit designers may want to check the circuit simulation results on more than one circuit simulator. It is better to use standard Berkeley models (level 2, level 3, BSIM, BSIM2, and BSIM3) in such cases.

If the subthreshold region is important, then level 2 or level 3 cannot be used, and probably not even BSIM; BSIM2 or BSIM3 must be used instead. These two models have enough parameters for fitting the subthreshold region.

If fitting G_{ds} is important, BSIM2 and BSIM3 are, again, the only choices. None of the other models have enough parameters for fitting G_{ds}.

Finally, if a very unusual technology is to be characterized, none of the standard models may be appropriate. In this case commercially available specialized models or the user's own models must be used. This will be a large task, so the goals must justify the effort.

Skew Parameter Files

This chapter discussed obtaining model parameters for a single wafer, usually one that has been chosen to represent a typical wafer for the technology being characterized. The parameter values obtained from this wafer correspond to a typical case. Circuit designers also want to simulate circuits with parameter values representing the extremes of process variation, the so-called fast and slow corners, or skew parameter files. These represent the best and worst case of the process variation over time.

Skew parameter values are obtained usually by tracking a few key parameters, measuring many wafers over a long period of time. The standard deviation of these key parameters is found and added to or subtracted from the typical parameter values to obtain the skew models. This method is extremely crude and will not normally produce a realistic skew model. It will almost always overestimate the process spread, because the various model parameters are not independent—they are correlated.

Obtaining realistic skew parameter values, taking into account all the subtle correlations between parameters, is more difficult. In fact, skew model generation is often more an art than a science. Many attempts have been made to utilize techniques from a branch of statistics called multivariate analysis [Dillon and Goldstein, 1984]. In this approach principal component or factor analysis is used to find parameters that are linear combinations of the original parameters. Only the first few of these new parameters will be kept; the others will be discarded because they have less significance. This new set will have fewer parameters than the original set and therefore will be more manageable in terms of finding their skews. The user sometimes must make many choices in the way the common factors are utilized, resulting in different users obtaining different results.

Unfortunately, a great deal of physical intuition is often required to use this approach effectively. To date, we have only seen it applied to the simpler MOS models such as level 3. It is not known if this is a viable approach for a much more complicated model such as BSIM2 [Power et al., 1993].

The world's most powerful digital signal processor, the TMS320C6x, performs at an unprecedented 1600 million-instructions-per-second (MIPS). MIPS are the key measure of a chip's capacity for executing signal processing tasks. This DSP delivers ten times the MIPS performance of any other DSP in history. The TMS320C6x is the first programmable DSP to adopt an advanced Very Long Instruction Word (VLIW) architecture which increases the parallel execution of instructions by packing up to eight 32-bit instructions into a single cycle. The VLIW architecture, combined with the most efficient C compiler ever developed, dramatically improves performance and helps reduce the code development time.

The computing power of the TMS320C6x DSP will change the way new products are designed. The future generations of the TMS320C6x DSP will include devices fabricated with a new 0.18-micron, five-level metal process, operating at speeds beyond 250 MHz. (Photo courtesy of Texas Instruments.)

Signal processing was defined at a meeting in 1991 of the National Science Foundation's MIPS (Microelectronics and Information Processing Systems) Advisory Committee as "the extraction of information-bearing attributes from measured data, and any subsequent transformation of those attributes for the purposes of detection, estimation, classification, or waveform synthesis." If we expand this concise definition, we observe that the signals we typically use in signal processing are functions of time, such as temperature measurements, velocity measurements, voltages, blood pressures, earth motion, and speech signals. Most of these signals are initially continuous signals (also called analog signals) which are measured by sensors that convert energy to electricity. Some of the common types of sensors used for collecting data are microphones, which measure acoustic or sound data; seismometers, which measure earth motion; photocells, which measure light intensity; thermistors, which measure temperature; and oscilloscopes, which measure voltage. When we

work with the continuous electrical signals collected by sensors, we often convert the continuous signal to a digital signal (a sequence of values) with a piece of hardware called an analog-to-digital (A/D) converter. Once we have collected the digital signal, we are ready to use the computer to apply digital signal processing (DSP) techniques to it. These DSP techniques can be designed to perform a number of operations such as:

- Removing noise that is distorting the signal, such as static on a communication line.
- Extracting information from the signal, such as the average value and the power in a signal.
- Separating components of the signal, such as the separation of a band of frequencies that represent the television signal for a specific channel.
- Encoding the information in a more efficient way for transmission, such as the encoding of speech signals into digital signals for transmitting across telephone lines.
- Detecting information in a signal, such as the detection of a surface ship in a sonar signal.

These are just a few of the types of operations that can be performed by signal processing techniques. For some applications, an analog or continuous output signal is needed, and thus a digital-to-analog (D/A) converter is used to convert the modified digital signal to a continuous signal. Another device called a transducer can be used to convert the continuous electrical signal to another form; for example, a speaker converts a continuous electrical signal to an acoustical signal.

In this section the variety and diversity of signal processing is presented from a theoretical point of view, from an implementation point of view, and from an applications point of view. The theoretical point of view includes the development of mathematical models and the development of software algorithms and computer simulations to evaluate and analyze the models both with simulated data and with real data. High-level software tools are important in both the development of new theoretical results and in establishing the validity of the results when applied to real data. The applications determine the way in which the theory is implemented; a key element in the implementation of a signal processing technique relates to whether the technique is applied in real-time (or close to real-time) or whether the processing can be handled off-line. Real-time implementation can use VLSI (very large scale integration) techniques, with commercial DSP chips, or it can involve custom design of chips, MCMs (multichip modules), or ASICs (application-specific integrated circuits). The selection of topics in this section covers the three points of view (theoretical, application, implementation) but should not be assumed to include a complete summary of these topics.

Nomenclature

Symbol	Quantity	Unit	Symbol	Quantity	Unit
AG	array gain	dB	$\phi(K)$	sampled degree phase spectrum	
$A(k)$	sampled amplitude spectrum		$G(e^{j\omega})$	spectral gain function	
C	compression rate		H	entropy

14.1 Fourier Transforms

W. Kenneth Jenkins

Introduction

The Fourier transform is a mathematical tool that is used to expand signals into a spectrum of sinusoidal components to facilitate signal analysis and system performance. In certain applications the Fourier transform is used for spectral analysis, or for spectrum shaping that adjusts the relative contributions of different frequency components in the filtered result. In other applications the Fourier transform is important for its ability to decompose the input signal into uncorrelated components, so that signal processing can be more effectively implemented on the individual spectral components. Decorrelating properties of the Fourier transform are important in frequency domain adaptive filtering, subband coding, image compression, and transform coding.

Classical Fourier methods such as the Fourier series and the Fourier integral are used for continuous-time (CT) signals and systems, i.e., systems in which the signals are defined at all values of t on the continuum $-\infty < t < \infty$. A more recently developed set of discrete Fourier methods, including the discrete-time (DT) Fourier transform and the discrete Fourier transform (DFT), are extensions of basic Fourier concepts for DT signals and systems. A DT signal is defined only for integer values of n in the range $-\infty < n < \infty$. The class of DT

Fourier methods is particularly useful as a basis for digital signal processing (DSP) because it extends the theory of classical Fourier analysis to DT signals and leads to many effective algorithms that can be directly implemented on general computers or special-purpose DSP devices.

The Classical Fourier Transform for CT Signals

A CT signal $s(t)$ and its Fourier transform $S(j\omega)$ form a transform pair that are related by Eqs. (14.1) for any $s(t)$ for which the integral (14.1a) converges:

$$S(j\omega) = \int_{-\infty}^{\infty} s(t)e^{-j\omega_t}dt \tag{14.1a}$$

$$s(t) = (1/2\pi)\int_{-\infty}^{\infty} S(j\omega)e^{j\omega_t}d\omega \tag{14.1b}$$

In most literature Eq. (14.1a) is simply called the Fourier transform, whereas Eq. (14.1b) is called the *Fourier integral*. The relationship $S(j\omega) = F\{s(t)\}$ denotes the Fourier transformation of $s(t)$, where $F\{\cdot\}$ is a symbolic notation for the integral operator and where ω is the continuous frequency variable expressed in radians per second. A transform pair $s(t) \leftrightarrow S(j\omega)$ represents a one-to-one invertible mapping as long as $s(t)$ satisfies conditions which guarantee that the Fourier integral converges.

In the following discussion the symbol $\delta(t)$ is used to denote a **CT impulse function** that is defined to be zero for all $t \neq 0$, undefined for $t = 0$, and has unit area when integrated over the range $-\infty < t < \infty$. From Eq. (14.1a) it is found that $F\{\delta(t - t_o)\} = e^{-j\omega t_o}$ due to the well-known sifting property of $\delta(t)$. Similarly, from Eq. (14.1b) we find that $F^{-1}\{2\pi\delta(\omega - \omega_o)\} = e^{j\omega_o t}$, so that $\delta(t - t_o) \leftrightarrow e^{-j\omega t_o}$ and $e^{j\omega_o t} \leftrightarrow 2\pi\delta(\omega - \omega_o)$ are Fourier transform pairs. By using these relationships, it is easy to establish the Fourier transforms of $\cos(\omega_o t)$ and $\sin(\omega_o t)$, as well as many other useful waveforms, many of which are listed in Table 14.1.

The CT Fourier transform is useful in the analysis and design of CT systems, i.e., systems that process CT signals. Fourier analysis is particularly applicable to the design of CT filters which are characterized by Fourier magnitude and phase spectra, i.e., by $|H(j\omega)|$ and $\arg H(j\omega)$, where $H(j\omega)$ is commonly called the frequency response of the filter.

Properties of the CT Fourier Transform

The CT Fourier transform has many properties that make it useful for the analysis and design of linear CT systems. Some of the more useful properties are summarized in this section, while a more complete list of the CT Fourier transform properties is given in Table 14.2. Proofs of these properties are found in Oppenheim et al. [1983] and Bracewell [1986]. Note that $F\{\cdot\}$ denotes the Fourier transform operation, $F^{-1}\{\cdot\}$ denotes the inverse Fourier transform operation, and "$*$" denotes the convolution operation defined as

$$f_1(t) * f_2(t) = \int_{-\infty}^{\infty} f_1(t - t)f_2(t)dt$$

1. *Linearity* (*superposition*): (a and b, complex constants) $F\{af_1(t) + bf_2(t)\} = aF\{f_1(t)\} + bF\{f_2(t)\}$
2. *Time Shifting:* $F\{f(t - t_o)\} = e^{-j\omega t_o}F\{f(t)\}$
3. *Frequency Shifting:* $e^{j\omega_o t}f(t) = F^{-1}\{F(j(\omega - \omega_o))\}$
4. *Time-Domain Convolution:* $F\{f_1(t) * f_2(t)\} = F\{f_1(t)\}F\{f_2(t)\}$
5. *Frequency-Domain Convolution:* $F\{f_1(t)f_2(t)\} = (1/2\pi)F\{f_1(t)\} * F\{f_2(t)\}$
6. *Time Differentiation:* $-j\omega F(j\omega) = F\{d(f(t))/dt\}$
7. *Time Integration:* $$F\left\{\int_{-\infty}^{t} f(t)dt\right\} = (1/j\omega)F(j\omega) + \pi F(0)\delta(\omega)$$

TABLE 14.1 CT Fourier Transform Pairs

Signal	Fourier Transform	Fourier Series Coefficients (if periodic)
$\sum_{k=-\infty}^{+\infty} a_k e^{jk\omega_0 t}$	$2\pi \sum_{k=-\infty}^{+\infty} a_k \delta(\omega - k\omega_0)$	a_k

$x(t) = 1$	$2\pi\delta(\omega)$	$a_0 = 1, \quad a_k = 0, \ k \neq 0$ (has this Forier series representation for any choice of $T_0 > 0$)
Periodic square wave $x(t) = \begin{cases} 1, & \lvert t \rvert < T_1 \\ 0, & T_1 < \lvert t \rvert \leq \frac{T_0}{2} \end{cases}$ and $x(t + T_0) = x(t)$	$\sum_{k=-\infty}^{+\infty} \frac{2 \sin k\omega_0 T_1}{k} \delta(\omega - k\omega_0)$	$\frac{\omega_0 T_1}{\pi} \operatorname{sinc}\left(\frac{k\omega_0 T_1}{\pi}\right) = \frac{\sin k\omega_0 T_1}{k\pi}$
$\sum_{n=-\infty}^{+\infty} \delta(t - nT)$	$\frac{2\pi}{T} \sum_{k=-\infty}^{+\infty} \delta\left(\omega - \frac{2\pi k}{T}\right)$	$a_k = \frac{1}{T}$ for all k
$x(t) = \begin{cases} 1, & \lvert t \rvert < T_1 \\ 0, & \lvert t \rvert > T_1 \end{cases}$	$2T_1 \operatorname{sinc}\left(\frac{\omega T_1}{\pi}\right) = \frac{2 \sin \omega T_1}{\omega}$	—
$\frac{W}{\pi} \operatorname{sinc}\left(\frac{Wt}{\pi}\right) = \frac{\sin Wt}{\pi t}$	$X(\omega) = \begin{cases} 1, & \lvert \omega \rvert < W \\ 0, & \lvert \omega \rvert > W \end{cases}$	—
$\delta(t)$	1	—
$u(t)$	$\frac{1}{j\omega} + \pi\delta(\omega)$	—
$\delta(t - t_0)$	$e^{-j\omega t_0}$	—
$e^{-at}u(t), \mathcal{R}e\{a\} > 0$	$\frac{1}{a + j\omega}$	—
$te^{-at}u(t), \mathcal{R}e\{a\} > 0$	$\frac{1}{(a + j\omega)^2}$	—
$\frac{t^{n-1}}{(n-1)!} e^{-at}u(t), \mathcal{R}e\{a\} > 0$	$\frac{1}{(a + j\omega)^n}$	—

The above properties are particularly useful in CT system analysis and design, especially when the system characteristics are easily specified in the frequency domain, as in linear filtering. Note that Properties 1, 6, and 7 are useful for solving differential or integral equations. Property 4 (time-domain convolution) provides the

TABLE 14.2 Properties of the CT Fourier Transform

Name	If $\mathcal{F} f(t) = F(j\omega)$, then:
Definition	$F(j\omega) = \int_{-\infty}^{\infty} f(t)e^{-j\omega t}dt$
	$f(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} F(j\omega)e^{j\omega t}d\omega$
Superposition	$\mathcal{F}\left[af_1(t) + bf_2(t)\right] = aF_1(j\omega) + bF_2(j\omega)$
Simplification if:	
(a) $f(t)$ is even	$F(j\omega) = 2\int_0^{\infty} f(t)\cos\omega t\,dt$
(b) $f(t)$ is odd	$F(j\omega) = 2j\int_0^{\infty} f(t)\sin\omega t\,dt$
Negative t	$\mathcal{F} f(-t) = F*(j\omega)$
Scaling:	
(a) Time	$\mathcal{F} f(at) = \frac{1}{\lvert a\rvert}F\left(\frac{j\omega}{a}\right)$
(b) Magnitude	$\mathcal{F} af(t) = aF(j\omega)$
Differentiation	$\mathcal{F}\left[\frac{d^n}{dt^n}f(t)\right] = (j\omega)^n F(j\omega)$
Integration	$\mathcal{F}\left[\int_{-\infty}^{t} f(x)dx\right] = \frac{1}{j\omega}F(j\omega) + \pi F(0)\delta(\omega)$
Time shifting	$\mathcal{F} f(t-a) = F(j\omega)e^{-j\omega a}$
Modulation	$\mathcal{F} f(t)e^{j\omega_0 t} = F\left[j(\omega - \omega_0)\right]$
	$\mathcal{F} f(t)\cos\omega_0 t = \frac{1}{2}\left\{F\left[j(\omega-\omega_0)\right] + F\left[j(\omega+\omega_0)\right]\right\}$
	$\mathcal{F} f(t)\sin\omega_0 t = \frac{1}{2}j\left\{F\left[j(\omega-\omega_0)\right] - F\left[j(\omega+\omega_0)\right]\right\}$
Time convolution	$\mathcal{F}^{-1}\left[F_1(j\omega)F_2(j\omega)\right] = \int_{-\infty}^{\infty} f_1(\tau)f_2(t-\tau)\,d\tau$
Frequency convolution	$\mathcal{F}\left[f_1(t)f_2(t)\right] = \frac{1}{2\pi}\int_{-\infty}^{\infty} F_1(j\lambda)F_2\left[j(\omega-\lambda)\right]d\lambda$

basis for many signal-processing algorithms, since many systems can be specified directly by their impulse or frequency response. Property 3 (frequency shifting) is useful for analyzing the performance of communication systems where different modulation formats are commonly used to shift spectral energy among different frequency bands.

Fourier Spectrum of a CT Sampled Signal

The operation of uniformly sampling a CT signal $s(t)$ at every T seconds is characterized by Eq. (14.2), where $\delta(t)$ is the CT impulse function defined earlier:

$$s_a(t) = \sum_{n=-\infty}^{\infty} s_a(t)\delta(t - nT) = \sum_{n=-\infty}^{\infty} s_a(nT)\delta(t - nT) \tag{14.2}$$

Since $s_a(t)$ is a CT signal, it is appropriate to apply the CT Fourier transform to obtain an expression for the spectrum of the sampled signal:

$$F\{s_a(t)\} = F\left\{\sum_{n=-\infty}^{\infty} s_a(nT)\delta(t - nT)\right\} = \sum_{n=-\infty}^{\infty} s_a(nT)\left[e^{j\omega T}\right]^{-n} \tag{14.3}$$

Since the expression on the right-hand side of Eq. (14.3) is a function of $e^{j\omega T}$, it is customary to express the transform as $F(e^{j\omega T}) = F\{s_a(t)\}$. It will be shown later that if ω is replaced with a normalized frequency $\omega' = \omega/T$, so that $-\pi < \omega' < \pi$, then the right side of Eq. (14.3) becomes identical to the DT Fourier transform that is defined directly for the sequence $s[n] = s_a(nT)$.

Fourier Series Representation of CT Periodic Signals

The classical Fourier series representation of a periodic time domain signal $s(t)$ involves an expansion of $s(t)$ into an infinite series of terms that consist of sinusoidal basis functions, each weighted by a complex constant (Fourier coefficient) that provides the proper contribution of that frequency component to the complete waveform. The conditions under which a periodic signal $s(t)$ can be expanded in a Fourier series are known as the **Dirichlet conditions**. They require that in each period $s(t)$ has a finite number of discontinuities, a finite number of maxima and minima, and that $s(t)$ satisfies the absolute convergence criterion of Eq. (14.4) [Van Valkenburg, 1974]:

$$\int_{-T/2}^{T/2} |s(t)|dt < \infty \tag{14.4}$$

It is assumed throughout the following discussion that the Dirichlet conditions are satisfied by all functions that will be represented by a Fourier series.

The Exponential Fourier Series

If $s(t)$ is a CT periodic signal with period T, then the exponential Fourier series expansion of $s(t)$ is given by

$$s(t) = \sum_{n=-\infty}^{\infty} a_n e^{jn\omega_o t} \tag{14.5a}$$

where $\omega_o = 2\pi/T$ and where the a_n terms are the complex Fourier coefficients given by

$$a_n = (1/T)\int_{-T/2}^{T/2} s(t)e^{-jn\omega_o t}dt \qquad -\infty < n < \infty \tag{14.5b}$$

For every value of t where $s(t)$ is continuous the right side of Eq. (14.5a) converges to $s(t)$. At values of t where $s(t)$ has a finite jump discontinuity, the right side of Eq. (14.5a) converges to the average of $s(t^-)$ and $s(t^+)$, where

$$s(t^-) = \lim_{\varepsilon \to 0} s(t - \varepsilon) \qquad \text{and} \qquad s(t^+) = \lim_{\varepsilon \to 0} s(t + \varepsilon)$$

For example, the Fourier series expansion of the sawtooth waveform illustrated in Fig. 14.1 is characterized by $T = 2\pi$, $\omega_o = 1$, $a_0 = 0$, and $a_n = a_{-n} = A\cos(n\pi)/(jn\pi)$ for $n = 1, 2, \ldots$. The coefficients of the exponential Fourier series given by Eq. (14.5b) can be interpreted as a spectral representation of $s(t)$, since the a_nth coefficient represents the contribution of the $(n\omega_o)$th frequency component to the complete waveform. Since the a_n terms are complex valued, the Fourier domain (spectral) representation has both magnitude and phase spectra. For example, the magnitude of the a_n values is plotted in Fig. 14.2 for the sawtooth waveform of Fig. 14.1. The fact that the a_n terms constitute a discrete set is consistent with the fact that a periodic signal has a **line spectrum**;

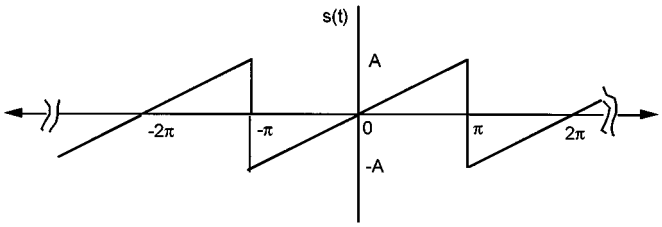

FIGURE 14.1 Periodic CT signal used in Fourier series example.

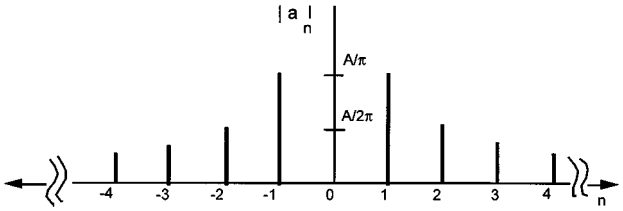

FIGURE 14.2 Magnitude of the Fourier coefficients for the example in Fig. 14.3.

i.e., the spectrum contains only integer multiples of the fundamental frequency ω_o. Therefore, the equation pair given by Eq. (14.5a) and (14.5b) can be interpreted as a transform pair that is similar to the CT Fourier transform for periodic signals. This leads to the observation that the classical Fourier series can be interpreted as a special transform that provides a one-to-one invertible mapping between the discrete-spectral domain and the CT domain.

Trigonometric Fourier Series

Although the complex form of the Fourier series expansion is useful for complex periodic signals, the Fourier series can be more easily expressed in terms of real-valued sine and cosine functions for real-valued periodic signals. In the following discussion it will be assumed that the signal $s(t)$ is real valued for the sake of simplifying the discussion. When $s(t)$ is periodic and real valued it is convenient to replace the complex exponential form of the Fourier series with a **trigonometric expansion** that contains $\sin(\omega_o t)$ and $\cos(\omega_o t)$ terms with corresponding real-valued coefficients [Van Valkenburg, 1974]. The trigonometric form of the Fourier series for a real-valued signal $s(t)$ is given by

$$s(t) = \sum_{n=0}^{\infty} b_n \cos(n\omega_0) + \sum_{n=1}^{\infty} c_n \sin(n\omega_0) \tag{14.6a}$$

where $\omega_o = 2\pi/T$. The b_n and c_n terms are real-valued Fourier coefficients determined by

$$b_0 = (1/T)\int_{-T/2}^{T/2} s(t)\,dt$$

$$b_n = (2/T)\int_{-T/2}^{T/2} s(t)\cos(n\omega_0 t)\,dt, \qquad n = 1, 2, \ldots$$

and

$$c_n = (2/T)\int_{-T/2}^{T/2} s(t)\sin(n\omega_0 t)\,dt, \qquad n = 1, 2, \ldots \tag{14.6b}$$

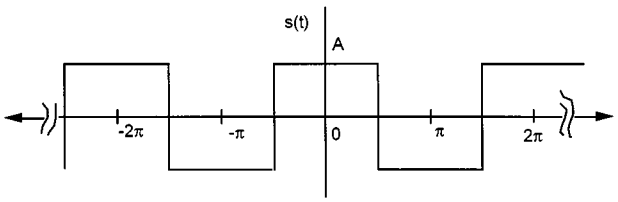

FIGURE 14.3 Periodic CT signal used in Fourier series example 2.

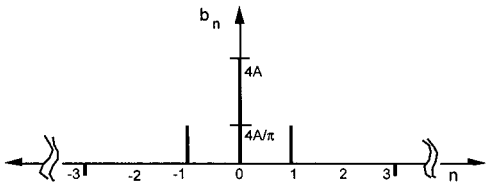

FIGURE 14.4 Fourier coefficients for example of Fig. 14.3.

An arbitrary real-valued signal $s(t)$ can be expressed as a sum of even and odd components, $s(t) = s_{even}(t) + s_{odd}(t)$, where $s_{even}(t) = s_{even}(-t)$ and $s_{odd}(t) = -s_{odd}(-t)$, and where $s_{even}(t) = [s(t) + s(-t)]/2$ and $s_{odd}(t) = [s(t) - s(-t)]/2$. For the trigonometric Fourier series, it can be shown that $s_{even}(t)$ is represented by the (even) cosine terms in the infinite series, $s_{odd}(t)$ is represented by the (odd) sine terms, and b_0 is the dc level of the signal. Therefore, if it can be determined by inspection that a signal has a dc level, or if it is even or odd, then the correct form of the trigonometric series can be chosen to simplify the analysis. For example, it is easily seen that the signal shown in Fig. 14.3 is an even signal with a zero dc level. Therefore, it can be accurately represented by the cosine series with $b_n = 2A \sin(\pi n/2)/(\pi n/2)$, $n = 1, 2, \ldots$, as illustrated in Fig. 14.4. In contrast, note that the sawtooth waveform used in the previous example is an odd signal with zero dc level, so that it can be completely specified by the sine terms of the trigonometric series. This result can be demonstrated by pairing each positive frequency component from the exponential series with its conjugate partner; i.e., $c_n = \sin(n\omega_o t) = a_n e^{jn\omega_0 t} + a_{-n} e^{-jn\omega_0 t}$, whereby it is found that $c_n = 2A \cos(n\pi)/(n\pi)$ for this example. In general, it is found that $a_n = (b_n - jc_n)/2$ for $n = 1, 2, \ldots$, $a_0 = b_0$, and $a_{-n} = a_n^*$. The trigonometric Fourier series is common in the signal processing literature because it replaces complex coefficients with real ones and often results in a simpler and more intuitive interpretation of the results.

Convergence of the Fourier Series

The Fourier series representation of a periodic signal is an approximation that exhibits mean-squared convergence to the true signal. If $s(t)$ is a periodic signal of period T and $s'(t)$ denotes the Fourier series approximation of $s(t)$, then $s(t)$ and $s'(t)$ are equal in the mean-squared sense if

$$\text{mse} = \int_{-T/2}^{T/2} \left| s(t) - s'(t) \right|^2 dt = 0 \tag{14.7}$$

Even when Eq. (14.7) is satisfied, **mean-squared error** (mse) convergence does not guarantee that $s(t) = s'(t)$ at every value of t. In particular, it is known that at values of t where $s(t)$ is discontinuous the Fourier series converges to the average of the limiting values to the left and right of the discontinuity. For example, if t_0 is a point of discontinuity, then $s'(t_0) = [s(t_0^-) + s(t_0^+)]/2$, where $s(t_0^-)$ and $s(t_0^+)$ were defined previously (note that at points of continuity, this condition is also satisfied by the very definition of continuity). Since the Dirichlet conditions require that $s(t)$ have at most a finite number of points of discontinuity in one period, the set S_t such that $s(t) \neq s'(t)$ within one period contains a finite number of points, and S_t is a set of measure zero in the formal mathematical sense. Therefore, $s(t)$ and its Fourier series expansion $s'(t)$ are *equal almost everywhere*, and $s(t)$ can be considered identical to $s'(t)$ for analysis in most practical engineering problems.

The condition described above of convergence almost everywhere is satisfied only in the limit as an infinite number of terms are included in the Fourier series expansion. If the infinite series expansion of the Fourier series is truncated to a finite number of terms, as it must always be in practical applications, then the approximation will exhibit an oscillatory behavior around the discontinuity, known as the **Gibbs phenomenon** [Van Valkenburg, 1974]. Let $s'_N(t)$ denote a truncated Fourier series approximation of $s(t)$, where only the terms in Eq. (14.5a) from $n = -N$ to $n = N$ are included if the complex Fourier series representation is used or where only the terms in Eq. (14.6a) from $n = 0$ to $n = N$ are included if the trigonometric form of the Fourier series is used. It is well known that in the vicinity of a discontinuity at t_0 the Gibbs phenomenon causes $s'_N(t)$ to be a poor approximation to $s(t)$. The peak magnitude of the Gibbs oscillation is 13% of the size of the jump discontinuity $s(t_0^-) - s(t_0^+)$ regardless of the number of terms used in the approximation. As N increases, the region which contains the oscillation becomes more concentrated in the neighborhood of the discontinuity, until, in the limit as N approaches infinity, the Gibbs oscillation is squeezed into a single point of mismatch at t_0. The Gibbs phenomenon is illustrated in Fig. 14.5, where an ideal low-pass frequency response is approximated by an impulse response function that has been limited to having only N nonzero coefficients, and hence the Fourier series expansion contains only a finite number of terms.

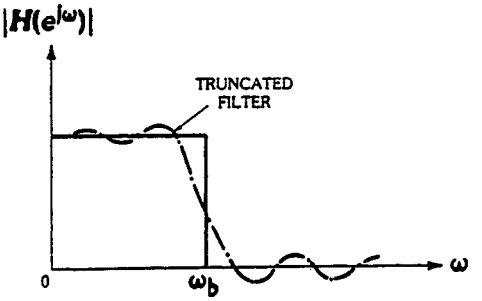

FIGURE 14.5 Gibbs phenomenon in a low-pass digital filter caused by truncating the impulse response to N terms.

If $s'(t)$ in Eq. (14.7) is replaced by $s'_N(t)$ it is important to understand the behavior of the error mse_N as a function of N, where

$$\text{mse}_N = \int_{-T/2}^{T/2} \left| s(t) - s'_N(t) \right|^2 dt \tag{14.8}$$

An important property of the Fourier series is that the exponential basis functions $e^{jn\omega_o t}$ (or $\sin(n\omega_o t)$ and $\cos(n\omega_o t)$ for the trigonometric form) for $n = 0, \pm 1, \pm 2, \ldots$ (or $n = 0, 1, 2, \ldots$ for the trigonometric form) constitute an **orthonormal set**; i.e., $t_{nk} = 1$ for $n = k$, and $t_{nk} = 0$ for $n \neq k$, where

$$t_{nk} = (1/T)\int_{-T/2}^{T/2} \left(e^{-jn\omega_o t}\right)\left(e^{jn\omega_o t}\right) dt \tag{14.9}$$

As terms are added to the Fourier series expansion, the orthogonality of the basis functions guarantees that the error decreases monotonically in the mean-squared sense, i.e., that mse_N monotonically decreases as N is increased. Therefore, when applying Fourier series analysis, including more terms always improves the accuracy of the signal representation.

Fourier Transform of Periodic CT Signals

For a periodic signal $s(t)$ the CT Fourier transform can then be applied to the Fourier series expansion of $s(t)$ to produce a mathematical expression for the "line spectrum" that is characteristic of periodic signals:

$$F\{s(t)\} = F\left\{\sum_{n=\infty}^{\infty} a_n e^{jn\omega_o t}\right\} = 2\pi \sum_{n=-\infty}^{\infty} a_n \delta(\omega - n\omega_o) \tag{14.10}$$

The spectrum is shown in Fig. 14.6. Note the similarity between the spectral representation of Fig. 14.6 and the plot of the Fourier coefficients in Fig. 14.2, which was heuristically interpreted as a line spectrum. Figures 14.2 and

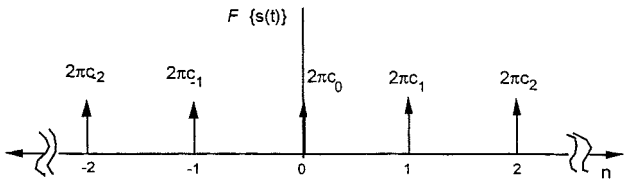

FIGURE 14.6 Spectrum of the Fourier representation of a periodic signal.

14.6 are different, but equivalent, representations of the Fourier line spectrum that is characteristic of periodic signals.

Generalized Complex Fourier Transform

The CT Fourier transform characterized by Eqs. (14.11a) and (14.11b) can be generalized by considering the variable $j\omega$ to be the special case of $u = \sigma + j\omega$ with $\sigma = 0$, writing Eqs. (14.11) in terms of u, and interpreting u as a complex frequency variable. The resulting complex Fourier transform pair is given by Eqs. (14.11a) and (14.11b):

$$s(t) = (1/2\pi j)\int_{\sigma - j\infty}^{\sigma + j\infty} S(u)e^{jut}du \tag{14.11a}$$

$$s(u) = \int_{-\infty}^{\infty} s(t)e^{-jut}dt \tag{14.11b}$$

The set of all values of u for which the integral of Eq. (14.11b) converges is called the region of convergence, denoted ROC. Since the transform $S(u)$ is defined only for values of u within the ROC, the path of integration in Eq. (14.11a) must be defined by s so the entire path lies within the ROC. In some literature this transform pair is called the *bilateral Laplace transform* because it is the same result obtained by including both the negative and positive portions of the time axis in the classical Laplace transform integral. The complex Fourier transform (bilateral Laplace transform) is not often used in solving practical problems, but its significance lies in the fact that it is the most general form that represents the place where Fourier and Laplace transform concepts merge. Identifying this connection reinforces the observation that Fourier and Laplace transform concepts share common properties because they are derived by placing different constraints on the same parent form.

DT Fourier Transform

The DT Fourier transform (DTFT) is obtained directly in terms of the sequence samples $s[n]$ by taking the relationship obtained in Eq. (14.3) to be the definition of the DTFT. By letting $T = 1$ so that the sampling period is removed from the equations and the frequency variable is replaced with a normalized frequency $\omega' = \omega T$, the DTFT pair is defined by Eqs. (14.12). In order to simplify notation it is not customary to distinguish between ω and ω', but rather to rely on the context of the discussion to determine whether ω refers to the normalized ($T = 1$) or to the unnormalized ($T \neq 1$) frequency variable.

$$S(e^{j\omega'}) = \sum_{n=-\infty}^{\infty} s[n]e^{-j\omega' n} \tag{14.12a}$$

$$s[n] = (1/2\pi)\int_{-\pi}^{\pi} S(e^{j\omega'})e^{jn\omega'}d\omega' \tag{14.12b}$$

TABLE 14.3 Some Basic DTFT Pairs

Sequence	Fourier Transform
1. $\delta[n]$	1
2. $\delta[n - n_0]$	$e^{-j\omega n_0}$
3. $1\ (-\infty < n < \infty)$	$\sum_{k=-\infty}^{\infty} 2\pi\delta(\omega + 2\pi k)$
4. $a^n u[n]\ (\lvert a\rvert < 1)$	$\frac{1}{1 - ae^{-j\omega}}$
5. $u[n]$	$\frac{1}{1 - e^{-j\omega}} + \sum_{k=-\infty}^{\infty} \pi\delta(\omega + 2\pi k)$
6. $(n + 1)a^n u[n]\ (\lvert a\rvert < 1)$	$\frac{1}{(1 - ae^{-j\omega})^2}$
7. $\frac{r^n \sin \omega_p(n + 1)}{\sin \omega_p} u[n]\ (\lvert r\rvert < 1)$	$\frac{1}{1 - 2r\cos\omega_p e^{-j\omega} + r^2 e^{-j2\omega}}$
8. $\frac{\sin \omega_c n}{\pi n}$	$X(e^{j\omega}) = \begin{cases} 1, & \lvert\omega\rvert < \omega_c, \\ 0, & \omega_c < \lvert\omega\rvert \le \pi \end{cases}$
9. $x[n] = \begin{cases} 1, & 0 \le n \le M \\ 0, & \text{otherwise} \end{cases}$	$\frac{\sin[\omega(M + 1)/2]}{\sin(\omega/2)} e^{-j\omega M/2}$
10. $e^{j\omega_0 n}$	$\sum_{k=-\infty}^{\infty} 2\pi\delta(\omega - \omega_0 + 2\pi k)$
11. $\cos(\omega_0 n + \phi)$	$\pi\sum_{k=-\infty}^{\infty} [e^{j\phi}\delta(\omega - \omega_0 + 2\pi k) + e^{-j\phi}\delta(\omega + \omega_0 + 2\pi k)]$

The spectrum $S(e^{j\omega'})$ is periodic in ω' with period 2π. The fundamental period in the range $-\pi < \omega' \le \pi$, sometimes referred to as the baseband, is the useful frequency range of the DT system because frequency components in this range can be represented unambiguously in sampled form (without aliasing error). In much of the signal-processing literature the explicit primed notation is omitted from the frequency variable. However, the explicit primed notation will be used throughout this section because there is a potential for confusion when so many related Fourier concepts are discussed within the same framework.

By comparing Eqs. (14.3) and (14.12a), and noting that $\omega' = \omega T$, we see that

$$F\{s_a(t)\} = \text{DTFT}\{s[n]\} \tag{14.13}$$

where $s[n] = s(t)|_{t = nT}$. This demonstrates that the spectrum of $s_a(t)$ as calculated by the CT Fourier transform is identical to the spectrum of $s[n]$ as calculated by the DTFT. Therefore, although $s_a(t)$ and $s[n]$ are quite different sampling models, they are equivalent in the sense that they have the same Fourier domain representation. A list of common DTFT pairs is presented in Table 14.3. Just as the CT Fourier transform is useful in CT signal system analysis and design, the DTFT is equally useful for DT system analysis and design.

In the same way that the CT Fourier transform was found to be a special case of the complex Fourier transform (or bilateral Laplace transform), the DTFT is a special case of the *bilateral z-transform* with $z = e^{j\omega' t}$. The more general bilateral z-transform is given by

$$S(z) = \sum_{n=-\infty}^{\infty} s[n] z^{-n} \tag{14.14a}$$

$$s[n] = (1/2\pi j) \int_C S(z) z^{n-1} dz \tag{14.14b}$$

where C is a counterclockwise contour of integration which is a closed path completely contained within the ROC of $S(z)$. Recall that the DTFT was obtained by taking the CT Fourier transform of the CT sampling model $s_a(t)$. Similarly, the bilateral z-transform results by taking the bilateral Laplace transform of $s_a(t)$. If the lower limit on the summation of Eq. (14.14a) is taken to be $n = 0$, then Eqs. (14.14a) and (14.14b) become the one-sided z-transform, which is the DT equivalent of the one-sided Laplace transform for CT signals.

Properties of the DTFT

Since the DTFT is a close relative of the classical CT Fourier transform, it should come as no surprise that many properties of the DTFT are similar to those of the CT Fourier transform. In fact, for many of the properties presented earlier there is an analogous property for the DTFT. The following list parallels the list that was presented in the previous section for the CT Fourier transform, to the extent that the same property exists. A more complete list of DTFT pairs is given in Table 14.4:

1. *Linearity* (*superposition*): (a and b, complex constants) $\text{DTFT}\{af_1[n] + bf_2[n]\} = a\text{DTFT}\{f_1[n]\} + b\text{DTFT}\{f_2[n]\}$
2. *Index Shifting:* $\text{DTFT}\{f[n - n_o]\} = e^{-j\omega n_o}\text{DTFT}\{f[n]\}$
3. *Frequency Shifting:* $e^{j\omega_o n} f[n] = \text{DTFT}^{-1}\{F(j(\omega - \omega_o))\}$
4. *Time-Domain Convolution:* $\text{DTFT}\{f_1[n] * f_2[n]\} = \text{DTFT}\{f_1[n]\}\ \text{DTFT}\{f_2[n]\}$
5. *Frequency-Domain Convolution:* $\text{DTFT}\{f_1[n]\ f_2[n]\} = (1/2\pi)\text{DTFT}\{f_1[n]\} * \text{DTFT}\{f_2[n]\}$
6. *Frequency Differentiation:* $nf[n] = \text{DTFT}^{-1}\{dF(j\omega)/d\omega\}$

Note that the time-differentiation and time-integration properties of the CT Fourier transform do not have analogous counterparts in the DTFT because time-domain differentiation and integration are not defined for DT signals. When working with DT systems practitioners must often manipulate difference equations in the frequency domain. For this purpose Property 1 (linearity) and Property 2 (index shifting) are important. As with the CT Fourier transform, Property 4 (time-domain convolution) is very important for DT systems because it allows engineers to work with the frequency response of the system in order to achieve proper shaping of the input spectrum, or to achieve frequency selective filtering for noise reduction or signal detection. Also, Property 3 (frequency shifting) is useful for the analysis of modulation and filtering common in both analog and digital communication systems.

Relationship between the CT and DT Spectra

Since DT signals often originate by sampling a CT signal, it is important to develop the relationship between the original spectrum of the CT signal and the spectrum of the DT signal that results. First, the CT Fourier transform is applied to the CT sampling model, and the properties are used to produce the following result:

$$F\{s_a(t)\} = F\left\{s_a(t) \sum_{n=-\infty}^{\infty} \delta(t - nT)\right\} = (1/2\pi) S(j\omega) F\left\{\sum_{n=-\infty}^{\infty} \delta(t - nT)\right\} \tag{14.15}$$

Table 14.4 Properties of the DTFT

Sequence $x[n]$ $y[n]$	Fourier Transform $X(e^{j\omega})$ $Y(e^{j\omega})$
1. $ax[n] + by[n]$	$aX(e^{j\omega}) + bY(e^{j\omega})$
2. $x[n - n_d]$ $(n_d$ an integer$)$	$e^{-j\omega n_d}X(e^{j\omega})$
3. $e^{j\omega_0 n}x[n]$	$X(e^{j(\omega-\omega_0)})$
4. $x[-n]$	$X(e^{-j\omega})$ if $x[n]$ real
	$X*(e^{j\omega})$
5. $nx[n]$	$j\dfrac{dX(e^{j\omega})}{d\omega}$
6. $x[n]*y[n]$	$X(e^{j\omega})Y(e^{j\omega})$
7. $x[n]y[n]$	$\dfrac{1}{2\pi}\int_{-\pi}^{\pi} X(e^{j\theta})Y(e^{j(\omega-\theta)})d\theta$
Parseval's Theorem	
8. $\sum_{n=-\infty}^{\infty}\lvert x[n]\rvert^2 = \dfrac{1}{2\pi}\int_{-\pi}^{\pi}\lvert X(e^{j\omega})\rvert^2 d\omega$	
9. $\sum_{n=-\infty}^{\infty} x[n]y*[n] = \dfrac{1}{2\pi}\int_{-\pi}^{\pi} X(e^{j\omega})Y*(e^{j\omega}d\omega)$	

In this section it is important to distinguish between ω and ω', so the explicit primed notation is used in the following discussion where needed for clarification. Since the sampling function (summation of shifted impulses) on the right-hand side of the above equation is periodic with period T it can be replaced with a CT Fourier series expansion as follows:

$$S(e^{j\omega T}) = F\{s_a(t)\} = (1/2\pi)S(j\omega)F\left\{\sum_{n=-\infty}^{\infty}(1/T)e^{j(2\pi/T)nt}\right\}$$

Applying the frequency-domain convolution property of the CT Fourier transform yields

$$S(e^{j\omega T}) = (1/2\pi)\sum_{n=-\infty}^{\infty} S(j\omega) * (2\pi/T)\delta(\omega - (2\pi/T)n) = (1/T)\sum_{n=-\infty}^{\infty} S(j[\omega - n\omega_s]) \quad (14.16a)$$

where $\omega_s = (2\pi/T)$ is the sampling frequency (rad/s). An alternate form for the expression of Eq. (14.16a) is

$$S(e^{j\omega'}) = (1/T)\sum_{n=-\infty}^{\infty} S(j[(\omega' - n2\pi)/T]) \quad (14.16b)$$

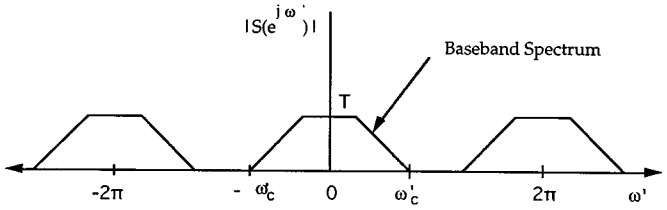

FIGURE 14.7 Relationship between the CT and DT spectra.

where $\omega' = \omega T$ is the normalized DT frequency axis expressed in radians. Note that $S(e^{j\omega T}) = S(e^{j\omega'})$ consists of an infinite number of replicas of the CT spectrum $S(j\omega)$, positioned at intervals of $(2\pi/T)$ on the ω axis (or at intervals of 2π on the ω' axis), as illustrated in Fig. 14.7. If $S(j\omega)$ is band limited with a bandwidth ω_c and if T is chosen sufficiently small so that $\omega_s > 2\omega_c$, then the DT spectrum is a copy of $S(j\omega)$ (scaled by $1/T$) in the baseband. The limiting case of $\omega_s = 2\omega_c$ is called the **Nyquist sampling frequency**. Whenever a CT signal is sampled at or above the Nyquist rate, no aliasing distortion occurs (i.e., the baseband spectrum does not overlap with the higher-order replicas) and the CT signal can be exactly recovered from its samples by extracting the baseband spectrum of $S(e^{j\omega'})$ with an ideal low-pass filter that recovers the original CT spectrum by removing all spectral replicas outside the baseband and scaling the baseband by a factor of T.

Discrete Fourier Transform

To obtain the DFT the continuous-frequency domain of the DTFT is sampled at N points uniformly spaced around the unit circle in the z-plane, i.e., at the points $\omega_k = (2\pi k/N)$, $k = 0, 1, \ldots, N-1$. The result is the DFT transform pair defined by Eqs. (14.17a) and (14.17b). The signal $s[n]$ is either a finite-length sequence of length N or it is a periodic sequence with period N.

$$S[k] = \sum_{n=0}^{N-1} s[n] e^{-j2\pi kn/N} \qquad k = 0, 1, \ldots, N-1 \tag{14.17a}$$

$$s[n] = (1/N) \sum_{n=0}^{N-1} S[k] e^{j2\pi kn/N} \qquad n = 0, 1, \ldots, N-1 \tag{14.17b}$$

Regardless of whether $s[n]$ is a finite-length or a periodic sequence, the DFT treats the N samples of $s[n]$ as though they characterize one period of a periodic sequence. This is an important feature of the DFT, and one that must be handled properly in signal processing to prevent the introduction of artifacts. Important properties of the DFT are summarized in Table 14.5. The notation $(k)_N$ denotes k modulo N, and $R_N[n]$ is a rectangular window such that $R_N[n] = 1$ for $n = 0, \ldots, N-1$, and $R_N[n] = 0$ for $n < 0$ and $n \geq N$. The transform relationship given by Eqs. (14.17a) and (14.17b) is also valid when $s[n]$ and $S[k]$ are periodic sequences, each of period N. In this case, n and k are permitted to range over the complete set of real integers, and $S[k]$ is referred to as the discrete Fourier series (DFS). The DFS is developed by some authors as a distinct transform pair in its own right [Oppenheim and Schafer, 1975]. Whether or not the DFT and the DFS are considered identical or distinct is not very important in this discussion. The important point to be emphasized here is that the DFT treats $s[n]$ as though it were a single period of a periodic sequence, and all signal processing done with the DFT will inherit the consequences of this assumed periodicity.

Properties of the DFT

Most of the properties listed in Table 14.5 for the DFT are similar to those of the z-transform and the DTFT, although there are some important differences. For example, Property 5 (time-shifting property), holds for circular shifts of the finite-length sequence $s[n]$, which is consistent with the notion that the DFT treats $s[n]$ as one period of a periodic sequence. Also, the multiplication of two DFTs results in the **circular convolution**

TABLE 14.5 Properties of the Discrete Fourier Transform (DFT)

Finite-Length Sequence (Length N)	N-Point DFT (Length N)
1. $x[n]$	$X[k]$
2. $x_1[n], x_2[n]$	$X_1[k], X_2[k]$
3. $ax_1[n] + bx_2[n]$	$aX_1[k] + bX_2[k]$
4. $X[n]$	$Nx[(-k)_N]$
5. $x[(n-m)_N]$	$W_N^{km}X[k]$
6. $W_N^{-\ell n}x[n]$	$X[(k-\ell)_N]$
7. $\sum_{m=0}^{N-1} x_1(m)x_2[(n-m)_N]$	$X_1[k]X_2[k]$
8. $x_1[n]x_2[n]$	$\frac{1}{N}\sum_{\ell=0}^{N-1} X_1(\ell)X_2[(k-\ell)_N]$
9. $x^*[n]$	$X^*[(-k)_N]$
10. $x^*[(-n)_N]$	$X^*[k]$
11. $\mathcal{R}e\{x[n]\}$	$X_{ep}[k] = \frac{1}{2}\{X[(k)_N] + X^*[(-k)_N]\}$
12. $j\mathcal{I}m\{x[n]\}$	$X_{op}[k] = \frac{1}{2}\{X[(k)_N] - X^*[(-k)_N]\}$
13. $x_{ep}[n] = \frac{1}{2}\{x[n] + x^*[(-n)_N]\}$	$\mathcal{R}e\{X[k]\}$
14. $x_{op}[n] = \frac{1}{2}\{x[n] - x^*[(-n)_N]\}$	$j\mathcal{I}m\{X[k]\}$
Properties 15–17 apply only when $x[n]$ is real.	
15. Symmetry properties	$\begin{cases} X[k] = X^*[(-k)_N] \\ \mathcal{R}e\{X[k]\} = \mathcal{R}e\{X[(-k)_N]\} \\ \mathcal{I}m\{X[k]\} = \mathcal{I}m\{X[(-k)]_N\} \\ \lvert X[k]\rvert = \lvert X[(-k)_N]\rvert \\ \measuredangle\{X[k]\} = -\measuredangle\{X[(-k)_N]\} \end{cases}$
16. $x_{ep}[n] = \frac{1}{2}\{x[n] + x[(-n)_N]\}$	$\mathcal{R}e\{X[k]\}$
17. $x_{op}[n] = \frac{1}{2}\{x[n] - x[(-n)_N]\}$	$j\mathcal{I}m\{X[k]\}$

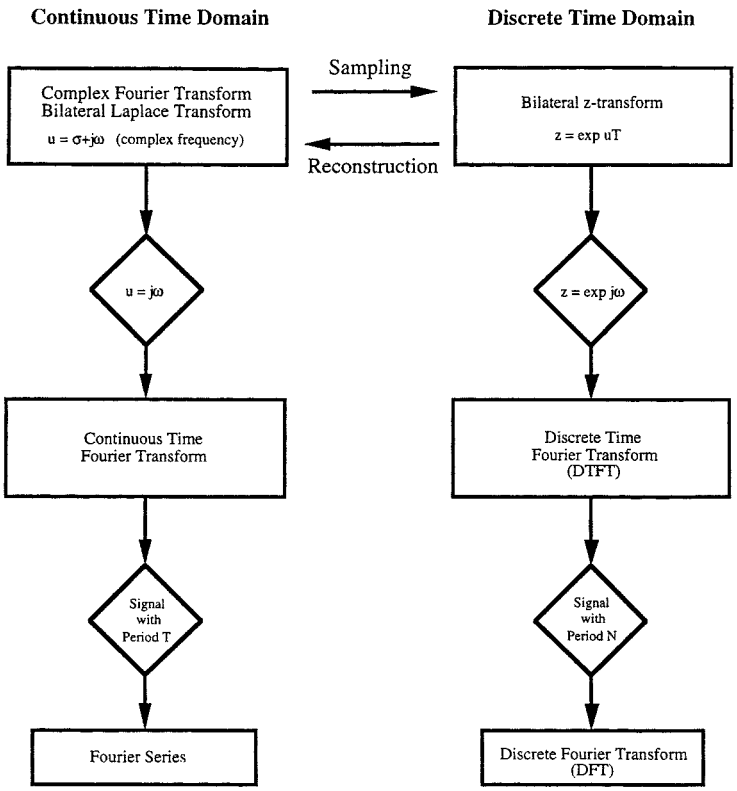

FIGURE 14.8 Functional relationships among various Fourier transforms.

of the corresponding DT sequences, as specified by Property 7. This latter property is quite different from the *linear convolution* property of the DTFT. Circular convolution is simply a linear convolution of the periodic extensions of the finite sequences being convolved, where each of the finite sequences of length N defines the structure of one period of the periodic extensions.

For example, suppose it is desired to implement the following finite impulse response (FIR) digital filter,

$$y[n] = \sum_{k=0}^{N-1} h[k]s[n-k] \tag{14.18}$$

the output of which is obtained by transforming $h[n]$ and $s[n]$ into $H[k]$ and $S[k]$ via the DFT (FFT), multiplying the transforms point-wise to obtain $Y[k] = H[k]S[k]$, and then using the inverse DFT (FFT) to obtain $y[n] = \text{IDFT}\{Y[k]\}$. If $s[n]$ is a finite sequence of length M, then the result of the circular convolution implemented by the DFT will correspond to the desired linear convolution if and only if the block length of the DFT is chosen so that $N_{\text{DFT}} \geq N + M - 1$ and both $h[n]$ and $s[n]$ are padded with zeros to form blocks of length N_{DFT}.

Relationships among Fourier Transforms

Figure 14.8 illustrates the functional relationships among the various forms of CT and DT Fourier transforms that have been discussed in the previous sections. The family of CT is shown on the left side of Fig. 14.8, whereas the right side of the figure shows the hierarchy of DTFTs. Fourier transforms. The complex Fourier transform is identical to the bilateral Laplace transform, and it is at this level that the classical Laplace transform techniques and the Fourier transform techniques become identical.

Defining Terms

Continuous-time (CT) impulse function: A generalized function $\delta(t)$ defined to be zero for all $t \neq 0$, undefined at $t = 0$, and having the special property that $\int_{-\infty}^{\infty} \delta(t)dt = 1$.

Circular convolution: A convolution of finite-length sequences in which the shifting operation is performed circularly within the finite support interval. Alternatively called *periodic convolution.*

Dirichlet conditions: Conditions that must be satisfied in order to expand a periodic signal $s(t)$ in a Fourier series: each period of $s(t)$ must have a finite number of discontinuities, a finite number of maxima and minima, and $\int_{-T/2}^{T/2} |s(t)|dt < \infty$ must be satisfied, where T is the period.

Gibbs phenomenon: Oscillatory behavior of Fourier series approximations in the vicinity of finite jump discontinuities.

Line spectrum: A common term for Fourier transforms of periodic *signals* for which the spectrum has nonzero components only at integer multiples of the fundamental frequency.

Mean-squared error (mse): A measure of "closeness" between two functions given by

$$\text{mse} = \frac{1}{T}\int_{-T/2}^{T/2} |f_1(t) - f_2(t)|^2 dt$$

where T is the period.

Nyquist sampling frequency: Minimum sampling frequency for which a CT signal $s(t)$ can be perfectly reconstructed from a set of uniformly spaced samples $s(nT)$.

Orthonormal set: A countable set of functions for which every pair in the set is mathematically orthogonal according to a valid norm, and for which each element of the set has unit length according to the same norm. The Fourier basis functions form an orthonormal set according to the mse norm.

Trigonometric expansion: A Fourier series expansion for a real-valued signal in which the basis functions are chosen to be $\sin(n\omega_o t)$ and $\cos(n\omega_o t)$

Further Information

A more thorough treatment of the complete family of CT and DT Fourier transform concepts is given in Jenkins [1995]. This article emphasizes the parallels between CT and DT Fourier concepts.

An excellent treatment of Fourier waveform analysis is given by D. C. Munson, Jr., in chapter 7 of *Reference Data for Engineers: Radio, Electronics, Computers, and Communications*, 8th ed., M. E. Van Valkenburg (ed.,) Carmel, Ind.: SAMS Publishing Co., 1993.

A classic reference on the CT Fourier transform is Bracewell [1986].

14.2 Fourier Transforms and the Fast Fourier Transform

Alexander D. Poularikas

The Discrete Time Fourier Transform (DTFT)

The discrete time Fourier transform of a signal $\{f(n)\}$ is defined by

$$\mathcal{F}_{dt}\left\{f(n)\right\} \equiv F(\omega) \equiv F\left(e^{j\omega}\right) = \sum_{n=-\infty}^{\infty} f(n)e^{-j\omega n} \tag{14.19}$$

and its inverse discrete time Fourier transform (IDTFT) is give by

$$f(n) = \frac{1}{2\pi}\int_{-\pi}^{\pi} F(\omega)e^{j\omega n}d\omega \tag{14.20}$$

The amplitude and phase spectra are periodic with a period of 2π and thus the frequency range of any discrete signal is limited to the range $(-\pi,\pi]$ or $(0,2\pi]$.

Example 1
Find the DTFT of the sequence $f(n) = 0.8^n$ for $n = 0,1,2,3\ldots$

Solution
From (14.19), we write

$$F(\omega) = \sum_{n=0}^{\infty} 0.8^n e^{-j\omega n} = \sum_{n=0}^{\infty}\left(0.8e^{-j\omega}\right)^n = \frac{1}{1 - 0.8e^{-j\omega}} \tag{14.21}$$

$$\left|F(\omega)\right| = \frac{1}{\sqrt{1.64 - 1.6\cos\omega}};\ Arg\,F(\omega) = \tan^{-1}\left(\frac{0.8\sin\omega}{1 - 0.8\cos\omega}\right) \tag{14.22}$$

If we set $\omega = -\omega$ in the last two equations we find that the amplitude is an even function and the argument is an odd function.

Relationship to the Z-Transform

$$F(z)\Big|_{z=e^{j\omega}} = \sum_{n=-\infty}^{\infty} f(n)z^{-n}\Big|_{z=e^{j\omega}}$$

Properties

Table 14.6 tabulates the DTFT properties of discrete time sequences.

Fourier Transforms of Finite Time Sequences

The trancated Fourier transform of a sequence is given by

$$F_N(\omega) = \sum_{n=0}^{N-1} f(n)e^{-j\omega n} = \sum_{n=-\infty}^{\infty} f(n)w(n)e^{-j\omega n} = \frac{1}{2\pi}F(\omega) * W(\omega) \tag{14.23}$$

TABLE 14.6

Property	Time Domain	Frequency Domain
Linearity	$af_1(n) + bf_2(n)$	$aF_1(\omega)+bF_2(\omega)$
Time Shifting	$f(n - n_0)$	$e^{-j\omega n_0}F(\omega)$
Time Reversal	$f(-n)$	$F(-\omega)$
Convolution	$f_1(n)*f_2(n)$	$F_1(\omega)F_2(\omega)$
Frequency Shifting	$e^{j\omega_0 n}f(n)$	$F(\omega - \omega_0)$
Time Multiplication	$nf(n)$	$-z\left.\dfrac{dF(z)}{dz}\right\|_{z=e^{j\omega}}$
Modulation	$f(n)\cos\omega_0 n$	$\frac{1}{2}F(\omega - \omega_0) + \frac{1}{2}F(\omega + \omega_0)$
Correlation	$f_1(n)\bullet f_2(n)$	$F_1(\omega)F_2(-\omega)$
Parseval's Formula	$\sum_{n=-\infty}^{\infty}\|f(n)\|^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi}\|F(\omega)\|^2 d\omega$	

where $w(n)$ is a window function that extends from $n = 0$ to $n = N - 1$. If the value of the sequence is unity for all n's, the window is known as the rectangular one. From (14.23) we observe that the trancation of a sequence results in a smoothered version of the exact spectrum.

Frequency Response of LTI Discrete Systems

A first order LTI discrete system is described by the difference equation

$$y(n) + a_1 y(n - 1) = b_0 x(n) + b_1 x(n - 1)$$

The DTFT of the above equation is given by

$$Y(\omega) + a_1 e^{-j\omega} Y(\omega) = b_0 X(\omega) + b_1 e^{-j\omega} X(\omega)$$

from which we write the system function

$$H(\omega) = \frac{Y(\omega)}{X(\omega)} = \frac{b_0 + b_1 e^{-j\omega}}{1 + a_1 e^{-j\omega}}$$

To approximate the continuous time Fourier transform using the DTFT we follow the following steps:

1. Select the time interval T such that $F(\omega_c) \approx 0$ for all $|\omega_c| > \pi/T$. ω_c designates the frequency of a continuous time function.
2. Sample $f(t)$ at times nT to obtain $f(nT)$.
3. Compute the DFT using the sequence $\{Tf(nT)\}$.
4. The resulting approximation is then $F(\omega_c) \approx F(\omega)$ for $-\pi/T < \omega_c < \pi/T$.

The Disrete Fourier Transform

One of the methods, and one that is used extensively, calls for replacing continuous Fourier transforms by an equivalent *discrete Fourier transform* (DFT) and then evaluating the DFT using the discrete data. However, evaluating a DFT with 512 samples (a small number in most cases) requires more than 1.5×10^6 mathematical operations. It was the development of the *fast Fourier transform* (**FFT**), a computational technique that reduces

the number of mathematical operations in the evaluation of the DFT to $N \log_2 (N)$ (approximately 2.5×10^4 operations for the 512-point case mentioned above), that makes DFT an extremely useful tool in most all fields of science and engineering.

A data sequence is available only with a finite time window from $n = 0$ to $n = N - 1$. The transform is discretized for N values by taking samples at the frequencies $2\pi/NT$, where T is the time interval between sample points. Hence, we define the DFT of a sequence of N samples for $0 \le k \le N-1$ by the relation

$$\begin{aligned} F(k\Omega) \doteq \mathcal{F}_d\{f(nT)\} &= T\sum_{n=0}^{N-1} f(nT)e^{-j2\pi nkT/NT} \\ &= T\sum_{n=0}^{N-1} f(nT)e^{-j\Omega Tnk} \quad n = 0, 1, \ldots, N-1 \end{aligned} \tag{14.24}$$

where N = number of sample values, T = sampling time interval, $(N-1)T$ = signal length, $f(nT)$ = sampled form of $f(t)$ at points nT, $\Omega = (2\pi/T)1/N = \omega_s/N$ = frequency sampling interval, $e^{-i\Omega T} = N$th principal root of unity, and $j = \sqrt{-1}$. The inverse DFT is given by

$$\begin{aligned} f(nT) \doteq \mathcal{F}_d^{-1}\{F(k\Omega)\} &= \frac{1}{NT}\sum_{k=0}^{N-1} F(k\Omega)e^{j2\pi nkT/NT} \\ &= \frac{1}{NT}\sum_{k=0}^{N-1} F(k\Omega)e^{i\Omega Tnk} \end{aligned} \tag{14.25}$$

The sequence $f(nT)$ can be viewed as representing N consecutive samples $f(n)$ of the continuous signal, while the sequence $F(k\Omega)$ can be considered as representing N consecutive samples $F(k)$ in the frequency domain. Therefore, Eqs. (14.24) and (14.25) take the compact form

$$\begin{aligned} F(k) \doteq \mathcal{F}_d\{f(n)\} &= \sum_{n=0}^{N-1} f(n)e^{-j2\pi nk/N} \\ &= \sum_{n=0}^{N-1} f(n)W_N^{nk} \quad k = 0, \ldots, N-1 \end{aligned} \tag{14.26}$$

$$\begin{aligned} f(n) \doteq \mathcal{F}_d^{-1}\{F(k)\} &= \frac{1}{N}\sum_{k=0}^{N-1} F(k)e^{j2\pi nk/N} \\ &= \sum_{k=0}^{N-1} F(k)W_N^{-nk} \quad k = 0, \ldots, N-1 \end{aligned} \tag{14.27}$$

where

$$W_N = e^{-j2\pi/N} \quad j = \sqrt{-1}$$

An important property of the DFT is that $f(n)$ and $F(k)$ are uniquely related by the transform pair (14.26) and (14.27).

We observe that the functions W^{kn} are N-periodic; that is,

$$W_N^{kn} = W_N^{k(n+N)} \qquad k, n = 1, \pm 1, \pm 2, \ldots \tag{14.28}$$

As a consequence, the sequences $f(n)$ and $F(k)$ as defined by (14.26) and (14.27) are also N-periodic.

It is generally convenient to adopt the convention

$$\{f(n)\} \leftrightarrow \{F(k)\} \tag{14.29}$$

to represent the transform pair (14.26) and (14.27).

Properties of the DFT

A detailed discussion of the properties of DFT can be found in the cited references at the end of this section. In what follows we consider a few of these properties that are of value for the development of the FFT.

1. *Linearity:*

$$\{af(n) + by(n)\} \leftrightarrow \{aF(k)\} + \{bY(k)\} \tag{14.30}$$

2. *Complex conjugate:* If $f(n)$ is real, $N/2$ is an integer and $\{f(n)\} \leftrightarrow \{F(k)\}$, then

$$F\left(\frac{N}{2} + l\right) = F^*\left(\frac{N}{2} - l\right) \quad l = 0, 1, \ldots, \frac{N}{2} \tag{14.31}$$

   where $F^*(k)$ denotes the complex conjugate of $F(k)$. The preceding identity shows the folding property of the DFT.

3. *Reversal:*

$$\{f(-n)\} \leftrightarrow \{F(-k)\} \tag{14.32}$$

4. *Time shifting:*

$$\{f(n + l)\} \leftrightarrow \{W^{-lk} F(k)\} \tag{14.33}$$

5. *Convolution of real sequences:* If

$$y(n) = \frac{1}{N} \sum_{l=0}^{N-1} f(l)h(n - l) \quad n = 0, 1, \ldots, N - 1 \tag{14.34}$$

   then

$$\{y(n)\} \leftrightarrow \{F(k)\ H(k)\} \tag{14.35}$$

6. *Correlation of real sequences:* If

$$y(n) = \frac{1}{N} \sum_{l=0}^{N-1} f(l)h(n + l) \quad n = 0, 1, \ldots, N - 1 \tag{14.36}$$

   then

$$\{y(n)\} \leftrightarrow \{F(r)\ H^*(k)\} \tag{14.37}$$

7. *Symmetry:*

$$\left\{\frac{1}{N}F(n)\right\} \leftrightarrow \{f(-k)\} \tag{14.38}$$

8. Parseval's theorem:

$$\sum_{n=0}^{N-1}\left|f(n)\right|^2 = \frac{1}{N}\sum_{k=0}^{N-1}\left|F(k)\right|^2 \tag{14.39}$$

where $|F(k)| = F(k)\ F^*(k)$.

Example 1

Verify Parseval's theorem for the sequence $\{f(n)\} = \{1, 2, -1, 3\}$.

Solution. With the help of (14.26) we obtain

$$\begin{aligned} F(k)\Big|_{k=0} &= F(0) = \sum_{n=0}^{3} f(n)e^{-j(2\pi/4)kn}\Big|_{k=0} \\ &= (1e^{-j(\pi/2)0\cdot 0} + 2e^{-j(\pi/2)0\cdot 1} - e^{-j(\pi/2)0\cdot 2} + 3e^{-j(\pi/2)0\cdot 3}) \\ &= 5 \end{aligned}$$

Similarly, we find

$$F(1) = 2 + j \quad F(2) = -5 \quad F(3) = 2 - j$$

Introducing these values in (14.39) we obtain

$$1^2 + 2^2 + (-1)^2 + 3^2 = 1/4[5^2 + (2 + j)(2 - j) + 5^2 + (2 - j)(2 + j)] \quad \text{or} \quad 15 = 60/4$$

which is an identity, as it should have been.

Relation between DFT and Fourier Transform

The sampled form of a continuous function $f(t)$ can be represented by N equally spaced sampled values $f(n)$ such that

$$f(n) = f(nT) \quad n = 0,1,\ldots, N-1 \tag{14.40}$$

where T is the sampling interval. The length of the continuous function is $L = NT$, where $f(N) = f(0)$.

We denote the sampled version of $f(t)$ by $f_s(t)$, which may be represented by a sequence of impulses. Mathematically it is represented by the expression

$$f_s(t) = \sum_{n=0}^{N-1}[Tf(n)]\delta(t - nT) \tag{14.41}$$

where $\delta(t)$ is the Dirac or impulse function.

Taking the Fourier transform of $f_s(t)$ in (14.41) we obtain

$$\begin{aligned} F_s(\omega) &= T\int_{\infty}^{\infty}\sum_{n=0}^{N-1} f(n)\delta(t - nT)e^{-j\omega t}\, dt \\ &= T\sum_{n=0}^{N-1} f(n)\int_{\infty}^{\infty}\delta(t - nT)e^{-j\omega t}dt \\ &= T\sum_{n=0}^{N-1} f(n)e^{-j\omega nT} \end{aligned} \tag{14.42}$$

Equation (14.42) yields $F_s(\omega)$ for all values of ω. However, if we are only interested in the values of $F_s(\omega)$ at a set of discrete equidistant points, then (14.42) is expressed in the form [see also (14.24)]

$$F_s(k\Omega) = T\sum_{n=0}^{N-1} f(n)e^{-jkn\Omega T} \qquad k = 0, \pm 1, \pm 2, \ldots, \pm N/2 \tag{14.43}$$

where $\Omega = 2\pi/L = 2\pi/NT$. Therefore, comparing (14.26) and (14.43) we observe that we can find $F(\omega)$from $F_s(\omega)$ using the relation

$$F(k) = F_s(\omega)\Big|_{\omega = k\Omega} \tag{14.44}$$

Power, Amplitude, and Phase Spectra

If $f(t)$ represents voltage or current waveform supplying a load of 1 Ω, the left-hand side of Parseval's theorem (14.39) represents the power dissipated in the 1-Ω resistor. Therefore, the right-hand side represents the power contributed by each harmonic of the spectrum. Thus the DFT **power spectrum** is defined as

$$P(k) = F(k)F^*(k) = |F(k)|^2 \qquad k = 0, 1, \ldots, N - 1 \tag{14.45}$$

For real $f(n)$ there are only $(N/2 + 1)$ independent DFT spectral points as the complex conjugate property shows (14.31). Hence we write

$$P(k) = |F(k)|^2 \qquad k = 0, 1, \ldots, N/2 \tag{14.46}$$

The *amplitude spectrum* is readily found from that of a power spectrum, and it is defined as

$$A(k) = |F(k)| \qquad k = 0, 1, \ldots, N - 1 \tag{14.47}$$

The power and amplitude spectra are invariant with respect to shifts of the data sequence $\{f(n)\}$.
The **phase spectrum** of a sequence $\{f(n)\}$ is defined as

$$\phi_f(k) = \tan^{-1}\frac{\mathrm{Im}\{F(k)\}}{\mathrm{Re}\{F(k)\}} \qquad k = 0, 1, \ldots, N - 1 \tag{14.48}$$

As in the case of the power spectrum, only $(N/2 + 1)$ of the DFT phase spectral points are independent for real $\{f(n)\}$. For a real sequence $\{f(n)\}$ the power spectrum is an *even function* about the point $k = N/2$ and the phase spectrum is an *odd function* about the point $k = N/2$.

Observations

1. The frequency spacing $\Delta\omega$ between coefficients is

$$\Delta\omega = \Omega = \frac{2\pi}{NT} = \frac{\omega_s}{N} \qquad \text{or} \qquad \Delta f = \frac{1}{NT} = \frac{f_s}{N} = \frac{1}{T_0} \tag{14.49}$$

2. The reciprocal of the record length defines the frequency resolution.
3. If the number of samples N is fixed and the sampling time is increased, the record length and the precision of frequency resolution is increased. When the sampling time is decreased, the opposite is true.
4. If the record length is fixed and the sampling time is decreased (N increases), the resolution stays the same and the computed accuracy of $F(n\Omega)$ increases.
5. If the record length is fixed and the sampling time is increased (N decreases), the resolution stays the same and the computed accuracy of $F(n\Omega)$ decreases.

Data Windowing

To produce more accurate frequency spectra it is recommended that the data are weighted by a **window** function. Hence, the new data set will be of the form$\{f(n)\ w(n)\}$. The following are the most commonly used windows:

1. Triangle (Fejer, Bartlet) window:

$$w(n) = \begin{cases} \dfrac{n}{N/2} & n = 0, 1, \ldots, \dfrac{N}{2} \\ w(N-n) & n = \dfrac{N}{2}, \ldots, N-1 \end{cases} \tag{14.50}$$

2. $\text{Cos}^{\alpha}(x)$ windows:

$$\begin{aligned} w(n) &= \sin^2\left(\frac{n}{N}\pi\right) \\ &= 0.5\left[1 - \cos\left(\frac{2n}{N}\pi\right)\right] \qquad n = 0, 1 \ldots, N-1 \qquad \alpha = 2 \end{aligned} \tag{14.51}$$

   This window is also called the raised cosine or Hamming window.
3. Hamming window:

$$w(n) = 0.54 - 0.46\ \cos\left(\frac{2\pi}{N}n\right) \qquad n = 0, 1, \ldots, N-1 \tag{14.52}$$

4. Blackman window:

$$w(n) = \sum_{m=0}^{K} (-1)^m a_m \cos\left(2\pi m \frac{n}{N}\right) \qquad n = 0, 1, \ldots, N-1 \qquad K \le \frac{N}{2} \tag{14.53}$$

   for $K = 2$, $a_0 = 0.42$, $a_1 = 0.50$, and $a_2 = 0.08$.

TABLE 14.7

No. of Terms in (13.30)	Maximum Sidelobe, dB	Parameter Values			
		a_0	a_1	a_2	a_3
3	–70.83	0.42323	0.49755	0.07922	
3	–62.05	0.44959	0.49364	0.05677	
4	–92	0.35875	0.48829	0.14128	0.01168
4	–74.39	0.40217	0.49703	0.09892	0.00188

5. Blackman-Harris window. Harris used a gradient search technique to find three- and four-term expansion of (14.53) that either minimized the maximum sidelobe level for fixed mainlobe width, or traded mainlobe width versus minimum sidelobe level (see Table 14.7)
6. Centered Gaussian window:

$$w(n) = \exp\left[-\frac{1}{2}\alpha\left(\frac{n}{N/2}\right)^2\right] \qquad 0 \le |n| \le \frac{N}{2} \qquad \alpha = 2, 3, \ldots \tag{14.54}$$

   As α increases, the mainlobe of the frequency spectrum becomes broader and the sidelobe peaks become lower.
7. Centered Kaiser-Bessel window:

$$w(n) = \frac{I_0\left[\pi a\sqrt{1.0 - \left(\frac{n}{N/2}\right)^2}\right]}{I_0(\pi\alpha)} \qquad 0 \le |n| \le \frac{N}{2} \tag{14.55}$$

   where

$$\begin{aligned} I_0(x) &= \text{zero-order modified Bessel function} \\ &= \sum_{k=0}^{\infty}\left(\frac{(x/2)^k}{k!}\right)^2 \\ k_! &= 1 \times 2 \times 3 \times \cdots \times k \\ \alpha &= 2,\ 2.5,\ 3 \qquad \text{(typical values)} \end{aligned} \tag{14.56}$$

Fast Fourier Transform

One of the approaches to speed the computation of the DFT of a sequence is the *decimation-in-time* method. This approach is one of breaking the N-point transform into two $(N/2)$-point transforms, breaking each $(N/2)$-point transform into two $(N/4)$-point transforms, and continuing the above process until we obtain the two-point transform. We start with the DFT expression and factor it into two DFTs of length $N/2$:

$$\begin{aligned} F(k) = &\sum_{n=0}^{N-2} f(n)W_N^{kn} \qquad n \text{ even} \\ &+ \sum_{n=1}^{N-1} f(n)W_N^{kn} \qquad n \text{ odd} \end{aligned} \tag{14.57}$$

Letting $n = 2m$ in the first sum and $n = 2m + 1$ in the second, (14.57) becomes

$$F(k) = \sum_{m=0}^{(N/2)-1} f(2m)W_N^{2mk} + \sum_{m=0}^{(N/2)-1} f(2m+1)W_N^{(2m+1)k} \tag{14.58}$$

However, because of the identities

$$W_N^{2mk} = (W_N^2)^{mk} = e^{-j(2\pi/N)2mk} = e^{-j(4\pi mk/N)} = W_{N/2}^{mk} \tag{14.59}$$

and the substitution $f(2m) = f_1(m)$ and $f(2m + 1) = f_2(m)$, $m = 0, 1, \ldots, N/2 - 1$, takes the form

$$\begin{aligned} F(k) = {} & \sum_{m=0}^{(N/2)-1} f_1(m)W_{N/2}^{mk} && \frac{N}{2}-\text{point DFT of even-indexed sequence} \\ & + W_N^k \sum_{m=0}^{(N/2)-1} f_2(m)W_{N/2}^{mk} && \frac{N}{2}-\text{point DFT of odd-indexed sequence} \\ & && k = 0, \ldots, N/2 - 1 \end{aligned} \tag{14.60}$$

We can also write (14.60) in the form

$$\begin{aligned} F(k) &= F_1(k) + W_N^k F_2(k) && k = 0, 1, \ldots, N/2 - 1 \\ F\left(k + \frac{N}{2}\right) &= F_1(k) + W_N^{k+N/2} F_2(k) \\ &= F_1(k) - W_N^k F_2(k) && k = 0, 1, \ldots, N/2 - 1 \end{aligned} \tag{14.61}$$

where $W_N^{k+N/2} = -W_N^k$ and $W_{N/2}^{m(k+N/2)} = W_{N/2}^{mk}$. Since the DFT is periodic, $F_1(k) = F_1(k + N/2)$ and $F_2(k) = F_2(k + N/2)$.

We next apply the same procedure to each $N/2$ samples, where $f_{11}(m) = f_1(2m)$ and $f_{21}(m) = f_2(2m + 1)$, $m = 0,1, \ldots, (N/4) - 1$. Hence,

$$F_1(k) = \sum_{m=0}^{(N/4)-1} f_{11}(m)W_{N/4}^{mk} + W_N^{2k} \sum_{m=0}^{(N/4)-1} f_{21}(m)W_{N/4}^{mk} \qquad k = 0, 1, \ldots, N/4 - 1 \tag{14.62}$$

or

$$\begin{aligned} F_1(k) &= F_{11}(k) + W_N^{2k} F_{21}(k) \\ F_1\left(k + \frac{N}{4}\right) &= F_{11}(k) - W_N^{2k} F_{21}(k) \quad k = 0, 1, \ldots, N/4 - 1 \end{aligned} \tag{14.63}$$

Therefore, each one of the sequences f_1 and f_2 has been split into two DFTs of length $N/4$.

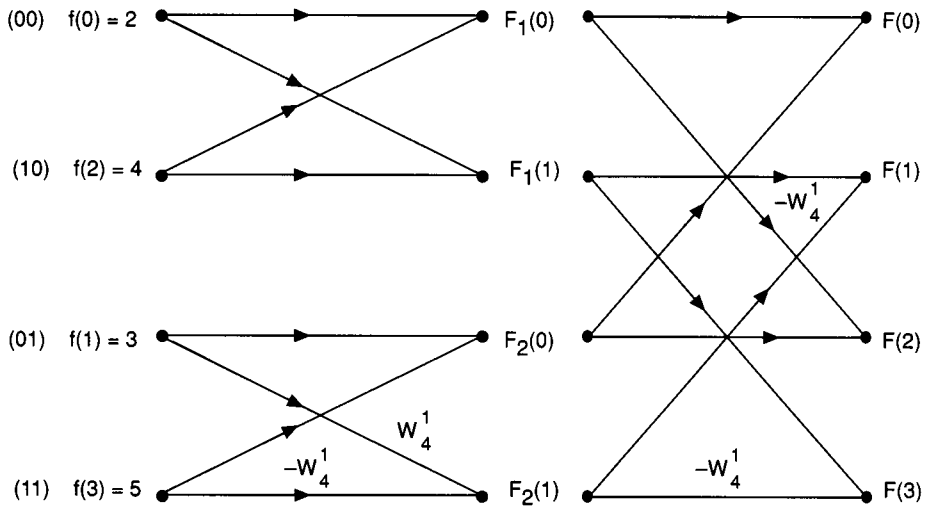

FIGURE 14.9 Illustration of Example 2.

Example 2

To find the FFT of the sequence {2, 3, 4, 5} we first bit reverse the position of the elements from their priority {00, 01, 10, 11} to {00, 10, 01, 11} position. The new sequence is {2, 4, 3, 5} (see also Fig. 14.9). Using (14.60) and (14.61) we obtain

$$F_1(0) = \sum_{m=0}^{1} f_1(m)W_2^{m0} = f_1(0)W_2^0 + f_1(1)W_2^0 = f(0)\cdot 1 + f(2)\cdot 1$$

$$F_1(1) = \sum_{m=0}^{1} f_1(m)W_2^{m\cdot 1} = f_1(0)W_2^{0\cdot 1} + f_1(1)W_2^1 = f(0) + f(2)(-j)$$

$$F_2(0) = W_4^0\sum_{m=0}^{1} f_2(m)W_2^{m\cdot 0} = f_2(0)W_2^0 + f_2(1)W_2^0 = f(1) + f(3)$$

$$F_2(1) = W_4^1\sum_{m=0}^{1} f_2(m)W_2^{m\cdot 1} = W_4^1\left[f(1)W_2^0 + f(3)W_2^1\right] = W_4^1 f(1) - W_4^1 f(3)$$

From (14.61) the output is

$$\begin{aligned} F(0) &= F_1(0) + W_4^0 F_2(0)\\ F(1) &= F_1(1) + W_4^1 F_2(1)\\ F(2) &= F_1(0) - W_4^0 F_2(0)\\ F(3) &= F_1(1) - W_4^1 F_2(1) \end{aligned}$$

Computation of the Inverse DFT

To find the inverse FFT using an FFT algorithm, we use the relation

$$f(n) = \frac{[FFT(F^*(k))]^*}{N} \tag{14.64}$$

TABLE 14.8 FFT Subroutine

For other transforms and their fast algorithms the reader should consult the references given at the end of this section.

Table 14.8 gives the FFT subroutine for fast implementation of the DFT of a finite sequence.

Defining Terms

FFT: A computational technique that reduces the number of mathematical operations in the evaluation of the discrete Fourier transform (DFT) to $N \log_2 N$.

Phase spectrum: All phases associated with the spectrum harmonics.

Power spectrum: A power contributed by each harmonic of the spectrum.

Window: Any appropriate function that multiplies the data with the intent to minimize the distortions of the Fourier spectra.

Fast algorithms appear frequently in the monthly magazine *Signal Processing*, published by The Institute of Electrical and Electronics Engineers.

14.3 Design and Implementation of Digital Filters

Bruce W. Bomar and L. Montgomery Smith

A *digital filter* is a linear, shift-invariant system for computing a **discrete output sequence** from a **discrete input sequence**. The input/output relationship is defined by the *convolution sum*

$$y(n) = \sum_{m=-\infty}^{\infty} h(m)x(n-m)$$

where $x(n)$ is the input sequence, $y(n)$ is the output sequence, and $h(n)$ is the *impulse response* of the filter. The filter is often conveniently described in terms of its frequency characteristics that are given by the *transfer function* $H(e^{j\omega})$. The impulse response and transfer function are a Fourier transform pair:

$$H(e^{j\omega}) = \sum_{n=-\infty}^{\infty} h(n)e^{-j\omega n} \qquad -\pi \le \omega \le \pi$$

$$h(n) = \frac{1}{2\pi}\int_{-\pi}^{\pi} H(e^{j\omega})e^{j\omega n}\, d\omega \qquad -\infty \le n \le \infty$$

Closely related to the Fourier transform of $h(n)$ is the z-transform defined by

$$H(z) = \sum_{n=-\infty}^{\infty} h(n)z^{-n}$$

The Fourier transform is then the z-transform evaluated on the unit circle in the z-plane ($z = e^{j\omega}$). An important property of the z-transform is that $z^{-1}H(z)$ corresponds to $h(n-1)$, so z^{-1} represents a one-sample delay, termed a *unit delay*.

In this section, attention will be restricted to *frequency-selective* filters. These filters are intended to pass frequency components of the input sequence in a given band of the spectrum while blocking the rest. Typical frequency-selective filter types are *low-pass, high-pass, bandpass,* and *band-reject*. Other special-purpose filters exist, but their design is an advanced topic that will not be addressed here. In addition, special attention is given to *causal* filters, that is, those for which the impulse response is identically zero for negative n and thus can be realized in real time. Digital filters are further separated into two classes depending on whether the impulse response contains a finite or infinite number of nonzero terms.

Finite Impulse Response Filter Design

The objective of **finite impulse response (FIR) filter** design is to determine $N + 1$ coefficients

$$h(0),\ h(1),\ \ldots,\ h(N)$$

so that the transfer function $H(e^{j\omega})$ approximates a desired frequency characteristic $H_d(e^{j\omega})$. All other impulse response coefficients are zero. An important property of FIR filters for practical applications is that they can be designed to be *linear phase*, that is, the transfer function has the form

$$H(e^{j\omega}) = A(e^{j\omega})e^{-j\omega N/2}$$

where the amplitude $A(e^{j\omega})$ is a real function of frequency. The desired transfer function can be similarly written

$$H_d(e^{j\omega}) = A_d(e^{j\omega})e^{-j\omega N/2}$$

where $A_d(e^{j\omega})$ describes the amplitude of the desired frequency-selective characteristics. For example, the amplitude frequency characteristics of an ideal low-pass filter are given by

$$A_d(e^{j\omega}) = \begin{cases} 1 & \text{for } |\omega| \le \omega_c \\ 0 & \text{otherwise} \end{cases}$$

where ω_c is the *cutoff frequency* of the filter.

A linear phase characteristic ensures that a filter has a constant group delay independent of frequency. Thus, all frequency components in the signal are delayed by the same amount, and the only signal distortion introduced is that imposed by the filter's frequency-selective characteristics. Since a FIR filter can only approximate a desired frequency-selective characteristic, some measures of the accuracy of approximation are needed to describe the quality of the design. These are the *passband ripple* δ_p, the *stopband attenuation* δ_s, and the *transition bandwidth* $\Delta\omega$. These quantities are illustrated in Fig. 14.10 for a prototype low-pass filter. The passband ripple gives the maximum deviation from the desired amplitude (typically unity) in the region where the input signal spectral components are desired to be passed unattenuated. The stopband attenuation gives the maximum deviation from zero in the region where the input signal spectral components are desired to be blocked. The transition bandwidth gives the width of the spectral region in which the frequency characteristics

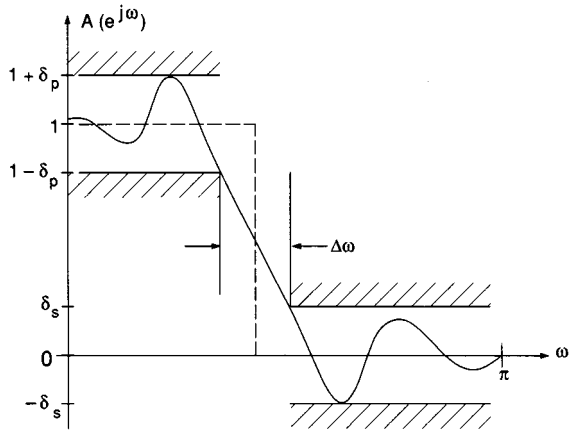

FIGURE 14.10 Amplitude frequency characteristics of a FIR low-pass filter showing definitions of passband ripple δ_p, stopband attenuation δ_s, and transition bandwidth $\Delta\omega$.

of the transfer function change from the passband to the stopband values. Often, the passband ripple and stopband attenuation are specified in decibels, in which case their values are related to the quantities δ_p and δ_s by

$$\text{Passband ripple (dB)} = P = -20 \log_{10} (1 - \delta_p)$$

$$\text{Stopband attenuation (dB)} = S = -20 \log_{10} \delta_s$$

FIR Filter Design by Windowing

The windowing design method is a computationally efficient technique for producing nonoptimal filters. Filters designed in this manner have equal passband ripple and stopband attenuation:

$$\delta_p = \delta_s = \delta$$

The method begins by finding the impulse response of the desired filter from

$$h_d(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} A_d(e^{j\omega}) e^{j\omega (n - N/2)} d\omega$$

For ideal low-pass, high-pass, bandpass, and band-reject frequency-selective filters, the integral can be solved in closed form. The impulse response of the filter is then found by multiplying this ideal impulse response with a window $w(n)$ that is identically zero for $n < 0$ and for $n > N$:

$$h(n) = h_d(n) w(n) \quad n = 0, 1, \ldots, N$$

Some commonly used windows are defined as follows:

1. Rectangular (truncation)

$$w(n) = \begin{cases} 1 & \text{for } 0 \le n \le N \\ 0 & \text{otherwise} \end{cases}$$

2. Hamming

$$w(n) = \begin{cases} 0.54 - 0.46 \cos \dfrac{2\pi n}{N} & \text{for } 0 \le n \le N \\ 0 & \text{otherwise} \end{cases}$$

3. Kaiser

$$w(n) = \begin{cases} \dfrac{I_0\left(\beta\sqrt{1 - [(2n - N)/N]^2}\right)}{I_0(\beta)} & \text{for } 0 \le n \le N \\ 0 & \text{otherwise} \end{cases}$$

In general, windows that slowly taper the impulse response to zero result in lower passband ripple and a wider transition bandwidth. Other windows (e.g., Hamming, Blackman) are also sometimes used but not as often as those shown above.

Of particular note is the Kaiser window where $I_0(.)$ is the 0th-order modified Bessel function of the first kind and β is a shape parameter. The proper choice of N and β allows the designer to meet given passband ripple/stopband attenuation and transition bandwidth specifications. Specifically, using S, the stopband attenuation in dB, the filter order must satisfy

$$N = \frac{S - 8}{2.285\Delta\omega}$$

Then, the required value of the shape parameter is given by

$$\beta = \begin{cases} 0 & \text{for } S < 21 \\ 0.5842(S - 21)^{0.4} + 0.07886(S - 21) & \text{for } 21 \le S \le 50 \\ 0.1102(S - 8.7) & \text{for } S > 50 \end{cases}$$

As an example of this design technique, consider a low-pass filter with a cutoff frequency of $\omega_c = 0.4\pi$. The ideal impulse response for this filter is given by

$$h_d(n) = \frac{\sin[0.4\pi(n - N/2)]}{\pi(n - N/2)}$$

Choosing $N = 8$ and a Kaiser window with a shape parameter of $\beta = 0.5$ yields the following impulse response coefficients:

$$h(0) = h(8) = -0.07568267$$

$$h(1) = h(7) = -0.06236596$$

$$h(2) = h(6) = 0.09354892$$

$$h(3) = h(5) = 0.30273070$$

$$h(4) = 0.40000000$$

Design of Optimal FIR Filters

The accepted standard criterion for the design of optimal FIR filters is to minimize the maximum value of the error function

$$E(e^{j\omega}) = W_d(e^{j\omega})\left|A_d(e^{j\omega}) - A(e^{j\omega})\right|$$

over the full range of $-\pi \le \omega \le \pi$. $W_d(e^{j\omega})$ is a desired weighting function used to emphasize specifications in a given frequency band. The ratio of the deviation in any two bands is inversely proportional to the ratio of their respective weighting.

A consequence of this optimization criterion is that the frequency characteristics of optimal filters are *equiripple:* although the maximum deviation from the desired characteristic is minimized, it is reached several times in each band. Thus, the passband and stopband deviations oscillate about the desired values with equal amplitude in each band. Such approximations are frequently referred to as *minimax* or *Chebyshev* approximations. In contrast, the maximum deviations occur near the band edges for filters designed by windowing.

Equiripple FIR filters are usually designed using the *Parks-McClellan* computer program [Parks and Burrus, 1987], which uses the *Remez exchange algorithm* to determine iteratively the *extremal frequencies* at which the maximum deviations in the error function occur. A listing of this program along with a detailed description of its use is available in several references including Parks and Burrus [1987] and DSP Committee [1979]. The program is executed by specifying as inputs the desired band edges, gain for each band (usually 0 or 1), band weighting, and FIR length. If the resulting filter has too much ripple in some bands, those bands can be weighted more heavily and the filter redesigned. Details on this design procedure are discussed in Rabiner [1973], along with approximate design relationships which aid in selecting the filter length needed to meet a given set of specifications.

Although we have focused attention on the design of frequency-selective filters, other types of FIR filters exist. For example, the Parks-McClellan program will also design linear-phase FIR filters for differentiating broadband signals and for approximating the Hilbert transform of such signals. A simple modification to this program permits arbitrary magnitude responses to be approximated with linear-phase filters. Other design techniques are available that permit the design of FIR filters which approximate an arbitrary complex response [Parks and Burrus, 1987; Chen and Parks, 1987], and, in cases where a nonlinear phase response is acceptable, design techniques are available that give a shorter impulse response length than would be required by a linear-phase design [Goldberg et al., 1981].

As an example of an equiripple filter design, an 8th-order low-pass filter with a passband $0 \le \omega \le 0.3\pi$, a stopband $0.5\pi \le \omega \le \pi$, and equal weighting for each band was designed. The impulse response coefficients generated by the Parks-McClellan program were as follows:

$$h(0) = h(8) = -0.06367859$$

$$h(1) = h(7) = -0.06912276$$

$$h(2) = h(6) = 0.10104360$$

$$h(3) = h(5) = 0.28574990$$

$$h(4) = 0.41073000$$

These values can be compared to those for the similarly specified filter designed in the previous subsection using the windowing method.

Infinite Impulse Response Filter Design

An **infinite impulse response (IIR) digital filter** requires less computation to implement than a FIR digital filter with a corresponding frequency response. However, IIR filters cannot generally achieve a perfect linear-phase response and are more susceptible to **finite wordlength effects.**

Techniques for the design of IIR analog filters are well established. For this reason, the most important class of IIR digital filter design techniques is based on forcing a digital filter to behave like a reference analog filter. This can be done in several different ways. For example, if the analog filter impulse response is $h_a(t)$ and the digital filter impulse response is $h(n)$, then it is possible to make $h(n) = h_a(nT)$, where T is the sample spacing of the digital filter. Such designs are referred to as *impulse-invariant* [Parks and Burrus, 1987]. Likewise, if $g_a(t)$ is the unit step response of the analog filter and $g(n)$ is the unit step response of the digital filter, it is possible to make $g(n) = g_a(nT)$, which gives a *step-invariant* design [Parks and Burrus, 1987].

The step-invariant and impulse-invariant techniques perform a time domain matching of the analog and digital filters but can produce aliasing in the frequency domain. For frequency-selective filters it is better to attempt matching frequency responses. This task is complicated by the fact that the analog filter response is defined for an infinite range of frequencies ($\Omega = 0$ to ∞), while the digital filter response is defined for a finite range of frequencies ($\omega = 0$ to π). Therefore, a method for mapping the infinite range of analog frequencies Ω into the finite range from $\omega = 0$ to π, termed the *bilinear transform,* is employed.

Bilinear Transform Design of IIR Filters

Let $H_a(s)$ be the Laplace transform transfer function of an analog filter with frequency response $H_a(j\,\Omega)$. The bilinear transform method obtains the digital filter transfer function $H(z)$ from $H_a(s)$ using the substitution

$$s = \frac{2(1 - z^{-1})}{T(1 + z^{-1})}$$

That is,

$$H(z) = H_a(s)\big|_{s = \frac{2}{T}\,\frac{1 - z^{-1}}{1 + z^{-1}}}$$

This maps analog frequency Ω to digital frequency ω according to

$$\omega = 2\tan^{-1}\frac{\Omega T}{2}$$

thereby warping the frequency response $H_a(j\,\Omega)$ and forcing it to lie between 0 and π for $H(e^{j\omega})$. Therefore, to obtain a digital filter with a cutoff frequency of ω_c it is necessary to design an analog filter with cutoff frequency

$$\Omega_c = \frac{2}{T}\tan\frac{\omega_c}{2}$$

This process is referred to as *prewarping* the analog filter frequency response to compensate for the warping of the bilinear transform. Applying the bilinear transform substitution to this analog filter will then give a digital filter that has the desired cutoff frequency.

Analog filters and hence IIR digital filters are typically specified in a slightly different fashion than FIR filters. Figure 14.11 illustrates how analog and IIR digital filters are usually specified. Notice by comparison to Fig. 14.10 that the passband ripple in this case never goes above unity, whereas in the FIR case the passband ripple is specified about unity.

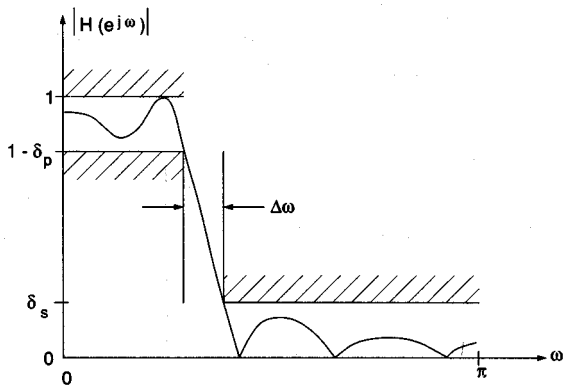

FIGURE 14.11 Frequency characteristics of an IIR digital low-pass filter showing definitions of passband ripple δ_p, stopband attenuation δ_s, and transition bandwith $\Delta\omega$.

Four basic types of analog filters are generally used to design digital filters: (1) Butterworth filters that are maximally flat in the passband and decrease monotonically outside the passband, (2) Chebyshev filters that are equiripple in the passband and decrease monotonically outside the passband, (3) inverse Chebyshev filters that are flat in the passband and equiripple in the stopband, and (4) elliptic filters that are equiripple in both the passband and stopband. Techniques for designing these analog filters are covered elsewhere [see, for example, Van Valkenberg, 1982] and will not be considered here.

To illustrate the design of an IIR digital filter using the bilinear transform, consider the design of a second-order Chebyshev low-pass filter with 0.5 dB of passband ripple and a cutoff frequency of $\omega_c = 0.4\,\pi$. The sample rate of the digital filter is to be 5 Hz, giving $T = 0.2$ s. To design this filter we first design an analog Chebyshev low-pass filter with a cutoff frequency of

$$\Omega_c = \frac{2}{0.2}\tan 0.2\pi = 7.2654 \text{ rad/s}$$

This filter has a transfer function

$$H(s) = \frac{0.9441}{1 + 0.1249s + 0.01249s^2}$$

Substituting

$$s = \frac{2}{0.2}\,\frac{z-1}{z+1}$$

gives

$$H(z) = \frac{0.2665(z+1)^2}{z^2 - 0.1406z + 0.2695}$$

Computer programs are available that accept specifications on a digital filter and carry out all steps required to design the filter, including prewarping frequencies, designing the analog filter, and performing the bilinear transform. Two such programs are given in the references [Parks and Burrus, 1987; Antoniou, 1979].

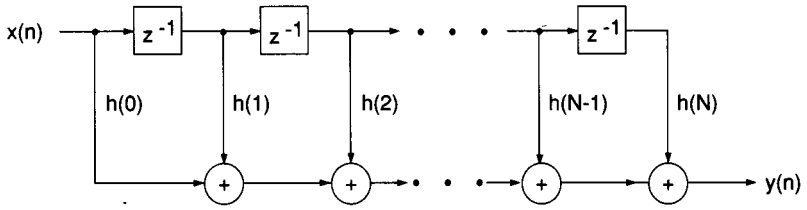

FIGURE 14.12 A direct-form implementation of a FIR filter.

Design of Other IIR Filters

For frequency-selective filters, the bilinear transformation of an elliptic analog filter provides an optimal equiripple design. However, if a design other than standard low-pass, high-pass, band-pass, or bandstop is needed or if it is desired to approximate an arbitrary magnitude or group delay characteristic, some other design technique is needed. Unlike the FIR case, there is no standard IIR design program for obtaining optimal approximations to an arbitrary response.

Four techniques that have been used for designing optimal equiripple IIR digital filters are [Parks and Burrus, 1987] (1) minimizing the L_p norm of the weighted difference between the desired and actual responses, (2) linear programming, (3) iteratively using the Remez exchange algorithm on the numerator and denominator of the transfer function, and (4) the differential correction algorithm. A computer program for implementing the first method is available in DSP Committee [1979].

Finite Impulse Response Filter Implementation

For FIR filters, the convolution sum represents a computable process, and so filters can be implemented by directly programming the arithmetic operations. Nevertheless, some options are available that may be preferable for a given processor architecture, and means for reducing computational loads exist. This section outlines some of these methods and presents schemes for FIR filter realization.

Direct Convolution Methods

The most obvious method for the implementation of FIR filters is to directly evaluate the sum of products in the convolution sum:

$$y(n) = h(0)x(n) + h(1)x(n-1) + \ldots + h(N)x(n-N)$$

The block diagram for this is shown in Fig. 14.12. This method involves storing the present and previous N values of the input, multiplying each sample by the corresponding impulse response coefficient, and summing the products to compute the output. This method is referred to as a *tapped delay line* structure.

A modification to this approach is suggested by writing the convolution as

$$y(n) = h(0)x(n) + \sum_{m=1}^{N} h(m)x(n-m)$$

In this approach, the output is computed by adding the product of $h(0)$ with the present input sample to a previously computed sum of products and updating a set of N sums of products with the present input sample value. The signal flow graph for this method is shown in Fig. 14.13.

FIR filters designed to have linear phase are usually obtained by enforcing the symmetry constraint

$$h(n) = h(N-n)$$

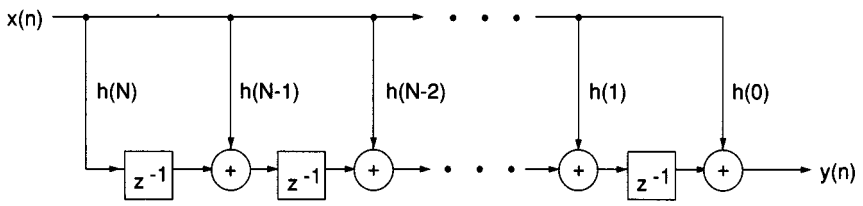

FIGURE 14.13 Another direct-form implementation of a FIR filter.

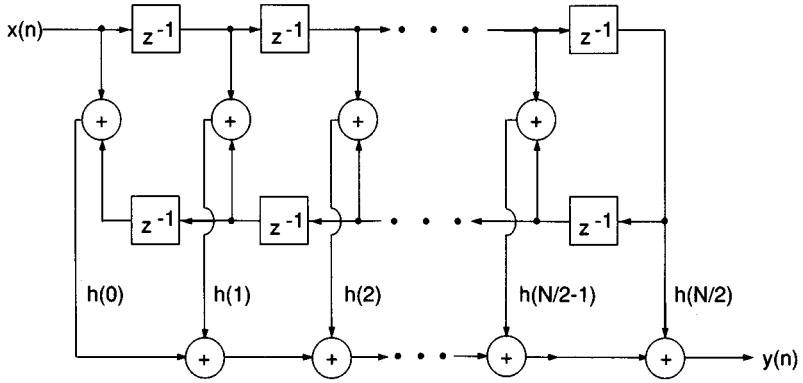

FIGURE 14.14 Implementation of a linear-phase FIR filter for even *N*.

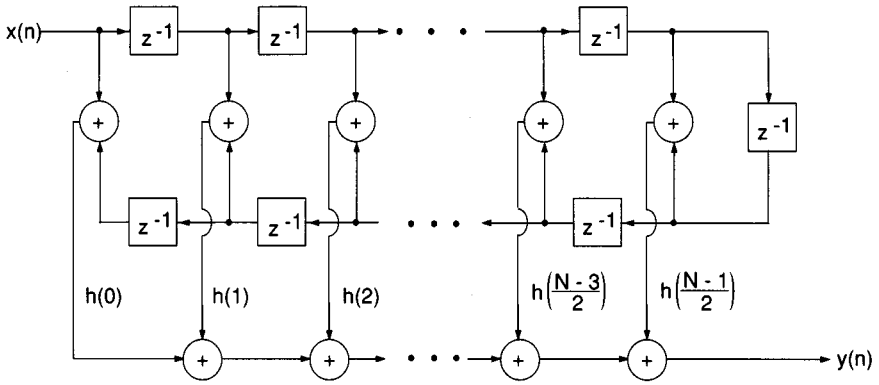

FIGURE 14.15 Implementation of a linear-phase FIR filter for odd *N*.

For these filters, the convolution sum can be written

$$y(n) = \begin{cases} \displaystyle\sum_{m=0}^{N/2-1} h(m)[x(n-m) + x(n+m-N)] + h\left(\frac{N}{2}\right)x\left(n-\frac{N}{2}\right) & N \text{ even} \\ \displaystyle\sum_{m=0}^{(N-1)/2} h(m)[x(n-m) + x(n+m-N)] & N \text{ odd} \end{cases}$$

Implementation of the filter according to these formulas reduces the number of multiplications by approximately a factor of 2 over direct-form methods. The block diagrams for these filter structures are shown in Figs. 14.14 and 14.15.

Implementation of FIR Filters Using the Discrete Fourier Transform

A method for implementing FIR filters that can have computational advantages over direct-form convolution involves processing the input data in blocks using the discrete Fourier transform (DFT) via the *overlap-save* method. The computational advantage arises primarily from use of the fast Fourier transform (FFT) algorithm (discussed in Section 14.2) to compute the DFTs of the individual data blocks. In this method, the input data sequence $\{x(n); -\infty < n < \infty\}$ is divided into L-point blocks

$$x_i(n) \quad 0 \le n \le L-1 \quad -\infty < i < \infty$$

where $L > N+1$, the length of the FIR filter. The L-point DFT of the impulse response is precomputed from

$$H[k] = \sum_{n=0}^{L-1} h(n)e^{-j2\pi kn/L} \qquad k = 0, 1, \ldots, L-1$$

where square brackets are used to distinguish the DFT from the continuous-frequency transfer function of the filter $H(e^{j\omega})$. Then, the DFT of each data block is computed according to

$$X_i[k] = \sum_{n=0}^{L-1} x_i(n)e^{-j2\pi kn/L} \qquad k = 0, 1, \ldots, L-1$$

These two complex sequences are multiplied together term by term to form the DFT of the output data block:

$$Y_i[k] = H[k]X_i[k] \quad k = 0, 1, \ldots, L-1$$

and the output data block is computed by the inverse DFT:

$$y_i(n) = \frac{1}{L}\sum_{k=0}^{L-1} Y_i[k]e^{j2\pi kn/L} \qquad n = 0, 1, \ldots, L-1$$

However, the output data block computed in this manner is the *circular convolution* of the impulse response of the filter and the input data block given by

$$y_i(n) = \sum_{m=0}^{N} h(m)x_i((n-m) \text{ modulo } L)$$

Thus, only the output samples from $n = N$ to $n = L-1$ are the same as those that would result from the convolution of the impulse response with the infinite-length data sequence $x(n)$. The first N data points are corrupted and must therefore be discarded. So that the output data sequence does not have N-point "gaps" in it, it is therefore necessary to *overlap* the data in adjacent input data blocks. In carrying out the processing, samples from block to block are *saved* so that the last N points of the ith data block $x_i(n)$ are the same as the first N points of the following data block $x_{i+1}(n)$. Each processed L-point data block thus produces $L-N$ output samples.

Another technique of block processing of data using DFTs is the *overlap-add* method in which $L-N$-point blocks of input data are zero-padded to L points, the resulting output blocks are overlapped by N points, and corresponding samples added together. This method requires more computation than the overlap-save method and is somewhat more difficult to program. Therefore, its usage is not as widespread as the overlap-save method.

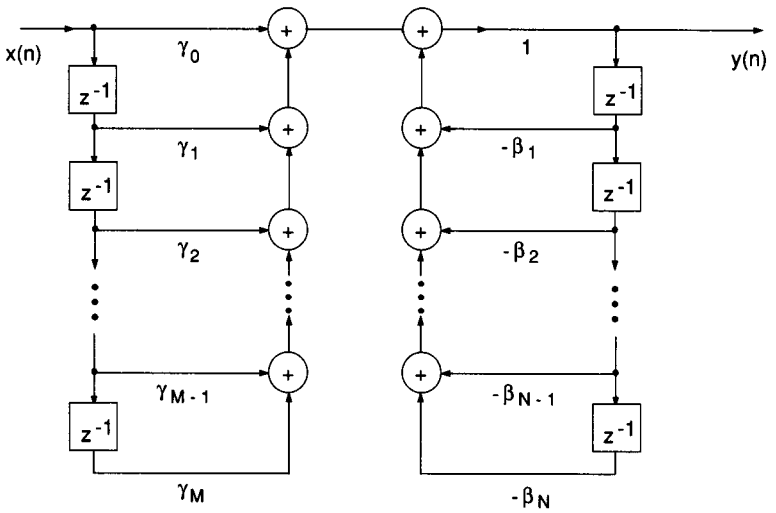

FIGURE 14.16 Direct-form I realization.

Infinite Impulse Response Filter Implementation

Direct-Form Realizations

For an IIR filter the convolution sum does not represent a computable process. Therefore, it is necessary to examine the general transfer function, which is given by

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\gamma_0 + \gamma_1 z^{-1} + \gamma_2 z^{-2} + \cdots + \gamma_M z^{-M}}{1 + \beta_1 z^{-1} + \beta_2 z^{-2} + \cdots + \beta_N z^{-N}}$$

where $Y(z)$ is the z-transform of the filter output $y(n)$ and $X(z)$ is the z-transform of the filter input $x(n)$. The unit-delay characteristic of z^{-1} then gives the following *difference equation* for implementing the filter:

$$y(n) = \gamma_0 x(n) + \gamma_1 x(n-1) + \ldots + \gamma_M x(n-M) - \beta_1 y(n-1) - \ldots - \beta_N y(n-N)$$

When calculating $y(0)$, the values of $y(-1)$, $y(-2)$, . . ., $y(-N)$ represent initial conditions on the filter. If the filter is started in an initially relaxed state, then these initial conditions are zero.

Figure 14.16 gives a block diagram realizing the filter's difference equation. This structure is referred to as the *direct-form I* realization. Notice that this block diagram can be separated into two parts, giving two cascaded networks, one of which realizes the filter zeros and the other the filter poles. The order of these networks can be reversed without changing the transfer function. This results in a structure where the two strings of delays are storing the same values, so a single string of delays of length $max(M, N)$ is sufficient, as shown in Fig. 14.17. The realization of Fig. 14.17 requires the minimum number of z^{-1} delay operations and is referred to as the *direct-form II* realization.

Cascade and Parallel Realizations

The transfer function of an IIR filter can always be factored into the product of second-order transfer functions as

$$H(z) = C\prod_{k=1}^{K} \frac{1 + a_{1k} z^{-1} + a_{2k} z^{-2}}{1 + b_{1k} z^{-1} + b_{2k} z^{-2}} = C\prod_{k=1}^{K} H_k(z)$$

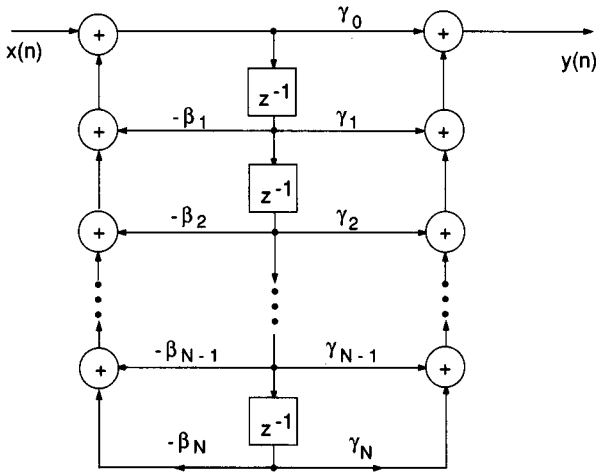

FIGURE 14.17 Direct-form II realization.

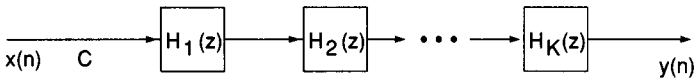

FIGURE 14.18 Cascade realization of an IIR filter.

where we have assumed $M = N$ in the original transfer function and where K is the largest integer contained in $(N + 1)/2$. If N is odd, the values of a_{2k} and b_{2k} in one term are zero. The realization corresponding to this transfer function factorization is shown in Fig. 14.18. Each second-order $H_k(z)$ term in this realization is referred to as a *biquad*. The digital filter design programs in Parks and Burrus [1987] and Antoniou [1979] give the filter transfer function in factored form.

If the transfer function of an IIR filter is written as a partial-fraction expansion and first-order sections with complex-conjugate poles are combined, $H(z)$ can be expressed in the form

$$H(z) = D + \sum_{k=1}^{K} \frac{\alpha_{0k} + \alpha_{1k} z^{-1}}{1 + b_{1k} z^{-1} + b_{2k} z^{-2}} = D + \sum_{k=1}^{K} G_k(z)$$

This results in the parallel realization of Fig. 14.19.

Finite Wordlength Effects in IIR Filters

Since practical digital filters must be implemented with limited-precision arithmetic, four types of finite wordlength effects result: (1) roundoff noise, (2) coefficient quantization error, (3) overflow oscillations, and (4) limit cycles. *Round-off noise* is that error in the filter output which results from rounding (or truncating) calculations within the filter. This error appears as low-level noise at the filter output. *Coefficient quantization error* refers to the deviation of a practical filter's frequency response from the ideal due to the filter's coefficients being represented with finite precision. The term *overflow oscillation*, sometimes also referred to as *adder overflow limit cycle*, refers to a high-level oscillation that can exist in an otherwise stable filter due to the nonlinearity associated with the overflow of internal filter calculations. A *limit cycle*, sometimes referred to as a *multiplier round-off limit cycle*, is a low-level oscillation that can exist in an otherwise stable filter as a result of the nonlinearity associated with rounding (or truncating) internal filter calculations. Overflow oscillations and limit cycles require recursion to exist and do not occur in nonrecursive FIR filters.

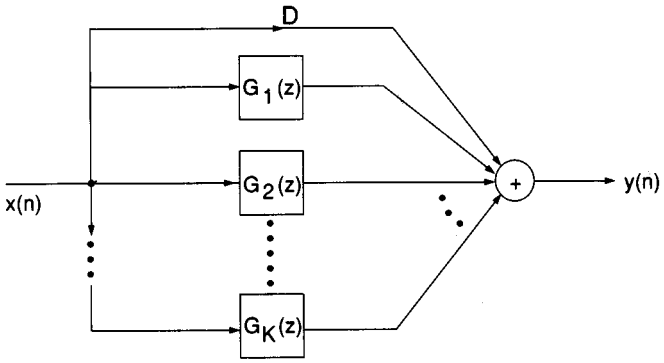

FIGURE 14.19 Parallel realization of an IIR filter.

The direct-form I and direct-form II IIR filter realizations generally have very poor performance in terms of all finite wordlength effects. Therefore, alternative realizations are usually employed. The most common alternatives are the cascade and parallel realizations where the direct-form II realization is used for each second-order section. By simply factoring or expanding the original transfer function, round-off noise and coefficient quantization error are significantly reduced. A further improvement is possible by implementing the cascade or parallel sections using *state-space* realizations [Roberts and Mullis, 1987]. The price paid for using state-space realizations is an increase in the computation required to implement each section. Another realization that has been used to reduce round-off noise and coefficient quantization error is the *lattice realization* [Parks and Burrus, 1987] which is usually formed directly from the unfactored and unexpanded transfer function.

Overflow oscillations can be prevented in several different ways. One technique is to employ floating-point arithmetic that renders overflow virtually impossible due to the large dynamic range which can be represented. In fixed-point arithmetic implementations it is possible to *scale* the calculations so that overflow is impossible [Roberts and Mullis, 1987], to use saturation arithmetic [Ritzerfeld, 1989], or to choose a realization for which overflow transients are guaranteed to decay to zero [Roberts and Mullis, 1987].

Limit cycles can exist in both fixed-point and floating-point digital filter implementations. Many techniques have been proposed for testing a realization for limit cycles and for bounding their amplitude when they do exist. In fixed-point realizations it is possible to prevent limit cycles by choosing a state-space realization for which any internal transient is guaranteed to decay to zero and then using magnitude truncation of internal calculations in place of rounding [Diniz and Antoniou, 1986].

Defining Terms

Discrete sequence: A set of values constituting a signal whose values are known only at distinct sampled points. Also called a digital signal.

Filter design: The process of determining the coefficients of a difference equation to meet a given frequency or time response characteristic.

Filter implementation: The numerical method or algorithm by which the output sequence is computed from the input sequence.

Finite impulse response (FIR) filter: A filter whose output in response to a unit impulse function is identically zero after a given bounded number of samples. A FIR filter is defined by a linear constant-coefficient difference equation in which the output depends only on the present and previous sample values of the input.

Finite wordlength effects: Perturbations of a digital filter output due to the use of finite precision arithmetic in implementing the filter calculations. Also called quantization effects.

Infinite impulse response (IIR) filter: A filter whose output in response to a unit impulse function remains nonzero for indefinitely many samples. An IIR filter is defined by a linear constant-coefficient difference equation in which the output depends on the present and previous samples of the input and on previously computed samples of the output.

Further Information

The monthly magazine *IEEE Transactions on Circuits and Systems II* routinely publishes articles on the design and implementation of digital filters. Finite wordlength effects are discussed in articles published in the April 1988 issue (pp. 365–374) and in the February 1992 issue (pp. 90–98).

Another journal containing articles on digital filters is the *IEEE Transactions on Signal Processing.* Overflow oscillations and limit cycles are discussed in the August 1978 issue (pp. 334–338).

The bimonthly journal *IEEE Transactions on Instrumentation and Measurement* also contains related information. The use of digital filters for integration and differentiation is discussed in the December 1990 issue (pp. 923–927).

14.4 Signal Restoration

James A. Cadzow

The concept of **signal restoration** has been applied with success to a number of fundamental problems found in interdisciplinary applications. In the typical signal restoration problem, there is given empirical data as symbolically designated by $\mathbf{x}$ that corresponds to corrupted measurements made on an underlying signal being monitored. By using attributes (properties) known to be or hypothesized as being possessed by the monitored signal, it is possible to devise signal restoration algorithms that effectively remove the corruption to give useful approximations of the underlying signal being monitored. Many of the more widely used restoration algorithms take the form of a sequence of *successive projections* as specified by

$$\mathbf{x}_n = P_1 P_2 \ldots P_m \mathbf{x}_{n-1}$$

In this algorithm, P_k designates the projection operator corresponding to the set of signals possessing attribute k while $\mathbf{x}_n$ denotes the enhanced signal at the nth iteration in which the initial point is $\mathbf{x}_o = \mathbf{x}$. In this section, we will give a historical perspective on the evolution of the **method of successive projections** as well as provide implementations of some of the most important projection operators.

Members of the class of signal restoration algorithms that are describable by a successive projection operator are primarily distinguished by the restrictions placed on the **attribute sets**. The earliest versions of these algorithms were highly restrictive and required that the attribute sets be closed subspaces. Unfortunately, this requirement severely limited the types of restoration problems that could be addressed. In recognition of this limitation, subsequent methods of successive projections algorithms eased the requirements on the attribute sets to that of being **closed convex sets** and eventually to the projection operators being closed mappings. This progression of less restrictive requirements significantly expands the types of signal processing problems that are amenable to signal restoration by successive projections.

Introduction

In a typical signal processing application, one is given empirically gathered data that arises from measurements made on a signal(s) characterizing a phenomenon under study. These measurements are invariably corrupted due to imperfections arising from the measurement instrumentation and environmental influences. To recover a reasonable facsimile of the original signal being monitored, it is generally necessary to process the measurement data in a manner that takes into account all information known about the monitored signal, the instrument dynamics, and the nature of the corruption. Although it is generally impossible to obtain a perfect recovery, remarkable approximations can be made in several important applications by employing the concept of *signal restoration* (or *signal recovery*). In signal restoration, *a priori* knowledge concerning the underlying signal's intrinsic nature may be effectively used to strip away the corruption in the measurement data. The philosophy behind this approach is to modify the measurement data to the smallest extent possible so that the modified data possesses the prescribed properties known (or hypothesized) as being possessed by the underlying signal(s). This modification then serves as a cleansing process whereby the measurement corruption is effectively removed.

Metric Space Formulation

To avail ourselves of the extensive analysis tools found in algebra, it is useful to formulate the basic signal restoration problem in a general metric space setting. This has the desirable effect of enabling us to treat a wide variety of applications in a single setting. With this in mind, the measurement signals are taken to lie in a *metric space* which is composed of a set of elements designated by X and a metric $d(\mathbf{x},\mathbf{y})$ that measures the distance between any two elements $\mathbf{x},\mathbf{y} \in X$. The elements of the set X are taken to possess a common form such as being composed of all $n \times 1$ real-valued vectors or all complex-valued continuous functions defined on a given interval. Moreover, the distance metric identifying this space must satisfy the axioms associated with a distance measure.[1] We will interchangeably refer to the elements of the metric space as vectors or signals. Depending on the nature of a particular application, the signals can take on such disparate forms as being composed of all real- (or complex-) valued $n \times 1$ vectors, $m \times n$ matrices, infinite-length sequences, continuous-time functions, and so forth.

Example 1. In digital signal processing, the two most commonly employed metric spaces correspond to the set of all real-valued $n \times 1$ vectors as designated by R^n and the set of all real-valued $m \times n$ matrices as designated by $R^{m \times n}$. The elements of a vector contained in R^n typically correspond to samples made of a one-dimensional signal. On the other hand, the elements of a matrix contained in $R^{m \times n}$ might correspond to the brightness levels of the pixels in a rectangular image or the entries of a data matrix formed from samples of a one-dimensional signal. It often happens in engineering applications that the data under analysis is complex valued. To treat such cases, we will have need to consider the set of all complex-valued $n \times 1$ tuples as designated by C^n and the set of all complex-valued $m \times n$ matrices as denoted by $C^{m \times n}$.

To complete the metric space description of spaces R^n and C^n, it is necessary to introduce a distance metric. The most commonly employed distance measure for either space is the Euclidean-induced metric

$$d(\mathbf{x},\mathbf{y}) = \sqrt{\sum_{k=1}^{n} |y(k) - x(k)|^2} \tag{14.65}$$

[1]The mapping $X \times X \rightarrow R$ designated by $d(\mathbf{x},\mathbf{y})$ is said to be a distance metric if it satisfies the four axioms: (1) $d(\mathbf{x},\mathbf{y})$ is nonnegative real-valued, (2) $d(\mathbf{x},\mathbf{y}) = 0$ if and only if $\mathbf{x} = \mathbf{y}$, (3) $d(\mathbf{x},\mathbf{y}) = d(\mathbf{y},\mathbf{x})$, and (4) $d(\mathbf{x},\mathbf{y}) \leq d(\mathbf{x},\mathbf{z}) + d(\mathbf{z},\mathbf{y})$.

In a similar fashion, the *Frobenius norm* distance metric on the spaces $R^{m\times n}$ and $C^{m\times n}$ is commonly used where

$$d(\mathbf{X},\mathbf{Y}) = \sqrt{\sum_{i=1}^{m}\sum_{j=1}^{n} |Y(i,j) - X(i,j)|^2} \tag{14.66}$$

It is a simple matter to show that either of these measures satisfies the axioms of a distance metric.

Attribute Sets

As indicated previously, the concept of signal restoration is directed towards applications in which a measurement process introduces inevitable distortion in a signal that is being monitored. The fundamental philosophy underlying signal restoration is based on the hypothesis that the signal under observation is known or presumed to lie in a restricted *attribute set C*, *X*. This attribute set is composed of all signals in *X* that possess a prescribed set of attributes (or properties). The measurement process, however, results in a measurement signal that is perturbed outside this set. The set *C* employed in a signal restoration problem is often decomposable as the intersection of a finite number of basic attribute sets that are each describable by elementary attributes (or properties). We will designate these basic attribute sets as

$$C_k = \{\mathbf{x} \in X : \mathbf{x} \text{ has attribute } \mathcal{A}_k\} \quad \text{for } 1 \le k \le m \tag{14.67}$$

We will hereafter refer to the intersection of these basic attribute subsets as the composite attribute set since its constituent elements satisfy all the required attributes believed to be possessed by the signal being monitored.

$$C = C_1 \cap C_2 \cap \ldots \cap C_m \tag{14.68}$$

The usefulness of signal restoration is critically dependent on one's ability to identify all essential basic sets C_k describing the underlying information signal.

Once the composite attribute set *C* has been identified, the fundamental signal restoration problem entails finding a signal contained in this set that lies closest to the measurement signal **x** in the underlying distance metric sense. This gives rise to the following optimization problem:

$$\min_{\mathbf{y}\in C} d(\mathbf{x},\mathbf{y}) \tag{14.69}$$

In finding that signal contained in *C* which lies closest to **x**, we are in effect seeking the smallest perturbation of the measured signal **x** which results in a modified signal that possesses the hypothesized properties of the signal being monitored. Implicit in this approach is the assumption that the measurement process introduces the smallest distortion possible compatible with the measured data. Although this assumption is generally violated in most applications, it is reasonably accurate so that the solution to signal restoration problem (14.69) typically provides for a useful reconstruction of the signal being monitored.

Example 2. To illustrate the concept of signal properties, let us consider the autocorrelation sequence associated with the wide-sense stationary time series $\{x(n)\}$. This two-sided sequence is formally defined by

$$r_{xx}(n) = E\{x(n+m)\,\bar{x}(m)\} \quad \text{for } n = 0, \pm 1, \pm 2 \quad \ldots \tag{14.70}$$

where *E* designates the *expected value operator*. It is well known that this autocorrelation sequence satisfies the two attributes of being conjugate symmetric and having a nonnegative Fourier transform. The set of signals associated with these two attributes are then formally given by

$$C_{\text{cs}} = \{\text{set of sequences } \{x(n)\} \text{ such that } x(n) = \bar{x}(-n)\}$$

$$C_{\text{nnd}} = \{\text{set of sequences } \{x(n)\} \text{ such that } X(\omega) = \sum_{n=-\infty}^{\infty} x(n)e^{-j\omega n} \ge 0\}$$

It can be shown that the set of conjugate-symmetric sequences C_{cs} is a closed vector space. Moreover, the set of nonnegative definite sequences C_{nnd} is a closed convex cone subset of C_{cs}.

Normed Vector Space Formulation

The primary objective of this paper is to present several algorithms which have been proposed for solving optimization problem (14.69) using an iterative approach. These algorithms take on a similar form and are distinguished by the algebraic restrictions placed on the underlying attribute subsets. To provide for a satisfactory mathematical characterization of the restoration problem and its solution, it is essential that we provide an algebraic structure to the underlying metric space. In particular, the ability to add vectors and multiply vectors by scalars provides a useful means for interpreting the measurement signal and more importantly considerably increases the arsenal of analysis tools at our disposal. Fortunately, little loss in generality is incurred by introducing these two algebraic operations since in most signal processing applications of interest there exists an intuitively obvious means for their implementation. For example, if the metric space is taken to be R^n (or C^n), then the sum of any two vectors $\mathbf{x},\mathbf{y} \in R^n$ (or C^n) has as its kth component $x(k) + y(k)$, while the scalar product $a\mathbf{x}$ has as its kth component $a\mathbf{x}(k)$ for $1 \le k \le n$.

One of the most important benefits of posing the signal restoration problem in a vector space setting is that of providing a widely invoked model for the measured signal (vector) as specified by

$$\mathbf{x} = \mathbf{s} + \mathbf{w} \tag{14.71}$$

where $\mathbf{s}$ designates the signal being monitored and $\mathbf{w}$ represents measurement error. From our previous discussion, it has been hypothesized that the monitored signal lies in each of the attribute sets so that $\mathbf{s} \in C_k$ for $1 \le k \le m$. To effectively recover $\mathbf{s}$ from $\mathbf{x}$ using signal restoration, it is tacitly assumed that the measurement error vector $\mathbf{w}$ has features which are distinctly different from those specified by these m attribute subsets.

The metric needed to measure the distance between any two elements in vector space X often follows in a natural fashion from the basic structure of the vector space. In particular, many of the vector spaces encountered in typical applications have an underlying vector norm measure.[2] A natural choice of a distance metric on a normed vector space is specified by

$$d(\mathbf{x},\mathbf{y}) = \| \mathrm{x} - \mathrm{y} \| \tag{14.72}$$

This distance metric is said to be induced by the norm defined on the underlying normed vector space X. A solution to the signal restoration problem in a normed vector space setting therefore requires solving the minimization problem

$$\min_{\mathbf{y} \in C} \| \mathbf{x} - \mathbf{y} \| \tag{14.73}$$

Example 3. As indicated previously, the vector spaces R^n and C^n play prominent roles in signal processing applications. The class of l_p norms as defined by

$$\| \mathbf{x} \|_p = \left[\sum_{k=1}^{n} | x(k) |^p \right]^{1/p} \tag{14.74}$$

are commonly used where the number p is restricted to lie in the interval $1 \le p < \infty$. Three of the most widely employed choices of the norm index are $p = 1$, 2, and ∞. In a similar manner, the l_p-induced norm for any matrix $A \in R^{m \times n}$ (or $C^{m \times n}$) is specified by

$$\| A \|_p = \max_{\mathbf{x}^*\mathbf{x}=1} \| A\mathbf{x} \|_p \tag{14.75}$$

[2]A mapping between X and R as designated by $\|\mathrm{x}\|$ is said to be a *norm* if it satisfies the axioms (1) $\|\mathrm{x}\| \ge 0$ for all $\mathrm{x} \in \mathrm{X}$ and $\|\mathrm{x}\| = 0$ if and only if $\mathrm{x} = 0$; (2) $\|\mathrm{x} + \mathrm{y}\| \le \|\mathrm{x}\| + \|\mathrm{y}\|$ for all $\mathrm{x}, \mathrm{y} \in \mathrm{X}$; (3) $\|\alpha\mathrm{x}\| = |\alpha| \, \|\mathrm{x}\|$ for all scalars α and all $\mathrm{x} \in \mathrm{X}$.

where the number p is again restricted to lie in the interval $1 \le p < \infty$.

Hilbert Space Setting

Much of the original research in signal restoration assumed that the underlying set of signals X is a complete inner product (i.e., a Hilbert) space. An inner product space is a vector space upon which there is defined an inner product $\langle \mathbf{x},\mathbf{y} \rangle$ which maps any two vectors $\mathbf{x},\mathbf{y} \in X$ into a scalar such that the axioms of an inner product axiom are satisfied.[3] This inner product induces a natural norm distance metric as specified by

$$\|\mathbf{x}\| = \sqrt{\langle \mathbf{x}, \mathbf{x} \rangle} \tag{14.76}$$

An inner product space is said to be complete if every Cauchy sequence contained in that space converges to an element of that space.[4] Our interest in Hilbert spaces arises in recognition of the fact that many important signal processing problems can be naturally formulated in such a setting.

A variety of algorithms have been proposed for iteratively solving minimization problem (14.73) when the signals are taken to lie in a Hilbert space. These algorithms differentiate themselves by the assumptions made on the characteristics of the attribute sets $C_1, C_2, \ldots, C_m$ in which the unknown signal being monitored is assumed to be contained. Of particular interest is the situation in which these sets are constrained to be made up exclusively of (1) closed subspaces or translated closed subspaces (i.e., linear varieties) and (2) closed convex sets. Some of the more important theoretical results characterizing these cases are examined in the next two subsections.

Attribute Sets: Closed Subspaces

Much of the original research in signal restoration was concerned with the highly restrictive case in which each of the individual attribute sets C_k is a closed subspace. The composite attribute set C as formed from their set intersection (14.68) must therefore also be a closed subspace. For this special case there exists a useful analytical characterization of the solution to the signal restoration problem (14.73). The notion of vector orthogonality is central to this discussion. In particular, the two vectors $\mathbf{x},\mathbf{y} \in X$ are said to be orthogonal if their inner product is zero, that is,

$$\langle \mathbf{x}, \mathbf{y} \rangle = 0 \tag{14.77}$$

Furthermore, if $\mathbf{x}$ and $\mathbf{y}$ are orthogonal, it follows that the squared inner product-induced norm (14.76) of their vector difference satisfies

$$\| x - y \|^2 = \| x \|^2 + \| y \|^2 \tag{14.78}$$

which is commonly known as the general *Pythagorean theorem*. This theorem is readily proven by direct substitution and using the orthogonality of the two vectors. With these preliminaries completed, the celebrated projection theorem is now given [Luenberger, 1969].

Theorem 1. Let C be a closed subspace of Hilbert space X. Corresponding to any vector $\mathbf{x} \in X$, there is a unique vector $\mathbf{x}^o \in C$ such that $\|\mathbf{x} - \mathbf{x}^o\| \le \|\mathbf{x} - \mathbf{y}\|$ for all $\mathbf{y} \in C$. Furthermore, a necessary and sufficient condition that $\mathbf{x}^o \in C$ be the unique minimization vector is that $\mathbf{x} - \mathbf{x}^o$ is orthogonal to every vector in C.

When the attribute sets C_k are each closed spaces, it follows that their intersection gives rise to a composite attribute set C which is also a closed subspace. The above theorem indicates that the solution to the signal restoration problem (14.73) is unique. It will be useful to interpret this solution from an algebraic viewpoint.

---

[3]The axioms of an inner product are (1) $\langle \mathbf{x},\mathbf{y} \rangle = \langle \overline{\mathbf{y},\mathbf{x}} \rangle$, (2) $\langle \mathbf{x}+\mathbf{y},\mathbf{z} \rangle = \langle \mathbf{x},\mathbf{z} \rangle + \langle \mathbf{y},\mathbf{z} \rangle$, (3) $\langle \alpha\mathbf{x},\mathbf{y} \rangle = \alpha\langle \mathbf{x},\mathbf{y} \rangle$, and (4) $\langle \mathbf{x},\mathbf{x} \rangle \ge 0$ and $\langle \mathbf{x},\mathbf{x} \rangle = 0$ if and only if $\mathbf{x} = \mathbf{0}$.

[4]The sequence $\{\mathbf{x}_n\}$ contained in X is said to be Cauchy if for every $\epsilon > 0$ there is an integer $N(\epsilon)$ such that $d(x_n, x_m) < \epsilon$ for all m and $n > N(\epsilon)$.

Specifically, the concept of orthogonal projection operator plays a central role in characterizing the basic nature of the vector $\mathbf{x}^o$ described in Theorem 1. The association of the given vector $\mathbf{x}$ with its unique approximating vector $\mathbf{x}^o \in C$ is notationally specified by

$$\mathbf{x}^o = P_C \mathbf{x} \tag{14.79}$$

It is straightforwardly shown that this one-to-one association P_C possesses the three properties of being:

1. Linear so that $P_C(\alpha\mathbf{x} + \beta\mathbf{y}) = \alpha P_C\mathbf{x} + \beta P_C\mathbf{y}$
2. Idempotent so that $P_C^2 = P_C$
3. Self-adjacent so that $P_C^\star = P_C$

A mapping that possesses these three properties is commonly referred to as an *orthogonal projection operator.* The mapping P_C designates the *orthogonal projection* of vector space X onto the closed subspace C. The term orthogonal arises from the observation that every vector in subspace C is orthogonal to the associated error vector $\mathbf{x} - P_C\mathbf{x}$. The concept of orthogonal projection operators is of fundamental importance in optimization theory and has many important practical and theoretical implications.

There exists a convenient means for obtaining a solution to the signal restoration problem (14.73) when the composite attribute set C is a finite-dimensional subspace. The following theorem summarizes the main points of this solution procedure.

Theorem 2. Let the nonempty closed subspace C of Hilbert space X be composed of all vectors which are linear combinations of the vectors $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_q$. Corresponding to any vector $\mathbf{x} \in X$, the unique vector that minimizes $\|\mathbf{x} - \mathbf{y}\|$ for all $\mathbf{y} \in C$ is of the form

$$\mathbf{x}^o = \sum_{k=1}^{q} a_k \mathbf{x}_k \tag{14.80}$$

The a_k coefficients in this linear combination are the components of any solution to the consistent system of linear equations

$$G\mathbf{a} = \mathbf{b} \tag{14.81}$$

where G is the $q \times q$ Gram matrix whose (i,j)th component is specified by $\langle \mathbf{x}_j, \mathbf{x}_i \rangle$ and $\mathbf{b}$ is the $q \times 1$ vector whose ith component is given by $\langle \mathbf{x}, \mathbf{x}_i \rangle$.

If the vectors $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_q$, that span subspace C are linearly independent, then the Gram matrix G is invertible and the linear system of equations (14.81) has a unique solution for the coefficient vector $\mathbf{a}$. On the other hand, this linear system of equations will have an infinity of coefficient vector solutions when the $\{\mathbf{x}_k\}$ vectors are linearly dependent. Nevertheless, each of these coefficient vector solutions lead to the same unique optimum solution (14.80).

Example 4. One of the most commonly studied signal restoration and signal recovery problems is concerned with the task of estimating the signal component in a noise-contaminated measurement as described by the relationship

$$\mathbf{x} = H\mathbf{a} + \mathbf{w} \tag{14.82}$$

In this expression the measurement signal $\mathbf{x}$ is assumed to lie in ϵC^m, H is a known matrix contained in $C^{m \times n}$ of full rank n, and $\mathrm{w} \in C^m$ is an unobserved noise vector. It is now desired to find a vector of form $\mathrm{y} = H\mathrm{a}$ that best approximates the measurement x in the sense of minimizing the quadratic criterion

$$f(\mathbf{a}) = [\mathbf{x} - H\mathbf{a}]^\star W[\mathbf{x} - H\mathbf{a}] \tag{14.83}$$

In this criterion W is a positive-definite Hermitian matrix, and the asterisk symbol designates the operation of complex transposition. It is to be noted that if $\mathbf{w}$ is a Gaussian random vector with covariance matrix W^{-1}, then the minimization of functional (14.83) corresponds to the maximum likelihood estimation of the signal component $H\mathbf{a}$.

Examination of this problem formulation reveals that it is of the same form treated in Theorem 1 in which the Hilbert space is C^n. In view of criterion (14.83) that is to be minimized, the inner product identifying this Hilbert space is taken to be $<\mathbf{x}, \mathbf{y}> \equiv \mathbf{x}^* W\mathbf{y}$. It is a simple matter to show that this measure satisfies the three axioms of an inner product. The closed subspace C corresponds to the set of all vectors that are expressible as $H\mathbf{a}$ (i.e., the range space of matrix H). Since matrix H is taken to have full column rank n, it follows that C has dimension n. If in a given application the elements of the coefficient vector $\mathbf{a}$ can take on complex values, it is readily shown that the orthogonal projection matrix P_C is specified by

$$P_C = H[H^* WH]^{-1} H^* W \tag{14.84}$$

Furthermore, the unique vector $\mathbf{a}^o \in C^n$ which minimizes functional (14.83) is obtained by using the projection relationship $H\mathbf{a}^o = P_C \mathbf{x}$ to yield

$$\mathbf{a}^o = [H^* WH]^{-1} H^* W\mathbf{x} \tag{14.85}$$

On the other hand, if the coefficient vector $\mathbf{a}$ is restricted to lie in R^n, the required orthogonal projection operation takes the form

$$P_C \mathbf{x} = H[\mathrm{Re}\{H^* WH\}]^{-1}\mathrm{Re}\{H^* W\mathbf{x}\} \tag{14.86}$$

where Re designates the "real part of" operator. Moreover, the unique real-valued coefficient vector minimizing functional (14.83) is specified by

$$\mathbf{a}^o = [\mathrm{Re}\{H^* WH\}]^{-1}\mathrm{Re}\{H^* W\mathbf{x}\} \tag{14.87}$$

A solution to the general signal restoration problem for the case in which the individual attribute sets are closed subspaces formally entails determining the orthogonal projection operator P_C on the closed composite attribute subspace (14.81). Unfortunately, an analytical expression for P_C is typically intractable even when the orthogonal projection operators P_k defined on each of the individual attribute subspaces C_k are readily constructed. The natural question arises as to whether it is possible to use these individual orthogonal projection operators to generate P_C. In recognition of this need, J. von Neumann developed a method for iteratively constructing the required projection operator [von Neumann, 1950] for the case of two ($m = 2$) closed subspaces (p. 55, theorem 14.7). This result was later extended by Halperin [1962] for the multiple attribute closed subspace case as described in the following theorem.

Theorem 3. Let P_k denote the orthogonal projection operators onto the closed subspaces C_k for $k = 1,2, ..., m$ of Hilbert space X. Moreover, let C designate the nonempty closed subspace formed by the intersection of these closed subspaces so that $C = C_1 \cap C_2 \cap \ldots \cap C_m$. If P_C designates the orthogonal projection matrix onto closed subspace C and $T = P_1 P_2 \ldots P_m$, it then follows that T^n converges strongly to P_C, that is,

$$\lim_{n \to \infty} \left\| T^n - P_C \right\| = 0 \tag{14.88}$$

This theorem indicates that repeated applications of operator T converge to the required orthogonal projection operator P_C. The practicality of this result arises from the observation that it is often possible to synthesize the individual orthogonal projection operators P_k but not the composite orthogonal projection operator P_C. This capability was illustrated in Theorem 2 for the case in which the subspaces were finite dimensional. To solve

the signal restoration problem (14.73) when the attribute sets are each closed subspaces, we then simply use the following iterative scheme

$$\mathbf{x}_n = T\mathbf{x}_{n-1} \quad \text{for } n = 1, 2, 3, \ldots \tag{14.89}$$

in which the initial point is taken to be the measurement signal so that $\mathbf{x}_o = \mathbf{x}$. The sequence of signals thereby generated is guaranteed to converge to the unique solution of the signal restoration problem.

Linear Variety Property Sets

Theorem 3 is readily generalized to the case in which the individual attribute sets are closed linear varieties. A set contained in vector space X is said to be a linear variety if it is a translation of a subspace contained in X. More specifically, if C is a subspace of X and $\mathbf{u}$ is a fixed vector contained in X, then the associated linear variety is specified by

$$\begin{aligned} V &= \mathbf{u} + C \\ &= \{\mathbf{x} \in X : \mathbf{x} = \mathbf{u} + \mathbf{y} \text{ for all } \mathbf{y} \in C\} \end{aligned} \tag{14.90}$$

It is to be noted that the vector $\mathbf{u}$ used in this linear variety formulation is not unique. In fact, any vector contained in V could have been used in place of $\mathbf{u}$. When subspace C is closed, there exists a unique vector contained in V of minimum norm that is of particular interest in many applications. It is formally specified by

$$\mathbf{u}^o = P_C\mathbf{u} \tag{14.91}$$

where P_C designates the orthogonal projection operator onto the closed subspace C. Vector $\mathbf{u}^o$ represents that unique vector contained in the closed linear variety V which lies closest to the origin in the inner product-induced norm sense. With these thoughts in mind, the following lemma is readily proven.

Lemma 1. Let $V_k = u_k + C_k$ be closed linear varieties associated with the closed subspaces C_k and vectors u_k contained in Hilbert space X for $k = 1, 2, \ldots, m$. Moreover, let V designate the nonempty closed linear variety formed by the intersection of these closed linear varieties so that $V = V_1 \cap V_2 \cap \ldots \cap V_m$. Corresponding to any vector $\mathbf{x} \in X$, the vector contained in V that lies closest to $\mathbf{x}$ in the inner product-induced sense is the limit of the sequence generated according to

$$\mathbf{x}_n = T_1 T_2 \ldots T_m \mathbf{x}_{n-1} \quad \text{for } n = 1, 2, 3, \ldots \tag{14.92}$$

where $\mathbf{x}_o = \mathbf{x}$. The operators appearing in this expression are formally defined by

$$T_k\mathrm{y} = P_{C_k}\mathrm{y} + \{I - P_{C_k}\}\mathrm{u}_k \qquad \text{for } k = 1, 2, \ldots, m \tag{14.93}$$

Attribute Sets: Closed Convex Sets

Although the case in which the signal attribute sets are closed subspaces is of theoretical interest, it is typically found to be too restrictive for most practical applications. As we will now see, however, it is possible to extend these concepts to the more general case of closed convex attribute sets. The set C is said to be convex if for any two vectors $\mathbf{x},\mathbf{y} \in C$ their convex sum as defined by $\lambda\,\mathbf{x} + (1 - \lambda)\mathbf{y}$ is also contained in C for all $0 \le \lambda \le 1$. The ability to broaden the class of attribute sets to include closed convex sets significantly expands the class of problems that can be treated by signal restoration. The following well-known functional analysis theorem provides the framework for this development.

Theorem 4. Let C be a nonempty closed convex set of Hilbert space X. Corresponding to any vector $\mathbf{x} \in X$, there is a unique vector $\mathbf{x}^o \in C$ such that $\|\mathbf{x} - \mathbf{x}^o\| \le \|\mathbf{x} - \mathbf{y}\|$ for all $\mathbf{y} \in C$. Furthermore, a necessary and sufficient condition that $\mathbf{x}^o$ be the unique minimizing vector is that $\langle \mathbf{x} - \mathbf{x}^o, \mathbf{y} - \mathbf{x}^o \rangle \le 0$ for all $\mathbf{y} \in C$.

From this theorem it is seen that there exists a one-to-one correspondence between a general vector $\mathbf{x} \in X$ and its closest approximation in the closed convex set C. This mapping is here operationally designated by

$$\mathbf{x}^o = P_C \mathbf{x} \tag{14.94}$$

and we will refer to P_C as the projection operator onto the closed convex set C. It is important to note that if the closed convex set C is not a subspace or a linear variety, then this associated projection operator is no longer linear. Moreover, if $\mathbf{x} \in C$, then $P_C \mathbf{x} = \mathbf{x}$, so that every vector of C is a *fixed point* of operator P_C.[5] Thus, the fixed points of P_C and the closed convex set C are equivalent. These concepts were used by Bregman [1965] and others to prove a type of convergence of the successive projection algorithm. The following theorem summarizes their results.

Theorem 5. Let P_k designate the projection operators onto the closed convex sets C_k for $k = 1, 2, \ldots, m$ of Hilbert space X and $C = C_1 \cap C_2 \cap \ldots \cap C_m$ be their nonempty closed convex set intersection. Furthermore, for every $\mathbf{x} \in X$ consider the sequence of successive projections as generated according to

$$\mathbf{x}_n = P_1 P_2 \quad \ldots P_m \mathbf{x}_{n-1} \quad \text{for } n = 1, 2, 3, \ldots \tag{14.95}$$

in which $\mathbf{x}^o = \mathbf{x}$. It then follows that this sequence converges:

1. Weakly to a point in the set intersection C[6]
2. Strongly to a point in the set intersection C if at least one of the sets C_k is bounded and compact[7]

The weak-point convergence theorem (1) was first proven by Bregman [1965], while the strong-point convergence theorem (2) was developed by Stiles [1965]. It is important to appreciate what this theorem does and does not say. Specifically, although it ensures that sequence (14.95) converges to a vector contained in the set intersection C, this convergent point need not minimize the original signal restoration criterion (14.73). This is the price paid when considering the more general case of closed convex attribute sets. Nonetheless, it is found that the vector to which sequence (14.95) converges often provides a satisfactory approximation.

To improve the convergence of algorithm (14.95), Gubin et al. introduced an overrelaxation modification that extends the projections beyond the boundary of the attribute sets [1967]. This overrelaxation approach was also adopted by Youla [1978] who proposed the algorithm

$$\mathbf{x}_n = T_1 T_2 \ldots T_m \mathbf{x}_{n-1} \quad \text{for } n = 1, 2, 3, \ldots \tag{14.96}$$

in which operators $T_k = [I + \lambda_k (P_k - I)]$ are employed. They proved that the sequence so generated converges weakly to a point of C for any choice of the relaxation constants λ_k in the open interval $0 < \lambda_k < 2$. Moreover, if at least one of the closed convex sets C_k is contained in a finite-dimensional subspace, then the convergence is strong.

In summary, the successive projection algorithm provides a useful signal-processing tool for the case in which the individual attribute sets are closed convex sets. Its primary deficiency is that although the signal sequence (14.95) so generated converges to an element of C, it need not converge to the closest approximation of the data signal $\mathbf{x}$ contained in C. Thus, the successive projection algorithm generally fails to provide a solution to the signal restoration problem (14.73). In recognition of this shortcoming, Dykstra [1983] developed an algorithm which does provide an algorithmic solution. This algorithm was further studied by Dykstra and Boyle [1987], Han [1988], and Gaffke and Mathar [1989]. The formulation as given by Gaffke and Mathar is now summarized.

[5]The vector $\mathbf{x}$ is said to be a fixed point of operator T if $T\mathbf{x} = \mathbf{x}$.

[6]The sequence $\{\mathbf{y}_n\}$ is said to converge weakly to $\mathbf{y}$ if $< y_n - \mathbf{y}, \mathbf{z} >$ converges to zero for every $\mathbf{z} \in X$ as n becomes unbounded.

[7]The sequence $\{\mathbf{y}_n\}$ is said to converge strongly to $\mathbf{y}$ if $\| y_n - y \|$ approaches zero as n becomes unbounded.

Theorem 6. Let P_k designate the projection operators onto the closed convex sets C_k for $k = 1, 2, \ldots, m$ of Hilbert space X in which the closed convex set intersection $C = C_1 \cap C_2 \cap \ldots \cap C_m$ is nonempty. Let the two sets of m vector sequences $\mathbf{x}_1^{(k)}, \mathbf{x}_2^{(k)}, \ldots, \mathbf{x}_m^{(k)}$ and $\mathbf{y}_1^{(k)}, \mathbf{y}_2^{(k)}, \ldots, \mathbf{y}_m^{(k)}$ for $k = 1,2,3, \ldots$ be generated according to

$$\begin{aligned} \mathbf{x}_i^{(k)} &= P_i\left(\mathbf{x}_{i-1}^{(k)} - \mathbf{y}_i^{(k-1)}\right) && \text{for } i = 1, 2, \ldots, m \\ \mathbf{x}_0^{(k+1)} &= \mathbf{x}_m^{(k)} \\ \mathbf{y}_i^{(k)} &= \mathbf{x}_i^{(k)} - \left(\mathbf{x}_{i-1}^{(k)} - d_i^{(k-1)}\right) && \text{for } i = 1, 2, \ldots, m \end{aligned} \tag{14.97}$$

in which the initial conditions are taken to be $\mathbf{y}_1^{(o)} = \mathbf{y}_2^{(o)} = \ldots = \mathbf{y}_m^{(o)} = \mathbf{0}$ and $\mathbf{x}_m^{(o)} = \mathbf{x}$. It then follows that the sequence $\{\mathbf{x}_m^k\}$ converges to the unique point in C that lies closest to $\mathbf{x}$ in the sense of minimizing functional (14.73).

This algorithm provides a useful means for iteratively finding a solution to the signal restoration problem for the case of closed convex sets.

Closed Projection Operators

A solution to the signal restoration problem (14.73) is generally intractable unless restrictive assumptions are made on the constituent attribute sets. In the previous two subsections, the method of successive projections and its variations were presented for iteratively finding a solution when the underlying attribute sets are closed subspaces, closed linear varieties, or closed convex sets. Unfortunately, some of the more important attribute sets encountered in signal processing do not fall into any of these categories. This is illustrated by the case in which the Hilbert space is taken to be $C^{m \times n}$ and one of the attribute sets corresponds to all $m \times n$ matrices which have rank q where $q < \min(m,n)$. It is readily shown that this set is neither a subspace nor a linear variety, nor is it convex. Thus, use of the extremely important rank q attribute set cannot be justified for any of the algorithms considered up to this point. This is a serious shortcoming when it is realized that this attribute set is used so extensively in many contemporary signal processing applications.

To provide a viable method for approximating a solution to the signal restoration problem for nonconvex attribute sets, we shall now broaden the approach taken. The signals are again assumed to lie in a metric space X with distance metric $d(\mathbf{x},\mathbf{y})$. Furthermore, it is assumed that it is possible to solve each of the individual *projection operator* problems as defined by

$$P_k(\mathbf{x}) = \{\mathbf{y} : d(x, y) = \min_{\mathbf{z} \in C_k} d(\mathbf{x}, \mathbf{z})\} \qquad \text{for } 1 \le k \le m \tag{14.98}$$

for an arbitrary signal $\mathbf{x} \in X$. These sets consist of all elements in C_k that lie closest to $\mathbf{x}$ in the distance-metric sense for $1 \le k \le m$. It is to be noted that the projection operators $P_k(\mathbf{x})$ are generally nonlinear and not one to one as was the case in the previous two subsections. When determining the individual projection operators (14.98), the fundamental issues of the existence and uniqueness of solution need to be addressed. It is tacitly assumed that the signal attributes and metrics under consideration are such that at least one solution exists and the solution(s) may be obtained in a reasonably simple fashion. Fortunately, the generation of solutions imposes no serious restrictions for many commonly invoked attribute sets. Moreover, many relevant signal attributes are characterized by the fact that more than one solution to optimization problems (14.98) exists.

The projection operators (14.98) are unusual in that they need not be of the traditional point-to-point variety as was the case when the attribute set is a closed subspace, closed linear variety or closed convex set. For general C_k sets, P_k is a point-to-set mapping. The concept of a *closed mapping* is of importance when extending the notion of signal restoration to nonconvex sets. A closed mapping is a generalization of the notion of continuity as applied to standard point-to-point mappings [Zangwill, 1969], that is:

Definition 1. The point-to-set projection mapping P is said to be closed at x ∈ X if the assumptions

1. $\mathbf{x}_k \rightarrow \mathbf{x}$ with $\mathbf{x}_k \in X$
2. $\mathbf{y}_k \rightarrow \mathbf{y}$ with $\mathbf{y}_k \in P(\mathbf{x}_k)$

imply that $\mathbf{y} \in P(\mathbf{x})$. The point-to-set **projection mapping** P is said to be closed on the set X_1 if it is closed at each point in X_1.

Signal Restoration Algorithm

We are now in a position to describe the signal restoration algorithm for the case of general attribute sets. This shall be formally done in the format of the following theorem [Cadzow, 1988].

Theorem 7. Let P_k be the projection operators associated with the attribute sets C_k contained in metric space X for $k = 1, 2, \ldots, m$. For any signal $\mathbf{x} \in X$, let the sequence $\{\mathbf{x}_k\}$ be generated according to

$$\mathbf{x}_k \in P_1 P_2 \ldots P_m(\mathbf{x}_{k-1}) \quad \text{for } k \geq 1 \tag{14.99}$$

in which the initial signal is specified by $\mathbf{x}_o = \mathbf{x}$. A subsequence of this sequence always exists which converges to an element of the set intersection $C = C_1 \cap C_2 \cap \ldots \cap C_m$ provided that: (1) the $d(\mathbf{x}_k, \mathbf{x}_r) < d(\mathbf{x}_{k-1}, \mathbf{x}_r)$, where $\mathbf{x}_r \in X$ designates a reference signal which is often the origin of X, and (2) the set of signals $\mathbf{y} \in X$ that satisfy the inequality $d(\mathbf{y}, \mathbf{x}_r) \leq d(\mathbf{x}, \mathbf{x}_r)$ defines a closed and bounded set.

A casual examination of signal restoration algorithm (14.99) indicates that it is of the same form as the sequence of projections algorithms described in the previous two subsections. It distinguishes itself from those algorithms in that the attribute sets C_k need not be closed subspaces, closed linear varieties, or closed convex sets. The proposed algorithm also distinguishes itself from several other signal restoration algorithms in that the metric d need not be inner product induced. These can be important considerations in specific applications. As an example, it has been conjectured by several authors that the l_1 norm provides for a more effective error measure when the data set has outliers (i.e., unrepresentative data). Signal restoration algorithm (14.99) can be directly applied to such problems since we have not restricted the metric. It must be observed, however, that the nature of the individual projection operators P_k is typically most easily characterized when the metric employed is inner product induced.

It is useful to represent the multiple mapping signal restoration algorithm by the *composite mapping* as defined by

$$P = P_1 P_2 \ldots P_m \tag{14.100}$$

The process of generating the solution set $P(\mathbf{x}_{k-1})$ from $\mathbf{x}_{k-1}$ is to be interpreted in the following sequential manner. First, the set $P_m(\mathbf{x}_{k-1})$ is found. This set consists of all signals possessing the mth attribute that lie closest to $\mathbf{x}_{k-1}$ in the given signal metric. Next, the set $P_{m-1}(P_m(\mathbf{x}_{k-1}))$ is formed and consists of all signals possessing the $(m-1)$th attribute that lie closest to each of the signals in set $P_m(\mathbf{x}_{k-1})$. It is to be noted that although each of the signals in $P_{m-1}(P_m(\mathbf{x}_{k-1}))$ possess the $(m-1)$th attribute, they need not possess the mth attribute. This process is continued in this fashion until the set $P(\mathbf{x}_{k-1})$ is generated. Finally, we arbitrarily select one signal from $P(\mathbf{x}_{k-1})$ to be equal to $\mathbf{x}_k$. When the individual projection mappings P_k are each point-to-point mappings, the signal $\mathbf{x}_k$ generated in this fashion will be unique.

Signal restoration algorithm (14.99) has been applied to many fundamental signal processing problems. It has produced effective results that often exceed those achieved by more traditional methods. The ultimate utility of signal restoration is dependent on the user's innovativeness in generating signal attributes that distinguish the underlying signal from the corruption in the data. In many applications, matrix descriptions of the data under analysis arise in a natural manner. With this in mind, we will now explore some salient matrix properties and how they can be used in typical signal restoration applications.

Algebraic Properties of Matrices

Many of the more important and interesting applications of signal restoration are related to the vector space $C^{m\times n}$. Matrices contained in $C^{m\times n}$ may occur in a natural manner as exemplified by digital images where the nonnegative elements of the matrix correspond to the brightness levels of associated pixels. The underlying signal restoration problem in such cases is commonly referred to as *image reconstruction* or *image restoration.* In other examples, however, the matrix under consideration may be a by-product of an associated data analysis solution routine. For example, in approximating a finite-length time series as a sum of weighted exponentials, one often forms an associated *data matrix* from the time series elements. Whatever the case, the matrix under analysis is typically corrupted in some manner, and it is desired to remove this corruption in order to recover the underlying information-bearing matrix. In using signal restoration for this purpose, it is necessary to employ attributes associated with the information-bearing signal. These attributes are normally of an algebraic or a structural description. In this subsection we will examine two of the more widely invoked algebraic attributes, and some commonly employed structural attributes are examined in the next subsection.

Singular Value Decomposition

The **singular value decomposition** (SVD) of a real- or complex-valued matrix plays an increasingly important role in contemporary signal processing applications. For a generally complex-valued matrix $A \in C^{m\times n}$, its associated SVD representation takes the form of the following sum of r weighted outer products,

$$A = \sum_{k=1}^{r} \sigma_k \mathbf{u}_k \mathbf{v}_k^{\star} \tag{14.101}$$

where r designates the rank of matrix A. In this SVD representation, the σ_k are positive *singular values* that are ordered in the monotonic fashion $\sigma_{k+1} \le \sigma_k$, while the $\mathbf{u}_k$ are the $m \times 1$ pairwise orthogonal *left singular vectors* and the $\mathbf{v}_k$ are the $n \times 1$ pairwise orthogonal *right singular vectors.* Upon examination of SVD representation (14.101) it is seen that the mn components of matrix A are equivalently replaced by the $r(m + n + 1)$ elements corresponding to the SVD singular values and singular vectors. For low-rank matrices [i.e., $r(1 + m + n) < mn$], the SVD provides for a more efficient representation of a matrix. This observation has been effectively used for the data compression of digital images. Furthermore, the concept of a low rank data matrix plays a vital role in the modeling of empirical data as a sum of weighted exponential signals. With these thoughts in mind, the important concept of low rank approximation of matrices is now examined.

Reduced-Rank Approximation

In various applications, it is frequently desired to find a matrix of rank q that best approximates a given matrix $A \in C^{m\times n}$, where $q < \text{rank}\{A\}$. If the Frobenius metric (14.66) is used to measure the distance between two matrices, it is well known that the best rank-q matrix approximation of A is obtained by simply dropping all but the q largest singular-valued weighted outer products in SVD representation (14.101), that is,

$$A^{(q)} = \sum_{k=1}^{q} \sigma_k \mathbf{u}_k \mathbf{v}_k^{\star} \tag{14.102}$$

where it is tacitly assumed that $q \le r$. From this expression, it follows that the mapping from A into $A^{(q)}$ is one-to-one when $\sigma_q > \sigma_{q+1}$ but is one-to-many (infinity) if $\sigma_q = \sigma_{q+1}$. The special case in which $\sigma_q = \sigma_{q+1}$ therefore results in a point-to-set mapping and gives rise to subtle issues which are addressed in the following theorem [Mittelmann and Cadzow, 1987].

Theorem 8. Let the $m \times n$ matrix $A \in C^{m\times n}$ have the SVD decomposition (14.101) in which $r = \text{rank}(A)$. The best rank-q Frobenius norm approximation of A as given by expression (14.102) is unique if and only if $\sigma_q > \sigma_{q+1}$. The projection operator $P^{(q)}$ from A into $A^{(q)}$ as designated by

$$A^{(q)} = P^{(q)} A \tag{14.103}$$

is nonlinear and closed. Furthermore, this mapping is continuous for $\sigma_q \neq \sigma_{q+1}$ and is not continuous when $\sigma_q = \sigma_{q+1}$.

When applying the reduced-rank approximation of a matrix as specified by relationship (14.103), it is desirable that the gap between the so-called *signal-level* singular values and *noise-level* singular values be large (i.e., $\sigma_q - \sigma_{q+1} >> 0$). If this is true, then the issues of nonuniqueness and continuity of mapping do not arise. Unfortunately, in many challenging applications, this gap is often small, and one must carefully examine the consequences of this fact on the underlying problem being addressed. For example, in modeling empirical data as a sum of exponentials, this gap is typically small, which in turn leads to potential undesirable algorithmic sensitivities. We will examine the exponential modeling problem in a later subsection.

Positive-Semidefinite Matrices

Positive-semidefinite matrices frequently arise in applications related to random and deterministic time series. For example, if $\mathbf{x} \in C^n$ is a vector whose components are random variables, it is well known that the associated $n \times n$ *correlation matrix* as defined by $R_{xx} = E\{\mathbf{x}\mathbf{x}^*\}$ is positive-semidefinite Hermitian, where E designates the expected value operator. Similarly, *orthogonal projection* matrices are often used to describe vector subspaces that identify signals present in empirical data. An orthogonal projection matrix is a positive-semidefinite matrix which has the additional requirements of being idempotent (i.e., $A^2 = A$) and Hermitian (i.e., $A^* = A$). It is well known that the eigenvalues associated with an orthogonal projection matrix are exclusively equal to zero and one. With these examples serving as motivation, we shall now examine some of the salient algebraic characteristics of positive-semidefinite matrices.

The $n \times n$ matrix $A \in C^{n \times n}$ is said to be positive semidefinite if the associated quadratic form inequality as specified by

$$\mathbf{x}^* A\mathbf{x} \geq 0 \quad \text{for all } \mathbf{x} \in C^n \tag{14.104}$$

is satisfied for all vectors $x \in C^n$. Furthermore, if the only vector that causes this quadratic form to be zero is the zero vector, then A is said to be *positive definite*. Since this quadratic form is real valued, we can further infer that any positive-semidefinite matrix must be Hermitian so that $A^* = A$. Moreover, using elementary reasoning it directly follows that the set of positive-definite matrices contained in C^n is a closed convex cone.

In many practical applications, there is given empirical time series data to be analyzed. This analysis is often predicated on one's having knowledge of the time series-associated correlation matrices or orthogonal projection matrices. Since such knowledge is generally unknown, these matrices must be estimated from the empirical data under analysis. These estimates, however, are almost always in error. For example, the estimate $\hat{R}_{xx}$ of a correlation matrix R_{xx} is often Hermitian but not positive semidefinite. To mitigate the effects of these errors, an intuitively appealing procedure would be to find a matrix lying close to $\hat{R}_{xx}$ that possesses the two prerequisite properties of being (1) Hermitian and (2) positive semidefinite. The concept of signal restoration can be used for this purpose if it is possible to develop a closed-form expression for the operator that maps a general Hermitian matrix into the closest positive-semidefinite Hermitian matrix in the Frobenius matrix norm sense. As is now shown, a simple expression for this operator is available using the SVD of the Hermitian matrix being approximated.

With these thoughts in mind, we will now consider the generic problem of finding a positive-semidefinite matrix that lies closest to a given Hermitian matrix $A \in C^{n \times n}$. In those applications where matrix A is not Hermitian, then this matrix is first replaced by its Hermitian component as defined by $(A + A^*)/2$ and then the closest positive-semidefinite matrix to this Hermitian component is found.[8] The problem at hand is readily solved by first making an eigenanalysis of the Hermitian matrix A, that is,

$$A\mathbf{x}_k = \lambda_k \mathbf{x}_k \quad \text{for} \quad 1 \leq k \leq n \tag{14.105}$$

[8]Any matrix A can be represented as the sum of a Hermitian matrix and a skew Hermitian matrix using the decomposition $A = (A + A^*)/2 + (A - A^*)/2$.

Since A is Hermitian, its eigenvalues must all be real and there exists a full set of n associated eigenvectors that can always be chosen orthonormal [i.e., $\mathbf{x}_k^* \mathbf{x}_m = \delta(k-m)$]. With this characterization, the following theorem is readily proven.

Theorem 9. Let A be a Hermitian matrix contained in $C^{n\times n}$ whose eigenanalysis is specified by relationship (14.105). Furthermore, let the eigenvalues be ordered in the monotonically nonincreasing fashion $\lambda_k \geq \lambda_{k+1}$ in which the first p eigenvalues are positive and the last $n-p$ are nonpositive. It then follows that the SVD of Hermitian matrix A can be decomposed as

$$\begin{aligned} A &= \sum_{k=1}^{p} \lambda_k \mathbf{x}_k \mathbf{x}_k^* + \sum_{k=p+1}^{n} \lambda_k \mathbf{x}_k \mathbf{x}_k^* \\ &= A^+ + A^- \end{aligned} \tag{14.106}$$

The Hermitian matrix A^+ is positive semidefinite of rank p, while the Hermitian matrix A^- is negative semidefinite. Furthermore, the unique positive-semidefinite matrix that lies closest to A in the Frobenius and Euclidean norm sense is given by the truncated SVD mapping

$$A^+ = P^+(A) = \sum_{k=1}^{p} \lambda_k \mathbf{x}_k \mathbf{x}_k^* \tag{14.107}$$

The projection operator P^+ is closed and continuous. Furthermore, an idempotent Hermitian (i.e., an orthogonal projection) matrix which lies closest to A in the Frobenius and Euclidean norm sense is specified by

$$A^{op} = P^{op}(A) = \sum_{k:\lambda_k \geq 0.5} \mathbf{x}_k \mathbf{x}_k^* \tag{14.108}$$

This closest idempotent Hermitian matrix is unique provided that none of the eigenvalues of A are equal to 0.5. Moreover, projection operator P^{op} is closed for any distribution of eigenvalues.

Examination of this theorem indicates that the left and right singular vectors of a Hermitian matrix corresponding to its positive eigenvalues are each equal to the associated eigenvector while those corresponding to its negative eigenvalues are equal to the associated eigenvector and its negative image. Furthermore, any Hermitian matrix may be uniquely decomposed into the sum of a positive- and negative-semidefinite Hermitian matrix as specified by (14.106).

This theorem's proof is a direct consequence of the fact that the Frobenius and Euclidean norm of the matrix A and Q^*AQ are equal for any unitary matrix Q. Upon setting Q equal to the $n \times n$ matrix whose columns are equal to the n orthonormal eigenvectors of matrix A, it follows that the Frobenius (Euclidean) norm of the matrices $A-B$ and $Q^*[A-B]Q$ are equal. From this equality the optimality of positive-definite matrix (14.107) immediately follows since Q^*AQ is equal to the diagonal matrix with the eigenvalues of A as its diagonal components. The closest positive-semidefinite matrix (14.107) is obtained by simply truncating the SVD to the positive singular value outer products. Similarly, the closest orthogonal projection matrix is obtained by replacing each singular value by 1 if the singular value is greater than or equal to 0.5 and by 0 otherwise.

Structural Properties of Matrices

In various applications, a matrix under consideration is known to have its elements functionally dependent on a relatively small set of parameters. A brief listing of some of the more commonly used matrix classes so characterized is given in Table 14.9. In each case, there exists a relatively simple relationship for the elements

TABLE 14.9 Structured Matrices

Matrix Class	Matrix Elements
Hermitian	$A(i, j) = \overline{A}(j, i)$
Toeplitz	$A(i + 1, j + 1) = A(i, j)$
Hankel	$A(i + 1, j) = A(i, j + 1)$
Circulant	$A(i + 1, j) = A(i, j - 1)$ with $A(i + 1, 1) = A(i,n)$
Vandermonde	$A(i, j) = A(2, j)^{i-1}$

of the matrix. For example, an $m \times n$ Toeplitz matrix is completely specified by the $m + n - 1$ elements of its first row and first column. We now formalize this concept.

Definition 2. Let $a_{ij}(\theta_1, \theta_2, \ldots, \theta_p)$ for $1 \le i \le m$ and $1 \le j \le n$ designate a set of mn functions that are dependent on a set of real-valued parameters $\theta_1, \theta_2, \ldots, \theta_p$ in which $p < mn$. Furthermore, consider the matrix $A \in C^{m \times n}$ whose elements are given by

$$A(i, j) = a_{ij}(\theta_1, \theta_2, \ldots, \theta_p) \quad \text{for } 1 \le i \le m \text{ and } 1 \le j \le n + 1 \tag{14.109}$$

for a specific choice of the parameters $\theta_1, \theta_2, \ldots, \theta_p$. These p parameters shall be compactly represented by the parameter vector $\boldsymbol{\theta} \in R^p$. The set of all matrices that can be represented in this fashion is designated by $\mathcal{M}$ and is said to have a structure induced by the functions $a_{ij}(\boldsymbol{\theta})$ and to have p degrees of freedom. If the functions $a_{ij}(\boldsymbol{\theta})$ are linearly dependent on the parameters, the matrix class $\mathcal{M}$ is said to have a linear structure.

In what is to follow, we will be concerned with the task of optimally approximating a given matrix $B \in C^{m \times n}$ by a matrix with a specific linear structure. For purposes of description, the specific class of matrices to be considered is denoted by $\mathcal{L}$ and its constituent matrices are functionally dependent on the real-valued parameter vector $\boldsymbol{\theta} \in R^p$. The matrix approximation problem is formally expressed as

$$\min_{\boldsymbol{\theta} \in R^p} \left\| B - A(\boldsymbol{\theta}) \right\|_F \tag{14.110}$$

where $A(\boldsymbol{\theta})$ designates a general matrix contained in $\mathcal{L}$ that is linearly dependent on the parameter vector $\boldsymbol{\theta}$.

It is possible to utilize standard analysis techniques to obtain a closed-form solution to matrix approximation problem (14.110). To begin this analysis, it is useful to represent matrix B by the $mn \times 1$ vector $\mathbf{b}_c$ whose elements are formed by concatenating the column vectors of B. This concatenation mapping is one to one and onto and is therefore invertible. Namely, given B there exists a unique concatenated vector image $\mathbf{b}_c$, and vice versa. It further follows that the Euclidean norm of $\mathbf{b}_c$ and the Frobenius norm of B are equal, that is,

$$\left\| \mathrm{b_c} \right\|_2 = \left\| \mathrm{B} \right\|_\mathrm{F} \tag{14.111}$$

Using this norm equivalency, it follows that the original matrix approximation problem (14.110) can be equivalently expressed as

$$\min_{\boldsymbol{\theta} \in R^p} \left\| B - A(\boldsymbol{\theta}) \right\|_F = \min_{\boldsymbol{\theta} \in R^p} \left\| \mathbf{b}_c - \mathbf{a}_c(\boldsymbol{\theta}) \right\|_2 \tag{14.112}$$

where $\mathbf{b}_c$ and $\mathbf{a}_c(\boldsymbol{\theta})$ designate the concatenated vector representations for matrices B and A($\boldsymbol{\theta}$), respectively. Since each element of matrix A($\boldsymbol{\theta}$) $\in \mathcal{L}$ is linearly dependent on the parameter vector $\boldsymbol{\theta}$, it follows that there exists a unique mn × p matrix L such that

$$a_c(\boldsymbol{\theta}) = \mathrm{L}\boldsymbol{\theta} \tag{14.113}$$

is the concatenated representation for matrix $A(\boldsymbol{\theta}) \in \mathcal{L}$. Thus, the original matrix approximation problem can be equivalently expressed as

$$\min_{\boldsymbol{\theta} \in R^p} \| \mathbf{b}_c - L\boldsymbol{\theta} \|_2 \tag{14.114}$$

This problem, however, is seen to be quadratic in the parameter vector $\boldsymbol{\theta}$, and an optimum parameter vector is obtained by solving the associated consistent system of normal equations

$$L^* L\boldsymbol{\theta}^o = \mathrm{L}^*\mathbf{b}_c \tag{14.115}$$

In many cases, the matrix product L^*L is invertible, thereby rendering a unique solution to these equations. Whatever the case, the associated vector representation for the optimum matrix contained in $\mathcal{L}$ is given by $\mathbf{a}_c(\boldsymbol{\theta}^o) = \mathrm{L}\boldsymbol{\theta}^o$. Finally, the corresponding optimum approximating matrix $\mathrm{A}(\boldsymbol{\theta}^o)$ is simply obtained by reversing the column vector concatenation mapping that generates $\mathbf{a}_c(\boldsymbol{\theta}^o)$.

Example 5. To illustrate the above procedure, let us consider the specific case of the class of real 3×2 Toeplitz matrices. A general parametric representation for a matrix in this class and its associated concatenated vector equivalent is given by

$$A(\boldsymbol{\theta}) = \begin{bmatrix} \theta_1 & \theta_2 \\ \theta_3 & \theta_1 \\ \theta_4 & \theta_3 \end{bmatrix} \leftrightarrow \mathbf{a}_c(\boldsymbol{\theta}) = \begin{bmatrix} \theta_1 \\ \theta_3 \\ \theta_4 \\ \theta_2 \\ \theta_1 \\ \theta_3 \end{bmatrix} \tag{14.116}$$

It then follows that the matrix mapping the parameter vector $\boldsymbol{\theta}$ into $\mathbf{a}_c(\boldsymbol{\theta})$is given by

$$\mathbf{a}_c(\boldsymbol{\theta}) = L\boldsymbol{\theta} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \theta_1 \\ \theta_2 \\ \theta_3 \\ \theta_4 \end{bmatrix} \tag{14.117}$$

It is seen that the structure matrix mapping L has a full column rank of four. Finally, the unique solution to relationship (14.115) for the optimum parameter vector used for representing the closest Euclidean norm approximation is specified by

$$\boldsymbol{\theta}^o = [L^* L]^{-1} L^* \mathbf{b}_c = \begin{bmatrix} \frac{1}{2}[B(1,1) + B(2,2)] \\ B(1,2) \\ \frac{1}{2}[B(2,1) + B(3,3)] \\ B(3,2) \end{bmatrix} \tag{14.118}$$

It is clear that the entities $A(\boldsymbol{\theta})$ and $\mathbf{a}_c(\boldsymbol{\theta})$are equivalent. Moreover, the class of real 3×2 Toeplitz matrices is seen to have four degrees of freedom (i.e., the real parameters θ_1, θ_2, θ_3, and θ_4).

It is readily established using the above arguments that the best Toeplitz approximation to a matrix B is obtained by first determining the mean value of each of its diagonals and then using these mean values as entries of the best approximating Toeplitz diagonals. Let us formalize this important result.

Theorem 10. Let C_T and C_H designate the set of all Toeplitz and Hankel matrices contained in the space $C^{m\times n}$, respectively. It follows that C_T and C_H are each complex $(m + n - 1)$-dimensional subspaces of $C^{n\times n}$. Furthermore, the Toeplitz matrix A_T which best approximates $A \in C^{m\times n}$ in the Frobenius norm sense has the constant element along its kth diagonal specified by

$$\alpha_k = \text{mean}[\mathbf{d}_k] \quad \text{for } -n + 1 \leq k \leq m - 1 \tag{14.119}$$

In this expression, mean $[\mathbf{d}_k]$ designates the arithmetic mean of vector $\mathbf{d}_k$ whose components correspond to the elements of matrix A along its kth diagonal. In particular, vector $\mathbf{d}_o$ has as its components the elements of the main diagonal [i.e, elements $A(1,1)$, $A(2,2)$, etc.], vector $\mathbf{d}_1$ has as its components the elements of the diagonal immediately below the main diagonal, vector $\mathbf{d}_{-1}$ has as its components the elements of the diagonal immediately above the main diagonal, and so forth. The projection operator P_T that maps A into A_T as governed by relationship (14.119) is designated by

$$A_T = P_T A \tag{14.120}$$

and is linear and one to one.

Similarly, the Hankel matrix A_H that lies closest to A in the Frobenius norm sense has the constant element along its kth antidiagonal specified by

$$\beta_k = \text{mean}[\mathbf{a}_k] \quad \text{for } -n + 1 \leq k \leq m - 1 \tag{14.121}$$

The components of $\mathbf{a}_k$ correspond to the elements of matrix A along its kth antidiagonal in which vector $\mathbf{a}_o$ corresponds to the main antidiagonal [i.e., elements $A(1,n)$, $A(2,n-1)$, etc.], vector $\mathbf{a}_1$ to the antidiagonal immediately below the main antidiagonal, and so forth. The projection operator P_H mapping A into A_H as governed by relationship (14.121) is designated by

$$A_H = P_H A \tag{14.122}$$

and is linear and one to one.

It is interesting to note that relationships (14.120) and (14.122) which identify the closest approximating Toeplitz and Hankel matrices are very much dependent on the Frobenius measure of matrix size. If a different metric had been incorporated, then different expressions for the best approximating Toeplitz and Hankel matrix approximations would have arisen. For example, in applications in which data outliers are anticipated, it is often beneficial to use the l_1-induced norm. In this case, the elements α_k and β_k are replaced by the median value of the kth diagonal and antidiagonal of matrix A, respectively. Similarly, if the l_∞-induced norm were used, the elements α_k and β_k would be replaced by the midpoint of the largest and smallest elements of the kth diagonal and the kth antidiagonal of matrix A, respectively.

In pure sinusoidal modeling applications, the concept of forward and backward prediction is often used. The data matrix arising from a forward-backward modeling will then have a block Toeplitz-Hankel structure. This in turn gives rise to the signal restoration task of finding a matrix of block Toeplitz-Hankel structure that most closely approximates a given matrix. The results of Theorem 10 can be trivially extended to treat this case.

Nonnegative Sequence Approximation

Two related fundamental problems which arise in various signal processing applications are that of finding (1) a nonnegative-definite sequence which lies closest to a given sequence, or (2) a nonnegative-definite matrix which lies closest to a given matrix. For example, in many commonly employed spectral estimation algorithms, estimates of a time series autocorrelation sequence are either explicitly or implicitly computed from a finite-length sample of the time series. It is well known that the autocorrelation sequence associated with a wide-sense stationary time series has a nonnegative-definite Fourier transform. However, the process of forming the autocorrelation lag estimates from empirical data often results in lag estimates whose Fourier transform can be negative. With this application (and others) in mind, we will now briefly explore some basic theory related to nonnegative-definite sequences and then employ the signal restoration algorithm to solve the second problem posed above.

To begin our development, the sequence $\{x(n)\}$ is said to be *nonnegative definite* if its Fourier transform is real nonnegative, that is,

$$X(\omega) = \sum_{n=-\infty}^{\infty} x(n)e^{-j\omega n} \geq 0 \qquad \text{for } \omega \in [0, 2\pi] \tag{14.123}$$

As one might suspect, nonnegative-definite time series possess a number of salient properties which distinguish themselves from more general time series. The following theorem provides an insight into some of the more important properties.

Theorem 11. Let C_{nnd} designate the set of all finite- and infinite-length nonnegative-definite time series. It follows that C_{nnd} is a closed convex cone whose vertex is located at the origin. Moreover, every time series contained in this cone is conjugate symmetric so that $x(-n) = \bar{x}(n)$ for all integers n. Furthermore, the data matrix of order k formed from any nonnegative-definite time series $\{x(n)\} \in C_{\text{nnd}}$ and having the Hermitian-Toeplitz structure given by

$$X_k = \begin{bmatrix} x(0) & \bar{x}(1) & \cdots & \bar{x}(k) \\ x(1) & x(0) & \cdots & \bar{x}(k-1) \\ \vdots & \vdots & \vdots & \vdots \\ x(k) & x(k-1) & \cdots & x(0) \end{bmatrix} \tag{14.124}$$

is positive semidefinite for all nonnegative integer values of the order parameter k.

If $\{x(n)\}$ is a nonnegative sequence of length $2q+1$, then the zeros of its z-transform always occur in conjugate reciprocal pairs, that is,

$$X(z) = \sum_{n=-q}^{q} x(n)z^{-n} = \alpha \prod_{k=1}^{q} [1 - z_k z][1 - \bar{z}_k z^{-1}] \tag{14.125}$$

where α is a positive scalar. In addition, there will exist scalars $b_0, b_1, \ldots, b_q$ such that this $(2q+1)$-length nonnegative sequence can be represented by

$$x(n) = \sum_{k=0}^{q-n} b_k b_{k+n} \qquad \text{for } 1 \leq n \leq q \tag{14.126}$$

A more detailed treatment of this topic is found in Cadzow and Sun [1986]. This theorem must be carefully interpreted in order not to inappropriately infer properties possessed by nonnegative sequences. For instance, it is not true that the positive semidefiniteness of a finite number of data matrices X_k implies that the underlying time series is nonnegative. As an example, the length-three sequence with elements $x(0) = 3$, $x(1) = x(-1) = 2$ is not positive although the data matrix X_1 is positive definite. In a similar fashion, this theorem does not indicate that the symmetric truncation of a nonnegative sequence is itself nonnegative.

Nonnegative-Definite Toeplitz-Hermitian Matrix Approximation

It is possible to employ the concept of signal restoration in a straightforward fashion to iteratively solve the two problems considered at the beginning of this section. We will demonstrate a solution procedure by treating the problem in which it is desired to find that unique nonnegative-definite Toeplitz-Hermitian matrix which lies closest to a given matrix $X \in C^{n \times n}$. To employ the concept of signal restoration to this problem, we now identify the two attribute sets in which the required approximating matrix must lie, namely,

$$C_+ = \{Y \in C^{n \times n} \quad \text{which are nonnegative}\} \tag{14.127}$$

$$C_{TH} = \{Y \in C^{n \times n} \quad \text{for which } Y \text{ is Toeplitz and Hermitian}\}$$

Relationship (14.107) provides the mapping corresponding to the attribute set C_+. Implementation of the mapping associated with attribute set C_{TH} is a straightforward modification of Toeplitz mapping (14.120). In particular, the mean value of the elements of the two diagonals equispaced k units above and below the main diagonal is employed to determine the constant element used in the Toeplitz-Hermitian approximation where $0 \le k \le n - 1$.

Since the attribute sets C_+ and C_{TH} are both closed convex sets, the sequence of successive projections algorithm as specified by

$$X_k = P_+ P_{TH} X_{k-1} \quad \text{for } k = 1, 2, \ldots \tag{14.128}$$

can be employed. The initial matrix for this algorithm is set equal to the matrix being approximated (i.e., $X_o = X$). This algorithm produces a matrix sequence that is guaranteed to converge to a positive-semidefinite matrix with the required Toeplitz-Hermitian structure. Unfortunately, this solution need not be the closest matrix contained in $C_+ \cap C_{TH}$ that lies closest to X in the Frobenius norm sense. To obtain the optimum approximating matrix contained in $C_+ \cap C_{TH}$, we can alternatively employ the algorithm described by Relationship (14.97).

Example 6. We will now illustrate the point that the sequence of vectors generated by the successive projections algorithm need not always converge to the closest vector in a closed convex set. This will be accomplished by considering the task of finding a positive-semidefinite Toeplitz matrix that lies closest to given matrix. The given matrix X is here taken to be

$$X = \begin{bmatrix} 2 & 4 \\ 2 & 4 \end{bmatrix}$$

Although this matrix is positive semidefinite, it is not Toeplitz, thereby necessitating the use of a signal restoration algorithm for finding a suitably close positive-semidefinite Toeplitz-Hermitian matrix approximation. The sequence of successive projections algorithm (14.128) has guaranteed convergence to a positive-semidefinite Toeplitz matrix approximation. To be assured of finding the positive-semidefinite Toeplitz matrix that lies closest to X in the Frobenius norm sense, however, it is generally necessary to employ the Dykstra algorithm (14.97). Using the given matrix X as the initial condition, the positive-semidefinite Toeplitz matrices to which these two algorithms converge are found to be

$$X_{\text{ssp}} = \begin{bmatrix} 3.0811 & 2.9230 \\ 2.9230 & 3.0811 \end{bmatrix} \quad \text{and} \quad X_{\text{dyk}} = \begin{bmatrix} 3 & 3 \\ 3 & 3 \end{bmatrix}$$

Clearly, the positive-semidefinite Toeplitz matrix approximation X_{dyk} lies slightly closer to X in the Frobenius norm sense than does X_{ssp}. Convergence was deemed to have occurred when the normed matrix error $\| X_n - X \| / \| X \|$ became less than 10^{-9}. The successive projection algorithms and Dykstra's algorithm took two and three iterations, respectively, to reach this normed error level.

Exponential Signals and the Data Matrix

In various applications, the basic objective is to approximate a finite sample of a time series by a linear combination of real- and/or complex-valued exponential signals. The set of data to be modeled is taken to be

$$x(1),\ x(2),\ \ldots,\ x(N) \tag{14.129}$$

where N designates the length of the data. It is well known that this data set can be exactly modeled by an exponential signal of order p or less if and only if there exists a nontrivial set of coefficients $a_o, a_1, \ldots, a_p$ such that the following homogeneous relationship is satisfied:

$$a_o x_n + a_1 x_{n-1} + \ldots + a_p x_{n-p} = 0 \quad \text{for } p + 1 \le n \le N \tag{14.130}$$

Upon examination of these relationships, it is clear that nontrivial solutions will always exist when the number of equations is fewer than the number of unknowns (i.e., $N - p < p$). Most data modeling applications, however, are concerned with the distinctly overdetermined case in which $N - p >> p$.

From the above comments, it is apparent that a characterization of the exponential data modeling problem can be obtained by analyzing the linear homogeneous relationships (14.130). It will be convenient to compactly represent these ideal relationships in the vector format

$$X\mathbf{a} = \mathbf{0} \tag{14.131}$$

where $\mathbf{a}$ is the $(p + 1) \times 1$ coefficient vector with elements a_k and X is the corresponding $(N - p) \times (p + 1)$ *data matrix* as specified by

$$\mathbf{X} = \begin{bmatrix} x(p+1) & x(p) & \cdots & x(1) \\ x(p+2) & x(p+1) & \cdots & x(2) \\ \vdots & \vdots & \vdots & \vdots \\ x(N) & x(N-1) & \cdots & x(N-p) \end{bmatrix} \tag{14.132}$$

This data matrix is seen to have a *Toeplitz* structure since the elements along each of its diagonals are equal. Furthermore, if relationship (14.131) is to have a nontrivial solution, it is clear that the rank of data matrix X must be equal to or less than p. These salient attributes play a critical role in various exponential modeling algorithms, and they are now formalized.

Theorem 12. The data set $\{x_1, x_2, \ldots, x_N\}$ is exactly representable as a qth-order exponential signal if and only if the associated $(N - p) \times (p + 1)$ Toeplitz-structured data matrix (14.132) has exactly q nonzero singular values provided that $q \le p$ and $N - p > p$.

The exponential modeling characterization spelled out in this theorem is only applicable to data that is exactly represented by an exponential model. In most practical applications, however, it is found that the data being analyzed can only be approximately represented by an exponential model of reasonably small order. For such situations, it is conceptually possible to employ the concept of signal restoration to slightly perturb the given data set so that the perturbed data set is exactly represented by a qth-order exponential model. To achieve this objective, we need to introduce signal attributes that facilitate this goal. From Theorem 12, it is apparent that the ideal data matrix should be contained in the two attribute sets

$$C^{(q)} = \{Y \in C^{(N-p)\times(p+1)} \quad \text{which have rank } q\}$$

$$C_T = \{Y \in C^{(N-p)\times(p+1)} \quad \text{which have Toeplitz structure}\}$$

The attribute set C_T is a closed subspace and therefore possesses a prerequisite property needed for signal restoration. On the other hand, attribute set $C^{(q)}$ is not convex, which seemingly precludes us from using the sequence of successive projections algorithm for signal restoration. Theorem 8, however, indicates that the associated rank-q operator $P^{(q)}$ is closed. We may therefore employ the sequence of successive projections algorithm to effect the desired signal restoration. This algorithm takes the form

$$X_k = P_T P^{(q)}(X_{k-1}) \quad \text{for } k \geq 1 \tag{14.133}$$

where the projection operators P_T and $P^{(q)}$ are described in Theorems 10 and 8, respectively. The initial data matrix used in this iterative scheme is set equal to the given data matrix (14.132), that is, $X_o = X$.

To implement algorithm (14.133), we first generate the rank-q approximation of the data matrix X. The corresponding matrix $P^{(q)}(X)$ is generally found to be non-Toeplitz in structure. To recover the prerequisite Toeplitz structure, we next apply projection operator P_T to matrix $P^{(q)}(X)$ to complete the first iteration of the signal restoration algorithm. It is generally found that this new Toeplitz-structured data matrix $X_1 = P_T P^{(q)}(X)$ has full rank. It is closer to a rank-q matrix, however, than was the original data matrix X. The first iteration has therefore led to a data matrix whose elements comprise a data sequence that is more compatible with a qth-order exponential model. Often, this first iteration is sufficient in many modeling applications.

To obtain a data sequence that is exactly representable by a qth-order exponential model, we continue this iterative process in an obvious manner. In particular, one sequentially computes the data matrices $X_{k+1} = P_T P^{(q)}(X_k)$ for $k = 0, 1, 2, \ldots$ until the rank of data matrix X_{k+1} is deemed sufficiently close to q. Since the projection operator $P^{(q)}$ and P_T are each closed, we are assured that this iterative process will eventually converge to a Toeplitz-structured data matrix of rank q. It has been empirically determined that the algorithmic process converges in a rapid fashion and typically takes from three to ten iterations for small-dimensioned matrices. Furthermore, the resulting enhanced data matrix has data elements that generally provide a better representation of the underlying signal components than did the original data. The restoration process has therefore effectively stripped away noise that contaminates the original data. We will now examine a special case of data restoration that has important practical applications.

Sinusoidal Signal Identification

In a surprisingly large number of important signal processing applications, the primary objective is that of identifying sinusoidal components in noise-corrupted data. For example, multiple plane waves incident on an equispaced linear array produce complex sinusoidal steering vectors. To identify sinusoidal signals in data, a widely employed procedure is to first form the data matrix whose upper and lower halves correspond to the forward and backward prediction equations associated with the data, respectively. If the data under analysis is specified by $x(1), x(2), \ldots, x(N)$, the associated forward-backward data matrix then takes the form

$$X_{fb} = \begin{bmatrix} X \\ \cdots \\ J_{N-p}\overline{X}J_{p+1} \end{bmatrix} \tag{14.134}$$

In this expression, the forward data matrix X is given by (14.132) while J_n designates the *order reversal matrix* whose elements are all zero except for ones which appear along its main antidiagonal [i.e., $J_n(i,j) = \delta(i, n + 1 - j)$]. The matrix $J_{N-p}\overline{X}J_{p+1}$ appearing in the lower half of the data matrix (14.134) corresponds to the backward prediction equations. The matrices X and $J_{N-p}\overline{X}J_{p+1}$ are seen to have a Toeplitz and Hankel structure, respectively. The combined forward-backward data matrix X_{fb} is therefore said to have a block Toeplitz-Hankel structure.

If the data is noise-free and composed of q complex sinusoids, then the block Toeplitz-Hankel data matrix X_{fb} has rank q. Various procedures for identifying the q (with $q < p$) complex sinusoidal signal components when noise is present have been proposed. Two related SVD-based methods that appeared at the same time have proven effective for this purpose and are now briefly described. In each method, the forward-backward data matrix (14.134) is first decomposed as

$$X_{fb} = [\mathbf{x}_1 \; X_r] \tag{14.135}$$

where $\mathbf{x}_1$ denotes the first column of X_{fb} and X_r its remaining p columns. In the method developed by the author [Cadzow, 1982], the rank-q approximation of the total forward-backward data matrix X is first determined using the truncated SVD (i.e., $X_{fb}^{(q)}$). Finally, the related coefficient vector is then specified by

$$\mathbf{a}_c^o = -[X_r^{(q)}]^\dagger \mathbf{x}_1^{(q)} \tag{14.136}$$

where † designates the pseudo matrix inverse operator while $\mathbf{x}_1^{(q)}$ and $X_r^{(q)}$ are the first and remaining p columns, respectively, of the rank-q approximation matrix $X^{(q)}$. In a very similar fashion, the Tufts-Kumaresan method is obtained by first determining the rank-q approximation of submatrix X_r which is here denoted by $X_{rkt}^{(q)}$ [Tufts and Kumaresan, 1982]. The corresponding coefficient vector is then given by

$$\mathbf{a}_{kt}^o = -[X_{rkt}^{(q)}]^\dagger \mathbf{x}_1 \tag{14.137}$$

It is to be noted that although these two coefficient vectors are similar, the latter approach excludes the first column of X in the rank-q approximation. As such, it does not achieve the full benefits of the SVD decomposition and therefore typically yields marginally poorer performance, as the example to follow illustrates. In both methods, the component sinusoids may be graphically identified by peaks that appear in the *detection functional*

$$d(f) = \frac{1}{\left| \sum_{n=0}^{p} a_n^o e^{j2\pi fn} \right|} \tag{14.138}$$

Rank-Reduced Data Matrix Enhancement

Although these algorithms are effective in identifying sinusoidal components, the application of signal restoration can improve their performance. In particular, one simply applies the signal restoration algorithm (14.133) with mapping P_T replaced by P_{TH}. The restoration algorithm for determining that rank-q data matrix with the block Toeplitz-Hankel structure (14.134) that approximates X is then given by

$$X_k = P_{TH} P^{(q)}(X_{k-1}) \quad \text{for } k \geq 1 \tag{14.139}$$

The mapping $P_{TH}(X)$ determines the block Toeplitz-Hankel matrix that lies closest to matrix X in the Frobenius norm. Implementation of $P_{TH}(X)$ is realized in a fashion similar to $P_T(X)$. The modified matrix achieved through iteration (14.139) is then used in expression (14.136) or (14.137) to provide an enhanced coefficient vector estimate.

Example 7. To illustrate the effectiveness of signal restoration preprocessing let us consider the following data set

$$x(n) = e^{j2\pi(0.25)n} + e^{j2\pi(0.26)n} + e^{j2\pi(0.29)n} + w(n) \quad 1 \leq n \leq 24 \tag{14.140}$$

where $w(n)$ is Gaussian white noise whose real and imaginary components have standard deviation 0.05. When estimation procedures (14.136) and (14.137) are applied to the original data with $p = 17$ (the choice advocated by Tufts and Kumaresan [1982]) and $m = 3$, the spectral estimates shown in Fig. 14.20 arise. Each estimate

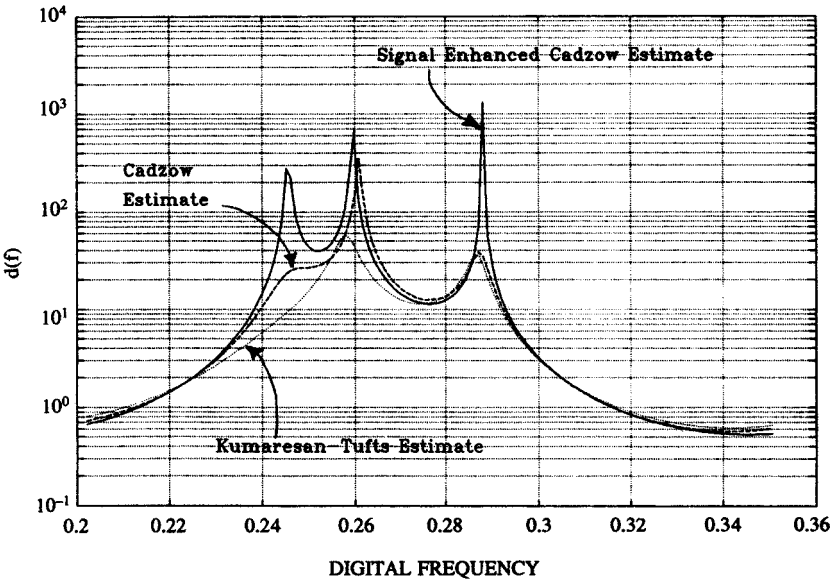

FIGURE 14.20 Sinusoid estimates.

produces two clear peaks with the Cadzow estimate also providing a hint of a third sinusoidal peak. When signal restoration is applied to the original block Toeplitz-Hankel data matrix (14.134), the enhanced Cadzow estimate also shown in Fig. 14.20 arises. This enhanced estimate clearly identifies the three sinusoids and their corresponding frequency estimates in an accurate fashion. The advantages accrued through signal restoration are made evident by this example.

Subsequence Restoration

It is possible to obtain further performance improvements in modeling data as a linear combination of exponentials by employing the concept of *data decimation*. As an example, any data sequence may be decomposed into two subsequences that are composed of its even and odd samples, respectively. If the data under analysis is exactly modeled as a linear combination of exponential signals, it is a simple matter to establish that the associated even and odd decimated subsequences are similarly characterized. The component exponentials in the even and odd decimated subsequences are found to equal the square of those in the original data. This decomposition procedure can be continued in an obvious fashion to generate an additional three subsequences, each of which is composed of every third sample of the original data, and so forth. This data decimation procedure has been combined with the signal restoration technique presented in this subsection to effect improved estimation performance. The interested reader will find this approach described in Cadzow and Wilkes [1991].

Recursive Modeling of Data

The linear recursive modeling of excitation-response data is of interdisciplinary interest in a variety of applications. For purposes of simplicity, we will only deal here with the case in which the data is dependent on a single time variable. The procedure to be described, however, is readily extended to the multidimensional time variable case. In the one-dimensional time case, there is given the pair of data sequences

$$(x(n),y(n)) \quad \text{for} \quad 0 \le n \le N \tag{14.141}$$

We will refer to $x(n)$ and $y(n)$ as being the excitation and response sequences, respectively. Without loss of generality, the measurement time interval has been selected to be $[0,N]$. The pair of data sequences (14.141)

is said to be recursively related if there exist a_k and b_k coefficients such that the following recursive relationship is satisfied:

$$y(n) + \sum_{k=1}^{p} a_k y(n-k) = \sum_{k=0}^{q} b_k x(n-k) \quad \text{for } 0 \le n \le N \tag{14.142}$$

In specifying the time interval over which this recursive relationship holds to be $0 \le n \le N$, it has been tacitly assumed that the sequence pairs are identically zero prior to $n = 0$. If this is not the case, then the time interval over which relationship (14.142) holds must be changed to $\max(p,q) \le n \le N$. In the analysis to follow, it is assumed that the appropriate time interval is $0 \le n \le N$. Modification of this analysis for the time interval $\max(p,q) \le n \le N$ is straightforward and not given.

It will be convenient to represent recursive relationships (14.142) in a matrix format so as to draw upon algebraic attributes that characterize an associated data matrix. This matrix representation takes the form

$$\begin{bmatrix} y(0) & 0 & \cdots & 0 \\ y(1) & y(0) & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ y(N) & y(N-1) & \cdots & y(N-p) \end{bmatrix} \begin{bmatrix} 1 \\ a_1 \\ \vdots \\ a_p \end{bmatrix} = \begin{bmatrix} x(0) & 0 & \cdots & 0 \\ x(1) & x(0) & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ x(N) & x(N-1) & \cdots & x(N-q) \end{bmatrix} \begin{bmatrix} b_o \\ b_1 \\ \vdots \\ b_q \end{bmatrix}$$

or, equivalently,

$$Y_p \mathbf{a}_p = X_q \mathbf{b}_q \tag{14.143}$$

In this latter representation, Y_p and X_q are referred to as the $(N+1) \times (p+1)$ *response matrix* and the $(N+1) \times (q+1)$ *excitation matrix*, respectively. Similarly, $\mathbf{a}_p$ and $\mathbf{b}_q$ are the recursive coefficient vectors identifying the recursive operator. With this preliminary development, the basic attributes characterizing recursively related data are now formally spelled out [see Cadzow and Solomon, 1988].

Theorem 13. Let the excitation-response data $(x(n),y(n))$ for $0 \le n \le N$ be related through a reduced-order recursive relationship $(\tilde{p}, \tilde{q})$ in which $\tilde{p} \le p$ and $\tilde{q} \le q$. It then follows that the extended-order recursive relationship (14.143) will always have a solution. Moreover, if the excitation and response matrices are full rank so that

$$\text{rank}[X_q] = q + 1 \quad \text{and} \quad \text{rank}[Y_p] = p + 1 \tag{14.144}$$

then all solutions are expressible as

$$\begin{bmatrix} \mathbf{a}_p \\ \cdots \\ \mathbf{b}_q \end{bmatrix} = \sum_{k=1}^{s} \alpha_k \mathbf{v}_k \tag{14.145}$$

with the α_k parameters selected to ensure that the first component of $\mathbf{a}_p$ is one as required. The upper limit in this sum is given by $s = 1 + \min(p - \tilde{p}, q - \tilde{q})$ while the vectors $\mathbf{v}_k$ correspond to the s eigenvectors associated with zero eigenvalue of multiplicity s of matrix $D_{p,q}^{*} D_{p,q}$ where $D_{p,q}$ is the $(N+1) \times (p+q+2)$ composite data matrix

$$D_{p,q} = [\, Y_p \,\vdots\, -X_q \,] \tag{14.146}$$

Furthermore, the transfer function associated with any solution to the system of equations (14.145) reduces to (after pole-zero cancelation) the underlying reduced-order transfer function of order $(\tilde{p}, \tilde{q})$.

When using the algebraic characteristics of the composite matrix to form a rational model of empirical data pairs, there is much to be gained by using an over-ordered model. By taking an over-ordered approach, the recursive model parameters are made less sensitive to quirks in the empirical data. A more detailed explanation of this concept is found in Cadzow and Solomon [1988].

Signal-Enhanced Data Modeling

From the above development, it follows that when the observed data $\{(x(n),y(n))\}$ are perfectly represented by a recursive relationship of order $(\tilde{p}, \tilde{q})$, the composite data matrix will satisfy the two attributes

- $D_{p,q}$ is a block Toeplitz matrix
- $D_{p,q}$ has nullity $s = 1 + \min(p - \tilde{p}, q - \tilde{p})$

In most practical applications, the given data observations are not perfectly represented by a low-order recursive relationship. This is typically manifested in the composite data matrix being full rank. To use the concept of signal restoration to achieve a suitably good approximate recursive model, we could suitably modify the given excitation-response data so that the modified data has an associated composite data matrix which satisfies the above two attributes. The signal restoration algorithm associated with this objective is given by

$$D_k = P_T P^{(p+q+2-s)}(D_{k-1}) \quad \text{for } k \geq 1 \tag{14.147}$$

where the initial composite matrix $D_o = [Y_p \vdots -X_q]$ has the given original excitation-response data as entries. We have dropped the subscript p,q in the composite data matrix to simplify the notation.

The signal restoration theorem ensures that the composite data matrix sequence (14.147) will contain a subsequence that converges to a composite data matrix which satisfies the prerequisite block Toeplitz–nullity s attributes. The recursive coefficient vectors as specified by (14.145) when applied to the convergent composite data matrix will typically give a satisfactory model of the data. It should be noted that in some applications it is known that either the excitation or the response data is accurate and should not be perturbed when applying the operator $P^{(p+q+2-s)}$. This is readily accomplished by inserting the original block after the rank reduction projection mapping $P^{(p+q+2-s)}$ has been applied to D_{k-1}. This is illustrated in the following numerical example.

Example 8. Let us apply the above signal restoration procedure to model recursively an unknown system when the input signal $x(n)$ and a noisy observation of the output signal $y(n)$ are available. The previously described signal-enhanced data modeling technique will be used with $p = q$ for simplicity. Clearly, if the excitation-response data were noiseless and the unknown system could be modeled by an autoregressive moving average (ARMA) (p,p) system, $D_{p,p}$ would not have full rank. The presence of noise in the response data will cause $D_{p,p}$ to have full rank, and the signal restoration algorithm will be applied to produce a block Toeplitz matrix having nullity $s = 1$. Since the input data is known exactly, its block will be inserted after each low rank approximation step. From (14.145) above it is clear that the resulting solution for the $\mathbf{a}_p$ and $\mathbf{b}_p$ coefficients will consist of the eigenvector associated with the zero eigenvalue of $D^*_{p,p}D_{p,p}$.

The system to be identified has the following ARMA relationship:

$$y_a(n) - 1.5y_a(n-1) + 0.7y_a(n-2) = x(n-1) + 0.5x(n-2) \tag{14.148}$$

and the observed output is $y(n) = y_a(n) + w(n)$, where $w(n)$ is the measurement noise at the output. In this example, the input signal is zero-mean unit variance white Gaussian noise. The signal-to-noise ratio at the output is 12 dB, and 300 samples of the input and output signals are used. The results for $p = 2$ are shown in Fig. 14.21; the true frequency response is given by the solid line, the dotted line is the solution that would result if no signal restoration were performed, and the dashed line depicts the solution after signal restoration (25 iterations).

Conclusion

The signal restoration algorithm has been shown to provide a useful means for solving a variety of important signal processing problems. In addition to the problems described in this chapter, it has been successfully applied to the missing data problem, deconvolution, and high-dimensional filter synthesis. Very useful results can be achieved by innovatively introducing signal attributes that characterize the underlying information signals.

Defining Terms

Attribute set: A set of vectors (signals) lying in a metric space that possess prescribed properties.

Closed convex sets: A set of vectors C such that if $\mathbf{x},\mathbf{y} \in C$ then $\lambda\mathbf{x} + (1 - \lambda)\mathbf{y} \in C$ for all $0 \le \lambda \le 1$.

Method of successive projections: An iterative procedure for modifying a signal so that the modified signal has properties which match an ideal objective.

Projection mapping: A mathematical procedure for determining a vector (signal) lying in a prescribed set that lies closest to a given vector.

Signal restoration: The restoring of data that has been corrupted by instrumentation dynamics and noise.

Singular value decomposition: A procedure for representing a matrix as a sum of positive weighted orthogonal outer products.

Structured matrix set: A set of common dimensioned matrices that have a prescribed algebraic structure (e.g., Toeplitz, Hankel, Hermitian).

Further Information

The monthly *IEEE Transactions on Acoustics, Speech, and Signal Processing* frequently publishes articles on the theory and application of signal restoration and recovery. Signal restoration concepts were discussed in articles published in the January 1988 issue (pp. 49–62), in the March 1989 issue (pp. 393–401), and in the May 1990 issue (pp. 778–786).

The *IEEE Transactions on Circuits and Systems* also publishes signal restoration application papers. Examples are to be found in the September 1975 issue (pp. 735–742) and the September 1978 issue (pp. 694–702).

Image restoration articles appear in the *IEEE Transactions on Medical Imaging* as illustrated by the articles that appeared in the October 1992 issue (pp. 81–94) and the January 1984 issue (pp. 91–98).

15.1 Coding, Transmission, and Storage

Stan McClellan and Jerry D. Gibson

Interest in speech coding is motivated by a wide range of applications, including commercial telephony, digital cellular mobile radio, military communications, voice mail, speech storage, and future personal communications networks. The goal of speech coding is to represent speech in digital form with as few bits as possible while maintaining the intelligibility and quality required for the particular application. At higher bit rates, such as 64 and 32 kbits/s, achieving good quality and intelligibility is not too difficult, but as the desired bit rate is lowered to 16 kbits/s and below, the problem becomes increasingly challenging. Depending on the application, many difficult constraints must be considered, including the issue of complexity.

For example, for the 32-kbits/s speech coding standard, the ITU-T[1] not only required highly intelligible, high-quality speech, but the coder also had to have low delay, withstand independent bit error rates up to 10^{-2}, have acceptable performance degradation for several synchronous or asynchronous tandem connections, and pass some voiceband modem signals. Other applications may have different criteria. Digital cellular mobile radio in the U.S. has no low delay or voiceband modem signal requirements, but the speech data rates required are under 8 kbits/s and the transmission medium (or channel) can be very noisy and have relatively long fades. These considerations affect the speech coder chosen for a particular application.

As speech coder data rates drop to 16 kbits/s and below, perceptual criteria taking into account human auditory response begin to play a prominent role. For *time domain coders,* the perceptual effects are incorporated using a frequency-weighted error criterion. The *frequency-domain coders* include perceptual effects by allocating

[1]International Telecommunications Union, Telecommunications Standardization Sector, formerly the CCITT.

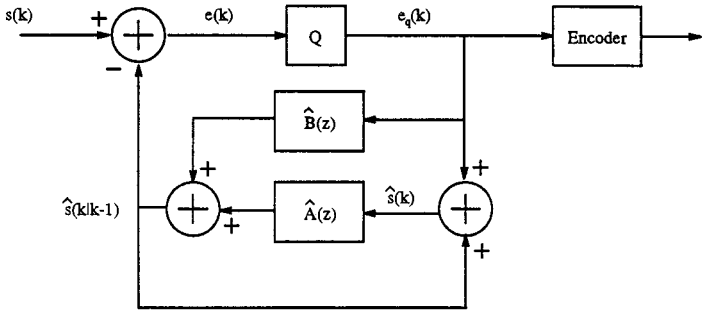

FIGURE 15.1 Differential encoder transmitter with a pole-zero predictor.

The focus of this article is the contrast among the three most important classes of speech coders that have representative implementations in several international standards—**time-domain coders, frequency-domain coders**, and **hybrid coders**. In the following, we define these classifications, look specifically at the important characteristics of representative, general implementations of each class, and briefly discuss the rapidly changing national and international standardization efforts related to speech coding.

General Approaches

Time Domain Coders and Linear Prediction

Linear Predictive Coding (LPC) is a modeling technique that has seen widespread application among time-domain speech coders, largely because it is computationally simple and applicable to the mechanisms involved in speech production. In LPC, general spectral characteristics are described by a parametric model based on estimates of autocorrelations or autocovariances. The model of choice for speech is the all-pole or *autoregressive* (*AR*) *model*. This model is particularly suited for voiced speech because the vocal tract can be well modeled by an all-pole transfer function. In this case, the estimated LPC model parameters correspond to an AR process which can produce waveforms very similar to the original speech segment. Differential Pulse Code Modulation (DPCM) coders (i.e., ITU-T G.721 ADPCM [CCITT, 1984]) and LPC vocoders (i.e., U.S. Federal Standard 1015 [National Communications System, 1984]) are examples of this class of time-domain predictive architecture. Code Excited Coders (i.e., ITU-T G728 [Chen, 1990] and U.S. Federal Standard 1016 [National Communications System, 1991]) also utilize LPC spectral modeling techniques.[1]

Based on the general spectral model, a predictive coder formulates an estimate of a future sample of speech based on a weighted combination of the immediately preceding samples. The error in this estimate (the *prediction residual*) typically comprises a significant portion of the data stream of the encoded speech. The residual contains information that is important in speech perception and cannot be modeled in a straightforward fashion. The most familiar form of predictive coder is the classical Differential Pulse Code Modulation (DPCM) system shown in Fig. 15.1. In DPCM, the predicted value at time instant k, $\hat{s}(k|k-1)$, is subtracted from the input signal at time k, $s(k)$, to produce the prediction error signal $e(k)$. The prediction error is then approximated (*quantized*) and the quantized prediction error, $e_q(k)$, is coded (represented as a binary number) for transmission to the receiver. Simultaneously with the coding, $e_q(k)$ is summed with $\hat{s}(k|k-1)$ to yield a reconstructed version of the input sample, $\hat{s}(k)$. Assuming no channel errors, an identical reconstruction, distorted only by the effects of quantization, is accomplished at the receiver. At both the transmitter and receiver, the predicted value at time instant $k+1$ is derived using reconstructed values up through time k, and the procedure is repeated.

The first DPCM systems had $\hat{B}(z) = 0$ and $\hat{A}(z) = \sum_{i=1}^{N} a_i z^{-i}$, where $\{a_i, i = 1 \ldots N\}$ are the LPC coefficients and z^{-1} represents unit delay, so that the predicted value was a weighted linear combination of previous reconstructed values, or

[1]However, codebook excitation is generally described as a *hybrid* coding technique.

$$\hat{s}\left(k\middle|k-1\right) = \sum_{i=1}^{N} a_i \hat{s}\left(k-i\right). \tag{15.1}$$

Later work showed that letting $\hat{B}(z) = \sum_{j=1}^{M} b_j z^{-j}$ improves the perceived quality of the reconstructed speech[1] by shaping the spectrum of the quantization noise to match the speech spectrum, as well as improving noisy-channel performance [Gibson, 1984]. To produce high-quality, highly intelligible speech, it is necessary that the quantizer and predictor parameters be adaptive to compensate for nonstationarities in the speech waveform.

Frequency Domain Coders

Coders that rely on spectral decomposition often use the usual set of sinusoidal basis functions from signal theory to represent the specific short-time spectral content of a segment of speech. In this case, the approximated signal consists of a linear combination of sinusoids with specified amplitudes and arguments (frequency, phase). For compactness, a countable subset of harmonically related sinusoids may be used. The two most prominent types of frequency domain coders are subband coders and multi-band coders.

Subband coders digitally filter the speech into nonoverlapping (as nearly as possible) frequency bands. After filtering, each band is decimated (effectively sampled at a lower rate) and coded separately using PCM, DPCM, or some other method. At the receiver, the bands are decoded, upsampled, and summed to reconstruct the speech. By allocating a different number of bits per sample to the subbands, the perceptually more important frequency bands can be coded with greater accuracy. The design and implementation of subband coders and the speech quality produced have been greatly improved by the development of digital filters called quadrature mirror filters (QMFs) [Johnston, 1980] and polyphase filters. These filters allow subband overlap at the encoder, which causes aliasing, but the reconstruction filters at the receiver can be chosen to eliminate the aliasing if quantization errors are small.

Multi-band coders perform a similar function by characterizing the contributions of individual sinusoidal components to the short-term speech spectrum. These parameters are then quantized, coded, transmitted, and used to configure a bank of tuned oscillators at the receiver. Outputs of the oscillators are mixed in proportion to the distribution of spectral energy present in the original waveform. An important requirement of multi-band coders is a capability to precisely determine perceptually significant spectral components and track the evolution of their energy and phase. Recent developments related to multi-band coding emphasize the use of harmonically related components with carefully intermixed spectral regions of bandlimited white noise. Sinusoidal Transform Coders (STC) and Multi-Band Excitation coders (MBE) are examples of this type of frequency domain coders.

Model Adaptation

Adaptation algorithms for coder predictor or quantizer parameters can be loosely grouped based on the signals that are used as the basis for adaptation. Generally, *forward adaptive* coder elements analyze the input speech (or a filtered version of it) to characterize predictor coefficients, spectral components, or quantizer parameters in a blockwise fashion. *Backward adaptive* coder elements analyze a reconstructed signal, which contains quantization noise, to adjust coder parameters in a sequential fashion. Forward adaptive coder elements can produce a more efficient model of speech signal characteristics, but introduce delay into the coder's operation due to buffering of the signal. Backward adaptive coder elements do not introduce delay, but produce signal models that have lower fidelity with respect to the original speech due to the dependence on the noisy reconstructed signal. Most low-rate coders rely on some form of forward adaptation. This requires moderate to high delay in processing for accuracy of parameter estimation (autocorrelations/autocovariances for LPC-based coders, sinusoidal resolution for frequency-domain coders). The allowance of significant delay for many coder architectures has enabled a spectrally matched pre- or post-processing step to reduce apparent quantization noise and provide significant perceptual improvements. Perceptual enhancements combined with **analysis-by-synthesis** optimization, and enabled by recent advances in high-power computing architectures such as digital signal processors, have tremendously improved speech coding results at medium and low rates.

[1] In this case, the predicted value is $\hat{s}(k|\,k-1) = \sum_{i=1}^{N} a_i \hat{s}\left(k-i\right) + \sum_{i=1}^{M} b_j e_q\left(k-j\right)$.

Analysis-by-Synthesis

A significant drawback to traditional "instantaneous" coding approaches such as DPCM lies in the perceptual or subjective relevance of the distortion measure and the signals to which it is applied. Thus, the advent of analysis-by-synthesis coding techniques poses an important milestone in the evolution of medium- to low-rate speech coding. An analysis-by-synthesis coder chooses the coder excitation by minimizing distortion between the original signal and the set of synthetic signals produced by every possible codebook excitation sequence.

In contrast, time-domain predictive coders must produce an estimated prediction residual (innovations sequence) to drive the spectral shaping filter(s) of the LPC model, and the classical DPCM approach is to quantize the residual sequence directly using scalar or vector quantizers. The incorporation of frequency-weighted distortion in the optimization of analysis-by-synthesis coders is significant in that it de-emphasizes (increases the tolerance for) quantization noise surrounding spectral peaks. This effect is perceptually transparent since the ear is less sensitive to error around frequencies having higher energy [Atal and Schroeder, 1979].

This approach has resulted in significant improvements in low-rate coder performance, and recent increases in processor speed and power are crucial enabling techniques for these applications. Analysis-by-synthesis coders based on linear prediction are generally described as hybrid coders since they fall between waveform coders and vocoders.

Particular Implementations

Currently, three coder architectures dominate the fields of medium and low-rate speech coding:

- *Code-Excited Linear Prediction* (*CELP*): an LPC-based technique which optimizes a vector of excitation samples (and/or pitch filter and lag parameters) using analysis-by-synthesis.
- *Multi-Band Excitation* (*MBE*): a direct spectral estimation technique which optimizes the spectral reconstruction error over a set of subbands using analysis-by-synthesis.
- *Mixed-Excitation Linear Prediction* (*MELP*): an optimized version of the traditional LPC vocoder which includes an explicit multiband model of the excitation signal.

Several realizations of these approaches have been adopted nationally and internationally as standard speech coding architectures at rates below 16 kbits/s (i.e., G.728, IMBE, U.S. Federal Standard 1016, etc.). The success of these implementations is due to LPC-based analysis-by-synthesis with a perceptual distortion criterion or short-time frequency-domain modeling of a speech waveform or LPC residual. Additionally, the coders that operate at lower rates all benefit from forward adaptation methods which produce efficient, accurate parameter estimates.

CELP

The general CELP architecture is described as a blockwise analysis-by-synthesis selection of an LPC excitation sequence. In low-rate CELP coders, a forward-adaptive linear predictive analysis is performed at 20 to 30 msec intervals. The gross spectral characterization is used to reconstruct, via linear prediction, candidate speech segments derived from a constrained set of plausible filter excitations (the "codebook"). The excitation vector that produces the synthetic speech segment with smallest perceptually weighted distortion (with respect to the original speech) is chosen for transmission. Typically, the excitation vector is optimized more often than the LPC spectral model. The use of *vectors* rather than *scalars* for the excitation is significant in bit-rate reduction. The use of perceptual weighting in the CELP reconstruction stage and analysis-by-synthesis optimization of the dominant low-frequency (pitch) component are key concepts in maintaining good quality encoded speech at lower rates. CELP-based speech coders are the predominant coding methodologies for rates between 4 kbits/s and 16 kbits/s due to their excellent subjective performance. Some of the most notable are detailed below.

- ITU-T Recommendation G.728 (LD-CELP) [Chen, 1990] is a low delay, backward adaptive CELP coder. In G.728, a low algorithmic delay (less than 2.5 msec) is achieved by using 1024 candidate excitation sequences, each only 5 samples long. A 50th-order LPC spectral model is used, and the coefficients are backward-adapted based on the transmitted excitation.
- The speech coder standardized by the CTIA for use in the U.S. (time-division multiple-access) 8 kbits/s digital cellular radio systems is called vector sum excited linear prediction (VSELP) [Gerson and Jasiuk,

1990]. VSELP is a forward-adaptive form of CELP where two excitation codebooks are used to reduce the complexity of encoding.

- Other approaches to complexity reduction in CELP coders are related to "sparse" codebook entries which have few nonzero samples per vector and "algebraic" codebooks which are based on integer lattices [Adoul and Lamblin, 1987]. In this case, excitation code vectors can be constructed on an as-needed basis instead of being stored in a table. ITU-T standardization of a CELP algorithm which uses lattice-based excitations has resulted in the 8 kbps G.729 (ACELP) coder.
- U.S. Federal Standard 1016 [National Communications System, 1991] is a 4.8 kbps CELP coder. It has both long- and short-term linear predictors which are forward adaptive, and so the coder has a relatively large delay (100 msec). This coder produces highly intelligible, good-quality speech in a variety of environments and is robust to independent bit errors.

Below about 4 kbps, the subjective quality of CELP coders is inferior to other architectures. Much research in variable-rate CELP implementations has resulted in alternative coder architectures which adjust their coding rates based on a number of channel conditions or sophisticated, speech-specific cues such as phonetic segmentation [Wang and Gersho, 1989; Paksoy et al., 1993]. Notably, most variable-rate CELP coders are implementations of finite-state CELP wherein a vector of speech cues controls the evolution of a state-machine to prescribe mode-dependent bit allocations for coder parameters. With these architectures, excellent speech quality at average rates below 2 kbps has been reported.

MBE

The MBE coder [Hardwick and Lim, 1991] is an efficient frequency-domain architecture partially based on the concepts of sinusoidal transform coding (STC) [McAulay and Quatieri, 1986]. In MBE, the instantaneous spectral envelope is represented explicitly by harmonic estimates in several subbands. The performance of MBE coders at rates below 4 kbps is generally "better" than that of CELP-based schemes.

An MBE coder decomposes the instantaneous speech spectrum into subbands centered at harmonics of the fundamental glottal excitation (pitch). The spectral envelope of the signal is approximated by samples taken at pitch harmonics, and these harmonic amplitudes are compared to adaptive thresholds (which may be determined via analysis-by-synthesis) to determine subbands of high spectral activity. Subbands that are determined to be "voiced" are labeled, and their energies and phases are encoded for transmission. Subbands having relatively low spectral activity are declared "unvoiced". These segments are approximated by an appropriately filtered segment of white noise, or a locally dense collection of sinusoids with random phase. Careful tracking of the evolution of individual spectral peaks and phases in successive frames is critical in the implementation of MBE-style coders.

An efficient implementation of an MBE coder was adopted for the International Maritime Satellite (INMARSAT) voice processor, and is known as Improved-MBE, or IMBE [Hardwick and Lim, 1991]. This coder optimizes several components of the general MBE architecture, including grouping neighboring harmonics for subband voicing decisions, using non-integer pitch resolution for higher speaker fidelity, and differentially encoding the log-amplitudes of voiced harmonics using a DCT-based scheme. The IMBE coder requires high delay (about 80 msec), but produces very good quality encoded speech.

MELP

The MELP coder [McCree and Barnwell, 1995] is based on the traditional LPC vocoder model where an LPC synthesis filter is excited by an impulse train (voiced speech) or white noise (unvoiced speech). The MELP excitation, however, has characteristics that are more similar to natural human speech. In particular, the MELP excitation can be a mixture of (possibly aperiodic) pulses with bandlimited noise. In MELP, the excitation spectrum is explicitly modeled using Fourier series coefficients and bandpass voicing strengths, and the time-domain excitation sequence is produced from the spectral model via an inverse transform. The synthetic excitation sequence is then used to drive an LPC synthesizer which introduces formant spectral shaping.

Common Threads

In addition to the use of analysis-by-synthesis techniques and/or LPC modeling, a common thread between low-rate, forward adaptive CELP, MBE, and MELP coders is the dependence on an estimate of the fundamental glottal frequency, or pitch period. CELP coders typically employ a pitch or long-term predictor to characterize

the glottal excitation. MBE coders estimate the fundamental frequency and use this estimate to focus subband decompositions on harmonics. MELP coders perform pitch-synchronous excitation modeling. Overall coder performance is enhanced in the CELP and MBE coders with the use of sub-integer lags [Kroon and Atal, 1991]. This is equivalent to performing pitch estimation using a signal sampled at a higher sampling rate to improve the precision of the spectral estimate. Highly precise glottal frequency estimation improves the "naturalness" of coded speech at the expense of increased computational complexity, and in some cases increased bit rate.

Accurate characterization of pitch and LPC parameters can also be used to good advantage in postfiltering to reduce apparent quantization noise. These filters, usually derived from forward-adapted filter coefficients transmitted to the receiver as side-information, perform post-processing on the reconstructed speech which reduces perceptually annoying noise components [Chen and Gersho, 1995].

Speech Quality and Intelligibility

To compare the performance of two speech coders, it is necessary to have some indicator of the intelligibility and quality of the speech produced by each coder. The term *intelligibility* usually refers to whether the output speech is easily understandable, while the term *quality* is an indicator of how natural the speech sounds. It is possible for a coder to produce highly intelligible speech that is low quality in that the speech may sound very machine-like and the speaker is not identifiable. On the other hand, it is unlikely that unintelligible speech would be called high quality, but there are situations in which perceptually pleasing speech does not have high intelligibility. We briefly discuss here the most common measures of intelligibility and quality used in formal tests of speech coders.

DRT

The diagnostic rhyme test (DRT) was devised by Voiers [1977] to test the intelligibility of coders known to produce speech of lower quality. Rhyme tests are so named because the listener must determine which consonant was spoken when presented with a pair of rhyming words; that is, the listener is asked to distinguish between word pairs such as meat-beat, pool-tool, saw-thaw, and caught-taught. Each pair of words differs on only one of six phonemic attributes: voicing, nasality, sustention, sibilation, graveness, and compactness. Specifically, the listener is presented with one spoken word from a pair and asked to decide which word was spoken. The final DRT score is the percent responses computed according to $P = \frac{1}{T}(R - W) \times 100$, where R is the number correctly chosen, W is the number of incorrect choices, and T is the total of word pairs tested. Usually, $75 \leq \text{DRT} \leq 95$, with a *good* being about 90 [Papamichalis, 1987].

MOS

The **Mean Opinion Score (MOS)** is an often-used performance measure [Jayant and Noll, 1984]. To establish a MOS for a coder, listeners are asked to classify the quality of the encoded speech in one of five categories: excellent (5), good (4), fair (3), poor (2), or bad (1). Alternatively, the listeners may be asked to classify the coded speech according to the amount of perceptible distortion present, i.e., imperceptible (5), barely perceptible but not annoying (4), perceptible and annoying (3), annoying but not objectionable (2), or very annoying and objectionable (1). The numbers in parentheses are used to assign a numerical value to the subjective evaluations, and the numerical ratings of all listeners are averaged to produce a MOS for the coder. A MOS between 4.0 and 4.5 usually indicates high quality.

It is important to compute the variance of MOS values. A large variance, which indicates an unreliable test, can occur because participants do not known what categories such as *good* and *bad* mean. It is sometimes useful to present examples of good and bad speech to the listeners before the test to calibrate the 5-point scale [Papamichalis, 1987]. The MOS values for a variety of speech coders and noise conditions are given in [Daumer, 1982].

DAM

The diagnostic acceptability measure (DAM) developed by Dynastat [Voiers, 1977] is an attempt to make the measurement of speech quality more systematic. For the DAM, it is critical that the listener crews be highly trained and repeatedly calibrated in order to get meaningful results. The listeners are each presented with encoded sentences taken from the Harvard 1965 list of phonetically balanced sentences, such as "Cats and dogs

TABLE 15.1 Speech Coder Performance Comparisons

Algorithm (acronym)	Standardization		Rate	Subjective		
	Body	Identifier	kbits/s	MOS	DRT	DAM

[a] Estimated.
[b] From results of 1996 U.S. DoD 2400 bits/s vocoder competition.

each hate the other" and "The pipe began to rust while new". The listener is asked to assign a number between 0 and 100 to characteristics in three classifications—signal qualities, background qualities, and total effect. The ratings of each characteristic are weighted and used in a multiple nonlinear regression. Finally, adjustments are made to compensate for listener performance. A typical DAM score is 45 to 55%, with 50% corresponding to a *good* system [Papamichalis, 1987].

The perception of "good quality" speech is a highly individual and subjective area. As such, no single performance measure has gained wide acceptance as an indicator of the quality and intelligibility of speech produced by a coder. Further, there is no substitute for subjective listening tests under the actual environmental conditions expected in a particular application. As a rough guide to the performance of some of the coders discussed here, we present the DRT, DAM, and MOS values in Table 15.1, which is adapted from [Spanias, 1994; Jayant, 1990]. From the table, it is evident that at 8 kbits/s and above, performance is quite good and that the 4.8 kbits/s CELP has substantially better performance than LPC-10e.

Standardization

The presence of international, national, and regional speech coding **standards** ensures the interoperability of coders among various implementations. As noted previously, several standard algorithms exist among the classes of speech coders. The ITU-T (formerly CCITT) has historically been a dominant factor in international standardization of speech coders, such as G.711, G.721, G.728, G.729, etc. Additionally, the emergence of digital cellular telephony, personal communications networks, and multimedia communications has driven the formulation of various national or regional standard algorithms such as the GSM full and half-rate standards for European digital cellular, the CTIA full-rate TDMA and CDMA algorithms and their half-rate counterparts for U.S. digital cellular, full and half-rate Pitch-Synchronous CELP [Miki et al., 1993] for Japanese cellular, as well as speech coders for particular applications [ITU-TS, 1991].

The standardization efforts of the U.S. Federal Government for secure voice channels and military applications have a historically significant impact on the evolution of speech coder technology. In particular, the recent re-standardization of the DoD 2400 bits/s vocoder algorithm has produced some competing algorithms worthy of mention here. Of the classes of speech coders represented among the algorithms competing to replace LPC-10, several implementations utilized STC or MBE architectures, some used CELP architectures, and others were novel combinations of multiband-excitation with LPC modeling [McCree and Barnwell, 1995] or pitch-synchronous prototype waveform interpolation techniques [Kleijn, 1991].

The final results of the U.S. DoD standard competition are summarized in Table 15.2 for "quiet" and "office" environments. In the table, the column labeled "FOM" is the overall Figure of Merit used by the DoD Digital Voice Processing Consortium in selecting the coder. The FOM is a unitless combination of *complexity* and *performance* components, and is measured with respect to FS-1016. The complexity of a coder is a weighted combination of memory and processing power required. The performance of a coder is a weighted combination of four factors: quality (Q—measured via MOS), intelligibility (I—measured via DRT), speaker recognition (R), and communicability (C). Recognizability and communicability for each coder were measured by tests

TABLE 15.2 Speech Coder Performance Comparisons Taken from Results of 1996 U.S. DoD 2400 bits/s Vocoder Competition

* Ineligible due to failure of the quality (MOS) criteria minimum requirements (better than CELP) in both quiet and office environments.

comparing processed vs. unprocessed data, and effectiveness of communication in application-specific cooperative tasks [Schmidt-Nielsen and Brock, 1996; Kreamer and Tardelli, 1996]. The MOS and DRT scores were measured in a variety of common DoD environments. Each of the four "finalist" coders ranked first in one of the four categories examined (Q,I,R,C), as noted in the table.

The results of the standardization process were announced in April, 1996. As indicated in Table 15.2, the new 2400 bits/s Federal Standard vocoder replacing LPC-10e is a version of the Mixed Excitation Linear Prediction (MELP) coder which uses several specific enhancements to the basic MELP architecture. These enhancements include multi-stage VQ of the formant parameters based on frequency-weighted bark-scale spectral distortion, direct VQ of the first 10 Fourier coefficients of the excitation using bark-weighted distortion, and a gain coding technique which is robust to channel errors [McCree et al., 1996].

Variable Rate Coding

Previous standardization efforts and discussion here have centered on fixed-rate coding of speech where a fixed number of bits are used to represent speech in digital form per unit of time. However, with recent developments in transmission architectures (such as CDMA), the implementation of *variable-rate* speech coding algorithms has become feasible. In **variable-rate coding**, the average data rate for conversational speech can be reduced by a factor of at least 2.

A variable-rate speech coding algorithm has been standardized by the CTIA for wideband (CDMA) digital mobile cellular telephony under IS-95. The algorithm, QCELP [Gardner et al., 1993], is the first practical variable-rate speech coder to be incorporated in a digital cellular system. QCELP is a multi-mode, CELP-type analysis-by-synthesis coder which uses blockwise spectral energy measurements and a finite-state machine to switch between one of four configurations. Each configuration has a fixed rate of 1, 2, 4, or 8 kbits/s with a predetermined allocation of bits among coder parameters (coefficients, gains, excitation, etc.). The subjective performance of QCELP in the presence of low background noise is quite good since the bit allocations per-mode and mode-switching logic are well-suited to high-quality speech. In fact, QCELP at an average rate of 4 kbits/s has been judged to be MOS-equivalent to VSELP, its 8 kbits/s, fixed-rate cellular counterpart. A time-averaged encoding rate of 4 to 5 kbits/s is not uncommon for QCELP, however the average rate tends toward the 8 kbits/s maximum in the presence of moderate ambient noise. The topic of robust fixed-rate and variable-rate speech coding in the presence of significant background noise remains an open problem.

Much recent research in speech coding below 8 kbits/s has focused on multi-mode CELP architectures and efficient approaches to source-controlled mode selection [Das et al., 1995]. Multimode coders are able to quickly invoke a coding scheme and bit allocation specifically tailored to the local characteristics of the speech signal. This capability has proven useful in optimizing perceptual quality at low coding rates. In fact, the majority of algorithms currently proposed for half-rate European and U.S. digital cellular standards, as well as many algorithms considered for rates below 2.4 kbits/s are multimode coders. The direct coupling between variable-rate (multimode) speech coding and the CDMA transmission architecture is an obvious benefit to both technologies.

Summary and Conclusions

The availability of general-purpose and application-specific digital signal processing chips and the ever-widening interest in digital communications have led to an increasing demand for speech coders. The worldwide desire to establish standards in a host of applications is a primary driving force for speech coder research and development. The speech coders that are available today for operation at 16 kbits/s and below are conceptually quite exotic compared with products available less than 10 years ago. The re-standardization of U.S. Federal Standard 1015 (LPC-10) at 2.4 kbits/s with performance constraints similar to those of FS-1016 at 4.8 kbits/s is an indicator of the rapid evolution of speech coding paradigms and VLSI architectures.

Other standards to be established in the near term include the European (GSM) and U.S. (CTIA) half-rate speech coders for digital cellular mobile radio. For the longer term, the specification of standards for forthcoming mobile personal communications networks will be a primary focus in the next 5 to 10 years.

In the preface to their book, Jayant and Noll [1984] state that "our understanding of speech and image coding has now reached a very mature point …" As of 1997, this statement rings truer than ever. The field is a dynamic one, however, and the wide range of commercial applications demands continual progress.

Defining Terms

Analysis-by-synthesis: Constructing several versions of a waveform and choosing the best match.
Predictive coding: Coding of time-domain waveforms based on a (usually) linear prediction model.
Frequency domain coding: Coding of frequency-domain characteristics based on a discrete time-frequency transform.
Hybrid coders: Coders that fall between waveform coders and vocoders in how they select the excitation.
Standard: An encoding technique adopted by an industry to be used in a particular application.
Mean Opinion Score (MOS): A popular method for classifying the quality of encoded speech based on a five-point scale.
Variable-rate coders: Coders that output different amounts of bits based on the time-varying characteristics of the source.

15.2 Speech Enhancement and Noise Reduction

Yariv Ephraim

Voice communication systems are susceptible to interfering **signals** normally referred to as **noise.** The interfering signals may have harmful effects on the performance of any speech communication system. These effects depend on the specific system being used, on the nature of the noise and the way it interacts with the clean signal, and on the relative intensity of the noise compared to that of the signal. The latter is usually measured by the **signal-to-noise ratio** (SNR), which is the ratio of the power of the signal to the power of the noise.

The speech communication system may simply be a recording which was performed in a noisy environment, a standard digital or analog communication system, or a speech recognition system for human-machine communication. The noise may be present at the input of the communication system, in the channel, or at the receiving end. The noise may be correlated or uncorrelated with the signal. It may accompany the clean signal in an additive, multiplicative, or any other more general manner. Examples of noise sources include competitive speech; background sounds like music, a fan, machines, door slamming, wind, and traffic; room reverberation; and white Gaussian channel noise.

The ultimate goal of **speech enhancement** is to minimize the effects of the noise on the performance of speech communication systems. The performance measure is system dependent. For systems which comprise recordings of noisy speech, or standard analog communication systems, the goal of speech enhancement is to improve perceptual aspects of the noisy signal. For example, improving the **quality** and **intelligibility** of the noisy signal are common goals. Quality is a subjective measure which reflects on the pleasantness of the speech or on the amount of effort needed to understand the speech material. Intelligibility, on the other hand, is an objective measure which signifies the amount of speech material correctly understood. For standard digital communication systems, the goal of speech enhancement is to improve perceptual aspects of the encoded speech signal. For human-machine speech communication systems, the goal of speech enhancement is to reduce the error rate in recognizing the noisy speech signals.

To demonstrate the above ideas, consider a "hands-free" cellular radio telephone communication system. In this system, the transmitted signal is composed of the original speech and the background noise in the car. The background noise is generated by an engine, fan, traffic, wind, etc. The transmitted signal is also affected by the radio channel noise. As a result, noisy speech with low quality and intelligibility is delivered by such systems. The background noise may have additional devastating effects on the performance of this system. Specifically, if the system encodes the signal prior to its transmission, then the performance of the speech coder may significantly deteriorate in the presence of the noise. The reason is that speech coders rely on some statistical model for the clean signal, and this model becomes invalid when the signal is noisy. For a similar reason, if the cellular radio system is equipped with a speech recognizer for automatic dialing, then the error rate of such recognizer will be elevated in the presence of the background noise. The goals of speech enhancement in this example are to improve perceptual aspects of the transmitted noisy speech signals as well as to reduce the speech recognizer error rate.

Other important applications of speech enhancement include improving the performance of:

1. Pay phones located in noisy environments (e.g., airports)
2. Air-ground communication systems in which the cockpit noise corrupts the pilot's speech
3. Teleconferencing systems where noise sources in one location may be broadcasted to all other locations
4. Long distance communication over noisy radio channels

The problem of speech enhancement has been a challenge for many researchers for almost three decades. Different solutions with various degrees of success have been proposed over the years. An excellent introduction to the problem, and review of the systems developed up until 1979, can be found in the landmark paper by Lim and Oppenheim [1979]. A panel of the National Academy of Sciences discussed in 1988 the problem and various ways to evaluate speech enhancement systems. The panel's findings were summarized in Makhoul et al. [1989]. Modern statistical approaches for speech enhancement were recently reviewed in Boll [1992] and Ephraim [1992].

In this section the principles and performance of the major speech enhancement approaches are reviewed, and the advantages and disadvantages of each approach are discussed. The signal is assumed to be corrupted by additive statistically independent noise. Only a single noisy version of the clean signal is assumed available for enhancement. Furthermore, it is assumed that the clean signal cannot be preprocessed to increase its robustness prior to being affected by the noise. Speech enhancement systems which can either preprocess the clean speech signal or which have access to multiple versions of the noisy signal obtained from a number of microphones are discussed in Lim [1983].

This presentation is organized as follows. In the second section the speech enhancement problem is formulated and commonly used models and performance measures are presented. In the next section signal estimation for improving perceptual aspects of the noisy signal is discussed. In the fourth section source coding techniques for noisy signals are summarized, and the last section deals with recognition of noisy speech signals. Due to the limited number of references (10) allowed in this publication, tutorial papers are mainly referenced. Appropriate credit will be given by pointing to the tutorial papers which reference the original papers.

Models and Performance Measures

The goals of speech enhancement as stated in the first section are to improve perceptual aspects of the noisy signal whether the signal is transmitted through analog or digital channels and to reduce the error rate in recognizing noisy speech signals. Improving perceptual aspects of the noisy signal can be accomplished by estimating the clean signal from the noisy signal using perceptually meaningful estimation performance measures. If the signal has to be encoded for transmission over digital channels, then source coding techniques can be applied to the given noisy signal. In this case, a perceptually meaningful fidelity measure between the clean signal and the encoded noisy signal must be used. Reducing error rate in speech communication systems can be accomplished by applying optimal signal classification approaches to the given noisy signals. Thus the speech enhancement problem is essentially a set of signal estimation, source coding, and signal classification problems.

The probabilistic approach for solving these problems requires explicit knowledge of the performance measure as well as the probability laws of the clean signal and noise process. Such knowledge, however, is not explicitly available. Hence, mathematically tractable performance measures and statistical models which are believed to be meaningful are used. In this section we briefly review the most commonly used statistical models and performance measures.

The most fundamental model for speech signals is the Gaussian **autoregressive (AR) model.** This model assumes that each 20- to 40-msec segment of the signal is generated from an excitation signal which is applied to a linear time-invariant all-pole filter. The excitation signal comprises a mixture of white Gaussian noise and a periodic sequence of impulses. The period of that sequence is determined by the pitch period of the speech signal. This model is described in Fig. 15.2. Generally, the excitation signal represents the flow of air through the vocal cords and the all-pole filter represents the vocal tract. The model for a given sample function of speech

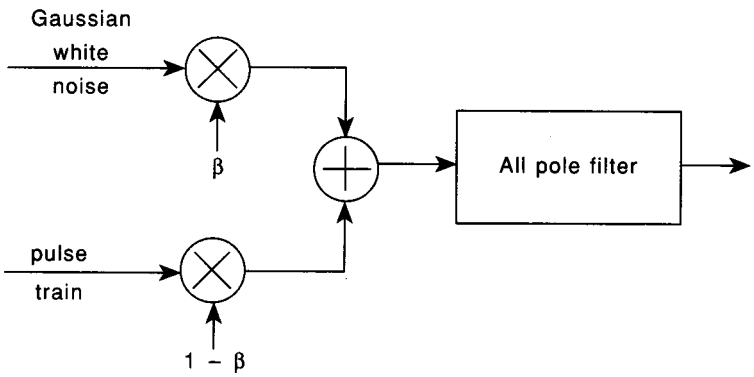

FIGURE 15.2 Gaussian autoregressive speech model.

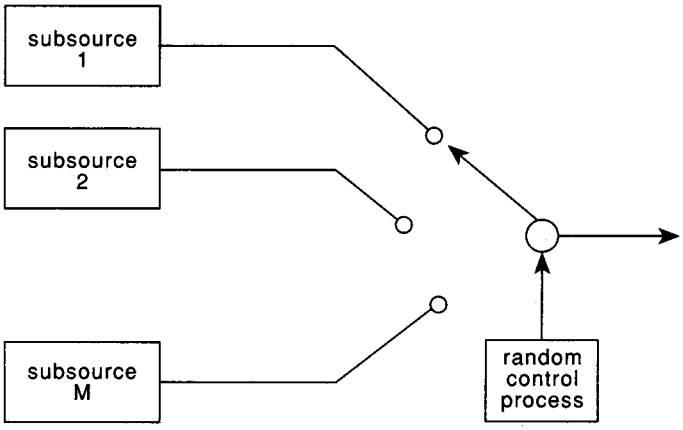

FIGURE 15.3 Composite source model.

signals, which is composed of several consecutive 20- to 40-msec segments of that signal, is obtained from the sequence of AR models for the individual segments. Thus, a linear time-varying AR model is assumed for each sample function of the speech signal. This model, however, is slowly varying in accordance with the slow temporal variation of the articulatory system. It was found that a set of approximately 2048 prototype AR models can reliably represent all segments of speech signals. The AR models are useful in representing the short time spectrum of the signal, since the spectrum of the excitation signal is white. Thus, the set of AR models represents a set of 2048 spectral prototypes for the speech signal.

The time-varying AR model for speech signals lacks the "memory" which assigns preference to one AR model to follow another AR model. This memory could be incorporated, for example, by assuming that the individual AR models are chosen in a Markovian manner. That is, given an AR model for the current segment of speech, certain AR models for the following segment of speech will be more likely than others. This results in the so-called *composite source model* (CSM) for the speech signal.

A block diagram of a CSM is shown in Fig. 15.3. In general, this model is composed of a set of M vector subsources which are controlled by a switch. The position of the switch at each time instant is chosen randomly, and the output of one subsource is provided. The position of the switch defines the state of the source at each time instant. CSMs for speech signals assume that the subsources are Gaussian AR sources, and the switch is controlled by a Markov chain. Furthermore, the subsources are usually assumed statistically independent and the vectors generated from each subsource are also assumed statistically independent. The resulting model is known as a **hidden Markov model** (HMM) [Rabiner, 1989] since the output of the model does not contain the states of the Markovian switch.

The performance measure for speech enhancement is task dependent. For signal estimation and coding, this measure is given in terms of a distortion measure between the clean signal and the estimated or the encoded signals, respectively. For signal classification applications the performance measure is normally the probability of misclassification. Commonly used distortion measures are the mean-squared error (MSE) and the Itakura-Saito distortion measures. The Itakura-Saito distortion measure is a measure between two power spectral densities, of which one is usually that of the clean signal and the other of a model for that signal [Gersho and Gray, 1991]. This distortion measure is normally used in designing speech coding systems and it is believed to be perceptually meaningful. Both measures are mathematically tractable and lead to intuitive estimation and coding schemes. Systems designed using these two measures need not be optimal only in the MSE and the Itakura-Saito sense, but they may as well be optimal in other more meaningful senses (see a discussion in Ephraim [1992]).

Signal Estimation

In this section we review the major approaches for speech signal estimation given noisy signals.

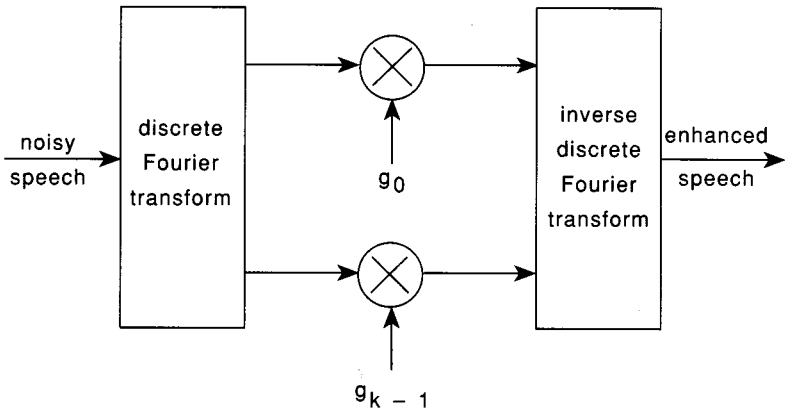

FIGURE 15.4 Spectral subtraction signal estimator.

Spectral Subtraction

The spectral subtraction approach [Weiss, 1974] is the simplest and most intuitive and popular speech enhancement approach. This approach provides estimates of the clean signal as well as of the short time spectrum of that signal. Estimation is performed on a frame-by-frame basis, where each frame consists of 20–40 msec of speech samples. In the spectral subtraction approach the signal is Fourier transformed, and spectral components whose variance is smaller than that of the noise are nulled. The surviving spectral components are modified by an appropriately chosen gain function. The resulting set of nulled and modified spectral components constitute the spectral components of the enhanced signal. The signal estimate is obtained from inverse Fourier transform of the enhanced spectral components. The short time spectrum estimate of the signal is obtained from squaring the enhanced spectral components. A block diagram of the spectral subtraction approach is shown in Fig. 15.4.

Gain functions motivated by different perceptual aspects have been used. One of the most popular functions results from linear minimum MSE (MMSE) estimation of each spectral component of the clean signal given the corresponding spectral component of the noisy signal. In this case, the value of the gain function for a given spectral component constitutes the ratio of the variances of the clean and noisy spectral components. The variance of the clean spectral component is obtained by subtracting an assumed known variance of the noise spectral component from the variance of the noisy spectral component. The resulting variance is guaranteed to be positive by the nulling process mentioned above. The variances of the spectral components of the noise process are normally estimated from silence portions of the noisy signal.

A family of spectral gain functions proposed in Lim and Oppenheim [1979] is given by

$$g_n = \left(\frac{|Z_n|^a - bE\left\{|V_n|^a\right\}}{|Z_n|^a} \right)^c \qquad n = 1, \ldots, N \tag{15.2}$$

where Z_n and V_n denote the nth spectral components of the noisy signal and the noise process, respectively, and $a > 0$, $b \geq 0$, $c > 0$. The MMSE gain function is obtained when $a = 2$, $b = 1$, and $c = 1$. Another commonly used gain function in the spectral subtraction approach is obtained from using $a = 2$, $b = 1$, and $c = 1/2$. This gain function results from estimating the spectral magnitude of the signal and combining the resulting estimate with the phase of the noisy signal. This choice of gain function is motivated by the relative importance of the spectral magnitude of the signal compared to its phase. Since both cannot be simultaneously optimally estimated [Ephraim, 1992], only the spectral magnitude is optimally estimated, and combined with an estimate of the complex exponential of the phase which does not affect the spectral magnitude estimate. The resulting estimate

of the phase can be shown to be the phase of the noisy signal within the HMM statistical framework. Normally, the spectral subtraction approach is used with $b = 2$, which corresponds to an artificially elevated noise level.

The spectral subtraction approach has been very popular since it is relatively easy to implement; it makes minimal assumptions about the signal and noise; and when carefully implemented, it results in reasonably clear enhanced signals. A major drawback of the spectral subtraction enhancement approach, however, is that the residual noise has annoying tonal characteristics referred to as "musical noise." This noise consists of narrowband signals with time-varying frequencies and amplitudes. Another major drawback of the spectral subtraction approach is that its optimality in any given sense has never been proven. Thus, no systematic methodology for improving the performance of this approach has been developed, and all attempts to achieve this goal have been based on purely heuristic arguments. As a result, a family of spectral subtraction speech enhancement approaches have been developed and experimentally optimized.

In a recent work [Ephraim et al., 1995] a version of the spectral subtraction was shown to be a signal subspace estimation approach which is asymptomatically optimal (as the frame length approaches infinity) in the linear MMSE sense.

Empirical Averages

This approach attempts to estimate the clean signal from the noisy signal in the MMSE sense. The conditional mean estimator is implemented using the conditional sample average of the clean signal given the noisy signal. The sample average is obtained from appropriate training sequences of the clean and noisy signals. This is equivalent to using the sample distribution or the histogram estimate of the probability density function (pdf) of the clean signal given the noisy signal. The sample average approach is applicable for estimating the signal as well as functionals of that signal, e.g., the spectrum, the logarithm of the spectrum, and the spectral magnitude.

Let $\{Y_t, t = 0, \ldots, T\}$ be a training data from the clean signal, where Y_t is a K-dimensional vector in the Euclidean space R^K. Let $\{Z_t, t = 0, \ldots, T\}$ be a training data from the noisy signal, where $Z_t \in R^K$. The sequence $\{Z_t\}$ can be obtained by adding a noise training sequence $\{V_t, t = 0, \ldots, T\}$ to the sequence of clean signals $\{Y_t\}$. Let $z \in R^K$ be a vector of the noisy signal from which the vector y of the clean signal is estimated. Let $\mathbf{Y}(z) = \{Y_t: Z_t = z, t = 0, \ldots, T\}$ be the set of all clean vectors from the training data of the clean signal which could have resulted in the given noisy observation z The cardinality of this set is denoted by $|\mathbf{Y}(z)|$. Then, the sample average estimate of the conditional mean of the clean signal y given the noisy signal z is given by

$$\begin{aligned} \hat{y} &= E\{y|z\} \\ &= \frac{\int yp(y,z)dy}{\int p(y,z)dy} \\ &= \frac{1}{|\mathbf{Y}(z)|} \sum_{\{Y_t \in \mathbf{Y}(z)\}} Y_t \end{aligned} \tag{15.3}$$

Obviously, this approach is only applicable for signals with finite alphabet since otherwise the set $Y(z)$ is empty with probability one. For signals with continuous pdf's, the approach can be applied only if those signals are appropriately quantized.

The sample average approach was first applied for enhancing speech signals by Porter and Boll in 1984 [Boll, 1992]. They, however, considered a simpler situation in which the noise true pdf was assumed known. In this case, enhanced signals with residual noise characterized as being a blend of wideband noise and musical noise were obtained. The balance between the two types of residual noise depended on the functional of the clean signal which was estimated.

The advantages of the sample average approach are that it is conceptually simple and it does not require *a priori* assumptions about the form of the pdf's of the signal and noise. Hence, it is a nonparametric estimation approach. This approach, however, has three major disadvantages. First, the estimator does not utilize any speech specific information such as the periodicity of the signal and the signal's AR model. Second, the training

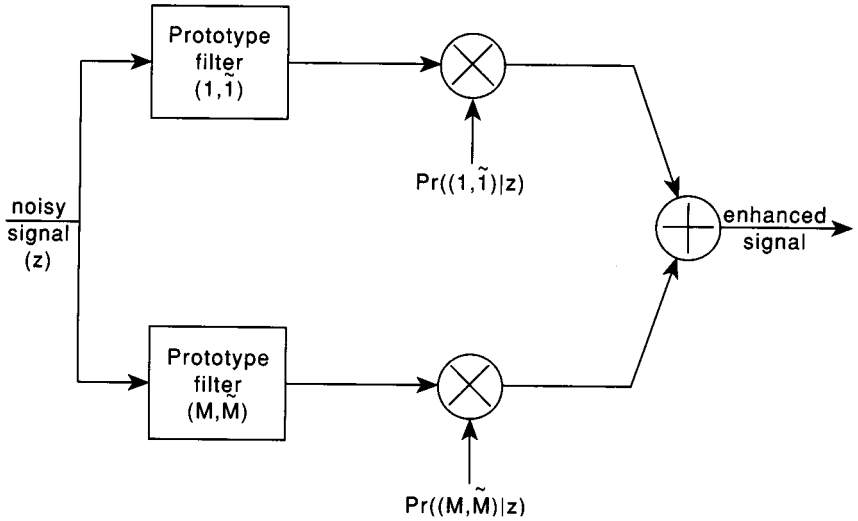

FIGURE 15.5 HMM-based MMSE signal estimator.

sequences from the signal and noise must be available at the speech enhancement unit. Furthermore, these training sequences must be applied for each newly observed vector of the noisy signal. Since the training sequences are normally very long, the speech enhancement unit must have extensive memory and computational resources. These problems are addressed in the model-based approach described next.

Model-Based Approach

The model-based approach [Ephraim, 1992] is a Bayesian approach for estimating the clean signal or any functional of that signal from the observed noisy signal. This approach assumes CSMs for the clean signal and noise process. The models are estimated from training sequences of those processes using the maximum likelihood (ML) estimation approach. Under ideal conditions the ML model estimate is consistent and asymptotically efficient. The ML model estimation is performed using the expectation-maximization (EM) or the Baum iterative algorithm [Rabiner, 1989; Ephraim, 1992]. Given the CSMs for the signal and noise, the clean signal is estimated by minimizing the expected value of the chosen distortion measure. The model-based approach uses significantly more statistical knowledge about the signal and noise compared to either the spectral subtraction or the sample average approaches.

The MMSE signal estimator is obtained from the conditional mean of the clean signal given the noisy signal. If $y_t \in R^K$ denotes the vector of the speech signal at time t, and z_0^t denotes the sequence of K-dimensional vectors of noisy signals $\{z_0, \ldots, z_t\}$ from time $\tau = 0$ to $\tau = t$, then the MMSE estimator of y_t is given by

$$\begin{aligned} \hat{y}_t &= E\{y_t \,|\, z_0^t\} \\ &= \sum_{\bar{x}_t} P(\bar{x}_t \,|\, z_0^t) E\{y_t \,|\, z_t, \bar{x}_t\} \end{aligned} \tag{15.4}$$

where $\bar{x}_t$ denotes the composite state of the noisy signal at time t. This state is given by $\bar{x}_t \triangleq (x_t, \tilde{x}_t)$, where x_t is the Markov state of the clean signal at time t and $\tilde{x}_t$ denotes the Markov state of the noise process at the same time instant t. The MMSE estimator, Eq. (15.4), comprises a weighted sum of conditional mean estimators for the composite states of the noisy signal, where the weights are the probabilities of those states given the noisy observed signal. A block diagram of this estimator is shown in Fig. 15.5.

The probability $P(\bar{x}_t \,|\, z_0^t)$ can be efficiently calculated using the forward recursion associated with HMMs. For CSMs with Gaussian subsources, the conditional mean $E\{y_t \,|\, z_t, \bar{x}_t\}$ is a linear function of the noisy vector z_t, given by

$$E(y_t|z_t, \bar{x}_t) = S_{xt}(S_{xt} + S_{\bar{x}t})^{-1} z_t \triangleq H_{\bar{x}t} z_t \tag{15.5}$$

where S_{xt} and $S_{\bar{x}t}$ denote the covariance matrices of the Gaussian subsources associated with the Markov states x_t and $\bar{x}_t$, respectively. Since, however, $P(\bar{x}_t | z_0^t)$ is a nonlinear function of the noisy signal z_0^t, the MMSE signal estimator $\hat{y}_t$ is a nonlinear function of the noisy signal z_0^t.

The MMSE estimator, Eq. (15.4), is intuitively appealing. It uses a predesigned set of filters $\{H_{\bar{x}_t}\}$ obtained from training data of speech and noise. Each filter is optimal for a pair of subsources of the CSMs for the clean signal and the noise process. Since each subsource represents a subset of signals from the corresponding source, each filter is optimal for a pair of signal subsets from the speech and noise. The set of predesigned filters covers all possible pairs of speech and noise signal subsets. Hence, for each noisy vector of speech there must exist an optimal filter in the set of predesigned filters. Since, however, a vector of the noisy signal could possibly be generated from any pair of subsources of the clean signal and noise, the most appropriate filter for a given noisy vector is not known. Consequently, in estimating the signal vector at each time instant, all filters are tried and their outputs are weighted by the probabilities of the filters to be correct for the given noisy signal. Other strategies for utilizing the predesigned set of filters are possible. For example, at each time instant only the most likely filter can be applied to the noisy signal. This approach is more intuitive than that of the MMSE estimation. It was first proposed in Drucker [1968] for a five-state model which comprises subsources for fricatives, stops, vowels, glides, and nasals. This approach was shown by Ephraim and Merhav [Ephraim, 1992] to be optimal only in an asymptotic MMSE sense.

The model-based MMSE approach provides reasonably good enhanced speech quality with significantly less structured residual noise than the spectral subtraction approach. This performance was achieved for white Gaussian input noise at 10 dB input SNR using 512-2048 filters. An improvement of 5–6 dB in SNR was achieved by this approach. The model-based approach, however, is more elaborate than the spectral subtraction approach, since it involves two steps of training and estimation, and training must be performed on sufficiently long data. The MMSE estimation approach is usually superior to the asymptotic MMSE enhancement approach. The reason is that the MMSE approach applies a "soft decision" rather than a "hard decision" in choosing the most appropriate filter for a given vector of the noisy signal.

A two-state version of the MMSE estimator was first applied to speech enhancement by McAulay and Malpass in 1980 [Ephraim, 1992]. The two states corresponded to speech presence and speech absence (silence) in the noisy observations. The estimator for the signal given that it is present in the noisy observations was implemented by the spectral subtraction approach. The estimator for the signal in the "silence state" is obviously equal to zero. This approach significantly improved the performance of the spectral subtraction approach.

Source Coding

An **encoder** for the clean signal maps vectors of that signal onto a finite set of representative signal vectors referred to as codewords. The mapping is performed by assigning each signal vector to its nearest neighbor codeword. The index of the chosen codeword is transmitted to the receiver in a signal communication system, and the signal is reconstructed using a copy of the chosen codeword. The codewords are designed to minimize the average distortion resulting from the nearest neighbor mapping. The codewords may simply represent waveform vectors of the signal. In another important application of low bit-rate speech coding, the codewords represent a set of parameter vectors of the AR model for the speech signal. Such coding systems synthesize the signal using the speech model in Fig. 15.2. The synthesis is performed using the encoded vector of AR coefficients as well as the parameters of the excitation signal. Reasonably good speech quality can be obtained using this coding approach at rates as low as 2400–4800 bits/sample [Gersho and Gray, 1991].

When only noisy signals are available for coding, the encoder operates on the noisy signal while representing the clean signal. In this case, the encoder is designed by minimizing the average distortion between the clean signal and the encoded signal. Specifically, let y denote the vector of clean signal to be encoded. Let z denote the corresponding given vector of the noisy signal. Let q denote the encoder. Let d denote a distortion measure. Then, the optimal encoder is designed by

$$\min_{q} E\{d(y, q(z))\} \tag{15.6}$$

When the clean signal is available for encoding the design problem is similarly defined, and it is obtained from Eq. (15.6) using $z = y$. The design problem in Eq. (15.6) is not standard since the encoder operates and represents different sources. The problem can be transformed into a standard coding problem by appropriately modifying the distortion measure. This was shown by Berger in 1971 and Ephraim and Gray in 1988 [Ephraim, 1992]. Specifically, define the modified distortion measure by

$$d'(z, q(z)) \triangleq E\{d(y, q(z)) \mid z\} \tag{15.7}$$

Then, by using iterated expectation in Eq. (15.8), the design problem becomes

$$\min_{q} E\{d'(z, q(z))\} \tag{15.8}$$

A useful class of encoders for speech signals are those obtained from vector quantization. Vector quantizers are designed using the Lloyd algorithm [Gersho and Gray, 1991]. This is an iterative algorithm in which the codewords and the nearest neighbor regions are alternatively optimized. This algorithm can be applied to design vector quantizers for clean and noisy signals using the modified distortion measure.

The problem of designing vector quantizers for noisy signals is related to the problem of estimating the clean signals from the noisy signals, as was shown by Wolf and Ziv in 1970 and Ephraim and Gray in 1988 [Ephraim, 1992]. Specifically, optimal waveform vector quantizers in the MMSE sense can be designed by first estimating the clean signal and then quantizing the estimated signal. Both estimation and quantization are performed in the MMSE sense. Similarly, optimal quantization of the vector of parameters of the AR model for the speech signal in the Itakura-Saito sense can be performed in two steps of estimation and quantization. Specifically, the autocorrelation function of the clean signal, which approximately constitutes the sufficient statistics of that signal for estimating the AR model, is first estimated in the MMSE sense. Then, optimal vector quantization in the Itakura-Saito sense is applied to the estimated autocorrelation.

The estimation-quantization approach has been most popular in designing encoders for speech signals given noisy signals. Since such design requires explicit knowledge of the statistics of the clean signal and the noise process, but this knowledge is not available as argued in the second section, a variety of suboptimal encoders were proposed. Most of the research in this area focused on designing encoders for the AR model of the signal due to the importance of such encoders in low bit-rate speech coding. The proposed encoders mainly differ in the estimators they used and the functionals of the speech signal these estimators have been applied to. Important examples of functionals which have commonly been estimated include the signal waveform, autocorrelation, and the spectral magnitude. The primarily set of estimators used for this application were obtained from the spectral subtraction approach and its derivatives. A version of the sample average estimator was also developed and applied to AR modeling by Juang and Rabiner in 1987 [Ephraim, 1992]. Recently, the HMM-based estimator of the autocorrelation function of the clean signal was used in AR model vector quantization [Ephraim, 1992].

Designing of AR model-based encoders from noisy signals has been a very successful application of speech enhancement. In this case both the quality and intelligibility of the encoded signal can be improved compared to the case where the encoder is designed for the clean signal and the input noise is simply ignored. The reason is that the input noise has devastating effects of the performance of AR model-based speech coders, and any "reasonable" estimation approach can significantly improve the performance of those coders in noisy environments.

Signal Classification

In recognition of clean speech signals a sample function of the signal is associated with one of the words in the vocabulary. The association or decision rule is designed to minimize the probability of classification error. When only noisy speech signals are available for recognition a very similar problem results. Specifically, a sample

function of the noisy signal is now associated with one of the words in the vocabulary in a way which minimizes the probability of classification error. The only difference between the two problems is that the sample functions of the clean and noisy signals from a given word have different statistics. The problem in both cases is that of partitioning the sample space of the given acoustic signals from all words in the vocabulary into L partition cells, where L is the number of words in the vocabulary.

Let $\{W_i,\ i = 1, \ldots, L\}$ denote a set of words in a given vocabulary. Let z denote the acoustic noisy signal from some word in the vocabulary. Let $\Omega \triangleq \{\omega_1, \ldots, \omega_L\}$ be a partition of the sample space of the noisy signals. The probability of error associated with this partition is given by

$$P_e(\Omega) = \sum_{i=1}^{L} P(W_i) \int_{z \notin \omega_i} p(z \mid W_i) dz \tag{15.9}$$

where $P(W_i)$ is the *a priori* probability of occurrence of the ith word, and $p(z \mid W_i)$ is the pdf of the noisy signal from the ith word. The minimization of $P_e(\Omega)$ is achieved by the well-known maximum *a posteriori* (MAP) decision rule. Specifically, z is associated with the word W_i for which $p(z \mid W_i)P(W_i) > p(z \mid W_j)P(W_j)$ for all $j = 1, \ldots, L$ and $j \neq i$. Ties are arbitrarily broken. In the absence of noise, the noisy signal z becomes a clean signal y, and the optimal recognizer is obtained by using the same decision rule with $z = y$. Hence, the only difference between recognition of clean signals and recognition of noisy signals is that in the first case the pdf's $\{p(y \mid W_i)\}$ are used in the decision rule, while in the second case the pdf's $\{p(z \mid W_i)\}$ are used in the same decision rule.

Note that optimal recognition of noisy signals requires explicit knowledge of the statistics of the clean signal and noise. Neither the clean signal nor any function of that signal needs to be estimated. Since, however, the statistics of the signal and noise are not explicitly available as argued in the second section, parametric models are usually assumed for these pdf's and their parameters are estimated from appropriate training data. Normally, HMMs with mixture of Gaussian pdf's at each state are attributed to both the clean signal and noise process. It can be shown (similarly to the case of classification of clean signals dealt with by Merhav and Ephraim in 1991 [Ephraim, 1992]) that if the pdf's of the signal and noise are precisely HMMs and the training sequences are significantly longer than the test data, then the MAP decision rule which uses estimates of the pdf's of the signal and noise is asymptotically optimal.

A key issue in applying hidden Markov modeling for recognition of speech signals is the matching of the energy contour of the signal to the energy contour of the model for that signal. Energy matching is required for two main reasons. First, speech signals are not strictly stationary and hence their energy contours cannot be reliably estimated from training data. Second, recording conditions during training and testing vary. An approach for gain adaptation was developed [Ephraim, 1992]. In this approach, HMMs for gain-normalized clean signals are designed and used together with gain contour estimates obtained from the noisy signals. The gain adaptation approach is implemented using the EM algorithm. This approach provides robust speech recognition at input SNRs greater than or equal to 10 dB.

The relation between signal classification and estimation was established in Kailath [1969] for *continuous* time signals contaminated by additive statistically independent Gaussian white noise. It was shown that minimum probability of error classification can be achieved by applying the MAP decision rule to the *causal* MMSE estimator of the clean signal. This interesting theoretical result provides the intuitive basis for a popular approach for recognition of noisy speech signals. In this approach, the clean signal or some feature vector of the signal is first estimated and then recognition is applied. In the statistical framework of hidden Markov modeling, however, the direct recognition approach presented earlier is significantly simpler since both the clean signal and the noisy signal are HMMs [Ephraim, 1992]. Hence, the complexity of recognizing the estimated signal is the same as that of recognizing the noisy signal directly.

Other commonly used approaches for recognition of noisy speech signals were developed for systems which are based on pattern recognition. When clean signals are available for recognition, these systems match the input signal to the nearest neighbor acoustic templet which represents some word in the vocabulary. The templets mainly comprise spectral prototypes of the clean signals. The matching is performed using a distance measure between the clean input signal and the templet. When only noisy signals are available for recognition,

several modifications of the pattern matching approach were proposed. Specifically, adapting the templets of the clean signal to reflect the presence of the noise was proposed by Roe in 1987 [Ephraim, 1992]; choosing templets for the noisy signal which are more robust than those obtained from adaptation of the templets for the clean signal was often proposed; and using distance measures which are robust to noise, such as the projection measure proposed by Mansour and Juang in 1989 [Ephraim, 1992]. These approaches along with the prefiltering approach in the sampled signal case are fairly intuitive and are relatively easy to implement. It is difficult, however, to establish their optimality in any well-defined sense. Another interesting approach based on robust statistics was developed by Merhav and Lee [Ephraim, 1992]. This approach was shown asymptotically optimal in the minimum probability of error sense within the hidden Markov modeling framework.

The speech recognition problem in noisy environments has also been a successful application of speech enhancement. Significant reduction in the error rate due to the noise presence was achieved by the various approaches mentioned above.

Comments

Three major aspects of speech enhancement were reviewed. These comprise improving the perception of speech signals in noisy environments and increasing the robustness of speech coders and recognition systems in noisy environments. The inherent difficulties associated with these problems were discussed, and the main solutions along with their strengths and weaknesses were presented. This section is an introductory presentation to the speech enhancement problem. A comprehensive treatment of the subject can be found in Lim [1979], Makhoul et al. [1989], Boll [1992], and Ephraim [1992]. Significant progress in understanding the problem and in developing new speech enhancement systems was made during the 1980s with the introduction of statistical model-based approaches. The speech enhancement problem, however, is far from being solved, and major progress is still needed. In particular, no speech enhancement system which is capable of simultaneously improving both the quality and intelligibility of the noisy signal is currently known. Progress in this direction can be made if more reliable statistical models for the speech signal and noise process as well as meaningful distortion measures can be found.

Defining Terms

Autoregressive model: Statistical model for resonant signals.
Classifier: Maps signal utterances into a finite set of word units, e.g., syllables.
Encoder: Maps signal vectors into a finite set of codewords. A vector quantizer is a particular type of encoder.
Hidden Markov model: Statistical model comprised of several subsources controlled by Markovian process.
Intelligibility: Objective quantitative measure of speech perception.
Noise: Any interfering signal adversely affecting the communication of the clean signal.
Quality: Subjective descriptive measure of speech perception.
Signal: Clean speech sample to be communicated with human or machine.
Signal-to-noise ratio: Ratio of the signal power to the noise power measured in decibels.
Speech enhancement: Improvement of perceptual aspects of speech signals.

15.3 Analysis and Synthesis

Jesse W. Fussell

After an acoustic speech signal is converted to an electrical signal by a microphone, it may be desirable to analyze the electrical signal to estimate some time-varying parameters which provide information about a model of the speech production mechanism. **Speech analysis** is the process of estimating such parameters. Similarly, given some parametric model of speech production and a sequence of parameters for that model, **speech synthesis** is the process of creating an electrical signal which approximates speech. While analysis and synthesis techniques may be done either on the continuous signal or on a sampled version of the signal, most modern analysis and synthesis methods are based on digital signal processing.

A typical speech production model is shown in Fig. 15.6. In this model the output of the excitation function is scaled by the gain parameter and then filtered to produce speech. All of these functions are time-varying.

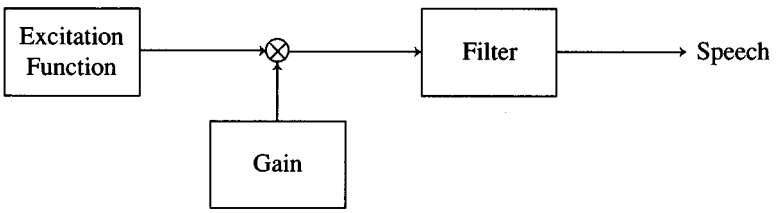

FIGURE 15.6 A general speech production model.

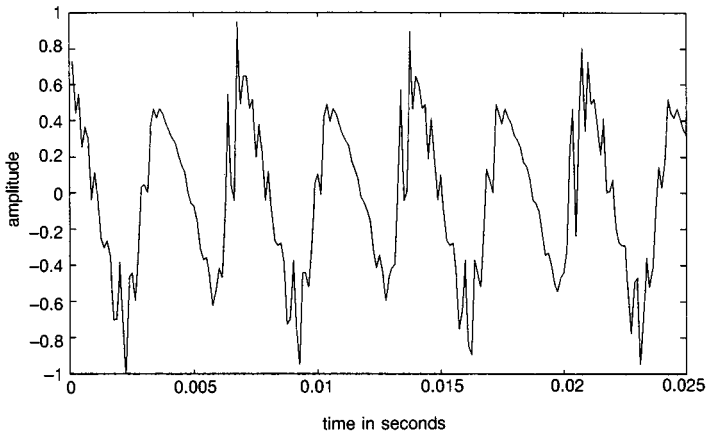

FIGURE 15.7 Waveform of a spoken phoneme /i/ as in beet.

For many models, the parameters are varied at a periodic rate, typically 50 to 100 times per second. Most speech information is contained in the portion of the signal below about 4 kHz.

The excitation is usually modeled as either a mixture or a choice of random noise and periodic waveform. For human speech, voiced excitation occurs when the vocal folds in the larynx vibrate; unvoiced excitation occurs at constrictions in the vocal tract which create turbulent air flow [Flanagan, 1965]. The relative mix of these two types of excitation is termed "**voicing**." In addition, the periodic excitation is characterized by a fundamental frequency, termed **pitch** or F0. The excitation is scaled by a factor designed to produce the proper amplitude or level of the speech signal. The scaled excitation function is then filtered to produce the proper spectral characteristics. While the filter may be nonlinear, it is usually modeled as a linear function.

Analysis of Excitation

In a simplified form, the excitation function may be considered to be purely periodic, for voiced speech, or purely random, for unvoiced. These two states correspond to voiced phonetic classes such as vowels and nasals and unvoiced sounds such as unvoiced fricatives. This binary voicing model is an oversimplification for sounds such as voiced fricatives, which consist of a mixture of periodic and random components. Figure 15.7 is an example of a time waveform of a spoken /i/ phoneme, which is well modeled by only periodic excitation.

Both time domain and frequency domain analysis techniques have been used to estimate the degree of voicing for a short segment or frame of speech. One time domain feature, termed the zero crossing rate, is the number of times the signal changes sign in a short interval. As shown in Fig. 15.7, the zero crossing rate for voiced sounds is relatively low. Since unvoiced speech typically has a larger proportion of high-frequency energy than voiced speech, the ratio of high-frequency to low-frequency energy is a frequency domain technique that provides information on voicing.

Another measure used to estimate the degree of voicing is the autocorrelation function, which is defined for a sampled speech segment, S, as

$$\mathrm{ACF}(\tau) = \frac{1}{N}\sum_{n=0}^{N-1} s(n)s(n-\tau) \tag{15.10}$$

where $s(n)$ is the value of the nth sample within the segment of length N. Since the autocorrelation function of a periodic function is itself periodic, voicing can be estimated from the degree of periodicity of the autocorrelation function. Figure 15.8 is a graph of the nonnegative terms of the autocorrelation function for a 64-ms frame of the waveform of Fig. 15.7. Except for the decrease in amplitude with increasing lag, which results from the rectangular window function which delimits the segment, the autocorrelation function is seen to be quite periodic for this voiced utterance.

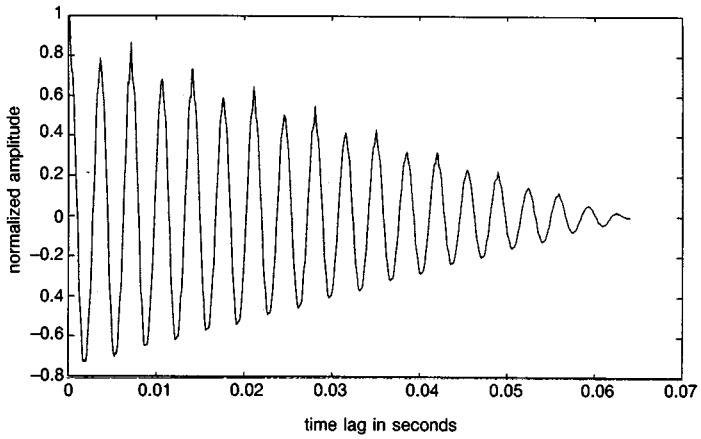

FIGURE 15.8 Autocorrelation function of one frame of /i/.

If an analysis of the voicing of the speech signal indicates a voiced or periodic component is present, another step in the analysis process may be to estimate the frequency (or period) of the voiced component. There are a number of ways in which this may be done. One is to measure the time lapse between peaks in the time domain signal. For example in Fig. 15.7 the major peaks are separated by about 0.0071 s, for a fundamental frequency of about 141 Hz. Note, it would be quite possible to err in the estimate of fundamental frequency by mistaking the smaller peaks that occur between the major peaks for the major peaks. These smaller peaks are produced by resonance in the vocal tract which, in this example, happen to be at about twice the excitation frequency. This type of error would result in an estimate of pitch approximately twice the correct frequency.

The distance between major peaks of the autocorrelation function is a closely related feature that is frequently used to estimate the pitch period. In Fig. 15.8, the distance between the major peaks in the autocorrelation function is about 0.0071 s. Estimates of pitch from the autocorrelation function are also susceptible to mistaking the first vocal track resonance for the glottal excitation frequency.

The absolute magnitude difference function (AMDF), defined as,

$$\text{AMDF}(\tau) = \frac{1}{N}\sum_{n=0}^{N-1}\left|s(n) - s(n-\tau)\right| \tag{15.11}$$

is another function which is often used in estimating the pitch of voiced speech. An example of the AMDF is shown in Fig. 15.9 for the same 64-ms frame of the /i/ phoneme. However, the minima of the AMDF is used as an indicator of the pitch period. The AMDF has been shown to be a good pitch period indicator [Ross et al., 1974] and does not require multiplications.

Fourier Analysis

One of the more common processes for estimating the spectrum of a segment of speech is the Fourier transform [Oppenheim and Schafer, 1975]. The Fourier transform of a sequence is mathematically defined as

$$S(e^{j\omega}) = \sum_{n=-\infty}^{\infty} s(n)e^{-j\omega n} \tag{15.12}$$

where $s(n)$ represents the terms of the sequence. The short-time Fourier transform of a sequence is a time-dependent function, defined as

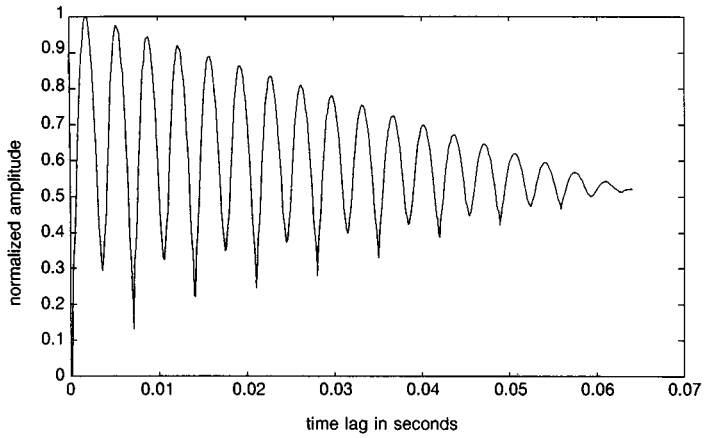

FIGURE 15.9 Absolute magnitude difference function of one frame of /i/.

$$S_m(e^{j\omega}) = \sum_{n=-\infty}^{\infty} w(m-n)\, s(n) e^{-j\omega n} \tag{15.13}$$

where the window function $w(n)$ is usually zero except for some finite range, and the variable m is used to select the section of the sequence for analysis. The discrete Fourier transform (DFT) is obtained by uniformly sampling the short-time Fourier transform in the frequency dimension. Thus an N-point DFT is computed using Eq. (15.14),

$$S(k) = \sum_{n=0}^{N-1} s(n) e^{-j2\pi nk/N} \tag{15.14}$$

where the set of N samples, $s(n)$, may have first been multiplied by a window function. An example of the magnitude of a 512-point DFT of the waveform of the /i/ from Fig. 15.10 is shown in Fig. 15.10. Note for this figure, the 512 points in the sequence have been multiplied by a Hamming window defined by

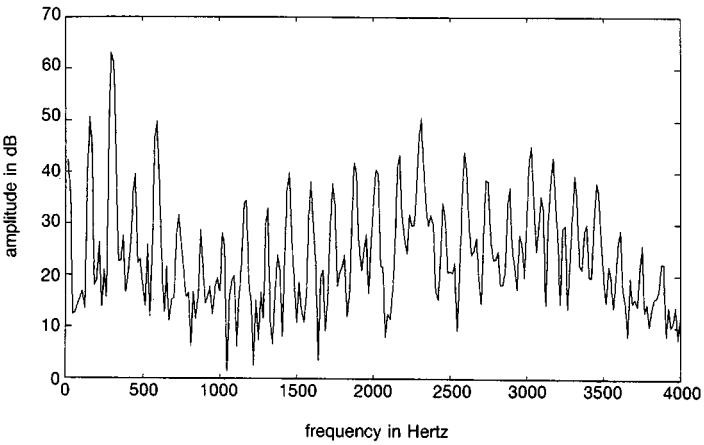

FIGURE 15.10 Magnitude of 512-point FFT of Hamming windowed /i/.

$$\begin{aligned} w(n) &= 0.54 - 0.46\ \cos\ (2\pi n\ /(N-1)) \quad 0 \le n \le N-1 \\ &= 0 \qquad\qquad\qquad\qquad\qquad\qquad\quad \text{otherwise} \end{aligned} \tag{15.15}$$

Since the spectral characteristics of speech may change dramatically in a few milliseconds, the length, type, and location of the window function are important considerations. If the window is too long, changing spectral characteristics may cause a blurred result; if the window is too short, spectral inaccuracies result. A Hamming window of 16 to 32 ms duration is commonly used for speech analysis.

Several characteristics of a speech utterance may be determined by examination of the DFT magnitude. In Fig. 15.10, the DFT of a voiced utterance contains a series of sharp peaks in the frequency domain. These peaks, caused by the periodic sampling action of the glottal excitation, are separated by the fundamental frequency which is about 141 Hz, in this example. In addition, broader peaks can be seen, for example at about 300 Hz and at about 2300 Hz. These broad peaks, called formants, result from resonances in the vocal tract.

Linear Predictive Analysis

Given a sampled (discrete-time) signal $s(n)$, a powerful and general parametric model for time series analysis is

$$s(n) = -\sum_{k=1}^{p} a(k)s(n-k) + G\sum_{l=0}^{q} b(l)\ u(n-l) \tag{15.16}$$

where $s(n)$ is the output and $u(n)$ is the input (perhaps unknown). The model parameters are $a(k)$ for $k = 1$, p, $b(l)$ for $l = 1$, q, and G. $b(0)$ is assumed to be unity. This model, described as an autoregressive moving average (ARMA) or pole-zero model, forms the foundation for the analysis method termed linear prediction. An autoregressive (AR) or all-pole model, for which all of the "b" coefficients except $b(0)$ are zero, is frequently used for speech analysis [Markel and Gray, 1976].

In the standard AR formulation of linear prediction, the model parameters are selected to minimize the mean-squared error between the model and the speech data. In one of the variants of linear prediction, the autocorrelation method, the minimization is carried out for a windowed segment of data. In the autocorrelation method, minimizing the mean-square error of the time domain samples is equivalent to minimizing the integrated ratio of the signal spectrum to the spectrum of the all-pole model. Thus, linear predictive analysis is a good method for spectral analysis whenever the signal is produced by an all-pole system. Most speech sounds fit this model well.

One key consideration for linear predictive analysis is the order of the model, p. For speech, if the order is too small, the formant structure is not well represented. If the order is too large, pitch pulses as well as formants begin to be represented. Tenth- or twelfth-order analysis is typical for speech. Figures 15.11 and 15.12 provide examples of the spectrum produced by eighth-order and sixteenth-order linear predictive analysis of the /i/ waveform of Fig. 15.7. Figure 15.11 shows there to be three formants at frequencies of about 300, 2300, and 3200 Hz, which are typical for an /i/.

Homomorphic (Cepstral) Analysis

For the speech model of Fig. 15.6, the excitation and filter impulse response are convolved to produce the speech. One of the problems of speech analysis is to separate or deconvolve the speech into these two components. One such technique is called homomorphic filtering [Oppenheim and Schafer, 1968]. The characteristic system for a system for homomorphic deconvolution converts a convolution operation to an addition operation. The output of such a characteristic system is called the complex **cepstrum.** The complex cepstrum is defined as the inverse Fourier transform of the complex logarithm of the Fourier transform of the input. If the input sequence is minimum phase (i.e., the z-transform of the input sequence has no poles or zeros outside the unit circle), the sequence can be represented by the real portion of the transforms. Thus, the real cepstrum can be computed by calculating the inverse Fourier transform of the log-spectrum of the input.

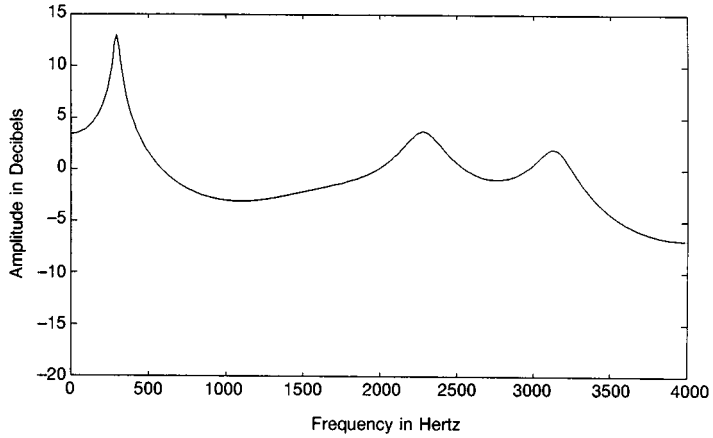

FIGURE 15.11 Eighth-order linear predictive analysis of an "i".

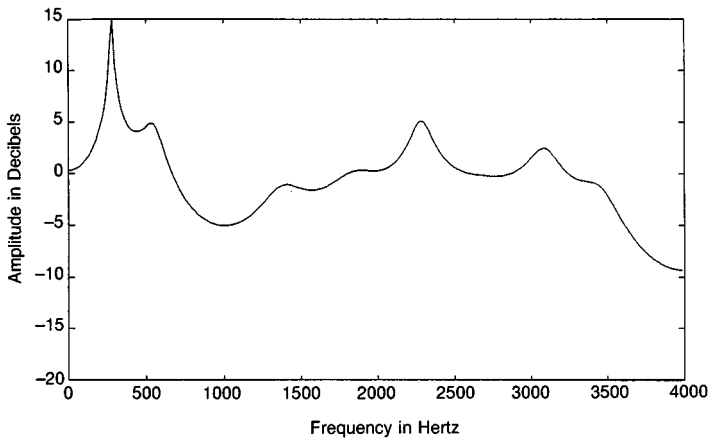

FIGURE 15.12 Sixteenth-order linear predictive analysis of an "i".

Figure 15.13 shows an example of the cepstrum for the voiced /i/ utterance from Fig. 15.7. The cepstrum of such a voiced utterance is characterized by relatively large values in the first one or two milliseconds as well as by pulses of decaying amplitudes at multiples of the pitch period. The first two of these pulses can clearly be seen in Fig. 15.13 at time lags of 7.1 and 14.2 ms. The location and amplitudes of these pulses may be used to estimate pitch and voicing [Rabiner and Schafer, 1978].

In addition to pitch and voicing estimation, a smooth log magnitude function may be obtained by windowing or "liftering" the cepstrum to eliminate the terms which contain the pitch information. Figure 15.14 is one such smoothed spectrum. It was obtained from the DFT of the cepstrum of Fig. 15.13 after first setting all terms of the cepstrum to zero except for the first 16.

Speech Synthesis

Speech synthesis is the creation of speech-like waveforms from textual words or symbols. In general, the speech synthesis process may be divided into three levels of processing [Klatt, 1982]. The first level transforms the text into a series of acoustic phonetic symbols, the second transforms those symbols to smoothed synthesis parameters, and the third level generates the speech waveform from the parameters. While speech synthesizers have

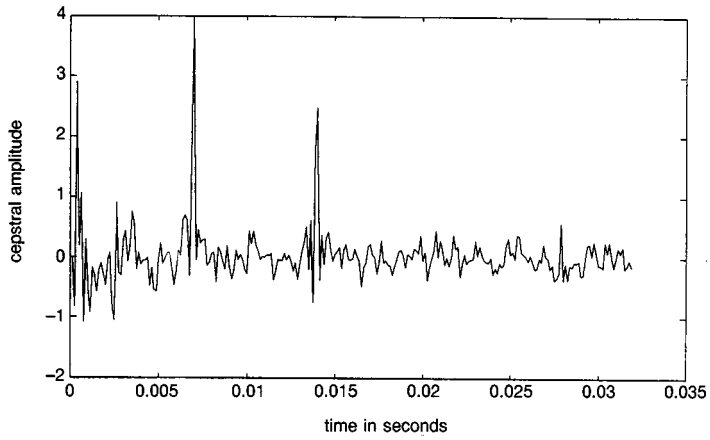

FIGURE 15.13 Real cepstrum of /i/.

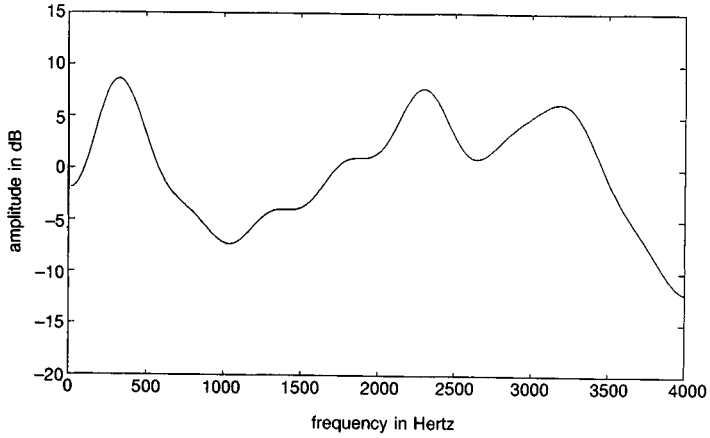

FIGURE 15.14 Smoothed spectrum of /i/ from 16 points of cepstrum.

been designed for a variety of languages and the processes described here apply to several languages, the examples given are for English text-to-speech.

In the first level of processing, abbreviations such as "Dr." (which could mean "doctor" or "drive"), numbers ("1492" could be a year or a quantity), special symbols such as "$", upper case acronyms (e.g., NASA), and nonspoken symbols such as "" (apostrophe) are converted to a standard form. Next prefixes and perhaps suffixes are removed from the body of words prior to searching for the root word in a lexicon, which defines the phonetic representation for the word. The lexicon includes words which do not obey the normal rules of pronunciation, such as "of". If the word is not contained in the lexicon, it is processed by an algorithm which contains a large set of rules of pronunciation.

In the second level, the sequences of words consisting of phrases or sentences are analyzed for grammar and syntax. This analysis provides information to another set of rules which determine the stress, duration, and pitch to be added to the phonemic representation. This level of processing may also alter the phonemic representation of individual words to account for coarticulation effects. Finally, the sequences of parameters which specify the pronunciation are smoothed in an attempt to mimic the smooth movements of the human articulators (lips, jaw, velum, and tongue).

The last processing level converts the smoothed parameters into a time waveform. Many varieties of waveform synthesizers have been used, including formant, linear predictive, and filter-bank versions. These waveform

synthesizers generally correspond to the synthesizers used in speech coding systems which are described in the first section of this chapter.

Defining Terms

Cepstrum: Inverse Fourier transform of the logarithm of the Fourier power spectrum of a signal. The complex cepstrum is the inverse Fourier transform of the complex logarithm of the Fourier tranform of the complex logarithm of the Fourier transform of the signal.

Pitch: Frequency of glottal vibration of a voiced utterance.

Spectrum or power density spectrum: Amplitude of a signal as a function of frequency, frequently defined as the Fourier transform of the autocovariance of the signal.

Speech analysis: Process of extracting time-varying parameters from the speech signal which represent a model for speech production.

Speech synthesis: Production of a speech signal from a model for speech production and a set of time-varying parameters of that model.

Voicing: Classification of a speech segment as being voiced (i.e., produced by glottal excitation), unvoiced (i.e., produced by turbulent air flow at a constriction) or some mix of those two.

15.4 Speech Recognition

Lynn D.Wilcox and Marcia A. Bush

Speech recognition is the process of translating an acoustic signal into a linguistic message. In certain applications, the desired form of the message is a verbatim transcription of a sequence of spoken words. For example, in using speech recognition technology to automate dictation or data entry to a computer, transcription accuracy is of prime importance. In other cases, such as when speech recognition is used as an interface to a database

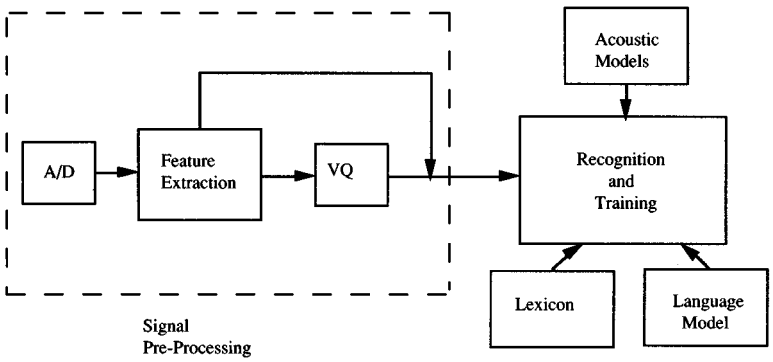

FIGURE 15.15 Architecture for a speech recognition system.

query system or to index by keyword into audio recordings, word-for-word transcription is less critical. Rather, the message must contain only enough information to reliably communicate the speaker's goal. The use of speech recognition technology to facilitate a dialog between person and computer is often referred to as "spoken language processing."

Speech recognition by machine has proven an extremely difficult task. One complicating factor is that, unlike written text, no clear spacing exists between spoken words; speakers typically utter full phrases or sentences without pause. Furthermore, acoustic variability in the speech signal typically precludes an unambiguous mapping to a sequence of words or subword units, such as phones.[1] One major source of variability in speech is coarticulation, or the tendency for the acoustic characteristics of a given speech sound or phone to differ depending upon the phonetic context in which it is produced. Other sources of acoustic variability include differences in vocal-tract size, dialect, speaking rate, speaking style, and communication channel.

Speech recognition systems can be constrained along a number of dimensions in order to make the recognition problem more tractable. Training the parameters of a recognizer to the speech of the user is one way of reducing variability and, thus, increasing recognition accuracy. Recognizers are categorized as speaker-dependent or speaker-independent, depending upon whether or not full training is required by each new user. Speaker-adaptive systems adjust automatically to the voice of a new talker, either on the basis of a relatively small amount of training data or on a continuing basis while the system is in use.

Recognizers can also be categorized by the speaking styles, vocabularies, and language models they accommodate. **Isolated word recognizers** require speakers to insert brief pauses between individual words. **Continuous speech recognizers** operate on fluent speech, but typically employ strict language models, or grammars, to limit the number of allowable word sequences. Wordspotters also accept fluent speech as input. However, rather than providing full transcription, wordspotters selectively locate relevant words or phrases in an utterance. **Wordspotting** is useful both in information-retrieval tasks based on keyword indexing and as an alternative to isolated word recogniton in voice command applications.

Speech Recognition System Architecture

Figure 15.15 shows a block diagram of a speech recognition system. Speech is typically input to the system using an analog transducer, such as a microphone, and converted to digital form. **Signal pre-processing** consists of computing a sequence of acoustic feature vectors by processing the speech samples in successive time intervals. In some systems, a clustering technique known as vector quantization is used to convert these continuous-valued features to a sequence of discrete codewords drawn from a codebook of acoustic prototypes. Recognition of an unknown utterance involves transforming the sequence of feature vectors, or codewords, into an appropriate message. The recognition process is typically constrained by a set of acoustic models which correspond to the basic units of speech employed in the recognizer, a lexicon which defines the vocabulary of the recognizer

[1]Phones correspond roughly to pronunciations of consonants and vowels.

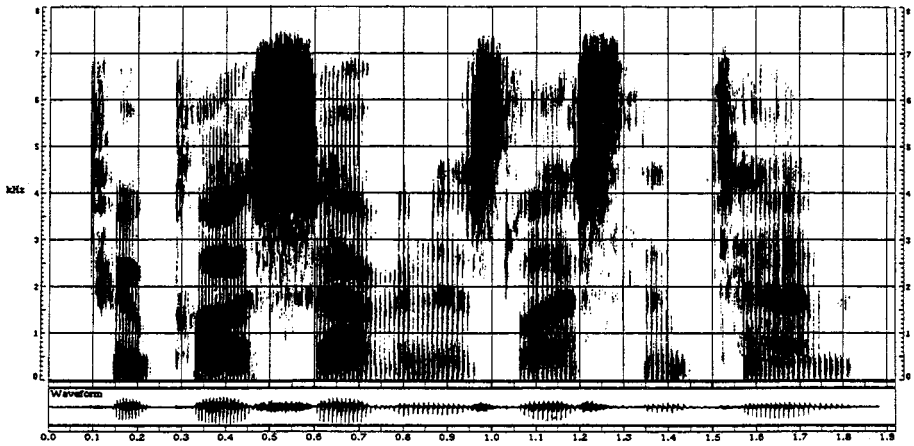

FIGURE 15.16 Speech spectrogram of the utterance "Two plus seven is less than ten." (*Source:* V.W. Zue, "The use of speech knowledge in automatic speech recognition," *Proc. IEEE,* vol. 73, no. 11, pp. 1602–1615, © 1985 IEEE. With permission.)

in terms of these basic units, and a language model which specifies allowable sequences of vocabulary items. The acoustic models, and in some cases the language model and lexicon, are learned from a set of representative training data. These components are discussed in greater detail in the remainder of this chapter, as are the two recognition paradigms most frequently employed in speech recognition: **dynamic time warping** and **hidden Markov models.**

Signal Pre-Processing

An amplitude waveform and speech spectrogram of the sentence "Two plus seven is less than ten" is shown in Fig. 15.16. The spectrogram represents the time evolution (horizontal axis) of the frequency spectrum (vertical axis) of the speech signal, with darkness corresponding to high energy. In this example, the speech has been digitized at a sampling rate of 16 kHz, or roughly twice the highest frequency of relevant energy in a high-quality speech signal. In general, the appropriate sampling rate is a function of the communication channel. In telecommunications, for example, a bandwidth of 4 kHz, and, thus, a Nyquist sampling rate of 8 kHz, is standard.

The speech spectrum can be viewed as the product of a source spectrum and the transfer function of a linear, time-varying filter which represents the changing configuration of the vocal tract. The transfer function determines the shape, or envelope, of the spectrum, which carries phonetic information in speech. When excited by a voicing source, the formants, or natural resonant frequencies of the vocal tract, appear as black bands running horizontally through regions of the speech spectrogram. These regions represent voiced segments of speech and correspond primarily to vowels. Regions characterized by broadband high-frequency energy, and by extremely low energy, result from noise excitation and vocal-tract closures, respectively, and are associated with the articulation of consonantal sounds.

Feature extraction for speech recognition involves computing sequences of numeric measurements, or feature vectors, which typically approximate the envelope of the speech spectrum. Spectral features can be extracted directly from the discrete Fourier transform (DFT) or computed using linear predictive coding (LPC) techniques. Cepstral analysis can also be used to deconvolve the spectral envelope and the periodic voicing source. Each feature vector is computed from a frame of speech data defined by windowing N samples of the signal. While a better spectral estimate can be obtained using more samples, the interval must be short enough so that the windowed signal is roughly stationary. For speech data, N is chosen such that the length of the interval covered by the window is approximately 25 to 30 msec. The feature vectors are typically computed at a frame rate of 10 to 20 msec by shifting the window forward in time. Tapered windowing functions, such as the Hamming window, are used to reduce dependence of the spectral estimate on the exact temporal position of

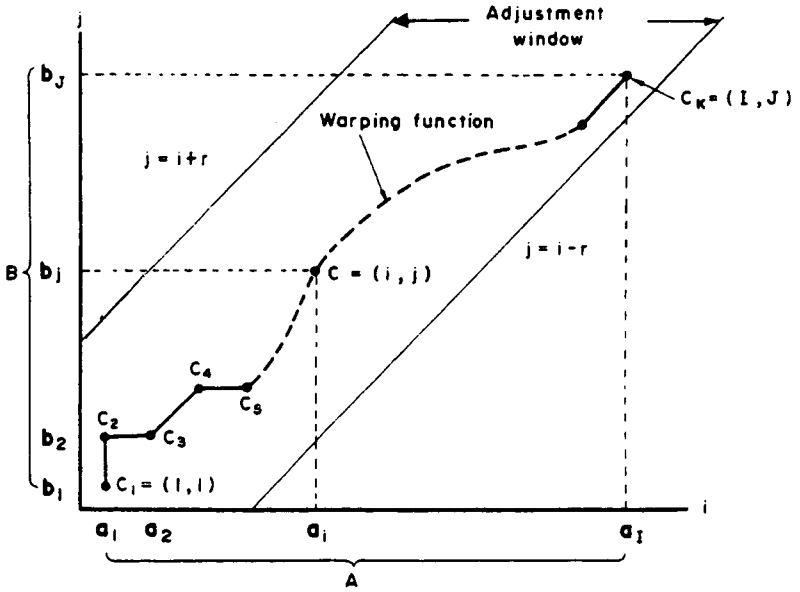

FIGURE 15.17 Dynamic time warping of utterances A and B. (*Source:* S. Furui, *Digital Speech Processing, Synthesis and Recognition,* New York: Marcel Dekker, 1989. With permission.)

the window. Spectral features are often augmented with a measure of the short time energy of the signal, as well as with measures of energy and spectral change over time [Lee, 1988].

For recognition systems which use discrete features, vector quantization can be used to quantize continuous-valued feature vectors into a set or codebook of K discrete symbols, or codewords [Gray, 1984]. The K codewords are characterized by prototypes $y^1 \ldots y^K$. A feature vector x is quantized to the kth codeword if the distance from x to y^k, or $d(x,y^k)$, is less than the distance from x to any other codeword. The distance $d(x,y)$ depends on the type of features being quantized. For features derived from the short-time spectrum and cepstrum, this distance is typically Euclidean or weighted Euclidean. For LPC-based features, the Itakura metric, which is based on spectral distortion, is typically used [Furui, 1989].

Dynamic Time Warping

Dynamic time warping (DTW) is a technique for nonlinear time alignment of pairs of spoken utterances. DTW-based speech recognition, often referred to as "template matching," involves aligning feature vectors extracted from an unknown utterance with those from a set of exemplars or templates obtained from training data. Nonlinear feature alignment is necessitated by nonlinear time-scale warping associated with variations in speaking rate.

Figure 15.17 illustrates the time correspondence between two utterances, A and B, represented as feature-vector sequences of unequal length. The time warping function consists of a sequence of points $F = c_1, \ldots, c_K$ in the plane spanned by A and B, where $c_k = (i_k, j_k)$. The local distance between the feature vectors a_i and b_j on the warping path at point $c = (i, j)$ is given as

$$d(c) = d(a_i, b_j) \tag{15.17}$$

The distance between A and B aligned with warping function F is a weighted sum of the local distances along the path,

$$D(F) = \frac{1}{N} \sum_{k=1}^{K} d(c_k) w_k \tag{15.18}$$

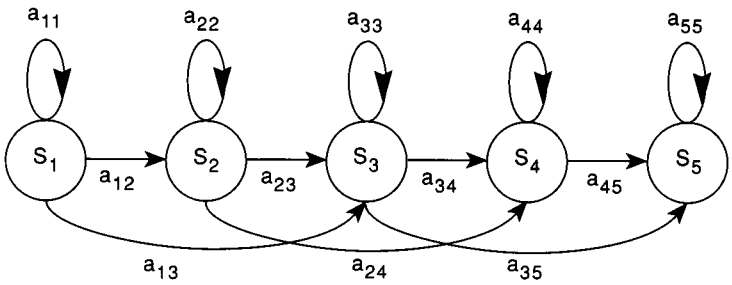

FIGURE 15.18 A typical HMM topology.

where w_k is a nonnegative weighting function and N is the sum of the weights. Path constraints and weighting functions are chosen to control whether or not the distance $D(F)$ is symmetric and the allowable degree of warping in each direction. Dynamic programming is used to efficiently determine the optimal time alignment between two feature-vector sequences [Sakoe and Chiba, 1978].

In DTW-based recognition, one or more templates are generated for each word in the recognition vocabulary. For speaker-dependent recognition tasks, templates are typically created by aligning and averaging the feature vectors corresponding to several repetitions of a word. For speaker-independent tasks, clustering techniques can be used to generate templates which better model pronunciation variability across talkers. In isolated word recognition, the distance $D(F)$ is computed between the feature-vector sequence for the unknown word and the templates corresponding to each vocabulary item. The unknown is recognized as that word for which $D(F)$ is a minimum. DTW can be extended to connected word recognition by aligning the input utterance to all possible concatenations of reference templates. Efficient algorithms for computing such alignments have been developed [Furui, 1989]; however, in general, DTW has proved most applicable to isolated word recognition tasks.

Hidden Markov Models[1]

Hidden Markov modeling is a probabilistic pattern matching technique which is more robust than DTW at modeling acoustic variability in speech and more readily extensible to continuous speech recognition. As shown in Fig. 15.18, hidden Markov models (HMMs) represent speech as a sequence of states, which are assumed to model intervals of speech with roughly stationary acoustic features. Each state is characterized by an output probability distribution which models variability in the spectral features or observations associated with that state. Transition probabilities between states model durational variability in the speech signal. The probabilities, or parameters, of an HMM are trained using observations (VQ codewords) extracted from a representative sample of speech data. Recognition of an unknown utterance is based on the probability that the speech was generated by the HMM.

More precisely, an HMM is defined by:

1. A set of N states $\{S_1 \ldots S_N\}$, where q_t is the state at time t.
2. A set of K observation symbols $\{v_1 \ldots v_K\}$, where O_t is the observation at time t.
3. A state transition probability matrix $A = \{a_{ij}\}$, where the probability of transitioning from state S_i at time t to state S_j at time $t + 1$ is $a_{ij} = P(q_{t+1} = S_j | q_t = S_i)$.
4. A set of output probability distributions B, where for each state j, $b_j(k) = P(O_t = v_k | q_t = S_j)$.
5. An initial state distribution $\pi = \{\pi_i\}$, where $\pi_i = P(q_1 = S_i)$.

At each time t a transition to a new state is made, and an observation is generated. State transitions have the Markov property, in that the probability of transitioning to a state at time t depends only on the state at time

[1]Although the discussion here is limited to HMMs with discrete observations, output distributions such as Gaussians can be defined for continuous-valued features.

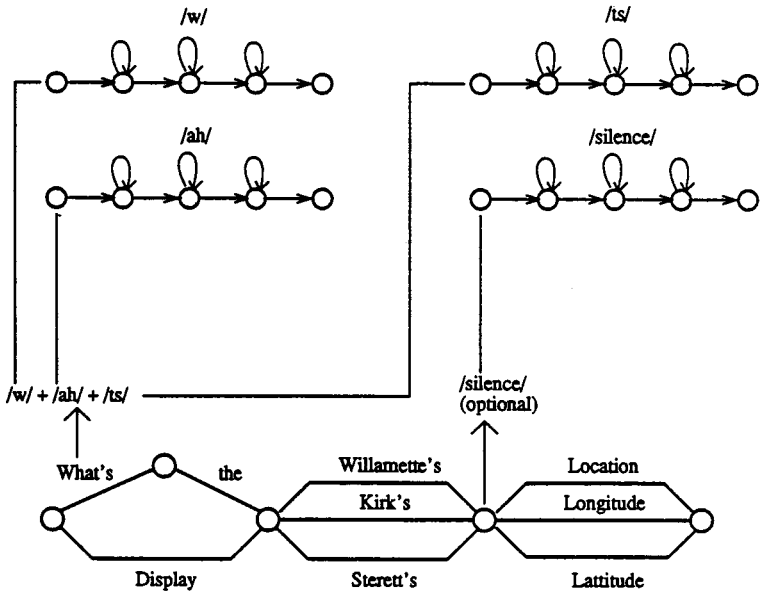

FIGURE 15.19 Language model, lexicon, and HMM phone models for a continuous speech recognition system. (*Source:* K.F. Lee, "Large-Vocabulary Speaker-Independent Continuous Speech Recognition: The SPHINX System," Ph.D. Dissertation, Computer Science Dept., Carnegie Mellon, April 1988. With permission.)

$t-1$. The observations are conditionally independent given the state, and the transition probabilites are not dependent on time. The model is called hidden because the identity of the state at time t is unknown; only the output of the state is observed. It is common to specify an HMM by its parameters $\lambda = (A, B, \pi)$.

The basic acoustic unit modeled by the HMM can be either a word or a subword unit. For small recognition vocabularies, the lexicon typically consists of whole-word models similar to the model shown in Fig. 15.18. The number of states in such a model can either be fixed or be made to depend on word duration. For larger vocabularies, words are more often defined in the lexicon as concatenations of phone or triphone models. Triphones are phone models with left and right context specified [Lee, 1988]; they are used to model acoustic variability which results from the coarticulation of adjacent speech sounds.

In isolated word recognition tasks, an HMM is created for each word in the recognition vocabulary. In continuous speech recognition, on the other hand, a single HMM network is generated by expressing allowable word strings or sentences as concatenations of word models, as shown in Fig. 15.19. In wordspotting, the HMM network consists of a parallel connection of keyword models and a background model which represents the speech within which the keywords are embedded. Background models, in turn, typically consist of parallel connections of subword acoustic units such as phones [Wilcox and Bush, 1992].

The language model or grammar of a recognition system defines the sequences of vocabulary items which are allowed. For simple tasks, deterministic finite-state grammars can be used to define all allowable word sequences. Typically, however, recognizers make use of stochastic grammars based on n-gram statistics [Jelinek, 1985]. A bigram language model, for example, specifies the probability of a vocabulary item given the item which precedes it.

Isolated word recognition using HMMs involves computing, for each word in the recognition vocabulary, the probability $P(O|\lambda)$ of the observation sequence $O = O_1 \ldots O_T$. The unknown utterance is recognized as the word which maximizes this probability. The probability $P(O|\lambda)$ is the sum over all possible state sequences $Q = q_1 \ldots q_T$ of the probability of O and Q given λ, or

$$p(O|\lambda) = \sum_{Q} P(O, Q|\lambda) = \sum_{Q} P(O|Q, \lambda)P(Q|\lambda) = \sum_{q_1 \ldots q_T} \pi_{q_1} b_{q_1}(O_1) a_{q_1 q_2} b_{q_2}(O_2) \ldots \quad (15.19)$$

Direct computation of this sum is computationally infeasible for even a moderate number of states and observations. However, an iterative algorithm known as the **forward-backward** procedure [Rabiner, 1989] makes this computation possible. Defining the forward variable α as

$$\alpha_t(i) = P(O_1 \ldots O_t, q_t = S_i|\lambda) \tag{15.20}$$

and initializing $\alpha_1(i) = \pi_i b_i(O_1)$, subsequent $\alpha_t(i)$ are computed inductively as

$$\alpha_{t+1}(j) = \sum_{i=1}^{N} \alpha_t(i) a_{ij} b_j(O_{t+1}) \tag{15.21}$$

By definition, the desired probability of the observation sequence given the model λ is

$$P(O|\lambda) = \sum_{i=1}^{N} \alpha_T(i) \tag{15.22}$$

Similarly, the backward variable β can be defined

$$\beta_t(i) = P(O_{t+1} \ldots O_T|q_t = S_i, \lambda) \tag{15.23}$$

The βs are computed inductively backward in time by first initializing $\beta_T(j) = 1$ and computing

$$\beta_t(i) = \sum_{j=1}^{N} a_{ij} b_j(O_{t+1}) \beta_{t+1}(j) \tag{15.24}$$

HMM-based continuous speech recognition involves determining an optimal word sequence using the **Viterbi** algorithm. This algorithm uses dynamic programming to find the optimal state sequence through an HMM network representing the recognizer vocabulary and grammar. The optimal state sequence $Q^* = (q_1^* \ldots q_T^*)$ is defined as the sequence which maximizes $P(Q|O,\lambda)$, or equivalently $P(Q,O|\lambda)$. Let $\delta_t(i)$ be the joint probability of the optimal state sequence and the observations up to time t, ending in state S_i at time t. Then

$$\delta_t(i) = \max P(q_1 \ldots q_{t-1}, q_t = S_i, O_1 \ldots O_t|\lambda) \tag{15.25}$$

where the maximum is over all state sequences $q_1 \ldots q_{t-1}$. This probability can be updated recursively by extending each partial optimal path using

$$\delta_{t+1}(j) = \max_i \delta_t(i) a_{ij} b_j(O_{t+1}) \tag{15.26}$$

At each time t, it is necessary to keep track of the optimal precursor to state j, that is, the state which maximized the above probability. Then, at the end of the utterance, the optimal state sequence can be retrieved by backtracking through the precursor list.

Training HMM-based recognizers involves estimating the parameters for the word or phone models used in the system. As with DTW, several repetitions of each word in the recognition vocabulary are used to train HMM-based isolated word recognizers. For continuous speech recognition, word or phone exemplars are typically extracted from word strings or sentences [Lee, 1988]. Parameters for the models are chosen based on a maximum likelihood criterion; that is, the parameters λ maximize the likelihood of the training data O, $P(O|\lambda)$. This maximization is performed using the **Baum-Welch** algorithm [Rabiner, 1989], a re-estimation

technique based on first aligning the training data O with the current models, and then updating the parameters of the models based on this alignment.

Let $\xi_t(i,j)$ be the probability of being in state S_i at time t and state S_j at time $t+1$ and observing the observation sequence O. Using the forward and backward variables $\alpha_t(i)$ and $\beta_t(j)$, $\xi_t(i,j)$ can be written as

$$\xi_t(i,\ j) = P(q_t = S_i,\ q_{t+1} = S_j \mid O, \lambda) = \frac{\alpha_t(i)a_{ij}\beta_{t+1}(j)b_j(O_{t+1})}{\sum_{ij=1}^{N} \alpha_t(i)a_{ij}\beta_{t+1}(j)b_j(O_{t+1})} \tag{15.27}$$

An estimate of a_{ij} is given by the expected number of transitions from state S_i to state S_j divided by the expected number of transitions from state S_i. Define $\gamma_t(i)$ as the probability of being in state S_i at time t, given the observation sequence O

$$\gamma_t(i) = P(q_t = S_i \mid O, \lambda) = \sum_{j=1}^{N} \xi_t(i,\ j) \tag{15.28}$$

Summing $\gamma_t(i)$ over t yields a quantity which can be interpreted as the expected number of transitions from state S_i. Summing $\xi_t(i,j)$ over t gives the expected number of transitions from state i to state j. An estimate of a_{ij} can then be computed as the ratio of these two sums. Similarly, an estimate of $b_j(k)$ is obtained as the expected number of times being in state j and observing symbol v_k divided by the expected number of times in state j.

$$\hat{a}_{ij} = \frac{\sum_{t=1}^{T-1} \xi_t(i,\ j)}{\sum_{t=1}^{T} \gamma_t(i)} \qquad \hat{b}_j(k) = \frac{\sum_{t:O_t=y_k} \gamma_t(j)}{\sum_{t=1}^{T} \gamma_t(j)} \tag{15.29}$$

State-of-the-Art Recognition Systems

Dictation-oriented recognizers which accommodate isolated word vocabularies of many thousands of words in speaker-adaptive manner are currently available commercially. So too are speaker-independent, continuous speech recognizers for small vocabularies, such as the digits; similar products for larger (1000-word) vocabularies with constrained grammars are imminent. Speech recognition research is aimed, in part, at the development of more robust pattern classification techniques, including some based on neural networks [Lippmann, 1989] and on the development of systems which accommodate more natural spoken language dialogs between human and machine.

Defining Terms

Baum-Welch: A re-estimation technique for computing optimal values for HMM state transition and output probabilities.

Continuous speech recognition: Recognition of fluently spoken utterances.

Dynamic time warping (DTW): A recognition technique based on nonlinear time alignment of unknown utterances with reference templates.

Forward-backward: An efficient algorithm for computing the probability of an observation sequence from an HMM.

Hidden Markov model (HMM): A stochastic model which uses state transition and output probabilities to generate observation sequences.

Isolated word recognition: Recognition of words or short phrases preceded and followed by silence.

Signal pre-processing: Conversion of an analog speech signal into a sequence of numeric feature vectors or observations.

Viterbi: An algorithm for finding the optimal state sequence through an HMM given a particular observation sequence.

Wordspotting: Detection or location of keywords in the context of fluent speech.

Further Information

Papers on speech recognition are regularly published in the *IEEE Speech and Audio Transactions* (formerly part of the *IEEE Transactions on Acoustics, Speech and Signal Processing*) and in the journal *Computer Speech and Language*. Speech recognition research and technical exhibits are presented at the annual IEEE International Conference on Acoustics, Speech and Signal Processing (ICASSP), the biannual European Conference on Speech Communication and Technology (Eurospeech), and the biannual International Conference on Spoken Language Processing (ICSLP), all of which publish proceedings. Commercial applications of speech recognition technology are featured at annual American Voice Input-Output Society (AVIOS) and Speech Systems Worldwide meetings. A variety of standardized databases for speech recognition system development are available from the National Institute of Standards and Technology in Gaithersburg, MD.

15.5 Large Vocabulary Continuous Speech Recognition

Yuqing Gao, Bhuvana Ramabhadran, and Michael Picheny

Speech recognition is the process of converting an acoustic signal to a textual message. High recognition accuracy is of prime importance in order for a speech interface to be of any practical use in a dictation task, or any kind of intelligent human–machine interaction. Speech recognition is made extremely difficult by **co-articulation**, variations in speaking styles, rates, vocal-tract size across speakers, and communication channels. Speech research has been underway for over 4 decades, and many problems have been addressed and solved fully or partially. High performance can be achieved on tasks such as isolated word recognition, small and middle vocabulary recognition, and recognition of speech in nonadverse conditions. Large vocabulary (over 30K words), speaker-independent, continuous speech recognition has been one of the major research targets for years. Although for some large vocabulary tasks, high recognition accuracies have been achieved [7], significant challenges emerge as more and more applications make themselves viable for speech input.

Continuous Speech Recognition

Continuous speech recognition is significantly more difficult than isolated word recognition. Its complexity stems from the following three properties of continuous speech.

1. Word boundaries are unclear in continuous speech, whereas in isolated word recognition they are well-known and can be used to improve the accuracy and limit the search. For example, in the phrase "this ship," the /s/ of "this" is often omitted. Similarly, in "we were away a year," the whole sentence is one long vocalic segment, and the word boundaries are difficult to locate.
2. Co-articulatory effects are much stronger than in isolated speech. Although we try to pronounce words as concatenated sequences of individual speech sounds **(phones),** our articulators possess inertia which retards their motion from one position to another. As a result, a phone is strongly influenced by the previous and the following phones. This effect occurs both within single words and between words and is aggravated as the speaking rate increases.
3. Function words (articles, prepositions, pronouns, short verbs, etc.) tend to be poorly articulated. In particular, the phones are often shortened, skipped, or deleted.

As a result, speech recognition error rates increase drastically from isolated word to continuous speech. Moreover, the processing power needed to recognize continuous speech increases as well.

The primary advantages of continuous speech are two-fold. First, typical speaking rates for continuous speech are 140 to 170 words per minute, while isolated word mode speakers seldom exceed 70 words per minute. Secondly, continuous speech is a natural mode of human communication. Forcing pauses between words introduces artificiality and reduces user friendliness. The unnaturalness of isolated word speech breaks the speaker's train of thought.

Large Vocabulary

In the 1990s, the term "large vocabulary" has come to mean 30K words or more. Although the vocabulary size is certainly not the best measure of a task's difficulty, it does affect the severity of many problems such as the acoustic confusability of words, the degradation in performance due to using sub-word unit models, and the computational complexity of the **hypothesis search**.

Clearly, the number of confusable words grows substantially with the vocabulary size. As the vocabulary size increases, it becomes impractical to model each word individually, because neither the necessary training data nor the requisite storage is available. Instead, models must be based on sub-word units. These sub-word models usually lead to degraded performance because they fail to capture **co-articulation** effects as well as whole-word models. Additionally, the computational complexity of the search requires the introduction of efficient search methods such as "fast match" [26] which reject all but the most plausible word hypotheses to limit the computation effort. These word hypotheses which survive the "fast match" are then subjected to the full detailed analysis. Naturally, this process may introduce search errors, reducing the accuracy.

Some of the key engineering challenges in building speech recognition systems are selecting a proper set of sub-word units (e.g., phones), assembling units into words **(baseforms),** modeling co-articulating effects, accomodating the different stress patterns of different languages, and modeling pitch contours for tone-based languages such as Mandarin.

Overview of a Speech Recognition System

The general architecture of a typical speech recognition system is given in Fig. 15.20. The speech signal is typically input to the system via a microphone or a telephone. Signal preprocessing consists of computing a series of acoustic vectors by processing the speech signal at regular time intervals (frames), which are typically 10 ms long. These acoustic vectors are usually a set of parameters, such as LPC **cepstra** [23] or filter bank outputs (PLP [30], RASTA [28], etc.). In order to capture the change in these vectors over time, they have been augmented with their time derivatives or discriminant projection techniques (e.g., see LDA [10, 29]).

The recognizer consists of three parts: the **acoustic model,** the **language model,** and the hypothesis search. The recognition process involves the use of acoustic models over these feature vectors to label them with their

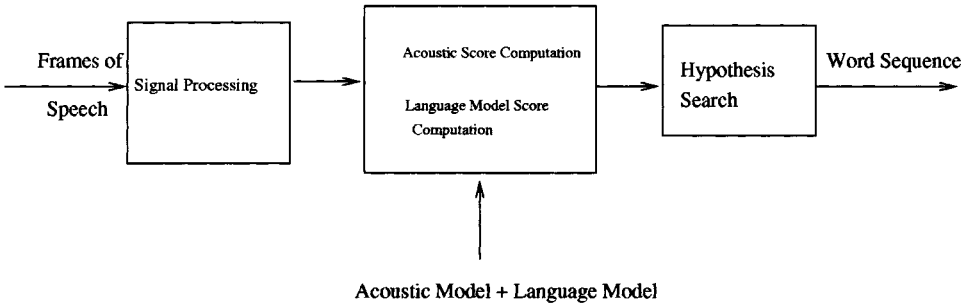

FIGURE 15.20 General architecture of a speech recognition system.

phonetic class. The **acoustic models** usually used are **Hidden Markov Models.** Artificial Neural Networks [16] or Dynamic Time Warping [17] based models have also been used, but will not be covered in this chapter section. Context-dependent acoustic models [9, 10] are obtained by querying the phonetic context using the concept of **tri-phones** or **decision trees** (networks) [2] that are constructed from a large amount of training data. A multidimensional **Gaussian mixture** model is used to model the feature vectors of the training data that have similar phonetic contexts. These models are then used as a set of observation densities in continuous Hidden Markov Models (HMMs). Each feature vector is labeled as a context-dependent phonetic class which is the closest acoustic class to the feature vector. A sequence of labels thus obtained is used to obtain a set of candidate words that are then pruned with the help of a **language model.** A language model bases its prediction of the next word on the history of the words preceding it. Finally, a **hypothesis search** is conducted through all possible sequences of hypothesized words to determine the optimal word sequence given the acoustic observations.

Several adaptation techniques have been proposed to derive speaker-dependent systems from the speaker-independent system described above. These techniques modify/tune the parameters of the acoustic models to the specific speaker.

Hidden Markov Models As Acoustic Models for Speech Recognition

There are many ways to characterize the temporal sequence of speech sounds as represented by a sequence of spectral observations. The most common way is to model the temporal sequence of spectra in terms of a Markov chain to describe the way one sound changes to another by imposing an explicitly probabilistic structure on the representation of the evolutional sequence.

If we denote the spectral vector at time t by O_t the observed spectral sequence, lasting from $t = 1$ to $t = T$, is then represented by

$$\left\{O_t\right\}_{t=1}^{T} = \left(O_1, O_2, \cdots, O_T\right)$$

Consider a first-order N-state Markov chain as illustrated for $N = 3$ in Fig. 15.21. Such a random process has the simplest memory: the value at time t depends only on the value at the preceding time and on nothing that went on before. However, it has a very useful property that leads to its application to speech recognition problem: the states of the chain generate observation sequences while the state sequence itself is hidden from the observer.

The system can be described as being one of the N distinct states, S_1, S_2, …, S_N, at any discrete time instant t. We use the state variable q_t as the state of the system at time t. Assume that the Markov chain is time invariant (homogeneous), so the transition probabilities do not depend on time. The Markov chain is then described by a state transition probability matrix $A = [a_{ij}]$, where

$$a_{ij} = P(q_t = S_j | q_{t-1} = S_i), \quad 1 \le i, j \le N \tag{15.30}$$

The transition probabilities satisfy the following constraints:

$$a_{ij} \ge 0 \tag{15.31}$$

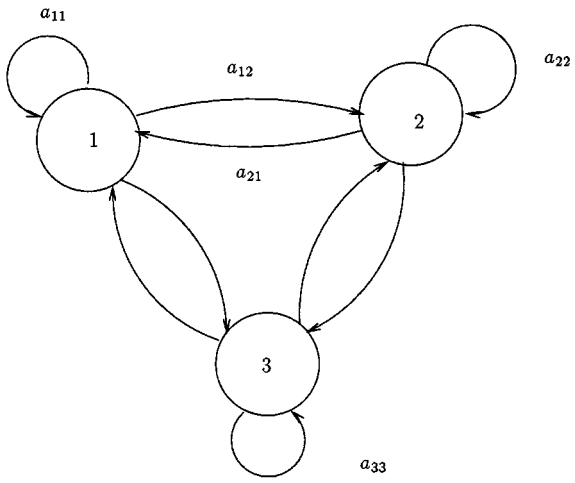

FIGURE 15.21 A first-order three-state hidden Markov model.

$$\sum_{j=1}^{N} a_{ij} = 1 \quad \forall i \tag{15.32}$$

Assume that at the initiated time, $t = 0$, the state of the system q_0 is specified by an initial state probability vector $\pi^T = [\pi_1, \pi_2, \ldots, \pi_N]$. Then for any state sequence $q = (q_0, q_1, q_2, \ldots, q_T)$, where $q_t \in \{S_1, S_2, \ldots, S_N\}$, the probability of q being generated by the Markov chain is

$$P(q|A, \pi) = \pi_{q0}, a_{q0q1} a_{q1q2} \ldots a_{qT-1qT} \tag{15.33}$$

Suppose now that the state sequence q is a sequence of speech sounds and cannot be observed directly. Instead, observation O_t is produced with the system in some unobserved state q_t (where $q_t \in \{S_1, S_2, \ldots, S_N\}$). Assume that the production of O_t in each possible S_i, $i = 1, 2, \ldots, N$ is stochastic and is characterized by a set of observation probability measures $B = \{b_i(O_t)_{i=1}^N\}$, where

$$b_i(O_t) = P(O_t|_{q_t} = S_i) \tag{15.34}$$

If the state sequence q that led to the observation sequence $O = (O_1, O_2, \ldots, O_T)$ is known, the probability of being generated by the system is assumed to be

$$P(O|q, B) = b_{q_1}(O_1) b_{q_2}(O_2) \ \ldots \ b_{q_T}(O_T) \tag{15.35}$$

Therefore, the joint probability of O and q being produced by the system is

$$P\left(O \mid \pi, A, b\right) = \pi_{q_0} \Pi_{t=1}^{T} a_{q_{t-1}q_t} b_{q_t}\left(O_t\right) \tag{15.36}$$

The probability of producing the observation sequence O by the random process without assuming knowledge of the state sequence is

$$P\left(O \mid \pi, A, B\right) = \sum_{q} P\left(O, q \mid \pi, A, B\right) = \sum_{q} \pi_{q_0} \Pi_{t-1}^{T} a_{q_t-1q_t} b_{q_t}\left(O_t\right) \tag{15.37}$$

Continuous Parameter Hidden Markow Models

The triple (π, A, B) defines a **Hidden Markov Model** (HMM). More specifically, a hidden Markov model is characterized by the following:

1. A state space $\{S_1, S_2, \ldots, S_N\}$. Although the states are not explicitly observed, for many applications there is often some physical significance attached to the states. In the case of speech recognition, this is often a phone or a portion–inital, middle, final–of a phone. We donote the state at time t as q_t.
2. A set of observations $O = (O_1, O_2, \ldots, O_T)$. The observations can be a set of discrete symbols chosen from a finite set, or continuous signals (or vectors). In speech recognition application, although it is possible to convert continuous speech representations into a sequence of discrete symbols via vector quantization codebooks and other methods, serious degradation tends to result from such discretization of the signal. In this article, we focus on HMMs with continuous observation output densities to model continuous signals.
3. The initial state distribution $\pi = \{\pi_i\}$ in which
4. The state transition probability distribution $A = \{a_{ij}\}$defined in Eq. (15.30).
5. The observations probability distribution, $B = \{b_j(O_t)\}$, defined in Eq. (15.34).

$$\pi_i = P(q_0 = S_i),\ 1 \le i \le N$$

Given the form of HMM, the following three basic problems of interest must be solved for the model to be useful in applications.

Task 1 (Evaluation): Given the observation sequence $O = (O_1, O_2, \ldots, O_T)$ and a model $\lambda = (\pi, A, B)$, how does one efficiently compute $P(O|\lambda)$?

Task 2 (Estimation): Given the observation sequence $O = (O_1, O_2, \ldots, O_T)$, how does one solve the inverse problem of estimating the parameters in λ?

Task 3 (Decoding): Given the observation sequence O and a model λ, how does we deduce the most likely state sequence q that is optimal in some sense or best explains the observations?

The Evaluation Problem

With unbounded computational power, Eq. (15.37) can be used to compute $P(O|\lambda)$. However, it involves on the order of $2TN^T$ calculations, because the summation in Eq. (15.37) has N^{T+1} possible sequences. This is computationally infeasible even for small values of N and T.

An iterative algorithm known as the **forward-backward** procedure makes this computation possible. Defining the forward variable α as

$$\alpha_t(i) = P(O_1, \ldots, O_t, q_t = S_i|\lambda) \tag{15.38}$$

and initializing $\alpha_1(i) = \pi_i b_i(O_1)$, subsequent $\alpha_t(i)$ are computed inductively as

$$\alpha_{t+1}(j) = \sum_{i=1}^{N} \alpha_t(i) a_{ij} b_j(O_{t+1}) \tag{15.39}$$

By definition, the desired probability of the observation sequence given the model λ is

$$P(O|\lambda) = \sum_{i=1}^{N} \alpha_T(i) \tag{15.40}$$

Another alternative is to use the backward procedure by defining the backward variable β:

$$\beta_t(i) = P(O_{t+1}, O_{t+2}, \ldots, O_T / q_t = S_i, \lambda) \tag{15.41}$$

$\beta_t(i)$ is the probability of the partial observation sequence from t + a to the end T, biven state S_i and model λ. The initial values are $\beta_T(i) = 1$ for all i. The values at time, $T - 1$, $T - 2$, …, 1, can be computed inductively:

$$\beta_t(i) = \sum_{j=1}^{N} a_{ij} b_j(O_{t+1}) \beta_{t+1}(j) \tag{15.42}$$

The probability of the observation sequence given the model λ can be expressed in terms of the forward and backward probabilities:

$$P(O|\lambda) = \sum_{i=1}^{N} \alpha_t(i) \beta_t(i) = \sum_{i=1}^{N} \alpha_T(i) \tag{15.43}$$

The forward and backward variables are very useful and will be used in the next section.

The Estimation Problem

Given an observation sequence or a set of sequences, (multiple utterances) the estimation problem is to find the "right" model parameter values that specify a model most likely to produce the given sequence. In speech recognition, this is called training. There is no known closed form analytic solution for the maximum likelihood model parameters. Nevertheless we can choose $\lambda = (\pi, A, B)$ such that its likelihood, $P(O|\lambda)$, is locally maximized using an iterative procedure such as the **Baum-Welch** re-estimation method (a form of the EM [expectation-maximization] method [4]. The method intoduces an auxiliary function $Q(\hat{\lambda}, \lambda)$ and maximizes it.

$$Q(\hat{\lambda}, \lambda) = \sum_{q} P(O, q | \hat{\lambda}) \log P(O, q | \lambda) \tag{15.44}$$

The re-estimation technique consists of first aligning the training data O with the current models, and then updating the parameters of the models based on the alignment to obtain a new estimate λ.

Let $\zeta_t(i, j)$ be the probability of being in state S_i at time t and state S_j at time $t + 1$, given the model λ and the observation sequence O:

$$\zeta_t(i, j) = P(q_t = S_i, q_{t+1} = S_j | O, \lambda) = \frac{P(q_t + S_i, q_{t+1} = S_j, O | \lambda)}{P(O|\lambda)} \tag{15.45}$$

Using the forward and backward variables defined in section 3.2, $\alpha_t(i)$ and $\beta_t(j)$, $\zeta_t(i, j)$ can be written as

$$\xi_t(i,j) = \frac{\alpha_t(i)\alpha_{ij}\beta_{t+1}(j)b_j(O_{t+1})}{\sum_{i,j=1}^{N}\alpha_t(i)\alpha_{ij}\beta_{t+1}(j)b_j(O_{t+1})} \tag{15.46}$$

An estimate of a_{ij} is given by the expected number of transitions from state S_i to state S_j, divided by the expected number of transitions from state S_i. Define $\gamma_t(i)$ as the probability of being in state S_i at time t, given the observation sequence O

$$\gamma_t(i) = P(q_t = S_i \mid O, \lambda) = \sum_{j=1}^{N}\zeta_t(i,j) \tag{15.47}$$

Summing $\gamma_t(i)$ over t yields a quantity that can be interpreted as the expected number of transitions from state S_i. Summing $\zeta_t(i, j)$ over t gives the expected number of transitions from state S_i to S_j. An estimate of a_{ij} can be computed as the ratio of these two sums.

$$\hat{a}_{ij} = \frac{\Sigma_{t=1}^{T-1}\zeta_t(i,j)}{\Sigma_{t=1}^{T}\gamma_t(i)} \tag{15.48}$$

For the discrete observation case, an estimate of $b_j(k)$ is obtained as the expected number of times being in state S_i and observing symbol ν_k divided by the expected number of times in state S_j.

$$\hat{b}_j(k) = \frac{\Sigma_{t:O_t=\nu_k}\gamma_t(j)}{\Sigma_{t=1}^{T}\gamma_t(j)} \tag{15.49}$$

The most general representation of a continuous density of HMMs is a finite mixture of the form

$$b_j(O) = \sum_{k=1}^{M} c_{jk} N(O, \mu_{jk}, U_{jk}), \quad 1 \le j \le N$$

where O is the observation vector being modeled, c_{jk} is the mixture coefficient for the kth mixture in state j and N is any log-concave or elliptically symmetric density. Typically, we assume that N is Gaussian with mean vector μ_{jk} and covariance matrix U_{jk} for the kth mixture component in state j. The mixture weights c_{jk} satisfy the constraint:

$$\sum_{k=1}^{M} c_{jk} = 1, \quad 1 \le j \le N \tag{15.50}$$

$$c_{jk} \ge 0, \quad 1 \le j \le N, \quad 1 \le k \le M \tag{15.51}$$

Let $\gamma_t(j,k)$ be the probability of being in state S_j at time t with k-th mixture component accounting for O_t:

$$\gamma_t(j,k) = P(q_t = S_j, k_t = k \mid O, \lambda) = \frac{P(q_t = S_j, k_t = k, O \mid \lambda)}{P(q_t = S_j, O \mid \lambda)} \tag{15.52}$$

The re-estimation formula for the coefficients of the mixture density are:

$$\hat{c}_{jk} = \frac{\Sigma_{t=1}^{T} \gamma_t(j,k)}{\Sigma_{t=1}^{T} \Sigma_{k=1}^{M} \gamma_t(j,k)} \tag{15.53}$$

$$\hat{\mu}_{jk} = \frac{\Sigma_{t=1}^{T} \gamma_t(j,k) o_t}{\Sigma_{t=1}^{T} \gamma_t(j,k)} \tag{15.54}$$

$$\hat{U}_{jk} = \frac{\Sigma_{t=1}^{T} \gamma_t(j,k)(o_t - \mu_{jk})(o_t - \mu_{jk})^T}{\Sigma_{t=1}^{T} \gamma_t(j,k)} \tag{15.55}$$

Details on how the re-estimation formulas are derived from the auxiliary function $Q(\hat{\lambda},\lambda)$ can be found in [25] and [23].

Viterbi Algorithm: One Solution for the Decoding Problem

We define the optimal state sequence $q^\star = (q_1^\star, \ldots, q_T^\star)$ is defined as the sequence which maximizes $P(q|O, \lambda)$, or equivalently $P(q, O|\lambda)$. Let $\delta_t(i)$ be the joint probability of the optimal state sequence and the observation up to time t, ending in state S_i at time t. Then,

$$\delta_t(i) = max\ P(q_1, \ldots\ q_{t-1}, q_t = S_i, O_1, \ldots, O_t|\lambda) \tag{15.56}$$

where the maximum is over all state sequences $q_1, \ldots, q_{t-1}$. This probability can be updated recursively by extending each partial optimal path using

$$\delta_t(i) = \max_i \delta_t(i) a_{ij} b_j(O_{t+1}) \tag{15.57}$$

At each time t, it is necessary to keep track of the optimal precursor t of state j, that is, the state that maximized the above probability. Then, at the end of the utterance, the optimal state sequence can be retrieved by backtracking through the precursor list [11].

Speaker Adaptation

In spite of recent progress in the design of speaker-independent (SI) systems, error rates are still typically two or three times higher than equivalent speaker-dependent (SD) systems. Variability in both anatomical and personal characteristics contribute to this effect. Anatomical differences include the length of the vocal tract, the size of the nasal cavity, etc. Similarly, there are variable speaking habits, such as accent, speed, and loudness. The straight-forward approach which blindly mixes the statistics for all speakers discards useful information.

The large amount of speaker-specific data required to train SD systems renders them impractical for many applications. However, it is possible to use a small amount of the new speaker's speech (adaptation data) to "tune" the SI models to the new speaker. Ideally, we would like to retain the robustness of well-trained SI models, yet improve the appropriateness of the models for the new speaker. Such methods are called speaker adaptation techniques. The adaptation is said to be *supervised* if the true text transcript of the adaptation data is known; otherwise, the adaption is said to be *unsupervised*.

Maximum *a posteriori* Estimation

A widely used speaker adaptation method maximizes the *posterior* estimation of HMMs [3]. The conventional maximum likelihood (ML) based algorithms assume the HMM parameters to be unknown but fixed, and the parameter estimators are derived entirely from the training observation sequence using the **Baum-Welch** algorithms. Sometimes, prior information about the HMM parameters is available, whether from subject matter

considerations or from previous experience. Designers may wish to use this prior information–in addition to the sample observations–to infer the HMM parameters.

The Maximum a Posteriori **(MAP)** framework naturally incorporates prior information into the estimation process, which is particularly useful for dealing with problems posed by sparse training data, where ML estimates become inaccurate. MAP parameter estimates approah the ML estimates when data is plentiful, but are governed by the prior information in the absence of data. If λ is the parameter vector to be estimated from the observation O with probability density function (pdf) $f(O|\lambda)$ and g is the prior pdf of λ, then the MAP estimate is defined as the maximum of the posterior pdf of λ, $g(\lambda|o)$.

Rather than maximizing the auxiliary function $Q(\hat{\lambda}, \lambda)$ as in Eq. 15.44, we instead maximize an auxiliary function that includes a contribution from the prior distribution of the model parameters.

$$R\left(\hat{\lambda}, \lambda\right) = Q\left(\hat{\lambda}, \lambda\right) + \log g\left(\hat{\lambda}\right) \tag{15.58}$$

The appropriate prior distributions are Gaussian distributions for the means, gamma distributions for the inverse variances, and Dirichlet distributions for the mixture weights [3].

The problem with MAP is that it adapts only parameters for which explicit training data is available, and it converges slowly for tasks where there are limited adaptation data and many parameters to be estimated. Many adaptation algorithms [15] [14] have been developed which attempt to generalize from "nearby" training data points to overcome this difficulty.

Transform-Based Adaptation

Another category of adaptation technique uses a set of regression-based transforms to tune the mean and variance of a **hidden Markov model** to the new speaker. Each of the transformations is applied to a number of HMMs and estimated from the corresponding data. Using this sharing of transformations and data, the method can produce improvements even if a small amount of adaptation data is available for the new speaker by using a global transform for all HMMs in the system. If more data is available, the number of transforms is increased.

Maximum Likelihood Linear Regression **(MLLR)**

The MLLR framework was first introduced in [27]. Consider the case of a continuous density HMM system with Gaussian output distributions. A particular Gaussian distribution, g, is characterized by a mean vector, μ_g, and a covariance matrix U_g. Given a speech vector o_t, the probability of that vector being generated by a Gaussian distribution g is $b_g(o_t)$:

$$b_g\left(o_t\right) = \frac{1}{\left(2\pi\right)^{d/2} |U_g|^{1/2}} e^{-1/2\left(o_t - \mu_g\right)^T U_g^{-1}\left(o_t - \mu_g\right)}$$

The adaptation of the mean vector is obtained by applying a transformation matrix W_g to the extended mean vector ζ_g to obtain an adapted mean vector $\hat{\mu}_g$

$$\hat{\mu}_g = W_g \zeta_g$$

where W_g is a d*(d + 1) matrix which maximizes the likelihood of the adaptation data, and the ζ_g is defined as

$$\zeta_g = [\Omega, \mu_1, \ldots, \mu_d]^T$$

where Ω is the offset term for the regression.

The probability for the adapted system becomes

$$b_g(o_t) = \frac{1}{(2\pi)^{d/2} |U_g|^{1/2}} e^{-1/2(o_t - W_g\mu_g)^T U_g^{-1}(o_t - W_g\mu_g)}$$

The auxiliary fuction in Eq. 15 can be used here to estimate W_g. It can be shown the W_g can be estimated using the equation below:

$$\sum_{t=1}^{T} \gamma_g(t) U_g^{-1} o_t \zeta_g^T = \sum_{t=1}^{T} \gamma_g(t) U_g^{-1} \hat{W}_g \zeta_g \zeta_g^T \tag{15.59}$$

where $\gamma_g(t)$ is the posterior probability of occupying state q at time t given that the observation sequence O is generated.

$$\gamma_g(t) = \frac{1}{P(O|\lambda)} \sum_{\phi \in \Phi} P(O, s_t = q|\lambda)$$

The **MLLR** algorithm can also be extended to transform the covariance matrices [38].

Cluster-Based Speaker Adaptation

Yet another category of speaker adaptation methodology is based on the fact that a speech training corpus contains a number of training speakers, some of whom are closer, acoustically, to the test speaker than others. Therefore, given a test speaker, if the **acoustic models** are re-estimated from a subset of the training speakers who are acoustically close to the test speaker, the system should be a better match to the test data of the speaker. A further improvement is obtained if the acoustic space of each of these selected training speakers is transformed, by using transform-based adaptation method, to come closer to the test speaker.

This scheme was shown to produce better speaker adaptation performance than other algorithms, for example MLLR [27] or **MAP** adaptation [3], when only a small amount of adaptation data was available.

However, the implementation of this method required the entire training corpus to be available online for the adaptation process, and this is not practical in many situations. This problem can be circumvented if a model is stored for each of the training speakers, and the transformation is applied to the model. The transformed models are then combined to produce the speaker-adapted model. However, due to the large number of training speakers, storing the models of each training speaker would require a prohibitively large amount of storage. Also, we may not have sufficient data from each training speaker to robustly estimate the parameters of the speaker-dependent model.

To solve this problem and retain the advantage of the method, a new algorithm is presented [21]. It is to precluster the training speakers acoustically into clusters. For each cluster, an HMM system (called a cluster-dependent system) is trained using speech data from the speakers who belong to the cluster. When a test speaker's data is available, we rank these cluster-dependent systems according to the distances between the test speaker and each cluster, and a subset of these clusters, acoustically closest to the test speaker, is chosen. Then the model for each of the selected clusters is transformed further to bring the model closer to the test speaker's acoustic space. Finally, these adapted cluster models are combined to form a speaker-adapted system. Hence, compared to [22], we now choose clusters that are acoustically close to the test speaker, rather than individual training speakers.

This method solves the problem of excessive storage for the training speaker models because the number of clusters is far fewer than the number of training speakers, and it is relatively inexpensive to store a model for each cluster. Also, as each cluster contains a number of speakers, we have enough data to robustly estimate the parameters of the model for the cluster.

Vocal Tract Length Normalization (VTL)

Several attempts have been made to model variations in vocal tract length across several speakers. The idea was originally introduced by Bamberg [42] and revived through a parametric approach in [39]. Assume a uniform tube with length L for the model of the vocal tract. Then each formant frequency will be proportional to $1/L$. The first-order effect of a difference in vocal tract length is the scaling of the frequency axis. The idea behind VTL is to rescale or warp the frequency axis during the signal processing step in a speech recognition system, to make speech from all speakers appear as if it was produced by a vocal tract of a single standard length. Such normalizations have led to significant gains in accuracy by reducing variability amongst speakers and allowing the pooling of training data for the construction of sharper models. Three VTL methods have been recently proposed. In [39], a parametric method of normalization which counteracts the effect of varied vocal tract length is presented. This method is particularly useful when only a small amount of training data is available and requires the determination of the formant frequencies. In [40], an automated method is presented that uses a simple generic voiced speech model to rapidly select appropriate frequency scales. This generic model is a mixture of 256 multiversity Gaussians with diagonal covariances trained on the unwarped data. Different warp scales are selected to linearly transform the frequency axis of the speaker's data. The resulting warped features are scored against the generic model. The warp scale that scores the best is selected as the warp scale for that speaker. An iterative process updates the generic model with the new features obtained after warping each speaker with the best warp scale. Once the best warp scales for each speaker have been determined, SI models are built with the appropriately warped feature vectors. This warp selection method allows data from all speakers to be merged into one set of cannonical models. In [41], a class of transforms are proposed which achieve a remapping of the frequency axis much like the conventional VTL methods. These mappings known as all-pass transforms, are linear in the cepstral domain which makes speaker normalization simple to implement. The parameters of these transforms are computed using conjugate gradient methods.

Modeling Context in Continuous Speech

Speech recognition cannot be accurately modeled by a concatenation of elementary HMMs corresponding to individual **phones** of a word baseform. A phone is a sub-word acoustic unit of speech. The realizations of the phones depend on their context. This is especially true for continuous speech where the phenomenon called *co-articulation* is observed. Co-articulation is when the pronunciation of a phoneme is affected by the phones preceding and following it, such as, the *t* in *top* and *pot*. This section discussed several methods that will yield HMM building blocks that take into account phonetic context. A word is specified by its phonetic baseform, the phones are transformed into their appropriate allophones according to the context in which they appear, and a concatenation of the HMMs of these allophones results in the word HMM. Two standard approaches are used to make use of contextual information:

1. **Tri-phones** as building blocks
2. **Decision trees** that lead to general contextual building blocks

Tri-Phones

In order to take into account the influence of context on pronunciation, many speech recognizers base their modeling on the tri-phone concept. The tri-phone concept was first introduced by Chow et al. [5, 24] and Lee et al. [7, 8] in the 1980s. In this concept, the pronunciation of a phone is influenced by the preceding and following phone (i.e., the triplet is used to model the realization of the phone). The phone p embedded in the context p_1 and p_2 is specified by the tri-phone p_1pp_2, where p_1 and p_2 are the previous and the following **phones**. Different such realizations of p are called allophones. This amounts to saying that the contextual influence of the preceding and following phone is most important. If this solution were carried out literally, the resulting allophone alphabet would be too large to be useful. For example, a phonetic alphabet of size M would produce M^3 allophones. Even though in practice, not all M^3 allophones occur, the number of possible allophones is still large.

So the tri-phone method relies on an equivalence classification of the context of phones. One simple scheme involves the clustering of tri-phones into distinct categories to characterize them. The criterion used for

clustering can be an information theoretic measure such as likelihood or entropy. This is the concept behind *generalized tri-phones* [8]. Decision trees (described in the next section) can also be used to determine the distinct categories. Another scheme is to tie the HMM distributions of these tri-phones. More recently, methods that cluster individual states of the HMM [1] have been introduced. A drawback in using tri-phones is that wider contexts (i.e., three, four, or five phones to the left) may be important.

Decision Trees

The purpose of the decision tree is to map a large number of conditions (i.e., phonetic contexts) to a small manageable number of equivalence classes. Each terminal node of the tree represents a set of phonetic contexts. The aim in decision tree construction is to find the best possible definition of equivalence classes [2].

During decoding, the acoustic models to be used for a given observation string are chosen based on the current acoustic context — that is, by pouring the data down the decision tree until a terminal node is reached and using the models at that terminal node to compute the likelihood of the data.

Decision Tree Construction

Maximum Likelihood (ML) estimation is one common technique used for constructing a decision tree; i.e., the aim is to find the different classes that maximize the likelihood of the given training data. A binary decision tree is grown in the following fashion.

1. From among a set of questions (at the phonetic or lexeme level), the best question for partitioning the data into two classes (i.e., the question that maximizes the likelihood) is found.
2. The above step is repeated recursively on each of the two classes until either there is insufficient data to continue or the best question is not sufficiently helpful.

The easiest way to construct a decision tree is to create — in advance — a list of possible questions for each variable that may be tested. Finding the best question at any given node consists of subjecting all the relevant variables to each of the questions on the corresponding list and picking the best combination of the variable and the question.

In building an acoustic decision tree using phonetic context, at least 10 variables may be interrogated, 5 preceding phones and 5 following phones. Since all of these variables belong to the same phonetic alphabet, only one set of questions needs to be prepared, where each question is a subset of the phonetic alphabet.

Typically, trees are less than 20 layers deep, as beyond that the algorithm runs out of data.

Let $X_1 \ldots X_n$ denote n discrete random variables whose values may be tested. Let Q_{ij} denote the jth predetermined question for X_i

1. Starting at the root node, try splitting each node into two subnodes.
2. For each variable X_i, evaluate questions Q_{i1}, Q_{i2}, etc. Let Q_b denote the best question estimated using any one of the criteria described earlier. The best question at a node is the question that maximizes the likelihood of the training data at that node after applying the question.
3. Find the best pair X_i, Q_b denoted as X, Q_b.
4. If the selected question is not sufficiently helpful (gain in likelihood due to the split is not significant) or does not have sufficient data points, make the current node a leaf.
5. Otherwise, split the current node into two new subnodes according to the answer of question Q_b on variable X_b.

The algorithm stops when all nodes are either too small to split further or have been marked as leaves. Overtraining is prevented by limiting the number of asked questions.

Questions

A decision tree has a question associated with every non-terminal node. These can be grouped into continuous and discrete questions.

Discrete questions. If X is a discrete random variable that takes values in some finite alphabet R, then a question about X has the form: Is X an element of S where S is a subset of R? Typically, questions are of the form "Is the preceding phone a vowel?" or "Is the following phone an unvoiced stop?"

Continuous questions. If X is a continuous random variable that takes real values, a question about X has the form: X ∈ t where t is some real value. Instead of limiting the questions to a predefined set, we could search for the best subset of values taken by the random variable at any node and use the best question found. This implies that we generate questions on the fly during tree construction. The disadvantages of this approach include too much CPU time to search for the best subset and because there are so many subsets, there is too much freedom in the tree-growing algorithm, resulting in over-training or spurious questions that do not generalize very well.

All of these questions can be constructed in advance by experts. For example, phonetic questions can be generated by linguists or by algorithms [9].

Language Modeling

Humans recognize words based not only on what they hear, but also on what they have heard in the past, as well as what they anticipate to hear in the future. It is this capability that make humans the best speech recognition systems. Modern speech recognition systems attempt to achieve this human capability through *language modeling*. Language modeling is the art and science of anticipating or predicting words or word sequences from nonacoustic sources of information such as context, structure, and grammar of the particular language, previously heard word sequences.

In large vocabulary speech recognition, in which word sequences W are uttered to convey some message, the language model $P(W)$ is of critical importance to the recognition accuracy. In most cases, the language model must be estimated from a large text corpus.

For practical reasons, the word sequence probability $P(W)$ is approximated by

$$P_N(W) = \prod_{i=1}^{Q} P(w_i \mid w_{i-1}, w_{i-2}, \ldots w_{i-N+1}) \tag{15.60}$$

This is called an N-gram language model, where N is the number of words from the history that are used in the computation. Typically, $N = 3$ and these are referred to as trigram language models, Q is the number of words in the sequence being decoded.

The conditional probabilities in Eq. (15.60) are estimated by the simple relative frequency approach described in [23].

The maximum entropy approach is a method of estimating the conditional probability distributions (discribed below). In cases when the text corpus is not large enough to reliably estimate the probabilities, smoothing techniques such as linear smoothing (deleted interpolation) are applied (described below).

Perplexity is a measure of performance of language models. Perplexity, defined in Eq. (15.61) is the average word branching factor of the language model.

$$B = 2^H = P(w_1, w_2, \ldots, w_Q)^{-1/Q} \tag{15.61}$$

Perplexity is an important parameter is specifying the degree of sophistication in a recognition task, from the source uncertainty to the quality of the language model.

Other techniques that have been used in language modeling include desision tree models [43] and automatically inferred linked grammars to model long range correlations [44].

Smoothing

In computing the language model probabilities, we desire the following: fewer parameters to estimate; the available data is sufficient for the estimation of parameters; and that the probability can be constructed at recognition time from the parameter values while occupying limited storage. Several smoothing techniques have been proposed to handle the scarcity of data [25]. These are essential in the construction of n-gram language models. They include linear smoothing, also known as deleted interpolation, backing-off, bucketing

and equivalence classification techniques. An extensive empirical study of these techniques for language modeling is given in [35]. A brief description of two smoothing techniques is covered in this section. Linear smoothing, is due to Jelinek and Mercer [37], where a class of smoothing models that involve linear interpolation are presented. The maximum-likelihood estimate is interpolated with the smoothed lower-order distribution defined analogously, i.e.

$$P_{\text{int}\,erp}\left(\omega_i \mid \omega_{i-n+1}^{i-1}\right) = \lambda_{\omega_{i-n+1}^{i-1}} P_{ML}\left(\omega_i \mid \omega_{i-n+1}^{i-1}\right) + \left(1 - \lambda_{\omega_{i-n+1}^{i-1}}\right) P_{\text{int}\,erp}\left(\omega_i \mid \omega_{i-n+2}^{i-1}\right) \tag{15.62}$$

To yield meaningful results, the training data used to estimate $\lambda_{\omega_{i-n+1}^{i-1}}$ need to be distinct from the data used to estimate P_{ML}. In *held-out interpolation*, a section of training data is reserved for this purpose. In[37], a technique called deleted interpolation is described where different parts of the training data rotate in train either P_{ML} or the $\lambda_{\omega_{i-n+1}^{i-1}}$ and the results are then averaged. The other widely used smoothing technique in speech recognition is the backing-off technique described by Katz [36]. Here, the Good-Turing estimate [36] is extended by adding the interpolation of higher-order models with lower-order models. This technique performs best for bigram models estimated from small training sets. The trigram **language model** probability is defined by,

$$p(\omega_3|\omega_1,\omega_2) = \lambda_3 f(\omega_3|\omega_1,\omega_2) + \lambda_2 f(\omega_3|\omega_2) + \lambda_1 f(\omega_3) \tag{15.63}$$

The backing-off technique suggests that if the counts $C(\omega_1, \omega_2)$ is sufficiently large, the $f(\omega_3|\omega_1,\omega_2)$ by itself is a better estimate of $p(\omega_3|\omega_1,\omega_2)$. Hence, for different values of counts, a different estimate of $p(\omega_3|\omega_1,\omega_2)$ is used. Several variations on the choice of this threshold and the Good-Turing type function are described in [25].

Maximum Entropy based Language Models

A maximum-likelihood approach for automatically constructing maximum entropy models is presented in [34]. The maximum entropy method finds a model that simultaneously satifies a set of constraints Such a model is a method of estimating the conditional probability distributions. The principle is simple: model all that is known and assume nothing about that which is not known. Let x and y be a set of random variables such that $P(y|\varkappa)$ is the probability that the model assigns an output y given $\varkappa$. Let $f(\varkappa, y)$ be the indicator function (the expected value of this function is the feature function) that takes a binary value of 1 or 0 to fit the training data. If $P(\varkappa)$ satisfies $\sum_{\varkappa,y} P(\varkappa)P(y|\varkappa)f(\varkappa,y) = d(i)$ where $d(i)$ are the constraints then there must be a probability $P(\varkappa)$ that satisfies all the constraints uniformly. A mathematical measure of uniformity of conditional distributions is the conditional entropy, H. The solution to this problem is obtained by selecting the model with maximum entropy from the set of possible models, C, i.e.,

$$\mathrm{p}^{\star} = \underset{p \epsilon C}{arg\max} H \tag{15.64}$$

It can be shown that p* is well-defined and that there is always a model with maximum entropy in any constrained set C. For simple cases, the above equation can be solved mathematically, but for a more general case, the use of Lagrange multipliers from constrained optimization theory is employed. This approach leads to the following statement. The maximum entropy model subject to a set of constraints, has the parametric form given by Eq. 15.65,

$$P\left(y \mid \aleph\right) = Q_{\lambda}\left(\aleph\right) \exp \sum_{i} \lambda_i f\left(\aleph, y\right) \tag{15.65}$$

where the Lagrangian multipliers, $\lambda_i s$ can be determined by maximizing the Lagrangian, $\lambda = H + \sum_i \lambda_i (p(f_i) - \hat{p}(f_i))$. $Q_{\lambda}(\varkappa)$ is the normalization constant and $p(f_i)$ and $\hat{p}(f_i)$ are the emperical and expected distributions. Since the Lagrangian is the log-likelihood for the exponential model, P, the solution states that the model with the maximum entropy is one that maximizes the likelihood of the training data.

Details on the construction of maximum entropy models, techniques for the selection of features to be included in models and the computations of the parameters of these models are addressed in [34]. Techniques for computing the parameters of such models such as, hill climbing, iterative projection and iterative scaling algorithms are described in [25].

Hypothesis Search

It is the aim of the speech recognizer to determine the best possible word sequence given the acoustic observation; that is, the word string $\hat{W}$ that satisfies

$$\hat{W} = \underset{w}{argmax}\, P(W)P(A \mid W) \tag{15.66}$$

Since the word string is made up of a sequence of words, the search for $\hat{W}$ is done from several possible hypotheses. **Viterbi** Search, a time-synchronous search strategy, and Tree Search, a time-asynchronous search strategy, are presented here.

Viterbi Search

The Viterbi algorithm [11] introduced previously finds the most likely path through an HMM. Equation (15.66) demands that we find for each candidate word string W, the probability of the set of paths that corresponds to the word string W and then identify the word string whose set of paths has the highest probability.

Section 2 described the hidden Markev Model concept. The Viterbi algorithm that finds the maximizing state sequence for successive levels i (there may be several), and deciding at the final level k, from among the competing sequences. At each level i, the paths whose probabilities fall below a threshold are purged. A traceback from the final state for which the probability is maximized to the start state in the purged trellis yields the most likely state sequence.

Each word is represented as a concatenation of several HMMs, one corresponding to each of the phones that make up the word. If we are using a bigram **language model**, then $P(W) = P(w_i)\Pi_{i=2}^{n}\, P(w_i|w_{i-1}) = 0$, and $\hat{W}$ the most likely path through these HMMs. The number of states is proportional to the vocabulary size, V. If we are using the trigram language model, then, $P(W) = P(w_1)P(w_2|w_1)\Pi_{i=3}^{n}\, P(w_i|w_{i-2}, w_{i-1})$, and the graph becomes more complicated with the number of states being proportional to $|V|^2$. No practical algorithms exist for finding the exact solution, but the Viterbi algorithm will find the most likely path through these HMMs whose identity can then determine the recognized word string.

One drawback of the Viterbi algorithm is the number of states that have to be evaluated for a bigram language model, even for a practical vocabulary size of 60,000 words. A shortcut that is commonly used is the *beam search*. Here, the maximal probability P_{i-1}^{m} of the states at stage $i - 1$, i.e., $\max_{s1, \ldots, sl} P(s_1, s_2, \ldots, s_{i-1}, s_{l=i}, y_1, \ldots, y_i|s_0)$ is computed and used as the basis for computing a dynamic threshold to prune out all states in the trellis whose path probabilities fall below this threshold. Multi-pass search strategies have been proposed over the thresholding used in the beam search to handle more complex language models [6].

Tree Search

The search for the most likely word sequence can be thought of as searching for a path in a tree whose branches are labeled with the various words of the vocabulary V such that there are $|V|$ branches leaving each node, one for each word (i.e., the size of the vocabulary). Typically, in large vocabulary continuous speech recognition, this search from a tree of possible hypotheses turns out to be a very large computational effort. Hence, the search is limited by a fast match approach [26] that will reject from consideration several branches of the tree without subjecting them to a detailed analysis. The Viterbi algorithm achieves the same kind of pruning using the beam search approach and multi-pass strategies.

Stack Search

Stack search algorithms for speech recognition have been used at IBM [19] and MIT Lincoln Labs [20]. This heuristic search algorithm helps to reduce computational and storage needs without sacrificing accuracy. Any

tree search must be based on some evaluation criterion related to the search's purpose. The algorithm below is a popular algorithm used for the heuristic determination of minimum-cost paths

1. Insert into a stack all the single-branch paths corresponding to the words of the vocabulary.
2. Sort these entries in descending order of a function $F(w_i)$, where $w_i \in$ vocabulary V.
3. If the top entry in the stack is the end of the utterance, the search ends; otherwise, each entry in the stack is extended using $F(\cdot)$ for all possible words in the vocabulary and inserted into the stack while maintaining the stack order.
   $F(\cdot)$ is

$$F\left(w_1^k\right) = \max_{w^r} P\left(a_1^m, w_1^k\right) \tag{15.67}$$

   where w^r denotes a word string of length r and a_1^m denotes the acoustic data to be recognized.

The methods described in [14] incorporate the definition of an envelope that is used to mark partial paths in the stack as *alive* or *dead*; these considerably speed up the search. In [13], a tree search strategy called the *envelope search* is presented. This is a time-asynchronous search that combines aspects of the A* search with the time-synchronous **Viterbi** search. Several bi-directional search strategies have been proposed by Li et al. [18]. Kenny et al. discuss several aspects of A* algorithms in [12]. A different approach involving majority decisions on observed discrete acoustic output strings leading to a polling fast match is introduced by Bahl et al. in [15]. The use of multiple stacks is yet another way to control the search procedure and is presented in [13].

Tree Search vs. Viterbi Search

A Viterbi search of a trellis finds the most likely succession of transitions through a composite HMM composed of word HMMs. The number of states in a trellis stage (determined by the end states of the word HMMs) must be limited to keep the search's storage and computational requirements feasible. The tree search imposed no such constraints on the number of end states as long as this search does not prune out the correct path. Both algorithms are suboptimal in the sense that they do not guarantee to find the most probable word string.

State-of-the-Art Systems

In the 1998 DARPA Hub-4E English Broadcast News Benchmark Test, an overall recognition error rate of 13.5% was achieved. This test includes recognition of baseline broadcast speech, spontaneous broadcast speech, speech over telephone channels, speech in the presence of background music, speech under degraded acoustic conditions, speech from non-native speakers, and all other kinds of speech. Details can be obtained from the NIST Web site. Another benchmark test is the Switchboard Task, which is the transcription of conversations between two people over the telephone. Error rates for this task are approximately 37%. In the Airline Travel Information System (ATIS) speech recognition evaluation conducted by DARPA, error rates close to 2% have been obtained. High recognition accuracies have been obtained for digit recognition, with error rates under 1% (TIMIT database [31]).

Challenges in Speech Recognition

Some of the issues that still arise in speech recognition, and make interesting research problems for the present and the future, include:

1. Accurate transcription of spontaneous speech compared to read speech is still a major challenge because of its inherent casual and incoherent nature, embedded disfluencies, and incomplete voicing of several **phones** or words.
2. Recognizing speech between individuals and/or multiple speakers in a conference.
3. Robustness of recognition to different kinds of channels, background noise in the form of music, speech over speech, variation in distances between the speaker and the microphone, etc.
4. Recognition across age groups, speaking rates, and accents.
5. Building of a **language model** for an unknown domain and the addition of out-of-vocabulary (oov) words.

6. In order to dynamically adapt to speakers (i.e., make use of their speech when no transcription is available), unsupervised adaptation is necessary. To do this accurately, we need a confidence measure on the decoded script.
7. Speech recognition systems do not have any understanding of decoded speech. To move toward understanding/machine translation, we need some post-processing of the transcription that could lead to intelligent conversational systems.

Applications

The use of speech as a means of input, in a fashion similar to the use of the keyboard and the mouse, has resulted in the application of speech recognition to a wide set of fields. These can be broadly divided into three segments: desktop, telephony, and embedded systems.

1. In the desktop areas, continuous speech recognition has been used for dictation of text documents, for commands to navigate the desktop environment, and Internet surfing. Dictation accuracies of the order of 96% and greater have been achieved. The main players in this field include IBM with their ViaVoice series of products. Dragon Systems, L&H, Philips, and Microsoft.[1] Software tailored to dictation in specialized fields, such as radiology, general medicine, and the legal domain, have also been put out by some of these companies. Recorded speech using hand-held digital recorders can also be transcribed subsequently by the same software.
2. Telephony is an emerging field for applications of speech recognition. These include repertory dialing, automated call type recognition, credit card validation, directory listening retrieval, speaker identification, financial applications such as trading of stocks and mutual funds, banking, voice mail transcription,

   companies have their own specialized products for telephony.
3. The use of speech input for embedded systems is a relatively new field because only recently handheld systems have adequate CPV and memory for accurate speech recognition.

Defining Terms

Acoustic Model: Any statistical or syntactic model that represents a speech signal.
Baseforms: Representation of a word as a sequence of phones.
Baum-Welch algorithm: A form of EM (expectation-maximization) is an iterative procedure to estimate the parameters of a stochastic model by maximizing the likelihood of the data.
Cepstra: The Fourier Transform of the logarithm of the power spectrum sampled at regular intervals.
Co-articulation: Pronunciation of **phones** being influenced by the previous and following phones.
Decision trees: A technique used to group several conditions into classes.
Forward-backward: A recursive algorithm for computing the posterior probability of a HMM using forward and backward variables.
Gaussian mixtures: Convex combination of Gaussian (a kind of probability distribution function) functions.
Hidden Markov Model (HMM): A stochastic model that uses state transition and output probabilities to generate observation sequences.
Hypothesis search: Search through a large set of hypotheses of word sequences to find the optimal word sequence.
Language Model: Language Models predict words or word sequences from nonacoustic sources of information, such as context, structure, and grammar of the particular language.
Linear Prediction Coefficients (LPC): A representation of an analog signal using an Auto Regressive model.
MAP: Maximum *a posteriori*. Technique for speaker adaptation.
MLLR: Maximum Likelihood Linear Regression. Technique for speaker adaptation.
Phones: Sub-word acoustic unit.

[1]While this is not an exhaustive list of companies with continuous speech recognition software products, they are the leaders in the field to date.

Signal pre-processing: Conversion of an analog speech signal into a sequence of numeric feature vectors or observations.

Speaker adaptation: The process of using a small amount of data from a new speaker to tune a set of speaker-independent acoustic models to a new speaker.

Supervised and Unsupervised Adaptation: In speaker adaptation, the procedure is said to be supervised if the true transcription of the adaptation data is known and is unsupervised otherwise.

Tri-phone: Context-dependent model of a phone as a function of its previous and succeeding phones.

Viterbi: An algorithm for finding the optimal state sequence through an HMM, given a particular observation sequence.

For Further Information

There are three major speech-related conferences each year, namely, *International Conference on Acoustics, Speech and Signal Processing (ICASSP), International Conference on Spoken Language Processing (ICSLP), and European Conference on Speech Communication and Technology (EUROSPEECH)*. Besides this, Defense Advanced Research Projects Agency (DARPA) conducts workshops on Broadcast News Transcription (transcription of live television broadcasts) and Switchboard (conversations between individuals over the telephone) tasks. Also, there are several conferences addressing specific issues such as phonetic sciences, robust methods for speech recognition in adverse conditions, etc. Journals related to speech include *IEEE Transactions on Speech and Audio Processing, IEEE Transactions on Signal Processing, Computer and Speech Language, Speech Communications* and *IEEE Transactions on Information Theory.* Additional details on the statistical techniques used in speech recognition can be found in several books [23, 25, 32]. A good review of current techniques can also be found in [6].

16.1 Spectral Analysis

S. Unnikrishna Pillai and Theodore I. Shim

Historical Perspective

Modern spectral analysis dates back at least to Sir Isaac Newton [Newton, 1671], whose prism experiments with sunlight led him to discover that each color represented a particular wavelength of light and that the sunlight contained all wavelengths. Newton used the word *spectrum,* a variant of the Latin word *specter,* to describe the band of visible light colors.

In the early eighteenth century, Bernoulli discovered that the solution to the wave equation describing a vibrating string can be expressed as an infinite sum containing weighted sine and cosine terms. Later, the French engineer Joseph Fourier in his *Analytical Theory of Heat* [Fourier, 1822] extended Bernoulli's wave equation results to arbitrary periodic functions that might contain a finite number of jump discontinuities. Thus, for some $T_0 > 0$, if $f(t) = f(t + T_0)$ for all t, then $f(t)$ represents a periodic signal with period T_0 and in the case of real signals, it has the Fourier series representation

$$f(t) = A_0 + 2\sum_{k=1}^{\infty} (A_k \cos k\omega_0 t + B_k \sin k\omega_0 t)$$

where $\omega_0 = 2\pi/T_0$, and

$$A_k = \frac{1}{T_0}\int_0^{T_0} f(t)\cos k\omega_0 t\, dt, \qquad B_k = \frac{1}{T_0}\int_0^{T_0} f(t)\sin k\omega_0 t\, dt$$

with A_0 representing the dc term ($k = 0$). Moreover, the infinite sum on the right-hand side of the above expression converges to $[f(t_{-0}) + f(t_{+0})]/2$. The total power P of the periodic function satisfies the relation

$$P = \frac{1}{T_0}\int_0^{T_0} |f(t)|^2\, dt = A_0^2 + 2\sum_{k=1}^{\infty}(A_k^2 + B_k^2)$$

implying that the total power is distributed only among the dc term, the fundamental frequency $\omega_0 = 2\pi/T_0$ and its harmonics $k\omega_0$, $k \geq 1$, with $2(A_k^2 + B_k^2)$ representing the power contained at the harmonic $k\omega_0$. For every periodic signal with finite power, since $A_k \to 0$, $B_k \to 0$, eventually the overharmonics become of decreasing importance.

The British physicist Schuster [Schuster, 1898] used this observation to suggest that the partial power $P_k = 2(A_k^2 + B_k^2)$ at frequency $k\omega_0$, $k = 0 \to \infty$, be displayed as the spectrum. Schuster termed this method the *periodogram*, and information over a multiple of periods was used to compute the Fourier coefficients and/or to smooth the periodogram, since depending on the starting time, the periodogram may contain irregular and spurious peaks. A notable exception to periodogram was the linear regression analysis introduced by the British statistician Yule [Yule, 1927] to obtain a more accurate description of the periodicities in noisy data. Because the sampled periodic process $x(k) = \cos k\omega_0 T$ containing a single harmonic component satisfies the recursive relation

$$x(k) = ax(k-1) - x(k-2)$$

where $a = 2\cos\omega_0 T$ represents the harmonic component, its noisy version $x(k) + n(k)$ satisfies the recursion

$$x(k) = ax(k-1) - x(k-2) + n(k)$$

Yule interpreted this time series model as a recursive harmonic process driven by a noise process and used this form to determine the periodicity in the sequence of sunspot numbers. Yule further generalized the above recursion to

$$x(k) = ax(k-1) + bx(k-2) + n(k)$$

where a and b are arbitrary, to describe a truly autoregressive process and since for the right choice of a, b the least-square solution to the above autoregressive equation is a damped sinusoid, this generalization forms the basis for the modern day parametric methods.

Modern Spectral Analysis

Norbert Wiener's classic work on Generalized Harmonic Analysis [Wiener, 1930] gave random processes a firm statistical foundation, and with the notion of ensemble average several key concepts were then introduced. The formalization of modern day probability theory by Kolmogorov and his school also played an indispensable part in this development. Thus, if $x(t)$ represents a continuous-time stochastic (random) process, then for every fixed t, it behaves like a **random variable** with some **probability density function** $f_x(x,t)$. The ensemble average or **expected value** of the process is given by

$$\mu_x(t) = E[x(t)] = \int_{-\infty}^{\infty} x f_x(x,t)\, dx$$

and the statistical correlation between two time instants t_1 and t_2 of the random process is described through its **autocorrelation function**

$$R_{xx}(t_1,t_2) = E[x(t_1)x^*(t_2)] = \int_{-\infty}^{\infty}\int_{-\infty}^{-\infty} x_1 x_2^* f_{x_1x_2}(x_1,x_2,t_1,t_2)dx_1dx_2 = R_{xx}^*(t_2,t_1)$$

where $f_{x1\,x2}(x_1, x_2, t_1, t_2)$ represents the joint probability density function of the random variable $x_1 = x(t_1)$ and $x_2 = x(t_2)$ and * denotes the complex conjugate transpose in general. Processes with autocorrelation functions that depend only upon the difference of the time intervals t_1 and t_2 are known as wide sense stationary processes. Thus, if $x(t)$ is wide sense stationary, then

$$E[x(t+\tau)x^*(t)] = R_{xx}(\tau) = R_{xx}^*(-\tau)$$

To obtain the distribution of power versus frequency in the case of a **stochastic process,** one can make use of the Fourier transform based on a finite segment of the data. Letting

$$P_T(\omega) = \frac{1}{2T}\left|\int_{-T}^{T} x(t)e^{-j\omega t}dt\right|^2$$

represent the power contained in a typical realization over the interval $(-T, T)$, its ensemble average value as $T \to \infty$ represents the true power contained at frequency ω. Thus, for wide sense stationary processes

$$\begin{aligned} S(\omega) &= \lim_{T\to\infty} E[P_T(\omega)] = \lim_{T\to\infty}\int_{-T}^{T}\int_{-T}^{T} R_{xx}(t_1 - t_2)e^{-j\omega(t_1-t_2)}dt_1dt_2 \\ &= \lim_{T\to\infty}\int_{-2T}^{2T} R_{xx}(\tau)\left(1 - \frac{|\tau|}{2T}\right)e^{-j\omega\tau}d\tau = \int_{-\infty}^{\infty} R_{xx}(\tau)e^{-j\omega\tau}d\tau \geq 0 \end{aligned} \tag{16.1}$$

Moreover, the inverse relation gives

$$R_{xx}(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} S(\omega)e^{j\omega\tau}d\omega \tag{16.2}$$

and hence

$$R_{xx}(0) = E\left[|x(t)|^2\right] = P = \frac{1}{2\pi}\int_{-\infty}^{\infty} S(\omega)\,d\omega$$

Thus $S(\omega)$ represents the power spectral density and from Eqs. (16.1) and (16.2), the power spectral density and the autocorrelation function form a Fourier transform pair, the well-known Wiener–Khinchin theorem.

If $x(kT)$ represents a discrete-time wide sense stationary stochastic process, then

$$r_k = E\{x\big((n+k)T\big)x^*(nT)\} = r_{-k}^*$$

and the power spectral density is given by

$$S(\omega) = \sum_{k=-\infty}^{\infty} r_k e^{-jk\omega T}$$

or in terms of the normalized variable $\theta = \omega T$,

$$S(\theta) = \sum_{k=-\infty}^{\infty} r_k e^{-jk\theta} = S(\theta + 2\pi k) \geq 0 \tag{16.3}$$

and the inverse relation gives the autocorrelations to be

$$r_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} S(\theta)e^{jk\theta}d\theta = r_{-k}^{*}$$

Thus, the power spectral density of a discrete-time process is periodic. Such a process can be obtained by sampling a continuous-time process at $t = kT$, $|k| = 0 \rightarrow \infty$, and if the original continuous-time process is band-limited with a two-sided bandwidth equal to $2\omega_b = 2\pi/T$, then the set of discrete samples so obtained is equivalent to the original process in a mean-square sense.

As Schur [Schur, 1917] has observed, for discrete-time stationary processes the nonnegativity of the **power spectrum** is equivalent to the nonnegative definiteness of the Hermitian Toeplitz matrices, i.e.,

$$S(\theta) \geq 0 \Leftrightarrow \mathbf{T}_k = \begin{pmatrix} r_0 & r_1 & \cdots & r_k \\ r_1^{*} & r_0 & \cdots & r_{k-1} \\ \vdots & \vdots & \ddots & \vdots \\ r_k^{*} & r_{k-1} & \cdots & r_0 \end{pmatrix} = \mathbf{T}_k^{\star} \geq 0, \qquad k = 0 \rightarrow \infty \tag{16.4}$$

If $x(nT)$ is the output of a discrete-time linear time-invariant causal system driven by $w(nT)$, then we have the following representation:

$$w(nT) \rightarrow \boxed{H(z) = \sum_{k=0}^{\infty} h(kT)z^k} \rightarrow x(nT) = \sum_{k=0}^{\infty} h(kT)w\Big((n-k)T\Big) \tag{16.5}$$

In the case of a stationary input, the output is also stationary, and its power spectral density is given by

$$S_x(\theta) = \left|H(e^{j\theta})\right|^2 S_w(\theta) \tag{16.6}$$

where $S_w(\theta)$ represents the power spectral density of the input process. If the input is a white noise process, then $S_w(\theta) = \sigma^2$ and

$$S_x(\theta) = \sigma^2\left|H(e^{j\theta})\right|^2$$

Clearly if $H(z)$ is rational, so is $S_x(\theta)$. Conversely, given a power spectral density

$$S_x(\theta) = \sum_{k=-\infty}^{\infty} r_k e^{jk\theta} \geq 0 \tag{16.7}$$

that satisfies the integrability condition

$$\int_{-\pi}^{\pi} S_x(\theta)\, d\theta < \infty \tag{16.8}$$

and the physical realizability (Paley–Wiener) criterion

$$\int_{-\pi}^{\pi} \ln S_x(\theta)\, d\theta > -\infty \tag{16.9}$$

there exists a unique function $H(z)$ that is analytic together with its inverse in $|z| < 1$ (minimum phase factor) such that

$$H(z) = \sum_{k=0}^{\infty} b_k z^k, \qquad |z| < 1 \tag{16.10}$$

and

$$S_x(\theta) = \lim_{r \to 1-0} |H(re^{j\theta})|^2 = |H(e^{j\theta})|^2, \; a.e.$$

$H(z)$ is known as the Wiener factor associated with $S_x(\theta)$ and as Eq. (16.5) shows, when driven by white noise, it generates a stochastic process $x(nT)$ from past samples and its power spectral density matches with the given $S_x(\theta)$.

In this context, given a finite set of autocorrelations $r_0, r_1, \ldots, r_n$, the spectral extension problem is to obtain the class of all extensions that match the given data, i.e., such an extension $K(\theta)$ must automatically satisfy

$$K(\theta) \geq 0$$

and

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} K(\theta) e^{jk\theta} d\theta = r_k, \quad k = 0 \to n$$

in addition to satisfying Eqs. (16.8) and (16.9).

The solution to this problem is closely related to the trigonometric moment problem, and it has a long and continuing history through the works of Schur [1917]; Nevanlinna, Akheizer and Krein [Akheizer and Krein, 1962]; Geronimus [1954]; and Shohat and Tamarkin [1970], to name a few. If the given autocorrelations are such that the matrix $\mathbf{T}_n$ in Eq. (16.4) is singular, then there exists an $m \leq n$ such that $\mathbf{T}_{m-1}$ is positive definite ($\mathbf{T}_{m-1} > 0$) and $\mathbf{T}_m$ is singular [$\det \mathbf{T}_m = 0$, $\det(.)$ representing the determinant of (.)]. In that case, there exists a unique vector $\mathbf{X} = (x_0, x_1, \ldots, x_m)^T$ such that $\mathbf{T}_m \mathbf{X} = 0$ and further, the autocorrelations have a unique extension given by

$$c_k = \sum_{i=1}^{m} P_i e^{jk\theta_i}, \qquad |k| = 0 \to \infty \tag{16.11}$$

where $e^{j\theta i}$, $i = 1 \to m$ are the m zeros of the polynomial $x_0 + x_1 z + \ldots + x_m z^m$ and $P_i > 0$. This gives

$$\mathbf{T}_{m-1} = \mathbf{A} \begin{pmatrix} P_1 & 0 & \cdots & 0 \\ 0 & P_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & P_m \end{pmatrix} \mathbf{A}^* \tag{16.12}$$

where **A** is an $m \times m$ Vandermonde matrix given by

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ \lambda_1 & \lambda_2 & \cdots & \lambda_m \\ \lambda_1^2 & \lambda_2^2 & \cdots & \lambda_m^2 \\ \vdots & \vdots & \cdots & \vdots \\ \lambda_1^{m-1} & \lambda_2^{m-1} & \cdots & \lambda_m^{m-1} \end{pmatrix}, \qquad \lambda_i = e^{j\theta_i}, \qquad i = 1 \to m$$

and Eq. (16.12) can be used to determine $P_k > 0$, $k = 1 \to m$. The power spectrum associated with Eq. (16.11) is given by

$$S(\theta) = \sum_{k=1}^{m} P_k \delta(\theta - \theta_k)$$

and it represents a discrete spectrum that corresponds to pure uncorrelated sinusoids with signal powers P_1, P_2, …, P_m.

If the given autocorrelations satisfy $\mathbf{T}_n > 0$, from Eq. (16.4), every unknown r_k, $k \geq n+1$, must be selected so as to satisfy $\mathbf{T}_k > 0$, and this gives

$$\left| r_{k+1} - \zeta_k \right|^2 \leq \mathrm{R}^2{}_k \tag{16.13}$$

where $\zeta_k = \mathbf{f}_k^T \mathbf{T}_k^{-1} \mathbf{b}_k$, $\mathbf{f}_k = (r_1, r_2, \ldots, r_k)^T$, $\mathbf{b}_k = (r_k, r_{k-1}, \ldots, r_1)$ and $R_k = \det \mathbf{T}_k / \det \mathbf{T}_{k-1}$.

From Eq. (16.13), the unknowns could be anywhere inside a sequence of circles with center ζ_k and radius R_k, and as a result, there are an infinite number of solutions to this problem. Schur and Nevanlinna have given an analytic characterization to these solutions in terms of bounded function extensions. A bounded function $\rho(z)$ is analytic in $|z| < 1$ and satisfies the inequality $|\rho(z)| \leq 1$ everywhere in $|z| < 1$.

In a network theory context, Youla [1980] has also given a closed form parametrization to this class of solutions. In that case, given $r_0, r_1, \ldots, r_n$, the minimum phase transfer functions satisfying Eqs. (16.8) and (16.9) are given by

$$H_\rho(z) = \frac{\Gamma(z)}{P_n(z) - z\rho(z)\tilde{P}_n(z)} \tag{16.14}$$

where $\rho(z)$ is an *arbitrary* bounded function that satisfies the inequality (Paley-Wiener criterion)

$$\int_{-\pi}^{\pi} \ln\left[1 - \left|\rho(e^{j\theta})\right|^2\right] d\theta > -\infty$$

and $\Gamma(z)$ is the minimum phase factor obtained from the factorization

$$1 - \left|\rho(e^{j\theta})\right|^2 = \left|\Gamma(e^{j\theta})\right|^2$$

Further, $P_n(z)$ represents the Levinson polynomial generated from $r_0 \to r_n$ through the recursion

$$\sqrt{1 - |s_n|^2}\, P_n(z) = P_{n-1}(z) - z s_n \tilde{P}_{n-1}(z)$$

that starts with $P_0(z) = 1/\sqrt{r_0}$, where

$$s_n = \left\{ P_{n-1}(z) \sum_{k=1}^{n} r_k z^k \right\}_n P_{n-1}(0) \tag{16.15}$$

represents the reflection coefficient at stage n. Here, $\{\ \}_n$ denotes the coefficient of z^n in the expansion $\{\ \}$, and $\tilde{P}_n(z) \triangleq z^n P_n^*(1/z^*)$ represents the polynomial reciprocal to $P_n(z)$. Notice that the given information $r_0 \rightarrow r_n$ enters $P_n(z)$ through Eq. (16.5). The power spectral density

$$K(\theta) = \left| H_\rho(e^{j\theta}) \right|^2$$

associated with Eq. (16.14) satisfies all the interpolation properties described before. In Eq. (16.14), the solution $\rho(z) \equiv 0$ gives $H(z) = 1/P_n(z)$, a pure AR(n) system that coincides with Burg's maximum entropy extension. Clearly, if $H_\rho(z)$ is rational, then $\rho(z)$ must be rational and, more interestingly, every rational system must follow from Eq. (16.14) for a specific rational bounded function $\rho(z)$. Of course, the choice of $\rho(z)$ brings in extra freedom, and this can be profitably used for system identification as well as rational and stable approximation of nonrational systems [Pillai and Shim, 1993].

Defining Terms

Autocorrelation function: The expected value of the product of two random variables generated from a random process for two time instants; it represents their interdependence.

Expected value (or mean) of a random variable: Ensemble average value of a random variable that is given by integrating the random variable after scaling by its probability density function (weighted average) over the entire range.

Power spectrum: A nonnegative function that describes the distribution of power versus frequency. For wide sense stationary processes, the power spectrum and the autocorrelation function form a Fourier transform pair.

Probability density function: The probability of the random variable taking values between two real numbers x_1 and x_2 is given by the area under the nonnegative probability density function between those two points.

Random variable: A continuous or discrete valued variable that maps the set of all outcomes of an experiment into the real line (or complex plane). Because the outcomes of an experiment are inherently random, the final value of the variable cannot be predetermined.

Stochastic process: A real valued function of time t, which for every fixed t behaves like a random variable.

16.2 Parameter Estimation

Stella N. Batalama and Dimitri Kazakos

Parameter estimation is the operation of assigning a value in a continuum of alternatives to an unknown parameter based on a set of observations involving some function of the parameter. **Estimate** is the value assigned to the parameter and **estimator** is the function of the observations that yields the estimate.

The basic elements in the parameter estimation are a vector parameter θ^m, a vector space $\mathcal{E}^m$ where θ^m takes its values, a stochastic process $X(t)$ parameterized by θ^m and a performance criterion or cost function. The estimate $\hat{\theta}^m(x^n)$ based on the observation vector $x^n = [x_1, x_2, ..., x_n]$ is a solution of some optimization problem according to the performance criterion. In the following, the function $f(x^n|\theta^m)$ will denote the conditional joint probability density function of the random variables $x_1, ..., x_n$.

There are several parameter estimation schemes. If the process $X(t)$ is parametrically known, i.e., if its conditional joint probability density functions are known for each fixed value θ^m of the vector parameter θ^m, then the corresponding parameter estimation scheme is called **parametric.** If the statistics of the process $X(t)$ are nonparametrically described, i.e., given $\theta^m \in \mathcal{E}^m$ any joint probability density function of the process is a member of some nonparametric class of probability density functions, then the **nonparametric estimation** schemes arise.

Let Γ^n denote the n-dimensional observation space. Then an estimator $\hat{\theta}(x^n)$ of a vector parameter θ^m is a function from the observation space, Γ^n, to the parameter space, $\mathcal{E}^m$. Since this is a function of random variables, it is itself a random variable (or random vector).

There are certain stochastic properties of estimators that quantify somehow their quality. In this sense an estimator is said to be **unbiased** if its expected value is the true parameter value, i.e., if

$$E_\theta\{\hat{\theta}^m(\mathbf{x}^n)\} = \theta^m$$

where the subscript θ on the expectation symbol denotes that the expectation is taken according to the probability density function $f(x^n|\theta^m)$. In the case where the observation space is the $\Re^n$ and the parameter is a scalar, it is

$$E_\theta\{\hat{\theta}(\mathbf{x}^n)\} = \int_{R^n} \hat{\theta}(x^n) f(x^n|\theta^m) dx^n$$

The **bias** of the estimate is the Euclidean norm $\|\theta^m - E_\theta\{\theta^m(x^n)\}\|^{1/2}$. Thus, the bias measures the distance between the expected value of the estimate and the true value of the parameter. Clearly, the estimator is unbiased when the bias is zero.

Usually it is of interest to know the conditional variance of an unbiased estimate. The bias of the estimate $\hat{\theta}^m(x^n)$ and the conditional variance

$$E_\theta\{\|\hat{\theta}^m(\mathbf{x}^n) - E_\theta\{\hat{\theta}^m(\mathbf{x}^n)\}\|^2|\theta^m\}$$

generally represent a trade-off. Indeed, an unbiased estimate may induce relatively large variance. On the other hand, the introduction of some low-level bias may then result in a significant reduction of the induced variance.

In general, the bias versus variance trade-off should be studied carefully for the correct evaluation of any given parameter estimate. A parameter estimate is called **efficient** if the conditional variance equals a lower bound known as the Rao-Cramèr bound.

It will be useful to present briefly this bound.

The Rao-Cramèr bound gives a theoretical minimum for the variance of any estimate. More specifically, let $\hat{\theta}(x^n)$ be the estimate of a scalar parameter θ given the observation vector x^n. Let $f(x^n|\theta)$ be given, twice continuously differentiable with respect to θ, and satisfy also some other mild regularity conditions. Then,

$$E_\theta\left\{\left[\hat{\theta}(\mathbf{x}^n) - \theta\right]^2\right\} \geq E_\theta\left\{\left[\frac{\partial}{\partial\theta}\log f(x^n|\theta)\right]^2\right\}^{-1}.$$

Sometimes we need to consider the case where the sample size n increases to infinity. In such a case, an estimator is said to be **consistent** if

$$\hat{\theta}^m(\mathbf{x}^n) \to \theta^m \text{ as } n \to \infty$$

Since the estimate $\hat{\theta}^m(\mathbf{x}^n)$ is a random variable, we have to specify in what sense the above holds. Thus, if the above limit holds w.p. 1, we say that $\hat{\theta}^m(x^n)$ is *strongly consistent* or *consistent w.p. 1*. In a similar way we can define a *weakly consistent* estimator.

As far as the asymptotic distribution of $\theta(x^n)$ as $n \to \infty$ is concerned, it turns out that the central limit theorem can often be applied to $\hat{\theta}(x^n)$ to infer that $\sqrt{n}[\hat{\theta}(x^n) - \theta]$ is asymptotically normal with zero mean as $n \to \infty$.

In order to examine certain parameter estimation schemes we need first to present the definition of some related functions. **Penalty or cost function** $c[\theta^m, \hat{\theta}^m(x^n)]$ is a scalar, nonnegative function whose values vary as θ^m varies in the parameter space $\mathscr{E}^m$ and as the sequence x^n takes different values in the observation space, Γ^n. *Conditional expected penalty* $c(\theta^m, \hat{\theta}^m)$ induced by the parameter estimate and the penalty function is a function defined as follows:

$$c(\theta^m, \hat{\theta}^m) = E_\theta\{c[\theta^m, \hat{\theta}^m(\mathbf{x}^n)]\}$$

If an *a priori* density function $p(\theta^m)$ is available, then the expected penalty $c(\hat{\theta}^m, p)$ can be evaluated.

The various existing parameter estimation schemes evolve as the solutions of optimization problems whose objective function is either the conditional expected penalty or the conditional density function $f(x^n|\theta^m)$.

Bayesian Estimation Scheme

In the **Bayesian estimation** scheme the available assets are:

1. A parametrically known stochastic process parameterized by θ^m, in other words, a given conditional joint density function $f(x^n|\theta^m)$ defined on the observation space Γ^n, where θ^m is a well-defined parameter vector.
2. A realization x^n from the underlying active process, where the implied assumption is that the process remains unchanged throughout the whole observation period.
3. A density function $p(\theta^m)$ defined on the parameter space $\mathscr{E}^m$.
4. For each data sequence x^n, parameter vector θ^m and parameter estimate $\hat{\theta}^m(x^n)$, a penalty scalar function $c[\theta^m, \hat{\theta}^m(x^n)]$ is given.
5. A performance criterion which is the minimization of the expected penalty $c(\theta^m, p)$.

The estimate $\hat{\theta}_0^m$ that minimizes the expected penalty is called *optimal Bayesian estimate at p*. Under some mild conditions the optimal Bayesian estimate $\hat{\theta}_0^m(x^n)$ is the conditional expectation $E\{\theta^m|x^n\}$.

If the penalty function has the form $c[\theta^m,\hat{\theta}^m] = 1 - \delta(\|\theta^m - \hat{\theta}^m\|)$, where $\delta()$ is the delta function, then the optimal Bayesian estimate is called maximum a posteriori estimate since it happens to maximize the a *posteriori* density $p(\theta^m|x^n)$.

Another special case of penalty function is the function $\|\theta^m - \hat{\theta}^m\|^2$. In this case the Bayesian estimate is called *minimum mean-square estimate* and equals the conditional expectation $E\{\theta^m|x^n\}$.

In the following we present some more details about **mean-square estimation** since it is one of the most popular schemes.

Mean-Square Estimation

For the simplicity of our discussion we consider the case of estimating a single continuous type random variable θ with density $p(\theta)$ instead of estimating a random vector. We also reduce the dimensionality of the observation space to one. In this framework the penalty function will be the square of the estimation error $(\theta - \hat{\theta})^2$ and the performance or optimality criterion will be the minimization of the mean (expected) square value of the estimation error.

We will first consider the case of estimating a random variable θ by a constant $\hat{\theta}$. This means that we wish to find a constant $\hat{\theta}$ such that the mean-square (MS) error

$$e = E\{(\theta - \hat{\theta})^2\} = \int_{\infty}^{\infty} (\theta - \hat{\theta})^2 p(\theta) d\theta$$

is minimum. Since e depends on $\hat{\theta}$, it is minimum if

$$\frac{de}{d\theta} = \int_{-\infty}^{\infty} 2(\theta - \hat{\theta}) p(\theta) d\theta = 0$$

i.e., if

$$\hat{\theta} = E\{\theta\} = \int_{-\infty}^{\infty} \theta p(\theta) d\theta$$

The case where θ is to be estimated by a function $\hat{\theta}(\mathbf{x})$ of the random variable (observation) $\mathbf{x}$, and not by a constant, is examined next. In this case the MS error takes the form:

$$e = E\{[\theta - \hat{\theta}(\mathbf{x})]^2\} = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} [\theta - \hat{\theta}(x)]^2 p(\theta, x) dx dy$$

where $p(\theta, x)$ is the joint density of the random variables $\boldsymbol{\theta}$ and x. In this case we need to find that function $\hat{\theta}(x)$ which minimizes the MS error. It can be proved that the function that minimizes the MS error is

$$\hat{\theta}(x) = E\{\theta \mid x\} = \int_{-\infty}^{\infty} \theta p(\theta \mid x) d\theta$$

The function $\hat{\theta}(\mathbf{x})$ is called **nonlinear MS estimate.**

As we have seen, when the penalty function is the quadratic function $(\theta - \hat{\theta})^2$, then the optimal Bayesian estimate is the conditional expectation $E\{\boldsymbol{\theta}|x\}$. If $\mathbf{x}$ and $\boldsymbol{\theta}$ are jointly Gaussian, then the above conditional expectation is a linear function of x. But when the above statistics are not Gaussian, then the optimal Bayesian estimate is generally a nonlinear function of x. Thus, to resolve this problem we introduce suboptimal Bayesian schemes for this quadratic penalty function. In particular we consider only the class of linear parameter estimates and we try to find that estimate which minimizes the expected quadratic penalty. This estimate is called linear MS estimate and it is used in many applications because of the simplicity of the solution.

The linear estimation problem is the estimation of a random variable $\boldsymbol{\theta}$ in terms of a linear function $Ax + B$ of $\mathbf{x}$, i.e., $\hat{\theta}(x) = Ax + B$. In this case we need to find the constants A and B in order to minimize the MS error

$$e = E\{[\theta - (A\mathbf{x} + B)]^2\}$$

A fundamental principle in the MS estimation is the **orthogonality principle.** This principle states that the optimum linear MS estimate $A\mathbf{x} + B$ of $\boldsymbol{\theta}$ is such that the estimation error $\boldsymbol{\theta} - (A\mathbf{x} + B)$ is orthogonal to the data $\mathbf{x}$, i.e.,

$$E\{[\boldsymbol{\theta} - (A\mathbf{x} + B)]\mathbf{x}\} = 0$$

Using the above principle, it can be proved that e is minimum if

$$A = \frac{r\sigma_\theta}{\sigma_x} \text{ and } B = \eta_\theta - A\eta_x$$

$$\eta_x = E\{\mathbf{x}\}, \qquad \eta_\theta = E\{\boldsymbol{\theta}\}$$

$$\sigma_x^2 = E\{(\mathbf{x} - \eta_x)^2\}, \; \sigma_\theta^2 = E\{(\theta - \eta_\theta)^2\}$$

$$r = \frac{E\{(\mathbf{x} - \eta_x)(\theta - \eta_\theta)\}}{\sigma_x \sigma_\theta}$$

i.e., η_x, η_θ are the means of $\mathbf{x}$ and $\boldsymbol{\theta}$; σ_x^2, σ_θ^2 are the corresponding variances; σ_x, σ_θ is the standard deviation of x and θ; and r is the correlation coefficient of $\mathbf{x}$ and $\boldsymbol{\theta}$. Thus the MS error takes the form $e = \sigma_\theta^2 (1 - r^2)$.

The estimate

$$\hat{\theta}(\mathbf{x}) = A\mathbf{x} + B$$

is called the **nonhomogeneous linear estimate** of $\boldsymbol{\theta}$ in terms of $\mathbf{x}$. If $\boldsymbol{\theta}$ is estimated by a function $\hat{\theta}(\mathbf{x}) = \alpha\mathbf{x}$, the estimate is called homogeneous. It can be also shown by the orthogonality principle that for the homogeneous estimate

$$\alpha = \frac{E\{\mathbf{x}\boldsymbol{\theta}\}}{E\{\mathbf{x}^2\}}$$

Using the orthogonality principle it can be shown that if the random variables $\boldsymbol{\theta}$ and $\mathbf{x}$ are Gaussian zero mean, then the optimum nonlinear estimate of θ equals the linear estimate. In other words if $\hat{\theta}(\mathbf{x}) = E\{\boldsymbol{\theta}|x\}$ is the optimum nonlinear estimate of $\boldsymbol{\theta}$ and $\hat{\theta} = \alpha\mathbf{x}$ is the optimum linear estimate, then $\hat{\theta}(\mathbf{x}) = E\{\hat{\theta}|x\} = \hat{\theta} = \alpha x$.

This is true since the random variables $\boldsymbol{\theta}$ and $\mathbf{x}$ have zero mean, $E\{\boldsymbol{\theta}\} = E\{\mathbf{x}\} = 0$, and thus the linear estimate $\hat{\theta}$ has zero mean too, $E\{\hat{\theta}\} = 0$. This implies that the linear estimation error $\varepsilon = \boldsymbol{\theta} - \hat{\theta}$ also has zero mean, $E\{\varepsilon\} = E\{\boldsymbol{\theta} - \hat{\theta}\} = 0$.

On the other hand, the orthogonality principle can be applied, which implies that the linear estimation error ε is orthogonal to the data, $E\{\varepsilon \mathbf{x}\} = 0$. Since ε is Gaussian, it is independent of $\mathbf{x}$ and thus $E\{\varepsilon | x\} = E\{\varepsilon\} = 0$, which is equivalent to the following:

$$\mathrm{E}\{\boldsymbol{\theta} - \hat{\boldsymbol{\theta}} | x\} = 0 \Rightarrow E\{\boldsymbol{\theta} | x\} - E\{\hat{\boldsymbol{\theta}} | x\} = 0$$

$$\Rightarrow E\{\boldsymbol{\theta} | x\} = E\{\hat{\boldsymbol{\theta}} | x\} \Rightarrow \hat{\theta}(\mathbf{x}) = \alpha \mathrm{x} \Rightarrow \hat{\theta}(\mathbf{x}) = \hat{\theta}$$

i.e., the nonlinear and the linear estimates coincide.

In addition, since the linear estimation error $\varepsilon = \boldsymbol{\theta} - \hat{\boldsymbol{\theta}}$ is independent of the data x, so is the square error, i.e.,

$$E\{(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^2 | \mathrm{x}\} = \mathrm{E}\{(\theta - \hat{\theta}^2\} = V$$

Thus, the conditional mean of $\boldsymbol{\theta}$ assuming the data x equals its MS estimate and the conditional variance the MS error. That simplifies the evaluation of conditional densities when Gaussian random variables are involved because since $f(\theta | x)$ is Gaussian, it has the form

$$f(\theta \,|\, X) = \frac{1}{\sqrt{2\pi V}} \exp\left\{\frac{-[\theta - \alpha x]^2}{2V}\right\}$$

Minimax Estimation Scheme

In the **minimax estimation** scheme the available assets are:

1. A parametrically known stochastic process parameterized by θ^m.
2. A realization x^n from the underlying active process.
3. A scalar penalty function $c[\theta^m, \hat{\theta}^m(x^n)]$ for each data sequence x^n, parameter vector θ^m, and parameter estimate $\hat{\theta}^m(x^n)$.

The minimax schemes are solutions of saddle-point game formalizations, with payoff function the expected penalty $c(\hat{\theta}^m, p)$ and with variables the parameter estimate $\hat{\theta}^m$ and the *a priori* parameter density function p. If a minimax estimate $\hat{\theta}_0^m$ exists, it is an optimal Bayesian estimate, at some least favorable *a priori* distribution p_0.

Maximum Likelihood Estimation Scheme

Maximum likelihood estimation was first introduced by Fisher. It is a very powerful estimation procedure that yields many of the well-known estimation methods as special cases.

The essential difference between Bayesian and maximum likelihood parameter estimation is that in Bayesian Estimation the parameter θ^m is considered to be random with a given density function, while in the maximum likelihood framework it is unknown but fixed.

Consider a random process $X(t)$ parameterized by θ^m, where θ^m is an unknown fixed parameter vector of finite dimensionality m (e.g., $\theta^m \in \Re^m$). More specifically the conditional joint probability density function $f(x_1, \ldots, x_n | \theta^m)$ is well known for every θ^m, where $x^n = [x_1, \ldots, x_n]$ is a realization (or observation vector or sample vector) of the process $X(t)$.

The problem is to find an estimate of the parameter vector θ^m based on the realization of $X(t)$. (Note that the dimensionality of the parameter vector θ^m in the joint probability density function is assumed to be fixed.)

The intuition behind the maximum likelihood method is that we choose those parameters $[\theta_1, \ldots, \theta_m]$ from which the actually observed sample vector is most likely to have come. This means that the estimator of θ^m is selected so that the observed sample vector becomes as "likely as possible."

In this sense we call the conditional joint probability density function $f(x^n|\theta^m)$ as likelihood function $\ell(\theta^m)$. The likelihood function $\ell(\theta^m)$ is a deterministic function of the parameter vector θ^m once the observed variables $x_1, \ldots, x_n$ are inserted. This means that θ^m is variable and the sample vector x^n is fixed, while the conditional joint probability density function is considered as a function of the observation vector x^n with θ^m fixed. The maximum likelihood estimator of θ^m is that value of the parameter vector for which the likelihood function is maximized.

In many cases it is more convenient to work with another function called log-likelihood function, $L(\theta^m)$, rather than the likelihood function. The log-likelihood function is the natural logarithm of $\ell(\theta^m)$. Since the logarithm is a monotone function, it follows that whenever $L(\theta)$ achieves its maximum value, $\ell(\theta^m)$ is maximized too, for the same value of the parameter vector θ^m. Thus the log-likelihood function is maximized for that value of the vector parameter θ^m for which the first partial derivatives with respect to θ_i, $i = 1, \ldots, m$ are equal to zero, i.e.,

$$\hat{\theta}_{ML} \; : \; \frac{\partial L(\theta^m)}{\partial \theta_i} = 0$$

where $\hat{\theta}_{ML}$ denotes the maximum likelihood estimate of the vector parameter θ^m.

It can be shown that when the process $X(t)$ is memoryless and stationary (i.e., when $x_1, \ldots, x_n$ are independent, identically distributed) then the ML estimators are consistent, asymptotically efficient, and asymptotically Gaussian.

Example: Let $\mathbf{x}_i$, $i = 1, \ldots, n$, be Gaussian independent random variables with mean θ and variance σ_i^2: $\mathbf{x}_i \in N(\theta, \sigma_i^2)$. The mean θ is to be estimated and the Rao-Cramèr bound is to be evaluated. Since θ is unknown but fixed, we will use the maximum likelihood estimation scheme. The random variable $\mathbf{x}_i$ has the probability density function

$$\frac{1}{\sqrt{2\pi\sigma_i}} \exp\left\{-\frac{(x_i - \theta)^2}{2\sigma_i^2}\right\}$$

Since $\mathbf{x}_i$, $i = 1, \ldots, n$, are independent, the joint density function is

$$f(x_i, \ldots, x_n|\theta) = \prod_{i=1}^{n} \frac{1}{\sqrt{2\pi\sigma_i}} \exp\left\{-\frac{(x_i - \theta)^2}{2\sigma_i^2}\right\}$$

which is exactly the likelihood function for this estimation problem. The log-likelihood function is

$$\log f(x_1, \ldots, x_n|\theta) = -\frac{n}{2} \log(2\pi) - \sum_{i=1}^{n} \log \sigma_i - \frac{1}{2} \sum_{i=1}^{n} \frac{(x_i - \theta)^2}{\sigma_i^2}$$

We can maximize the log-likelihood function with respect to θ and find the maximizing value to be equal to

$$\hat{\theta}_{ML}(x^n) = \frac{1}{\sum_{i=1}^{n} \frac{1}{\sigma_i^2}} \sum_{i=1}^{n} \frac{x_i}{\sigma_i^2}$$

Note that for equal variances the maximum likelihood estimate coincides with the commonly used sample mean.

The Rao-Cramèr bound can be found as follows:

$$E_\theta\left\{\left[\frac{d}{d\theta}\log f(x^n|\theta)\right]^2\right\}^{-1} = -E_\theta\left\{\frac{d^2}{d\theta^2}\log f(x^n|\theta)\right\} = \sum_{i=1}^{n}\frac{1}{\sigma_i^2}$$

In conclusion, we see that for Gaussian data the sample mean estimate is efficient because it coincides with the maximum likelihood estimate.

When the data are contaminated with a fraction of data coming from an unknown probability density function, the so called *outliers*, the sample mean performs poorly even when the fraction of outliers is small. This observation gave birth to the branch of statistics called robust statistics.

Other Parameter Estimation Schemes

The Bayesian, minimax, and maximum likelihood estimation schemes described above make up the class of parametric parameter estimation procedures. The common characteristic of those procedures is the availability of some parametrically known stochastic process that generates the observation sequence x^n. When for every given parameter value θ^m the stochastic process that generates x^n is nonparametrically described, the nonparametric estimation schemes arise. The latter schemes may evolve as the solutions of certain saddle-point games, whose payoff function originates from the parametric maximum likelihood formalizations. It is assumed that, in addition to the nonparametrically described data-generating process, the only assets available are a realization x^n from the underlying active process and the parameter space $\mathcal{C}^m$. The **qualitative robustness** in parameter estimation corresponds to local performance stability for small deviations from a nominal, parametrically known, data-generating process.

Defining Terms

Bayesian estimation: An estimation scheme in which the parameter to be estimated is modeled as a random variable with known probability density function.

Bias: The norm of the difference between the true value of the estimate and its mean value.

Consistent estimator: An estimator whose value converges to the true parameter value as the sample size tends to infinity. If the convergence holds w.p. 1, then the estimator is called *strongly consistent* or *consistent w.p. 1.*

Efficient estimator: An estimator whose variance achieves the Rao-Cramèr bound.

Estimate: Our best guess of the parameter of interest based on a set of observations.

Estimator: A mapping from the data space to the parameter space that yields the estimate.

Homogeneous linear estimator: An estimator which is a homogeneous linear function of the data.

Maximum likelihood estimate: An estimate that maximizes the probability density function of the data conditioned on the parameter.

Mean-square estimation: An estimation scheme in which the cost function is the mean-square error.

Minimax estimate: The optimum estimate for the least favorable prior distribution.

Nonhomogeneous linear estimator: An estimator which is a nonhomogeneous linear function of the data.

Nonlinear MS estimate: The optimum estimate under the mean-square performance criterion.

Nonparametric estimation: An estimation scheme in which no parametric description of the statistical model is available.

Orthogonality principle: The fundamental principle for MS estimates. It states that the estimation error is orthogonal to the data.

Parameter estimation: The procedure by which we combine all available data to obtain our best guess about a parameter of interest.

Parametric estimation: An estimation scheme in which the statistical description of the data is given according to a parametric family of statistical models.

Penalty or cost function: A nonnegative scalar function which represents the cost incurred by an inaccurate value of the estimate.

Qualitative robustness: A geometric formulation of robust estimation.

Robust estimation: An estimation scheme in which we optimize performance for the least favorable statistical environment among a specified statistical class.

Unbiased estimator: An estimator whose mean value is equal to the true parameter value.

IEEE Transactions on Signal Processing is a monthly journal which presents applications of estimation theory to speech recognition and processing, acoustical signal processing, and communication.

IEEE Transactions on Communications is a monthly journal presenting applications of estimation theory to data communication problems, synchronization of communication systems, channel equalization, and image processing.

16.3 Kalman Filtering

Fred Daum

The **Kalman filter** is a linear recursive algorithm that solves the least squares problem for time-varying linear systems with non-stationary noise. It estimates the state of a linear dynamical system given linear measurements corrupted by additive noise. It is an optimal estimator, assuming that the measurement noise is Gaussian, and assuming that all other relevant probability densities are also Gaussian.

For example, the location of your car can be estimated using a Kalman filter to combine noisy measurements of distance from four or more satellites. As a second example, the position and velocity of an airplane can be estimated by a Kalman filter using noisy measurements of range, azimuth, and elevation from one or more radars. As a third example, the future price of IBM stock can be predicted using a Kalman filter to combine noisy data on thousands of relevant economic variables, using a dynamic model of the stock market and the overall economy.

The Kalman filter has been applied to solve many diverse real-world engineering problems, including spacecraft navigation, GPS navigation, robotics, air traffic control, missile guidance, chemical plant control, stock market prediction, weather prediction, speech recognition, speech encoding and compression, radar target tracking, satellite orbit estimation, and inertial navigation. See [Sorenson, 1985] for other applications.

Most real-world engineering problems have measurement equations or dynamical system equations that are nonlinear in the **state vector.** Therefore, the Kalman filter equations cannot be applied directly; rather, the problem must be approximated using linear equations. This linear approximation is very straightforward, and it is called the **"extended Kalman filter" (EKF)**. One of the main reasons for the wide application ofthe Kalman filter is the ease with which a nonlinear system can be approximated by a linear system. The resulting approximation is often very good, resulting in good EKF performance. Unfortunately, the EKF performance is sometimes poor, in which case a plethora of alternative approximations can be attempted.

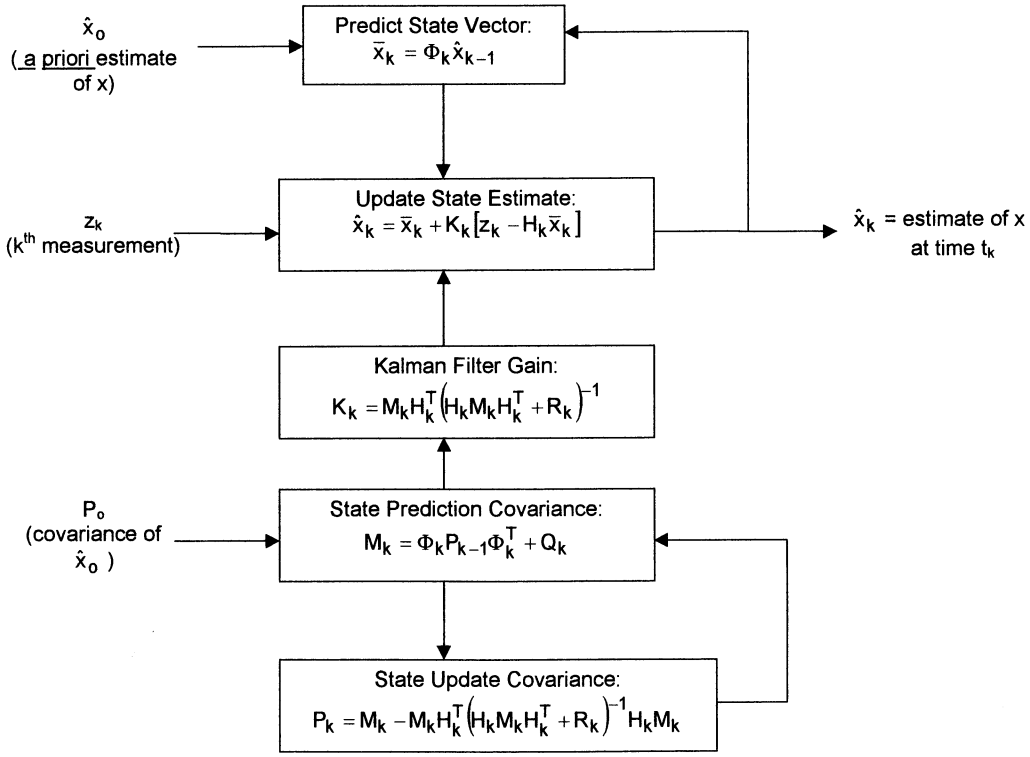

FIGURE 16.1 Block diagram of Kalman filter.

Kalman Filter Equations

The **Kalman filter** algorithm is shown as a block diagram in Fig. 16.1. The estimate of x is updated recursively as new measurements become available. Each measurement update corresponds to one iteration of Fig. 16.1. The symbols in Fig. 16.1 are defined in Table 16.1.

The Kalman filter uses both a model of the system dynamics

$$x_k = \Phi_k x_{k-1} + w_k \tag{16.16}$$

as well as a model of the measurements

$$z_k = H_k x_k + v_k \tag{16.17}$$

These models are a combination of deterministic and random effects. One can think of the true state vector, x_k, evolving in time according to a deterministic linear dynamical system:

$$x_k = \Phi_k x_{k-1} \tag{16.18}$$

with a random perturbation modeled by w_k. Likewise, the measurement model consists of a deterministic linear part:

$$z_k = H_k x_k \tag{16.19}$$

with an additive random perturbation of v_k. As shown in Fig. 16.1, the Kalman filter predicts the state vector from one time (t_{k-1}) to the next (t_k) using the deterministic part of the linear dynamical system. This is the

TABLE 16.1 Definition of Symbols

Symbol	Meaning	Mathematical Definition	Value
x_k	State vector of a linear dynamical system at time t_k	$x_k = \Phi_k x_{k-1} + w_k$	Vector of dimension n
t_k	Time of the k^{th} measurement	—	Scalar
k	Index of discrete time measurements	—	Integer
z_k	k^{th} measurement	$z_k = H_k x_k + v_k$	Vector of dimension m
H_k	Measurement matrix at time t_k	See above	m × n matrix
R_k	Covariance matrix of measurement noise at time t_k	$R_k = E(v_k v_k^T)$	m × m matrix
v_k	Measurement noise at time t_k	Gaussian zero mean random variable with covariance matrix R_k, statistically independent from sample to sample, and statistically independent of x_k	Vector of dimension m
Φ_k	Transition matrix of linear dynamical system from time t_{k-1} to t_k	See above	n × n matrix
w_k	Process noise	Gaussian zero mean random variable with covariance matrix Q_k, statistically independent from sample to sample, and statistically independent of x_k	Vector of dimension n
Q_k	Covariance matrix of process noise at time t_k	$Q_k = E(w_k w_k^T)$	n × n matrix
P_k	Error covariance matrix of x_k conditioned on Z_k	$P_k = E\left[\left(x_k - \hat{x}_k\right)\left(x_k - \hat{x}_k\right)^T \middle| Z_k\right]$	n × n matrix
M_k	Error covariance matrix of x_k conditioned on Z_{k-1}	$M_k = E\left[\left(x_k - \bar{x}_k\right)\left(x_k - \bar{x}_k\right)^T \middle| Z_{k-1}\right]$	n × n matrix
$\hat{x}_k$	Estimate of x at time t_k conditioned on Z_k	$\hat{x}_k = E\left(x_k \middle| Z_k\right)$	Vector of dimension n
$\bar{x}_k$	Estimate of x at time t_k conditioned on Z_{k-1}	$\bar{x}_k = E\left(x_k \middle| Z_{k-1}\right)$	Vector of dimension n
Z_k	Set of measurements up to and including time t_k	$Z_k = \left\{z_1, z_2, \ldots, z_k\right\}$	Set of m-dimensional vectors
$\hat{x}_o$	Initial estimate of x at time t_o, prior to any measurements	$\hat{x}_o = E\left(x_o\right)$	Vector of dimension n
P_o	Initial error covariance matrix of $\hat{x}_o$, prior to any measurements	$P_o = E\left[\left(x_o - \hat{x}_o\right)\left(x_o - \hat{x}_o\right)^T\right]$	n × n matrix
$E(\cdot)$	Expected value of $(\cdot)$	$E(A) = \int A\, p(A) dA$	—
$p(A)$	Probability density of A	Gaussian probability density	Function
$p(A\|B)$	Probability density of A conditioned on B	Gaussian probability density	Function
$(\cdot)^T$	Transpose of $(\cdot)$	$(A^T)_{ij} = A_{ji}$ for a matrix A with ij^{th} element A_{ij}	Operation
$(\cdot)^{-1}$	Inverse of matrix $(\cdot)$	A^{-1} is the inverse of matrix A if and only if $A^{-1}A = AA^{-1} = I$	Operation
I	Identity matrix	$I_{ij} = \begin{cases} 1 & \text{for } i = j \\ 0 & \text{otherwise} \end{cases}$	n × n matrix

best prediction of $x(t_k)$ given $x(t_{k-1})$, assuming that w_k is a zero-mean random variable uncorrelated with $x(t_{k-1})$. Hence, the **state vector** prediction in the **Kalman filter** is intuitively exactly what one would expect.The state vector update is also intuitively reasonable. In particular, it is a linear combination of the predicted value of x and the latest measurement z_k. This linear combination of $\bar{x}_k$ and z_k is computed as a compromise between prediction errors in $\bar{x}_k$ and the measurement noise errors in z_k. That is, the Kalman filter gain is computed to optimally combine $\bar{x}_k$ and z_k, using the known models of system dynamics and measurements. More specifically, the Kalman filter gain is computed to minimize the following error criterion at the time of the k^{th} measurement:

$$J = \left(\bar{x}_k - \hat{x}_k\right)^T M_k^{-1} \left(\bar{x}_k - \hat{x}_k\right) + \left(z_k - H_k \hat{x}_k\right)^T R_k^{-1} \left(z_k - H_k \hat{x}_k\right) \tag{16.20}$$

The **covariance matrix** of the prediction errors is M_k, and R_k is the measurement error covariance matrix. If M_k is large, then the first term in J is weighted less because the prediction, $\bar{x}_k$, is relatively inaccurate. Similarly, if R_k is large, then the second term in J is weighted less because the measurement, z_k, is relatively inaccurate. The weighted least squares criterion, J, strikes a balance between prediction errors and measurement errors. To find the value of $\hat{x}_k$ that minimizes J, we can set the derivative of J with respect to $\hat{x}_k$ equal to zero:

$$\frac{\partial J}{\partial \hat{x}_k} = 2\left(\hat{x}_k - \bar{x}_k\right)^T M_k^{-1} + 2\left(z_k - H_k \hat{x}_k\right)^T R_k^{-1} \left(-H_k\right) = 0 \tag{16.21}$$

Using the fact that covariance matrices are symmetric, and rearranging terms, we get:

$$\left(M_k^{-1} + H_k^T R_k^{-1} H_k\right)\hat{x}_k = M_k^{-1} \bar{x}_k + H_k^T R_k^{-1} z_k \tag{16.22}$$

and solving for $\hat{x}_k$:

$$\hat{x}_k = \left(M_k^{-1} + H_k^T R_k^{-1} H_k\right)^{-1} \left[M_k^{-1} \bar{x}_k + H_k^T R_k^{-1} z_k\right] \tag{16.23}$$

This can be put into the form:

$$\hat{x}_k = \bar{x}_k + K_k \left[z_k - H_k \bar{x}_k\right] \tag{16.24}$$

where:

$$K_k = \left(M_k^{-1} + H_k^T R_k^{-1} H_k\right)^{-1} H_k^T R_k^{-1} \tag{16.25}$$

Further matrix algebra can be used to represent the Kalman filter gain in two other forms:

$$K_k = M_k H_k^T \left(H_k M_k H_k^T + R_k\right)^{-1} \tag{16.26}$$

$$K_k = P_k H_k^T R_k^{-1} \tag{16.27}$$

in which P_k is the error covariance matrix of $\hat{x}_k$.

The above calculation of the **Kalman filter** gain is by no means a derivation of the Kalman filter, but rather it is merely a simple heuristic calculation that gives insight into these equations. The error criterion, J, is the logarithm of a Gaussian probability density of x conditioned on Z_k. A lucid derivation of the Kalman filter is given in Ho and Lee [1964], from a Bayesian viewpoint. In contrast, Kalman's original derivation does not use Bayesian methods; see Kalman [1960]. Other derivations of the Kalman filter are in Gelb [1974] and Jazwinski [1970]. The Kalman filter is "optimal" in a number of ways, under different assumptions, which are discussed in these references.

The Kalman filter is stable under rather mild assumptions, which can always be achieved in practice, by using a **state vector** with minimum dimension to realize the linear dynamical model and the linear measurement model. This corresponds to a *completely controllable* dynamical system and a *completely observable* measurement model. Stability of the Kalman filter under these conditions was proved in a beautiful paper by Kalman (1963). Kalman's stability theory has great practical value because engineers do not need to check for Kalman filter stability as a separate issue. This result is all the more impressive when we consider that the Kalman filter is a time-varying linear dynamical system that can be very complex and have very high dimension. Nevertheless, the Kalman filter is automatically stable under the simple minimality assumption given above.

It is important to emphasize that both the linear dynamical system and the measurement model can be time-varying, and both the process noise and measurement noise can be nonstationary. That is, all of the following matrices can vary with time: Φ_k, H_k, Q_k, and R_k. Also, the discrete times at which measurements are made (t_k for $k = 1, 2, \ldots$) are completely arbitrary; that is, the sample rate can be nonuniform.

Kalman Filter Examples

A good way to understand the Kalman filter equations is to look at some simple low-dimensional examples.

Example 1

Consider the problem of estimating the value of an unknown constant scalar, x, given a sequence of noisy measurements:

$$z_k = x_k + v_k \tag{16.28}$$

where the variance of measurement noise is constant, and the variance of the *a priori* estimate of x is infinite. For this example, using the Kalman filter notation:

$$\Phi_k = 1$$

$$Q_k = 0$$

$$H_k = 1$$

$$R_k = \text{constant} = c$$

$$P_o = \infty$$

the corresponding Kalman filter equations given in Fig. 16.1 are

$$\bar{x}_k = \hat{x}_{k-1} \tag{16.29}$$

$$\hat{x}_k = \bar{x}_k + K_k\left(z_k - \bar{x}_k\right) \tag{16.30}$$

$$K_k = M_k \big/ \left(M_k + c\right) \tag{16.31}$$

$$M_k = P_{k-1} \tag{16.32}$$

$$P_k = M_k - M_k^2 / \left(M_k + c\right) \tag{16.33}$$

$$P_o = \infty \tag{16.34}$$

which simplifies to

$$\hat{x}_k = \hat{x}_{k-1} + K_k \left(z_k - \hat{x}_{k-1}\right) \tag{16.35}$$

$$K_k = P_{k-1} / \left(P_{k-1} + c\right) \tag{16.36}$$

$$P_k = P_{k-1} - P_{k-1}^2 / \left(P_{k-1} + c\right) \tag{16.37}$$

After some more algebra, it turns out that

$$P_k^{-1} = P_{k-1}^{-1} + \frac{1}{c} \tag{16.38}$$

where $P_o^{-1} = 0$, and hence

$$P_k^{-1} = \sum_{j=1}^{k} 1/c \tag{16.39}$$

$$P_k^{-1} = k/c \tag{16.40}$$

Therefore, the variance of estimation error after k measurements is

$$P_k = c/k \tag{16.41}$$

which is exactly what we should expect for this example. Also, the Kalman filter gain is

$$K_k = P_{k-1} / \left(P_{k-1} + c\right) \tag{16.42}$$

$$K_k = \frac{1}{1 + c/P_{k-1}} \tag{16.43}$$

$$K_k = \frac{1}{1 + k - 1} \tag{16.44}$$

$$K_k = 1/k \tag{16.45}$$

which is intuitively very reasonable. Furthermore, the Kalman filter can now be written as:

$$\hat{x}_k = \hat{x}_{k-1} + \frac{1}{k}\left(z_k - \hat{x}_{k-1}\right) \tag{16.46}$$

which has the solution

$$\hat{x}_k = \frac{1}{k}\sum_{j=1}^{k} z_j \tag{16.47}$$

The Kalman filter for this simple example is nothing more than our old friend, the arithmetic average.

Example 2

Consider the same problem as in Example 1, but with R_k not constant. It is easy to show that the Kalman filter in this case is

$$\hat{x}_k = \hat{x}_{k-1} + \left(P_k / R_k\right)\left(z_k - \hat{x}_{k-1}\right) \tag{16.48}$$

where the estimation error variance after k measurements is given by

$$P_k = 1\Big/\sum_{j=1}^{k}\left(1/R_j\right) \tag{16.49}$$

and the Kalman filter estimate of x after k measurements is:

$$\hat{x}_k = \frac{\sum_{j=1}^{k}\left(z_j/R_j\right)}{\sum_{j=1}^{k}\left(1/R_j\right)} \tag{16.50}$$

This result is intuitively very reasonable. In particular, the more accurate measurements (corresponding to small R_j) are weighted more heavily in estimating x; conversely, relatively inaccurate measurements (with large R_j) are given little weight.

Example 3

Consider the problem of estimating the value of a quantity, y, that changes linearly with time with an unknown rate of change, given a sequence of measurements of y corrupted by additive noise that is statistically independent from sample to sample. In the Kalman filter setup, we could model this problem as follows. Let the state vector be:

$$x = \begin{bmatrix} y \\ \dot{y} \end{bmatrix} \tag{16.51}$$

The transition matrix would be:

$$\Phi_k = \begin{bmatrix} 1 & \Delta t_k \\ 0 & 1 \end{bmatrix} \tag{16.52}$$

where $\Delta t_k = t_k - t_{k-1}$. Furthermore,

$$H_k = [1 \quad 0]$$

$$Q_k = 0$$

$$R_k = \text{constant}$$

$$P_o^{-1} = 0$$

Assuming a constant value of $\Delta t_k = T$, it turns out that the error **covariance matrix** is:

$$M_k = \begin{bmatrix} 2(2k-1) & 6/T \\ 6/T & 12/T^2(k-1) \end{bmatrix} \frac{R}{k(k+1)} \tag{16.53}$$

See [Sorenson, 1967] for details.

Extended Kalman Filter

In practical applications, it is rather rare to find a problem with dynamical equations and measurement equations that are linear in x. Nevertheless, engineers use the **Kalman filter** theory applied to a linear approximation of the actual nonlinear dynamics and measurements. This approximation is called the **extended Kalman filter (EKF)**; it is very straightforward and popular. The Kalman filter itself is almost never used in real-world applications, but rather the EKF is essentially ubiquitous.

Figure 16.2 shows a block diagram of the EKF. Note that the EKF uses the nonlinear dynamics and nonlinear measurement equations to predict $\bar{x}_k$ and $\bar{z}_k$, rather than using a linear approximation. In contrast, the EKF uses linear approximations of f(x) and h(x) to compute the covariance matrices and the Kalman filter gain. The nonlinear dynamical model for x is:

$$x_k = f(x_{k-1}) + w_k \tag{16.54}$$

and the nonlinear measurement model is:

$$z_k = h(x_k) + v_k \tag{16.55}$$

Also, note in Fig. 16.2 that the estimate of x is used to compute the Kalman filter gain, unlike the Kalman filter, in which the filter gain and the error covariance matrices do not depend on x (see Fig. 16.1). Unlike the Kalman filter, there is no guarantee that the EKF is stable. Moreover, there is no reason to suppose that the EKF will give optimal performance. Although in many applications the EKF performance is good, it is well known that the EKF performance is often poor or far from optimal. Unfortunately, there is no theory that predicts when the EKF will give good performance, but rather engineers use Monte Carlo simulations to evaluate EKF performance.

There is a vast literature on methods to improve the EKF performance, including second-order Taylor series, iteration of Fig. 16.2 to improve the linearization, tuning the process noise covariance matrix, decoupling the

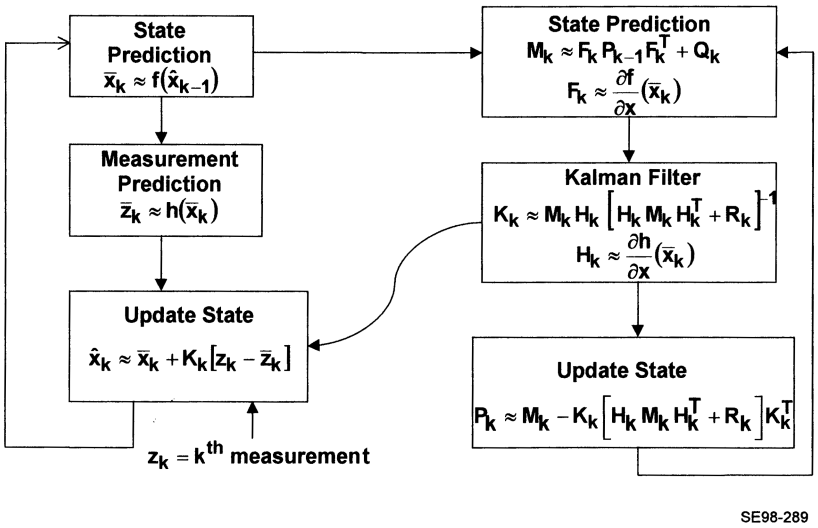

FIGURE 16.2 The extended Kalman (EKF) is a linear approximation.

error **covariance matrix**, preferred order of processing the components of a vector-valued measurement,careful choice of coordinates (e.g., polar vs. Cartesian), hybrid coordinate systems, etc. There is no guarantee that any of these methods will improve EKF performance; in some cases, second-order corrections and/or iteration actually make EKF performance worse, contrary to intuition. Reviews of these techniques are given in Tanizaki [1996], as well as Wishner et al. [1969], Mehra [1971], Leskiw et al. [1982], Gelb [1974], Bellaire et al. [1995], Henriksen [1982], Fang [1976], Daum et al. [1983], and Jazwinski [1970].

Nonlinear Filters

Considering the frequently disappointing performance of the EKF noted in the previous section, there has been intense research to develop better nonlinear filters. An exact nonlinear recursive filter was derived by Beneš (for a certain class of nonlinear problems) in a seminal paper [1981]. The Beneš filter is "exact" in the sense that it computes an optimal estimate of x, without any approximations, in contrast to the EKF, which uses linear approximations. A generalization of the Beneš filter and the **Kalman filter** was developed by Daum [1986a; 1986b]. Figure 16.3 shows the superior performance of this new nonlinear filter compared to the EKF for certain practical applications; see Schmidt [1993] for details. A more general class of exact nonlinear recursive filters is based on the exponential family of probability densities. The Kalman filter theory is based on a Gaussian density, which is a special case of the exponential family; see Daum [1988; 1997a, b] for a development of this theory, which is summarized in Table 16.2.

Another alternative to the EKF, reported in Julier et al. [1995], is called the *unscented filter*, and in contrast to the EKF, does not use Jacobians, but rather evaluates multidimensional integrals by sampling at carefully selected points much like Gauss-Hermite quadrature formulas. The unscented filter shows much better performance than the EKF in certain applications, with less computational complexity than the EKF.

Exact recursive filters for nonlinear estimation problems generally do not exist. This is not surprising, considering that the existence of an exact recursive filter corresponds to the following minor miracle:

$$\underset{\substack{\uparrow \\ \text{growing} \\ \text{dimension} \\ \text{with k}}}{p\left(x,\ t\middle|Z_k\right)} = \underset{\substack{\uparrow \\ \text{fixed} \\ \text{dimension} \\ \text{for all k}}}{p\left(x,\ t\middle|\psi_k\right)} \tag{16.56}$$

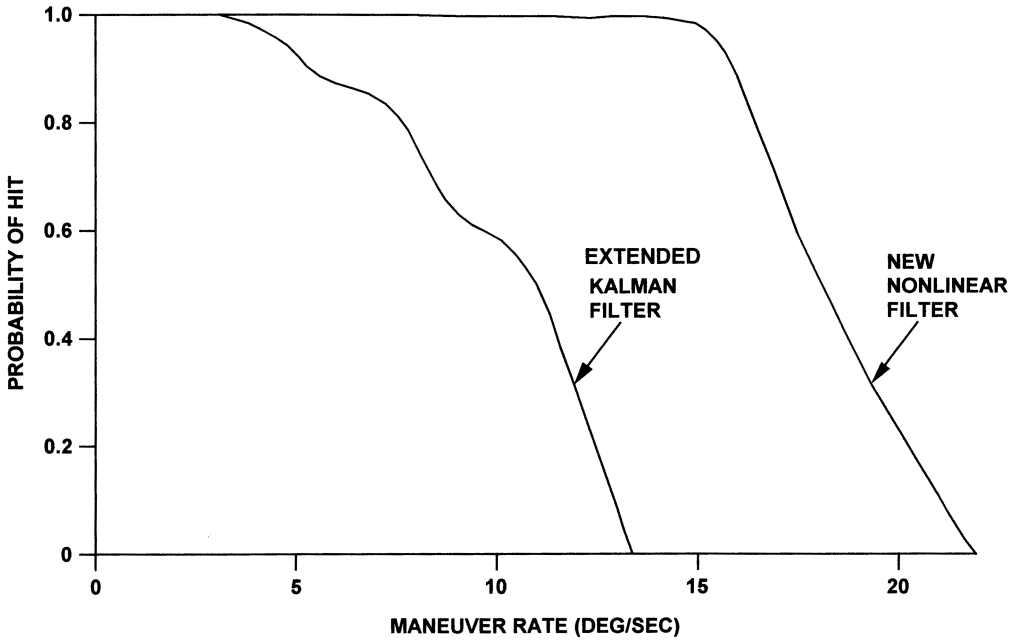

FIGURE 16.3 New nonlinear filter vs. extended Kalman filter [See Schmidt (1993)].

in which ψ_k is a sufficient statistic for x. A *recursive* filter exists when there is a sufficient statistic with fixed finite dimension. In classical statistics, for parameter estimation, it is well known that this will happen (assuming certain regularity conditions) if and only if the conditional density is from an exponential family; see Daum [1988]. The theory of fixed finite dimensional filters has also been developed from a completely different perspective, using Lie algebras; see Beneš [1987].

Non-recursive filters generally have superior performance compared with the EKF, at the cost of higher computational complexity. For parameter estimation problems (corresponding to zero process noise, $Q_k = 0$), these non-recursive filters are popular in practical applications despite the increased computational complexity compared with the EKF. Gauss invented this type of non-recursive nonlinear filter over 200 years ago; see Sorenson [1980]. On the other hand, non-recursive filters for estimating x, where x is a Markov process with non-zero process noise ($Q_k \neq 0$), generally have much greater computational complexity. Nevertheless, with a sufficiently fast computer, it would be practical to implement such a non-recursive algorithm. The theory to design such algorithms is well known, and some Monte Carlo simulations have shown excellent performance relative to the EKF; see Sorenson [1988] and Kastella et al. [1997]. Presumably, with computers getting ten times faster (at fixed cost) every 5 years, the application of such non-recursive filters will become common in the future, despite very high computational complexity relative to the EKF.

Practical Issues

Data Association

One of the best ways to ruin the performance of a **Kalman filter** is to put the wrong data into it. In a dense multiple-target environment, for applications with sensors such as radar, passive infrared, sonar, acoustic, or optical, the question of which measurement originated from which target is a very serious issue. In addition, the measurements could be unresolved mixtures from two or more objects. There is a plethora of algorithms to mitigate these problems, as well as a vast literature on this subject, including Blackman [1986]; Blackman et al. [1999], Bar-Shalom [1995], and Daum [1992].

TABLE 16.2 Exact Recursive Filters

Filter	Conditional Density $p(x, t \mid Z_k)$	Class of Dynamics	Propagation Equations
1. Kalman (1960)	η = Gaussian	$\frac{\partial f}{\partial x} = A(t)$	$\dot{m} = Am$ $\dot{P} = AP + PA^T + GG^T$
2. Beneš (1981)	$\eta \exp\left[\int^x f(x)dx\right]$	$\frac{\partial f}{\partial x} = \left(\frac{\partial f}{\partial x}\right)^T$ and $\left\|f(x)\right\|^2 + \mathrm{tr}\left(\frac{\partial f}{\partial x}\right) = x^T Ax + b^T x + c$	$\dot{m} = -P\ Am - \frac{1}{2}Pb$ $\dot{P} = I - PAP$
3. Daum (1986)	$\eta\, P_{ss}^{\alpha}(x)$	$f - \alpha Q r^T = Dx + E$ and $\mathrm{tr}\left(\frac{\partial f}{\partial x}\right) + \frac{\alpha}{2} r Q r^T = x^T Ax + b^T x + c$ where $r = \frac{\partial}{\partial x} \log P_{ss}(x)$	$\dot{m} = 2(\alpha - 1)PAm + Dm + (\alpha - 1)Pb + E$ $\dot{P} = 2(\alpha - 1)PAP + DP + PD^T + Q$
4. Daum (1986)	$\eta\, q^{\alpha}(x, t)$	Same as filter 3, but with $r = \frac{\partial}{\partial x} \log q(x, t)$	Same as filter 3
5. Daum (1986)	$\eta Q(x, t)$	$\frac{\partial f}{\partial x} - \left(\frac{\partial f}{\partial x}\right)^T = D^T - D$ and $\frac{\partial f}{\partial t} + \dot{D}x + \dot{E} = -\frac{\partial f^T}{\partial x} f - \frac{1}{2}\left[\frac{\partial}{\partial x}\mathrm{tr}\left(\frac{\partial f}{\partial x}\right)\right]^T$ $+ (2A + D^T D)x + D^T E + b$	$\dot{m} = -(2PA + D)m - E - Pb$ $\dot{P} = -2PAP - PD^T - DP + I$
6. Daum (1988)	$p(x, t)\exp\left[\theta^T(x, t)\psi(Z_k, t)\right]$	Solution of PDE for $\theta(x, t)$	$\frac{d\psi}{dt} = A^T \psi + \Gamma$ where $\Gamma = (\Gamma_1, \Gamma_2, \ldots, \Gamma_M)^T$ with $\Gamma_j = \psi^T B_j \psi$

Ill-Conditioning

The **Kalman filter** covariance matrix can be extremely ill-conditioned in certain applications, as analyzed in Daum et al. [1983]. A Kalman filter is ill-conditioned if its performance is significantly degraded by numerical errors. Special factorizations of the covariance matrices have been developed to mitigate this problem; the standard reference is Bierman [1977]. There are many other methods to mitigate ill-conditioning, as discussed by Daum et al. [1983].

Adaptive Kalman Filters

The Kalman filter was derived assuming that the process noise covariance matrix, Q_k, as well as all other matrices (Φ_k, H_k, R_k) are known exactly *a priori*. In practice, however, these assumptions may be inappropriate. To mitigate this uncertainty a number of adaptive Kalman filter algorithms can be used. Most of these algorithms consist of a bank of Kalman filters combined adaptively using Bayes' rule. This basic structure was invented by Magill [1965], and it has now evolved into a more sophisticated algorithm, called *interacting multiple models* invented by Blom [1984]. A recent survey of this topic is given by Bar-Shalom et al. [1995].

Measurement Models

The Kalman filter theory assumes Gaussian measurement errors that are statistically independent from sample to sample, with zero mean and exactly known covariance matrix (R_k). However, in many practical applications, these are poor approximations of reality. For example, in radar applications, the measurments of range, azimuth, and elevations are often biased, non-Gaussian, and correlated with time, owing to diverse physical effects including multipath, tropospheric refraction, ducting, ionospheric refraction, glint, RV wake, rocket exhaust plume, RFI, ECM, unresolved measurements, bias errors in time, location and angular orientation for the radar itself, radar hardware errors, etc. Gauss himself cautioned against naïve least squares fitting of data with bias and drift; see Gauss [1995].

Performance Evaluation

As shown in Fig. 16.1, the Kalman filter computes the covariance matrix of the estimation error (P_k). However, in practical applications, this theoretical covariance matrix may be extremely optimistic, owing to the effects noted earlier (nonlinearity, ill-conditioning, data association errors, unresolved data, errors in modeling both measurement errors and target dynamics) as well as bugs in the software itself. Therefore, the standard approach to evaluate Kalman filter performance is Monte Carlo simulation. However, no one in their right mind would believe the results of a complex Monte Carlo simulation without a back-of-the-envelope calculation that is in rough agreement with the simulation results. A good source of such simple formulas is Brookner [1998].

Obviously, the very best way to evaluate Kalman filter performance is to conduct extensive real-world testing. Unfortunately, the cost and practicality of this approach is often prohibitive or is deemed to be not cost-effective. A judicious combination of extensive Monte Carlo simulation and limited real-world testing is often the most practical approach to performance evaluation.

The best possible performance for EKFs can be computed using theoretical lower bounds on the error covariance matrix, such as the Cramér-Rao bound (CRB) for parameter estimation. For the standard Kalman filter setup with zero process noise ($Q_k = 0$), it turns out that the CRB is simply the Kalman filter error covariance matrix itself; see Taylor [1979]. On the other hand, for non-zero process noise, the available bounds are much more complex to compute and they are generally not tight; see Kerr [1989] for a detailed review of the state of the art. More generally, the theory of error bounds when data association errors are considered is developed in Daum [1997a, b].

Digital Realization

All of the algorithms discussed here are always implemented using digital computers, owing to their superior accuracy, flexibility, and dynamic range, as compared to currently available analog devices. Generally, 32-bit or 64-bit floating point arithmetic is required for most practical applications, although extra precision may be required for extremely ill-conditioned problems.

The idea of using analog computers to implement Kalman filters (which is sometimes suggested in academic circles) is rather naïve, owing to the limited accuracy, limited dynamic range, and inflexibility of analog

computers. Likewise, the filtering theory for continuous time measurements (which dominates the academic literature on nonlinear filtering) is also impractical because measurements must be made in discrete time to accommodate digital computers. The naïve approximation of discrete time measurements by continuous time data generally results in poor performance, and it is not used by practical engineers. The academic literature is out of touch with such practical issues; for example, see Hazewinkel et al. [1981].

Defining Terms

Kalman filter: A recursive algorithm that estimates the state vector of a linear dynamical system given noisy measurements that are linear in the state vector. This algorithm was invented by Rudolf E. Kalman, and it was published in 1960.

Extended Kalman filter: A recursive algorithm for estimating the state of nonlinear dynamical systems that uses the Kalman filter equations based on a linear approximation to the nonlinear dynamical system and/or nonlinear measurement equations.

State vector: A vector that specifies the state of a dynamical system. For example, the position and velocity of a leaf falling to the ground could be the state vector for the leaf. For deterministic systems, this corresponds to the initial conditions for a system of ordinary differential equations. For a special type of random process, called a Markov process, the future state is statistically independent of the past, conditioned on knowledge of the state at the present time.

Covariance matrix: A matrix that gages the uncertainty in a vector using second moments. The diagonal elements of this matrix are the variances of uncertainty in the components of the vector.

Further Information

The best concise introduction to Kalman filtering is Chapter 12 in Bryson and Ho [1969]. The three best books on Kalman filters are Gelb [1974], Sorenson [1985], and Brown et al. [1997]. The standard reference on nonlinear filters is Jazwinski [1970]. The best journal on Kalman filter applications is the *IEEE Transactions on Aerospace and Electronic Systems*, which typically has several practical papers on Kalman filters each issue. Two good conferences with many papers on Kalman filters are the *IEEE Conference on Decision and Control* (mid-December annually) and the *SPIE Conference on Signal and Data Processing* (April each year).

17.1 Digital Image Processing

Edward J. Delp, Jan Allebach, and Charles A. Bouman

What is a **digital image**? What is digital image processing? Why does the use of computers to process pictures seem to be everywhere? The space program, robots, and even people with personal computers are using digital image processing techniques. In this section we shall describe what a digital image is, how one obtains digital images, what the problems with digital images are (they are not trouble-free), and finally how these images are used by computers. A discussion of processing the images is presented later in the section. At the end of this section is a bibliography of selected references on digital image processing.

The use of computers to process pictures is about 30 years old. While some work was done more than 50 years ago, the year 1960 is usually the accepted date when serious work was started in such areas as optical character recognition, **image coding**, and the space program. NASA's Ranger moon mission was one of the first programs to return digital images from space. The Jet Propulsion Laboratory (JPL) established one of the early general-purpose image processing facilities using second-generation computer technology.

The early attempts at digital image processing were hampered because of the relatively slow computers used, i.e., the IBM 7094, the fact that computer time itself was expensive, and that image digitizers had to be built by the research centers. It was not until the late 1960s that image processing hardware was generally available (although expensive). Today it is possible to put together a small laboratory system for less than $60,000; a system based on a popular home computer can be assembled for about $5,000. As the cost of computer hardware

decreases, more uses of digital image processing will appear in all facets of life. Some people have predicted that by the turn of the century at least 50% of the images we handle in our private and professional lives will have been processed on a computer.

Image Capture

A digital image is nothing more than a matrix of numbers. The question is how does this matrix represent a real image that one sees on a computer screen?

Like all imaging processes, whether they are analog or digital, one first starts with a sensor (or transducer) that converts the original imaging energy into an electrical signal. These sensors, for instance, could be the photomultiplier tubes used in an x-ray system that converts the x-ray energy into a *known* electrical voltage. The transducer system used in ultrasound imaging is an example where sound pressure is converted to electrical energy; a simple TV camera is perhaps the most ubiquitous example. An important fact to note is that the process of conversion from one energy form to an electrical signal is not necessarily a *linear* process. In other words, a proportional charge in the input energy to the sensor will not always cause the same proportional charge in the output electrical signal. In many cases calibration data are obtained in the laboratory so that the relationship between the input energy and output electrical signal is known. These data are necessary because some transducer performance characteristics change with age and other usage factors.

The sensor is not the only thing needed to form an image in an imaging system. The sensor must have some spatial extent before an image is formed. By spatial extent we mean that the sensor must not be a simple point source examining only one location of energy output. To explain this further, let us examine two types of imaging sensors used in imaging: a CCD video camera and the ultrasound transducer used in many medical imaging applications.

The CCD camera consists of an *array* of light sensors known as charge-coupled devices. The image is formed by examining the output of each sensor in a preset order for a finite time. The electronics of the system then forms an electrical signal which produces an image that is shown on a cathode-ray tube (CRT) display. The image is formed because there is an array of sensors, each one examining only one spatial location of the region to be sensed.

The process of **sampling** the output of the sensor array in a particular order is known as *scanning*. Scanning is the typical method used to convert a two-dimensional energy signal or image to a one-dimensional electrical signal that can be handled by the computer. (An image can be thought of as an energy field with spatial extent.) Another form of scanning is used in ultrasonic imaging. In this application there is *only* one sensor instead of an array of sensors. The ultrasound transducer is moved or steered (either mechanically or electrically) to various spatial locations on the patient's chest or stomach. As the sensor is moved to each location, the output electrical signal of the sensor is sampled and the electronics of the system then form a television-like signal which is displayed. Nearly all the transducers used in imaging form an image by either using an array of sensors or a single sensor that is moved to each spatial location.

One immediately observes that both of the approaches discussed above are equivalent in that the energy is sensed at various spatial locations of the object to be imaged. This energy is then converted to an electrical signal by the transducer. The image formation processes just described are classical analog image formation, with the distance between the sensor locations limiting the spatial resolution in the system. In the array sensors, resolution is determined by how close the sensors are located in the array. In the single-sensor approach, the spatial resolution is limited by how far the sensor is moved. In an actual system spatial resolution is also determined by the performance characteristics of the sensor. Here we are assuming for our purposes *perfect* sensors.

In digital image formation one is concerned about two processes: *spatial sampling* and **quantization**. Sampling is quite similar to scanning in analog image formation. The second process is known as *quantization* or *analog-to-digital conversion,* whereby at each spatial location a *number* is assigned to the amount of energy the transducer observes at that location. This number is usually proportional to the electrical signal at the output of the transducer. The overall process of sampling and quantization is known as *digitization*. Sometimes the digitization process is just referred to as analog-to-digital conversion, or A/D conversion; however, the reader should remember that digitization also includes spatial sampling.

The digital image formulation process is summarized in Fig. 17.1. The spatial sampling process can be considered as overlaying a grid on the object, with the sensor examining the energy output from each grid box

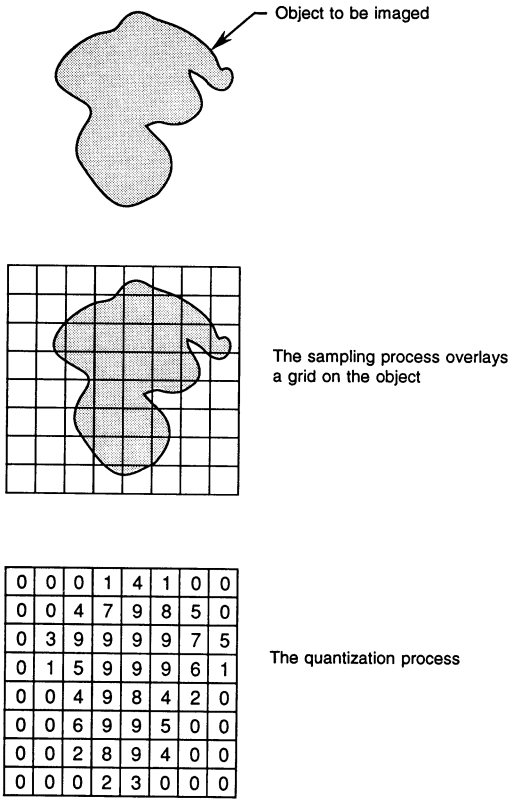

FIGURE 17.1 Digital image formation: sampling and quantization.

and converting it to an electrical signal. The quantization process then assigns a number to the electrical signal; the result, which is a *matrix* of numbers, is the digital representation of the image. Each spatial location in the image (or grid) to which a number is assigned is known as a *picture element* or **pixel** (or pel). The size of the sampling grid is usually given by the number of pixels on each side of the grid, e.g., 256 × 256, 512 × 512, 488 × 380.

The quantization process is necessary because all information to be processed using computers must be represented by numbers. The quantization process can be thought of as one where the input energy to the transducer is represented by a finite number of energy values. If the energy at a particular pixel location does not take on one of the finite energy values, it is assigned to the closest value. For instance, suppose that we assume *a priori* that only energy values of 10, 20, 50, and 110 will be represented (the units are of no concern in this example). Suppose at one pixel an energy of 23.5 was observed by the transducer. The A/D converter would then assign this pixel the energy value of 20 (the closest one). Notice that the quantization process makes mistakes; this error in assignment is known as *quantization* error or *quantization noise.*

In our example, each pixel is represented by one of four possible values. For ease of representation of the data, it would be simpler to assign to each pixel the index value 0, 1, 2, 3, instead of 10, 20, 50, 110. In fact, this is typically done by the quantization process. One needs a simple table to know that a pixel assigned the value 2 corresponds to an energy of 50. Also, the number of possible energy levels is typically some integer power of two to also aid in representation. This power is known as the number of *bits* needed to represent the energy of each pixel. In our example each pixel is represented by two bits.

One question that immediately arises is how accurate the digital representation of the image is when one compares the digital image with a corresponding analog image. It should first be pointed out that after the digital image is obtained one requires special hardware to convert the matrix of pixels back to an image that can be viewed on a CRT display. The process of converting the digital image back to an image that can be viewed is known as *digital-to-analog conversion,* or *D/A conversion.*

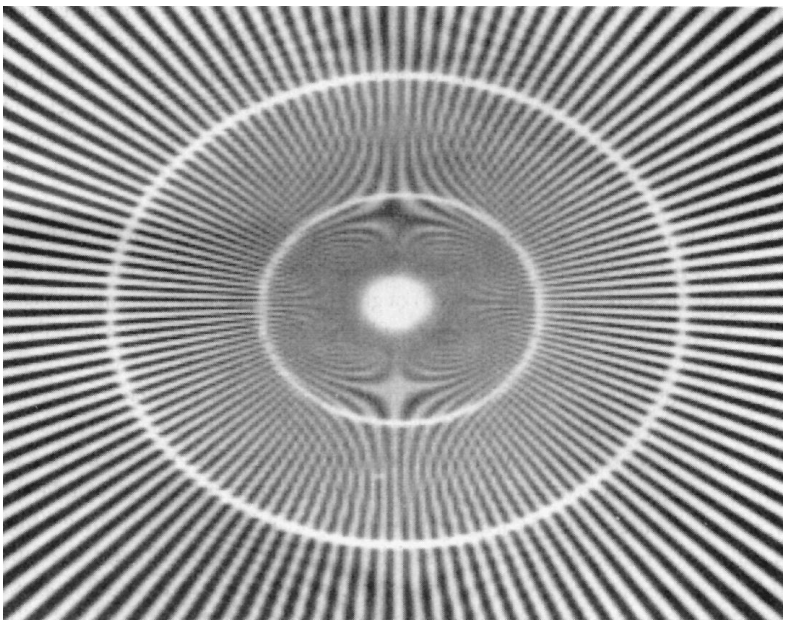

FIGURE 17.2 This image shows the effects of aliasing due to sampling the image at too low a rate. The image should be straight lines converging at a point. Because of undersampling, it appears as if there are patterns in the lines at various angles. These are known as moiré patterns.

The quality of representation of the image is determined by how close spatially the pixels are located and how many levels or numbers are used in the quantization, i.e., how coarse or fine is the quantization. The sampling accuracy is usually measured in how many pixels there are in a given area and is cited in pixels/unit length, i.e., pixels/cm. This is known as the *spatial sampling rate*. One would desire to use the lowest rate possible to minimize the number of pixels needed to represent the object. If the sampling rate is too low, then obviously some details of the object to be imaged will not be represented very well. In fact, there is a mathematical theorem which determines the lowest sampling rate possible to preserve details in the object. This rate is known as the *Nyquist* sampling rate (named after the late Bell Laboratories engineer Harry Nyquist). The theorem states that the sampling rate must be *twice* the highest possible detail one expects to image in the object. If the object has details closer than, say 1 mm, one must take at least 2 pixels/mm. (The Nyquist theorem actually says more than this, but a discussion of the entire theorem is beyond the scope of this section.) If we sample at a lower rate than the theoretical lowest limit, the resulting digital representation of the object will be distorted. This type of distortion or sampling error is known as *aliasing* errors. Aliasing errors usually manifest themselves in the image as moiré patterns (Fig. 17.2). The important point to remember is that there is a *lower limit* to the spatial sampling rate such that object detail can be maintained. The sampling rate can also be stated as the total number of pixels needed to represent the digital image, i.e., the matrix size (or grid size). One often sees these sampling rates cited as 256×256, 512×512, and so on. If the same object is imaged with a large matrix size, the sampling rate has obviously increased. Typically, images are sampled on 256×256, 512×512, or 1024×1024 grids, depending on the application and type of modality. One immediately observes an important issue in digital representation of images: that of the large number of pixels needed to represent the image. A 256×256 image has 65,536 pixels and a 512×512 image has 262,144 pixels! We shall return to this point later when we discuss processing or storage of these images.

The quality of the representation of the digital image is also determined by the number of levels or shades of gray that are used in the quantization. If one has more levels, then fewer mistakes will be made in assigning values at the output of the transducer. Figure 17.3 demonstrates how the number of gray levels affects the digital representation of an artery. When a small number of levels are used, the quantization is coarse and the quantization error is large. The quantization error usually manifests itself in the digital image by the appearance

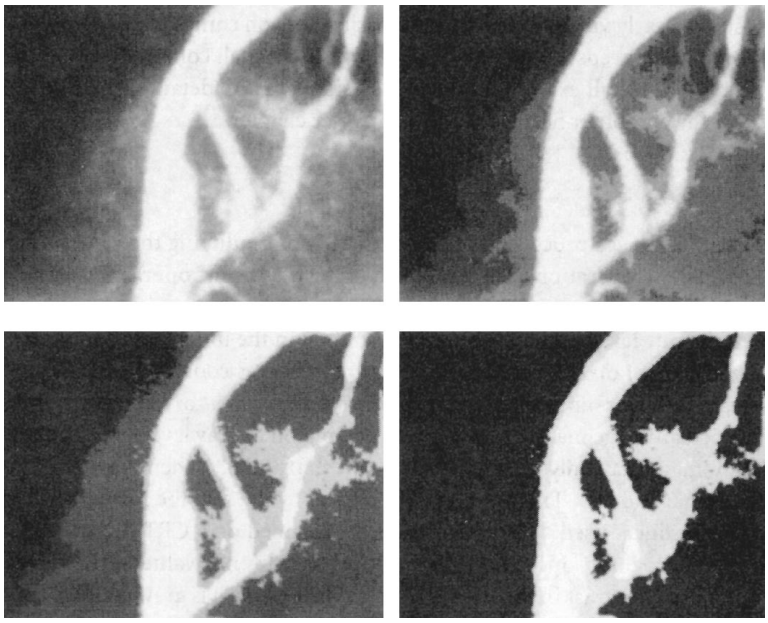

FIGURE 17.3 This image demonstrates the effects of quantization error. The upper left image is a coronary artery image with 8 bits (256 levels or shades of gray) per pixel. The upper right image has 4 bits/pixel (16 levels). The lower left image has 3 bits/pixel (8 levels). The lower right image has 2 bits/pixel (4 levels). Note the false contouring in the images as the number of possible levels in the pixel representation is reduced. This false contouring is the quantization error, and as the number of levels increases the quantization error decreases because fewer mistakes are being made in the representation.

of *false contouring* in the picture. One usually needs at least 6 bits or 64 gray levels to represent an image adequately. Higher-quality imaging systems use 8 bits (256 levels) or even as many as 10 bits (1024 levels) per pixel. In most applications, the human observer cannot distinguish quantization error when there are more than 256 levels. (Many times the number of gray levels is cited in bytes. One byte is 8 bits, i.e., high-quality monochrome digital imaging systems use one byte per pixel.)

One of the problems briefly mentioned previously is the large number of pixels needed to represent an image, which translates into a large amount of digital data needed for the representation. A 512×512 image with 8 bits/pixel (1 byte/pixel) of gray level representation requires 2,097,152 bits of computer data to describe it. A typical computer file that contains 1000 words usually requires only about 56,000 bits to describe it. The 512×512 image is 37 times larger! (A picture is truly worth more than 1000 words.) This data requirement is one of the major problems with digital imaging, given that the storage of digital images in a computer file system is expensive. Perhaps another example will demonstrate this problem. Many computers and word processing systems have the capability of transmitting information over telephone lines to other systems at data rates of 2400 bits per second. At this speed it would require nearly 15 minutes to transmit a 512×512 image! Moving objects are imaged digitally by taking *digital snapshots* of them, i.e., digital video. True digital imaging would acquire about 30 images/s to capture all the important motion in a scene. At 30 images/s, with each image sampled at 512×512 and with 8 bits/pixel, the system must handle 62,914,560 bits/s. Only very expensive acquisition systems are capable of handling these large data rates.

The greatest advantage of digital images is that they can be processed on a computer. Any type of operation that one can do on a computer can be done to a digital image. Recall that a digital image is just a (huge) matrix of numbers. Digital image processing is the process of using a computer to extract useful information from this matrix. Processing that cannot be done optically or with analog systems (such as early video systems) can be easily done on computers. The disadvantage is that a large amount of data needs to be processed and on some small computer systems this can take a long time (hours). We shall examine image processing in more detail in the next subsection and discuss some of the computer hardware issues in a later chapter.

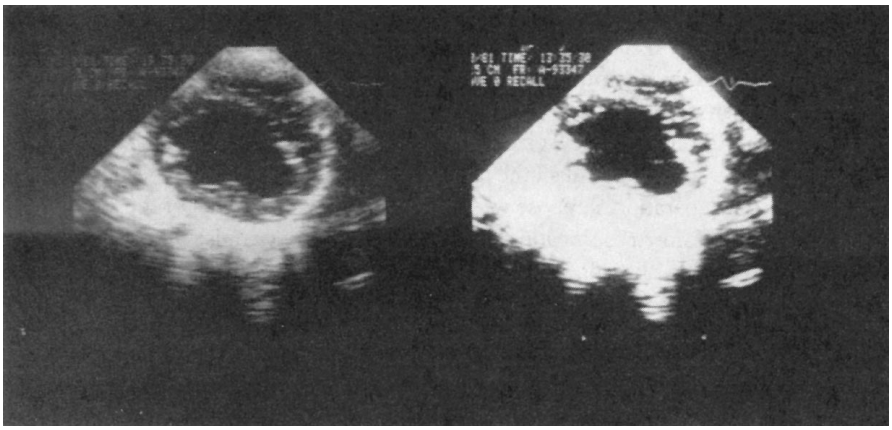

FIGURE 17.4 Contrast stretching. The image on the right has gray values between 0 and 63, causing the contrast to look washed out. The image on the right has been contrast enhanced by multiplying the gray levels by four.

Point Operations

Perhaps the simplest image processing operation is that of modifying the values of individual pixels in an image. These operations are commonly known as **point operations**. A point operation might be used to highlight certain regions in an image. Suppose one wished to know where all the pixels in a certain gray level region were *spatially* located in the image. One would modify all those pixel values to 0 (black) or 255 (white) such that the observer could see where they were located.

Another example of a point operation is *contrast enhancement* or *contrast stretching*. The pixel values in a particular image may occupy only a small region of gray level distribution. For instance, the pixels in an image may only take on values between 0 and 63, when they could nominally take on values between 0 and 255. This is sometimes caused by the way the image was digitized and/or by the type of transducer used. When this image is examined on a CRT display the contrast looks washed out. A simple point operation that multiplies each pixel value in the image by four will increase the apparent contrast in the image; the new image now has gray values between 0 and 252. This operation is shown in Fig. 17.4. Possibly the most widely used point operation in medical imaging is *pseudo-coloring*. In this point operation all the pixels in the image with a particular gray value are assigned a *color*. Various schemes have been proposed for appropriate pseudo-color tables that assign the gray values to colors. It should be mentioned that point operations are often cascaded, i.e., an image undergoes contrast enhancement and then pseudo-coloring.

The operations described above can be thought of as operations (or *algorithms*) that modify the range of the gray levels of the pixels. An important feature that describes a great deal about an image is the *histogram* of the pixel values. A histogram is a table that lists how many pixels in an image take on a particular gray value. These data are often plotted as a function of the gray value. Point operations are also known as *histogram modification* or *histogram stretching*. The contrast enhancement operation shown in Fig. 17.4 modifies the histogram of the resultant image by stretching the gray values from a range of 0–63 to a range of 0–252. Some point operations are such that the resulting histogram of the processed image has a particular shape. A popular form of histogram modification is known as *histogram equalization*, whereby the pixels are modified such that the histogram of the processed image is almost flat, i.e., all the pixel values occur equally.

It is impossible to list all possible types of point operations; however, the important thing to remember is that these operations process one pixel at a time by modifying the pixel based *only* on its gray level value and *not* where it is distributed spatially (i.e., location in the pixel matrix). These operations are performed to enhance the image, make it easier to see certain structures or regions in the image, or to force a particular shape to the histogram of the image. They are also used as initial operations in a more complicated image processing algorithm.

Image Enhancement

Image enhancement is the use of image processing algorithms to remove certain types of distortion in an image. The image is enhanced by removing noise, making the edge structures in the image stand out, or any other operation that makes the image *look* better.[1] Point operations discussed above are generally considered to be enhancement operations. Enhancement also includes operations that use groups of pixels and the spatial location of the pixels in the image.

The most widely used algorithms for enhancement are based on pixel functions that are known as **window operations**. A window operation performed on an image is nothing more than the process of examining the pixels in a certain region of the image, called the window region, and computing some type of mathematical function derived from the pixels in the window. In most cases the windows are square or rectangle, although other shapes have been used. After the operation is performed, the result of the computation is placed in the center pixel of the window where a 3×3 pixel window has been extracted from the image. The values of the pixels in the window, labeled $a_1, a_2, \ldots, a_9$, are used to compute a new pixel value which replaces the value of a_5, and the window is moved to a new center location until all the pixels in the original image have been processed. As an example of a window operation, suppose we computed the average value of the pixels in the window. This operation is known as *smoothing* and will tend to reduce noise in the image, but unfortunately it will also tend to blur edge structures in the image.

Another window operation often used is the computation of a linear weighted sum of the pixel values. Let a'_5 be the new pixel value that will replace a_5 in the original image. We then form

$$a'_5 = \sum_{i=1}^{9} \alpha_i a_i \tag{17.1}$$

where the α_i's are any real numbers. For the simple smoothing operation described above we set $\alpha_i = 1/9$ for all *i*. By changing the values of the α_i weights, one can perform different types of enhancement operations to an image. Any window operation that can be described by Eq. 17.1 is known as a *linear window operation* or *convolution* operator. If some of the α_i coefficients take on negative values, one can enhance the appearance of edge structures in the image.

It is possible to compute a nonlinear function of the pixels in the window. One of the more powerful nonlinear window operations is that of *median filtering*. In this operation all the pixels in the window are listed in descending magnitude and the middle, or *median,* pixel is obtained. The median pixel then is used to replace a_5. The median filter is used to remove noise from an image and at the same time preserve the edge structure in the image. More recently there has been a great deal of interest in *morphological operators*. These are also nonlinear window operations that can be used to extract or enhance shape information in an image.

In the preceding discussion, all of the window operations were described on 3×3 windows. The current research in window operations is directed at using large window sizes, i.e., 9×9, 13×13, or 21×21. The philosophy in this work is that small window sizes only use local information and what one really needs to use is information that is more global in nature.

Digital Image Compression

Image compression refers to the task of reducing the amount of data required to store or transmit a digital image. As discussed earlier, in its natural form, a digital image comprises an array of numbers. Each such

[1]Image enhancement is often confused with *image restoration*. Image enhancement is the ad hoc application of various processing algorithms to enhance the appearance of the image. Image restoration is the application of algorithms that use knowledge of the degradation process to enhance or restore the image, i.e., deconvolution algorithms used to remove the effect of the aperture point spread function in blurred images. A discussion of image restoration is beyond the scope of this section.

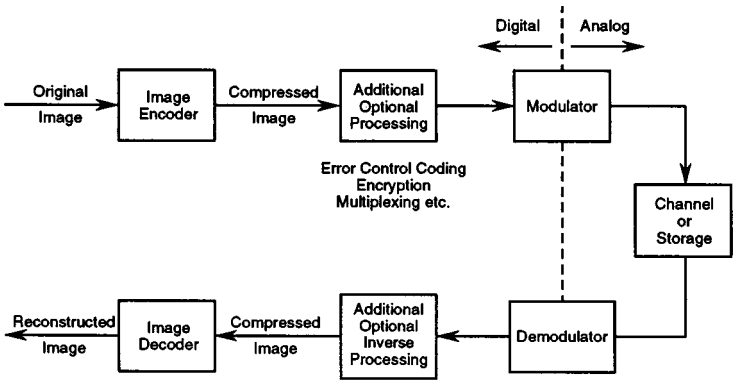

FIGURE 17.5 Overview of an image compression system.

number is the sampled value of the image at a pixel (picture element) location. These numbers are represented with finite precision using a fixed number of bits. Until recently, the dominant image size was 512×512 pixels with 8 bits or 1 byte per pixel. The total storage size for such an image is $512^2 \approx 0.25 \times 10^6$ bytes or 0.25 Mbytes. When digital image processing first emerged in the 1960s, this was considered to be a formidable amount of data, and so interest in developing ways to reduce this storage requirement arose immediately. Since that time, image compression has continued to be an active area of research. The recent emergence of standards for image coding algorithms and the commercial availability of very large scale integration (VLSI) chips that implement image coding algorithms is indicative of the present maturity of the field, although research activity continues apace.

With declining memory costs and increasing transmission bandwidths, 0.25 Mbytes is no longer considered to be the large amount of data that it once was. This might suggest that the need for image compression is not as great as previously. Unfortunately (or fortunately, depending on one's point of view), this is not the case because our appetite for image data has also grown enormously over the years. The old 512×512 pixels $\times$ 1 byte per pixel "standard" was a consequence of the spatial and gray scale resolution of sensors and displays that were commonly available until recently. At this time, displays with more than $10^3 \times 10^3$ pixels and 24 bits/pixel to allow full color representation (8 bits each for red, green, and blue) are becoming commonplace. Thus, our 0.25-Mbyte standard image size has grown to 3 Mbytes. This is just the tip of the iceberg, however. For example, in desktop printing applications, a 4-color (cyan, magenta, yellow, and black) image of an 8.5×11 in.^{2} page sampled at 600 dots per in. requires 134 Mbytes. In remote sensing applications, a typical hyperspectral image contains terrain irradiance measurements in each of 200 10-nm-wide spectral bands at 25-m intervals on the ground. Each measurement is recorded with 12-bit precision. Such data are acquired from aircraft or satellite and are used in agriculture, forestry, and other fields concerned with management of natural resources. Storage of these data from just a 10×10 km^2 area requires 4800 Mbytes.

Figure 17.5 shows the essential components of an image compression system. At the system input, the image is encoded into its compressed form by the image coder. The compressed image may then be subjected to further digital processing, such as error control coding, encryption, or multiplexing with other data sources, before being used to modulate the analog signal that is actually transmitted through the channel or stored in a storage medium. At the system output, the image is processed step by step to undo each of the operations that was performed on it at the system input. At the final step, the image is decoded into its original uncompressed form by the image decoder. Because of the role of the image encoder and decoder in an image compression system, **image coding** is often used as a synonym for image compression. If the reconstructed image is identical to the original image, the compression is said to be **lossless**. Otherwise, it is **lossy**.

Image compression algorithms depend for their success on two separate factors: redundancy and irrelevancy. *Redundancy* refers to the fact that each pixel in an image does not take on all possible values with equal probability, and the value that it does take on is not independent of that of the other pixels in the image. If this were not true, the image would appear as a white noise pattern such as that seen when a television receiver is tuned to an unused channel. From an information-theoretic point of view, such an image contains the

FIGURE 17.6 Key elements of an image encoder.

maximum amount of information. From the point of view of a human or machine interpreter, however, it contains no information at all. *Irrelevancy* refers to the fact that not all the information in the image is required for its intended application. First, under typical viewing conditions, it is possible to remove some of the information in an image without producing a change that is perceptible to a human observer. This is because of the limited ability of the human viewer to detect small changes in luminance over a large area or larger changes in luminance over a very small area, especially in the presence of detail that may mask these changes. Second, even though some degradation in image quality may be observed as a result of image compression, the degradation may not be objectionable for a particular application, such as teleconferencing. Third, the degradation introduced by image compression may not interfere with the ability of a human or machine to extract the information from the image that is important for a particular application. Lossless compression algorithms can only exploit redundancy, whereas lossy methods may exploit both redundancy and irrelevancy.

A myriad of approaches have been proposed for image compression. To bring some semblance of order to the field, it is helpful to identify those key elements that provide a reasonably accurate description of most encoding algorithms. These are shown in Fig. 17.6. The first step is *feature extraction*. Here the image is partitioned into $N \times N$ blocks of pixels. Within each block, a feature vector is computed which is used to represent all the pixels within that block. If the feature vector provides a complete description of the block, i.e., the block of pixel values can be determined exactly from the feature vector, then the feature is suitable for use in a lossless compression algorithm. Otherwise, the algorithm will be lossy. For the simplest feature vector, we let the block size $N = 1$ and take the pixel values to be the features. Another important example for $N = 1$ is to let the feature be the error in the prediction of the pixel value based on the values of neighboring pixels which have already been encoded and, hence, whose values would be known as the decoder. This feature forms the basis for *predictive encoding*, of which differential pulse-code modulation (DPCM) is a special case. For larger size blocks, the most important example is to compute a two-dimensional (2-D) Fourier-like transform of the block of pixels and to use the N^2 transform coefficients as the feature vector. The widely used Joint Photographic Experts Group (JPEG) standard image coder is based on the discrete cosine transform (DCT) with a block size of $N = 8$. In all of the foregoing examples, the block of pixel values can be reconstructed exactly from the feature vector. In the last example, the inverse DCT is used. Hence, all these features may form the basis for a lossless compression algorithm. A feature vector that does not provide a complete description of the pixel block is a vector consisting of the mean and variance of the pixels within the block and an $N \times N$ binary mask indicating whether or not each pixel exceeds the mean. From this vector, we can only reconstruct an approximation to the original pixel block which has the same mean and variance as the original. This feature is the basis for the lossy block truncation coding algorithm. Ideally, the feature vector should be chosen to provide as nonredundant as possible a representation of the image and to separate those aspects of the image that are relevant to the viewer from those that are irrelevant.

The second step in image encoding is **vector quantization**. This is essentially a clustering step in which we partition the feature space into cells, each of which will be represented by a single prototype feature vector. Since all feature vectors belonging to a given cell are mapped to the same prototype, the quantization process is irreversible and, hence, cannot be used as part of a lossless compression algorithm. Figure 17.7 shows an example for a two-dimensional feature space. Each dot corresponds to one feature vector from the image. The X's signify the prototypes used to represent all the feature vectors contained within its quantization cell, the boundary of which is indicated by the dashed lines. Despite the simplicity with which vector quantization may be described, the implementation of a vector quantizer is a computationally complex task unless some structure is imposed on it. The clustering is based on minimizing the distortion between the original and quantized feature vectors, averaged over the entire image. The distortion measure can be chosen to account for the relative sensitivity of the human viewer to different kinds of degradation. In one dimension, the vector quantizer reduces to the Lloyd-Max scalar quantizer.

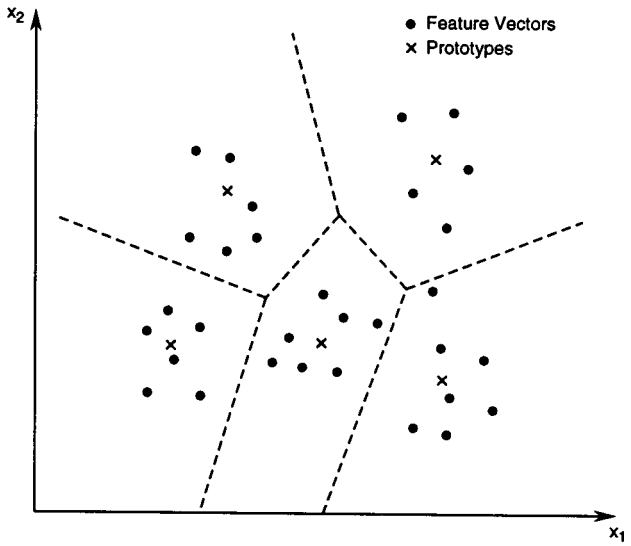

FIGURE 17.7 Vector quantization of a 2-D feature space.

The final step in image encoding is ***entropy*** *coding*. Here we convert the stream of prototype feature vectors to a binary stream of 0's and 1's. Ideally, we would like to perform this conversion in a manner that yields the minimum average number of binary digits per prototype feature vector.

In 1948, Claude Shannon proved that it is possible to code a discrete memoryless source using on the average as few binary digits per source symbol as the *source entropy* defined as

$$H = -\sum_n p_n \log_2 p_n$$

Here p_n denotes the probability or relative frequency of occurrence of the nth symbol in the source alphabet, and $\log_2(x) = \ln(x)/\ln(2)$ is the base 2 logarithm of x. The units of H are bits/source symbol. The proof of Shannon's theorem is based on grouping the source symbols into large blocks and assigning binary code words of varying length to each block of source symbols. More probable blocks of source symbols are assigned shorter code words, whereas less probable blocks are assigned longer code words. As the block length approaches infinity, the bit rate tends to H. Huffman determined the *optimum* variable-length coding scheme for a discrete memoryless source using blocks of any finite length.

Table 17.1 provides an example illustrating the concept of source coding. The source alphabet contains eight symbols with the probabilities indicated. For convenience, these symbols have been labeled in order of decreasing probability. In the context of image encoding, the source alphabet would simply consist of the prototype feature vectors generated by the vector quantizer. The entropy of this source is 2.31 bits/source symbol. If we were to use a fixed-length code for this source, we would need to use three binary digits for each source symbol as shown in Table 17.1. On the other hand, the code words for the Huffman code contain from 1 to 4 code letters (binary digits). In this case, the average code word length

$$\bar{l} = \sum_n p_n l_n$$

is $\bar{l} = 2.31$ binary digits. Here l_n is the number of code letters in the code word for the source symbol a_n. This is the average number of binary digits per source symbol that would be needed to encode the source, and it is equal to the entropy. Thus, for this particular source, the Huffman code achieves the lower bound. It can be shown that in general the rate for the Huffman code will always be within 1 binary digit of the source entropy. By grouping source symbols into blocks of length L and assigning code words to each block, this maximum

TABLE 17.1 A Discrete Source with an Eight-Symbol Alphabet and Two Schemes for Encoding It

Source Symbol	Probability p_n	Fixed-Length Code	Huffman Code
a_1	1/2	000	0
a_2	1/8	001	100
a_3	1/8	010	101
a_4	1/16	011	1100
a_5	1/16	100	1101
a_6	1/16	101	1110
a_7	1/32	110	11110
a_8	1/32	111	11111
	$H = 2.31$ bits/source symbol	$\bar{l} = 3$ binary digits/source symbol	$\bar{l} = 2.31$ binary digits/source symbol

distance can be decreased to $1/L$ binary digits. Note the subtle distinction here between *bits*, which are units of information, a property of the source alone, and *binary digits*, which are units of code word length, and hence only a property of the code used to represent the source. Also note that the Huffman code satisfies the *prefix condition,* i.e., no code word is the prefix of another longer code word. This means that a stream of 0's and 1's may be uniquely decoded into the corresponding sequence of source symbols without the need for markers to delineate boundaries between code words.

The Huffman code is determined from the *binary tree* shown in Fig. 17.8. This tree is constructed recursively by combining the two least probable symbols in the alphabet into one composite symbol whose probability of occurrence is the sum of the probabilities of the two symbols that it represents. The code words for these two symbols are the same as that of the composite symbol with a 0 or a 1 appended at the end to distinguish between them. This procedure is repeated until the reduced alphabet contains only a single code word. Then the code word for a particular source symbol is determined by traversing the tree from its root to the leaf node for that source symbol.

Reconstruction

The objective of **image reconstruction** is to compute an unknown image from many complex measurements of the image. Usually, each measurement depends on many pixels in the image which may be spatially distant from one another.

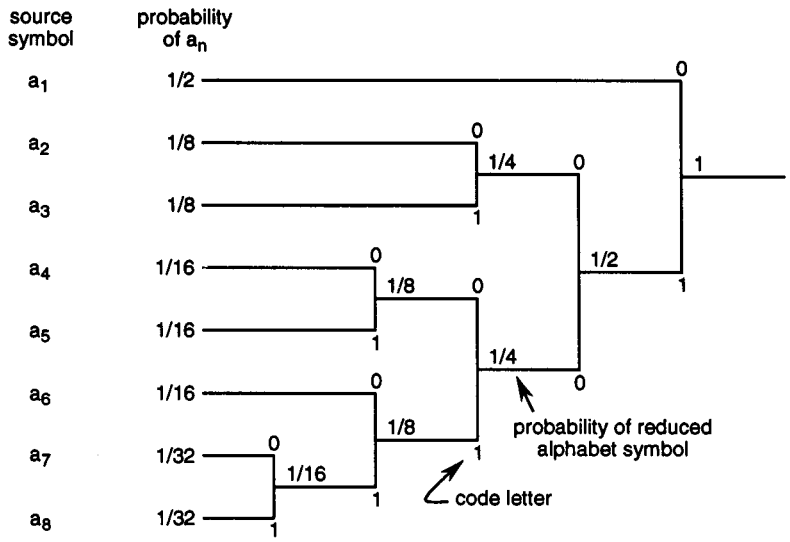

FIGURE 17.8 Binary tree used to generate the Huffman code for the source shown in Table 17.1.

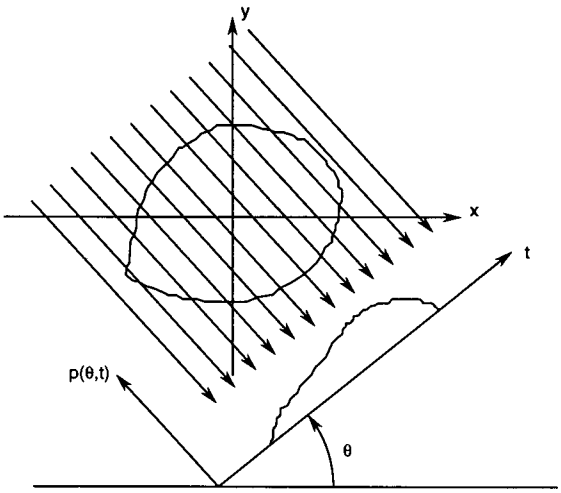

FIGURE 17.9 Projection data for angle θ, resulting in the one-dimensional function $p(\theta,t)$.

A typical reconstruction problem is **tomography**, in which each measurement is obtained by integrating the pixel values along a ray through the image. Figure 17.9 illustrates the measurement of these ray integrals in the **projection** process. For each angle θ a set of ray integrals is computed by varying the position t at which the ray passes through the image. The points along a ray are given by all the solutions (x,y) to the equation

$$t = x \cos\theta + y \sin\theta$$

We may therefore compute the ideal projection integrals by the following expression known as the Radon transform

$$p(\theta, t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y)\delta(t - x\cos\theta - y\sin\theta)dxdy \tag{17.2}$$

where $\delta(t - x\cos\theta - y\sin\theta)$ is an impulse function that is nonzero along the projection ray.

In practice, these projection integrals may be measured using a variety of physical techniques. In transmission tomography, λ_T photons are emitted into an object under test. A detector then counts the number of photons, $\lambda(\theta,t)$, which pass through the object without being absorbed. Collimators are used to ensure the detected energy passes straight through the object along the desired path. Since the attenuation of energy as it passes through the object is exponentially related to the integral of the object's density, the projection integral may be computed from the formula

$$p(\theta,t) = -\log\left(\frac{\lambda(\theta,t)}{\lambda_T}\right)$$

In emission tomography, one wishes to measure the rate of photon emission at each pixel. In this case, various methods may be used to collect and count all the photons emitted along a ray passing through the object.

Once the projections $p(\theta,t)$ have been measured, the objective is to compute the unknown cross section $f(x,y)$. The image and projections may be related by first computing the Fourier transform of the 2-D image

$$F(\omega_x, \omega_y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x,y)e^{j(\omega_x x + \omega_y y)}dxdy$$

and the 1-D projection for each angle

$$P(\theta, \omega) = \int_{-\infty}^{\infty} p(\theta, t) e^{j\omega t} dt$$

These two transforms are then related by the Fourier slice theorem.

$$F(\omega \cos \theta, \omega \sin \theta) = P(\theta, \omega)$$

In words, $P(\theta,\omega)$ corresponds to the value of the 2-D Fourier transform $F(\omega_x, \omega_y)$ along a 1-D line at an angle of θ passing through the origin.

The Fourier slice theorem may be used to develop two methods for inverting the Radon transform and thereby computing the image f. The first method, known as filtered back projection, computes the inverse Fourier transform in polar coordinates using the transformed projection data.

$$f(x, y) = \frac{1}{2\pi} \int_0^{\pi} \int_{-\infty}^{\infty} P(\theta, \omega) |\omega| e^{j\omega(x \cos \theta + y \sin \theta)} d\omega d\theta$$

Notice that the $|\omega|$ term accounts for the integration in polar coordinates.

A second inversion method results from performing all computations in the space domain rather than first transforming to the frequency domain ω. This can be done by expressing the inner integral of filtered back projection as a convolution in the space domain.

$$\frac{1}{2\pi} \int_{-\infty}^{\infty} P(\theta, \omega) |\omega| e^{j\omega s} d\omega = \int_{-\infty}^{\infty} p(\theta, t) h(s - t) dt$$

Here $h(t)$ is the inverse Fourier transform of $|\omega|$. This results in the inversion formula known as convolution back projection

$$f(x, y) = \int_0^{\pi} \int_{-\infty}^{\infty} p(\theta, t) h(x \cos \theta + y \sin \theta - t) dt d\theta$$

In practice, h must be a low-pass approximation to the true inverse Fourier transform of $|\omega|$. This is necessary to suppress noise in the projection data. In practice, the choice of h is the most important element in the design of the reconstruction algorithm.

Edge Detection

The ability to find gray level edge structures in images is an important image processing operation. We shall define an **edge** to be regions in the image where there is a large change in gray level over a relatively small spatial region. The process of finding edge locations in digital images is known as edge detection. Most edge detection operators, also known as edge operators, use a window operator to first enhance the edges in the image, followed by thresholding the enhanced image.

There has been a great deal of research performed in the area of edge detection. Some of the research issues include robust threshold selection, window size selection, noise response, edge linking, and the detection of edges in moving objects. While it is beyond the scope of this section to discuss these issues in detail, it is obvious that such things as threshold selection will greatly affect the performance of the edge detection algorithm. If the threshold is set too high, then many edge points will be missed; if set too low, then many "false" edge points will be obtained because of the inherent noise in the image. The investigation of the "optimal" choice of the threshold is an important research area. Selection of the particular window operation to enhance the edges of an image, as an initial step in edge detection, has recently been based on using models of the performance of the human visual system in detecting edges.

Analysis and Computer Vision

The process of extracting useful measurements from an image or sequence of images is known as *image analysis* or *computer vision*. Before analysis can be performed one must first determine pertinent features or attributes of the object in the scene and extract information about these features. The selection of which features in the image to measure must be chosen *a priori*, based on empirical results. Most features used consist of shape properties, shape change properties, shading, texture, motion, depth, and color. After the features are extracted, one must then use the feature measurements to determine scene characteristics such as object identification. In the past, simple pattern recognition algorithms, i.e., nearest-neighbor classification, have been used to compare the feature measurements of an image to a set of feature measurements that correspond to a known object. A decision is then made as to whether or not the features of the image match those of the known type.

Recently, there has been work in the application of *artificial intelligence* techniques to image analysis. These approaches are very much different from classical statistical pattern recognition in that the feature measurements are used in a different manner as part of a larger system that attempts to model the scene and then determine what is in it based on the model.

Defining Terms

Digital image: An array of numbers representing the spatial distribution of energy in a scene which is obtained by a process of sampling and quantization.

Edge: A localized region of rapid change in gray level in the image.

Entropy: A measure of the minimum amount of information required on the average to store or transmit each quantized feature vector.

Image compression or coding: The process of reducing the number of binary digits or bits required to represent the image.

Image enhancement: An image processing operation that is intended to improve the visual quality of the image or to emphasize certain features.

Image feature: An attribute of a block of image pixels.

Image reconstruction: The process of obtaining an image from nonimage data that characterizes that image.

Lossless vs. lossy compression: If the reconstructed or decoded image is identical to the original, the compression scheme is lossless. Otherwise, it is lossy.

Pixel: A single sample or picture element in the digital image which is located at specific spatial coordinates.

Point operation: An image processing operation in which individual pixels are mapped to new values irrespective of the values of any neighboring pixels.

Projection: A set of parallel line integrals across the image oriented at a particular angle.

Quantization: The process of converting from a continuous-amplitude image to an image that takes on only a finite number of different amplitude values.

Sampling: The process of converting from a continuous-parameter image to a discrete-parameter image by discretizing the spatial coordinate.

Tomography: The process of reconstructing an image from projection data.

Vector quantization: The process of replacing an exact vector of features by a prototype vector that is used to represent all feature vectors contained within a cluster.

Window operation: An image processing operation in which the new value assigned to a given pixel depends on all the pixels within a window centered at that pixel location.

Further Information

A number of textbooks are available that cover the broad area of image processing and several that focus on more specialized topics within this field. The texts by Gonzalez and Wintz [1991], Jain [1989], Pratt [1991], and Rosenfeld and Kak (Vol. 1) [1982] are quite broad in their scope. Gonzalez and Wintz's treatment is written at a somewhat lower level than that of the other texts. For a more detailed treatment of computed tomography and other medical imaging modalities, the reader may consult the texts by Herman [1979], Macovski [1983], and Kak and Slaney [1988]. To explore the field of computer vision, the reader is advised to consult the text by Ballard and Brown [1982]. Current research and applications of image processing are reported in a number of journals. Of particular note are the *IEEE Transactions on Image Processing;* the *IEEE Transactions on Pattern Analysis and Machine Intelligence;* the *IEEE Transactions on Geoscience and Remote Sensing;* the *IEEE Transactions on Medical Imaging;* the *Journal of the Optical Society of America, A: Optical Engineering;* the *Journal of Electronic Imaging;* and *Computer Vision, Graphics, and Image Processing.*

17.2 Video Signal Processing

Sarah A. Rajala

Video signal processing is the area of specialization concerned with the processing of time sequences of image data, i.e., video. Because of the significant advances in computing power and increases in available transmission bandwidth, there has been a proliferation of potential applications in the area of video signal processing. Applications such as high-definition television, digital video, multimedia, video phone, interactive video, medical imaging, and information processing are the driving forces in the field today. As diverse as the applications may seem, it is possible to specify a set of fundamental principles and methods that can be used to develop the applications.

Considerable understanding of a video signal processing system can be gained by representing the system with the block diagram given in Fig. 17.10. Light from a real-world scene is captured by a **scanning system** and causes an image frame $f(x,y,t_0)$ to be formed on a focal plane. A video signal is a sequence of image frames that are created when a scanning system captures a new image frame at periodic intervals in time. In general, each frame of the video sequence is a function of two spatial variables x and y and one temporal variable t. An integral part of the scanning system is the process of converting the original analog signal into an appropriate digital representation. The conversion process includes the operations of sampling and quantization. **Sampling**

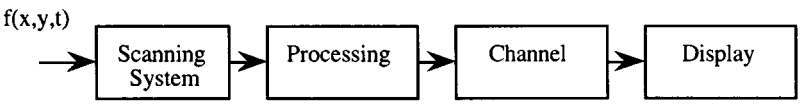

FIGURE 17.10 Video signal processing system block diagram.

is the process of converting a continuous-time/space signal into a discrete-time/space signal. **Quantization** is the process of converting a continuous-valued signal into a discrete-valued signal.

Once the video signal has been sampled and quantized, it can be processed digitally. Processing can be performed on special-purpose hardware or general-purpose computers. The type of processing performed depends on the particular application. For example, if the objective is to generate high-definition television, the processing would typically include compression and motion estimation. In fact, in most of the applications listed above these are the fundamental operations. **Compression** is the process of compactly representing the information contained in an image or video signal. **Motion estimation** is the process of estimating the displacement of the moving objects in a video sequence. The displacement information can then be used to interpolate missing frame data or to improve the performance of compression algorithms.

After the processing is complete, a video signal is ready for transmission over some channel or storage on some medium. If the signal is transmitted, the type of channel will vary depending on the application. For example, today analog television signals are transmitted one of three ways: via satellite, terrestrially, or by cable. All three channels have limited transmission bandwidths and can adversely affect the signals because of the imperfect frequency responses of the channels. Alternatively, with a digital channel, the primary limitation will be the bandwidth.

The final stage of the block diagram shown in Fig. 17.10 is the display. Of critical importance at this stage is the human observer. Understanding how humans respond to visual stimuli, i.e., the psychophysics of vision, will not only allow for better evaluation of the processed video signals but will also permit the design of better systems.

Sampling

If a continuous-time video signal satisfies certain conditions, it can be exactly represented by and be reconstructed from its sample values. The conditions which must be satisfied are specified in the *sampling theorem.* The sampling theorem can be stated as follows:

Sampling Theorem:

Let $f(x,y,t)$ be a bandlimited signal with $F(\omega_x,\omega_y,\omega_t) = 0$ for $|\omega_x| > \omega_{xM}$, $|\omega_y| > \omega_{yM}$, and $|\omega_t| > \omega_{tM}$. Then $f(x,y,t)$ is uniquely determined by its samples $f(jX_S, kY_S, lT_S) = f(j,k,l)$, where $j,k,l = 0, \pm 1, \pm 2, \ldots$ if

$$\omega_{sx} > 2\omega_{xM},\ \omega_{sy} > 2\omega_{yM},\ \text{and}\ \omega_{st} > 2\omega_{tM}$$

and

$$\omega_{sx} = 2\pi/X_S,\ \omega_{sy} = 2\pi/Y_S,\ \text{and}\ \omega_{st} = 2\pi/T_S$$

X_S is the sampling period along the x direction, $\omega_x = 2\pi/X_S$ is the spatial sampling frequency along the x direction, Y_S is the sampling period along the y direction, $\omega_y = 2\pi/Y_S$ is the spatial sampling frequency along the y direction, T_S is the sampling period along the temporal direction, and $\omega_t = 2\pi/T_S$ is the temporal sampling frequency.

Given these samples, $f(x,y,t)$ can be reconstructed by generating a periodic impulse train in which successive impulses have amplitudes that are successive sample values. This impulse train is then processed through an ideal low-pass filter with appropriate gain and cut-off frequencies. The resulting output signal will be exactly equal to $f(x,y,t)$. (*Source:* Oppenheim et al., 1983, p. 519.)

If the sampling theorem is not satisfied, **aliasing** will occur. Aliasing occurs when the signal is undersampled and therefore no longer recoverable by low-pass filtering. Figure 17.11(a) shows the frequency spectrum of a sampled bandlimited signal with no aliasing. Figure 17.11(b) shows the frequency response of the same signal with aliasing. The aliasing occurs at the points where there is overlap in the diamond-shaped regions. For video signals aliasing in the temporal direction will give rise to flicker on the display. For television systems, the standard temporal sampling rate is 30 frames per second in the United States and Japan and 25 frames per second in Europe. However, these rates would be insufficient without the use of interlacing.

If the sampling rate (spatial and/or temporal) of a system is fixed, a standard approach for minimizing the effects of aliasing for signals that do not satisfy the sampling theorem is to use a presampling filter. Presampling

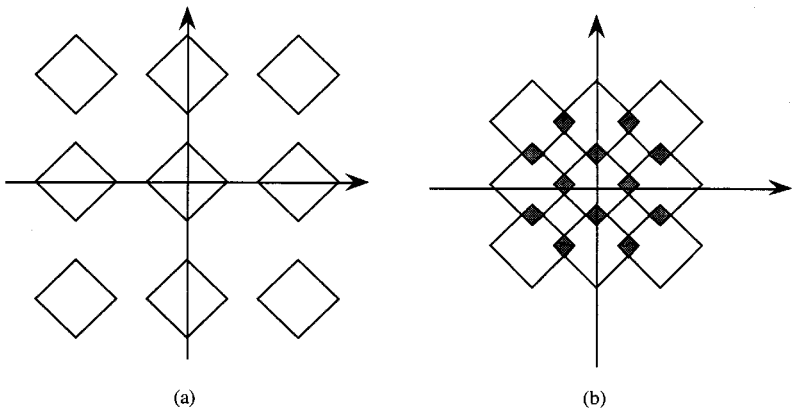

FIGURE 17.11 (a) Frequency spectrum of a sampled signal with no aliasing. (b) Frequency spectrum of a sampled signal with aliasing.

filters are low-pass filters whose cut-off frequencies are chosen to be less than $\omega_M, \omega_M, \omega_M$. Although the signal will still not be able to be reconstructed exactly, the degradations are less annoying. Another problem in a real system is the need for an ideal low-pass filter to reconstruct an analog signal. An ideal filter is not physically realizable, so in practice an approximation must be made. Several very simple filter structures are common in video systems: sample and hold, bilinear, and raised cosine.

Quantization

Quantization is the process of converting the continuous-valued amplitude of the video signal into a discrete-valued representation, i.e., a finite set of numbers. The output of the quantizer is characterized by quantities that are limited to a finite number of values. The process is a many-to-one mapping, and thus there is a loss of information. The quantized signal can be modeled as

$$f_q(j,k,l) = f(j,k,l) - e(j,k,l)$$

where $f_q(j,k,l)$ is the quantized video signal and $e(j,k,l)$ is the quantization noise. If too few bits per sample are used, the quantization noise will produce visible false contours in the image data.

The quantizer is a mapping operation which generally takes the form of a staircase function (see Fig. 17.12). A rule for quantization can be defined as follows: Let $\{d_k, k = 1, 2, \ldots, N+1\}$ be the set of decision levels with d_1 the minimum amplitude value and d_N the maximum amplitude value of $f(j,k,l)$. If $f(j,k,l)$ is contained in the interval (d_k, d_{k+1}), then it is mapped to the kth reconstruction level r. Methods for designing quantizers can be broken into two categories: uniform and nonuniform. The input-output function for a typical uniform quantizer is shown in Fig. 17.12. The mean square value of the quantizing noise can be easily calculated if it is assumed that the amplitude probability distribution is constant within each quantization step. The quantization step size for a uniform quantizer is

$$q = \frac{d_{N+1} - d_1}{N}$$

and all errors between $q/2$ and $-q/2$ are equally likely. The mean square quantization error is given by:

$$\left\langle e^2(j,k,l) \right\rangle = \int_{-q/2}^{q/2} \frac{f^2}{q}\, df = \frac{q^2}{12}$$

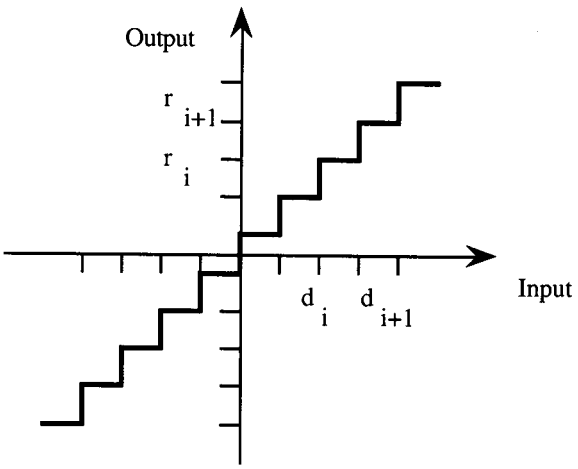

FIGURE 17.12 Characteristics of a uniform quantizer.

If one takes into account the exact amplitude probability distribution, an optimal quantizer can be designed. Here the objective is to choose a set of decision levels and reconstruction levels that will yield the minimum quantization error. If f has a probability density function $p_f(f)$, the mean square quantization error is

$$\left\langle e^2(j,k,l)\right\rangle = \sum_{i=1}^{N} \int_{di}^{di+1} (f - r_i)^2 p_f(f) df$$

where N is the number of quantization levels. To minimize, the mean square quantization error is differentiated with respect to d_i and r_i. This results in the Max quantizer:

$$d_i = \frac{r_i + r_{i-1}}{2}$$

and

$$r_i = \frac{\int_{di}^{di+1} f p_f(f) df}{\int_{di}^{di+1} p_f(f) df}$$

Thus, the quantization levels need to be midway between the reconstruction levels, and the reconstruction levels are at the centroid of that portion of $p_f(f)$ between d_i and f_{d+1}. Unfortunately these requirements do not lead to an easy solution. Max used an iterative numerical technique to obtain solutions for various quantization levels assuming a zero-mean Gaussian input signal. These results and the quantization levels for other standard amplitude distributions can be found in Jain [1989].

A more common and less computationally intense approach to nonuniform quantization is to use a compandor (compressor–expander). The input signal is passed through a nonlinear compressor before being quantized uniformly. The output of the quantizer must then be expanded to the original dynamic range (see Fig. 17.13). The compression and expansion functions can be determined so that the compandor approximates a Max quantizer.

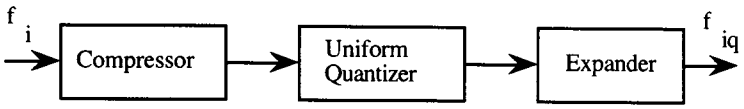

FIGURE 17.13 Nonuniform quantization using a compandor.

Vector Quantization

Quantization does not have to be done on a single pixel at a time. In fact, better results can be achieved if the video data are quantized on a vector (block) basis. In vector quantization, the image data are first processed into a set of vectors. A code book (set of code words or templates) that best matches the data to be quantized is then generated. Each input vector is then quantized to the closest code word. Compression is achieved by transmitting only the indices for the code words. At the receiver, the images are reconstructed using a table look-up procedure. Two areas of ongoing research are finding better methods for designing the code books and developing better search and update techniques for matching the input vectors to the code words.

Video Compression

Digital representations of video signals typically require a very large number of bits. If the video signal is to be transmitted and/or stored, compression is often required. Applications include conventional and high-definition television, video phone, video conferencing, multi-media, remote-sensed imaging, and magnetic resonance imaging. The objective of compression (source encoding) is to find a representation that maximizes picture quality while minimizing the data per picture element (pixel). A wealth of compression algorithms have been developed during the past 30 years for both image and video compression. However, the ultimate choice of an appropriate algorithm is application dependent. The following summary will provide some guidance in that selection process.

Compression algorithms can be divided into two major categories: information-preserving, or lossless, and lossy techniques. Information-preserving techniques introduce no errors in the encoding/decoding process; thus, the original signal can be reconstructed exactly. Unfortunately, the achievable compression rate, i.e., the reduction in bit rate, is quite small, typically on the order of 3:1. On the other hand, lossy techniques introduce errors in the coding/decoding process; thus, the received signal cannot be reconstructed exactly. The advantage of the lossy techniques is the ability to achieve much higher compression ratios. The limiting factor on the compression ratio is the required quality of the video signal in a specific application.

One approach to compression is to reduce the spatial and/or temporal sampling rate and the number of quantization levels. Unfortunately, if the sampling is too low and the quantization too coarse, aliasing, contouring, and flickering will occur. These distortions are often much greater than the distortions introduced by more sophisticated techniques at the same compression rate. Compression systems can generally be modeled by the block diagram shown in Fig. 17.14. The first stage of the compression system is the mapper. This is an operation in which the input pixels are mapped into a representation that can be more effectively encoded. This stage is generally reversible. The second stage is the quantizer and performs the same type of operation as described earlier. This stage is not reversible. The final stage attempts to remove any remaining statistical redundancy. This stage is reversible and is typically achieved with one of the information-preserving coders.

Information-Preserving Coders

The data rate required for an original digital video signal may not represent its average information rate. If the original signal is represented by M possible independent symbols with probabilities p_i, $i = 0, 1,..., M-1$, then the information rate as given by the first-order entropy of the signal H is

$$H = -\sum_{i=1}^{M-1} p_i \log_2 p_i \text{ bits per sample}$$

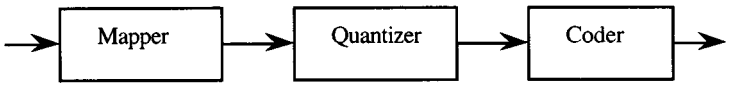

FIGURE 17.14 Three-stage model of an encoder.

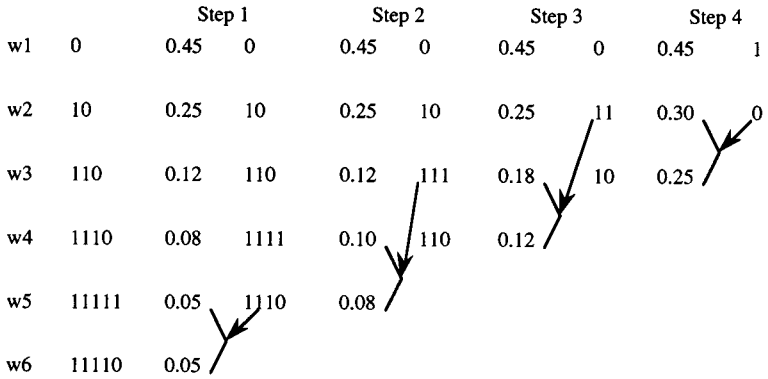

FIGURE 17.15 An example of constructing a Huffman code.

According to Shannon's coding theorem [see Jain, 1989], it is possible to perform lossless coding of a source with entropy H bits per symbol using $H + \varepsilon$ bits per symbol. ε is a small positive quantity. The maximum obtainable compression rate C is then given by:

$$C = \frac{\text{average bit rate of the original data}}{\text{average bit rate of the encoded data}}$$

Huffman Coding

One of the most efficient information-preserving (entropy) coding methods is Huffman coding. Construction of a Huffman code involves arranging the symbol probabilities in decreasing order and considering them as leaf nodes of a tree. The tree is constructed by merging the two nodes with the smallest probability to form a new node. The probability of the new node is the sum of the two merged nodes. This process is continued until only two nodes remain. At this point, 1 and 0 are arbitrarily assigned to the two remaining nodes. The process now moves down the tree, decomposing probabilities and assigning 1's and 0's to each new pair. The process continues until all symbols have been assigned a code word (string of 1's and 0's). An example is given in Fig. 17.15. Many other types of information-preserving compression schemes exist (see, for example, Gonzalez and Wintz [1987]), including arithmetic coding, Lempel-Ziv algorithm, shift coding, and run-length coding.

Predictive Coding

Traditionally one of the most popular methods for reducing the bit rate has been predictive coding. In this class, differential pulse-code modulation (DPCM) has been used extensively. A block diagram for a basic DPCM system is shown in Fig. 17.16. In such a system the difference between the current pixel and a predicted version of that pixel gets quantized, coded, and transmitted to the receiver. This difference is referred to as the prediction error and is given by

$$e_i = f_i - \hat{f}_i$$

The prediction is based on previously transmitted and decoded spatial and/or temporal information and can be linear or nonlinear, fixed or adaptive. The difference signal e_i is then passed through a quantizer. The signal

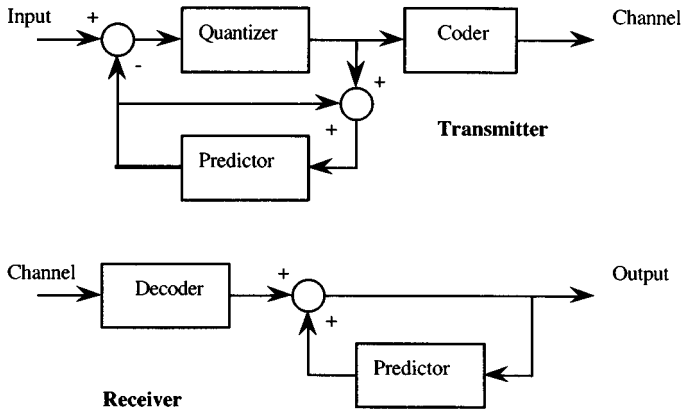

FIGURE 17.16 Block diagram of a basic DPCM system.

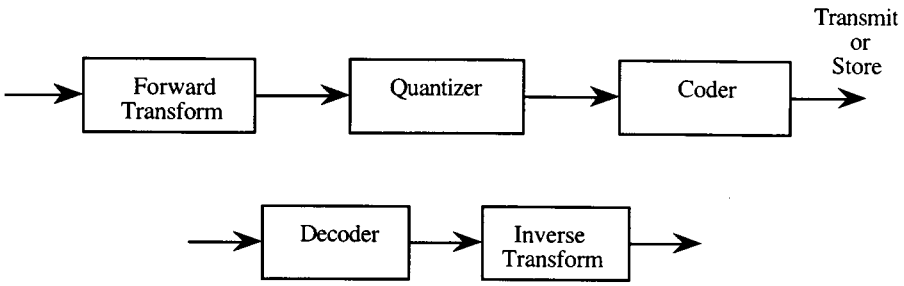

FIGURE 17.17 Transform coding system.

at the output of the quantizer is the quantized prediction error e_{iq}, which is entropy encoded transmission. The first step at the receiver is to decode the quantized prediction error. After decoding, d_{iq} is added to the predicted value of the current pixel $\hat{f}_i$ to yield the reconstructed pixel value. Note that as long as a quantizer is included in the system, the output signal will not exactly equal the input signal.

The predictors can include pixels from the present frame as well as those from previous frames (see Fig. 17.17). If the motion and the spatial detail are not too high, frame (or field) prediction works well. If the motion is high and/or the spatial detail is high, intrafield prediction generally works better. A primary reason is that there is less correlation between frames and fields when the motion is high.

For more information on predictive coding, see Musmann et al. [1985] or Jain [1989].

Motion-Compensated Predictive Coding

Significant improvements in image quality, at a fixed compression rate, can be obtained when adaptive prediction algorithms take into account the frame-to-frame displacement of moving objects in the sequence. Alternatively, one could increase the compression rate for a fixed level of image quality. The amount of increase in performance will depend on one's ability to estimate the motion in the scene. Techniques for estimating the motion are described in a later subsection.

Motion-compensated prediction algorithms can be divided into two categories. One category estimates the motion on a block-by-block basis and the other estimates the motion one pixel at a time. For the block-based methods an estimate of the displacement is obtained for each block in the image. The block matching is achieved by finding the maximum correlation between a block in the current frame and a somewhat larger search area in the previous frame. A number of researchers have proposed ways to reduce the computational complexity,

including using a simple matching criterion and using logarithmic searches for finding the peak value of the correlation.

The second category obtains a displacement estimate at each pixel in a frame. These techniques are referred to as pel recursive methods. They tend to provide more accurate estimates of the displacement but at the expense of higher complexity. Both categories of techniques have been applied to video data; however, block matching is used more often in real systems. The primary reason is that more efficient implementations have been feasible. It should be noted, however, that every pixel in a block will be assigned the same displacement estimate. Thus, the larger the block size the greater the potential for errors in the displacement estimate for a given pixel. More details can be found in Musmann et al. [1985].

Transform Coding

In transform coding, the video signal $f(x,y,t)$ is subjected to an invertible transform, then quantized and encoded (see Fig. 17.17). The purpose of the transformation is to convert statistically dependent picture elements into a set of statistically independent coefficients. In practice, one of the separable fast transforms in the class of unitary transforms is used, e.g., cosine, Fourier, or Hadamard. In general, the transform coding algorithms can be implemented in 2-D or 3-D. However, because of the real-time constraints of many video signal processing applications, it is typically more efficient to combine a 2-D transform with a predictive algorithm in the temporal direction, e.g., motion compensation.

For 2-D transform coding the image data are first subdivided into blocks. Typical block sizes are 8×8 or 16×16. The transform independently maps each image block into a block of transform coefficients; thus, the processing of each block can be done in parallel. At this stage the data have been mapped into a new representation, but no compression has occurred. In fact, with the Fourier transform there is an expansion in the amount of data. This occurs because the transform generates coefficients that are complex-valued. To achieve compression the transform coefficients must be quantized and then coded to remove any remaining redundancy.

Two important issues in transform coding are the choice of transformation and the allocation of bits in the quantizer. The most commonly used transform is the discrete cosine transform (DCT). In fact, many of the proposed image and video standards utilize the DCT. The reasons for choosing a DCT include: its performance is superior to the other fast transforms and is very close to the optimal Karhunen-Loeve transform, it produces real-valued transform coefficients, and it has good symmetry properties, thus reducing the blocking artifacts inherent in block-based algorithms. One way to reduce these artifacts is by using a transform whose basis functions are even, i.e., the DCT, and another is to use overlapping blocks. For bit allocation, one can determine the variance of the transform coefficients and then assign the bits so the distortion is minimized. An example of a typical bit allocation map is shown in Fig. 17.18.

FIGURE 17.18 A typical bit allocation for 16×16 block coding of an image using the DCT.

Subband Coding

Recently, subband coding has proved to be an effective technique for image compression. Here, the original video signal is filtered into a set of bandpass signals (subbands), each sampled at successively lower rates. This process is known as the subband analysis stage. Each of the bandpass images is then quantized and encoded for transmission/storage. At the receiver, the signals must be decoded and then an image reconstructed from the subbands. The process at the receiver is referred to as the subband synthesis stage. A one-level subband

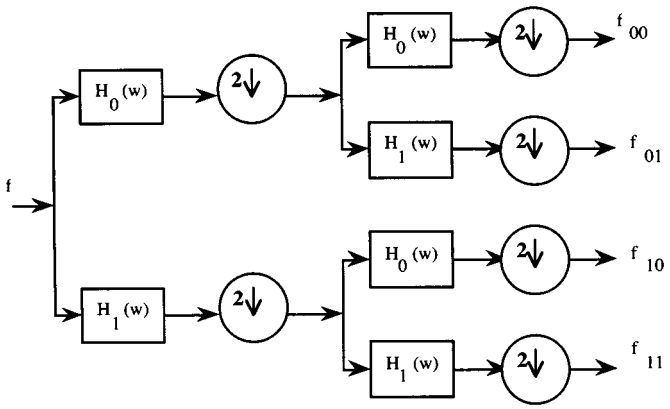

FIGURE 17.19 A two-dimensional subband analysis system for generating four equal subbands.

analysis results in 4 subbands and a 2-level analysis in 16 equal subbands or 7 unequal subbands. A block diagram for a separable two-dimensional subband analysis system is shown in Fig. 17.19.

HDTV

High-definition television (HDTV) has received much attention in the past few years. With the recent push for all digital implementations of HDTV, the need for video signal processing techniques has become more obvious. In order for the digital HDTV signal to fit in the transmission bandwidth, there is a need for a compression ratio of approximately 10:1, with little or no degradation introduced. The goal of HDTV is to produce high-quality video signals by enhancing the detail, improving the aspect ratio and the viewing distance. The detail is enhanced by increasing the video bandwidth. The proposed aspect ratio of 16/9 will allow for a wide-screen format which is more consistent with the formats used in the motion-picture industry. The eye's ability to resolve fine detail is limited. To achieve full resolution of the detail, the HDTV image should be viewed at a distance of approximately three times the picture height. To accommodate typical home viewing environments, larger displays are needed.

Motion Estimation Techniques

Frame-to-frame changes in luminance are generated when objects move in video sequences. The luminance changes can be used to estimate the displacement of the moving objects if an appropriate model of the motion is specified. A variety of motion models have been developed for dynamic scene analysis in machine vision and for video communications applications. In fact, motion estimates were first used as a control mechanism for the efficient coding of a sequence of images in an effort to reduce the temporal redundancy. Motion estimation algorithms can be classified in two broad categories: gradient or differential-based methods and token matching or correspondence methods. The gradient methods can be further divided into pel recursive, block matching, and optical flow methods.

Pel Recursive Methods

Netravali and Robbins [1979] developed the first pel recursive method for television signal compression. The algorithm begins with an initial estimate of the displacement, then iterates recursively to update the estimate. The iterations can be performed at a single pixel or at successive pixels along a scan line. The true displacement **D** at each pixel is estimated by

$$\hat{\mathbf{D}}^i = \hat{\mathbf{D}}^{i-1} + \mathbf{U}^i$$

where $\hat{\mathbf{D}}^i$ is the displacement estimate at the ith iteration and $\mathbf{U}^i$ is the update term. $\mathbf{U}^i$ is an estimate of $\mathbf{D} - \hat{\mathbf{D}}^{i-1}$. They then used the displaced frame difference (DFD):

$$DFD(x, y, \hat{\mathbf{D}}^{i-1}) = I(x, y, t) - I(x - \hat{\mathbf{D}}^{i-1}, t - T_S)$$

to obtain a relationship for the update term $\mathbf{U}^i$. In the previous equation, T_S is the temporal sample spacing. If the displacement estimate is updated from sample to sample using a steepest-descent algorithm to minimize the weighted sum of the squared displaced frame differences over a neighborhood, then $\hat{\mathbf{D}}^i$ becomes

$$\hat{\mathbf{D}}^i = \hat{\mathbf{D}}^{i-1} - \frac{\varepsilon}{2} \nabla \hat{\mathbf{D}}^i \left[\sum_j W_j [DFD(x_{k-j}, \hat{\mathbf{D}}^{i-1})]^2 \right]$$

where $W_j \geq 0$ and

$$\sum_j W_j = 1$$

A graphical representation of pel recursive motion estimation is shown in Fig. 17.20.

A variety of methods to calculate the update term have been reported. The advantage of one method over another is mainly in the improvement in compression. It should be noted that pel recursive algorithms assume that the displacement to be estimated is small. If the displacement is large, the estimates will be poor. Noise can also affect the accuracy of the estimate.

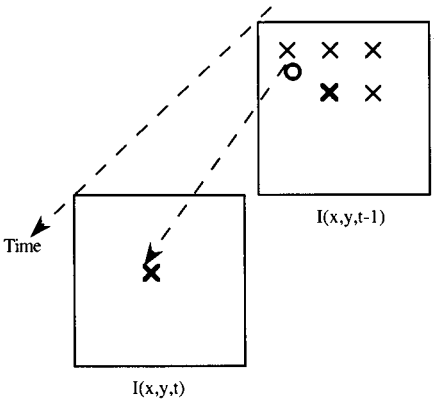

FIGURE 17.20 A graphical illustration of pel recursive motion estimation. The distance between the x and o pixels in the frame at $t - 1$ is $\hat{\mathbf{D}}^{i-1}$.

Block Matching

Block matching methods estimate the displacement within an $M \times N$ block in an image frame. The estimate is determined by finding the best match between the $M \times N$ block in a frame at time t and its best match from frame at $t - T_S$. An underlying assumption in the block matching techniques is that each pixel within a block has the same displacement. A general block matching algorithm is given as follows:

1. Segment the image frame at time t into a fixed number of blocks of size $M \times N$.
2. Specify the size of the search area in the frame at time $t - 1$. This depends on the maximum expected displacement. If $D_{\max}$ is the maximum displacement in either the horizontal or vertical direction, then the size of the search area, SA, is

$$\text{SA} = (M + 2D_{\max}) \times (N + 2D_{\max})$$

   Figure 17.21 illustrates the search area in the frame at time $t - 1$ for an $M \times N$ block at time t.
3. Using an appropriately defined matching criterion, e.g., mean-squared error or sum of absolute difference, find the best match for the $M \times N$ block.
4. Proceed to the next block in frame t and repeat step 3 until displacement estimates have been determined for all blocks in the image.

Optical Flow Methods

The optical flow is defined as the apparent motion of the brightness patterns from one frame to the next. The optical flow is an estimate of the velocity field and hence requires two equations to solve for it. Typically a

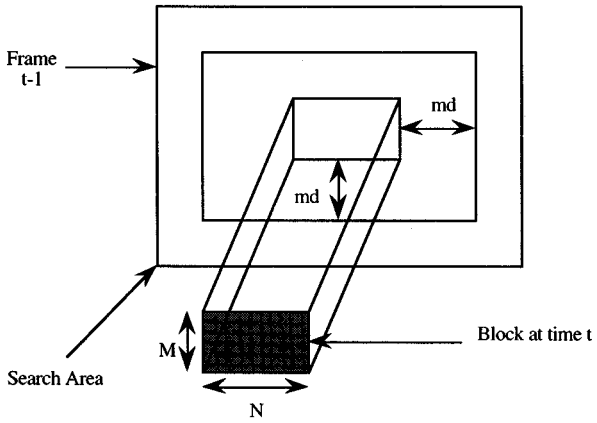

FIGURE 17.21 An illustration of block matching.

constraint is imposed on the motion model to provide the necessary equations. Optical flow can give useful information about the spatial arrangement of the objects in a scene, as well as the rate of change of those objects. Horn [1986] also defines a motion field, which is a two-dimensional velocity field resulting from the projection of the three-dimensional velocity field of an object in the scene onto the image plane. The motion field and the optical flow are not the same.

In general, the optical flow has been found difficult to compute because of the algorithm sensitivity to noise. Also, the estimates may not be accurate at scene discontinuities. However, because of its importance in assigning a velocity vector at each pixel, there continues to be research in the field.

The optical flow equation is based on the assumption that the brightness of a pixel at location (x,y) is constant over time; thus,

$$I_x \frac{dx}{dt} + I_y \frac{dy}{dt} + I_t = 0$$

where dx/dt and dy/dt are the components of the optical flow. Several different constraints have been used with the optical flow equation to solve for dx/dt and dy/dt. A common constraint to impose is that the velocity field is smooth.

Token Matching Methods

Token matching methods are often referred to as discrete methods since the goal is to estimate the motion only at distinct image features (tokens). The result is a sparse velocity field. The algorithms attempt to match the set of discrete features in the frame at time $t-1$ with a set that best resembles them in the frame at time t. Most of the algorithms in this group assume that the estimation will be achieved in a two-step process. In the first step, the features are identified. The features could be points, corners, centers of mass, lines, or edges. This step typically requires segmentation and/or feature extraction. The second step determines the various velocity parameters. The velocity parameters include a translation component, a rotation component, and the rotation axis. The token matching algorithms fail if there are no distinct features to use.

All of the methods described in this subsection assume that the intensity at a given pixel location is reasonably constant over time. In addition, the gradient methods assume that the size of the displacements is small. Block matching algorithms have been used extensively in real systems, because the computational complexity is not too great. The one disadvantage is that there is only one displacement estimate per block. To date, optical flow algorithms have found limited use because of their sensitivity to noise. Token matching methods work well for applications in which the features are well defined and easily extracted. They are probably not suitable for most video communications applications.

TABLE 17.2 Quality and Impairment Ratings

5 Excellent	5 Imperceptible	3 Much better
4 Good	4 Perceptible but not annoying	2 Better
3 Fair	3 Slightly annoying	1 Slightly better
2 Poor	2 Annoying	0 Same
1 Bad	1 Very annoying	–1 Slightly worse
		–2 Worse
		–3 Much worse

Image Quality and Visual Perception

An important factor in designing video signal processing algorithms is that the final receiver of the video information is typically a human observer. This has an impact on how the quality of the final signal is assessed and how the processing should be performed. If our objective is video transmission over a limited bandwidth channel, we do not want to waste unnecessary bits on information that cannot be seen by the human observer. In addition, it is undesirable to introduce artifacts that are particularly annoying to the human viewer. Unfortunately, there are no perfect quantitative measures of visual perception. The human visual system is quite complicated. In spite of the advances that have been made, no complete model of human perception exists. Therefore, we often have to rely on subjective testing to evaluate picture quality. Although no comprehensive model of human vision exists, certain functions can be characterized and then used in designing improved solutions. For more information, see Netravali and Haskell [1988].

Subjective Quality Ratings

There are two primary categories of subjective testing: *category-judgment* (*rating-scale*) methods and *comparison* methods. Category-judgment methods ask the subjects to view a sequence of pictures and assign each picture (video sequence) to one of several categories. Categories may be based on overall quality or on visibility of impairment (see Table 17.2).

Comparison methods require the subjects to compare a distorted test picture with a reference picture. Distortion is added to the test picture until both pictures appear of the same quality to the subject. Viewing conditions can have a great impact on the results of such tests. Care must be taken in the experimental design to avoid biases in the results.

Visual Perception

In this subsection, a review of the major aspects of human psychophysics that have an impact in video signal processing is given. The phenomena of interest include light adaptation, visual thresholding and contrast sensitivity, masking, and temporal phenomena.

Light Adaptation

The human visual system (HVS) has two major classes of photoreceptors, the rods and the cones. Because these two types of receptors adapt to light differently, two different adaptation time constants exist. Furthermore, these receptors respond at different rates going from dark to light than from light to dark. It should also be noted that although the HVS has an ability to adapt to an enormous range of light intensity levels, on the order of 10^{10} in millilamberts, it does so adaptively. The simultaneous range is on the order of 10^3.

Visual Thresholding and Contrast Sensitivity

Determining how sensitive an observer is to small changes in luminance is important in the design of video systems. One's sensitivity will determine how visible noise will be and how accurately the luminance must be represented. The contrast sensitivity is determined by measuring the just-noticeable difference (JND) as a

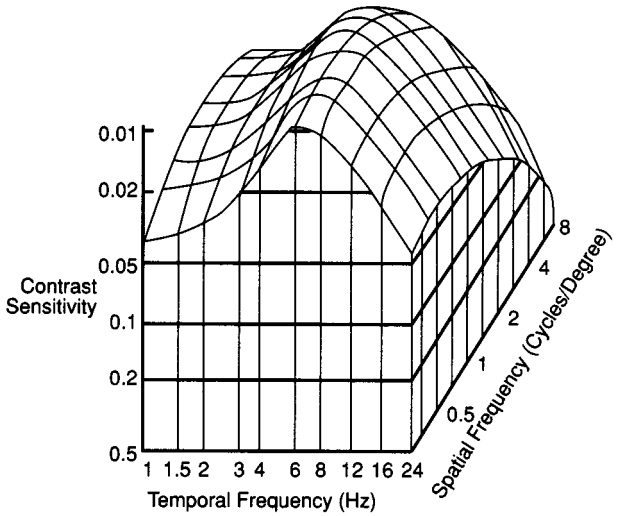

FIGURE 17.22 A perspective view of the spatio-temporal threshold surface.

function of the brightness. The JND is the amount of additional brightness needed to distinguish a patch from the background. It is a visibility threshold. What is significant is that the JND is dependent on the background and surrounding luminances, the size of the background and surrounding areas, and the size of the patch, with the primary dependence being on the luminance of the background.

Masking

The response to visual stimuli is greatly affected by what other visual stimuli are in the immediate neighborhood (spatially and temporally). An example is the reduced sensitivity of the HVS to noise in areas of high spatial activity. Another example is the masking of details in a new scene by what was present in the previous scene. In both cases, the masking phenomenon can be used to improve the quality of image compression systems.

Temporal Effects

One relevant temporal phenomenon is the flicker fusion frequency. This is a temporal threshold which determines the point at which the HVS fuses the motion in a sequence of frames. Unfortunately this frequency varies as a function of the average luminance. The HVS is more sensitive to flicker at high luminances than at low luminances. The spatial-temporal frequency response of the HVS is important in determining the sensitivity to small-amplitude stimuli. In both the temporal and spatial directions, the HVS responds as a bandpass filter (see Fig. 17.22). Also significant is the fact that the spatial and temporal properties are not independent of one another, especially at low frequencies.

For more details on image quality and visual perception see Schreiber [1991] and Netravali and Haskell [1988].

Defining Terms

Aliasing: Distortion introduced in a digital signal when it is undersampled.
Compression: Process of compactly representing the information contained in a signal.
Motion estimation: Process of estimating the displacement of moving objects in a scene.
Quantization: Process of converting a continuous-valued signal into a discrete-valued signal.
Sampling: Process of converting a continuous-time/space signal into a discrete-time/space signal.
Scanning system: System used to capture a new image at periodic intervals in time and to convert the image into a digital representation.

17.3 Sensor Array Processing

N. K. Bose and L. H. Sibul

Multidimensional signal processing tools apply to aperture and sensor array processing. Planar sensor arrays can be considered to be sampled apertures. Three-dimensional or volumetric arrays can be viewed as multidimensional spatial filters. Therefore, the topics of sensor array processing, aperture processing, and multidimensional signal processing can be studied under a unified format. The basic function of the receiving array is transduction of propagating waves in the medium into electrical signals. Propagating waves are fundamental in radar, communication, optics, sonar, and geophysics. In electromagnetic applications, basic transducers are antennas and arrays of antennas. A large body of literature that exists on antennas and antenna arrays can be exploited in the areas of aperture and sensor array processing. Much of the antenna literature deals with transmitting antennas and their radiation patterns. Because of the reciprocity of transmitting and receiving transducers, key results that have been developed for transmitters can be used for analysis of receiver aperture and/or array processing. Transmitting transducers radiate energy in desired directions, whereas receiving apertures/arrays act as spatial filters that emphasize signals from a desired look direction while discriminating against interferences from other directions. The spatial filter **wavenumber** response is called the receiver beam pattern. Transmitting apertures are characterized by their radiation patterns.

Conventional beamforming deals with the design of fixed beam patterns for given specifications. Optimum beamforming is the design of beam patterns to meet a specified optimization criterion. It can be compared to optimum filtering, detection, and estimation. Adaptive **beamformers** sense their operating environment (for example, noise covariance matrix) and adjust beamformer parameters so that their performance is optimized [Monzingo and Miller, 1980]. Adaptive beamformers can be compared with adaptive filters.

Multidimensional signal processing techniques have found wide application in seismology—where a group of identical seismometers, called seismic arrays, are used for event location, studies of the earth's sedimentation structure, and separation of coherent signals from noise, which sometimes may also propagate coherently across the array but with different horizontal velocities—by employing **velocity filtering** [Claerbout, 1976]. Velocity filtering is performed by multidimensional filters and allows also for the enhancement of signals which may occupy the same wavenumber range as noise or undesired signals do. In a broader context, beamforming can be used to separate signals received by sensor arrays based on frequency, wavenumber, and velocity (speed as well as direction) of propagation. Both the transfer and unit impulse-response functions of a velocity filter are two-dimensional functions in the case of one-dimensional arrays. The transfer function involves frequency and wavenumber (due to spatial sampling by equally spaced sensors) as independent variables, whereas the unit impulse response depends upon time and location within the array. Two-dimensional filtering is not limited to velocity filtering by means of seismic array. Two-dimensional spatial filters are frequently used, for example, in the interpretation of gravity and magnetic maps to differentiate between regional and local features. Input data for these filters may be observations in the survey of an area conducted over a planar grid over the earth's surface. Two-dimensional wavenumber digital filtering principles are useful for this purpose. Velocity filtering by means of two-dimensional arrays may be accomplished by properly shaping a three-dimensional response function $H(k_1,k_2,\omega)$. Velocity filtering by three-dimensional arrays may be accomplished through a four-dimensional function $H(k_1,k_2,k_3,\omega)$ as explained in the following subsection.

Spatial Arrays, Beamformers, and FIR Filters

A propagating plane wave, $s(\mathbf{x},t)$, is, in general, a function of the three-dimensional space variables and the time variable $(x_1, x_2, x_3) \Delta = \mathbf{x}$ and the time variable t. The 4-D Fourier transform of the stationary signal $s(\mathbf{x},t)$ is

$$S(\mathbf{k},\omega) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} s(\mathbf{x},t)e^{-j(\omega t-\sum_{i=1}^{3}k_i x_i)}dx_1dx_2dx_3dt \tag{17.3}$$

which is referred to as the wavenumber–frequency spectrum of $s(\mathbf{x},t)$, and $(k_1,k_2,k_3) \underline{\underline{\Delta}}\ \mathbf{k}$ denotes the wavenumber variables in radians per unit distance and ω is the frequency variable in radians per second. If c denotes the velocity of propagation of the plane wave, the following constraint must be satisfied

$$k_1^2 + k_2^2 + k_3^2 = \frac{\omega^2}{c^2}$$

If the 4-D Fourier transform of the unit impulse response $h(\mathbf{x},t)$ of a 4-D linear shift-invariant (LSI) filter is denoted by $H(k,\omega)$, then the response $y(\mathbf{x},t)$ of the filter to $s(\mathbf{x},t)$ is the 4-D linear convolution of $h(\mathbf{x},t)$ and $s(\mathbf{x},t)$, which is, uniquely, characterized by its 4-D Fourier transform

$$Y(\mathbf{k},\omega) = H(\mathbf{k},\omega)S(\mathbf{k},\omega) \tag{17.4}$$

The inverse 4-D Fourier transform, which forms a 4-D Fourier transform pair with Eq. (17.3), is

$$s(\mathbf{x},t) = \frac{1}{(2\pi)^4}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} S(\mathbf{k},\omega)e^{j(\omega t-\sum_{i=1}^{3}k_i x_i)}dk_1dk_2dk_3d\omega \tag{17.5}$$

It is noted that $S(\mathbf{k},\omega)$ in Eq. (17.3) is product separable, i.e., expressible in the form

$$S(\mathbf{k},\omega) = S_1(k_1)\,S_2(k_2)\,S_3(k_3)\,S_4(\omega) \tag{17.6}$$

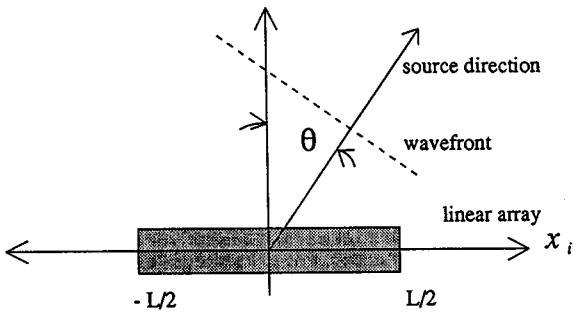

FIGURE 17.23 Uniformly weighted linear array.

where each function on the right-hand side is a univariate function of the respective independent variable, if and only if $s(\mathbf{x},t)$ in Eq. (17.3) is also product separable. In beamforming, $S_i(k_i)$ in Eq. (17.6) would be the far-field beam pattern of a linear array along the x_i-axis. For example, the normalized beam pattern of a uniformly weighted (shaded) linear array of length L is

$$S(k,\theta) = \frac{\sin\left(\frac{kL\sin\theta}{2}\right)}{\left(\frac{kL}{2}\sin\theta\right)}$$

where $\lambda = (2\pi/k)$ is the wavelength of the propagating plane wave and θ is the angle of arrival at array site as shown in Fig. 17.23. Note that θ is explicitly admitted as a variable in $S(k,\theta)$ to allow for the possibility that for a fixed wavenumber, the beam pattern could be plotted as a function of the angle of arrival. In that case, when θ is zero, the wave impinges the array broadside and the normalized beam pattern evaluates to unity.

The counterpart, in aperture and sensor array processing, of the use of window functions in spectral analysis for reduction of sidelobes is the use of aperture shading. In aperture shading, one simply multiplies a uniformly weighted aperture by the shading function. The resulting beam pattern is, then, simply the convolution of the beam pattern of the uniformly shaded volumetric array and the beam pattern of the shading function. Fourier transform relationship between the stationary signal $s(\mathbf{x},t)$ and the wavenumber frequency spectrum $S(\mathbf{k},\omega)$ allows one to exploit high-resolution spectral analysis techniques for the high-resolution estimation of the direction of arrival [Pillai, 1989]. The superscript *, t, and H denote, respectively, complex conjugate, transpose, and conjugate transpose.

Discrete Arrays for Beamforming

An array of sensors could be distributed at distinct points in space in various ways. Line arrays, planar arrays, and volumetric arrays could be either uniformly spaced or nonuniformly spaced, including the possibility of placing sensors randomly according to some probability distribution function. Uniform spacing along each coordinate axis permits one to exploit the well-developed multidimensional signal processing techniques concerned with filter design, DFT computation via FFT, and high-resolution spectral analysis of sampled signals [Dudgeon, 1977]. Nonuniform spacing sometimes might be useful for reducing the number of sensors, which otherwise might be constrained to satisfy a maximum spacing between uniformly placed sensors to avoid **grating lobes** due to aliasing, as explained later. A discrete array, uniformly spaced, is convenient for the synthesis of a digital filter or beamformer by the performing of digital signal processing operations (namely delay, sum, and multiplication or weighting) on the signal received by a collection of sensors distributed in space. The sequence of the nature of operations dictates the types of beamformer. Common beamforming systems are of

the straight summation, delay-and-sum, and weighted delay-and-sum types. The geometrical distribution of sensors and the weights w_i associated with each sensor are crucial factors in the shaping of the filter characteristics. In the case of a linear array of N equispaced sensors, which are spaced D units apart, starting at the origin $x_1 = 0$, the function

$$W(k_1) = \frac{1}{N} \sum_{n=0}^{N-1} w_n e^{-jk_1 nD} \tag{17.8}$$

becomes the **array pattern**, which may be viewed as the frequency response function for a finite impulse response (FIR) filter, characterized by the unit impulse response sequence $\{w_n\}$. In the case when $w_n = 1$, Eq. (17.8) simplifies to

$$W(k_1) = \frac{1}{N} \frac{\sin\left(\dfrac{k_1 ND}{2}\right)}{\sin\left(\dfrac{k_1 D}{2}\right)} \exp\left\{-j \frac{(N-1)k_1 D}{2}\right\}$$

If the N sensors are symmetrically placed on both sides of the origin, including one at the origin, and the sensor weights are $w_n = 1$, then the linear array pattern becomes

$$W(k_1) = \frac{1}{N} \frac{\sin\left(\dfrac{k_1 ND}{2}\right)}{\sin\left(\dfrac{k_1 D}{2}\right)}$$

For planar arrays, direct generalizations of the preceding linear array results can be obtained. To wit, if the sensors with unity weights are located at coordinates (kD, lD), where $k = 0, \pm 1, \pm 2, \ldots, \pm[(N-1)/2]$, and $l = 0, \pm 1, \pm 2, \ldots, \pm[(M-1)/2]$, for odd integer values of N and M, then the array pattern function becomes

$$\begin{aligned} W(k_1, k_2) &= \frac{1}{NM} \sum_{k=-\left(\frac{N-1}{2}\right)}^{\left(\frac{N-1}{2}\right)} \sum_{l=-\left(\frac{M-1}{2}\right)}^{\left(\frac{M-1}{2}\right)} \exp\{-j(k_1 kD + k_2 lD\} \\ &= \frac{1}{NM} \frac{\sin\left(\dfrac{k_1 ND}{2}\right)}{\sin\left(\dfrac{k_1 D}{2}\right)} \frac{\sin\left(\dfrac{k_2 MD}{2}\right)}{\sin\left(\dfrac{k_2 D}{2}\right)} \end{aligned} \tag{17.10}$$

Routine generalizations to 3-D spatial arrays are also possible. The array pattern functions for other geometrical distributions may also be routinely generated. For example, if unit weight sensors are located at the six vertices and the center of a regular hexagon, each of whose sides is D units long, then the array pattern function can be shown to be

$$W(k_1, k_2) = \frac{1}{7}\left[1 + 2\cos k_1 D + 4\cos\frac{k_1 D}{2}\cos\frac{\sqrt{3}k_2 D}{2}\right] \tag{17.11}$$

The array pattern function reveals how selective a particular beamforming system is. In the case of a typical array function shown in Eq. (17.9), the beamwidth, which is the width of the main lobe of the array pattern, is inversely proportional to the array aperture. Because of the periodicity of the array pattern function, the main lobe is repeated at intervals of $2\pi/D$. These repetitive lobes are called grating lobes, whose existence may be interpreted in terms of spatial frequency aliasing resulting from a sampling interval D due to the N receiving sensors located at discrete points in space. If the spacing D between sensors satisfies

$$D \leq \frac{\lambda}{2} \tag{17.12}$$

where λ is the smallest wavelength component in the signal received by the array of sensors, then the grating lobes have no effect on the received signal. A plane wave of unit amplitude which is incident upon the array at bearing angle θ degrees, as shown in Fig. 17.23, produces outputs at the sensors given by the vector

$$\mathbf{s}(\theta) \underline{\underline{\Delta}} \; \mathbf{s}_\theta = [\exp(j0)\ \exp(jk_1 D\sin\theta)\ \ldots\ \exp(jk_1(N-1)D\sin\theta)]^t \tag{17.13}$$

where $k_1 = 2\pi/\lambda$ is the wavenumber. In array processing, the array output y_θ may be viewed as the inner product of an array weight vector $\mathbf{w}$ and the steering vector $\mathbf{s}_\theta$. Thus, the beamformer response along a direction characterized by the angle θ is, treating $\mathbf{w}$ as complex,

$$y_\theta = \left\langle \mathbf{w}(\theta), \mathbf{s}_\theta \right\rangle = \sum_{k=0}^{N-1} w_k^\star \exp(jk_1 kD\sin\theta) \tag{17.14}$$

The beamforming system is said to be robust if it performs satisfactorily despite certain perturbations [Ahmed and Evans, 1982]. It is possible for each component $s_{k\theta}$ of $\mathbf{s}_\theta$ to belong to an interval $[s_{k\theta} - \phi_{k\theta}, s_{k\theta} + \phi_{k\theta}]$, and a robust beamformer will require the existence of at least one weight vector $\mathbf{w}$ which will guarantee the output y_θ to belong to an output envelope for each $\mathbf{s}_\theta$ in the input envelope. The robust beamforming problem can be translated into an optimization problem, which may be tackled by minimizing the value of the array output power

$$P(\theta) = \mathbf{w}^H(\theta) R \mathbf{w}(\theta) \tag{17.15}$$

when the response to a unit amplitude plane wave incident at the steering direction θ is constrained to be unity, i.e., $\mathbf{w}^H(\theta)\mathbf{s}(\theta) = 1$, and R is the additive noise-corrupted signal autocorrelation matrix. The solution is called the minimum variance beamformer and is given by

$$\mathbf{w}_{\mathrm{MV}}(\theta) = \frac{R^{-1}\mathbf{s}(\theta)}{\mathbf{s}^H(\theta)R^{-1}\mathbf{s}(\theta)} \tag{17.16}$$

and the corresponding power output is

$$P_{\mathrm{MV}}(\theta) = \frac{1}{\mathbf{s}^H(\theta)R^{-1}\mathbf{s}(\theta)} \tag{17.17}$$

The minimum variance power as a function of θ can be used as a form of the data-adaptive estimate of the directional power spectrum. However, in this mode of solution, the coefficient vector is unconstrained except

at the steering direction. Consequently, a signal tends to be regarded as an unwanted interference and is, therefore, suppressed in the beamformed output unless it is almost exactly aligned with the steering direction. Therefore, it is desirable to broaden the signal acceptance angle while at the same time preserving the optimum beamformer's ability to reject noise and interference outside this region of angles. One way of achieving this is by the application of the principle of superdirectivity.

Discrete Arrays and Polynomials

It is common practice to relate discrete arrays to polynomials for array synthesis purposes [Steinberg, 1976]. For volumetric equispaced arrays (it is only necessary that the spacing be uniform along each coordinate axis so that the spatial sampling periods D_i and D_j along, respectively, the ith and jth coordinate axes could be different for $i \neq j$), the weight associated with sensors located at coordinate $(i_1 D_1, i_2 D_2, i_3 D_3)$ is denoted by $w(i_1, i_2, i_3)$. The function in the complex variables (z_1, z_2, and z_3) that is associated with the sequence $\{w(i_1, i_2, i_3)\}$ is the generating function for the sequence and is denoted by

$$W(z_1, z_2, z_3) = \sum_{i_1} \sum_{i_2} \sum_{i_3} w(i_1, i_2, i_3) z_1^{i_1} z_2^{i_2} z_3^{i_3} \tag{17.18}$$

In the electrical engineering and geophysics literature, the generating function $W(z_1, z_2, z_3)$ is sometimes called the z-transform of the sequence $\{w(i_1, i_2, i_3)\}$. When there are a finite number of sensors, a realistic assumption for any physical discrete array, $W(z_1, z_2, z_3)$ becomes a trivariate polynomial. In the special case when $w(i_1, i_2, i_3)$ is product separable, the polynomial $W(z_1, z_2, z_3)$ is also product separable. Particularly, this separability property holds when the shading is uniform, i.e., $w(i_1, i_2, i_3) = 1$. When the support of the uniform shading function is defined by $i_1 = 0,1, \ldots, N_1 - 1$, $i_2 = 0,1, \ldots, N_2 - 1$, and $i_3 = 0,1, \ldots, N_3 - 1$, the associated polynomial becomes

$$W(z_1, z_2, z_3) = \sum_{i_1=0}^{N_1-1} \sum_{i_2=0}^{N_2-1} \sum_{i_3=0}^{N_3-1} z_1^{i_1} z_2^{i_2} z_3^{i_3} = \prod_{i=1}^{3} \frac{z_i^{N_i} - 1}{z_i - 1} \tag{17.19}$$

In this case, all results developed for the synthesis of linear arrays become directly applicable to the synthesis of volumetric arrays. For a linear uniform discrete array composed of N sensors with intersensor spacing D_1 starting at the origin and receiving a signal at a known fixed wavenumber k_1 at a receiving angle θ, the far-field beam pattern

$$S(k_1, \theta) \triangleq S(\theta) = \sum_{r=0}^{N-1} e^{jk_1 r D_1 \sin\theta}$$

may be associated with a polynomial $\Sigma_{r=0}^{N-1} z_1^r$, by setting $z_1 = e^{jk1D1\sin\theta}$. This polynomial has all its zeros on the unit circle in the z_1-plane. If the array just considered is not uniform but has a weighting factor w_r, for $r = 0,1, \ldots, N_1 - 1$, the space factor,

$$Q(\theta) \triangleq \sum_{r=0}^{N_1-1} w_r e^{jk_1 D_1 r \sin\theta}$$

may again be associated with a polynomial $\Sigma_{r=0}^{N_1-1} w_r z_1^r$. By the pattern multiplication theorem, it is possible to get the polynomial associated with the total beam pattern of an array with weighted sensors by multiplying the polynomials associated with the array element pattern and the polynomial associated with the space factor $Q(\theta)$. The array factor $|Q(\theta)|^2$ may also be associated with the polynomial spectral factor

$$\left|Q(\theta)\right|^2 \leftrightarrow \sum_{r=0}^{N_1-1} w_r z_1^r \sum_{r=0}^{N_1-1} w_r^{\star} (z_1^{\star})^r \tag{17.20}$$

where the weighting (shading) factor is allowed to be complex. Uniformly distributed apertures and uniformly spaced volumetric arrays which admit product separable sensor weightings can be treated by using the well-developed theory of linear discrete arrays and their associated polynomial. When the product separability property does not hold, scopes exist for applying results from multidimensional systems theory [Bose, 1982] concerning multivariate polynomials to the synthesis problem of volumetric arrays.

Velocity Filtering

Combination of individual sensor outputs in a more sophisticated way than the delay-and-sum technique leads to the design of multichannel velocity filters for linear and planar as well as spatial arrays. Consider, first, a linear (1-D) array of sensors, which will be used to implement velocity discrimination. The pass and rejection zones are defined by straight lines in the (k_1,ω)-plane, where

$$k_1 = \frac{\omega}{V} = \frac{\omega}{(v/\sin\theta)}$$

is the wavenumber, ω the angular frequency in radians/second, V the apparent velocity on the earth's surface along the array line, v the velocity of wave propagation, and θ the horizontal arrival direction. The transfer function

$$H(\omega, k_1) = \begin{cases} 1, & -\dfrac{|\omega|}{V} \le k_1 \le \dfrac{|\omega|}{V} \\ 0, & \text{otherwise} \end{cases}$$

of a "pie-slice" or "fan" velocity filter [Bose, 1985] rejects totally wavenumbers outside the range $-|\omega|/V \le k_1 \le |\omega|/V$ and passes completely wavenumbers defined within that range. Thus, the transfer function defines a high-pass filter which passes signals with apparent velocities of magnitude greater than V at a fixed frequency ω. If the equispaced sensors are D units apart, the spatial sampling results in a periodic wavenumber response with period $k_1 = 1/(2D)$. Therefore, for a specified apparent velocity V, the resolvable wavenumber and frequency bands are, respectively, $-1/(2D) \le k_1 \le 1/(2D)$ and $-V/(2D) \le \omega \le V/(2D)$ where $\omega/(2D)$ represents the folding frequency in radians/second.

Linear arrays are subject to the limitation that the source is required to be located on the extended line of sensors so that plane wavefronts approaching the array site at a particular velocity excite the individual sensors, assumed equispaced, at arrival times which are also equispaced. In seismology, the equispaced interval between successive sensor arrival times is called a move-out or step-out and equals $(D \sin\theta)/v = D/V$. However, when the sensor-to-source azimuth varies, two or more independent signal move-outs may be present. Planar (2-D) arrays are then required to discriminate between velocities as well as azimuth. Spatial (3-D) arrays provide additional scope to the enhancement of discriminating capabilities when sensor/source locations are arbitrary. In such cases, an array origin is chosen and the mth sensor location is denoted by a vector $(x_{1m}\, x_{2m}\, x_{3m})^t$ and the frequency wavenumber response of an array of sensors is given by

$$H(\omega, k_1, k_2, k_3) = \frac{1}{N} \sum_{m=1}^{N} H_m(\omega) \exp\left[\sum_{i=1}^{3} -j2\pi k_i x_{im}\right]$$

where $H_m(\omega)$ denotes the frequency response of a filter associated with the mth recording device (sensor). The sum of all N filters provides flat frequency response so that waveforms arriving from the estimated directions of arrival at estimated velocities are passed undistorted and other waveforms are suppressed. In the planar

specialization, the 2-D array of sensors leads to the theory of 3-D filtering involving a transfer function in the frequency wavenumber variables f, k_1, and k_2. The basic design equations for the optimum, in the least-mean-square error sense, frequency wavenumber filters have been developed [Burg, 1964]. This procedure of Burg can be routinely generalized to the 4-D filtering problem mentioned above.

Acknowledgment

Defining Terms

Array pattern: Fourier transform of the receiver weighting function taking into account the positions of the receivers.

Beamformers: Systems commonly used for detecting and isolating signals that are propagating in a particular direction.

Grating lobes: Repeated main lobes in the array pattern interpretable in terms of spatial frequency aliasing.

Velocity filtering: Means for discriminating signals from noise or other undesired signals because of their different apparent velocities.

Wavenumber: 2π (spatial frequency in cycles per unit distance).

17.4 Video Processing Architectures

Wayne Wolf

Video processing has become a major application of computing: personal computers display multimedia data, digital television provides more channels, etc. The characteristics of video algorithms are very different from traditional applications of computers; these demands require new architectures.

Two fundamental characteristics of video processing make it challenging and different than applications like database processing. First, the video processor must handle streaming data that arrives constantly. Traditional applications assume that data has a known, fixed location. In video processing, not only are new input samples always arriving, but our time reference in the stream is constantly changing. At one time instant, we may consider a sample x_t, but at the next sampling interval that sample becomes x_{t-1}. The need to sweep through the data stream puts additional demands on the memory system. Since streaming data must be processed in realtime. If the deadline for completing an output is missed, the results will be visible on the screen. When designing realtime systems, it is not sufficient to look at aggregate throughput because data can become backed up for a period and still meet some long-term timing requirements. Processing must complete every realtime result by the appointed deadline. Architectures must provide underlying support for predictable computation times.

The challenges of processing streaming data in realtime are made greater by the fact that video processing algorithms are becoming very complex. Video compression algorithms make use of several different techniques and complex search algorithms to maximize their ability to compress the video data; video display systems provide much more sophisticated controls to the user; content analysis systems make use of multiple complex algorithms working together; mixed computer graphics-video systems combine geometric algorithms with traditional video algorithms. Expect video processing algorithms to become more complex in the future. This complexity puts greater demands on the realtime nature of the video architecture: more complex algorithms generally have less predictable execution times. The architecture should be designed so that algorithms can take advantage of idle hardware caused by early completions of functions, rather than letting hardware sit idle while it waits for other operations to complete.

Luckily, VLSI technology is also advancing rapidly and allows us to build ever more sophisticated video processing architectures. The state of video processing architectures will continue to advance as VLSI allows us to integrate more transistors on a chip; in particular, the ability to integrate a significant amount of memory along with multiple processing elements will provide great strides in video processing performance over the next several years. However, the basic techniques for video processing used today [Pir98] will continue to be the basis for video architectures in the long run.

This chapter section first reviews two basic techniques for performing video operations: single instruction multiple data (SIMD) and vectorization; and then looks at the three major styles of video architectures: heterogeneous multiprocessors, video signal processors, and microprocessor instruction set extensions.

Computational Techniques

Many of the fundamental operations in video processing are filters that can be described as linear equations; for example,

$$\sum_{1 \le i \le n} c_i x_i$$

There are two techniques for implementing such equations: single-instruction multiple data (SIMD) processing and vector processing. The two are similar in underlying hardware structure; the most important differences come in how they relate to the overall computer architecture of which they are a part.

SIMD

The term **SIMD** comes from Flynn's classification of computer architectures, based on the number of data elements they processed simultaneously and the number of instructions used to control the operations on those

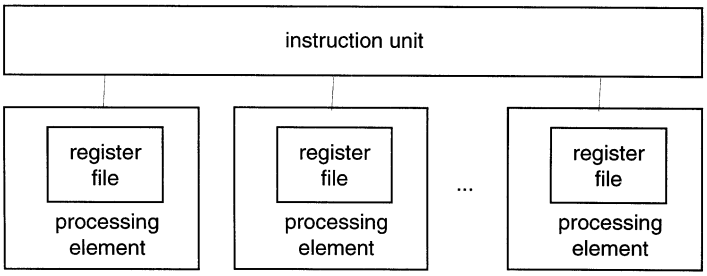

FIGURE 17.24 A SIMD architecture.

data. In a SIMD machine, a single instruction is used to control the operation performed on many data elements. Thus, the same operation is performed simultaneously on all that data. Figure 17.24 shows a SIMD structure: several function units, each with its own register file, has an **ALU** for performing operations on data; the controller sends identical signals to all function units so that the same operation is performed on all function units at the same; there is also a network that allows processing elements to pass data among themselves.

Consider how to use a SIMD machine to perform the filtering operation given at the beginning of this section. The multiplications are all independent, so we can perform N multiplications in parallel on the N processing elements. We need to perform N – 1 additions on the multiplication results; by properly arranging the computation in a tree, many of those operations can be performed in parallel as well. We will need to use the data transfer network in two ways: to transfer x values between processing elements for the data streaming time shift; and to transfer the partial addition results in the addition tree. SIMD architectures can of course be used to implement multidimensional functions as well. For example, two-dimensional correlation is used in video compression, image recognition, etc., and can easily be mapped onto a SIMD machine.

SIMD architectures provide a high degree of parallelism at high speeds. Instruction distribution and decoding is not a bottleneck. Furthermore, each **processing element** has its own data registers and the communication network between the processing elements can be designed to be fast. However, not all algorithms can be efficiently mapped onto SIMD architectures. Global computation is difficult in SIMD machines. Operations that cause global changes to the machine state also create problems.

Vectorization

Vector instructions were originally invented for supercomputers to improve the performance of scientific calculations. Although video operations are generally done in fixed-point rather than floating-point arithmetic, vector instructions are well-suited to the many video operations that can be expressed in linear algebra. Vectorization was used in many early video processors. More recently, SIMD has become more popular, but with vectorization becoming more popular in general-purpose microprocessors, there may be a resurgence of vector units for multimedia computation.

A vector is a data structure supported by hardware. The vector is stored in memory as a set of memory locations; special vector registers are also provided to hold the vectors for arithmetic operations. Our filter example could be implemented as a single vector instruction (after loading the vector registers with the c and x vectors): a vector multiply-accumulate instruction, similar to scalar multiply-accumulate instructions in DSPs, could multiply the x_i's by the c_i's and accumulate the result.

The motivation for supporting vector instructions is pipelining the arithmetic operations. If an arithmetic operation takes several clock cycles, pipelining allows high throughput at a high clock rate at the cost of latency. As shown in Fig. 17.25 vectors are well-suited to pipelined execution because all the operations in the vector are known to be independent in advance.

Vector units allow linear algebra to be performed at very high speeds with high hardware utilization. Furthermore, because they have a long history in scientific computing, compiling high-level languages into vector instructions is well understood. However, the latencies of integer arithmetic operations for video operations is smaller than that for the floating-point operations typically used in scientific **vector processors**.

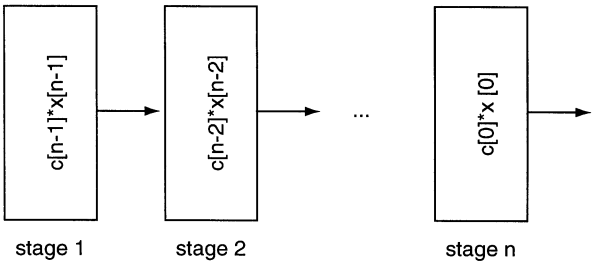

FIGURE 17.25 Pipelining to support vector operations.

Heterogeneous Multiprocessors

The earliest style of video processor is the **heterogeneous multiprocessor**. These machines cannot execute arbitrary programs — they are restricted to a single algorithm or variations on that algorithm. The microarchitecture of the machine is tuned to the target application. In the early days of digital video, special-purpose heterogeneous multiprocessors were the only way to implement VLSI video processing because chips were not large enough to support the hardware required for instruction-set processors. Today, heterogeneous multiprocessors are used to implement low-cost video systems, since by specializing the hardware for a particular application, less hardware is generally required, resulting in smaller, less-expensive chips.

A simple heterogeneous architecture is shown in Fig. 17.26. This machine implements a sum-of-absolute-differences correlation in two dimensions for block motion estimation. The architecture of this machine is derived from the data flow of the computation, where for each offset (r, s), the sum-of-absolute differences between a $n \times n$ macroblock and a $T \times T$ reference area can be computed:

$$\sum_{1 \le i \le n} \sum_{1 \le i \le n} | M(i, j) - R(i + r, j + s) |$$

The machine executes one column of the computation per clock cycle: n absolute differences are formed and then passed onto a summation unit. This machine is not a SIMD architecture because it does not execute instructions — it is designed to perform one algorithm.

Heterogeneous architectures can also be used for more complex algorithms. Figure 17.27 shows a sketch for a possible architecture for MPEG-style video compression [MPE]. The unit has separate blocks for the major operations: block motion estimation, discrete cosine transform (DCT) calculation, and channel coding; it also has a processor used for overall control.

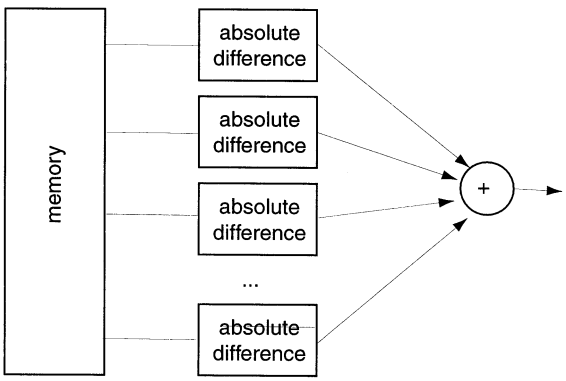

FIGURE 17.26 A heterogeneous multiprocessor.

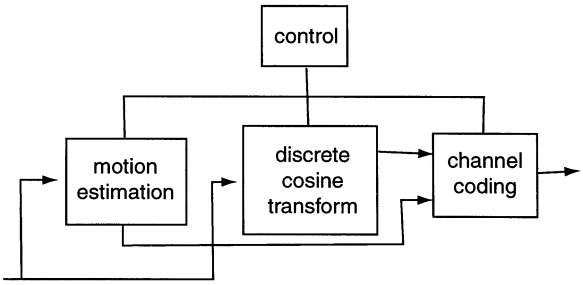

FIGURE 17.27 A heterogeneous architecture for MPEG-style compression.

Heterogeneous architectures are designed by careful examination of the algorithm to be implemented. The most time-critical functions must be identified early. Those operations are typically implemented as special-purpose function units. For example, the block motion estimation engine of Fig. 17.26 can be used as a special-purpose function unit in a more complex application like an MPEG video compressor. Communication links must be provided between the function units to provide adequate bandwidth for the data transfers. In structured communication architectures, data transfers can be organized around buses or more general communication networks like crossbars. Heterogeneous communication systems make specialized connections as required by the algorithm. Many modern heterogeneous video processors use as much structured communication as possible but add specialized communication links as required to meet performance requirements. Many modern heterogeneous processors are at least somewhat programmable. Basic architectures may use registers to control certain parameters of the algorithm. More complex algorithms may use general-purpose microprocessors as elements of the architecture. Small microcontrollers are frequently used for system interfacing, such as talking to a keyboard or other controlling device. Larger microprocessors can be used to run algorithms that do not benefit from special-purpose function units.

Heterogeneous multiprocessors will continue to dominate high-volume, low-cost markets for video and multimedia functions. When an application is well-defined, it is often possible to design a special-purpose architecture that performs only that operation but is significantly cheaper than a system built from a programmable processor. Furthermore, heterogeneous multiprocessors may require significantly less power than programmable solutions and, therefore, an increasing number of battery-operated multimedia devices. However, heterogeneous multiprocessors are not well-suited to other application areas. If the algorithm is not well-defined, if the system must be able to execute a variety of algorithms, or if the size of the market will not support the cost of designing an application-specific solution, heterogeneous multiprocessors are not appropriate.

Video Signal Processors

The term digital signal processor (DSP) is generally reserved for microprocessors optimized for signal processing algorithms and which run at audio rates. A video signal processor (VSP) is a DSP that is capable of running at video rates. Using separate names for audio and video rate processors is reasonable because VSPs provide much greater parallelism and significantly different microarchitectures.

Many early video processors were vector machines because vector units provide high throughput with relatively small amounts of hardware. Today, most VSPs today make use of very-long instruction word (VLIW) processor technology, as shown in Fig. 17.28. The architecture has several function units connected to a single register file. The operations on all the function units are controlled by the instruction decoder based on the current instruction. A **VLIW** machine differs from a SIMD machine in two important ways. First, the VLIW machine connects all function units to the same register file, while the SIMD machine uses separate registers for the function units. The common register file gives the VLIW machine much more flexibility; for example, a data value can be used on one function unit on one cycle and on another function unit on the next cycle without having to copy the value. Second, the function units in the VLIW machine need not perform the same operation. The instruction is divided into fields, one for each unit. Under control of its instruction field, each instruction unit can request data from the register file and perform operations as required.

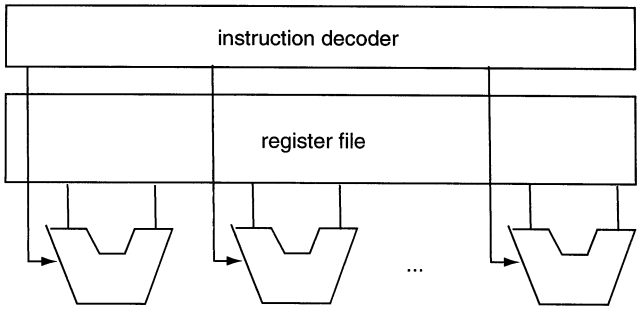

FIGURE 17.28 A simple VLIW machine.

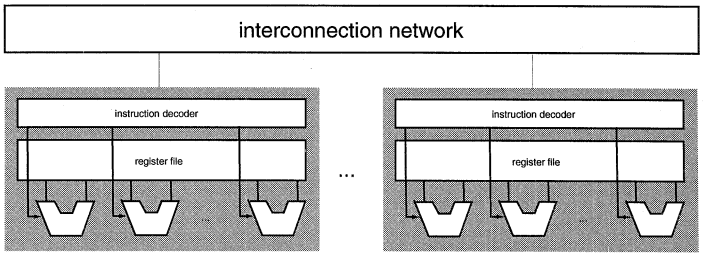

FIGURE 17.29 A clustered VLIW machine.

Although having a common register file is very flexible, there are physical limitations on the number of function units that can be connected to a single register file. A single addition requires three ports to the register file: one to read each operand and a third to write the result back to the register file. Register files are built from static random access memory (SRAMs) and slow down as the number of read/write ports grows. As a result, VLIW machines are typically built in clusters as shown in Fig. 17.29. Each cluster has its own register file and function units, with three or four function units per cluster typical in today's technology. A separate interconnection network allows data transfers between the clusters. When data held in one register file is needed in a different cluster, an instruction must be executed to transfer the data over the interconnection network to the other register file.

The major difference between VLIW architectures and the superscalar architectures found in modern microprocessors is that VLIW machines have statically scheduled operations. A superscalar machine has hardware that examines the instruction stream to determine what operations can be performed in parallel; for example, when two independent operations appear in consecutive instructions, those instructions can be executed in parallel. A VLIW machine relies on a compiler to identify parallelism in the program and to pack those operations into instruction words. This requires sophisticated compilers that can extract parallelism and effectively make use of it when generating instructions. Video is especially well-suited to VLIW because video programs have a great deal of parallelism that is relatively easy to identify and take advantage of in a VLIW machine.

VLIW has potential performance advantages because its control unit is relatively simple. Because the work of finding parallelism is performed by the compiler, a VLIW machine does not require the sophisticated execution unit of a superscalar processor. This allows a VLIW video processor to run at high clock rates. However, it does rely on the compiler's ability to find enough parallelism to keep the function units busy. Furthermore, complex algorithms may have some sections that are not highly parallel and therefore will not be sped up by the VLIW mechanism. If one is not careful, these sequential sections of code can come to limit the overall performance of the application.

Practical video signal processors are not pure VLIW machines, however. In general, they are in fact hybrid machines that use VLIW processing for some operations and heterogeneous multiprocessing techniques for others. This is necessary to meet the high performance demand on video processing; certain critical operations can be sped up with special-purpose function units, leaving the VLIW processor to perform the rest. An example

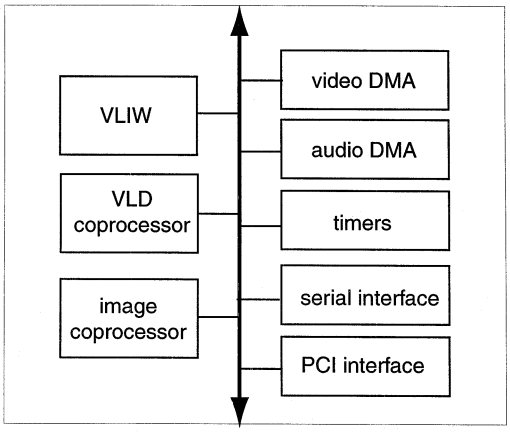

FIGURE 17.30 The Trimedia TM-1 video signal processor.

of this technique is the Trimedia TM-1 processor [Rat96] shown in Fig. 17.30. This machine has a VLIW processor. It also has several function units for specialized video operations, principal among these being a variable-length decoding for channel coding, an image coprocessor. The TM-1 also supports multiple DMA channels to speed up data transfers as well as timers to support realtime operation.

VLIW VSPs represent one end of the programmable video processor spectrum. These machines are designed from the ground up to execute video algorithms. The VLIW architecture is very well-suited to video applications due to the embarrassing levels of parallelism available in video programs. Special-purpose function units can be used to speed up certain key operations. However, VLIW VSPs may not be as well-suited to executing code that is more typically found on workstation microprocessors, such as error checking, bit-level operations, etc. As a result, VLIW VSPs can be used in conjunction with standard microprocessors to implement a complex video application, with the VSP performing traditional parallel video sections of the code and the microprocessor performing the less regular computations.

Instruction Set Extensions

Both heterogeneous multiprocessors and VSPs are specialized architectures for video. However, there are many applications in which it is desirable to execute video programs directly on a workstation or PC: programs that are closely tied to the operating system, mixed video/graphics applications, etc. Traditional microprocessors are fast but are not especially well-utilized by video programs. For these applications, microprocessor instruction set extensions have been developed to allow video algorithms to be executed more efficiently on traditional microprocessors.

The basic principle of instruction set extensions is subword parallelism [Lee95], as illustrated in Fig. 17.31. This technique takes advantage of the fact that modern microprocessors support native 32- or 64-bit operations while most video algorithms require much smaller data accuracy, such as 16 bits or even 8 bits. One can divide the microprocessor data path, on which the instructions are executed, into subwords. This is a relatively simple operation, mainly entailing adding a small amount of logic to cut the ALU's carry chain at the appropriate points when subword operations are performed. When a 64-bit data path is divided for use by 16-bit subwords, the machine can support four simultaneous subword operations. Subword parallelism is often referred to as SIMD because a single microprocessor instruction causes the same operation to be performed on all the subwords in parallel. However, there is no separate SIMD instruction unit — all the work is done by adding a small amount of hardware to the microprocessor data path. Subword parallelism is powerful because it has a very small cost in the microprocessor (both in terms of chip area and performance) and because it provides substantial speedups on parallel code.

A typical instruction set extension will of course support logical and arithmetic operations on subwords. They may support saturation arithmetic as well as two's-complement arithmetic. Saturation arithmetic generates the maximum value on overflow, more closely approximating physical devices. They may also support

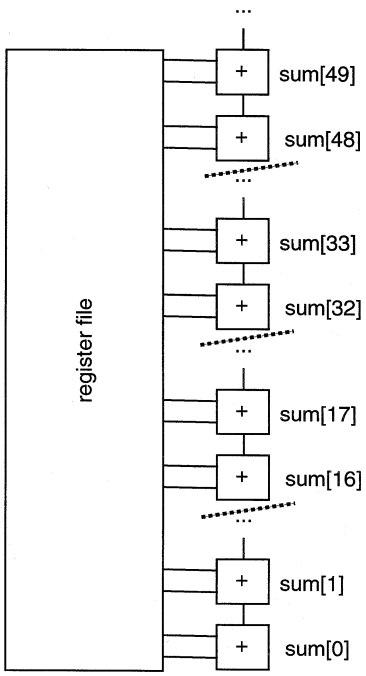

FIGURE 17.31 Implementing subword parallelism on a microprocessor.

permutation operations so that the order of subwords in a word can be shuffled. Loads and stores are performed on words — not subwords.

ISA extensions have been defined for the major microprocessor architectures. The MAX extension for the HP PA-RISC architecture [Lee96] was the first ISA extension and introduced the notion of subword parallelism. The VIS (Visual Instruction Set) extension [Tre96] has been added to the Sun SPARC architecture. The Intel x86 architecture has been extended with the MMX instructions [Pel96].

The MMX extension is based on the well-known Intel architecture. It supports operations on 8-bit bytes, 16-bit words, 32-bit doublewords, and 64-bit quadwords. All these data types are packed into 64-bit words. All MMX operations are performed in the floating-point registers; this means that the floating-point registers must be saved at the beginning of MMX code and restored at its end. (Although floating-point operations access these registers as a stack, MMX instructions can arbitrarily address the registers.) MMX supports addition, subtraction, comparison, multiplication, shifts, and logical operations. Arithmetic can optionally be performed in saturation mode. There are also instructions for packing and unpacking subwords into words. Some conversion operations are provided so that intermediate calculations can be performed at higher precisions and then converted to a smaller format.

The Sun VIS extension also uses the floating-point registers. The MAX-2 extension is the latest extension to the HP architecture. It uses integer registers rather than floating-point registers. It does not directly implement multiplication, but instead provides a shift-and-add operation for software-driven multiplication. MAX-2 also supports a permutation operation to allow subwords to be rearranged in a word.

The ability to mix multimedia instructions with other instructions on a standard microprocessor is the clear advantage of instruction set extensions. These extensions are very well-suited to the implementation of complex algorithms because the microprocessor can efficiently execute the nonlinear algebra operations as well as the highly parallel video operations. Furthermore, instruction set extensions take advantage of the huge resources available to microprocessor manufacturers to build high-performance chips.

The main disadvantages of instruction set extensions are related to the tight coupling of the video and non-video instructions. First, the memory system is not changed to fit the characteristics of the video application.

The streaming data typical of video is not very well-suited to the caches used in microprocessors. Caches rely on temporal and spatial locality; they assume that a variable is used many times after its initial use. In fact, streaming data will be used a certain number of times and then be discarded, to be replaced with a new datum. Second, the available parallelism is limited by the width of the data path. A 64-bit data path can exhibit at most four-way parallelism when subdivided into 16-bit subwords. Other architectures can be more easily extended for greater parallelism when technology and cost permit.

Summary

There is no one best way to design a video processing architecture. The structure of the architecture depends on the intended application environment, algorithms to be run, performance requirements, cost constraints, and other factors. Computer architects have developed a range of techniques that span a wide range of this design space: heterogeneous multiprocessors handle low-cost applications effectively; VLIW video signal processors provide specialized video processing; instruction set extensions to microprocessors enhance video performance on traditional microprocessors. As VLSI technology improves further, these techniques will be extended to create machines that hold significant amounts of video memory on-chip with the processing elements that operate on the video data.

Defining Terms

ALU: Arithmetic/logic unit.
MPEG: A set of standards for video compression.
Processing element: A computational unit in a parallel architecture.
SIMD (single-instruction multiple data): An architecture in which a single instruction controls the operation of many separate processing elements.
Heterogeneous multiprocessors: An architecture in which several dissimilar processing units are connected together to perform a particular computation.
Vector processor: A machine that operates on vector and matrix quantities in a pipelined fashion.
VLIW (very-long instruction word): An architecture in which several ALUs are connected to a common register file, under the control of an instruction word that allows the ALU operations to be determined separately.

17.5 MPEG-4 Based Multimedia Information System

Ya-Qin Zhang[1]

Recent creation and finalization of the Motion-Picture Expert Group (**MPEG-4**) international standard has provided a common platform and unified framework for multimedia information representation. In addition to providing highly efficient compression of both natural and synthetic audio-visual (AV) contents such as video, audio, sound, texture maps, graphics, still images, MIDI, and animated structure, MPEG-4 enables greater capabilities for manipulating AV contents in the compressed domain with object-based representation. MPEG-4 is a natural migration of the technological convergence of several fields: digital television, computer graphics, interactive multimedia, and Internet. This tutorial chapter briefly discusses some example features and applications enabled by the MPEG-4 standard.

During the last decade, a spectrum of standards in digital video and multimedia has emerged for different applications. These standards include: the ISO JPEG for still images [1]; ITU-T H.261 for video conferencing from 64 kilobits per second (kbps) to 2 megabits per second (Mbps) [2]; ITU-T H.263 for PSTN-based video telephony [3]; ISO MPEG-1 for CD-ROM and storage at VHS quality [4]; the ISO MPEG-2 standard for digital television [5]; and the recently completed ISO/MPEG-4 international standard for multimedia representation and integration [6]. Two new ISO standards are under development to address the next-generation still image coding (JPEG-2000) and content-based multimedia information description (MPEG-7). Several special issues of *IEEE* journals have been devoted to summarizing recent advances in digital image, video compression, and advanced television in terms of standards, algorithms, implementations, and applications [7–11].

The successful convergence and implementation of MPEG-1 and MPEG-2 have become a catalyst for propelling the new digital consumer markets such as Video CD, Digital TV, DVD, and DBS. While the MPEG-1 and MPEG-2 standards were primarily targeted at providing high compression efficiency for storage and transmission of pixel-based video and audio, MPEG-4 envisions to support a wide variety of multimedia applications and new functionalities of object-based audio-visual (AV) contents. The recent completion of MPEG-4 Version 1 is expected to provide a stimulus to the emerging multimedia applications in wireless networks, Internet, and content creation.

The MPEG-4 effort was originally conceived in late 1992 to address very low bit rate (VLBR) video applications at below 64 kbps such as PSTN-based videophone, video e-mail, security applications, and video over cellular networks. The main motivations for focusing MPEG-4 at VLBR applications were:

- Applications such as PSTN videophone and remote monitoring were important, but not adequately addressed by established or emerging standards. In fact, new products were introduced to the market with proprietary schemes. The need for a standard at rates below 64 kbps was imminent.
- Research activities had intensified in VLBR video coding, some of which have gone beyond the boundary of the traditional statistical-based and pixel-oriented methodology.

It was felt that a new breakthrough in video compression was possible within a five-year time window. This "quantum leap" would likely make compressed-video quality at below 64 kbps, adequate for many applications such as videophone.

Based on the above assumptions, a workplan was generated to have the MPEG-4 Committee Draft (CD) completed in 1997 to provide a generic audio visual coding standard at very low bit rates. Several MPEG-4 seminars were held in parallel with the WG11 meetings, many workshops and special sessions have been organized, and several special issues have been devoted to such topics. However, as of July 1994 in the Norway WG11 meeting, there was still no clear evidence that a "quantum leap" in compression technology was going to happen within the MPEG-4 timeframe. On the other hand, ITU-T has embarked on an effort to define the H.263 standard for videophone applications in PSTN and mobile networks. The need for defining a pure compression standard at very low bit rates was, therefore, not entirely justified.

[1]The author was the director of Multimedia Technology Laboratory at Sarnoff Corporation in Princeton, New Jersey when this work was performed.

In light of the situation, a change of direction was called to refocus on new or improved functionalities and applications that are not addressed by existing and emerging standards. Examples include object-oriented features for content-based multimedia database, error-robust communications in wireless networks, hybrid nature and synthetic image authoring and rendering. With the technological convergence of digital video, computer graphics, and Internet, MPEG-4 aims at providing an audiovisual coding standard allowing for interactivity, high compression, and/or universal accessibility, with a high degree of flexibility and extensibility.

In particular, MPEG-4 intends to establish a flexible content-based audio-visual environment that can be customized for specific applications and that can be adapted in the future to take advantage of new technological advances. It is foreseen that this environment will be capable of addressing new application areas ranging from conventional storage and transmission of audio and video to truly interactive AV services requiring content-based AV database access, e.g., video games or AV content creation. Efficient coding, manipulation, and delivery of AV information over Internet will be key features of the standard.

MPEG-4 Multimedia System

Figure 17.32 shows an architectural overview of MPEG-4. The standard defines a set of syntax to represent individual *audiovisual objects*, with both natural and synthetic contents. These objects are first encoded independently into their own elementary streams. Scene description information is provided separately, defining the location of these objects in space and time that are composed into the final scene presented to the user. This representation includes support for user interaction and manipulation. The scene description uses a tree-based structure, following the Virtual Reality Modeling Language (VRML) design. Moving far beyond the capabilities of VRML, MPEG-4 scene descriptions can be dynamically constructed and updated, enabling much higher levels of interactivity. Object descriptors are used to associate scene description components that relate digital video to the actual elementary streams that contain the corresponding coded data. As shown in Fig. 17.32, these components are encoded separately and transmitted to the receiver. The receiving terminal then has the responsibility of composing the individual objects for presentation and for managing user interaction.

Following are eight MPEG-4 functionalities, defined and clustered into three classes:

- Content-based interactivity: Content-based manipulation and bit stream editing; content-based multimedia data access tools; hybrid natural and synthetic data coding; improved temporal access.
- Compression: Improved coding efficiency; coding of multiple concurrent data streams.
- Universal access: Robustness in error-prone environments; content-based scalability.

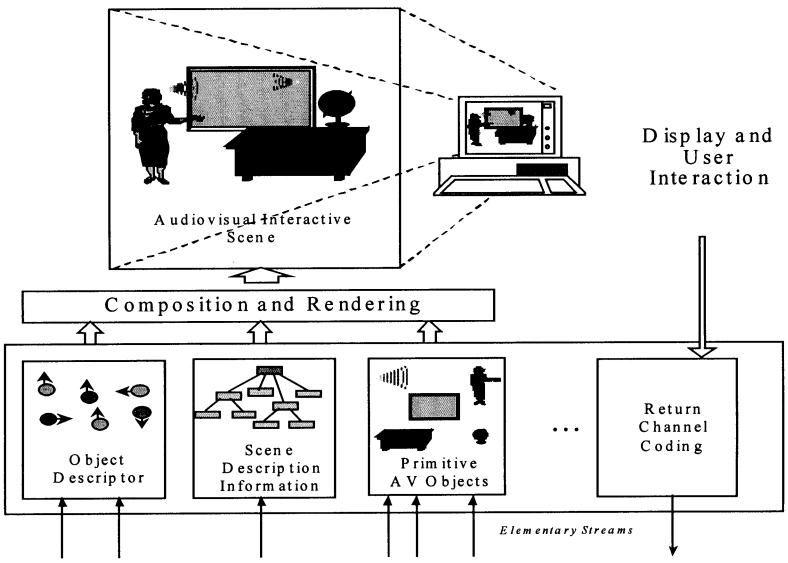

FIGURE 17.32 MPEG-4 Overview. Audio-visual objects, natural audio, as well as synthetic media are independently coded and then combined according to scene description information (courtesy of the ISO/MPEG-4 committee).

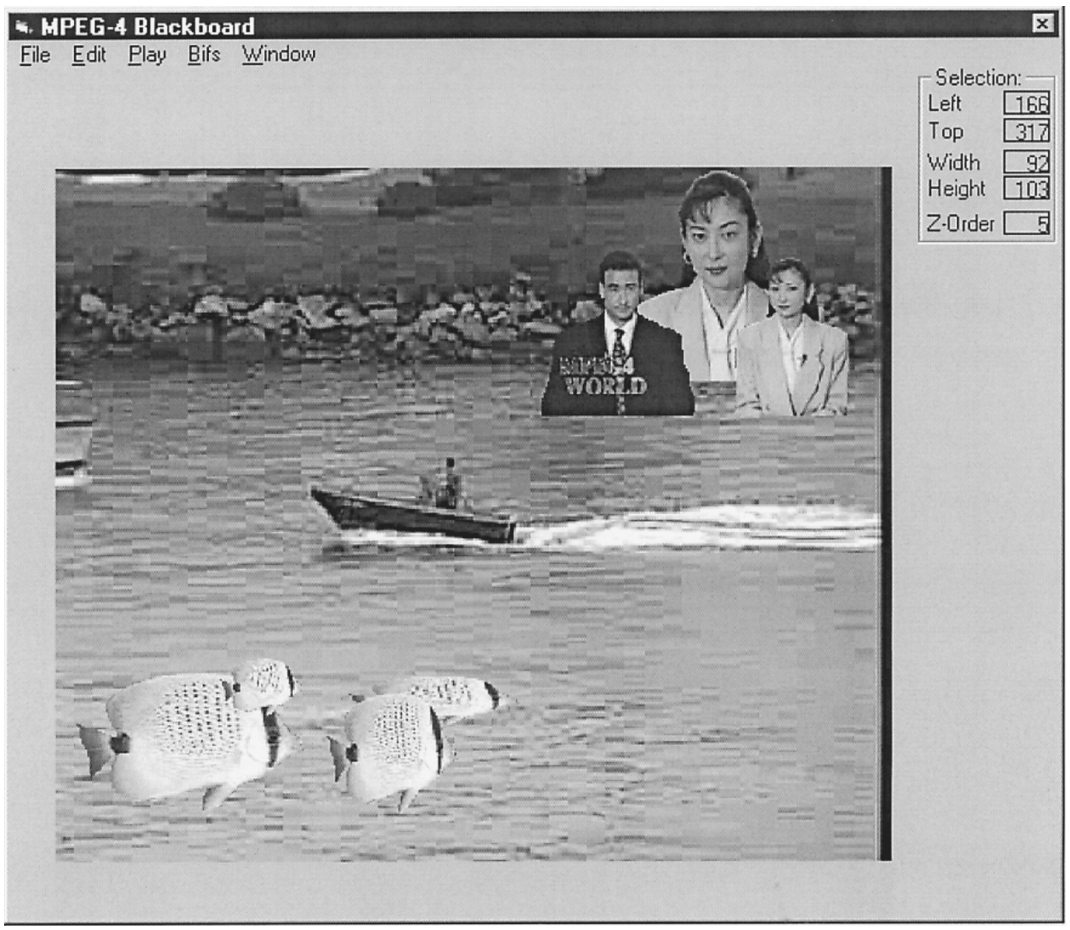

FIGURE 17.33 An example of a multimedia authoring system using MPEG-4 tools and functionalities (courtesy of Sarnoff Corporation).

Some of the applications enabled by these functionalities include:

- Video streaming over Internet.
- Multimedia authoring and presentations.
- View of the contents of video data in different resolutions, speeds, angles, and quality levels.
- Storage and retrieval of multimedia database in mobile links with high error rates and low channel capacity (e.g., Personal Digital Assistant).
- Multipoint teleconference with selective transmission, decoding, and display of "interesting" parties.
- Interactive home shopping with customers' selection from a video catalogue.
- Stereo-vision and multiview of video contents, e.g., sports.
- "Virtual" conference and classroom.
- Video email, agents, and answering machines.

Object-based Authoring Tool Example

Figure 17.33 shows an example of an object-based authoring tool for MPEG-4 AV contents, recently developed by the Multimedia Technology Laboratory at Sarnoff Corporation in Princeton, New Jersey. This tool has the following features:

- Compression/decompression of different visual objects into MPEG-4-compliant bitstreams.
- Drag-and-drop of video objects into a window while resizing the objects or adapting them to different frame rates, speeds, transparencies, and layers.

- Substitution of different backgrounds.
- Mixing natural image and video objects with computer-generated, synthetic texture and animated objects.
- Creating metadata information for each visual objects.

This set of authoring tools can be used for interactive Web design, digital studio, and multimedia presentation. It empowers users to compose and interact with digital video on a higher semantic level.

18.1 Special Architectures

Keshab K. Parhi

Digital signal processing (DSP) is used in numerous applications. These applications include telephony, mobile radio, satellite communications, speech processing, video and image processing, biomedical applications, radar, and sonar. Real-time implementations of DSP systems require design of hardware that can match the application sample rate to the hardware processing rate (which is related to the clock rate and the implementation style). Thus, real-time does not always mean high speed. Real-time architectures are capable of processing samples as they are received from the signal source, as opposed to storing them in buffers for later processing as done in batch processing. Furthermore, real-time architectures operate on an infinite time series (since the number of the samples of the signal source is so large that it can be considered infinite). While speech and sonar applications require lower sample rates, radar and video image processing applications require much higher sample rates. The sample rate information alone cannot be used to choose the architecture. The algorithm complexity is also an important consideration. For example, a very complex and computationally intensive algorithm for a low-sample-rate application and a computationally simple algorithm for a high-sample-rate application may require similar hardware speed and complexity. These ranges of algorithms and applications motivate us to study a wide variety of architecture styles.

Using very large scale integration (VLSI) technology, DSP algorithms can be prototyped in many ways. These options include (1) single or multiprocessor programmable digital signal processors, (2) the use of core programmable digital signal processor with customized interface logic, (3) semicustom gate-array implementations, and (4) full-custom dedicated hardware implementation. The DSP algorithms are implemented in the programmable processors by translating the algorithm to the processor assembly code. This can require an extensive amount of time. On the other hand, high-level compilers for DSP can be used to generate the assembly code. Although this is currently feasible, the code generated by the compiler is not as efficient as hand-optimized code. Design of DSP compilers for generation of efficient code is still an active research topic. In the case of

dedicated designs, the challenge lies in a thorough understanding of the DSP algorithms and theory of architectures. For example, just minimizing the number of multipliers in an algorithm may not lead to a better dedicated design. The area saved by the number of multipliers may be offset by the increase in control, routing, and placement costs.

Off-the-shelf programmable digital signal processors can lead to faster prototyping. These prototyped systems can prove very effective in fast simulation of computation-intensive algorithms (such as those encountered in speech recognition, video compression, and seismic signal processing) or in benchmarking and standardization. After standards are determined, it is more useful to implement the algorithms using dedicated circuits.

Design of dedicated circuits is not a simple task. Dedicated circuits provide limited or no programming flexibility. They require less silicon area and consume less power. However, the low production volume, high design cost, and long turnaround time are some of the difficulties associated with the design of dedicated systems. Another difficulty is the availability of appropriate computer-aided design (CAD) tools for DSP systems. As time progresses, however, the architectural design techniques will be better understood and can be incorporated into CAD tools, thus making the design of dedicated circuits easier. Hierarchical CAD tools can integrate the design at various levels in an automatic and efficient manner. Implementation of standards for signal and image processing using dedicated circuits will lead to higher volume production. As time progresses, dedicated designs will be more acceptable to customers of DSP.

Successful design of dedicated circuits requires careful algorithm and architecture considerations. For example, for a filtering application, different equivalent realizations may possess different levels of concurrency. Thus, some of these realizations may be suitable for a particular application while other realizations may not be able to meet the sample rate requirements of the application. The lower-level architecture may be implemented in a word-serial or word-parallel manner. The arithmetic functional units may be implemented in bit-serial or digit-serial or bit-parallel manner. The synthesized architecture may be implemented with a dedicated data path or shared data path. The architecture may be systolic or nonsystolic.

Algorithm transformations play an important role in the design of dedicated architectures [Parhi, 1989]. This is because the transformed algorithms can be made to operate with better performance (where the performance may be measured in terms of speed, area, or power). Examples of these transformations include pipelining, parallel processing, retiming, unfolding, folding, look-ahead, associativity, and distributivity. These transformations and other architectural concepts are described in detail in subsequent sections.

Pipelining

Pipelining can increase the amount of concurrency (or the number of activities performed simultaneously) in an algorithm. Pipelining is accomplished by placing latches at appropriate intermediate points in a data flow graph that describes the algorithm. Each latch also refers to a storage unit or buffer or register. The latches can be placed at *feed-forward cutsets* of the data flow graph. In synchronous hardware implementations, pipelining can increase the clock rate of the system (and therefore the sample rate). The drawbacks associated with pipelining are the increase in system latency and the increase in the number of registers. To illustrate the speed increase using pipelining, consider the second-order three-tap finite impulse response (FIR) filter shown in Fig. 18.1(a). The signal $x(n)$ in this system can be sampled at a rate limited by the throughput of one multiplication and two additions. For simplicity, if we assume the multiplication time to be two times the addition time (T_{add}), the effective sample or clock rate of this system is $1/4T_{add}$. By placing latches as shown in Fig. 18.1(b) at the cutset shown in the dashed line, the sample rate can be improved to the rate of one multiplication or two additions. While pipelining can be easily applied to all algorithms with no feedback loops by the appropriate placement of latches, it cannot easily be applied to algorithms with feedback loops. This is because the cutsets in feedback algorithms contain feed-forward and feedback data flow and cannot be considered as feed-forward cutsets.

Pipelining can also be used to improve the performance in software programmable multiprocessor systems. Most software programmable DSP processors are programmed using assembly code. The assembly code is generated by high-level compilers that perform scheduling. Schedulers typically use the acyclic precedence graph to construct schedules. The removal of all edges in the signal (or data) flow graph containing delay

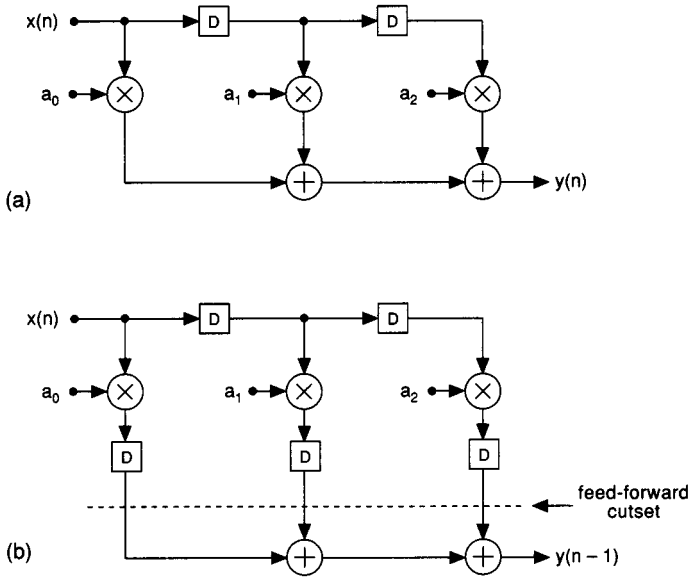

FIGURE 18.1 (a) A three-tap second-order nonrecursive digital filter; (b) the equivalent pipelined digital filter obtained by placing storage units at the intersection of the signal wires and the feed-forward cutset. If the multiplication and addition operations require 2 and 1 unit of time, respectively, then the maximum achievable sampling rates for the original and the pipelined architectures are 1/4 and 1/2 units, respectively.

elements converts the signal flow graph to an acyclic precedence graph. By placing latches to pipeline a data flow graph, we can alter the acyclic precedence graph. In particular, the critical path of the acyclic precedence graph can be reduced. The new precedence graph can be used to construct schedules with lower iteration periods (although this may often require an increase in the number of processors).

Pipelining of algorithms can increase the sample rate of the system. Sometimes, for a constant sample rate, pipelining can also reduce the power consumed by the system. This is because the data paths in the pipelined system can be charged or discharged with lower supply voltage. Since the capacitance remains almost constant, the power can be reduced. Achieving low power can be important in many battery-powered applications [Chandrakasan et al., 1992].

Parallel Processing

Parallel processing is related to pipelining but requires replication of hardware units. Pipelining exploits concurrency by breaking a large task into multiple smaller tasks and by separating these smaller tasks by storage units. On the other hand, parallelism exploits concurrency by performing multiple larger tasks simultaneously in separate hardware units.

To illustrate the speed increase due to parallelism, consider the parallel implementation of the second-order three-tap FIR filter of Fig. 18.1(a) shown in Fig. 18.2. In the architecture of Fig. 18.2, two input samples are processed and two output samples are generated in each clock cycle period of four addition times. Because each clock cycle processes two samples, however, the effective sample rate is $1/2T_{\text{add}}$ which is the same as that of Fig. 18.1(b). The parallel architecture leads to the speed increase with significant hardware overhead. The entire data flow graph needs to be replicated with an increase in the amount of parallelism. Thus, it is more desirable to use pipelining as opposed to parallelism. However, parallelism may be useful if pipelining alone cannot meet the speed demand of the application or if the technology constraints (such as limitations on the clock rate by the I/O technology) limit the use of pipelining. In obvious ways, pipelining and parallelism can be combined also. Parallelism, like pipelining, can also lead to power reduction but with significant overhead in hardware requirements. Achieving pipelining and parallelism can be difficult for systems with feedback loops. Concurrency may be created in these systems by using the look-ahead transformation.

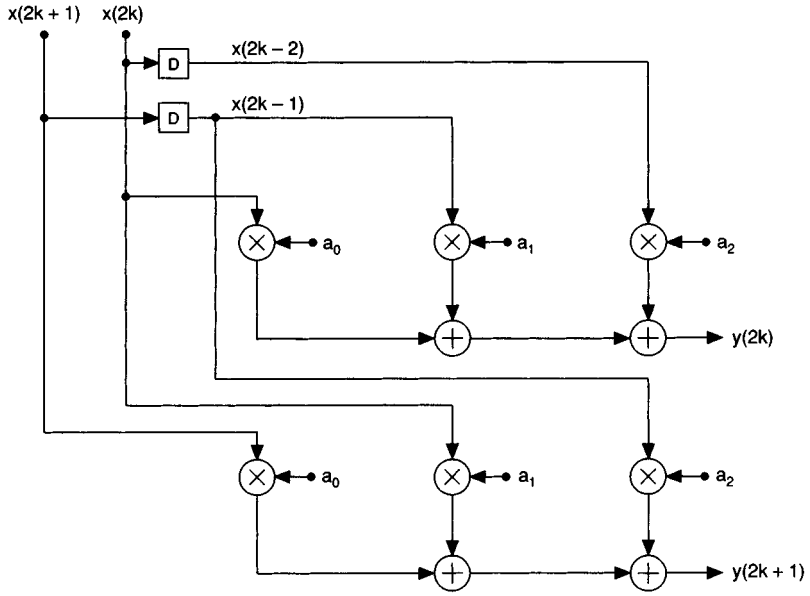

FIGURE 18.2 Twofold parallel realization of the three-tap filter of Fig. 18.1(a).

Retiming

Retiming is similar to pipelining but yet different in some ways [Leiserson et al., 1983]. Retiming is the process of moving the delays around in the data flow graph. Removal of one delay from all input edges of a node and insertion of one delay to each outgoing edge of the same node is the simplest example of retiming. Unlike pipelining, retiming does not increase the latency of the system. However, retiming alters the number of delay elements in the system. Retiming can reduce the critical path of the data flow graph. As a result, it can lead to clock period reduction in hardware implementations or critical path of the acyclic precedence graph or the iteration period in programmable software system implementations.

The single host formulation of the retiming transformation preserves the latency of the algorithm. The retiming formulation with no constraints on latency (i.e., with separate input and output hosts) can also achieve *pipelining with no retiming* or *pipelining with retiming*. Pipelining with retiming is the most desirable transformation in DSP architecture design. Pipelining with retiming can be interpreted to be identical to retiming of the original algorithm with a large number of delays at the input edges. Thus, we can increase the system latency arbitrarily and remove the appropriate number of delays from the inputs after the transformation.

The retiming formulation assigns retiming variables $r(.)$ to each node in the data flow graph. If $i(U \rightarrow V)$ is the number of delays associated with the edge $U \rightarrow V$ in the original data flow graph and $r(V)$ and $r(U)$, respectively, represent the retiming variable value of the nodes V and U, then the number of delays associated with the edge $U \rightarrow V$ in the retimed data flow graph is given by

$$i_r(U \rightarrow V) = i(U \rightarrow V) + r(V) - r(U)$$

For the data flow graph to be realizable, $i_r(U \rightarrow V) \geq 0$ must be satisfied. The retiming transformation formulates the problem by calculating path lengths and by imposing constraints on certain path lengths. These constraints are solved as a shortest-path problem.

To illustrate the usefulness of retiming, consider the data flow graph of a two-stage pipelined lattice digital filter graph shown in Fig. 18.3(a) and its equivalent pipelined-retimed data flow graph shown in Fig. 18.3(b). If the multiply time is two units and the add time is one unit, the architecture in Fig. 18.3(a) can be clocked with period 10 units whereas the architecture in Fig. 18.3(b) can be clocked with period 2 units.

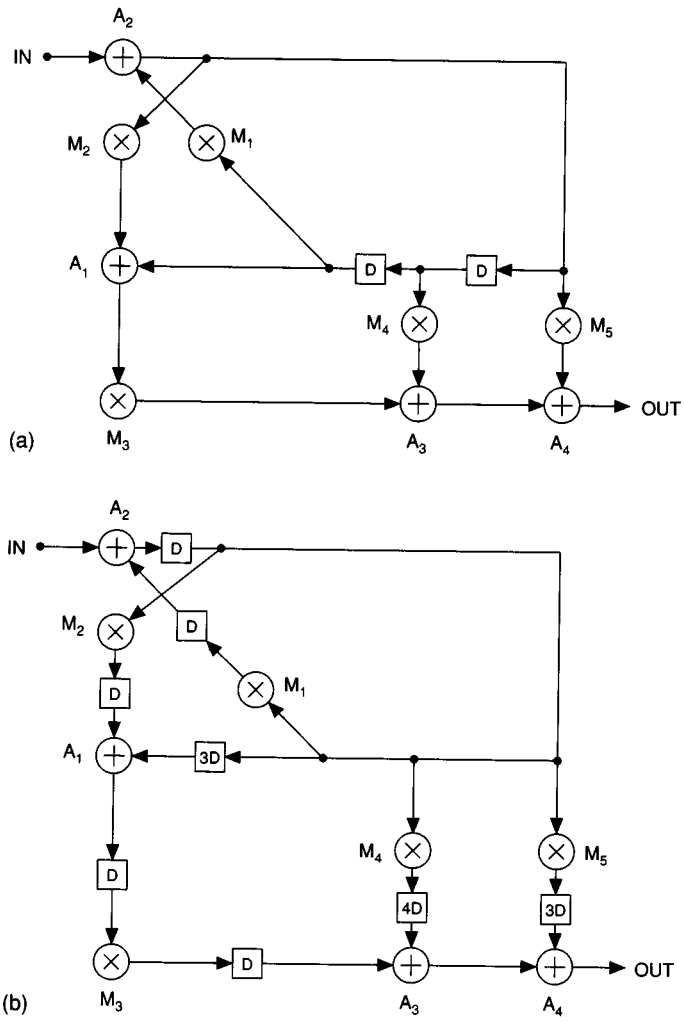

FIGURE 18.3 (a) A two-stage pipelinable time-invariant lattice digital filter. If multiplication and addition operations require 2 and 1 time units, respectively, then this data flow graph can achieve a sampling period of 10 time units (which corresponds to the critical path $M_1 \rightarrow A_2 \rightarrow M_2 \rightarrow A_1 \rightarrow M_3 \rightarrow A_3 \rightarrow A_4$). (b) The pipelined/retimed lattice digital filter can achieve a sampling period of 2 time units.

Unfolding

The **unfolding** transformation is similar to loop unrolling. In *J*-unfolding, each node is replaced by *J* nodes and each edge is replaced by *J* edges. The *J*-unfolded data flow graph executes *J* iterations of the original algorithm [Parhi, 1991].

The unfolding transformation can unravel the hidden concurrency in a data flow program. The achievable iteration period for a *J*-unfolded data flow graph is $1/J$ times the critical path length of the unfolded data flow graph. By exploiting interiteration concurrency, unfolding can lead to a lower iteration period in the context of a software programmable multiprocessor implementation.

The unfolding transformation can also be applied in the context of hardware design. If we apply an unfolding transformation on a (word-serial) nonrecursive algorithm, the resulting data flow graph represents a **word-parallel** (or simply parallel) algorithm that processes multiple samples or words in parallel every clock cycle. If we apply 2-unfolding to the 3-tap FIR filter in Fig. 18.1(a), we can obtain the data flow graph of Fig. 18.2.

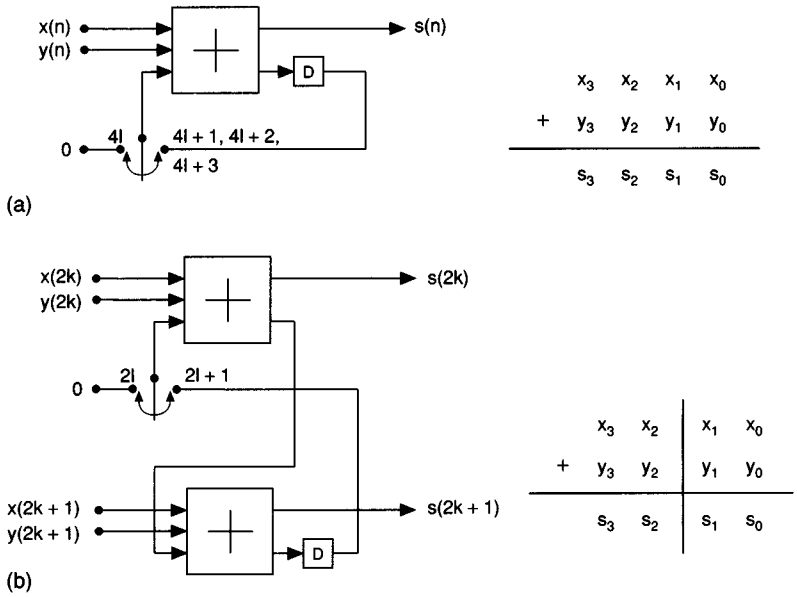

FIGURE 18.4 (a) A least-significant-bit first bit-serial adder for word length of 4; (b) a digit-serial adder with digit size 2 obtained by two-unfolding of the bit-serial adder. The bit position 0 stands for least significant bit.

Because the unfolding algorithm is based on graph theoretic approach, it can also be applied at the bit level. Thus, unfolding of a **bit-serial** data flow program by a factor of J leads to a **digit-serial** program with digit size J. The *digit size* represents the number of bits processed per clock cycle. The digit-serial architecture is clocked at the same rate as the bit-serial (assuming that the clock rate is limited by the communication I/O bound much before reaching the computation bound of the bit-serial program). Because the digit-serial program processes J bits per clock cycle the effective bit rate of the digit-serial architecture is J times higher. A simple example of this unfolding is illustrated in Fig. 18.4, where the bit-serial adder in Fig. 18.4(a) is unfolded by a factor of 2 to obtain the digit-serial adder in Fig. 18.4(b) for digit size 2 for a word length of 4. In obvious ways, the unfolding transformation can be applied to both word level and bit level simultaneously to generate word-parallel digit-serial architectures. Such architectures process multiple words per clock cycle and process a digit of each word (not the entire word).

Folding Transformation

The **folding** transformation is the reverse of the unfolding transformation. While the unfolding transformation is simpler, the folding transformation is more difficult [Parhi et al., 1992].

The folding transformation can be applied to fold a bit-parallel architecture to a digit-serial or bit-serial one or to fold a digit-serial architecture to a bit-serial one. It can also be applied to fold an algorithm data flow graph to a hardware data flow for a specified folding set. The folding set indicates the processor in which and the time partition at which a task is executed. A specified folding set may be infeasible, and this needs to be detected first. The folding transformation performs a preprocessing step to detect feasibility and in the feasible case transforms the algorithm data flow graph to an equivalent pipelined/retimed data flow graph that can be folded. For the special case of regular data flow graphs and for linear space–time mappings, the folding tranformation reduces to **systolic** array design.

In the folded architecture, each edge in the algorithm data flow graph is mapped to a communicating edge in the hardware architecture data flow graph. Consider an edge $U \rightarrow V$ in the algorithm data flow graph with associated number of delays $i(U \rightarrow V)$. Let the tasks U and V be mapped to the hardware units H_U and H_V respectively. Assume that N time partitions are available, i.e., the iteration period is N. A modulo operation determines the time partition. For example, the time unit 18 for $N = 4$ corresponds to time partition 18 modulo

4 or 2. Let the tasks U and V be executed in time partitions u and v, i.e., the lth iterations of tasks U and V are executed in time units $Nl + u$ and $Nl + v$, respectively. The $i(U \rightarrow V)$ delays in the edge $U \rightarrow V$ implies that the result of the lth iteration of U is used for the $(l + i)$th iteration of V. The $(l + i)$th iteration of V is executed in time unit $N(l + i) + v$. Thus the number of storage units needed in the folded edge corresponding to the edge $U \rightarrow V$ is

$$D_F(U \rightarrow V) = N(l + i) + v - Nl - u - P_u = Ni + v - u - P_u$$

where P_u is the level of pipelining of the hardware operator H_U. The $D_F(U \rightarrow V)$ delays should be connected to the edge between H_U and H_V and this signal should be switched to the input of H_V at time partition v. If the $D_F(U \rightarrow V)$'s as calculated here were always nonnegative for all edges $U \rightarrow V$, then the problem would be solved. However, some $D_F()$'s would be negative. The algorithm data flow graph needs to be pipelined and retimed such that all the $D_F()$'s are nonnegative. This can be formulated by simple inequalities using the retiming variables. The retiming formulation can be solved as a path problem, and the retiming variables can be determined if a solution exists. The algorithm data flow graph can be retimed for folding and the calculation of the $D_F()$'s can be repeated. The folded hardware architecture data flow graph can now be completed. The folding technique is illustrated in Fig. 18.5. The algorithm data flow graph of a two-stage pipelined lattice recursive digital filter of Fig. 18.3(a) is folded for the folding set shown in Fig. 18.5. Fig. 18.5(a) shows the pipelined/retimed data flow graph (preprocessed for folding) and Fig. 18.5(b) shows the hardware architecture data flow graph obtained after folding.

As indicated before, a special case of folding can address systolic array design for regular data flow graphs and for linear mappings. The systolic architectures make use of extensive pipelining and local communication and operate in a synchronous manner [Kung, 1988]. The systolic processors can also be made to operate in an asynchronous manner, and such systems are often referred to as wavefront processors. Systolic architectures have been designed for a variety of applications including convolution, matrix solvers, matrix decomposition, and filtering.

Look-Ahead Technique

The **look-ahead** technique is a very powerful technique for pipelining of recursive signal processing algorithms [Parhi and Messerschmitt, 1989]. This technique can transform a sequential recursive algorithm to an equivalent concurrent one, which can then be realized using pipelining or parallel processing or both. This technique has been successfully applied to pipeline many signal processing algorithms, including recursive digital filters (in direct form and lattice form), adaptive lattice digital filters, two-dimensional recursive digital filters, Viterbi decoders, Huffman decoders, and finite state machines. This research demonstrated that the recursive signal processing algorithms can be operated at high speed. This is an important result since modern signal processing applications in radar and image processing and particularly in high-definition and super-high-definition television video signal processing require very high throughput. Traditional algorithms and topologies cannot be used for such high-speed applications because of the inherent speed bound of the algorithm created by the feedback loops. The look-ahead transformation creates additional concurrency in the signal processing algorithms and the speed bound of the transformed algorithms is increased substantially. The look-ahead transformation is not free from its drawbacks. It is accompanied by an increase in the hardware overhead. This difficulty has encouraged us to develop inherently pipelinable topologies for recursive signal processing algorithms. Fortunately, this is possible to achieve in adaptive digital filters using relaxations on the look-ahead or by the use of relaxed look-ahead [Shanbhag and Parhi, 1992].

To begin, consider a time-invariant one-pole recursive digital filter transfer function

$$H(z) = \frac{X(z)}{U(z)} = \frac{1}{1 - az^{-1}}$$

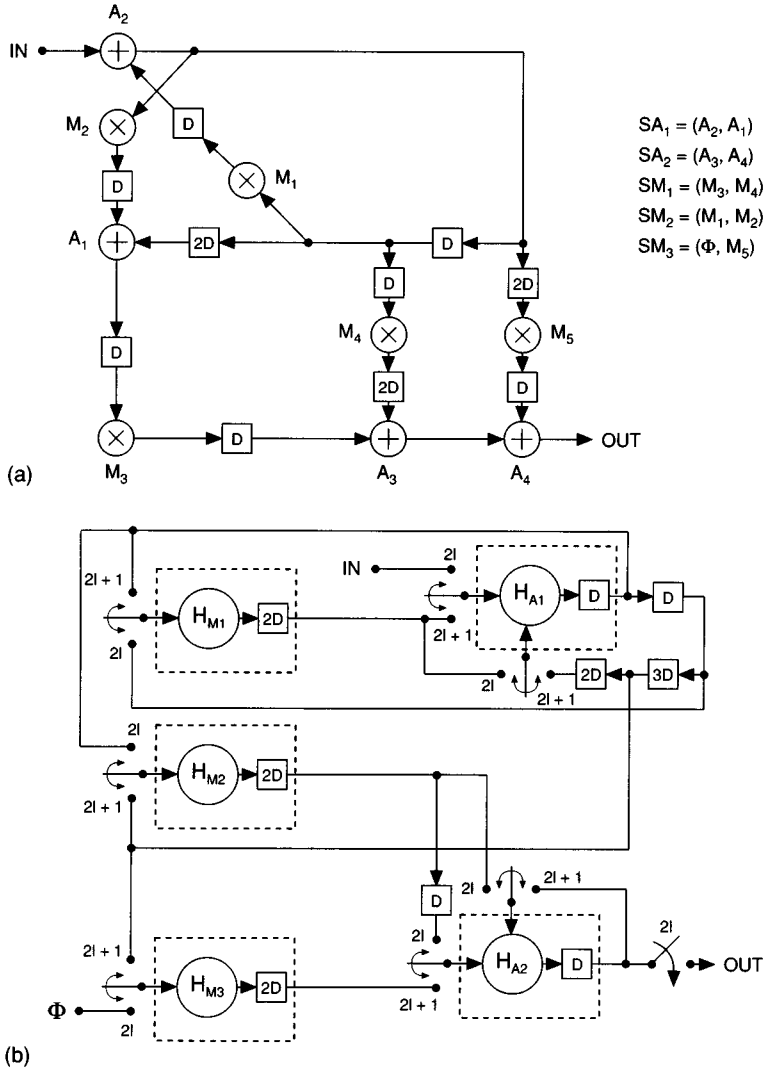

FIGURE 18.5 (a) A pipelined/retimed data flow graph obtained from Fig. 18.3(a) by preprocessing for folding; (b) the folded hardware architecture data flow graph. In our folding notation, the tasks are ordered within a set and the ordering represents the time partition in which the task is executed. For example, $SA_1 = (A_2, A_1)$ implies that A_2 and A_1 are, respectively, executed in even and odd time partitions in the same processor. The notation **Φ** represents a null operation.

described by the difference equation

$$x(n) = ax(n-1) + u(n)$$

and shown in Fig. 18.6(a). The maximum achievable speed in this system is limited by the operating speed of one multiply–add operation. To increase the speed of this system by a factor of 2, we can express $x(n)$ in terms of $x(n-2)$ by substitution of one recursion within the other:

$$x(n) = a[ax(n-2) + u(n-1)] + u(n) = a^2x(n-2) + au(n-1) + u(n)$$

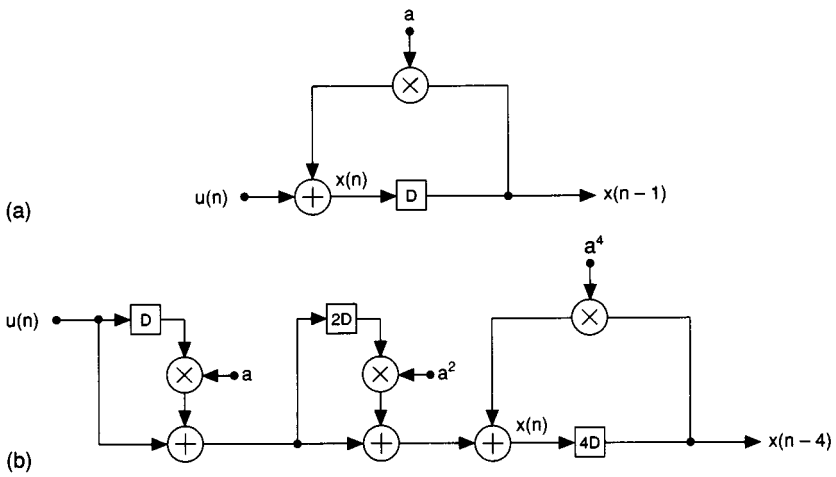

FIGURE 18.6 (a) A first-order recursive digital filter; (b) a four-stage pipelinable equivalent filter obtained by look-ahead computation.

The transfer function of the emulated second-order system is given by

$$H(z) = \frac{1 + az^{-1}}{1 - a^2 z^{-2}}$$

and is obtained by using a pole-zero cancellation at $-a$. In the modified system, $x(n)$ is computed using $x(n-2)$ as opposed to $x(n-1)$; thus we *look ahead*. The modified system has two delays in the multiply–add feedback loop, and these two delays can be distributed to pipeline the multiply–add operation by two stages. Of course, the additional multiply–add operation that represents one zero would also need to be pipelined by two stages to keep up with the sample rate of the system. To increase the speed by four times, we can rewrite the transfer function as:

$$H(z) = \frac{(1 + az^{-1})(1 + a^2 z^{-2})}{(1 - a^4 z^{-4})}$$

This system is shown in Fig. 18.6(b). Arbitrary speed increase is possible. However, for power-of-two speed increase the hardware complexity grows logarithmically with speed-up factor. The same technique can be applied to any higher-order system. For example, a second-order recursive filter with transfer function

$$H(z) = \frac{1}{1 - 2r\cos\theta z^{-1} + r^2 z^{-2}}$$

can be modified to

$$H(z) = \frac{1 + 2r\cos\theta z^{-1} + r^2 z^{-2}}{1 - 2r^2\cos 2\theta z^{-2} + r^4 z^{-4}}$$

for a twofold increase in speed. In this example, the output $y(n)$ is computed using $y(n-2)$ and $y(n-4)$; thus, it is referred to as *scattered look-ahead*.

While look-ahead can transform any recursive digital filter transfer function to pipelined form, it leads to a hardware overhead proportional to $N \log_2 M$, where N is the filter order and M is the speed-up factor. Instead of starting with a sequential digital filter transfer function obtained by traditional design approaches and transforming it for pipelining, it is more desirable to use a constrained filter design program that can satisfy the filter spectrum and the pipelining constraint. The pipelining constraint is satisfied by expressing the denominator of the transfer function in scattered look-ahead form. Such filter design programs have now been developed in both time domain and frequency domain. The advantage of the constrained filter design approach is that we can obtain pipelined digital filters with marginal or zero hardware overhead compared with sequential digital filters. The pipelined transfer functions can also be mapped to pipelined lattice digital filters. The reader might note that the data flow graph of Fig. 18.3(a) was obtained by this approach.

The look-ahead pipelining can also be applied for the design of transversal and adaptive lattice digital filters. Although look-ahead transformation can be used to modify the adaptive filter recursions to create concurrency, this requires large hardware overhead. The adaptive filters are based on weight update operations, and the weights are adapted based on the current error. Finally, the error becomes close to zero and the filter coefficients have been adapted. Thus, making relaxations on the error can reduce the hardware overhead substantially without degradation of the convergence behavior of the adaptive filter. Three types of relaxations of look-ahead are possible. These are referred to as *sum relaxation, product relaxation,* and *delay relaxation.* To illustrate these three relaxations, consider the weight update recursion

$$w(n+1) = a(n)w(n) + f(n)$$

where the term $a(n)$ is typically 1 for transversal least mean square (LMS) adaptive filters and of the form $(1 - \varepsilon(n))$ for lattice LMS adaptive digital filters, and $f(n) = \mu e(n)u(n)$ where μ is a constant, $e(n)$ is the error, and $u(n)$ is the input. The use of look-ahead transforms the above recursion to

$$w(n+M) = \prod_{i=0}^{M-1} a(n+M-i-1) \quad w(n)$$

$$+ \left[1a(n+M-1) \prod_{i=0}^{1} a(n+M-i-1) \ldots \prod_{i=0}^{M-2} a(n+M-i-1) \right] \begin{bmatrix} f(n+M-1) \\ f(n+M-2) \\ \cdot \\ \cdot \\ \cdot \\ f(n) \end{bmatrix}$$

In sum relaxation, we only retain the single term dependent on the current input for the last term of the look-ahead recursion. The relaxed recursion after sum relaxation is given by

$$w(n+M) = \prod_{i=0}^{M-1} a(n+M-i-1) \quad w(n) + f(n+M-1)$$

In lattice digital filters, the coefficient $a(n)$ is close to 1 for all n, since it can be expressed as $(1 - \varepsilon(n))$ and $\varepsilon(n)$ is close to zero for all n and is positive. The product relaxation on the above equation leads to

$$w(n+M) = (1 - M\varepsilon(n+M-1))\, w(n) + f(n+M-1)$$

The delay relaxation assumes the signal to be slowly varying or to be constant over D samples and replaces the look-ahead by

$$w(n+M) = (1 - M\varepsilon(n+M-1))\ w(n) + f(n+M-D-1)$$

These three types of relaxations make it possible to implement pipelined transversal and lattice adaptive digital filters with marginal increase in hardware overhead. Relaxations on the weight update operations change the convergence behavior of the adaptive filter, and we are forced to examine carefully the convergence behavior of the relaxed look-ahead adaptive digital filters. It has been shown that the relaxed look-ahead adaptive digital filters do not suffer from degradation in adaptation behavior. Futhermore, when coding, the use of pipelined adaptive filters could lead to a dramatic increase in pixel rate with no degradation in signal-to-noise ratio of the coded image and no increase in hardware overhead [Shanbhag and Parhi, 1992].

The concurrency created by look-ahead and relaxed look-ahead transformations can also be exploited in the form of parallel processing. Furthermore, for a constant speed, concurrent architectures (especially the pipelined architectures) can also lead to low power consumption.

Associativity Transformation

The addition operations in many signal processing algorithms can be interchanged since the add operations satisfy associativity. Thus, it is possible to move the add operations outside the critical loops to increase the maximum achievable speed of the system. As an example of the associative transformation, consider the realization of a second-order recursion $x(n) = 5/8x(n-1) - 3/4x(n-2) + u(n)$. Two possible realizations are shown in Fig. 18.7(a). The realization on the left contains one multiplication and two add operations in the critical inner loop, whereas the realization on the right contains one multiplication and one add operation in the critical inner loop. The realization on the left can be transformed to the realization on the right using the associativity transformation. Figure 18.7(b) shows a bit-serial implementation of this second-order recursion for the realization on the right for a word length of 8. This bit-serial system can be operated in a functionally correct manner for any word length greater than or equal to 5 since the inner loop computation latency is 5 cycles. On the other hand, if associativity were not exploited, then the minimum realizable word length would be 6. Thus, associativity can improve the achievable speed of the system.

Distributivity

Another local transformation that is often useful is distributivity. In this transformation, a computation $(A \times B) + (A \times C)$ may be reorganized as $A \times (B + C)$. Thus, the number of hardware units can be reduced from two multipliers and one adder to one multiplier and one adder.

Arithmetic Processor Architectures

In addition to algorithms and architecture designs, it is also important to address implementation styles and arithmetic processor architectures.

Most DSP systems use fixed-point hardware arithmetic operators. While many number system representations are possible, the two's complement number system is the most popular number system. The other number systems include the residue number system, the redundant or signed-digit number system, and the logarithmic number system. The residue and logarithmic number systems are rarely used or are used in very special cases such as nonrecursive digital filters. Shifting or scaling and division are difficult in the residue number system. Difficulty with addition and the overhead associated with logarithm and antilogarithm converters reduce the attractiveness of the logarithm number system. The use of the redundant number system leads to carry-free operation but is accompanied by the overhead associated with redundant-to-two's complement conversion. Another approach often used is distributed arithmetic. This approach has recently been used in a few video transformation chips.

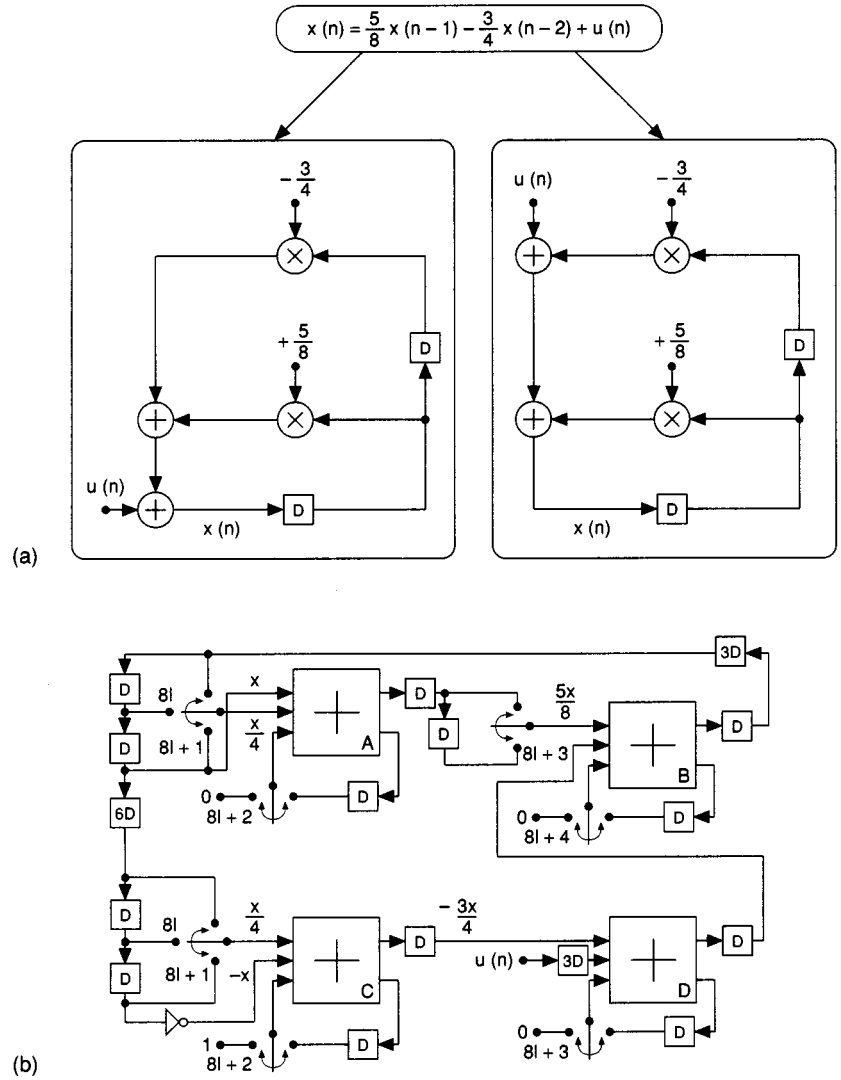

FIGURE 18.7 (a) Two associative realizations of a second-order recursion; (b) an efficient bit-serial realization of the recursion for a word length of 8.

The simplest arithmetic operation is addition. Multiplication can be realized as a series of add-shift operations, and division and square-root can be realized as a series of controlled add–subtract operations. The conventional two's complement adder involves carry ripple operation. This limits the throughput of the adder operation. In DSP, however, the combined multiply–add operation is most common. Carry–save operations have been used to realize pipelined multiply-adders using fewer pipelining latches. In conventional pipelined two's complement multiplier, the multiplication time is approximately two times the bit-level addition time. Recently, a technique has been proposed to reduce the multiplication time from $2W$ bit-level binary adder times to $1.25W$ bit-level binary adder times where W is the word length. This technique is based on the use of hybrid number system representation, where one input operand is in two's complement number representation and the other in redundant number representation [Srinivas and Parhi, 1992]. Using an efficient sign-select redundant-to-two's complement conversion technique, this multiplier can be made to operate faster and, in the pipelined mode, would require fewer pipelining latches and less silicon area.

Computer-Aided Design

With progress in the theory of architectures, the computer-aided design (CAD) systems for DSP application also become more powerful. In early 1980, the first silicon compiler system for signal processing was developed at the University of Edinburgh and was referred to as the FIRST design system. This system only addressed the computer-aided design of bit-serial signal processing systems. Since then more powerful systems have been developed. The Cathedral I system from Katholieke Universiteit Leuven and the BSSC (bit-serial silicon compiler) from GE Research Center in Schenectady, New York, also addressed synthesis of bit-serial circuits. The Cathedral system has now gone through many revisions, and the new versions can systhesize parallel multiprocessor data paths and can perform more powerful scheduling and allocation. The Lager design tool at the University of California at Berkeley was developed to synthesize the DSP algorithms using parametrizable macro building blocks (such as ALU, RAM, ROM). This system has also gone through many revisions. The Hyper system also developed at the University of California at Berkeley and the MARS design system developed at the University of Minnesota at Minneapolis perform higher level transformations and perform scheduling and allocation. These CAD tools are crucial to rapid prototyping of high-performance DSP integrated circuits.

Future VLSI DSP Systems

Future VLSI systems will make use of a combination of many types of architectures such as dedicated and programmable. These systems can be designed successfully with proper understanding of the algorithms, applications, theory of architectures, and with the use of advanced CAD systems.

Defining Terms

Bit serial: Processing of one bit per clock cycle. If word length is W, then one sample or word is processed in W clock cycles. In contrast, all W bits of a word are processed in the same clock cycle in a bit-parallel system.

Digit serial: Processing of more than one but not all bits in one clock cycle. If the digit size is W_1 and the word length is W, then the word is processed in W/W_1 clock cycles. If $W_1 = 1$, then the system is referred to as a bit-serial and if $W_1 = W$, then the system is referred to as a bit-parallel system. In general, the digit size W_1 need not be a divisor of the word length W, since the least and most significant bits of consecutive words can be overlapped and processed in the same clock cycle.

Folding: The technique of mapping many tasks to a single processor.

Look-ahead: The technique of computing a state $x(n)$ usng previous state $x(n - M)$ without requiring the intermediate states $x(n - 1)$ through $x(n - M + 1)$. This is referred to as a M-step look-ahead. In the case of higher-order computations, there are two forms of look-ahead: clustered look-ahead and scattered look-ahead. In clustered look-ahead, $x(n)$ is computed using the clustered states $x(n - M - N + 1)$ through $x(n - M)$ for an Nth order computation. In scattered look-ahead, $x(n)$ is computed using the scattered states $x(n - iM)$ where i varies from 1 to N.

Parallel processing: Processing of multiple tasks independently by different processors. This also increases the throughput.

Pipelining: A technique to increase throughput. A long task is divided into components, and each component is distributed to one processor. A new task can begin even though the former tasks have not been completed. In the pipelined operation, different components of different tasks are executed at the same time by different processors. Pipelining leads to an increase in the system latency, i.e., the time elapsed between the starting of a task and the completion of the task.

Retiming: The technique of moving the delays around the system. Retiming does not alter the latency of the system.

Systolic: Flow of data in a rhythmic fashion from a memory through many processors, returning to the memory just as blood flows

Unfolding: The technique of transforming a program that describes one iteration of an algorithm to another equivalent program that describes multiple iterations of the same algorithm.

Word parallel: Processing of multiple words in the same clock cycle.

18.2 Signal Processing Chips and Applications

Rulph Chassaing and Bill Bitler

Recent advances in very large scale integration (VLSI) have contributed to the current digital signal processors. These processors are just special-purpose fast microprocessors characterized by architectures and instructions suitable for real-time digital signal processing (DSP) applications. The commercial DSP processor, a little more than a decade old, has emerged because of the ever-increasing number of signal processing applications. DSP processors are now being utilized in a number of applications from communications and controls to speech and image processing. They have found their way into talking toys and music synthesizers. A number of texts [such as Chassaing, 1992] and articles [such as Ahmed and Kline, 1991] have been written, discussing the applications that use DSP processors and the recent advances in DSP systems.

DSP Processors

Digital signal processors are currently available from a number of companies, including Texas Instruments, Inc. (Texas), Motorola, Inc. (Arizona), Analog Devices, Inc. (Massachusetts), AT&T (New Jersey), and NEC (California). These processors are categorized as either **fixed-point** or **floating-point processors.** Several companies are now supporting both types of processors. **Special-purpose digital signal processors,** designed for a specific signal processing application such as for fast Fourier transform (FFT), have also emerged. Currently available digital signal processors range from simple, low cost processing units through high performance units such as Texas Instruments' (TI) TMS320C40 (Chassaing and Martin, 1995) and TMS320C80, and Analog Devices[1] ADSP-21060 SHARC (Chassaing and Ayers, 1996).

One of the first-generation digital signal processors is the (N-MOS technology) TMS32010, introduced by Texas Instruments in 1982. This first-generation fixed-point processor is based on the Harvard architecture, with a fast on-chip hardware multiplier/accumulator, and with data and instructions in separate memory spaces, allowing for concurrent accesses. This type of **pipelining feature** enables the processor to execute one instruction while fetching at the same time the next instruction. Other features include 144 (16-bit) words of on-chip data RAM and a 16-bit by 16-bit multiply operation in one instruction cycle time of 200 ns. Since many instructions can be executed in one single cycle, the TMS32010 is capable of executing 5 million instructions per second (MIPS). Major drawbacks of this first-generation processor are its limited **on-chip memory** size and much slower execution time for accessing external memory. Improved versions of this first-generation processor are now available in C-MOS technology, with a faster instruction cycle time of 160 ns.

The second-generation fixed-point processor TMS32020, introduced in 1985 by TI, was quickly followed by an improved C-MOS version TMS320C25 [Chassaing and Horning, 1990] in 1986. Features of the TMS320C25 include 544 (16-bit) words of on-chip data RAM, separate program and data memory spaces (each 64 K words), and an instruction cycle time of 100 ns, enabling the TMS320C25 to execute 10 MIPS. A faster version, TI's fixed-point TMS320C50 processor, is available with an instruction cycle time of 35 ns.

The third-generation TMS320C30 (by TI) supports fixed- as well as floating-point operations [Chassaing, 1992]. Features of this processor include 32-bit by 32-bit floating-point multiply operations in one instruction cycle time of 60 ns. Since a number of instructions, such as load and store, multiply and add, can be performed in parallel (in one cycle time), the TMS320C30 can execute a pair of parallel instructions in 30 ns, allowing for 33.3 MIPS. The Harvard-based architecture of the fixed-point processors was abandoned for one allowing four levels of pipelining with three subsequent instructions being consequently fetched, decoded, and read while the current instruction is being executed. The TMS320C30 has 2 K words of on-chip memory and a total of 16 million words of addressable memory spaces for program, data, and input/output. Specialized instructions are available to make common DSP algorithms such as filtering and spectral analysis execute fast and efficiently. The architecture of the TMS320C30 was designed to take advantage of higher-level languages such as C and ADA. The TMS320C31 and TMS320C32, recent members of the third-generation floating-point processors, are available with a 40 ns instruction cycle time.

DSP starter kits (DSK) are inexpensive development systems available from TI and based on both the fixed-point TMS320C50 and the floating-point TMS320C31 processors. We will discuss both the fixed-point TMS320C25 and the floating-point TMS320C30 digital signal processors, including the development tools available for each of these processors and DSP applications.

Fixed-Point TMS320C25-Based Development System

TMS320C25-based development systems are now available from a number of companies such as Hyperception Inc., Texas, and Atlanta Signal Processors, Inc., Georgia. The Software Development System (SWDS), available from TI includes a board containing the TMS320C25, which plugs into a slot on an IBM compatible PC. Within the SWDS environment, a program can be developed, assembled, and run. Debugging aids supported by the SWDS include single-stepping, setting of breakpoints, and display/modification of registers.

A typical workstation consists of:

1. An IBM compatible PC. Commercially available DSP packages (such as from Hyperception or Atlanta Signal Processors) include a number of utilities and filter design techniques.
2. The SWDS package, which includes an assembler, a linker, a debug monitor, and a **C compiler.**
3. Input/output alternatives such as TI's analog interface board (AIB) or analog interface chip (AIC).

The AIB includes a 12-bit analog-to-digital converter (ADC) and a 12-bit digital-to-analog converter (DAC). A maximum sampling rate of 40 kHz can be obtained. With (input) antialiasing and (output) reconstruction filters mounted on a header on the AIB, different input/output (I/O) filter bandwidths can be achieved. Instructions such as **IN** and **OUT** can be used for input/output accesses. The AIC, which provides an inexpensive I/O alternative, includes 14-bit ADC and DAC, antialiasing/reconstruction filters, all on a single C-MOS chip. Two inputs and one output are available on the AIC. (A TMS320C25/AIC interface diagram and communication routines can be found in Chassaing and Horning, 1990.) The TLC32047 AIC is a recent member of the TLC32040 family of voiceband analog interface circuits, with a maximum sampling rate of 25 kHz.

Implementation of a Finite Impulse Response Filter with the TMS320C25

The convolution equation

$$\begin{aligned} y(n) &= \sum_{k=0}^{N-1} h(k)x(n-k) \qquad (18.1)\\ &= h(0)x(n) + h(1)x(n-1) + \ldots + h(N-2)x(n-(N-2)) \\ &\quad + h(N-1)x(n-(N-1)) \end{aligned}$$

TABLE 18.1 TMS320C25 Memory Organization for Convolution

	Input Samples		
Coefficients	Time n	Time $n+1$	Time $n+2$
PC $\rightarrow h(N-1)$	$x(n)$	$x(n+1)$	$x(n+2)$
$h(N-2)$	$x(n-1)$	$x(n)$	$x(n+1)$
.	.	.	.
.	.	.	.
.	.	.	.
$h(2)$	$x(n-(N-3))$	$x(n-(N-4))$	$x(n-(N-5))$
$h(1)$	$x(n-(N-2))$	$x(n-(N-3))$	$x(n-(N-4))$
$h(0)$	AR1 $\rightarrow x(n-(N-1))$	$x(n-(N-2))$	$x(n-(N-3))$

represents a finite impulse response (FIR) filter with length N. The memory organization for the coefficients $h(k)$ and the input samples $x(n-k)$ is shown in Table 18.1. The coefficients are placed within a specified internal program memory space and the input samples within a specified data memory space. The program counter (PC) initially points at the memory location that contains the last coefficient $h(N-1)$, for example at memory address FF00h (in hex). One of the (8) auxiliary registers points at the memory address of the last or least recent input sample. The most recent sample is represented by $x(n)$. The following program segment implements (18.1):

```
LARP    AR1
RPTK    N-1
MACD    FF00h,*-
APAC
```

The first instruction selects auxiliary register AR1, which will be used for indirect addressing. The second instruction RPTK causes the subsequent MACD instruction to execute N times (repeated $N-1$ times). The MACD instruction has the following functions:

1. Multiplies the coefficient value $h(N-1)$ by the input sample value $x(n-(N-1))$.
2. Accumulates any previous product stored in a special register (TR).
3. Copies the data memory sample value into the location of the next-higher memory. This "data move" is to model the input sample delays associated with the next unit of time $n+1$.

The last instruction APAC accumulates the last multiply operation $h(0)x(n)$.

At time $n+1$, the convolution Eq. (18.1) becomes

$$y(n+1) = h(0)x(n+1) + h(1)x(n) + \ldots + h(N-2)x(n-(N-3)) + h(N-1)x(n-(N-2)) \tag{18.2}$$

The previous program segment can be placed within a loop, with the PC and the auxiliary register AR1 reinitialized (see the memory organization of the samples $x(k)$ associated with time $n+1$ in Table 18.1). Note that the last multiply operation is $h(0)x(.)$, where $x(.)$ represents the newest sample. This process can be continuously repeated for time $n+2$, $n+3$, and so on.

The characteristics of a frequency selective FIR filter are specified by a set of coefficients that can be readily obtained using commercially available filter design packages. These coefficients can be placed within a generic FIR program. Within 5–10 minutes, an FIR filter can be implemented in real time. This includes finding the coefficients; assembling, linking and downloading the FIR program into the SWDS; and observing the desired frequency response displayed on a spectrum analyzer. A different FIR filter can be quickly obtained since the only necessary change in the generic program is to substitute a new set of coefficients.

The approach for modeling the sample delays involves moving the data. A different scheme is used with the floating-point TMS320C30 processor with a circular mode of addressing.

TABLE 18.2 TMS320C30 Memory Organization for Convolution

Coefficients	Time n	Time $n+1$	Time $n+2$
AR0 $\rightarrow h(N-1)$	AR1 $\rightarrow x(n-(N-1))$	$x(n+1)$	$x(n+1)$
$h(N-2)$	$x(n-(N-2))$	AR1 $\rightarrow x(n-(N-2))$	$x(n+2)$
$h(N-3)$	$x(n-(N-3))$	$x(n-(N-3))$	AR1 $\rightarrow x(n-(N-3))$
.	.	.	.
.	.	.	.
.	.	.	.
$h(1)$	$x(n-1)$	$x(n-1)$	$x(n-1)$
$h(0)$	$x(n)$	$x(n)$	$x(n)$

Floating-Point TMS320C30-Based Development System

TMS320C30-based DSP development systems are also currently available from a number of companies. The following are available from Texas Instruments:

1. An evaluation module (EVM). The EVM is a powerful, yet relatively inexpensive 8-bit card that plugs into a slot on an IBM AT compatible. It includes the third-generation TMS320C30, 16 K of user RAM, and an AIC for I/O. A serial port connector available on the EVM can be used to interface the TMS320C30 to other input/output devices (the TMS320C30 has two serial ports). An additional AIC can be interfaced to the TMS320C30 through this serial port connector. A very powerful, yet inexpensive, analog evaluation fixture, available from Burr-Brown (Arizona), can also be readily interfaced to the serial port on the EVM. This complete two-channel analog evaluation fixture includes an 18-bit DSP102 ADC, an 18-bit DSP202 DAC, antialiasing and reconstruction filters. The ADC has a maximum sampling rate of 200 kHz.
2. An XDS1000 emulator—powerful but quite expensive. A module can be readily built as a target system to interface to the XDS1000 [Chassaing, 1992]. This module contains the TMS320C30, 16 K of static RAM. Two connectors are included on this module, for interfacing to either an AIC module or to a second-generation analog interface board (AIB). The AIC was discussed in conjunction with the TMS320C25. The AIB includes Burr-Brown's 16-bit ADC and DAC with a maximum sampling rate of 58 kHz. An AIC is also included on this newer AIB version.

EVM Tools

The EVM package includes an assembler, a linker, a simulator, a C compiler, and a C source debugger. The second-generation TMS320C25 fixed-point processor is supported by C with some degrees of success. The architecture and instruction set of the third-generation TMS320C30 processor facilitate the development of high-level language compilers. An optimizer option is available with the C compiler for the TMS320C30. A C-code program can be readily compiled, assembled, linked, and downloaded into either a simulator or the EVM for real-time processing. A run-time support library of C functions, included with the EVM package, can be used during linking. During simulation, the input data can be retrieved from a file and the output data written into a file. Input and output port addresses can be appropriately specified. Within a real-time processing environment with the EVM, the C source debugger can be used. One can single-step through a C-code program while observing the equivalent step(s) through the assembly code. Both the C code and the corresponding assembly code can be viewed through the EVM windows. One can also monitor at the same time the contents of registers, memory locations, and so on.

Implementation of a Finite Impulse Response Filter with the TMS320C30

Consider again the convolution equation, Eq. (18.1), which represents an FIR filter. Table 18.2 shows the TMS320C30 memory organization used for the coefficients and the input samples. Initially, all the input samples can be set to zero. The newest sample $x(n)$, at time n, can be retrieved from an ADC using the following instructions:

```
        FLOAT     *AR3,R3
        STF       R3, *AR1++%
```

These two instructions cause an input value $x(n)$, retrieved from an input port address specified by auxiliary register AR3, to be loaded into a register R3 (one of eight 40-bit-wide extended precision registers), then stored in a memory location pointed by AR1 (AR1 would be first initialized to point at the "bottom" or higher-memory address of the table for the input samples). AR1 is then postincremented in a circular fashion, designated with the modulo operator %, to point at the oldest sample $x(n - (N - 1))$, as shown in Table 18.2. The size of the circular buffer must first be specified. The following program segment implements (18.1):

```
        RPTS      LENGTH-1
        MPYF      *AR0++%,*AR1++%,R0
||      ADDF      R0,R2,R2
        ADDF      R0,R2
```

The repeat "single" instruction RPTS causes the next (multiply) floating-point instruction MPYF to be executed LENGTH times (repeated LENGTH-1), where LENGTH is the length of the FIR filter. Furthermore, since the first ADDF addition instruction is in parallel (designated by ||) with the MPYF instruction, it is also executed LENGTH times. From Table 18.2, AR0, one of the eight available auxiliary registers, initially points at the memory address (a table address) which contains the coefficient $h(N-1)$, and a second auxiliary register AR1 now points to the address of the oldest input sample $x(n-(N-1))$. The second indirect addressing mode instruction multiplies the content in memory (address pointed by AR0) $h(N-1)$ by the content in memory (address pointed by AR1) $x(n-N-1)$), with the result stored in R0. Concurrently (in parallel), the content of R0 is added to the content of R2, with the result stored in R2. Initially R0 and R2 are set to zero; hence, the resulting value in R2 is *not* the product of the first multiply operation. After the first multiply operation, both AR0 and AR1 are incremented, and $h(N-2)$ is multiplied by $x(n-(N-2))$. Concurrently, the result of the first multiply operation (stored in R0) is accumulated into R2. The second addition instruction, executed only once, accumulates the last product $h(0)x(n)$ (similar to the APAC instruction associated with the fixed-point TMS320C25). The overall result yields an output value $y(n)$ at time n. After the last multiply operation, both AR0 and AR1 are postincremented to point at the "top" or lower-memory address of each circular buffer. The process can then be repeated for time $n+1$ in order to obtain a second output value $y(n+1)$. Note that the newest sample $x(n+1)$ would be retrieved from an ADC using the FLOAT and STF instructions, then placed at the top memory location of the buffer (table) containing the samples, overwriting the initial value $x(n-(N-1))$. AR1 is then incremented to point at the address containing $x(n-(N-2))$, and the previous four instructions can be repeated. The last multiply operation involves $h(0)$ and $x(.)$, where $x(.)$ is the newest sample $x(n+1)$, at time $n+1$. The foregoing procedure would be repeated to produce an output $y(n+2)$, $y(n+3)$, and so on. Each output value would be converted to a fixed-point equivalent value before being sent to a DAC. The frequency response of an FIR filter with 41 coefficients and a center frequency of 2.5 kHz, obtained from a signal analyzer, is displayed in Fig. 18.8.

FIR and IIR Implementation Using C and Assembly Code

A real-time implementation of a 45-coefficient bandpass FIR filter and a sixth-order IIR filter with 345 samples, using C code and TMS320C30 code, is discussed in Chassaing and Bitler [1991]. Tables 18.3 and 18.4 show a comparison of execution times of those two filters. The C language FIR filter, implemented without the modulo operator %, and compiled with a C compiler V4.1, executed two times slower[1] than an equivalent assembly language filter (which has a similar execution time as one implemented with a filter routine in assembly, called by a C program). The C language IIR filter ran 1.3 times slower than the corresponding assembly language IIR filter. These slower execution times may be acceptable for many applications. Where execution speed is crucial,

[1] 1.5 times slower using a newer C compiler V4.4.

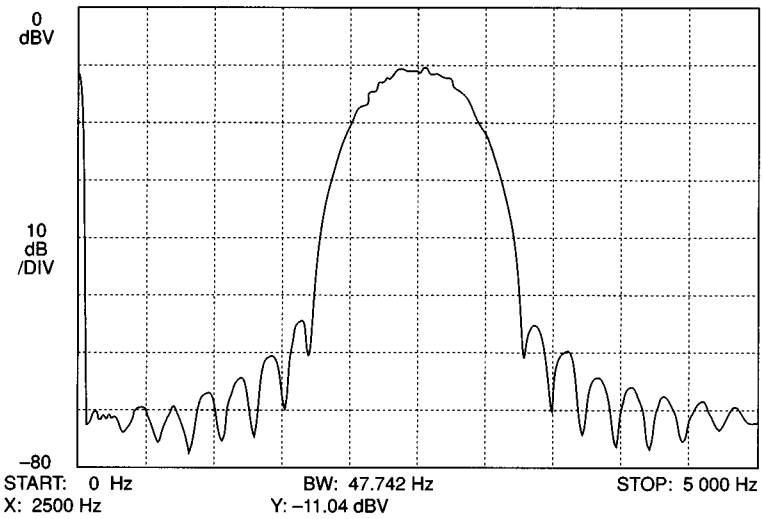

FIGURE 18.8 Frequency response of 41-coefficient FIR filter.

TABLE 18.3 Execution Time and Program Size of FIR Filter

FIR (45 samples)	Execution Time (msec)	Size (words)
C with modulo	4.16	122
C without modulo	0.338	116
C-called assembly	0.1666	74
Assembly	0.1652	27

TABLE 18.4 Execution Time and Program Size of 6th-Order IIR Filter

IIR (345 samples)	Execution Time (msec)	Size (words)
C	1.575	109
Assembly	1.18	29

a time-critical function may be written in assembly and called from a C program. In applications where speed is not absolutely crucial, C provides a better environment because of its portability and maintainability.

Real-Time Applications

A number of applications are discussed in Chassaing and Horning (1990) using TMS320C25 code and in Chassaing (1992) using TMS320C30 and C code. These applications include multirate and adaptive filtering, modulation techniques, and graphic and parametric equalizers. Two applications are briefly discussed here: a ten-band multirate filter and a video line rate analysis.

1. The functional block diagram of the multirate filter is shown in Fig. 18.9. The multirate design provides a significant reduction in processing time and data storage, compared to an equivalent single-rate design. With multirate filtering, we can use a decimation operation in order to obtain a sample rate reduction or an interpolation operation (as shown in Fig. 18.9) in order to obtain a sample rate increase [Crochiere and Rabiner, 1983]. A pseudorandom noise generator implemented in software provides the input noise to the ten octave band filters. Each octave band filter consists of three 1/3-octave filters (each with 41 coefficients), which can be individually controlled. A controlled noise source can be obtained with this design. Since each 1/3-octave band filter can be turned *on* or *off*, the noise spectrum can be shaped accordingly. The interpolation filter is a low-pass FIR filter with a 2:1 data-rate increase, yielding two sample outputs for each input sample. The sample rate of the highest octave-band filter is set at 32,768 samples per second, with each successively lower band processing at half the rate of the next-higher band. The multirate filter (a nine-band version) was implemented with the TMS320C25 [Chassaing et al., 1990]. Figure 18.10 shows the three 1/3-octave band filters of band 10 implemented with the EVM

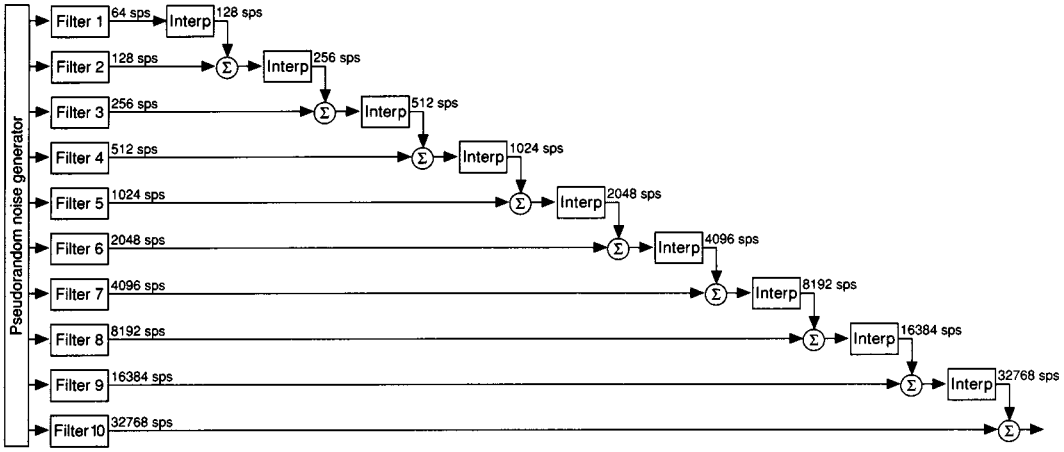

FIGURE 18.9 Multirate filter functional block diagram.

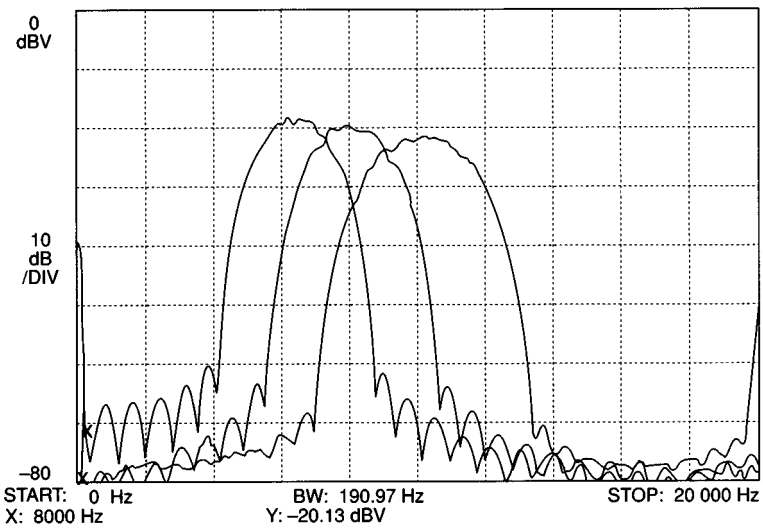

FIGURE 18.10 Frequency responses of the 1/3-octave band ten filters.

in conjunction with the two-channel analog fixture (made by Burr-Brown). The center frequency of the middle 1/3-octave band 10 filter is at approximately 8 kHz since the coefficients were designed for a center frequency of 1/4 the sampling rate (the middle 1/3-octave band 9 filter would be centered at 4 kHz, the middle 1/3-octave band 8 filter at 2 kHz, and so on). Note that the center frequency of the middle 1/3-octave band 1 filter would be at 2 Hz if the highest sampling rate is set at 4 kHz. Observe from Fig. 18.10 that the crossover frequencies occur at the 3-dB points. Since the main processing time of the multirate filter (implemented in assembly code) was measured to be 8.8 ms, the maximum sampling rate was limited to 58 ksps.

2. A video line rate analysis implemented entirely in C code is discussed in Chassaing and Bitler [1992]. A module was built to sample a video line of information. This module included a 9.8-MHz clock, a high sampling rate 8-bit ADC and appropriate support circuitry (comparator, FIFO buffer, etc.). Interactive features allowed for the selection of one (out of 256) horizontal lines of information and the execution of algorithms for digital filtering, averaging, and edge enhancement, with the resulting effects displayed on the PC screen. Figure 18.11 shows the display of a horizontal line (line #125) of information

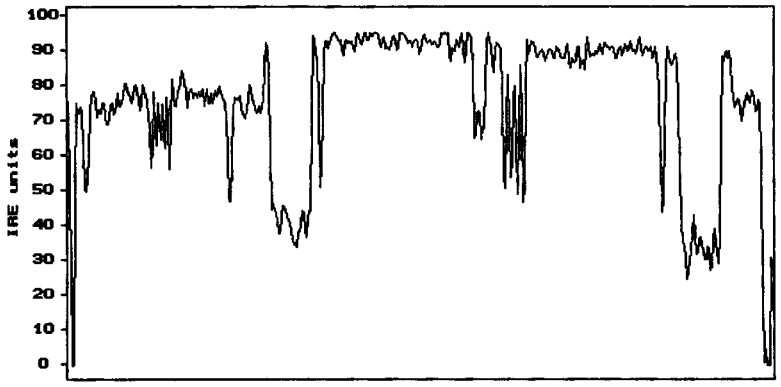

FIGURE 18.11 Display of a horizontal line of video signal.

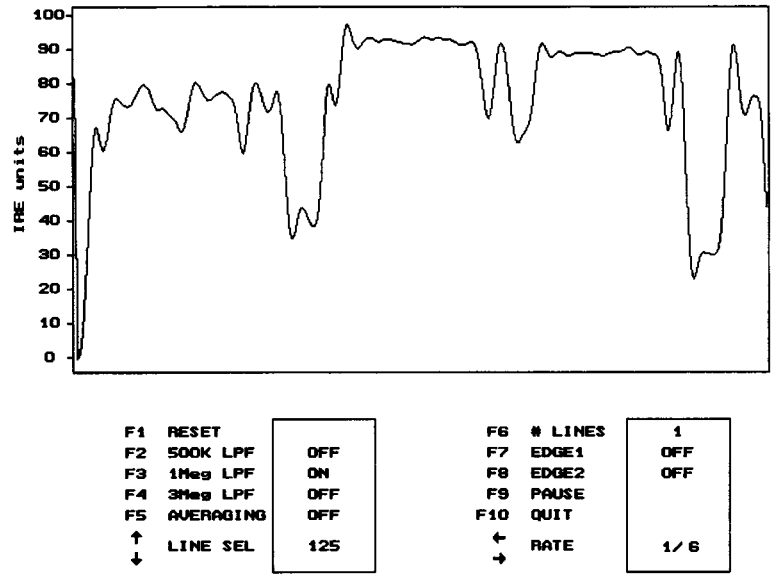

FIGURE 18.12 Video line signal with 1-MHz filtering.

obtained from a test chart with a charge coupled device (CCD) camera. The function key **F3** selects the 1-MHz low-pass filter resulting in the display shown in Fig. 18.12. The 3-MHz filter (with **F4**) would pass more of the higher-frequency components of the signal but with less noise reduction. **F5** implements the noise averaging algorithm. The effect of the edge enhancement algorithm (with **F7**) is displayed in Fig. 18.13.

Conclusions and Future Directions

DSP processors have been used extensively in a number of applications, even in non-DSP applications such as graphics. The fourth-generation floating-point TMS320C40, code compatible with the TMS320C30, features an instruction cycle time of 40 ns and six serial ports. The fifth-generation fixed-point TMS320C50, code compatible with the first two generations of fixed-point processors, features an instruction cycle time of 35 ns and 10 K words (16-bit) of on-chip data and program memory. Currently, both the fixed-point and floating-point processors are being supported by TI.

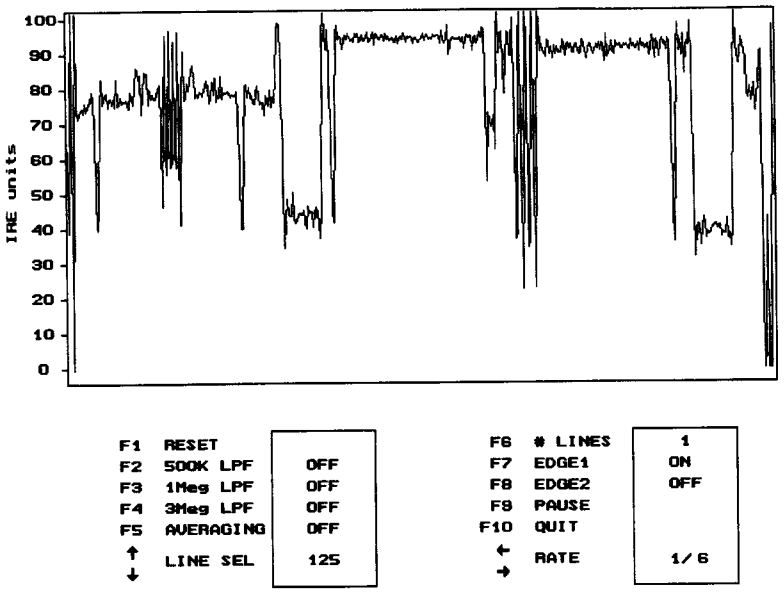

FIGURE 18.13 Video line signal with edge enhancement.

Defining Terms

C compiler: Program that translates C code into assembly code.

Digital signal processor: Special-purpose microprocessor with an architecture suitable for fast execution of signal processing algorithms.

Fixed-point processor: A processor capable of operating on scaled integer and fractional data values.

Floating-point processor: Processor capable of operating on integers as well as on fractional data values without scaling.

On-chip memory: Internal memory available on the digital signal processor.

Pipelining feature: Feature that permits parallel operations of fetching, decoding, reading, and executing.

Special-purpose digital signal processor: Digital signal processor with special feature for handling a specific signal processing application, such as FFT.

19.1 Digital Signal Processing in Audio and Electroacoustics

Juergen Schroeter

In this section we will focus on advances in algorithms and technologies in digital signal processing (DSP) that have already had or, most likely, will soon have, a major impact on **audio** and **electroacoustics** (A&E). Because A&E embraces a wide range of topics, it is impossible for us to go here into any depth in any one of them. Instead, this section will try to give a compressed overview of the topics the author judges to be most important.

In the following, we will look into steerable microphone arrays, digital hearing aids, spatial processing, audio coding, echo cancellation, and active noise and sound control. We will *not* cover basic techniques in digital recording [Pohlmann, 1989] and computer music [Moore, 1990].

Steerable Microphone Arrays

Steerable microphone arrays have controllable directional characteristics. One important application is in teleconferencing. Here, sound pickup can be highly degraded by reverberation and room noise. One solution to this problem is to utilize highly directional microphones. Instead of pointing such a microphone manually to a desired talker, steerable microphone arrays can be used for reliable automatic tracking of speakers as they move around in a noisy room or auditorium, if combined with a suitable speech detection algorithm.

Figure 19.1 depicts the simplest kind of steerable array using N microphones that are uniformly spaced with distance d along the linear x-axis. It can be shown that the response of this system to a plane wave impinging at an angle θ is:

$$H(j\omega) = \sum_{n=0}^{N-1} a_n e^{-j(\omega/c)nd\cos\theta} \tag{19.1}$$

Here, $j = \sqrt{-1}$, ω is the radian frequency, and c is the speed of sound. Equation (19.1) is a spatial filter with coefficients a_n and the delay operator $z^{-1} = \exp(-jd\omega/c\cos\theta)$. Therefore, we can apply finite impulse response (FIR) filter theory. For example, we could taper the weights a_n to suppress sidelobes of the array. We also have to guard against spatial aliasing, that is, grating lobes that make the directional characteristic of the array

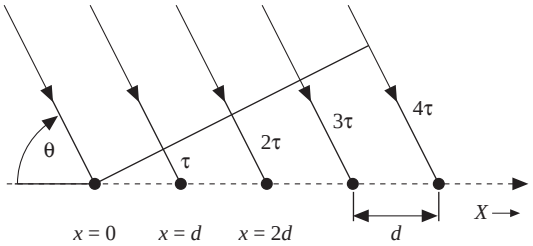

FIGURE 19.1 A linear array of N microphones (here, $N = 5$; $\tau = d/c \cos\theta$).

FIGURE 19.2 Three superimposed linear arrays depicted by large, midsize, and small circles. The largest array covers the low frequencies, the midsize array covers the midrange frequencies, and the smallest covers the high frequencies.

ambiguous. The array is steered to an angle θ_0 by introducing appropriate delays into the N microphone lines. In Eq. (19.1), we can incorporate these delays by letting a_n

$$a_n = e^{-j\omega\tau_0} \; e^{+j(\omega/c)nd\cos\theta_0} \tag{19.2}$$

Here τ_0 is an overall delay equal to or larger than $Nd/c \cos\theta_0$ that ensures causality, while the second term in Eq. (19.2) cancels the corresponding term in Eq. (19.1) at $\theta = \theta_0$. Due to the axial symmetry of the one-dimensional (linear, 1-D) array, the directivity of the array is a figure of revolution around the x-axis. Therefore, in case we want the array to point to a *single* direction in space, we need a 2-D array.

Since most of the energy of typical room noise and the highest level of reverberation in a room is at low frequencies, one would like to use arrays that have their highest directivity (i.e., narrowest beamwidth) at low frequencies. Unfortunately, this need collides with the physics of arrays: the smaller the array relative to the wavelength, the wider the beam. (Again, the corresponding notion in filter theory is that systems with shorter impulse responses have wider bandwidth.) One solution to this problem is to superimpose different-size arrays and filter each output by the appropriate bandpass filter, similar to a crossover network used in two- or three-way loudspeaker designs. Such a superposition of three five-element arrays is shown in Fig. 19.2. Note that we only need nine microphones in this example, instead of $5 \times 3 = 15$.

Another interesting application is the use of an array to mitigate discrete noise sources in a room. For this, we need to attach an FIR filter to each of the microphone signal outputs. For any given frequency, one can show that N microphones can produce $N - 1$ nulls in the directional characteristic of the array. Similarly, attaching an M-point FIR filter to each of the microphones, we can get these zeros at $M - 1$ frequencies. The weights for these filters have to be adapted, usually under the constraint that the transfer function (frequency characteristic) of the array for the *desired* source is optimally flat. In practical tests, systems of this kind work nicely in (almost) anechoic environments. Their performance degrades, however, with increasing reverberation.

More information on microphone arrays can be found in Flanagan et al. [1991]; in particular, they describe how to make arrays adapt to changing talker positions in a room by constantly scanning the room with a moving search beam and by switching the main beam accordingly. Current research issues are, among others, 3-D arrays and how to take advantage of low-order wall reflections.

Digital Hearing Aids

Commonly used hearing aids attempt to compensate for sensorineural (cochlear) hearing loss by delivering an amplifed acoustic signal to the external ear canal. As will be pointed out below, the most important problem is how to find the best aid for a given patient.

Historically, technology has been the limiting factor in hearing aids. Early on, carbon hearing aids provided a limited gain and a narrow, peaky frequency response. Nowadays, hearing aids have a broader bandwidth and a flatter frequency response. Consequently, more people can benefit from the improved technology. With the advent of digital technology, the promise is that even more people would be able to do so. Unfortunately, as will be pointed out below, we have not fulfilled this promise yet.

We distinguish between *analog*, *digitally controlled analog*, and *digital* hearing aids. Analog hearing aids contain only (low-power) pre-amp, filter(s), (optional) automatic gain control (AGC) or compressor, power amp, and output limiter. Digitally controlled aids have certain additional components: one kind adds a digital controller to monitor and adjust the analog components of the aid. Another kind contains switched-capacitor circuits that represent sampled signals in analog form, in effect allowing simple discrete-time processing (e.g., filtering). Aids with switched-capacitor circuits have a lower power consumption compared to digital aids. Digital aids—none are yet commercially available—contain A/D and D/A converters and at least one programmable digital signal processing (DSP) chip, allowing for the use of sophisticated DSP algorithms, (small) microphone arrays, speech enhancement in noise, etc. Experts disagree, however, as to the usefulness of these techniques. To date, the most successful approach seems to be to ensure that all parts of the signal get amplified so that they are clearly audible but not too loud and to "let the brain sort out signal and noise."

Hearing aids pose a tremendous challenge for the DSP engineer, as well as for the audiologist and acoustician. Due to the continuing progress in chip technology, the physical size of a digital aid should no longer be a serious problem in the near future; however, power consumption will still be a problem for quite some time. Besides the obvious necessity of avoiding howling (acoustic feedback), for example, by employing sophisticated models of the electroacoustic transducers, acoustic leaks, and ear canal to control the aid accordingly, there is a much more fundamental problem: since DSP allows complex schemes of splitting, filtering, compressing, and (re-) combining the signal, hearing aid performance is no longer limited by bottlenecks in technology. It is still limited, however, by the lack of basic knowledge about how to map an arbitrary input signal (i.e., speech from a desired speaker) onto the reduced capabilities of the auditory system of the targeted wearer of the aid. Hence, the *selection and fitting of an appropriate aid* becomes the most important issue. This serious problem is illustrated in Fig. 19.3.

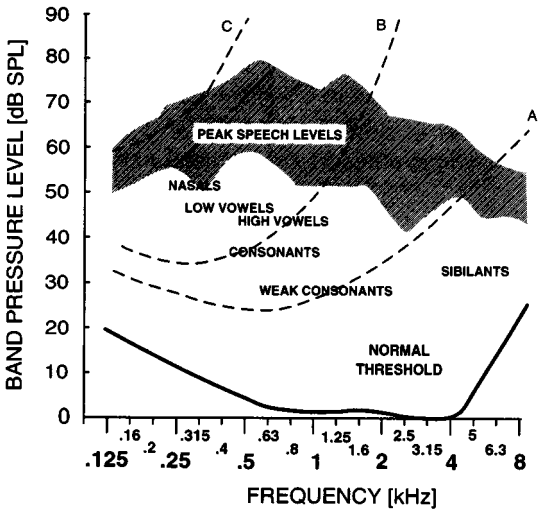

FIGURE 19.3 Peak third-octave band levels of normal to loud speech (hatched) and typical levels/dominant frequencies of speech sounds (identifiers). Both can be compared to the third-octave threshold of normal-hearing people (solid line), thresholds for a mildly hearing-impaired person (A), for a severely hearing-impaired person (B), and for a profoundly hearing-impaired person (C). For example, for person (A), sibilants and some weak consonants in a normal conversation cannot be perceived. (*Source:* H. Levitt, "Speech discrimination ability in the hearing impaired: spectrum considerations," in *The Vanderbilt Hearing-Aid Report: State of the Art-Research Needs*, G.A. Studebaker and F.H. Bess (Eds.), Monographs in Contemporary Audiology, Upper Darby, Pa., 1982, p. 34. With permission.)

It is important to note that for speech presented at a constant level, a linear (no compression) hearing aid can be tuned to do as well as a hearing aid with compression. However, if parameters like signal and background noise levels change dynamically, compression aids, in particular those with two bands or more, should have an advantage.

While a patient usually has no problem telling whether setting A or B is "clearer," adjusting more than just 2–3 (usually interdependent) parameters is very time consuming. For a multiparameter aid, an efficient fitting procedure that maximizes a certain objective is needed. Possible objectives are, for example, **intelligibility maximization** or **loudness restoration**. The latter objective is assumed in the following.

It is known that an impaired ear has a reduced dynamic range. Therefore, the procedure for fitting a patient with a hearing aid could estimate the so-called loudness-growth function (LGF) that relates the sound pressure

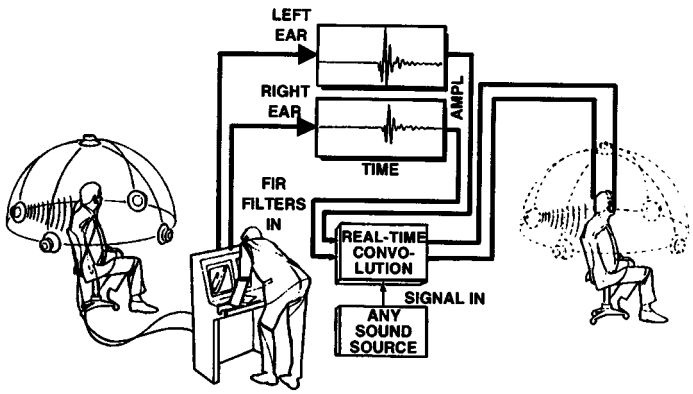

FIGURE 19.4 Measuring and using transfer functions of the external ear for binaural mixing (FIR = finite impulse response). (*Source:* E.M. Wenzel, Localization in virtual acoustic displays, *Presence*, vol. 1, p. 91, 1992. With permission.)

level of a specific (band-limited) sound to its loudness. An efficient way of measuring the LGF is described by Allen et al. [1990]. Once the LGF of an impaired ear is known, a multiband hearing aid can implement the necessary compression for each band [Villchur, 1973]. Note, however, that this assumes that interactions between the bands can be neglected (problem of summation of partial loudnesses). This might not be valid for aids with a large number of bands. Other open questions include the choice of widths and filter shape of the bands, and optimization of dynamic aspects of the compression (e.g., time constants). For aids with just two bands, the crossover frequency is a crucial parameter that is difficult to optimize.

Spatial Processing

In spatial processing, audio signals are modified to give them new spatial attributes, such as, for example, the perception of having been recorded in a specific concert hall. The auditory system—using only the two ears as inputs—is capable of perceiving the direction and distance of a sound source with a high degree of accuracy, by exploiting **binaural** and **monaural** spectral cues. Wave propagation in the ear canal is essentially one-dimensional. Hence, the 3-D spatial information is coded by sound diffraction into spectral information before the sound enters the ear canal. The sound diffraction is caused by the head/torso (on the order of 20-dB and 600-μs **interaural** level difference and delay, respectively) and at the two pinnae (auriculae); see, for example, Shaw [1980]. Binaural techniques like the one discussed below can be used for evaluating room and concert-hall acoustics (optionally in reduced-scale model rooms using a miniature dummy head), for noise assessment (e.g., in cars), and for "Kunstkopfstereophonie" (dummy-head stereophony). In addition, there are techniques for *loudspeaker reproduction* (like "Q-Sound") that try to extend the range in horizontal angle of traditional stereo speakers by using interaural cross cancellation. Largely an open question is how to reproduce spatial information for large audiences, for example, in movie theaters.

Figure 19.4 illustrates the technique for filtering a single-channel source using measured headrelated transfer functions, in effect, creating a virtual sound source in a given direction of the listener's auditory space (assuming plane waves, i.e., infinite source distance). On the left in this figure, the measurement of head-related transfer functions is shown. Focusing on the *left* ear for a moment (subscript l), we need to estimate the so-called free-field transfer function (subscript ff) for given angles of incidence in the horizontal plane (azimuth φ) and vertical plane (elevation δ):

$$H_{\mathrm{ff,l}}(j\omega, \varphi, \delta) = P_{\mathrm{probe,l}}(j\omega, \varphi, \delta)/P_{\mathrm{ref}}(j\omega) \tag{19.3}$$

where $P_{\mathrm{probe,l}}$ is the Fourier transform of the sound pressure measured in the subject's left ear, and P_{ref} is the Fourier transform of the pressure measured at a suitable reference point in the free field without the subject being present (e.g., at the midpoint between the two ears). (Note that P_{ref} is independent of the direction of sound incidence since we assume an anechoic environment.) The middle of Fig. 19.4 depicts the convolution

of any "dry" (e.g., mono, low reverberation) source with the stored $H_{ff,l}(j\omega, \varphi, \delta)$s and corresponding $H_{ff,r}(j\omega, \varphi, \delta)$s. On the right side in the figure, the resulting binaural signals are reproduced via equalized headphones. The equalization ensures that a sound source with a flat spectrum (e.g., white noise) does not suffer any perceivable coloration for any direction (φ, δ).

Implemented in a real-time "binaural mixing console," the above scheme can be used to create "virtual" sound sources. When combined with an appropriate scheme for interpolating head-related transfer functions, moving sound sources can be mimicked realistically. Furthermore, it is possible to superimpose early reflections of a hypothetical recording room, each filterered by the appropriate head-related transfer function. Such inclusion of a room in the simulation makes the spatial reproduction more robust against individual differences between "recording" and "listening" ears, in particular, if the listener's head movements are fed back to the binaural mixing console. (Head movements are useful for disambiguating spatial cues.) Finally, such a system can be used to create "virtual acoustic displays," for example, for pilots and astronauts [Wenzel, 1992]. Other research issues are, for example, the required accuracy of the head-related transfer functions, intersubject variability, and psychoacoustic aspects of room simulations.

Audio Coding

Audio coding is concerned with compressing (reducing the bit rate) of audio signals. The uncompressed digital audio of compact disks (CDs) is recorded at a rate of 705.6 kbit/s for each of the two channels of a stereo signal (i.e., 16 bit/sample, 44.1-kHz sampling rate; 1411.2 kbit/s total). This is too high a bit rate for digital audio broadcasting (DAB) or for transmission via end-to-end digital telephone connections (integrated services digital network, ISDN). Current audio coding algorithms provide at least "better than FM" quality at a combined rate of 128 kbit/s for the two stereo channels (2 ISDN B channels!), "transparent coding" at rates of 96 to 128 kbit/s per mono channel, and "studio quality" at rates between 128 and 196 kbit/s per mono channel. (While a large number of people will be able to detect distortions in the first class of coders, even so-called "golden ears" should not be able to detect any differences between original and coded versions of known "critical" test signals; the highest quality category adds a safety margin for editing, filtering, and/or recoding.)

To compress audio signals by a factor as large as eleven while maintaining a quality exceeding that of a local FM radio station requires sophisticated algorithms for reducing the **irrelevance and redundancy** in a given signal. A large portion (but usually less than 50%) of the bit-rate reduction in an audio coder is due to the first of the two mechanisms. Eliminating irrelevant portions of an input signal is done with the help of psychoacoustic models. It is obvious that a coder can eliminate portions of the input signal that—when played back—will be below the threshold of hearing. More complicated is the case when we have multiple signal components that tend to cover each other, that is, when weaker components cannot be heard due to the presence of stronger components. This effect is called *masking*. To let a coder take advantage of masking effects, we need to use good masking models. Masking can be modeled in the time domain where we distinguish so-called simultaneous masking (masker and maskee occur at the *same* time), forward masking (masker occurs *before* maskee), and backward masking (masker occurs *after* maskee). Simultaneous masking usually is modeled in the frequency domain. This latter case is illustrated in Fig. 19.5.

Audio coders that employ common frequency-domain models of masking start out by splitting and subsampling the input signal into different frequency bands (using filterbanks such as subband filterbanks or time-frequency transforms). Then, the masking threshold (i.e., *predicted* masked threshold) is determined, followed by quantization of the spectral information and (optional) noiseless compression using variable-length coding. The encoding process is completed by multiplexing the spectral information with side information, adding error protection, etc.

The first stage, the filter bank, has the following requirements. First, decomposing and then simply reconstructing the signal should not lead to distortions ("perfect reconstruction filterbank"). This results in the advantage that all distortions are due to the quantization of the spectral data. Since each quantizer works on band-limited data, the distortion (also band-limited due to refiltering) is controllable by using the masking models described above. Second, the bandwidths of the filters should be narrow to provide sufficient coding gain. On the other hand, the length of the impulse responses of the filters should be short enough (time resolution of the coder!) to avoid so-called pre-echoes, that is, backward spreading of distortion components

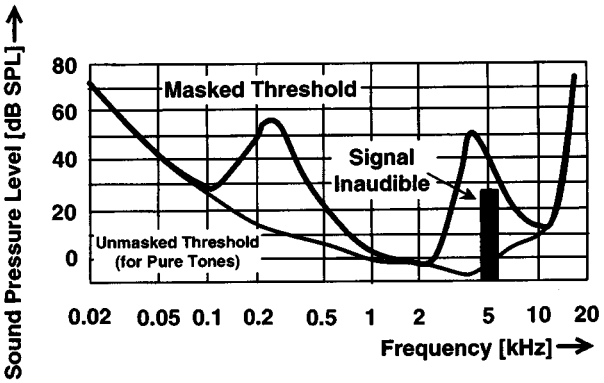

FIGURE 19.5 Masked threshold in the frequency domain for a hypothetical input signal. In the vicinity of high-level spectral components, signal components below the current masked threshold cannot be heard.

that result from sudden onsets (e.g., castanets). These two contradictory requirements, obviously, have to be worked out by a compromise. "**Critical band**" filters have the shortest impulse responses needed for coding of transient signals. On the other hand, the optimum frequency resolution (i.e., the one resulting in the highest coding gain) for a typical signal can be achieved by using, for example, a 2048-point modified discrete cosine transform (MDCT).

In the second stage, the (time-varying) masking threshold as determined by the psychoacoustic model usually controls an iterative analysis-by-synthesis quantization and coding loop. It can incorporate rules for masking of tones by noise and of noise by tones, though little is known in the psychoacoustic literature for more general signals. Quantizer step sizes can be set and bits can be allocated according to the known spectral estimate, by block companding with transmission of the scale factors as side information or iteratively in a variable-length coding loop (Huffman coding). In the latter case, one can low-pass filter the signal if the total required bit rate is too high.

The decoder has to invert the processing steps of the encoder, that is, do the error correction, perform Huffman decoding, and reconstruct the filter signals or the inverse-transformed time-domain signal. Since the decoder is significantly less complex than the encoder, it is usually implemented on a single DSP chip, while the encoder uses several DSP chips.

Current research topics encompass tonality measures and time-frequency representations of signals. More information can be found in Johnston and Brandenburg [1991].

Echo Cancellation

Echo cancellers were first deployed in the U.S. telephone network in 1979. Today, they are virtually ubiquitous in long-distance telephone circuits where they cancel so-called line echoes (i.e., *electrical* echoes) resulting from nonperfect hybrids (the devices that couple local two-wire to long-distance four-wire circuits). In satellite circuits, echoes bouncing back from the far end of a telephone connection with a round-trip delay of about 600 ms are very annoying and disruptive. *Acoustic* echo cancellation—where the echo path is characterized by the transfer function $H(z)$ between a loudspeaker and a microphone in a room (e.g., in a speakerphone)—is crucial for teleconferencing where two or more parties are connected via full-duplex links. Here, echo cancellation can also alleviate acoustic feedback ("howling").

The principle of acoustic echo cancellation is depicted in Fig. 19.6(a). The echo path $H(z)$ is cancelled by modeling $H(z)$ by an adaptive filter and subtracting the filter's output $\hat{y}(t)$ from the microphone signal $y(t)$. The adaptability of the filter is necessary since $H(z)$ changes appreciably with movement of people or objects in the room and because periodic measurements of the room would be impractical. *Acoustic* echo cancellation is more challenging than cancelling line echoes for several reasons. First, room impulse responses $h(t)$ are longer than 200 ms compared to less than 20 ms for line echo cancellers. Second, the echo path of a room $h(t)$ is likely to change constantly (note that even small changes in temperature can cause significant changes of h). Third,

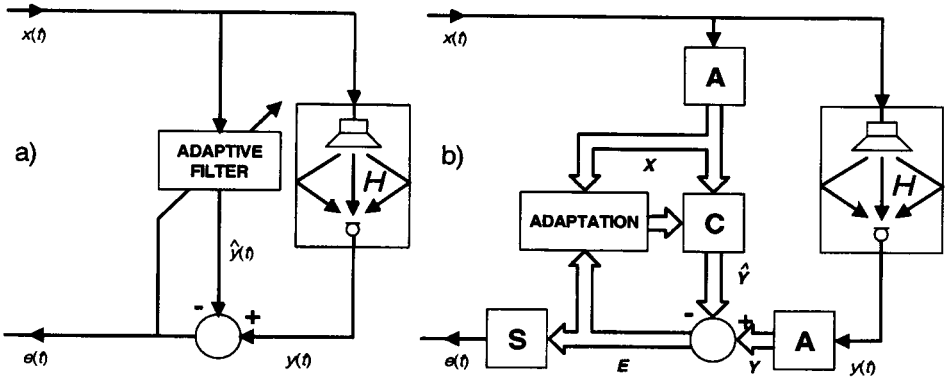

FIGURE 19.6 (a) Principle of using an echo canceller in teleconferencing. (b) Realization of the echo canceller in subbands. (After M. M. Sondhi and W. Kellermann, "Adaptive echo cancellation for speech signals," in *Advances in Speech Signal Processing*, S. Furui and M. M. Sondhi, Eds., New York: Marcel Dekker, 1991. By courtesy of Marcel Dekker, Inc.)

teleconferencing eventually will demand larger audio bandwidths (e.g., 7 kHz) compared to standard telephone connections (about 3.2 kHz). Finally, we note that echo cancellation in a stereo setup (*two* microphones and *two* loudspeakers at each end) is an even harder problem on which very little work has been done so far.

It is obvious that the initially unknown echo path $H(z)$ has to be "learned" by the canceller. It is also clear that for adaptation to work there needs to be a nonzero input signal $x(t)$ that excites all the eigenmodes of the system (resonances, or "peaks" of the system magnitude response $|H(j\omega)|$). Another important problem is how to handle double-talk (speakers at both ends are talking simultaneously). In such a case, the canceller could easily get confused by the speech from the near end that acts as an uncorrelated noise in the adaptation. Finally, the convergence rate, that is, how fast the canceller adapts to a change in the echo path, is an important measure to compare different algorithms.

Adaptive filter theory suggests several algorithms for use in echo cancellation. The most popular one is the so-called *least-mean square* (LMS) algorithm that models the echo path by an FIR filter with an impulse response $\hat{h}(t)$. Using vector notation h for the true echo path impulse response, $\hat{\mathrm{h}}$ for its estimate, and x for the excitation time signal, an estimate of the echo is obtained by $\hat{y}(t) = \hat{\mathrm{h}}'\mathrm{x}$, where the prime denotes vector transpose. A reasonable objective for a canceller is to minimize the instantaneous squared error $e^2(t)$, where $e(t) = y(t) - \hat{y}(t)$. The time derivative of $\hat{\mathrm{h}}$ can be set to

$$\frac{\mathrm{d}\hat{\mathbf{h}}}{\mathrm{d}t} = -\mu\nabla_{\hat{\mathbf{h}}}\, e^2(t) = -2\mu e(t)\nabla_{\hat{\mathbf{h}}}\, e(t) = 2\mu e(t)\mathbf{x} \tag{19.4}$$

resulting in the simple update equation $\hat{h}_{k+1} = \hat{h}_k + \alpha e_k x_k$, where α (or μ) control the rate of change. In practice, whenever the far-end signal $x(t)$ is low in power, it is a good idea to freeze the canceller by setting $\alpha = 0$. Sophisticated logic is needed to detect double talk. When it occurs, then also set $\alpha = 0$. It can be shown that the spread of the eigenvalues of the autocorrelation matrix of $x(t)$ determines the convergence rate, where the slowest-converging eigenmode corresponds to the smallest eigenvalue. Since the eigenvalues themselves scale with the power of the predominant spectral components in $x(t)$, setting $\alpha = 2\mu/(\mathrm{x}'\mathrm{x})$ will make the convergence rate independent of the far-end power. This is the *normalized* LMS method. Even then, however, all eigenmodes will converge at the same rate only if $x(t)$ is white noise. Therefore, pre-whitening the far-end signal will help in speeding up convergence.

The LMS method is an iterative approach to echo cancellation. An example of a noniterative, block-oriented approach is the *least-squares* (LS) algorithm. Solving a system of equations to get $\hat{\mathrm{h}}$, however, is computationally more costly. This cost can be reduced considerably by running the LS method on a sample-by-sample basis and by taking advantage of the fact that the new signal vectors are the old vectors with the oldest sample dropped and one new sample added. This is the *recursive least-squares* (RLS) algorithm. It also has the advantage

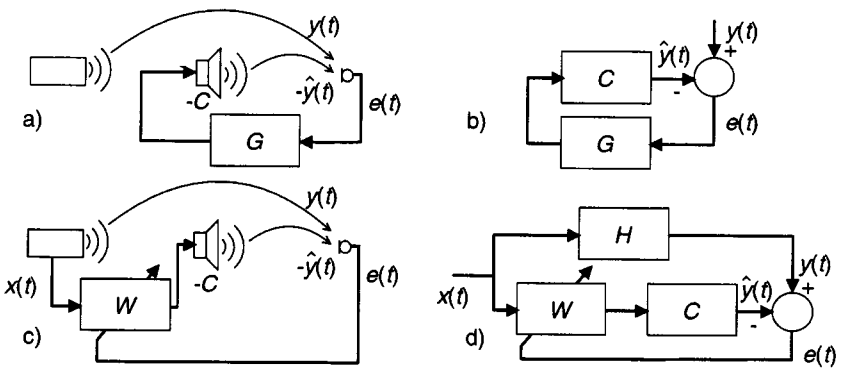

FIGURE 19.7 Two principles of active noise control. Feedback control system (a) and (b); feedforward control system (c) and (d). Physical block diagrams (a) and (c), and equivalent electrical forms (b) and (d). (After P. A. Nelson and S. J. Elliott, *Active Control of Sound*, London: Academic Press, 1992. With permission.)

of normalizing x by multiplying it with the inverse of its autocorrelation matrix. This, in effect, equalizes the adaptation rate of all eigenmodes.

Another interesting approach is outlined in Fig. 19.6(b). As in subband coding (discussed earlier), splitting the signals x and y into subbands with analysis filterbanks **A**, doing the cancellation in bands, and resynthesizing the outgoing ("error") signal e through a synthesis filterbank **S** also reduces the eigenvalue spread of each bandpass signal compared to the eigenvalue spread of the fullband signal. This is true for the eigenvalues that correspond to the "center" (i.e., unattenuated) portions of each band. It turns out, however, that the slowly converging "transition-band" eigenmodes get attenuated significantly by the synthesis filter **S**. The main advantage of the subband approach is the reduction in computational complexity due to the down-sampling of the filterbank signals. The drawback of the subband approach, however, is the introduction of the combined delay of **A** and **S**. Eliminating the analysis filterbank on $y(t)$ and moving the synthesis filterbank into the adaptation branch $\hat{Y}$ will remove this delay with the result that the canceller will not be able to model the earliest portions of the echo-path impulse response $h(t)$. To alleviate this problem, we could add in parallel a fullband echo canceller with a short filter. Further information and an extensive bibliography can be found in Haensler [1992].

Active Noise and Sound Control

Active noise control (ANC) is a way to reduce the sound pressure level of a given noise source through electroacoustic means. ANC and echo cancellation are somewhat related. While even *acoustic* echo cancellation is actually done on electrical signals, ANC could be labeled "wave cancellation," since it involves using one or more secondary acoustic or vibrational sources. Another important difference is the fact that in ANC one usually would like to cancel a given noise in a whole *region* in space, while echo cancellation commonly involves only one microphone picking up the echo signal at a single *point* in space. Finally, the transfer function of the transducer used to generate a cancellation ("secondary source") signal needs to be considered in ANC.

Active sound control (ASC) can be viewed as an offspring of ANC. In ASC, instead of trying to cancel a given sound field, one tries to control specific spatial and temporal characteristics of the sound field. One application is in adaptive sound reproduction systems. Here, ASC aims at solving the large-audience spatial reproduction problem mentioned in the spatial processing section of this chapter.

Two important principles of ANC are depicted in Fig. 19.7. In the upper half [Fig. 19.7(a) and (b)], a feedback loop is formed between the controller $G(s)$ and the transfer function $C(s)$ of the secondary source, and the acoustic path to the error microphone. Control theory suggests that $E/Y = 1/[1 + C(s)G(s)]$, where $E(s)$ and $Y(s)$ are Laplace transforms of $e(t)$ and $y(t)$, respectively. Obviously, if we could make C a real constant and $G \rightarrow \infty$, we would get a "zone of quiet" around the error microphone. Unfortunately, in practice, $C(s)$ will introduce at least a delay, thus causing stability problems for too large a magnitude $|G|$ at high enough frequencies. The system can be kept stable, for example, by including a low-pass filter in G and by positioning the secondary source in close vicinity to the error microphone. A highly successful application of the feedback

control in ANC is in *active* hearing protective devices (HPDs) and high-quality headsets and "motional-feedback" loudspeakers. *Passive* HPDs offer little or no noise attenuation at low frequencies due to inherent physical limitations. Since the volume enclosed by earmuffs is rather small, HPDs can benefit from the increase in low-frequency attenuation brought about by feedback-control ANC. Finally, note that the same circuit can be used for high-quality reproduction of a communications signal $s(t)$ fed into a headset by subtracting $s(t)$ electrically from $e(t)$. The resulting transfer function is $E/S = C(s)G(s)/[1 + C(s)G(s)]$ assuming $Y(s) = 0$. Thus, a high loop gain $|G(s)|$ will ensure both, a high noise attenuation at low frequencies and a faithful bass reproduction of the communications signal.

The principle of the feedforward control method in ANC is outlined in the lower half of Fig. 19.6(c) and (d). The obvious difference to the feedback control method is that the separate reference signal $x(t)$ is used. Here, cancellation is achieved for the filter transfer function $W = H(s)/C(s)$ which is most often implemented by an adaptive filter. The fact that $x(t)$ reaches the ANC system earlier than $e(t)$ allows for a causal filter, needed in broadband systems. However, a potential problem with this method is the possibility of feedback of the secondary source signal $\hat{y}(t)$ into the path of the reference signal $x(t)$. This is obviously the case when $x(t)$ is picked up by a microphone in a duct just upstream of the secondary source C. An elegant solution for ANC in a duct without explicit feedback cancellation is to use a recursive filter W.

Single error signal/single secondary source systems cannot achieve *global* cancellation or sound control in a room. An intuitive argument for this fact is that one needs *at least* as many secondary sources and error microphones as there are orthogonal wave modes in the room. Since the number of wave modes in a room below a given frequency is approximately proportional to the third power of this frequency, it is clear that ANC (and ASC) is practical only at low frequencies. In practice, using small (point-source) transducers, it turns out that one should use more error microphones than secondary sources. Examples of such multidimensional ANC systems are employed for cancelling the lowest few harmonics of the engine noise in an airplane cabin and in a passenger car. In both of these cases, the adaptive filter matrix is controlled by a multiple-error version of the LMS algorithm. Further information can be found in Nelson and Elliott [1992].

Summary and Acknowledgment

In this section, we have touched upon several topics in audio and electroacoustics. The reader may be reminded that the author's choice of these topics was biased by his background in communication acoustics (and by his lack of knowledge in music). Furthermore, ongoing efforts in integrating different communication modalities into systems for teleconferencing [see, e.g., Flanagan et al., 1990] had a profound effect in focusing this contribution. Experts in topics covered in this contribution, like Jont Allen, David Berkley, Gary Elko, Joe Hall, Jim Johnston, Mead Killion, Harry Levitt, Dennis Morgan, and—last, but not least—Mohan Sondhi, are gratefully acknowledged for their patience and help.

Defining Terms

Audio: Science of processing signals that are within the frequency range of hearing, that is, roughly between 20 Hz and 20 kHz. Also name for this kind of signal.

Critical bands: Broadly used to refer to psychoacoustic phenomena of limited frequency resolution in the cochlea. More specifically, the concept of critical bands evolved in experiments on the audibility of a tone in noise of varying bandwidth, centered around the frequency of the tone. Increasing the noise bandwidth beyond a certain critical value has little effect on the audibility of the tone.

Electroacoustics: Science of interfacing between acoustical waves and corresponding electrical signals. This includes the engineering of transducers (e.g., loudspeakers and microphones), but also parts of the psychology of hearing, following the notion that it is not necessary to present to the ear signal components that cannot be perceived.

Intelligibility maximization and loudness restoration: Two different objectives in fitting hearing aids. Maximizing intelligibility involves conducting laborious intelligibility tests. Loudness restoration involves measuring the mapping between a given sound level and its perceived loudness. Here, we assume that recreating the loudness a normal hearing person would perceive is close to maximizing the intelligibility of speech.

Irrelevance and redundancy: In audio coding, irrelevant portions of an audio signal can be removed without perceptual effect. Once removed, however, they cannot be regenerated in the decoder. Contrary to this, redundant portions of a signal that have been removed in the encoder can be regenerated in the decoder. The "lacking" irrelevant parts of an original signal constitute the major cause for a (misleadingly) low signal-to-noise ratio (SNR) of the decoded signal while its subjective quality can still be high.

Monaural/interaural/binaural: *Monaural* attributes of ear input signals (e.g., timbre, loudness) require, in principle, only one ear to be detected. *Interaural* attributes of ear input signals (e.g., localization in the horizontal plane) depend on differences between, or ratios of measures of, the two ear input signals (e.g., delay and level differences). Psychoacoustic effects (e.g., cocktail-party effect) that depend on the fact that we have two ears are termed *binaural*.

Bloom, "High-quality digital audio in the entertainment industry: An overview of achievements and challenges," *IEEE-ASSP Magazine*, Oct. 1985. An excellent introduction to the fundamentals of audio, including music synthesis and digital recording, is contained in the 1992 book *Music Speech Audio*, by W. J. Strong and G. R. Plitnik, available from Soundprint, 2250 North 800 East, Provo, UT 84604 (ISBN 0-9611938-2-4). *Oversampling Delta-Sigma Data Converters* is a 1992 collection of papers edited by J. C. Candy and G. C. Temes. It is available from IEEE Press (IEEE order number PC0274-1). Specific issues of the *Journal of Rehabilitation Research and Development* (ISSN 007-506X), published by the Veterans Administration, are a good source of information on hearing aids, in particular the Fall 1987 issue. *Spatial Hearing* is the title of a 1982 book by J. Blauert, available from MIT Press (ISBN 0-262-02190-0). Anyone interested in *Psychoacoustics* should look into the 1990 book of this title by E. Zwicker and H. Fastl, available from Springer-Verlag (ISBN 0-387-52600-5).

The Institute of Electrical and Electronics Engineers (IEEE) *Transactions on Speech and Audio Processing* is keeping up-to-date on algorithms in audio. Every two to three years, a workshop on applications of signal processing to audio and electroacoustics covers the latest advances in areas introduced in this article. IEEE can be reached at 445 Hoes Lane, Piscataway, NJ 08855-1331, ph. (908) 981-0060. *The Journal of the Audio Engineering Society* (AES) is another useful source of information on audio. The AES can be reached at 60 East 42nd St., Suite 2520, New York, NY 10165-0075, ph. (212) 661-8528. *The Journal of the Acoustical Society of America* (ASA) contains information on physical, psychological, and physiological acoustics, as well as on acoustic signal processing, among other things. ASA's "Auditory Demonstrations" CD contains examples of signals demonstrating hearing-related phenomena ranging from "critical bands" over "pitch" to "binaural beats." ASA can be reached at 500 Sunnyside Blvd., Woodbury, NY 11797-2999, ph. (516) 576-2360.

19.2 Underwater Acoustical Signal Processing

Sanjay K. Mehta and G. Clifford Carter

What Is Underwater Acoustical Signal Processing?

The use of acoustical signals that have propagated through water to detect, classify, and localize underwater objects is referred to as underwater acoustical signal processing.

Why Exploit Sound for Underwater Applications?

It has been found that acoustic energy propagates better under water than other types of energy. For example, both light and radio waves (used for satellite or above-ground communications) are attenuated to a far greater degree under water than are sound waves. For this reason sound waves have generally been used to extract information about underwater objects. A typical underwater acoustical signal processing scenario is shown in Fig. 19.8.

Technical Overview

In underwater acoustics, a number of units are used: distances of nautical miles (1852 m), yards (0.9144 m) and kiloyards; speeds of knots (nautical mile/h); depths of fathoms (6 ft or 1.8288 m); and bearing of degrees (0.01745 rad). However, in the past two decades there has been a conscious effort to be totally metric, i.e., to use MKS or Standard International units.

Underwater acoustic signals to be processed for detection, classification, and localization can be characterized from a statistical point of view. When time averages of each waveform are the same as the ensemble average of waveforms, the signals are ergodic. When the statistics do not change with time, the signals are said to be stationary. The spatial equivalent to stationary is homogeneous. For many introductory problems, only stationary signals and homogeneous noise are considered; more complex problems involve nonstationary, inhomogeneous environments.

Acoustic waveforms of interest have a probability density function (PDF); for example, the PDF may be Gaussian or in the case of clicking, sharp noise spikes, or crackling ice noise, the PDF may be non-Gaussian. In addition to being characterized by a PDF, signals can be characterized in the frequency domain by their power spectral density functions, which are Fourier transforms of the autocorrelation functions. White signals, which are uncorrelated from sample to sample, have a delta function autocorrelation and equivalently a flat (constant) power spectral density. Ocean signals in general are much more colorful and not limited to being stationary.

Passive sonar signals are primarily modeled as random signals. Their first-order PDFs are typically Gaussian; one exception is a stable sinusoidal signal that is non-Gaussian and has a power spectral density function that is a Dirac delta function in the frequency domain. However, in the ocean environment, an arbitrarily narrow frequency width is never observed, and signals have some finite narrow bandwidth. Indeed, the full spectrum of most underwater signals is quite "colorful."

Received active sonar signals can be viewed as consisting of the results of a deterministic component (known transmit waveform) convolved with the medium and reflector transfer functions and a random (noise) component. Moreover, the **Doppler** imparted (frequency shift) to the reflected signal makes the total system effect nonlinear, thereby complicating analysis and processing of these signals.

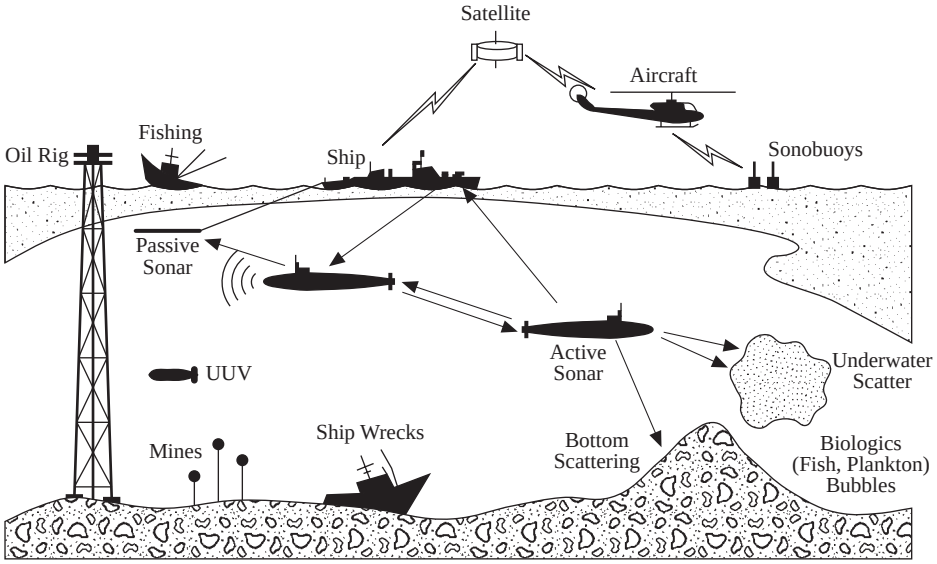

FIGURE 19.8 Active and passive underwater acoustical signal processing.

SONAR

SONAR, "SOund NAvigation and Ranging," the acronym adopted in the 1940s, similar to the popular RADAR, "RAdio Detection And Ranging," involves the use of sound to explore the ocean and underwater objects

- *Passive sonar* uses sound radiated from the underwater object itself. The duration of the radiated sound may be short or long in time and narrow or broad in frequency. Only one-way transmission through the ocean, from the acoustic source to a receiving sensor, is involved in this case.
- *Active sonar* involves echo-ranging where an acoustical signal is transmitted from a source, and reflected echoes are received back from the object. Here one is concerned with two-way transmissions from a transmitter to an object and back to a receiving sensor. There are three types of active sonar systems:

  1. *Monostatic:* In this most common form, the source and receiver are either identical or distinct but located on the same platform (e.g., a surface ship).
  2. *Bistatic:* In this form, the transmitter and receiver are on different platforms.
  3. *Multistatic:* Here, a single (or more) source or transmitter and multiple receivers, which can be located on different receiving platforms or ships, are used.

The performance of sonar systems can be assessed by the passive and active *sonar equations*. The major parameters in the sonar equation, measured in **decibels (dB)**, are as follows:

L_S = source level
L_N = noise level
N_{DI} = directivity index
N_{TS} = echo level or target strength
N_{RD} = recognition differential

Here, L_S is the target-radiated signal strength (for passive) or transmitted signal strength (for active), and L_N is the total background noise level. N_{DI}, or DI, is the directivity index, which is a measure of the capability of a receiving array to discriminate against unwanted noise. N_{TS} is the received echo level or target strength. Underwater objects with large values of N_{TS} are more easily detectable with active sonar than are those with small values of N_{TS}. In general, N_{TS} varies as a function of object size, aspect angle, (i.e., the direction at which impinging acoustic energy reaches the underwater object), and reflection angle (the direction at which the impinging acoustic energy is reflected off the underwater object). N_{RD} is the recognition differential of the processing system.

TABLE 19.1 Expressions for Sound Speed in Meters per Second

Expression	Limits
$c = 1492.9 + 3(T-10) - 6 \times 10^{-3}(T-10)^2$	$-2 \le T \le 24.5°$
$\quad 4 \times 10^{-2}(T-18)^2 + 1.2(S-35)$	$30 \le S \le 42$
$\quad - 10^{-2}(T-18)(S-35) + D/61$	$0 \le D \le 1.000$
$c = 1449.2 + 4.6T - 5.5 \times 10^{-2}T^2$	$0 \le T \le 35°$
$\quad + 2.9 \times 10^{-4}T^3 + (1.34 - 10^{-2}T)(S-35)$	$0 \le S \le 45$
$\quad + 1.6 \times 10^{-2}D$	$0 \le D \le 1{,}000$
$c = 1448.96 + 4.591T - 5.304 \times 10^{-2}T^2$	$0 \le T \le 30°$
$\quad + 2.374 \times 10^{-4}T^3 + 1.340(S-35)$	$30 \le S \le 40$
$\quad + 1.630 \times 10^{-2}D + 1.675 \times 10^{-7}D^2$	$0 \le D \le 8{,}000$
$\quad - 1.025 \times 10^{-2}T(S-35) - 7.139 \times 10^{-13}TD^3$	

D = depth, in meters. S = salinity, in parts per thousand. T = temperature, in degrees Celsius.

The **figure of merit** (FOM), a basic performance measure involving parameters of the sonar system, ocean, and target, is computed for active and passive sonar systems (in dBs) as follows:
For passive sonar,

$$\text{FOM}_P = L_S - (L_N - N_{DI}) - N_{RD} \tag{19.5}$$

For active sonar,

$$\text{FOM}_A = (L_S + N_{TS}) - (L_N - N_{DI}) - N_{RD} \tag{19.6}$$

Sonar systems, for a given set of parameters of the sonar equations, are designed so that the FOM exceeds the acoustic propagation loss. The amount above the FOM is called the *signal excess*. When two sonar systems are compared, the one with the largest signal excess is said to hold the *acoustic advantage*. However, it should be noted that the set of parameters in the preceding FOM equations is not unique. Depending on the design or parameter measurability conditions, different parameters can be combined or expanded in terms of quantities such as frequency dependency of the sonar system in particular ocean conditions, speed and bearing of the receiving or transmitting platforms, reverberation loss, and so forth. Furthermore, due to multipaths, differences in sonar system equipment and operation, and the constantly changing nature of the ocean medium, the FOM parameters fluctuate with time. Thus, the FOM is not an absolute measure of performance but rather an expected value of performance over time in a stochastic sense [for details, see Urick, 1983].

Underwater Propagation

Speed/Velocity of Sound

Sound speed, c, in the ocean, in general lies between 1450–1540 m/s and varies as a function of several physical parameters, such as temperature, salinity, and pressure (depth). Variations in sound speed can significantly affect the propagation (range or quality) of sound in the ocean. Table 19.1 gives approximate expressions for sound speed as a function of these physical parameters.

Sound Velocity Profiles

Sound rays that are normal (perpendicular) to the acoustic wavefront can be traced from the source to the receiver by a process called ray tracing.[1] In general, the acoustic ray paths are not straight, but bend in a manner analogous to optical rays focused by a lens. In underwater acoustics, the ray paths are determined by the **sound velocity profile** (SVP) or *sound speed profile* (SSP), that is, the speed of sound in water as a function of water

[1]Ray tracing models are used for high-frequency signals and in deep water. Generally, if the depth-to-wavelength ratio is 100 or more, ray tracing models are accurate. Below that, corrections must be made to the ray trace models. In shallow water or low frequencies, i.e., when depth-to-wavelength is about 30 or less, "mode theory" models are used.

depth. The sound speed not only varies with depth but also varies in different regions of the ocean and with time as well. In deep water, the SVP fluctuates the most in the upper ocean due to variations of temperature and weather. Just below the sea surface is the *surface layer* where the sound speed is greatly affected by temperature and wind action. Below this layer lies the *seasonal thermocline* where the temperature and speed decrease with depth, and the variations are seasonal. In the next layer, the *main thermocline*, the temperature and speed decrease with depth and surface conditions or seasons have little effect. Finally, there is the *deep isothermal layer* where the temperature is nearly constant at 39°F, and the sound velocity increases almost linearly with depth. A typical deep water sound velocity profile as a function of depth is shown in Fig. 19.9.

If the sound speed is a minimum at a certain depth below the surface, then this depth is called axis of the underwater sound channel.[2] The sound velocity increases both above and below this axis. When the sound wave travels through a medium with a sound speed gradient, the direction of travel of sound wave is bent towards the area of lower sound speed.

Although the definition of shallow water can be signal dependent, in terms of depth-to-wavelength ratio, water depth of less than 1000 meters is generally referred to as shallow water. In shallow water the SVP is irregular and difficult to predict because of large surface temperature and salinity variations, wind effects, and multiple reflections of sound from the ocean bottom.

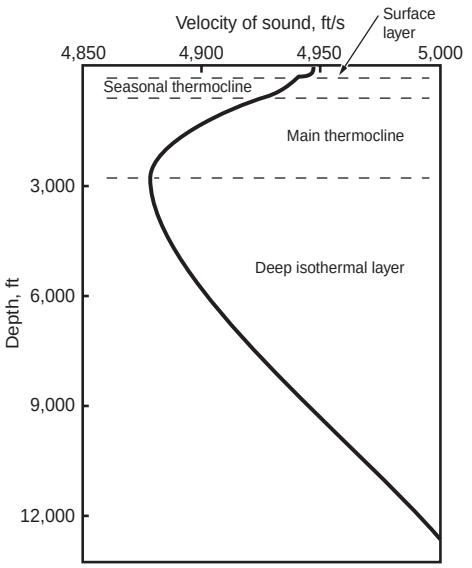

FIGURE 19.9 A typical sound velocity profile (SVP).

Propagation Modes

In general, there are three dominant propagation paths that depend on the distance or range between the acoustic source and the receiver (Fig. 19.10).

- *Direct Path:* Sound energy travels in (nominal) straight line path between the source and receiver, usually present at short ranges.
- *Bottom Bounce Path:* Sound energy is reflected from the ocean bottom (present at intermediate ranges).
- *Convergence Zone (CZ) Path:* Sound energy converges at longer ranges where multiple acoustic ray paths add or recombine coherently to reinforce the presence of acoustic energy from the radiating/reflecting source.

Figure 19.11 shows the propagation loss as a function of range for different frequencies of the signal. Note the recombination of energy at the convergence zones.

Multipaths

The ocean contains multiple acoustic paths that split the acoustic energy. When the receiving system can resolve these multiple paths (or multipaths), then they should be recombined by optimal signal processing to fully exploit the available acoustic energy for detection [Chan, 1989]. It is also theoretically possible to exploit the geometrical properties of multipaths present in the bottom bounce path by investigation of the apparent aperture created by the different path arrivals to localize the energy source. In the case of first-order bottom bounce transmission, i.e., only one bottom interaction, there are four paths (from source to receiver):

1. A bottom bounce ray path (B).
2. A surface interaction followed by a bottom interaction (SB).
3. A bottom bounce followed by a surface interaction (BS).
4. A path that first hits the surface, then the bottom, and finally the surface (SBS).

Typical first-order bottom bounce ocean propagation paths are depicted in Fig. 19.12.

[2]Often called the SOFAR (Sound Fixing and Ranging) channel.

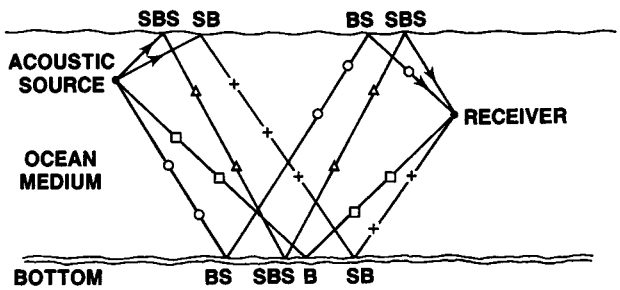

FIGURE 19.12 Multipaths for a first-order bottom bounce propagation model.

Performance Limitations

In a typical reception of a signal wavefront, noise and interference can degrade the performance of a sonar system and limit the system's ability to detect signals in the underwater environment. The noise or interference could be sounds from a school of fish, shipping (surface or subsurface) noise, active transmission interference (e.g., jammers), or interference when multiple receivers or sonar systems are in operation simultaneously. Also, the ambient noise may have unusual vertical or horizontal directivity and in some environments, such as the Arctic, the noise due to ice motion may produce unfamiliar interference. Unwanted backscatters, similar to the headlights of a car driving in fog, can cause a signal-induced noise that degrades processing gain without proper processing. Some other performance-limiting factors are the loss of signal level and acoustic coherence due to boundary interaction as a function of grazing angle; the radiated pattern (signal level) of the object and its spatial coherence; the presence of surface, bottom, and volume **reverberation** (in active sonar); signal spreading owing to the modulating effect of surface motion; biologic noise as a function of time (both time of day and time of year); and statistics of the noise in the medium. (Does the noise arrive in the same or at different ray path angles as the signal?)

Hydrophone Sensors and Output

Hydrophone sensors are underwater microphones capable of operating in water and under hydrostatic pressure. These sensors receive radiated and reflected acoustic energy that arrives through the multiple paths of the ocean medium from a variety of sources and reflectors. As with a microphone, hydrophones convert acoustic pressure to electrical voltages or to optical signals.

A block diagram model of a stationary acoustic source, $s(t)$, input to M unique hydrophone receivers is shown in Fig. 19.13. Multipaths from the source to each receiver can be characterized by the source to (each individual) receiver impulse response. The inverse Fourier transforms of these impulse responses are the transfer functions shown in the block diagram as $A_j(f)$, where the subscript, $j = 1,\ldots, M$, denotes the appropriate source-to-receiver transfer function. For widely spaced receivers, there will be a different transfer function from the source to each receiver. Also, for multiple sources and widely spaced receivers, there will be a different transfer function from each source to each receiver. The receiver outputs from a single source are modeled as being corrupted by additive noise, $n_j(t)$, as shown in Fig. 19.13.

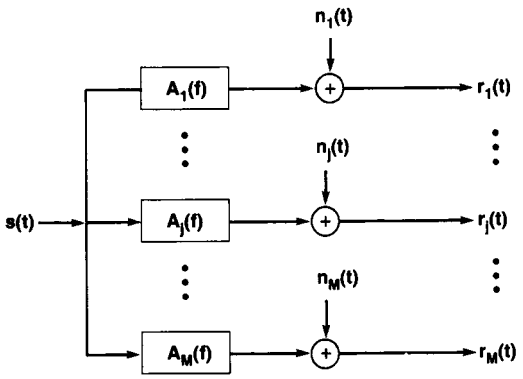

FIGURE 19.13 Hydrophone receiver model: source signal $s(t)$ through medium filter $A_j(t)$, corrupted by additive noise received at one of M hydrophones.

Processing Functions

Beamforming

Beamforming is a process in which outputs from the hydrophone sensors of an array are coherently combined by delaying and summing the outputs to provide enhanced detection and estimation. In underwater applications, one is trying to detect a directional (single direction) signal in the presence of normalized background noise that is ideally isotropic (nondirectional). By arranging the hydrophone (array) sensors in different physical geometries and electronically steering them in a particular direction, one can increase the signal-to-noise ratio (**SNR**) in a given direction by rejecting or canceling the noise in other directions. There are many different kinds of arrays (e.g., equally spaced line, continuous line, circular, cylindrical, spherical, or random sonobuoy arrays). The beam pattern specifies the response of these arrays to the variation in direction. In the simplest case, the increase in SNR due to the beamformer, called the *array gain* (in dB), is given by

$$\mathrm{AG} = 10 \log \frac{\mathrm{SNR}_{\text{array (output)}}}{\mathrm{SNR}_{\text{single sensor (input)}}} \tag{19.7}$$

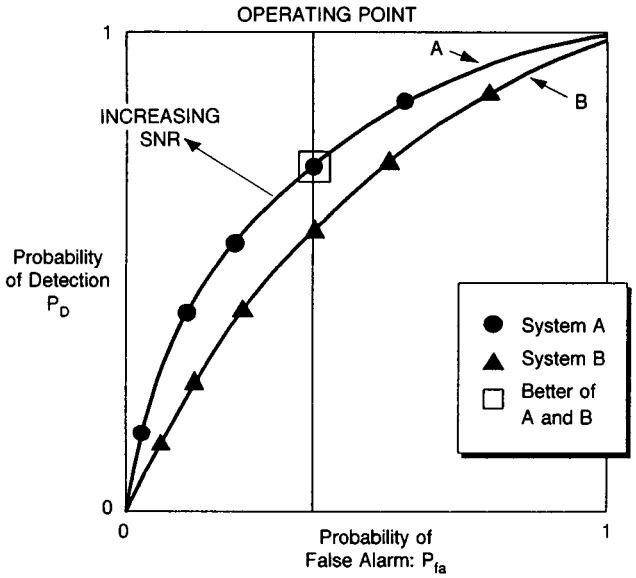

FIGURE 19.14 Typical ROC curves. Note points (0,0) and (1,1) are on all ROC curves; upper curve represents higher P_D for fixed P_{fa} and hence better performance by having higher SNR or processing time.

Detection

Detection of signals in the presence of noise, using classical Bayes or Neyman-Pearson decision criteria, is based on hypothesis testing. In the simplest binary hypothesis case, the detection problem is posed as two hypotheses:

- H_0: Signal is not present (referred to as the null hypothesis).
- H_1: Signal is present.

For a received wavefront, H_0 relates to the noise-only case and H_1 to the signal-plus-noise case. Complex hypotheses (M-hypotheses) can also be formed if detecting a signal among a variety of sources is required.

Probability is a measure, between zero and unity, of how likely an event is to occur. For a received wavefront the likelihood ratio, Λ, is the ratio of P_{H1} (probability that hypothesis H_1 is true) to P_{H0} (probability that hypothesis H_0 is true). A decision (detection) is made by comparing the likelihood, or logarithm of the likelihood ratio called the log-likelihood ratio, to a predetermined threshold η. That is, if $\Lambda = P_{H1}/P_{H0} > \eta$, a decision is made that the signal is present.

Probability of detection, P_D, measures the likelihood of detecting an event or object when the event does occur. *Probability of false alarm*, P_{fa}, is a measure of the likelihood of saying something happened when the event did NOT occur. **Receiver operating characteristics (ROC)** curves plot P_D versus P_{fa} for a particular (sonar signal) processing system. A single plot of P_D versus P_{fa} for one system must fix the SNR and processing time. The threshold η is varied to sweep out the ROC curve. The curve is often plotted on either log-log scale or "probability" scale. In comparing a variety of processing systems one would like to select the system (or develop a new one) that maximizes the P_D for every given P_{fa}. Processing systems must operate on their ROC curves, but most processing systems allow the operator to select where on the ROC curve the system is operated by adjusting a threshold; low thresholds ensure a high probability of detection at the expense of high false alarm rate. A sketch of two monotonically increasing ROC curves is given in Fig. 19.14. By proper adjustment of the decision threshold, one can trade off detection performance for false alarm performance. Since the points (0,0) and (1,1) are on all ROC curves, one can always guarantee 100% probability of detection with an arbitrarily low threshold (albeit at the expense of 100% probability of false alarm) or 0% probability of false alarm with an arbitrarily high threshold (albeit at the expense of 0% probability of detection). The (log) *likelihood detector* is a detector that achieves the maximum probability of detection for fixed probability of false alarm; it is shown in Fig. 19.15 for detecting Gaussian signals reflected or radiated from the stationary objects modeled in Fig. 19.13. For moving objects more complicated time compression or Doppler compensation processing is

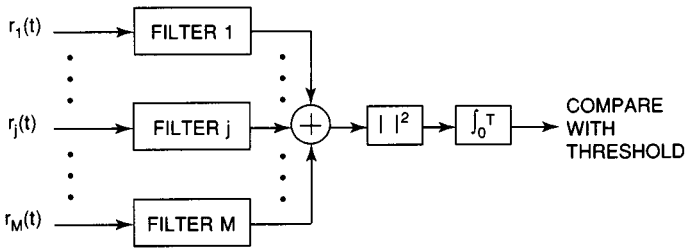

FIGURE 19.15 Log likelihood detector structure for uncorrelated Gaussian noise in the received signal $r_j(t)$, $j = 1,...,M$.

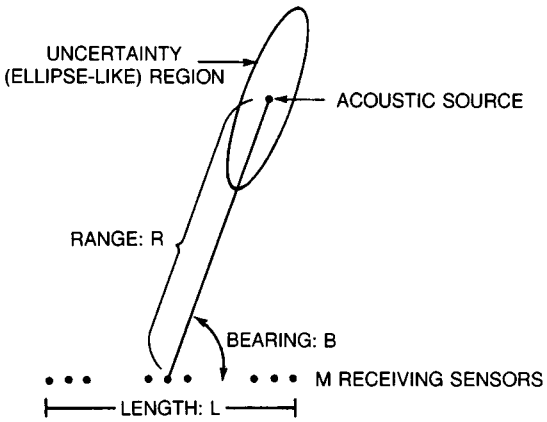

FIGURE 19.16 Array geometry used to estimate source position. (*Source:* G.C. Carter, "Coherence and time delay estimation," *Proceedings IEEE*, vol. 75, no. 2, p. 251, © 1987 IEEE. With permission.)

required. For spiky non-Gaussian noise, other signal processing is required; indeed, clipping prior to filtering improves detection performance, by "eliminating" strong noise "pulses".

In active sonar, the filters are matched to the known transmitted waveforms. If the object (acoustic reflector) has motion, it will induce Doppler on the reflected signal, and the receiver will be complicated by the addition of a bank of Doppler compensators. Returns from a moving object are shifted in frequency by $\Delta f = (2v/c)f$, where v is the relative velocity (range rate) between the source and object, c is the speed of sound in water, and f is the operating frequency of the source transmitter.

In passive sonar, at low SNR, the optimal filters in Fig. 19.15 (so-called Eckart filters) are functions of $G_{ss}^{1/2}(f)/G_{nn}(f)$, where f is frequency in hertz, $G_{ss}(f)$ is the signal power spectrum, and $G_{nn}(f)$ is the noise power spectrum [see page 484 Carter (1993)].

Estimation/Localization

The second function of underwater acoustic signal processing estimates the parameters that localize the position of the detected object. The source position is estimated in range, bearing, and depth, typically from the underlying parameter of **time delay** associated with the acoustic wavefront. The statistical uncertainty of the positional estimates is important. Knowledge of the first order probability density function or its first- and second-order moments, the mean (expected value) and the variance, are vital to understanding the expected performance of the processing system. In the passive case, the ability to estimate range is extremely limited by the geometry of the measurements; indeed, the variance of passive range estimates can be extremely large, especially when the true range to the acoustic source is long when compared with the aperture length of the receiving array. Figure 19.16 depicts direct path passive ranging uncertainty from a collinear array with sensors clustered so as to minimize the bearing and uncertainty region. Beyond the direct path, multipath signals can be processed to estimate source depth covertly. Range estimation accuracy is not difficult with the active sonar, but active sonar is not covert, which for some applications can be important.

Classification

The third function of sonar signal processing is classification. This function determines the type of object that has radiated or reflected acoustic energy. For example, was the sonar signal return from a school of fish or a reflection from the ocean bottom? The action one takes is highly dependent upon this important function. The amount of radiated or reflected signal power relative to the background noise (that is, SNR) necessary to achieve good classification may be higher than for detection. Also, the type of signal processing required for classification may be different than the type of processing for detection. Processing methods that are developed on the basis of detection might not have the requisite SNR to adequately perform the classification function. Classifiers are, in general, divided into feature (or clue) extractors followed by a classifier decision box. A key to successful classification is feature extraction. Performance of classifiers is plotted as in ROC detection curves as probability of deciding on class A, given A was actually present, or $P(A/A)$, versus the probability of deciding on class B, given that A was present, i.e., $P(B/A)$, for two different classes of objects, A and B. Of course, for the same class of objects, one could also plot $P(B/B)$ versus $P(A/B)$.

Motion Analysis or Tracking

The fourth function of underwater acoustic signal processing is to perform contact (or target) motion analysis (TMA), that is, to estimate parameters of bearing and speed. Generally, nonlinear filtering methods, including Kalman-Bucy filters, are applied; typically these methods rely on a state space model for the motion of the contact. For example, the underlying model of motion could assume a straight-line course and constant speed of the contact of interest. When the acoustic source of interest behaves like the model, then results consistent with the basic theory can be expected. It is also possible to incorporate motion compensation into the signal processing detection function. For example, in the active sonar case, proper waveform selection and processing can reduce the degradation of detector performance caused by uncompensated Doppler. Moreover, joint detection and estimation can provide clues to the TMA and classification processes. For example, if the processor simultaneously estimates depth in the process of performing detection, then a submerged object would not be classified as a surface object. Also, joint detection and estimation using Doppler for detection can directly improve contact motion estimates.

Normalization

Another important signal processing function for the detection of weak signals in the presence of unknown and (temporal and spatial) varying noise is normalization. The statistics of noise or reverberation for oceans typically varies in time, frequency, and/or bearing from measurement to measurement and location to location. To detect a weak signal in a broadband, nonstationary, and inhomogeneous background, it is usually desirable to make the noise background statistics as uniform as possible for the variations in time, frequency, and/or bearing. The noise background estimates are first obtained from a window of resolution cells (which usually surrounds the test data cell). These estimates are then used to normalize the test cell, thus reducing the effects of the background noise on detection. Window length and distance from the test cell are two of the parameters that can be adjusted to obtain accurate estimates of the different types of stationary or nonstationary noise.

Advanced Signal Processing

Adaptive Beamforming

Beamforming was discussed in an earlier section. The cancellation of noise through beamforming can also be done adaptively, which can improve the array gain further. Some of the various adaptive beamforming techniques are [Knight et al., 1981], Dicanne, sidelobe cancellers, maximum entropy array processing, and maximum-likelihood (ML) array processing.

Coherence Processing

Coherence is a normalized (to lie between zero and unity) cross-spectral density function that is a measure of the similarity of received signals and noise between any sensors of the array. The complex coherence function between two wide-sense-stationary processes x and y is defined by

$$\gamma_{xy}(f) = \frac{G_{xy}(f)}{\sqrt{G_{xx}(f)G_{yy}(f)}} \tag{19.8}$$

where, as before, f is the frequency in hertz and G is the power spectrum function. Array gain depends on the coherence of the signal and noise between the sensors of the array. To increase the array gain, it is necessary to have good coherence among the sensors for the signal, but poor coherence (incoherent) for the noise. Coherence of the signal between sensors improves with decreasing separation between the sensors, frequency of the received waveform, total bandwidth, and integration time. Loss of coherence of the signal could be due to ocean motion, object motion, multipaths, reverberation, or scattering. The coherence function has many uses, including measurement of SNR or array gain, system identification, and determination of time delays [Carter, 1987].

Acoustic Data Fusion

Acoustic data fusion is a technique that combines information from multiple receivers or receiving platforms about a common object or channel. Instead of each receiver making a decision, relevant information from the different receivers is sent to a common control unit where the acoustic data is combined and processed (hence the name *data fusion*). After fusion, a decision can be relayed or "fed" back to each of the receivers. If data transmission is a concern, due to time constraints, cost, or security, other techniques can be used in which each receiver makes a decision and transmits only the decision. The control unit makes a global decision based on the decisions of all the receivers and relays this global decision back to the receivers. This is called "distributed detection." The receivers can then be asked to re-evaluate their individual decisions based on the new global decision. This process could continue until all the receivers are in agreement or could be terminated whenever an acceptable level of consensus is attained.

An advantage of data fusion is that the receivers can be located at different ranges (e.g., on two different ships), in different mediums (shallow or deep water, or even at the surface), and at different bearings from the object, thus giving comprehensive information about the object or the underwater acoustic channel.

Application

Since World War II, in addition to military applications, there has been an expansion in commercial and industrial underwater acoustics applications. Table 19.2 lists the military and nonmilitary functions of sonar along with some of the current applications.

Defining Terms

Decibels (dB): Logarithmic scale of representing the ratio of two quantities given as $10 \log_{10}(P_1/P_0)$ for power level ratios and $20 \log_{10}(V_1/V_0)$ for comparing acoustic pressure or voltage ratios. A standard reference pressure or intensity level in SI units is equal to 1 micropascal (1 pascal = 1 newton per square meter = 10 dyne per square centimeter).

Doppler shift: Shift in frequency of transmitted waveform due to the relative motion between the source and object.

Figure of merit/sonar equation: Performance evaluation measure for the various target and equipment parameters of a sonar system. It is a subset of the broader sonar performance given by the *sonar equations*, which includes reverberation effects.

Hydrophone: Receiving sensors that convert sound energy into electrical or optical energy (analogous to underwater microphones).

Receiver operating characteristics (ROC) curves: Plots of the probability of detection (likelihood of detecting the object when the object is present) versus the probability of false alarm (likelihood of detecting the object when the object is not present) for a particular processing system.

TABLE 19.2 Underwater Acoustics Applications

Function	Description
Military	
Detection	Deciding if a target is present or not.
Classification	Deciding if a detected target does or does not belong to a specific class.
Localization	Measuring at least one of the instantaneous positions and velocity components of a target (either relative or absolute), such as range, bearing, range rate, or bearing rate.
Navigation	Determining, controlling, and/or steering a course through a medium (includes avoidance of obstacles and the boundaries of the medium).
Communications	Instead of a wire link, transmitting and receiving acoustic power and information.
Control	Using a sound-activated release mechanism.
Position marking	Transmitting a sound signal continuously (beacons) or transmitting only when suitably interrogated (transponders).
Depth sounding	Sending short pulses downward and timing the bottom return.
Acoustic-speedometers	Using pairs of transducers pointing obliquely downwards to obtain speed over the bottom from the Doppler shift of the bottom return.
Commercial Applications:	
Industrial	**Oceanological**
Fish finders/fish herding	Subbottom geological mapping
Oil and mineral explorations	Ocean topography
River flow meter	Bathyvelocimeter
Acoustic holography	Emergency telephone
Viscosimeter	Seismic simulation and measurement
Acoustic ship docking system	Biological signal and noise measurement
Ultrasonic grinding/drilling	Sonar calibration

Reverberation/clutter: Inhomogeneities, such as dust, sea organisms, schools of fish, sea mounds on the bottom of the sea, form mass density discontinuities in the ocean medium. When an acoustic wave strikes these inhomogeneities, some of the acoustic energy is reflected and reradiated. The sum total of all such reradiations is called reverberation. Reverberation is present only in active sonar, and in the case where the object echoes are completely masked by reverberation, the sonar system is said to be "reverberation limited."

SONAR: Acronym for "SOund NAvigation and Ranging," adopted in the 1940s, involves the use of sound to explore the ocean and underwater objects.

Sound velocity profile (SVP): Description of the speed of sound in water as a function of water depth.

SNR: The signal-to-noise (power) ratios, usually measured in decibels (dB).

Time delay: The time (delay) difference in seconds from when an acoustic wavefront impinges on one hydrophone or receiver until it strikes another.

20.1 Definitions and Scope

Introduction

Artificial neural networks (ANN) are among the newest signal-processing technologies in the engineer's toolbox. The field is highly interdisciplinary, but our approach will restrict the view to the engineering perspective. In engineering, neural networks serve two important functions: as pattern classifiers and as nonlinear adaptive filters. We will provide a brief overview of the theory, learning rules, and applications of the most important neural network models.

Definitions and Style of Computation

An ANN is an adaptive, most often nonlinear system that learns to perform a function (an input/output map) from data. Adaptive means that the system parameters are changed during operation, normally called the *training phase*. After the training phase the ANN parameters are fixed and the system is deployed to solve the problem at hand (the *testing phase*). The ANN is built with a systematic step-by-step procedure to optimize a performance criterion or to follow some implicit internal constraint, which is commonly referred to as the *learning rule*. The input/output training data are fundamental in neural network technology, because they convey the necessary information to "discover" the optimal operating point. The nonlinear nature of the neural network processing elements (PEs) provides the system with lots of flexibility to achieve practically any desired input/output map, i.e., some ANNs are *universal mappers*.

There is a style in neural computation that is worth describing (Fig. 20.1). An input is presented to the network and a corresponding desired or target response set at the output (when this is the case the training is called *supervised*). An error is composed from the difference between the desired response and the system

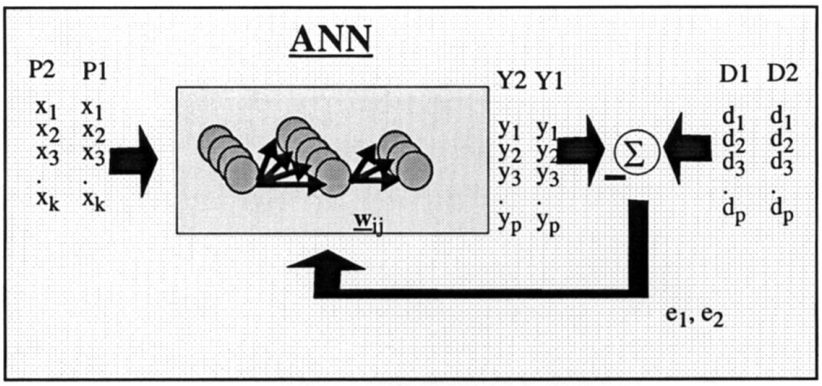

FIGURE 20.1 The style of neural computation.

output. This error information is fed back to the system and adjusts the system parameters in a systematic fashion (the learning rule). The process is repeated until the performance is acceptable. It is clear from this description that the performance hinges heavily on the data. If one does not have data that cover a significant portion of the operating conditions or if they are noisy, then neural network technology is probably not the right solution. On the other hand, if there is plenty of data and the problem is poorly understood to derive an approximate model, then neural network technology is a good choice.

This operating procedure should be contrasted with the traditional engineering design, made of exhaustive subsystem specifications and intercommunication protocols. In ANNs, the designer chooses the network topology, the performance function, the learning rule, and the criterion to stop the training phase, but the system automatically adjusts the parameters. So, it is difficult to bring *a priori* information into the design, and when the system does not work properly it is also hard to incrementally refine the solution. But ANN-based solutions are extremely efficient in terms of development time and resources, and in many difficult problems ANNs provide performance that is difficult to match with other technologies. Denker 10 years ago said that "ANNs are the second best way to implement a solution" motivated by the simplicity of their design and because of their universality, only shadowed by the traditional design obtained by studying the physics of the problem. At present, ANNs are emerging as the technology of choice for many applications, such as pattern recognition, prediction, system identification, and control.

ANN Types and Applications

It is always risky to establish a taxonomy of a technology, but our motivation is one of providing a quick overview of the application areas and the most popular topologies and learning paradigms.

Application	Topology	Supervised Learning	Unsupervised Learning
Association	Hopfield [Zurada, 1992; Haykin, 1994]	—	Hebbian [Zurada, 1992; Haykin, 1994; Kung, 1993]
	Multilayer perceptron [Zurada, 1992; Haykin, 1994; Bishop, 1995]	Back-propagation [Zurada, 1992; Haykin, 1994; Bishop, 1995]	—
	Linear associative mem. [Zurada, 1992; Haykin, 1994]	—	Hebbian
Pattern recognition	Multilayer perceptron [Zurada, 1992; Haykin, 1994; Bishop, 1995]	Back-propagation	—
	Radial basis functions [Zurada, 1992; Bishop, 1995]	Least mean square	*k*-means [Bishop, 1995]
Feature extraction	Competitive [Zurada, 1992; Haykin, 1994]	—	Competitive
	Kohonen [Zurada, 1992; Haykin, 1994]	—	Kohonen
	Multilayer perceptron [Kung, 1993]	Back-propagation	—
	Principal comp. anal. [Zurada, 1992; Kung, 1993]	—	Oja's [Zurada, 1992; Kung, 1993]
Prediction, system ID	Time-lagged networks [Zurada, 1992; Kung, 1993; de Vries and Principe, 1992]	Back-propagation through time [Zurada, 1992]	—
	Fully recurrent nets [Zurada, 1992]		

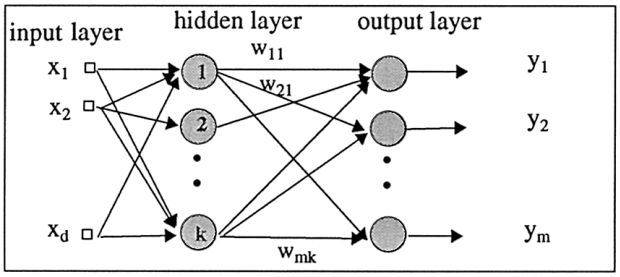

FIGURE 20.2 MLP with one hidden layer (*d*-*k*-*m*).

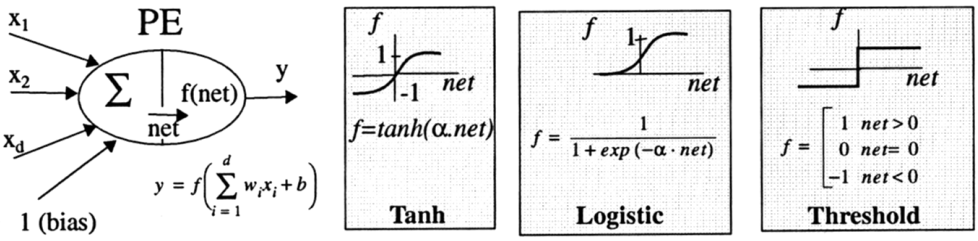

FIGURE 20.3 A PE and the most common nonlinearities.

It is clear that *multilayer perceptrons* (MLPs), the *back-propagation algorithm* and its extensions — time-lagged networks (TLN) and back-propagation through time (BPTT), respectively — hold a prominent position in ANN technology. It is therefore only natural to spend most of our overview presenting the theory and tools of back-propagation learning. It is also important to notice that *Hebbian learning* (and its extension, the Oja rule) is also a very useful (and biologically plausible) learning mechanism. It is an *unsupervised learning* method since there is no need to specify the desired or target response to the ANN.

20.2 Multilayer Perceptrons

Multilayer perceptrons are a layered arrangement of nonlinear PEs as shown in Fig. 20.2. The layer that receives the input is called the *input layer*, and the layer that produces the output is the *output layer*. The layers that do not have direct access to the external world are called *hidden layers*. A layered network with just the input and output layers is called the *perceptron*. Each connection between PEs is weighted by a scalar, w_i, called a *weight*, which is adapted during learning.

The PEs in the MLP are composed of an adder followed by a smooth saturating nonlinearity of the sigmoid type (Fig. 20.3). The most common saturating nonlinearities are the logistic function and the hyperbolic tangent. The threshold is used in other nets. The importance of the MLP is that it is a universal mapper (implements arbitrary input/output maps) when the topology has at least two hidden layers and sufficient number of PEs [Haykin, 1994]. Even MLPs with a single hidden layer are able to approximate continuous input/output maps. This means that rarely we will need to choose topologies with more than two hidden layers. But these are existence proofs, so the issue that we must solve as engineers is to choose how many layers and how many PEs in each layer are required to produce good results.

Many problems in engineering can be thought of in terms of a transformation of an input space, containing the input, to an output space where the desired response exists. For instance, dividing data into classes can be thought of as transforming the input into 0 and 1 responses that will code the classes [Bishop, 1995]. Likewise, identification of an unknown system can also be framed as a mapping (function approximation) from the input to the system output [Kung, 1993]. The MLP is highly recommended for these applications.

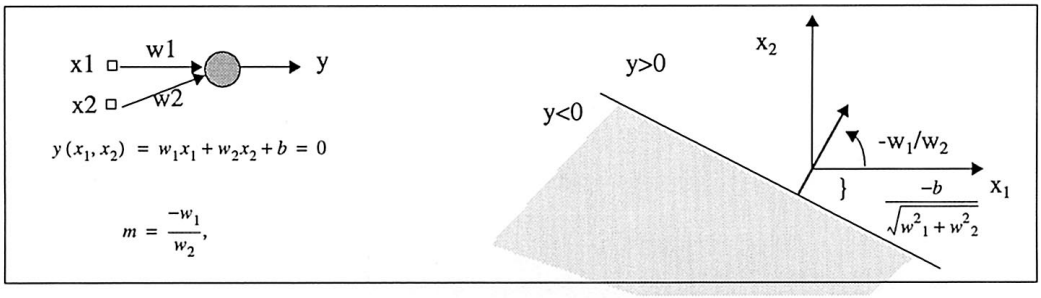

FIGURE 20.4 A two-input PE and its separation surface.

Function of Each PE

Let us study briefly the function of a single PE with two inputs [Zurada, 1992]. If the nonlinearity is the threshold nonlinearity we can immediately see that the output is simply 1 and –1. The surface that divides these subspaces is called a *separation surface,* and in this case it is a line of equation

$$y(w_1, w_2) = w_1 x_1 + w_2 x_2 + b = 0 \tag{20.1}$$

i.e., the PE weights and the bias control the orientation and position of the separation line, respectively (Fig. 20.4). In many dimensions the separation surface becomes an hyperplane of dimension one less than the dimensionality of the input space. So, each PE creates a dichotomy in the input space. For smooth nonlinearities the separation surface is not crisp; it becomes fuzzy but the same principles apply. In this case, the size of the weights controls the width of the fuzzy boundary (larger weights shrink the fuzzy boundary).

The perceptron input/output map is built from a juxtaposition of linear separation surfaces, so the perceptron gives zero classification error only for *linearly separable classes* (i.e., classes that can be exactly classified by hyperplanes).

When one adds one layer to the perceptron creating a one hidden layer MLP, the type of separation surfaces changes drastically. It can be shown that this learning machine is able to create "bumps" in the input space, i.e., an area of high response surrounded by low responses [Zurada, 1992]. The function of each PE is always the same, no matter if the PE is part of a perceptron or an MLP. However, notice that the output layer in the MLP works with the result of hidden layer activations, creating an embedding of functions and producing more complex separation surfaces. The one-hidden-layer MLP is able to produce *nonlinear separation surfaces.*

If one adds an extra layer (i.e., two hidden layers), the learning machine now can combine at will bumps, which can be interpreted as a *universal mapper,* since there is evidence that any function can be approximated by localized bumps. One important aspect to remember is that changing a single weight in the MLP can drastically change the location of the separation surfaces; i.e., the MLP achieves the input/output map through the interplay of all its weights.

How to Train MLPs

One fundamental issue is how to adapt the weights w_i of the MLP to achieve a given input/output map. The core ideas have been around for many years in optimization, and they are extensions of well-known engineering principles, such as the *least mean square (LMS) algorithm* of adaptive filtering [Haykin, 1994]. Let us review the theory here. Assume that we have a linear PE (f(net) = net) and that one wants to adapt the weights as to minimize the square difference between the desired signal and the PE response (Fig. 20.5).

This problem has an analytical solution known as the *least squares* [Haykin, 1994]. The optimal weights are obtained as the product of the inverse of the input autocorrelation function (R^{-1}) and the cross-correlation vector (**P**) between the input and the desired response. The analytical solution is equivalent to a search for the minimum of the quadratic performance surface $J(w_i)$ using gradient descent, where the weights at each iteration k are adjusted by

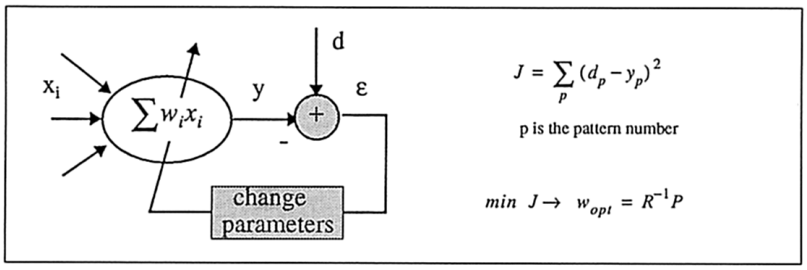

FIGURE 20.5 Computing analytically optimal weights for the linear PE.

$$w_i(k+1) = w_i(k) - \eta \nabla J_i(k) \qquad \nabla J_i = \frac{\partial J}{\partial w_i} \tag{20.2}$$

where η is a small constant called the *step size*, and $\nabla J(k)$ is the gradient of the performance surface at iteration k. Bernard Widrow in the late 1960s proposed a very efficient estimate to compute the gradient at each iteration

$$\nabla J_i(k) = \frac{\partial}{\partial w_i} J(k) \qquad \sim \frac{1}{2} \frac{\partial}{\partial w_i} \left(\varepsilon^2(k)\right) = -\varepsilon(k)\, x_i(k) \tag{20.3}$$

which when substituted into Eq. (20.2) produces the so-called *LMS algorithm*. He showed that the LMS converged to the analytic solution provided the step size η is small enough. Since it is a steepest descent procedure, the largest step size is limited by the inverse of the largest eigenvalue of the input autocorrelation matrix. The larger the step size (below this limit), the faster is the convergence, but the final values will "rattle" around the optimal value in a basin that has a radius proportional to the step size. Hence, there is a fundamental trade-off between speed of convergence and accuracy in the final weight values. One great appeal of the LMS algorithm is that it is very efficient (just one multiplication per weight) and requires only local quantities to be computed.

The LMS algorithm can be framed as a computation of partial derivatives of the cost with respect to the unknowns, i.e., the weight values. In fact, with the chainrule one writes

$$\frac{\partial J}{\partial w_i} = \frac{\partial J}{\partial y} \frac{\partial y}{\partial w_i} = \frac{\partial}{\partial y} \left(\sum (d - y)^2\right) \frac{\partial}{\partial w_i} \left(\sum w_i x_i\right) = -\varepsilon x_i \tag{20.4}$$

we obtain the LMS algorithm for the linear PE. What happens if the PE is nonlinear? If the nonlinearity is differentiable (smooth), we still can apply the same method, because of the chain rule, which prescribes that (Fig. 20.6)

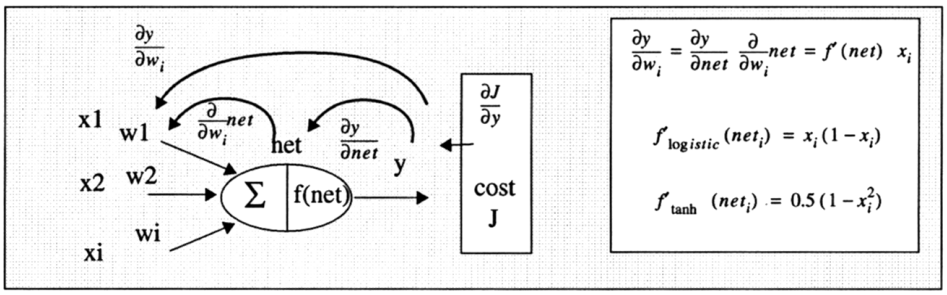

FIGURE 20.6 How to extend LMS to nonlinear PEs with the chain rule.

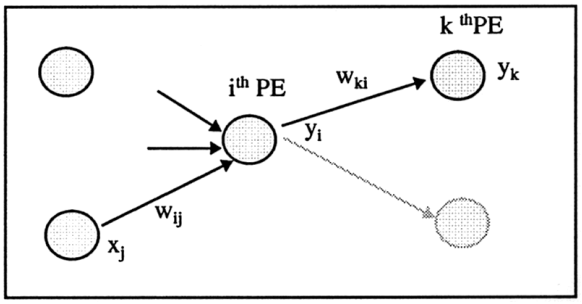

FIGURE 20.7 How to adapt the weights connected to *i*th PE.

$$\frac{\partial J}{\partial w_i} = \frac{\partial J}{\partial y}\frac{\partial y}{\partial \text{net}}\frac{\partial}{\partial w_i} net = -(d - y) f'(\text{net})\, x_i = -\varepsilon f'(\text{net})\, x_i \tag{20.5}$$

where $f'(\text{net})$ is the derivative of the nonlinearity computed at the operating point. Equation (20.5) is known as the *delta rule*, and it will train the perceptron [Haykin, 1994]. Note that throughout the derivation we skipped the pattern index p for simplicity, but this rule is applied for each input pattern. However, the delta rule cannot train MLPs since it requires the knowledge of the error signal at each PE.

The principle of the ordered derivatives can be extended to multilayer networks, provided we organize the computations in flows of activation and error propagation. The principle is very easy to understand, but a little complex to formulate in equation form [Haykin, 1994].

Suppose that we want to adapt the weights connected to a hidden layer PE, the *i*th PE (Fig. 20.7). One can decompose the computation of the partial derivative of the cost with respect to the weight w_{ij} as

$$\frac{\partial J}{\partial w_{ij}} = \underbrace{\frac{\partial J}{\partial y_i}}_{1}\underbrace{\frac{\partial y_i}{\partial \text{net}_i}\frac{\partial}{\partial w_{ij}}\text{net}_i}_{2} \tag{20.6}$$

i.e., the partial derivative with respect to the weight is the product of the partial derivative with respect to the PE state — part 1 in Eq. (20.6) — times the partial derivative of the local activation to the weights — part 2 in Eq. (20.6). This last quantity is exactly the same as for the nonlinear PE ($f'(\text{net}_i)x_j$), so the big issue is the computation of $\frac{\partial J}{\partial y}$. For an output PE, $\frac{\partial J}{\partial y}$ becomes the injected error ε in Eq. (20.4). For the hidden *i*th PE $\frac{\partial J}{\partial y}$ is evaluated by summing all the errors that reach the PE from the top layer through the topology when the injected errors ε_k are clamped at the top layer, or in an equation

$$\frac{\partial J}{\partial y_i} = \left(\sum_k \frac{\partial J}{\partial y_k}\frac{\partial y_k}{\partial \text{net}_k}\frac{\partial}{\partial y_i}\text{net}_k\right) = \sum_k \varepsilon_k f'(\text{net}_k) w_{ki} \tag{20.7}$$

Substituting back in Eq. (20.6) we finally get

$$\frac{\partial J}{\partial w_{ij}} = \underbrace{-x_j f'(\text{net}_i)}_{1}\underbrace{\left(\sum_k \varepsilon_k\, f'(\text{net}_k)\, w_{ki}\right)}_{2} \tag{20.8}$$

This equation embodies the *back-propagation training algorithm* [Haykin, 1994; Bishop, 1995]. It can be rewritten as the product of a local activation (part 1) and a local error (part 2), exactly as the LMS and the delta rules. But now the local error is a composition of errors that flow through the topology, which becomes equivalent to the existence of a desired response at the PE.

There is an intrinsic flow in the implementation of the back-propagation algorithm: first, inputs are applied to the net and activations computed everywhere to yield the output activation. Second, the external errors are computed by subtracting the net output from the desired response. Third, these external errors are utilized in Eq. (20.8) to compute the local errors for the layer immediately preceding the output layer, and the computations chained up to the input layer. Once all the local errors are available, Eq. (20.2) can be used to update every weight. These three steps are then repeated for other training patterns until the error is acceptable.

Step three is equivalent to injecting the external errors in the *dual topology* and back-propagating them up to the input layer [Haykin, 1994]. The dual topology is obtained from the original one by reversing data flow and substituting summing junctions by splitting nodes and vice versa. The error at each PE of the dual topology is then multiplied by the activation of the original network to compute the weight updates. So, effectively the dual topology is being used to compute the local errors which makes the procedure highly efficient. This is the reason back-propagation trains a network of N weights with a number of multiplications proportional to N, $(O(N))$, instead of $(O(N^2))$ for previous methods of computing partial derivatives known in control theory. Using the dual topology to implement back-propagation is the best and most general method to program the algorithm in a digital computer.

Applying Back-Propagation in Practice

Now that we know an algorithm to train MLPs, let us see what are the practical issues to apply it. We will address the following aspects: size of training set vs. weights, search procedures, how to stop training, and how to set the topology for maximum generalization.

Size of Training Set

The size of the training set is very important for good performance. Remember that the ANN gets its information from the training set. If the training data do not cover the full range of operating conditions, the system may perform badly when deployed. Under no circumstances should the training set be less than the number of weights in the ANN. A good size of the training data is ten times the number of weights in the network, with the lower limit being set around three times the number of weights (these values should be taken as an indication, subject to experimentation for each case) [Haykin, 1994].

Search Procedures

Searching along the direction of the gradient is fine if the performance surface is quadratic. However, in ANNs rarely is this the case, because of the use of nonlinear PEs and topologies with several layers. So, gradient descent can be caught in local minima, which makes the search very slow in regions of small curvature. One efficient way to speed up the search in regions of small curvature and, at the same time, to stabilize it in narrow valleys is to include a momentum term in the weight adaptation

$$w_{ij}(n+1) = w_{ij}(n) + \eta\delta(n)x_j(n) + \alpha\left(w_{ij}(n) - w_{ij}(n-1)\right) \tag{20.9}$$

The value of momentum α should be set experimentally between 0.5 and 0.9. There are many more modifications to the conventional gradient search, such as adaptive step sizes, annealed noise, conjugate gradients, and second-order methods (using information contained in the Hessian matrix), but the simplicity and power of momentum learning is hard to beat [Haykin, 1994; Bishop, 1995].

How to Stop Training

The stop criterion is a fundamental aspect of training. The simple ideas of capping the number of iterations or of letting the system train until a predetermined error value are not recommended. The reason is that we want the ANN to perform well in the test set data; i.e., we would like the system to perform well in data it

never saw before (good *generalization*) [Bishop, 1995]. The error in the training set tends to decrease with iteration when the ANN has enough degrees of freedom to represent the input/output map. However, the system may be remembering the training patterns (*overfitting*) instead of finding the underlying mapping rule. This is called *overtraining*. To avoid overtraining the performance in a *validation set*, i.e., a set of input data that the system never saw before, must be checked regularly during training (i.e., once every 50 passes over the training set). The training should be stopped when the performance in the validation set starts to increase, despite the fact that the performance in the training set continues to decrease. This method is called *cross validation*. The validation set should be 10% of the training set, and distinct from it.

Size of the Topology

The size of the topology should also be carefully selected. If the number of layers or the size of each layer is too small, the network does not have enough degrees of freedom to classify the data or to approximate the function, and the performance suffers.

On the other hand, if the size of the network is too large, performance may also suffer. This is the phenomenon of *overfitting* that we mentioned above. But one alternative way to control it is to reduce the size of the network. There are basically two procedures to set the size of the network: either one starts small and adds new PEs or one starts with a large network and prunes PEs [Haykin, 1994]. One quick way to prune the network is to impose a penalty term in the performance function — a *regularizing term* — such as limiting the slope of the input/output map [Bishop, 1995]. A regularization term that can be implemented locally is

$$w_{ij}(n+1) = w_{ij}(n)\left(1 - \frac{\lambda}{\left(1 + w_{ij}(n)\right)^2}\right) + \eta\delta_i(n)\,x_j(n) \tag{20.10}$$

where λ is the *weight decay* parameter and δ the local error. Weight decay tends to drive unimportant weights to zero.

A Posteriori Probabilities

We will finish the discussion of the MLP by noting that this topology when trained with the mean square error is able to estimate directly at its outputs *a posteriori* probabilities, i.e., the probability that a given input pattern belongs to a given class [Bishop, 1995]. This property is very useful because the MLP outputs can be interpreted as probabilities and operated as numbers. In order to guarantee this property, one has to make sure that each class is attributed to one output PE, that the topology is sufficiently large to represent the mapping, that the training has converged to the absolute minimum, and that the outputs are normalized between 0 and 1. The first requirements are met by good design, while the last can be easily enforced if the *softmax activation* is used as the output PE [Bishop, 1995],

$$y = \frac{\exp(\text{net})}{\sum_j \exp(\text{net}_j)} \tag{20.11}$$

20.3 Radial Basis Function Networks

The radial basis function (RBF) network constitutes another way of implementing arbitrary input/output mappings. The most significant difference between the MLP and RBF lies in the PE nonlinearity. While the PE in the MLP responds to the full input space, the PE in the RBF is local, normally a Gaussian kernel in the input space. Hence, it only responds to inputs that are close to its center; i.e., it has basically a *local response*.

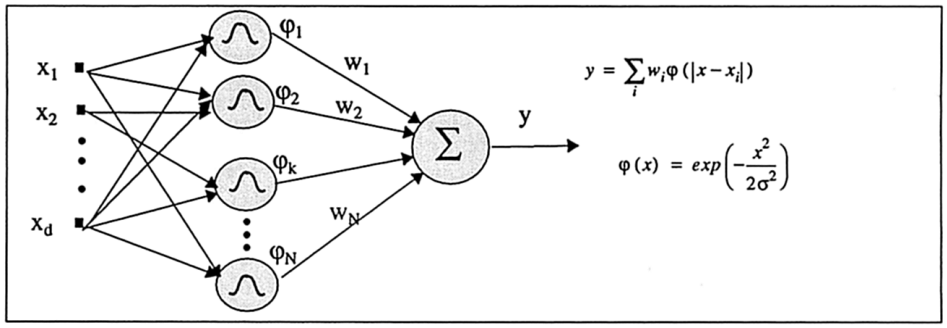

FIGURE 20.8 Radial Basis Function (RBF) network.

The RBF network is also a layered net with the hidden layer built from Gaussian kernels and a linear (or nonlinear) output layer (Fig. 20.8). Training of the RBF network is done normally in two stages [Haykin, 1994]: first, the centers x_i are adaptively placed in the input space using competitive learning or k means clustering [Bishop, 1995], which are unsupervised procedures. Competitive learning is explained later in the chapter. The variances of each Gaussian are chosen as a percentage (30 to 50%) to the distance to the nearest center. The goal is to cover adequately the input data distribution. Once the RBF is located, the second layer weights w_i are trained using the LMS procedure.

RBF networks are easy to work with, they train very fast, and they have shown good properties both for function approximation as classification. The problem is that they require lots of Gaussian kernels in high-dimensional spaces.

20.4 Time-Lagged Networks

The MLP is the most common neural network topology, but it can only handle instantaneous information, since the system has no memory and it is feedforward. In engineering, the processing of signals that exist in time requires systems with memory, i.e., linear filters. Another alternative to implement memory is to use feedback, which gives rise to *recurrent networks*. Fully recurrent networks are difficult to train and to stabilize, so it is preferable to develop topologies based on MLPs but where explicit subsystems to store the past information are included. These subsystems are called *short-term memory structures* [de Vries and Principe, 1992]. The combination of an MLP with short-term memory structures is called a *time-lagged network* (*TLN*). The memory structures can be eventually recurrent, but the feedback is local, so stability is still easy to guarantee. Here, we will cover just one TLN topology, called *focused*, where the memory is at the input layer. The most general TLN have memory added anywhere in the network, but they require other more-involved training strategies (BPTT [Haykin, 1994]). The interested reader is referred to de Vries and Principe [1992] for further details.

The function of a short-term memory in the focused TLN is to represent the past of the input signal, while the nonlinear PEs provide the mapping as in the MLP (Fig. 20.9).

Memory Structures

The simplest memory structure is built from a *tap delay line* (Fig. 20.10). The *memory by delays* is a single-input, multiple-output system that has no free parameters except its size K. The tap delay memory is the memory utilized in the *time-delay neural network* (TDNN) which has been utilized successfully in speech recognition and system identification [Kung, 1993].

A different mechanism for linear memory is the *feedback* (Fig. 20.11). Feedback allows the system to remember past events because of the exponential decay of the response. This memory has limited resolution because of the low pass required for long memories. But notice that unlike the memory by delay, memory by feedback provides the learning system with a free parameter μ that controls the length of the memory. Memory by feedback has been used in Elman and Jordan networks [Haykin, 1994].

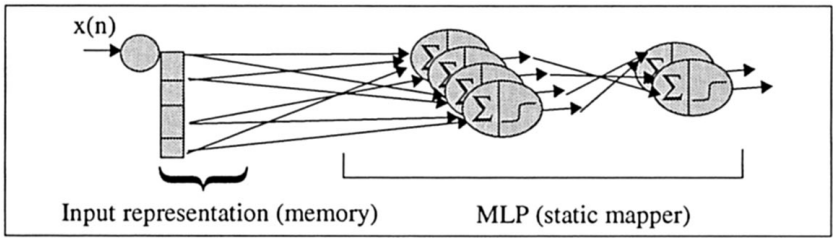

FIGURE 20.9 A focused TLN.

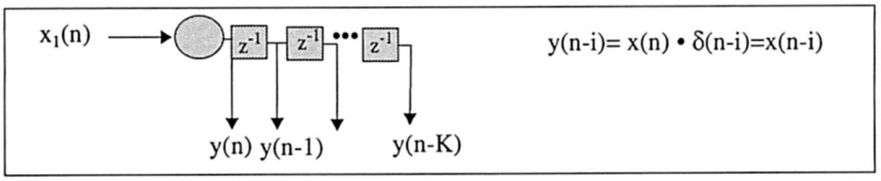

FIGURE 20.10 Tap delay line memory.

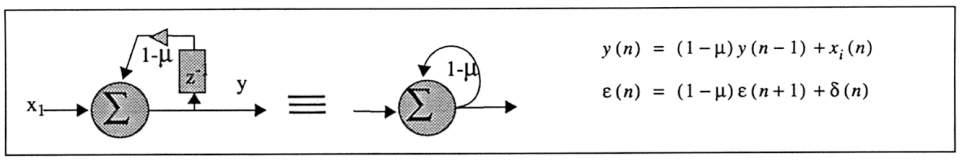

FIGURE 20.11 Memory by feedback (context PE).

It is possible to combine the advantages of memory by feedback with the ones of the memory by delays in linear systems called *dispersive delay lines*. The most studied of these memories is a cascade of low-pass functions called the *gamma memory* [de Vries and Principe, 1992]. The gamma memory has a free parameter μ that controls and decouples memory depth from resolution of the memory. *Memory depth D* is defined as the first moment of the impulse response from the input to the last tap *K*, while *memory resolution R* is the number of taps per unit time. For the gamma memory $D = K/\mu$, and $R = \mu$; i.e., changing μ modifies the memory depth and resolution inversely. This recursive parameter μ can be adapted with the output MSE as the other network parameters; i.e., the ANN is able to choose the best memory depth to minimize the output error, which is unlike the tap delay memory.

Training-Focused TLN Architectures

The appeal of the focused architecture is that the MLP weights can be still adapted with back-propagation. However, the input/output mapping produced by these networks is static. The input memory layer is bringing in past input information to establish the value of the mapping.

As we know in engineering, the size of the memory is fundamental to identify, for instance, an unknown plant or to perform prediction with a small error. But note now that with the focused TLN the models for system identification become nonlinear (i.e., nonlinear moving average — NMA).

When the tap delay implements the short-term memory, straight back-propagation can be utilized since the only adaptive parameters are the MLP weights. When the gamma memory is utilized (or the context PE), the recursive parameter is adapted in a total adaptive framework (or the parameter is preset by some external consideration). The equations to adapt the context PE and the gamma memory are shown in Figs. 20.11 and 20.12, respectively. For the context PE $\delta(n)$ refers to the total error that is back-propagated from the MLP and that reaches the dual context PE.

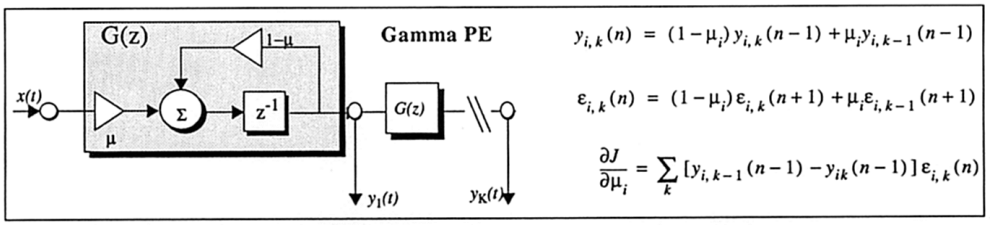

FIGURE 20.12 Gamma memory (dispersive delay line).

20.5 Hebbian Learning and Principal Component Analysis Networks

Hebbian Learning

Hebbian learning is an unsupervised learning rule that *captures similarity* between an input and an output through *correlation*. To adapt a weight w_i using Hebbian learning we adjust the weights according to $\Delta w_i = \eta x_i y$ or in an equation [Haykin, 1994]

$$w_i(n+1) = w_i(n) + \eta\, x_i(n) y(n) \tag{20.12}$$

where η is the step size, x_i is the ith input and y is the PE output.

The output of the single PE is an inner product between the input and the weight vector (formula in Fig. 20.13). It measures the similarity between the two vectors — i.e., if the input is close to the weight vector the output y is large; otherwise it is small. The weights are computed by an outer product of the input X and output Y, i.e., $W = XY^T$, where T means transpose. The problem of Hebbian learning is that it is unstable; i.e., the weights will keep on growing with the number of iterations [Haykin, 1994].

Oja proposed to stabilize the Hebbian rule by normalizing the new weight by its size, which gives the rule [Haykin, 1994]:

$$w_i(n+1) = w_i(n) + \eta\, y(n)\left[x_i(n) - y(n)\, w_i(n)\right] \tag{20.13}$$

The weights now converge to finite values. They still define in the input space the direction where the data cluster has its largest projection, which corresponds to the eigenvector with the largest eigenvalue of the input correlation matrix [Kung, 1993]. The output of the PE provides the largest eigenvalue of the input correlation matrix.

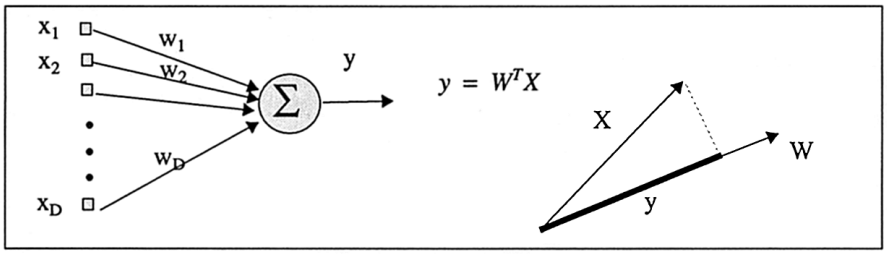

FIGURE 20.13 Hebbian PE.

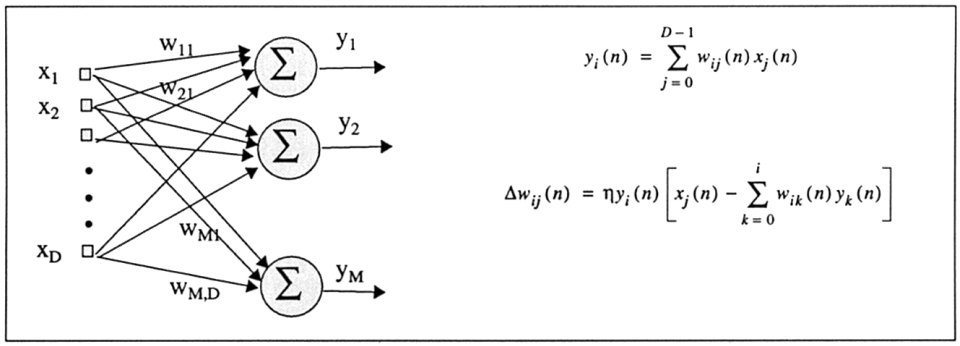

FIGURE 20.14 PCA network.

Principal Component Analysis

Principal component analysis (PCA) is a well-known technique in signal processing that is used to project a signal into a signal-specific basis. The importance of PCA analysis is that it provides *the best linear projection* to a subspace in terms of preserving the signal energy [Haykin, 1994]. Normally, PCA is computed analytically through a singular value decomposition. PCA networks offer an alternative to this computation by providing an iterative implementation that may be preferred for real-time operation in embedded systems.

The PCA network is a one-layer network with linear-processing elements (Fig. 20.14). One can extend Oja's rule for many-output PEs (less or equal to the number of input PEs), according to the formula shown in Fig. 20.14 which is called the Sanger's rule [Haykin, 1994]. The weight matrix rows (that contain the weights connected to the output PEs in descending order) are the eigenvectors of the input correlation matrix. If we set the number of output PEs equal to $M < D$, we will be projecting the input data onto the M largest principal components. Their outputs will be proportional to the M largest eigenvalues. Note that we are performing an eigendecomposition through an iterative procedure.

Associative Memories

Hebbian learning is also the rule to create *associative memories* [Zurada, 1992]. The most-utilized associative memory implements *heteroassociation*, where the system is able to associate an input X to a designated output Y which can be of a different dimension (Fig. 20.15). So, in heteroassociation the signal Y works as the desired response.

We can train such a memory using Hebbian learning or LMS, but the LMS provides a more efficient encoding of information. Associative memories differ from conventional computer memories in several respects. First, they are content addressable, and the information is distributed throughout the network, so they are robust to noise in the input. With nonlinear PEs or recurrent connections (as in the famous Hopfield network) [Haykin, 1994] they display the important property of *pattern completion;* i.e., when the input is distorted or only partially available, the recall can still be perfect.

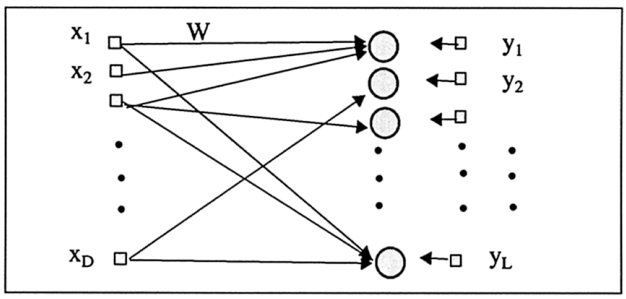

FIGURE 20.15 Associative memory (heteroassociation).

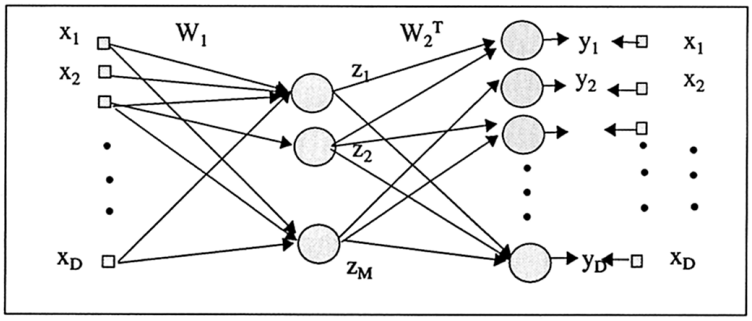

FIGURE 20.16 Autoassociator.

A special case of associative memories is called the *autoassociator* (Fig. 20.16), where the training output of size D is equal to the input signal (also a size D) [Kung, 1993]. Note that the hidden layer has fewer PEs ($M \ll D$) than the input (bottleneck layer). $W_1 = W_2^T$ is enforced. The function of this network is one of *encoding or data reduction*. The training of this network (W_2 matrix) is done with LMS. It can be shown that this network also implements PCA with M components, even when the hidden layer is built from nonlinear PEs.

20.6 Competitive Learning and Kohonen Networks

Competition is a very efficient way to divide the computing resources of a network. Instead of having each output PE more or less sensitive to the full input space, as in the associative memories, in a competitive network each PE specializes into a piece of the input space and represents it [Haykin, 1994]. Competitive networks are linear, single-layer nets (Fig. 20.17). Their functionality is directly related to the competitive learning rule, which belongs to the unsupervised category. First, only the PE that has the largest output gets its weights updated. The weights of the winning PE are updated according to the formula in Fig. 20.17 in such a way that they approach the present input. The step size exactly controls how much is this adjustment (see Fig. 20.17).

Notice that there is an intrinsic nonlinearity in the learning rule: only the PE that has the largest output (the winner) has its weights updated. All the other weights remain unchanged. This is the mechanism that allows the competitive net PEs to specialize.

Competitive networks are used for clustering; i.e., an M output PE net will seek M clusters in the input space. The weights of each PE will correspond to the centers of mass of one of the M clusters of input samples. When a given pattern is shown to the trained net, only one of the outputs will be active and can be used to *label* the sample as belonging to one of the clusters. No more information about the input data is preserved.

Competitive learning is one of the fundamental components of the Kohonen self-organizing feature map (SOFM) network, which is also a single-layer network with linear PEs [Haykin, 1994]. Kohonen learning creates annealed competition in the output space, by adapting not only the winner PE weights but also their spatial

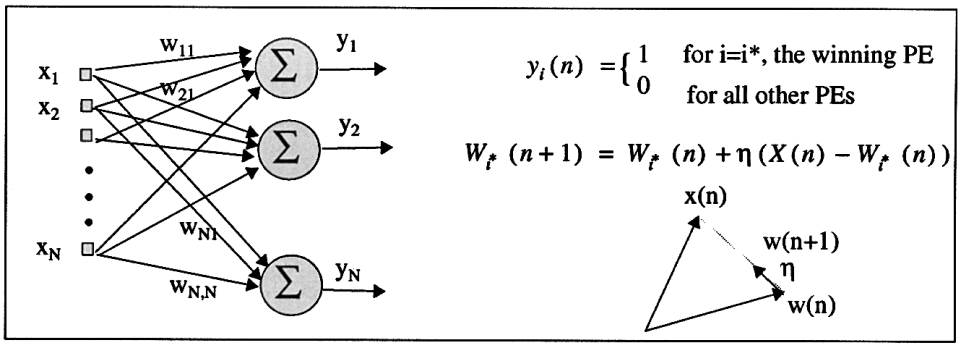

FIGURE 20.17 Competitive neural network.

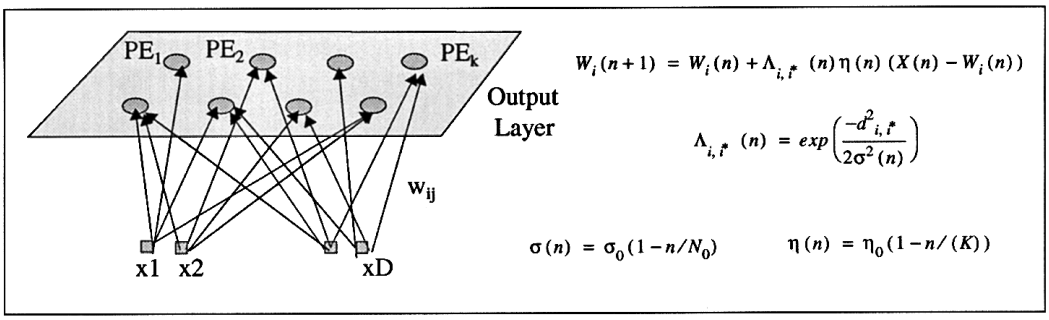

FIGURE 20.18 Kohonen SOFM.

neighbors using a Gaussian neighborhood function Λ. The output PEs are arranged in linear or two-dimensional neighborhoods (Fig. 20.18)

Kohonen SOFM networks produce a mapping between the continuous input space to the discrete output space preserving topological properties of the input space (i.e., local neighbors in the input space are mapped to neighbors in the output space). During training, both the spatial neighborhoods and the learning constant are decreased slowly by starting with a large neighborhood σ_0, and decreasing it (N_0 controls the scheduling). The initial step size η_0 also needs to be scheduled (by K).

The Kohonen SOFM network is useful to project the input to a subspace as an alternative to PCA networks. The topological properties of the output space provide more information about the input than straight clustering.

Further Information

The literature in this field is voluminous. We decided to limit the references to text books for an engineering audience, with different levels of sophistication. Zurada is the most accessible text, Haykin the most comprehensive. Kung provides interesting applications of both PCA networks and nonlinear signal processing and system identification. Bishop concentrates on the design of pattern classifiers.

Computing Environments for Digital Signal Processing

21.1 MATLAB Environment
21.2 Example 1: Signal Analysis
21.3 Example 2: Filter Design and Analysis
21.4 Example 3: Multirate Signal Processing

Delores M. Etter
University of Colorado

Computing environments provided by many software tools and packages allow users to design, simulate, and implement digital signal processing (DSP) techniques with speed, accuracy, and confidence. With access to libraries of high-performance algorithms and to advanced visualization capabilities, we can design and analyze systems using the equations and notations that we use to think about signal processing problems; we do not have to translate the equations and techniques into a different notation and syntax. The graphics interface provides an integral part of this design environment, and is accessible from any point within our algorithms. Within this type of computing environment, we are more productive. But, even more important, we develop better solutions because we have so many more tools for analyzing solutions, for experimenting with **"what if" questions**, and for developing extensive simulations to test our solutions. To illustrate the power of these environments, we present a brief description of MATLAB, one of the most popular technical computing environments in both industry and academia, and then present three examples that use MATLAB.

21.1 MATLAB Environment

MATLAB is an integrated technical environment designed to provide accelerated DSP design capabilities. In addition to the basic software package that contains powerful functions for numeric computations, advanced graphics and visualization capabilities, a high-level programming language, and tools for designing **graphical user interfaces (GUI)**, MATLAB also provides a number of application-specific **toolboxes** that contain specialized libraries of functions. The discussion and examples that follow in this article use capabilities from the Signal Processing Toolbox. Other toolboxes that are applicable to solving signal processing problems include the following: Control Systems, Frequency Domain System Identification, Fuzzy Logic, Higher-Order Spectral Analysis, Image Processing, LMI (Linear Matrix Inequality) Control, Model Predictive Control, μ-Analysis and Synthesis, Neural Networks, Optimization, Partial Differential Equations, QFT (Quantitation Feedback Theory) Control, Robust Control, Signal Processing, Splines, Statistics, Symbolic Math, System Identification, and Wavelets.

An interactive environment for modeling, analyzing, and simulating a wide variety of dynamic systems is also provided by MATLAB through SIMULINK—a graphical user interface designed to construct block diagram

models using **"drag-and-drop" operations**. Simulations of the block diagrams can be used to test a number of "what-if" questions. Special purpose block libraries are available for DSP algorithm development, and include a DSP Blockset, a Fixed-Point Blockset, and a Nonlinear Control Design Blockset.

In order to bridge the gap between interactive prototyping and embedded systems, MATLAB has developed a compiler to generate optimized C code from MATLAB code. Automatic C code generation eliminates manual coding and algorithm recoding, thus providing a hierarchical framework for designing, simulating, and prototyping DSP solutions.

21.2 Example 1: Signal Analysis

One of the most common DSP applications is the analysis of signals that have been collected from experiments or from a physical environment. These signals are typically stored in data files, and often need preprocessing steps applied to them before we are able to extract the desired information. Preprocessing can include removing means or linear trends, filtering noise, removing anomalies, and interpolating for missing data. Once the data is ready to analyze, we are usually interested in statistical information (mean, median, variance, autocorrelation, etc.) along with an estimate of the distribution of the values (uniform, Gaussian, etc.). The frequency content of a signal is also important to determine; if the signal is non-stationary, the frequency content needs to be determined using short time windows.

To illustrate the use of MATLAB in computing some of the steps mentioned above, we use a speech signal collected at 8 kHz. After loading the signal from a data file, we will remove any linear trend that might have been introduced in the collection process (this also removes any constant term). Figure 21.1 contains a plot of the signal which clearly shows the time-varying nature of the signal. Figure 21.2 contains a histogram of the distribution of the values, showing that the values are closer to a Laplacian or Gamma distribution than to a uniform or Gaussian distribution. Figure 21.3 contains a spectogram which displays the frequency content of the signal computed using short overlapping time windows. The MATLAB code that generated these plots is shown in Fig. 21.4. This code illustrates some of the important characteristics of high-level computational tools. The fundamental data structure is a matrix, and all operations and functions are designed to work with matrices. Hence, loops are rarely necessary, and thus the code is generally much shorter, more readable, and more self-documenting.

21.3 Example 2: Filter Design and Analysis

MATLAB gives us a number of different options for designing both IIR and FIR digital filters. We can design classical IIR filters (Butterworth, Chebyshev type I, Chebyshev type II, and elliptic) that are lowpass, highpass, bandpass, or bandstop filters. We can also use other techniques, such as the Yule-Walker technique, to design IIR filters with arbitrary passbands. Several techniques allow us to design FIR filters using windowed least squares techniques. The Parks-McClellan algorithm uses the Remez exchange algorithm to design filters with

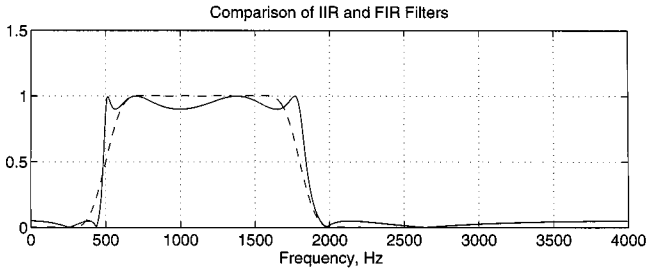

FIGURE 21.5

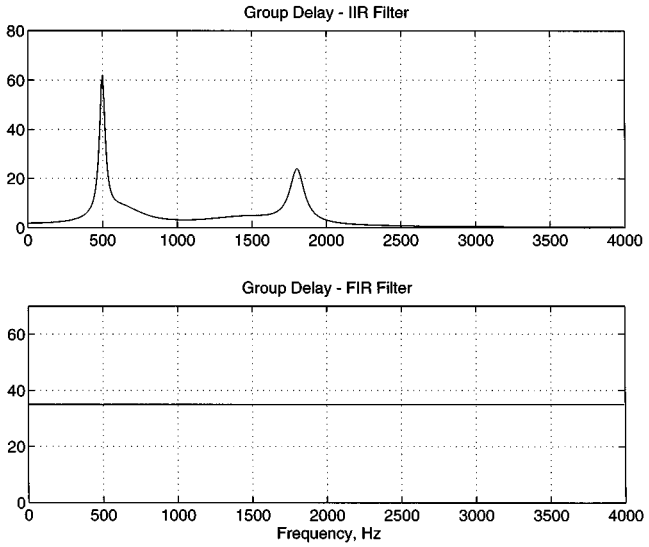

FIGURE 21.6

an optimal fit to an arbitrary desired response. Once a filter is designed, it can be easily translated to other forms, including transfer functions, impulse responses, and poles/zeros.

Assume that we are going to analyze the dial tones from a telephone network that uses dual-tone multifrequency (DTMF) signaling. In this system, pairs of tones are used to signal each character on the telephone keypad. For example, the digit 1 is represented by tones at 697 Hz and 1209 Hz. All of the tones are between 697 Hz and 1633 Hz. Thus, before analyzing the signal to determine the two tones that it contains, we might want to filter out all signals outside of the band that contains all possible tones in order to increase the signal-to-noise ratio. In this example, we design a bandpass filter with a passband between 500 Hz and 1800 Hz. Designs are compared using an elliptic IIR filter of order 8 and a causal FIR filter of order 70. Figure 21.5 contains magnitude plots of the two filters, and clearly shows the characteristics of the filters. The elliptic filter has sharp transitions with ripple in the passband and in the stopband, while the FIR filter (which also uses a Hamming window) is flat in the passband and the stopband, but has wider transition bands. Figure 21.6 contains the group delays for the two filters. The FIR filter has a linear phase response, and thus the group delay is a fixed value of 35 samples; the IIR filter has a nonlinear phase, but has a relatively constant delay in the passband. Figure 21.7 contains the corresponding impulse responses, illustrating the finite impulse response of the FIR filter and the infinite impulse response of the IIR filter. Figure 21.8 contains the pole/zero plot for the IIR solution. The code for performing the designs and generating all the plots is shown in Fig. 21.9.

21.4 Example 3: Multirate Signal Processing

Given a signal that has been collected or computed using a process that eliminates or minimizes aliasing from components above the Nyquist frequency (one-half the sampling frequency), we have a great deal of flexibility in modifying the sampling rate. For example, if the frequency content of the signal is much lower than the Nyquist frequency, then the sampling rate can be reduced without losing any of the signal content. This "decimation" process allows us to compress the signal into a form that requires less memory requirements. An "interpolation" process can be used to interpolate new data points between points of the decimated signal in such a way that the frequency content of the new signal is essentially the same as the original signal. The decimation process requires a reduction of data points by an integer factor, *M,* such as a factor of 3. The

FIGURE 21.9

interpolation process requires that an integral number of points, L-1, be interpolated between existing points, such as interpolation of 5 new points between existing pairs of points. The decimation process increases a sampling interval by M, and the interpolation process decreases a sampling interval by a factor of L. MATLAB contains functions for decimation and interpolation, as well as a function for a resampling of a signal using a non-integer factor of P/Q where P and Q are integers.

Consider a signal that is one sinusoid modulated by another sinusoid. The signal has been sampled at a frequency chosen to provide efficient storage of the data. However, when plotting the data for further analysis, we want to interpolate by a factor of 8 so that the signal looks smoother. Therefore, we use the MATLAB interpolation function. Figure 21.10 contains plots of the original and interpolated time signals. Figure 21.11 contains frequency plots to confirm that the interpolation did not significantly affect the frequency content. Figure 21.12 contains the MATLAB code for this process.

The Cheetah disc drive is produced by Seagate Technology, Scotts Valley, California, and has been dubbed the industry's fastest disc drive. The Cheetah is the world's first-announced drive to utilize 10,000-rpm technology. The increased rotational remarkably increases data transfer rates to 15 Mbytes/sec which is 40% greater than that of 7,200-rpm drives. The 10,000-rpm rotational rate also significantly reduces the seek time.

Seagate's pioneering of the 10,000-rpm technology enables OEMs, VARs, and system integrators to take advantage of performance levels that were previously unattainable. Seagate has developed and manufactured some of the industry's highest-performance disc drives which not only enable users to achieve higher levels of system performance, but will also introduce exciting new electronic applications. THE TRULY INCREDIBLE CHANGES in the technology associated with electronics over the past three decades have certainly been the driving force for most of the growth in the field of electrical engineering. Recall that 30 years ago the transistor was a novel device and that the majority of electronic systems still used vacuum tubes. Then look at the section headings in the following chapters and appreciate the range of ways that electronics has impacted electrical engineering. Amplifiers, integrated circuits, filters, power electronics, and optoelectronics are examples of how electronics transformed the practice of electrical engineering in such diverse fields as power generation and distribution, communications, signal processing, and computers.

The various contributors to this section have done an outstanding job of providing concise and practical coverage of this immense field. By necessity, the content ranges from rather theoretical considerations, such as physical principles of semiconductors, to quite practical issues such as printed circuit board technology and circuits for active filter realizations. There are areas of overlap with other chapters in the *Handbook*, such as those covering electrical effects and devices, biomedical electronics, digital devices, and computers. The contributors to this section, however, have maintained a focus on providing practical and useful information directly related to electronics as needed by a practicing electrical engineer.

The author(s) of each chapter was given the task of providing broad coverage of the field while being restricted to only a few pages of text. As a result, the information content is quite high and tends to treat the main principles or most useful topics in each area without giving the details or extensions of the subject. This practice, followed throughout the *Handbook*, is what makes it a valuable new work in electrical engineering. In most cases the information here will be complete enough. When this is not the case, the references will point the way to whatever added information is necessary.

Nomenclature

Symbol	Quantity	Unit
A	area	m^2
A_i	current gain	
A_v	terminal voltage gain	
α_i	ionization coefficient	
B	bandwidth	Hz
C	velocity of light in vacuum	2.998×10^8 m/s
C	specific heat	W/kg K

22.1 Physical Properties

Gennady Sh. Gildenblat and Boris Gelmont

Electronic applications of semiconductors are based on our ability to vary their properties on a very small scale. In conventional semiconductor devices, one can easily alter charge carrier concentrations, fields, and current densities over distances of 0.1–10 μm. Even smaller characteristic lengths of 10–100 nm are feasible in materials with an engineered band structure. This section reviews the essential physics underlying modern semiconductor technology.

Energy Bands

In crystalline semiconductors atoms are arranged in periodic arrays known as crystalline lattices. The lattice structure of silicon is shown in Fig. 22.1. Germanium and diamond have the same structure but with different interatomic distances. As a consequence of this periodic arrangement, the allowed energy levels of electrons are grouped into **energy bands**, as shown in Fig. 22.2. The probability that an electron will occupy an allowed quantum state with energy E is

$$f = [1 + \exp(E - F)/k_B T]^{-1} \tag{22.1}$$

Here $k_B = 1/11{,}606$ eV/K denotes the Boltzmann constant, T is the absolute temperature, and F is a parameter known as the Fermi level. If the energy $E > F + 3k_B T$, then $f(E) < 0.05$ and these states are mostly empty. Similarly, the states with $E < F - 3k_B T$ are mostly occupied by electrons. In a typical metal [Fig. 22.2(a)], the

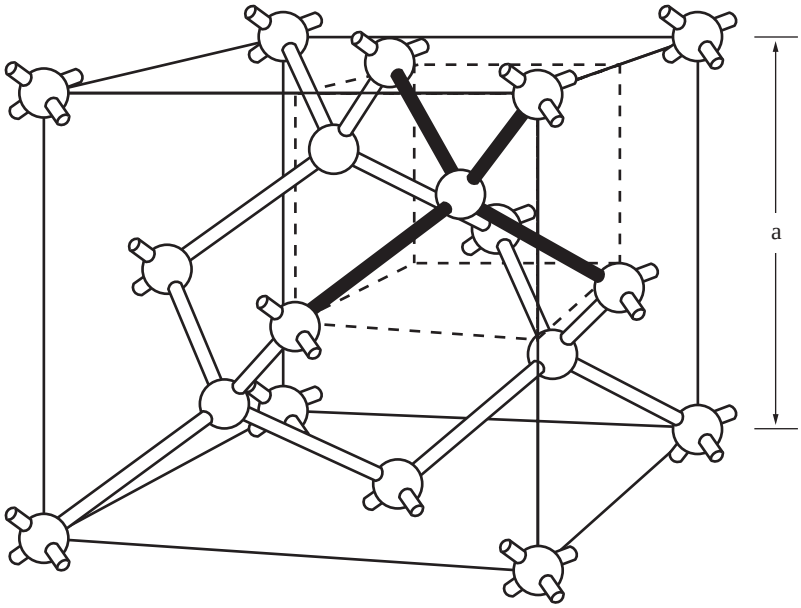

FIGURE 22.1 Crystalline lattice of silicon, $a = 5.43$ Å at 300°C.

energy level $E = F$ is allowed, and only one energy band is partially filled. (In metals like aluminum, the partially filled band in Fig. 22.2(a) may actually represent a combination of several overlapping bands.) The remaining energy bands are either completely filled or totally empty. Obviously, the empty energy bands do not contribute to the charge transfer. It is a fundamental result of solid-state physics that energy bands that are completely filled also do not contribute. What happens is that in the filled bands the average velocity of electrons is equal to zero. In semiconductors (and insulators) the Fermi level falls within a forbidden **energy gap** so that two of the energy bands are partially filled by electrons and may give rise to electron current. The upper partially filled band is called the **conduction band** while the lower is known as the **valence band**. The number of electrons in the conduction band of a semiconductor is relatively small and can be easily changed by adding impurities. In metals, the number of free carriers is large and is not sensitive to doping.

A more detailed description of energy bands in a crystalline semiconductor is based on the Bloch theorem, which states that an electron wave function has the form (Bloch wave)

$$\Psi_{bk} = u_{bk}(r)\ \exp(ikr) \tag{22.2}$$

where **r** is the radius vector of electron, the modulating function $u_{bk}(\mathbf{r})$ has the periodicity of the lattice, and the quantum state is characterized by wave vector **k** and the band number b. Physically, (22.2) means that an electron wave propagates through a periodic lattice without attenuation. For each energy band one can consider the dispersion law $E = E_b(\mathbf{k})$. Since (see Fig. 22.2b) in the conduction band only the states with energies close to the bottom, E_c, are occupied, it suffices to consider the $E(\mathbf{k})$ dependence near E_c. The simplified band diagrams of Si and GaAs are shown in Fig. 22.3.

Electrons and Holes

The concentration of electrons in the valence band can be controlled by introducing impurity atoms. For example, the substitutional doping of Si with As results in a local energy level with an energy about $\Delta W_d \approx 45$ meV below the conduction band edge, E_c [Fig. 22.2(b)]. At room temperature this impurity center is readily ionized, and (in the absence of other impurities) the concentration of electrons is close to the concentration of As atoms. Impurities of this type are known as donors.

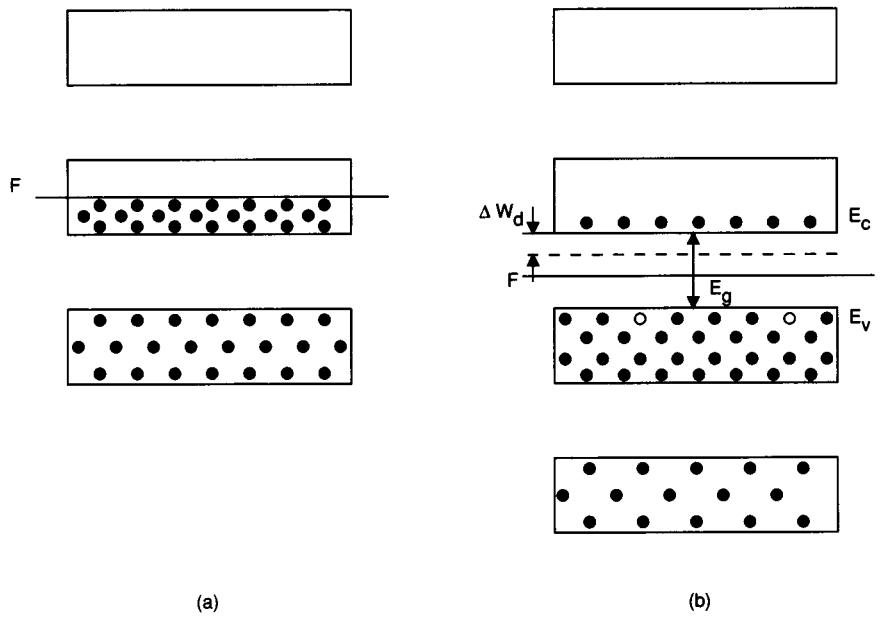

FIGURE 22.2 Band diagrams of metal (a) and semiconductor (b); ●, electron; ○, missing electron (hole).

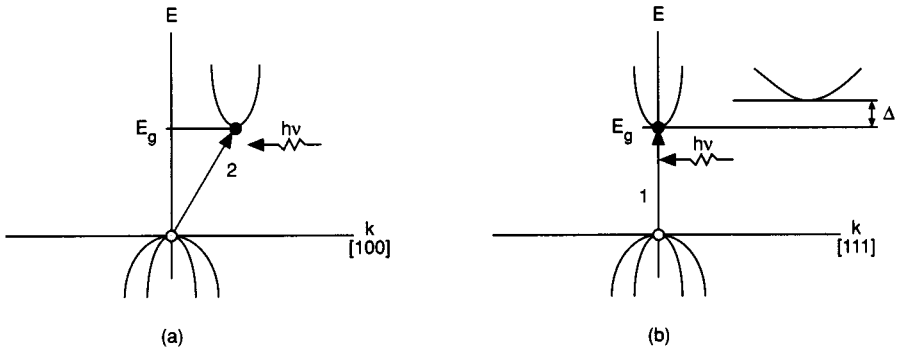

FIGURE 22.3 Simplified $E(\mathrm{k})$ dependence for Si (a) and GaAs (b). At room temperature $E_g(\mathrm{Si}) = 1.12$ eV, $E_g(\mathrm{GaAs}) = 1.43$ eV, and $\Delta = 0.31$ eV; (1) and (2) indicate direct and indirect band-to-band transitions.

While considering the contribution $\mathbf{j}_p$ of the predominantly filled valence band to the current density, it is convenient to concentrate on the few missing electrons. This is achieved as follows: let $v(k)$ be the velocity of electron described by the wave function (20.2). Then

$$\mathbf{j}_p = -q\sum_{\substack{\text{filled}\\ \text{states}}} \mathbf{v}(\mathbf{k}) = -q\left[\sum_{\text{all states}} \mathbf{v}(\mathbf{k}) - \sum_{\substack{\text{empty}\\ \text{states}}} \mathbf{v}(\mathbf{k})\right] = q\sum_{\substack{\text{empty}\\ \text{states}}} \mathbf{v}(\mathbf{k}) \tag{22.3}$$

Here we have noted again that a completely filled band does not contribute to the current density. The picture emerging from (22.3) is that of particles (known as **holes**) with the charge $+q$ and velocities corresponding to those of missing electrons. The concentration of holes in the valence band is controlled by adding acceptor-type impurities (such as boron in silicon), which form local energy levels close to the top of the valence band. At room temperature these energy levels are occupied by electrons that come from the valence band and leave

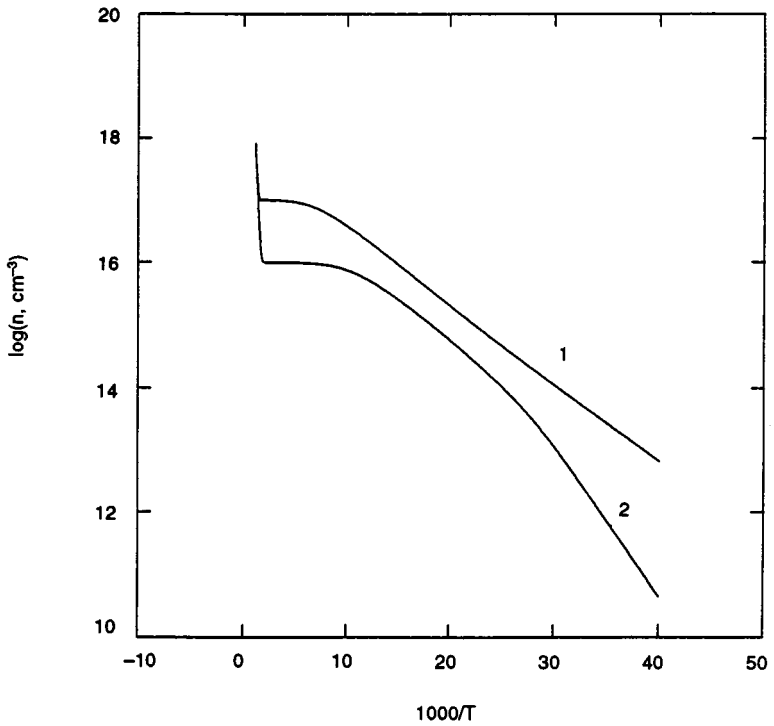

FIGURE 22.4 The inverse temperature dependence of electron concentration in Si; 1: $N_d = 10^{17}$ cm^{-3}, $N_a = 0$; 2: $N_d = 10^{16}$ cm^{-3}, $N_a = 10^{14}$ cm^{-3}.

the holes behind. Assuming that the Fermi level is removed from both E_c and E_v by at least $3k_BT$ (a nondegenerate semiconductor), the concentrations of electrons and holes are given by

$$n = N_c \exp[(F - E_c)/k_BT] \tag{22.4}$$

and

$$p = N_v \exp[(E_v - F)/k_BT] \tag{22.5}$$

where $N_c = 2\ (2m_n^*\pi k_BT)^{3/2}/h^3$ and $N_v = 2(2m_p^*\pi k_BT)^{3/2}/h^3$ are the effective densities of states in the conduction and valence bands, respectively, h is Plank constant, and the effective masses m_n^* and m_p^* depend on the details of the band structure [Pierret, 1987].

In a nondegenerate semiconductor, $np = N_cN_v \exp(-E_g/k_BT) \triangleq n_i^2$ is independent of the doping level. The neutrality condition can be used to show that in an n-type ($n > p$) semiconductor at or below room temperature

$$n(n + N_a)(N_d - N_a - n)^{-1} = (N_c/2)\ \exp(-\Delta W_d/k_BT) \tag{22.6}$$

where N_d and N_a denote the concentrations of **donors** and **acceptors**, respectively.

Corresponding temperature dependence is shown for silicon in Fig. 22.4. Around room temperature $n = N_d - N_a$, while at low temperatures n is an exponential function of temperature with the activation energy $\Delta W_d/2$ for $n > N_a$ and ΔW_d for $n < N_a$. The reduction of n compared with the net impurity concentration $N_d - N_a$ is known as a freeze-out effect. This effect does not take place in the heavily doped semiconductors.

For temperatures $T > T_i = (E_g/2k_B)/\ln[\sqrt{N_cN_v}/(N_d - N_a)]$ the electron concentration $n \approx n_i >> N_d - N_a$ is no longer dependent on the doping level (Fig. 22.4). In this so-called intrinsic regime electrons come directly from the valence band. A loss of technological control over n and p makes this regime unattractive for electronic

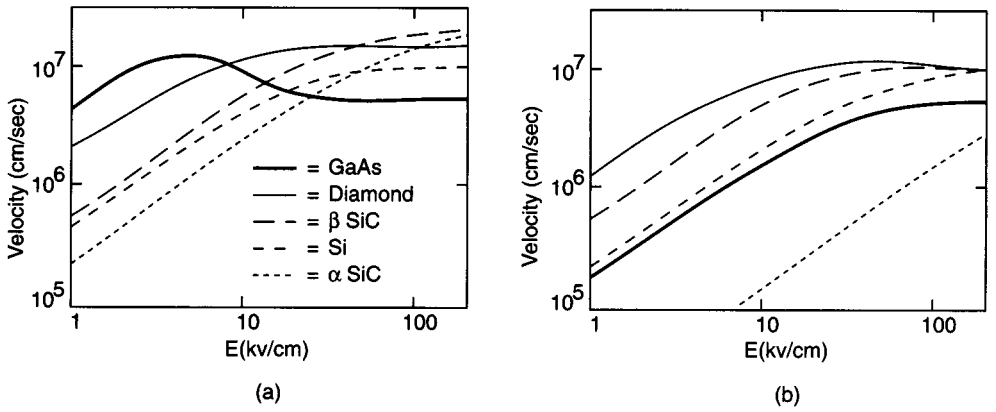

FIGURE 22.5 Electron (a) and hole (b) drift velocity versus electric field dependence for several semiconductors at $N_d = 10^{17}$ cm^{-3}. (*Source:* R.J. Trew, J.-B. Yan, and L.M. Mack, *Proc. IEEE,* vol. 79, no. 5, p. 602, May 1991. © 1991 IEEE.)

applications. Since $T_i \propto E_g$ the transition to the intrinsic region can be delayed by using widegap semiconductors. Both silicon carbide (several types of SiC with different lattice structures are available with E_g = 2.2–2.86 eV) and diamond (E_g = 5.5 eV) have been used to fabricate diodes and transistors operating in the 300–700°C temperature range.

Transport Properties

In a semiconductor the motion of an electron is affected by frequent collisions with **phonons** (quanta of lattice vibrations), impurities, and crystal imperfections. In weak uniform electric fields, $\mathscr{E}$, the carrier drift velocity, $\mathbf{v}_d$, is determined by the balance of the electric and collision forces:

$$m_n^* \mathbf{v}_d / \tau = -q\mathscr{E} \tag{22.7}$$

where τ is the momentum relaxation time. Consequently $\mathbf{v}_d = -\mu_n \mathscr{E}$, where $\mu_n = q\tau/m_n^*$ is the electron mobility. For an *n*-type semiconductor with uniform electron density, *n*, the current density $\mathbf{j}_n = -qn\mathbf{v}_d$ and we obtain Ohm's law $\mathbf{j}_n = \sigma\mathscr{E}$ with the conductivity $\sigma = qn\mu_n$. The momentum relaxation time can be approximately expressed as

$$1/\tau = 1/\tau_{ii} + 1/\tau_{ni} + 1/\tau_{ac} + 1/\tau_{npo} + 1/\tau_{po} + 1/\tau_{pe} + \ldots \tag{22.8}$$

where τ_{ii}, τ_{ni}, τ_{ac}, τ_{npo}, τ_{po}, τ_{pe} are the relaxation times due to ionized impurity, neutral impurity, acoustic phonon, nonpolar optical, polar optical, and piezoelectric scattering, respectively.

In the presence of concentration gradients, electron current density is given by the drift-diffusion equation

$$\mathbf{j}_n = qn\mu_n\mathscr{E} + qD_n\nabla n \tag{22.9}$$

where the diffusion coefficient D_n is related to mobility by the Einstein relation $D_n = (k_B T/q)\mu_n$.

A similar equation can be written for holes and the total current density is $\mathbf{j} = \mathbf{j}_n + \mathbf{j}_p$. The right-hand side of (22.9) may contain additional terms corresponding to temperature gradient and compositional nonuniformity of the material [Wolfe et al., 1989].

In sufficiently strong electric fields the drift velocity is no longer proportional to the electric field. Typical velocity–field dependencies for several semiconductors are shown in Fig. 22.5. In GaAs $v_d(\mathscr{E})$ dependence is not monotonic, which results in negative differential conductivity. Physically, this effect is related to the transfer of electrons from the conduction band to a secondary valley (see Fig. 22.3).

The limiting value v_s of the drift velocity in a strong electric field is known as the saturation velocity and is usually within the 10^7–$3{\cdot}10^7$ cm/s range. As semiconductor device dimensions are scaled down to the submicrometer range, v_s becomes an important parameter that determines the upper limits of device performance.

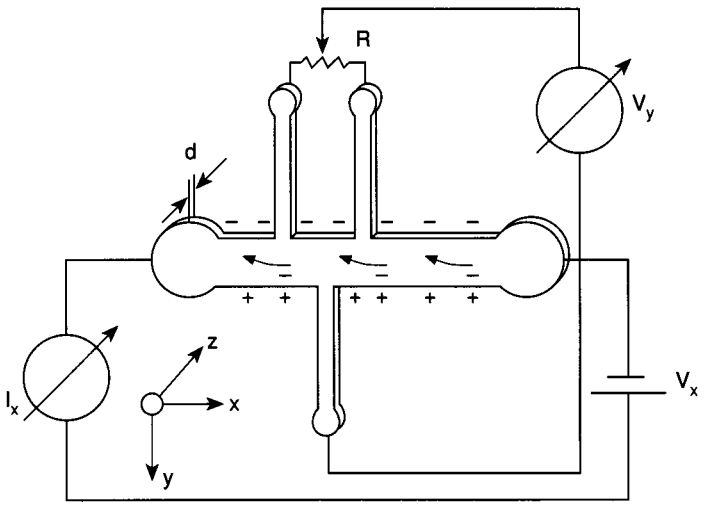

FIGURE 22.6 Experimental setup for Hall effect measurements in a long two-dimensional sample. The Hall angle is determined by a setting of the rheostat that renders $j_y = 0$. Magnetic field $B = B_z$. (*Source:* K.W. Böer, *Surveys of Semiconductor Physics,* New York: Chapman & Hall, 1990, p. 760. With permission.)

The curves shown in Fig. 22.5 were obtained for uniform semiconductors under steady-state conditions. Strictly speaking, this is not the case with actual semiconductor devices, where velocity can "overshoot" the value shown in Fig. 22.5. This effect is important for Si devices shorter than 0.1μm (0.25 μm for GaAs devices) [Shur, 1990; Ferry, 1991]. In such extreme cases the drift-diffusion equation (22.9) is no longer adequate, and the analysis is based on the Boltzmann transport equation

$$\frac{\partial f}{\partial t} + \mathbf{v}\nabla f + q\mathscr{E}\ \nabla_{\mathrm{p}} f = \left(\frac{\partial f}{\partial t}\right)_{\mathrm{coll}} \tag{22.10}$$

Here f denotes the distribution function (number of electrons per unit volume of the phase space, i.e., $f = dn/d^3rd^3p$), $\mathbf{v}$ is electron velocity, $\mathbf{p}$ is momentum, and $(\partial f/\partial t)_{\mathrm{coll}}$ is the "collision integral" describing the change of f caused by collision processes described earlier. For the purpose of semiconductor modeling, Eq. (22.10) can be solved directly using various numerical techniques, including the method of moments (hydrodynamic modeling) or Monte Carlo approach. The drift-diffusion equation (22.9) follows from (22.10) as a special case. For even shorter devices quantum effects become important and device modeling may involve quantum transport theory [Ferry, 1991].

Hall Effect

In a uniform magnetic field electrons move along circular orbits in a plane normal to the magnetic field $\mathbf{B}$ with the angular (cyclotron) frequency $\omega_c = qB/m_n^\star$. For a uniform semiconductor the current density satisfies the equation

$$\mathbf{j} = \sigma(\mathscr{E} + R_H[\mathbf{jB}]) \tag{22.11}$$

In the usual weak-field limit $\omega_c\tau << 1$ the Hall coefficient $R_H = -r/nq$ and the Hall factor r depend on the dominating scattering mode. It varies between $3\pi/8 \approx 1.18$ (acoustic phonon scattering) and $315\pi/518 \approx 1.93$ (ionized impurity scattering).

The Hall coefficient can be measured as $R_H = V_y d/I_x B$ using the test structure shown in Fig. 22.6. In this expression V_y is the Hall voltage corresponding to $I_y = 0$ and d denotes the film thickness.

Combining the results of the Hall and conductivity measurements one can extract the carrier concentration type (the signs of V_y are opposite for n-type and p-type semiconductors) and Hall mobility $\mu_H = r\mu$:

$$\mu_H = -R_H\sigma, \quad n = -r/qR_H \tag{22.12}$$

Measurements of this type are routinely used to extract concentration and mobility in doped semiconductors. The weak-field Hall effect is also used for the purpose of magnetic field measurements.

In strong magnetic fields $\omega_c\tau >> 1$ and on the average an electron completes several circular orbits without a collision. Instead of the conventional $E_b(\mathbf{k})$ dependence, the allowed electron energy levels in the magnetic field are given by ($\hbar = h/2\pi$; $s = 0, 1, 2, \ldots$)

$$E_s = \hbar\omega_c\,(s + 1/2) + \hbar^2 k_z^2 / 2m_n^* \tag{22.13}$$

The first term in Eq. (22.13) describes the so-called Landau levels, while the second corresponds to the kinetic energy of motion along the magnetic field $B = B_z$. In a pseudo-two-dimensional system like the channel of a field-effect transistor the second term in Eq. (22.13) does not appear, since the motion of electrons occurs in the plane perpendicular to the magnetic field.[1] In such a structure the electron density of states (number of allowed quantum states per unit energy interval) is peaked at the Landau level. Since $\omega_c \propto B$, the positions of these peaks relative to the Fermi level are controlled by the magnetic field.

The most striking consequence of this phenomenon is the quantum Hall effect, which manifests itself as a stepwise change of the Hall resistance $\rho_{xy} = V_y/I_x$ as a function of magnetic field (see Fig. 22.7). At low temperature (required to establish the condition $\tau << \omega_c^{-1}$) it can be shown [von Klitzing, 1986] that

$$\rho_{xy} = h/sq^2 \tag{22.14}$$

where s is the number of the highest occupied Landau level. Accordingly, when the increased magnetic field pushes the sth Landau level above the Fermi level, ρ_{xy} changes from h/sq^2 to $h/(s–1)q^2$. This stepwise change of ρ_{xy} is seen in Fig. 22.7. Localized states produced by crystal defects determine the shape of the $\rho_{xy}(B)$ dependence between the plateaus given by Eq. (22.14). They are also responsible for the disappearance of $\rho_{xx} = V_x/I_x$ between the transition points (see Fig. 22.7). The quantized Hall resistance ρ_{xy} is expressed in terms of fundamental constants and can be used as a resistance standard that permits one to measure an electrical resistance with better accuracy than any wire resistor standard. In an ultraquantum magnetic field, i.e., when only the lowest Landau level is occupied, plateaus of the Hall resistance are also observed at fractional s (the fractional quantum Hall effect). These plateaus are related to the Coulomb interaction of electrons.

Electrical Breakdown

In sufficiently strong electric fields a measurable fraction of electrons (or holes) acquires sufficient energy to break the valence bond. Such an event (called impact ionization) results in the creation of an electron–hole pair by the energetic electron. Both the primary and secondary electrons as well as the hole are accelerated by the electric field and may participate in further acts of impact ionization. Usually, the impact ionization is balanced by recombination processes. If the applied voltage is high enough, however, the process of electron multiplication leads to avalanche breakdown. The threshold energy E_{th} (the minimum electron energy required to produce an electron–hole pair) is determined by energy and momentum conservation laws. The latter usually results in $E_{\text{th}} > E_g$, as shown in Table 22.1.

The field dependence of the impact ionization is usually described by the impact ionization coefficient α_i, defined as the average number of electron–hole pairs created by a charge carrier per unit distance traveled. A simple analytical expression for α_i [Okuto and Crowell, 1972] can be written as

$$\alpha_i = (\lambda/x)\exp\left(a - \sqrt{a^2 + x^2}\right) \tag{22.15}$$

[1]To simplify the matter we do not discuss surface subbands, which is justified as long as only the lowest of them is occupied.

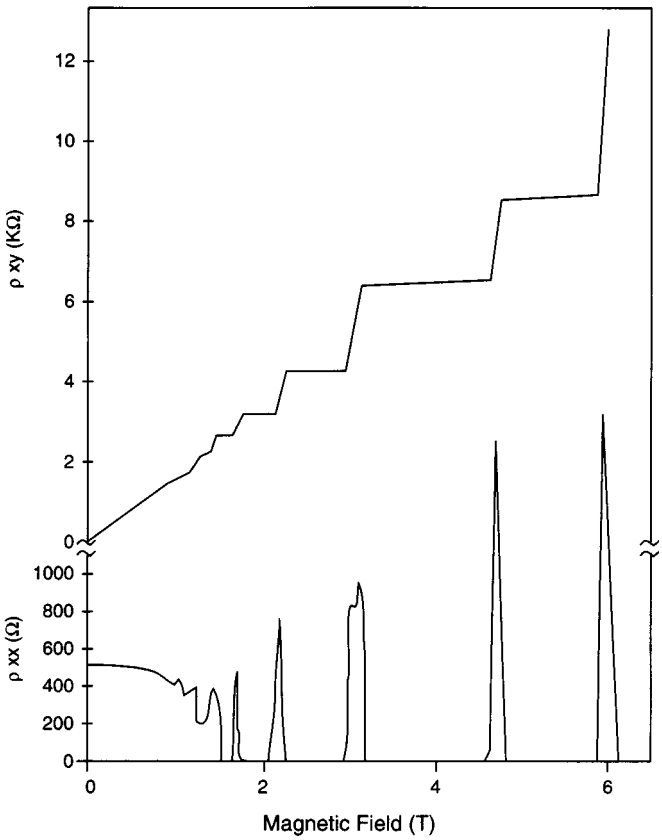

FIGURE 22.7 Experimental curves for the Hall resistance $\rho_{xy} = \mathscr{E}_y/j_x$ and the resistivity $\rho_{xx} = \mathscr{E}_x/j_x$ of a heterostructure as a function of the magnetic field at a fixed carrier density. TABLE 22.1 Impact Ionization Threshold Energy (eV)

Semiconductor	Si	Ge	GaAs	GaP	InSb
Energy gap, E_g	1.1	0.7	1.4	2.3	0.2
E_{th}, electron-initiated	1.18	0.76	1.7	2.6	0.2
E_{th}, hole-initiated	1.71	0.88	1.4	2.3	0.2

where $x = q\mathscr{E}\lambda/E_{th}$, $a = 0.217\ (E_{th}/E_{opt})^{1.14}$, λ is the carrier mean free path, and E_{opt} is the optical phonon energy ($E_{opt} = 0.063$ eV for Si at 300°C).

An alternative breakdown mechanism is tunneling breakdown, which occurs in highly doped semiconductors when electrons may tunnel from occupied states in the valence band into the empty states of the conduction band.

Optical Properties and Recombination Processes

If the energy of an incident **photon** $\hbar\omega > E_g$, then the energy conservation law permits a direct band-to-band transition, as indicated in Fig. 22.2(b). Because the photon's momentum is negligible compared to that of an electron or hole, the electron's momentum $\hbar\mathbf{k}$ does not change in a direct transition. Consequently, direct transitions are possible only in direct-gap semiconductors where the conduction band minimum and the valence band maximum occur at the same $\mathbf{k}$. The same is true for the reverse transition, where the electron is transferred

from the conduction to the valence band and a photon is emitted. Direct-gap semiconductors (e.g., GaAs) are widely used in optoelectronics.

In indirect-band materials [e.g., Si, see Fig. 22.3(a)], a band-to-band transition requires a change of momentum that cannot be accomplished by absorption or emission of a photon. Indirect band-to-band transitions require the emission or absorption of a phonon and are much less probable than direct transitions.

For $\hbar\omega < E_g$ [i.e., for $\lambda > \lambda_c = 1.24\ \mu m/E_g\ (eV)$ – cutoff wavelength] band-to-band transitions do not occur, but light can be absorbed by a variety of the so-called subgap processes. These processes include the absorption by free carriers, formation of excitons (bound electron–hole pairs whose formation requires less energy than the creation of a free electron and a free hole), transitions involving localized states (e.g., from an acceptor state to the conduction band), and phonon absorption. Both band-to-band and subgap processes may be responsible for the increase of the free charge carriers concentration. The resulting reduction of the resistivity of illuminated semiconductors is called *photoconductivity* and is used in photodetectors.

In a strong magnetic field ($\omega_c\tau >> 1$) the absorption of microwave radiation is peaked at $\omega = \omega_c$. At this frequency the photon energy is equal to the distance between two Landau levels, i.e., $\hbar\omega = E_{S+1} - E_S$ with reference to Eq. (22.13). This effect, known as cyclotron resonance, is used to measure the effective masses of charge carriers in semiconductors [in a simplest case of isotropic $E(\mathbf{k})$ dependence, $m_n^\star = qB/\omega_c$].

In indirect-gap materials like silicon, the generation and annihilation (or recombination) of electron–hole pairs is often a two-step process. First, an electron (or a hole) is trapped in a localized state (called a recombination center) with the energy near the center of the energy gap. In a second step, the electron (or hole) is transferred to the valence (conduction) band. The net rate of recombination per unit volume per unit time is given by the Shockley–Read–Hall theory as

$$R = \frac{np - n_i^2}{\tau_n(p + p_1) + \tau_p(n + n_1)} \tag{22.16}$$

where τ_n, τ_p, p_1, and n_1 are parameters depending on the concentration and the physical nature of recombination centers and temperature. Note that the sign of R indicates the tendency of a semiconductor toward equilibrium (where $np = n_i^2$, and $R = 0$). For example, in the depleted region $np < n_i^2$ and $R < 0$, so that charge carriers are generated.

Shockley–Read–Hall recombination is the dominating recombination mechanism in moderately doped silicon. Other recombination mechanisms (e.g., Auger) become important in heavily doped semiconductors [Wolfe et al., 1989; Shur, 1990; Ferry, 1991].

The recombination processes are fundamental for semiconductor device theory, where they are usually modeled using the continuity equation

$$\frac{\partial n}{\partial t} = div\,\frac{\mathbf{j}_n}{q} - R \tag{22.17}$$

Nanostructure Engineering

Epitaxial growth techniques, especially molecular beam epitaxy and metal-organic chemical vapor deposition, allow monolayer control in the chemical composition process. Both single thin layers and superlattices can be obtained by such methods. The electronic properties of these structures are of interest for potential device applications. In a single quantum well, electrons are bound in the confining well potential. For example, in a rectangular quantum well of width b and infinite walls, the allowed energy levels are

$$E_s(\mathbf{k}) = \pi^2 s^2 \hbar^2/(2m_n^\star b^2) + \hbar^2 k^2/(2m_n^\star), \quad s = 1, 2, 3, \ldots \tag{22.18}$$

where $\mathbf{k}$ is the electron wave vector parallel to the plane of the semiconductor layer. The charge carriers in quantum wells exhibit confined particle behavior. Since $E_s \propto b^{-2}$, well structures can be grown with distance

between energy levels equal to a desired photon energy. Furthermore, the photoluminescence intensity is enhanced because of carrier confinement. These properties are advantageous in fabrication of lasers and photodetectors.

If a quantum well is placed between two thin barriers, the tunneling probability is greatly enhanced when the energy level in the quantum well coincides with the Fermi energy (resonant tunneling). The distance between this "resonant" energy level and the Fermi level is controlled by the applied voltage. Consequently, the current peaks at the voltage corresponding to the resonant tunneling condition. The resulting negative differential resistance effect has been used to fabricate microwave generators operating at both room and cryogenic temperatures.

Two kinds of superlattices are possible: compositional and doping. Compositional superlattices are made of alternating layers of semiconductors with different energy gaps. Doping superlattices consist of alternating *n*- and *p*-type layers of the same semiconductor. The potential is modulated by electric fields arising from the charged dopants. Compositional superlattices can be grown as lattice matched or as strained layers. The latter are used for modification of the band structure, which depends on the lattice constant to produce desirable properties.

In superlattices energy levels of individual quantum wells are split into minibands as a result of electron tunneling through the wide-bandgap layers. This occurs if the electron mean free path is larger than the superlattice period. In such structures the electron motion perpendicular to the layer is quantized. In a one-dimensional tight binding approximation the miniband can be described as

$$E(k) = E_o[1 - \cos(ka)] \tag{22.19}$$

where a is the superlattice period and E_o is the half-width of the energy band. The electron group velocity

$$v = \hbar^{-1}\partial E(k)/\partial k = (E_o a/\hbar)\ \sin(ka) \tag{22.20}$$

is a decreasing function of k (and hence of energy) for $k > \pi/2a$. The higher energy states with $k > \pi/2a$ may become occupied if the electrons are heated by the external field. As a result, a negative differential resistance can be achieved at high electric fields. The weak-field mobility in a superlattice may exceed that of the bulk material because of the separation of dopants if only barriers are doped. In such modulated structures, the increased spatial separation between electrons and holes is also responsible for a strong increase in recombination lifetimes.

Disordered Semiconductors

Both amorphous and heavily doped semiconductors are finding increasing applications in semiconductor technology. The electronic processes in these materials have specific features arising from the lack of long-range order.

Amorphous semiconductors do not have a crystalline lattice, and their properties are determined by the arrangement of the nearest neighboring atoms. Even so, experimental data show that the forbidden energy band concept can be applied to characterize their electrical properties. However, the disordered nature of these materials results in a large number of localized quantum states with energies within the energy gap. The localized states in the upper and lower half of the gap behave like acceptors and donors, respectively. As an example, consider the density of states in hydrogenated amorphous silicon (a-Si) shown in Fig. 22.8. The distribution of the localized states is not symmetrical with respect to the middle of the energy gap. In particular, the undoped hydrogenated amorphous silicon is an *n*-type semiconductor.

Usually amorphous semiconductors are not sensitive to the presence of impurity atoms, which saturate all their chemical bonds in the flexible network of the host atoms. (Compare this with a situation in crystalline silicon where an arsenic impurity can form only four chemical bonds with the host lattice, leaving the fifth responsible for the formation of the donor state.) Consequently, the doping of amorphous semiconductors is difficult to accomplish. However, in hydrogenated a-Si (which can be prepared by the glow discharge decomposition of silane), the density of the localized states is considerably reduced and the conductivity of this material can be controlled by doping. As in crystalline semiconductors, the charge carrier concentration in hydrogenated

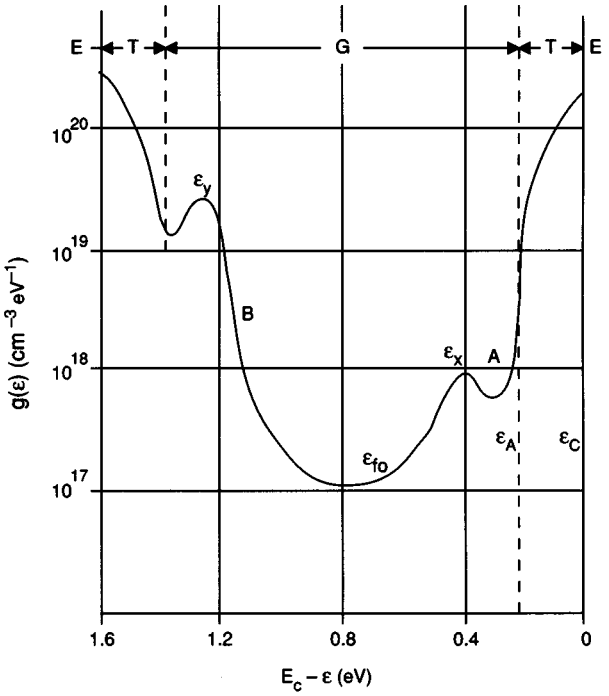

FIGURE 22.8 Experimentally determined density of states for a-Si. *A* and *B* are acceptor-like and donor-like states, respectively. The arrow marks the position of the Fermi level ε_{fo} in undoped hydrogenated a-Si. The energy spectrum is divided into extended states *E*, band-tail states *T*, and gap states *G*. (*Source:* M.H. Brodsky, Ed., *Amorphous Semiconductors,* 2nd ed., Berlin: Springer-Verlag, 1985. With permission.)

a-Si can also be affected by light and strong field effects. The a-Si is used in applications that require deposition of thin-film semiconductors over large areas [xerography, solar cells, thin-film transistors (TFT) for liquid-crystal displays]. The a-Si device performance degrades with time under electric stress (TFTs) or under illumination (Staebler–Wronski effect) because of the creation of new localized states.

An impurity band in crystalline semiconductors is another example of a disordered system. Indeed, the impurity atoms are randomly distributed within the host lattice. For lightly doped semiconductors at room temperature, the random potential associated with charged impurities can usually be ignored. As the doping level increases, however, a single energy level of a donor or an acceptor is transformed into an energy band with a width determined by impurity concentrations. Unless the degree of compensation is unusually high, this reduces the activation energy compared to lightly doped semiconductors. The activation energy is further reduced by the overlap of the wave functions associated with the individual donor or acceptor states.

For sufficiently heavy doping, i.e., for $N_d > N_{dc} = (0.2/a_B)^3$, the ionization energy is reduced to zero, and the transition to metal-type conductivity (the Anderson–Mott transition) takes place. In this expression the effective electron Bohr radius $a_B = \hbar/\sqrt{2m_n^* E_i}$, where E_i is the ionization energy of the donor state. For silicon, $N_{dc} \approx 3.8 \cdot 10^{18}$ cm^{-3}. This effect explains the absence of freeze-out in heavily doped semiconductors.

Defining Terms

Conduction/valence band: The upper/lower of the two partially filled bands in a semiconductor.

Donors/acceptors: Impurities that can be used to increase the concentration of electrons/holes in a semiconductor.

Energy band: Continuous interval of energy levels that are allowed in the periodic potential field of the crystalline lattice.

Energy gap: The width of the energy interval between the top of the valence band and the bottom of the conduction band.

Hole: Fictitious positive charge representing the motion of electrons in the valence band of a semiconductor; the number of holes equals the number of unoccupied quantum states in the valence band.
Phonon: Quantum of lattice vibration.
Photon: Quantum of electromagnetic radiation.

Further Information

Engineering aspects of semiconductor physics are often discussed in the *IEEE Transactions on Electron Devices*, *Journal of Applied Physics*, and *Solid-State Electronics*.

22.2 Diodes

Miran Milkovic

Diodes are the most widely used devices in low- and high-speed electronic circuits and in rectifiers and power supplies. Other applications are in voltage regulators, detectors, and demodulators. Rectifier diodes are capable of conducting several hundred amperes in the forward direction and less than 1 μA in the reverse direction. Zener diodes are ordinary diodes operated in the Zener or avalanche region and are used as voltage regulators. Varactor diodes are ordinary diodes used in reverse biasing as voltage-dependent capacitors. Tunnel diodes and quantum well devices have a negative differential resistance and are capable of operating in the upper gigahertz region. Photodiodes are ordinary diodes operated in the reverse direction. They are sensitive to light and are used as light sensors. Solar cells are diodes which convert light energy into electrical energy. Schottky diodes, also known as metal-semiconductor diodes, are extremely fast because they are **majority carrier** devices.

pn-Junction Diode

A *pn*-diode is a semiconductor device having a *p*-region, a *n*-region, and a junction between the regions. Modern planar semiconductor *pn*-junction diodes are fabricated by **diffusion** or implantation of impurities into a semiconductor. An *n*-type semiconductor has a relatively large density of free electrons to conduct electric current, and the *p*-type semiconductor has a relatively large concentration of "free" holes to conduct electric current. The *pn*-junction is formed during the fabrication process. There is a large concentration of holes in the *p*-semiconductor and a large concentration of electrons in the *n*-semiconductor. Because of their large concentration gradients, holes and electrons start to diffuse across the junction. As holes move across the junction, negative immobile charges (**acceptors**) are uncovered on the *p* side, and positive immobile charges (**donors**) are uncovered on the *n* side due to the movement of electrons across the junction. When sufficient numbers of the immobile charges on both sides of the junction are uncovered, a potential energy barrier voltage V_0 is created by the uncovered acceptors and donors. This **barrier voltage** prevents further diffusion of holes and electrons across the junction. The charge distribution of acceptors and donors establishes an opposing

electric field, E, which at equilibrium prevents a further diffusion of carriers across the junction. This equilibrium can be regarded as the flow of two equal and opposite currents across the junction, such that the net current across the junction is equal to zero. Thus, one component represents the diffusion of carriers across the junction and the other component represents the **drift** of carriers across the junction due to the electric field E in the junction. The barrier voltage V_0 is, according to the **Boltzmann relation**, [Grove, 1967; Foustad, 1994]

$$V_0 = V_T \ln[p_p/p_n] \tag{22.21}$$

In this equation, p_p is the concentration of holes in the p-material and p_n is the concentration of holes in the n-material. V_T is the thermal voltage. V_T = 26 mV at room temperature (300 K). With

$$p_p \approx N_A \quad \text{and} \quad p_n \approx \frac{n_i^2}{N_D}$$

where n_i is the intrinsic concentration, the barrier voltage V_0 becomes approximately [Sze, 1985; Fonstad, 1994]

$$V_0 = V_T \ln[N_A N_D / n_i^2] \tag{22.22}$$

Here N_A denotes the concentration of immobile acceptors on the p side of the junction and N_D is the concentration of immobile donors on the n side of the junction. A depletion layer of immobile acceptors and donors causes an electric field E across the junction. For silicon, V_0 is at room temperature T = 300°K, typically V_0 = 0.67 V for an abrupt junction with $N_A = 10^{17}$ at/cm^3 and $N_D = 10^{15}$ at/cm^3. The depletion layer width is typically about 4 μm, and the electric field E is about 60 kV/cm. Note the magnitude of the electric field across the junction.

pn-Junction with Applied Voltage

If the externally applied voltage V_D to the diode is opposite to the barrier voltage V_0, then p_p in the Boltzmann relation in Eq. (22.21) is altered to

$$p_p = p_n \exp(V_0 - V_D)/V_T \tag{22.23}$$

This implies that the effective barrier voltage is reduced and the diffusion of carriers across the junction, is increased. Accordingly the concentration of diffusing holes into the n material is at $x = 0$,

$$p_n(x = 0) = p_n \exp V_D/V_T \tag{22.24}$$

and accordingly the concentration of electrons

$$n_n(x = 0) = n_n \exp V_D/V_T \tag{22.25}$$

Most modern planar diodes are unsymmetrical. Figure 22.9 shows a pn-diode with the n region W_n much shorter than the diffusion length L_{pn} of holes in the n-semiconductor region. This results in a linear **concentration gradient** of injected diffusing holes in the n region given by

$$dp/dx = -(p_n \exp V_D/V_T - p_n)/W_n \tag{22.26}$$

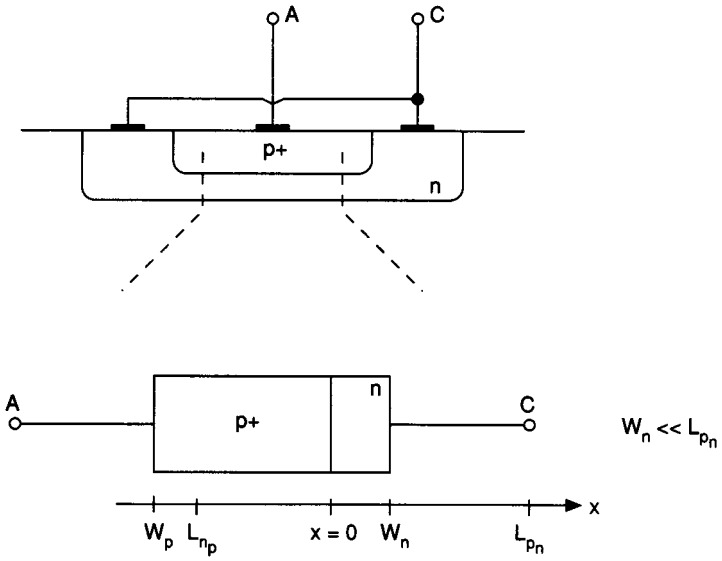

FIGURE 22.9 Planar diodes are fabricated in planar technology. Most modern diodes are unsymmetrical; thus $W_n << L_{pn}$. The *p*-type region is more highly doped than the *n* region.

The diffusion gradient is negative since the concentration of positive holes decreases with distance due to the hole–electron recombinations. The equation for the hole diffusion current is

$$I_p = -qA_jD_p\ dp/dx \tag{22.27}$$

where A_j is the junction area, D_p is the **diffusion constant** for holes, and q is the elementary charge.

By combining of above equations we obtain

$$I_p = (qA_jD_pp_n/W_n)\ (\exp\ V_D/V_T - 1) \tag{22.28}$$

In the *p*-semiconductor we assume that $L_{np} << W_p$; then

$$dn/dx = n_p\ \exp(V_D/V_T - 1) \tag{22.29}$$

By substituting this into the electron diffusion equation,

$$I_n = qA_jD_n\ dn/dx \tag{22.30}$$

we obtain

$$I_n = (qA_jD_nn_p)/L_{np}(\exp\ V_D/V_T - 1) \tag{22.31}$$

Thus, the total junction diffusion current is

$$I_D = I_p + I_n = \{qA_jD_pp_n/W_n + qA_jD_nn_p/L_{np}\}\ (\exp\ V_D/V_T - 1) \tag{22.32}$$

Since the recombination of the injected carriers establishes a diffusion gradient, this in turn yields a flow of current proportional to the slope. For $|-V_D| >> V_T$, i.e., $V_D = -0.1\ V$,

$$I_S = (qA_iD_pp_n/W_n + qA_i\ D_n\ n_p/L_{np}) \tag{22.33}$$

Here I_S denotes the **reverse saturation current**. In practical junctions, the p region is usually much more heavily doped than the n region; thus $n_p << p_n$. Also, since $W_n << L_{np}$ in Eq. (22.33), we obtain

$$I_S = qA_jD_p p_n / W_n = qA_j D_p \, n_i^2 / W_n N_D \tag{22.34}$$

The reverse saturation current in short diodes is mainly determined by the diffusion constant D_p and the width W_n of the n region, by intrinsic concentration n_i, by the doping concentration N_D in the n region, and by the diode area A_j. (In reality, I_S is also slightly dependent on the reverse voltage [Phillips, 1962].)

If V_D is made positive, the exponential term in Eq. (22.32) rapidly becomes larger than one; thus

$$I_D = I_S \exp V_D / V_T \tag{22.35}$$

where I_D is the diode forward current and I_S is the reverse saturation current.

Another mechanism predominates the reverse current I_S in silicon. Due to the recombination centers in the depletion region, a generation-recombination hole–electron current I_G is generated in the depletion region [Phillips, 1962; Sze, 1985].

$$I_G = KqA_jeX_d \tag{22.36a}$$

Here e is the generation rate unit volume, A_j is the junction area, q is the elementary charge, X_d is the depletion layer thickness, and K is a dimensional constant. I_G is proportional to the thickness X_d of the depletion layer and to the junction area A_j. Since X_d increases with the square root of the reverse voltage, I_G increases accordingly, yielding a slight slope in the reverse I-V characteristic. The forward I-V characteristic of the practical diode is only slightly affected (slope $m = 2$) at very small forward currents ($I_D = 1$ nA to 1 μA). In practical diodes $n \approx 1$ at small to medium currents ($I_D = 1$ μA to 10 mA). At large currents ($I_D > 10$ mA), $m = 1$ to 2 due to the high current effects [Phillips, 1962] and due to the series bulk resistance of the diode.

The reverse current I_R in silicon is voltage dependent. The predominant effect is the voltage dependence of the generation-recombination current I_G and to a smaller extent the voltage dependence of I_S.

The total reverse current of the diode is thus equal to

$$I_R = I_G + I_S \tag{22.36b}$$

Forward-Biased Diode

For most practical applications

$$I_D = I_S \exp V_D / mV_T \tag{22.37}$$

where I_S is the reverse saturation current (about 10^{-14} A for a small-signal diode); $V_T = kT/q$ is the thermal voltage equal to 26 mV at room temperature; k = Boltzmann's constant, $1.38 \cdot 10^{-23}$ J/K; T is the absolute temperature in kelvin; q is the elementary charge $1.602 \cdot 10^{-19}$ C; m is the **ideality factor**, $m = 1$ for medium currents, $m = 2$ for very small and very large currents; I_S is part of the total reverse current I_R of the diode $I_R = I_S + I_G$; and I_S is the reverse saturation current and I_G is the generation-recombination current, also called diode leakage current because I_G is not a part of the carrier diffusion process in the diode. I_D is exponentially related to V_D in Fig. 22.10.

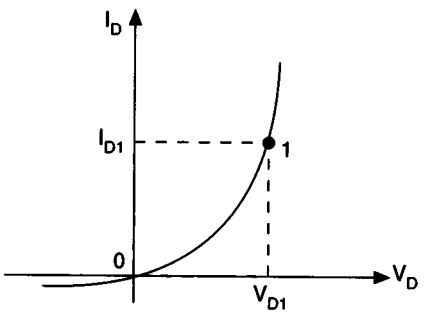

FIGURE 22.10 I_D versus V_D of a diode.

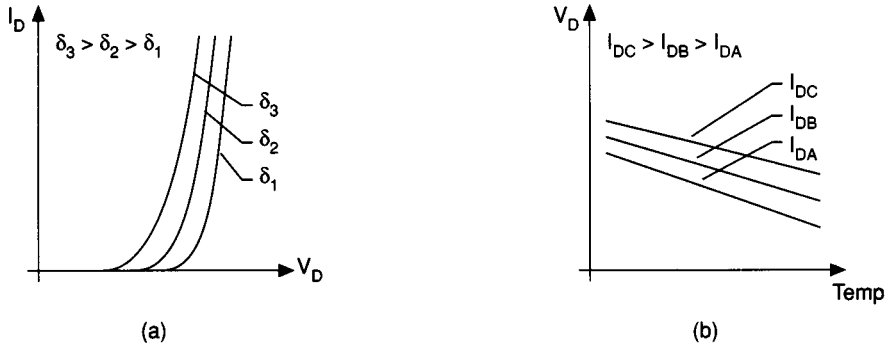

FIGURE 22.11 (a) I_D versus V_D of a diode at three different temperatures $\delta_3 > \delta_2 > \delta_1$. (b) $V_D = f(\text{Temp})$, $I_{DC} > I_{DB} > I_{DA}$.

Temperature Dependence of V_D

Equation (22.37) solved for V_D yields

$$V_D = mV_T \ln(I_D/I_S) \tag{22.38}$$

at constant current I_D, the diode voltage V_D is temperature dependent because V_T and I_S are temperature dependent. Assume $m = 1$. The reverse saturation current I_S from Eq. (22.34) is

$$I_S = qA_j n_i^2 D_p / W_n N_D = B_1 n_i^2 D_p = B_2 n_i^2 \mu_p$$

where $D_p = V_T \mu_p$. With $\mu_p = B_3 T^{-n}$ and for n_i^2

$$n_i^2 = B_4 T^{\gamma} \exp(-V_{G0}/V_T) \tag{22.39}$$

where $\gamma = 4 - n$, and V_{G0} is the extrapolated **bandgap energy** [Gray and Meyer, 1993]. With Eq. (22.39) into Eq. (22.38), the derivative dV_D/dT for $I_D = \text{const}$ yields

$$dV_D/dT = (V_D - V_{G0})/T - \gamma k/q \tag{22.40}$$

At room temperature ($T = 300$ K), and $V_D = 0.65$ V, $V_{G0} = 1.2$ V, $\gamma = 3$, $V_T = 26$ mV, and $k/q = 86$ μV/degree, one gets $dV_D/dT \approx -2.1$ mV/degree.The **temperature coefficient** TC of V_D is thus

$$TC = dV_D/V_D\ dT = 1/T - V_{G0}/V_D T - \gamma k/qV_D \tag{22.41}$$

For the above case $TC \approx -0.32\%$/degree. In practical applications it is more convenient to use the expression

$$V_D(\delta_2) = V_D(\delta_1) - TC(\delta_2 - \delta_1) \tag{22.42}$$

where δ_1 and δ_2 are temperatures in degrees Celsius. For $TC = -0.32\%$/degree and $V_D = 0.65$ V at $\delta_1 = 27°C$, $V_D = 0.618$ V at $\delta_2 = 37°C$. Both dV_D/dT and TC are I_D dependent. At higher I_D, both dV_D/dT and TC are smaller than at a lower I_D, as shown in Fig. 22.11.

I_D-V_D Characteristic

From the I_D-V_D characteristic of the diode one can find for $m = 1$

$$I_{D1} = I_S \exp(V_{D1}/V_T) \quad \text{and} \quad I_{D2} = I_S \exp(V_{D2}/V_T) \tag{22.43}$$

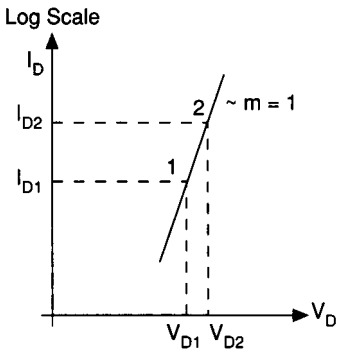

FIGURE 22.12 I_D versus V_D of a diode on a semi-logarithmic plot.

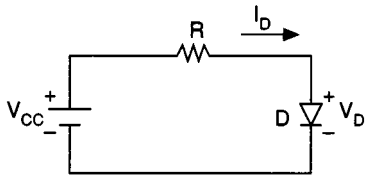

FIGURE 22.13 Diode-resistor biasing circuit.

Thus, the ratio of currents is

$$I_{D2}/I_{D1} = \exp\,(V_{D2} - V_{D1})/V_T \tag{22.44}$$

or the difference voltage

$$V_{D2} - V_{D1} = V_T \ln(I_{D2}/I_{D1}) \tag{22.45}$$

in terms of base 10 logarithm

$$V_{D2} - V_{D1} = V_T\, 2.3\, \log(I_{D2}/I_{D1}) \tag{22.46}$$

For $(I_{D2}/I_{D1}) = 10$ (one decade), $V_{D2} - V_{D1} = \sim 60$ mV, or $V_{D2} - V_{D1} = 17.4$ mV for $(I_{D2}/I_{D1}) = 2$. In a typical example, $m = 1$, $V_D = 0.67$ V at $I_D = 100$ μA. At $I_D = 200$ μA, $V_D = 0.67$ V + 17.4 mV = 0.687 V.

DC and Large-Signal Model

The diode equation in Eq. (22.37) is widely utilized in diode circuit design. I_S and m can sometimes be found from the data book or they can be determined from measured I_D and V_D. From two measurements of I_D and V_D, for example, $I_D = 0.2$ mA at $V_D = 0.670$ V and $I_D = 10$ mA at $V_D = 0.772$ V, one can find $m = 1.012$ and $I_S = 1.78 \cdot 10^{-15}$ A for the particular diode. A practical application of the large-signal diode model is shown in Fig. 22.13. Here, the current I_D through the series resistor R and a diode D is to be found,

$$I_D = (V_{CC} - V_D)/R \tag{22.47}$$

The equation is implicit and cannot be solved for I_D since V_D is a function of I_D. Here, V_D and I_D are determined by using iteration. By assuming $V_D = V_{D0} = 0.6$ V (cut-in voltage), the first iteration yields

$$I_D(1) = (5\text{ V} - 0.6\text{ V})/1\text{ k}\Omega = 4.4\text{ mA}$$

Next, the first iteration voltage $V_D(1)$ is calculated (by using m and I_S above and $I_{D1} = 4.4$ mA), thus

$$V_D(1) = mV_T[\ln\, I_D(1)/I_S] = 1.012 \times 26\text{ mV}\ln(4.4\text{ mA}/1.78 \cdot 10^{-15}\text{ A})$$

$$= 0.751\text{ V}$$

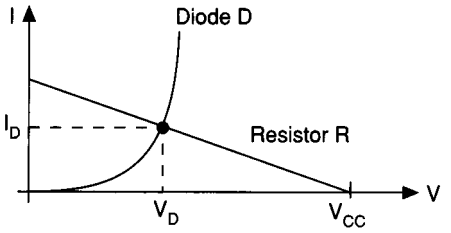

FIGURE 22.14 Graphical analysis of a diode-resistor circuit.

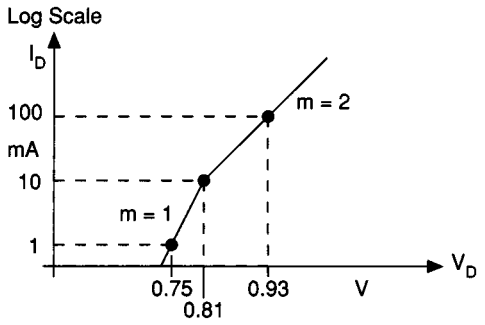

FIGURE 22.15 I_D versus V_D of a diode at low and high forward currents.

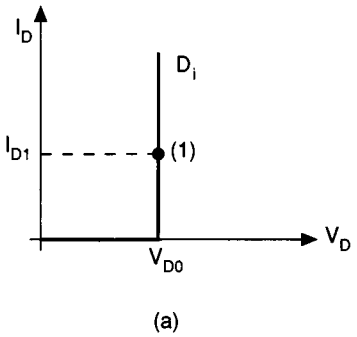

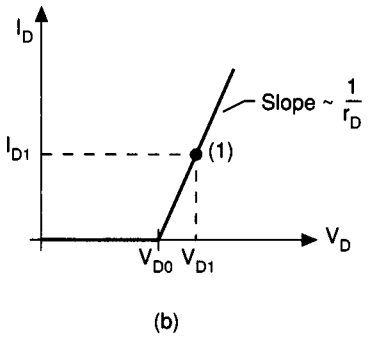

FIGURE 22.16 (a) Simplified piecewise linear model of a diode; (b) improved piecewise linear model of a diode. The diode cut-in voltage V_{D0} is defined as the voltage V_D at a very small current I_D typically at about 1 nA. For silicon diodes this voltage is typically $V_{D0} = 0.6$ V.

From the second iteration $I_D(2) = [V_{CC} - V_D(1)]/R = 4.25$ mA and thus $V_D(2) = 0.75$ V. The third iteration yields $I_D(3) = 4.25$ mA, and $V_D(3) = 0.75$ V. These are the actual values of I_D and V_D for the above example, since the second and the third iterations are almost equal.

Graphical analysis (in Fig. 22.14) is another way to analyze the circuit in Fig. 22.13. Here the load line R is drawn with the diode I-V characteristic, where $V_{CC} = V_D + I_D R$. This type of analysis is illustrative but not well suited for a numerical analysis.

High Forward Current Effects

In the *pn*-junction diode analysis it was assumed that the density of injected carriers from the *p* region into the *n* region is small compared to the density of majority carriers in that region. Thus, all of the forward voltage V_D appears across the junction. Therefore, the injected carriers move only because of the diffusion. At high forward currents this is not the case anymore. When the voltage drop across the bulk resistance becomes comparable with the voltage across the junction, the effective applied voltage is reduced [Phillips, 1962]. Due to the electric field created by the voltage drop in the bulk (neutral) regions, the current is not only a diffusion current anymore. The drift current due to the voltage drop across the bulk region opposes the diffusion current. The net effect is that, first, the current becomes proportional to twice the diffusion constant, second, the high-level current becomes independent of resistivity, and, third, the magnitude of the exponent is reduced by a factor of two in Eq. (22.37). The effect of high forward current on the I-V characteristic is shown in Fig. 22.15. In all practical designs, $m \approx 2$ at $I_D \geq 20$ mA in small-signal silicon diodes.

Large-Signal Piecewise Linear Model

Piecewise linear model of a diode is a very useful tool for quick circuit design containing diodes. Here, the diode is represented by asymptotes and not by the exponential *I-V* curve. The simplest piecewise linear model is shown in Fig. 22.16(a). Here D_i is an ideal diode with $V_D = 0$ at $I_D \geq 0$, in series with V_{D0}, where V_{D0} is the diode cut-in or threshold voltage. The current in the diode will start to flow at $V_D \geq V_{D0}$.

An improved model is shown in Fig. 22.16(b), where V_{D0} is again the diode voltage at a very small current I_{D0}, r_D is the extrapolated diode resistance, and I_{D1} is the diode current in operating point 1. Thus, the diode voltage is

$$V_{D1} = V_{D0} + I_{D1}\, r_D \tag{22.48}$$

where V_{D1} is the diode voltage at I_{D1}. V_{D0} for silicon is about 0.60 V. r_D is estimated from the fact that V_D in a real diode is changing per decade of current by m 2.3 V_T. Thus, V_D changes about 60 mV for a decade change of current I_D at $m = 1$. Thus in a 0.1 to 10 mA current change, V_D changes about 120 mV, which corresponds to $anr_D \approx 120$ mV/10 mA = 12 Ω.

The foregoing method is an approximation; however, it is quite practical for first-hand calculations. To compare this with the above iterative approach let us assume $m = 1$, $V_{D0} = 0.60$ V, $r_D = 12$ Ω, $V_{CC} = 5$ V, $R =$ 1 kΩ. The current $I_{D1} = [V_{CC} - V_{D0}]/(R + r_D) = 4.34$ mA compared with $I_{D1} = 4.25$ mA in the iterative approach.

Small-Signal Incremental Model

In the small-signal **incremental model**, the diode is represented by linear elements. In small-signal (incremental) analysis, the diode voltage signals are assumed to be about $V_T/2$ or less, thus much smaller than the dc voltage V_D across the diode. In the forward-biased diode, three elements are of practical interest: **incremental resistance** (or small-signal or differential resistance) r_d, the **diffusion capacitance** C_d, and the **junction capacitance** C_j.

Incremental Resistance, r_d

For small signals the diode represents a small-signal resistance (often called incremental or differential resistance) r_d in the operating point (I_D, V_D) where

$$r_d = dV_D/dI_D = mV_T/I_S \exp(V_D/mV_T) = mV_T/I_D \tag{22.49}$$

In Fig. 22.17, r_d is shown as the tangent in the dc operating point (V_D, I_D). Note that r_d is independent of the geometry of the device and inversely proportional to the diode dc current. Thus for $I_D = 1$ mA, $m = 1$ and $V_T = 26$ mV, the incremental resistance is $r_d = 26$ Ω.

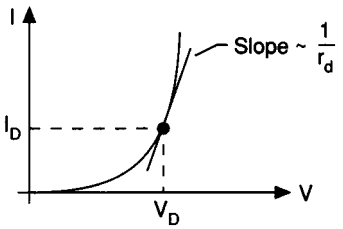

FIGURE 22.17 Small-signal incremental resistance r_d of a diode.

Diffusion Capacitance, C_d

C_d is associated with the injection of holes and electrons in the forward-biased diode. In steady state, holes and electrons are injected across the junction. Hole and electron currents flow due to the diffusion gradients on both sides of the junction in Fig. 22.18. In a short diode, holes are traveling a distance $W_n << L_{p_n}$. For injected holes, and since $w_n << L_{p_n}$

$$I_p = dq_p/dt = dq_p\, v/dx \tag{22.50}$$

where v is the average carrier velocity, D_p is the diffusion constant for holes and W_n is the travel distance of holes. By integrating of Eq. (22.50) one gets

$$I_p \int_0^{W_n} dx = v \int_0^{Q_p} dq_p$$

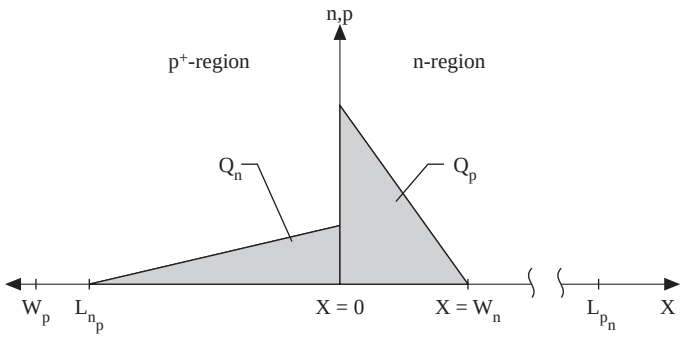

FIGURE 22.18 Minority carrier charge injection in a diode.

and the charge Q_p of holes becomes

$$Q_p = I_p W_n / v = I_p \tau_p. \tag{22.51}$$

$\tau_p = W_n / v$ is the transit time holes travel the distance W_n. Similarly, for electron charge Q_n, since $W_p >> L_{np}$

$$Q_n = I_n L_{np} / v = I_n \tau_n. \tag{22.52}$$

Thus the total diffusion charge Q_d is

$$Q_d = Q_p + Q_n, \tag{22.53}$$

and the total transit time is

$$\tau_F = \tau_p + \tau_n, \tag{22.54}$$

and with $I_p + I_n = I_D = I_S \exp V_D / mV_T$ and Eqs. (22.51), (22.52), and (22.54) one gets

$$Q_d = \tau_F I_S \exp V_D / mV_T = \tau_F I_D. \tag{22.55}$$

The total diffusion capacitance is

$$C_d = C_p + C_n = dQ_d / dV_D = Q_d / mV_T \tag{22.56}$$

and from Eqs. (22.55) and (22.56)

$$C_d = I_D \tau_F / mV_T. \tag{22.57}$$

C_d is thus directly proportional to I_D and to the carrier transit time τ_F. For an unsymmetrical diode with $W_n << L_{pn}$ and $N_A >> N_D$ [Gray and Meyer, 1984]

$$\tau_F \approx W_n^2 / 2D_p \tag{22.58}$$

τ_F is usually given in data books or it can be measured.

For $W_n = 6\ \mu$ and $D_p = 14\ \text{cm}^2/\text{s}$, $\tau_F \approx 13$ ns, $I_D = 1$ mA, $V_T = 26$ mV, and $m = 1$, the diffusion capacitance is $C_d = 500$ pF.

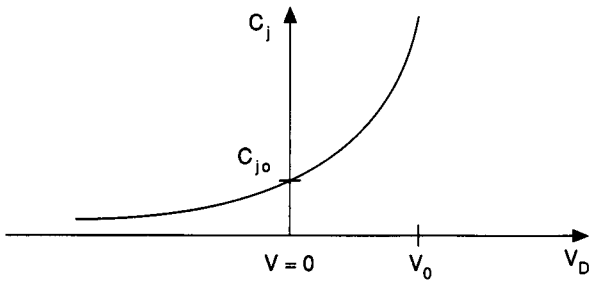

FIGURE 22.19 Depletion capacitance C_j of a diode versus diode voltage V_R.

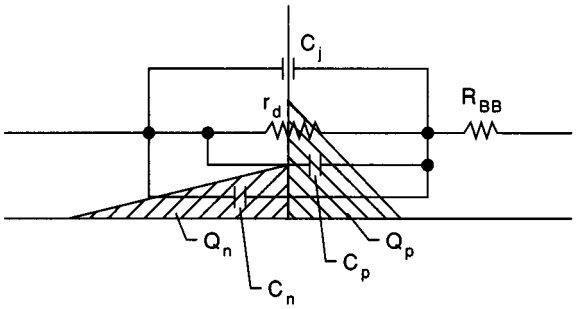

FIGURE 22.20 Simplified small-signal model of a diode.

Depletion Capacitance, C_j

The depletion region is always present in a *pn*-diode. Because of the immobile ions in the depletion region, the junction acts as a voltage-dependent plate capacitor C_j [Gray and Meyer, 1993; Horenstein, 1990]

$$C_j = C_{j0} \Big/ \sqrt{V_0 - V_D} \tag{22.59}$$

V_D is the diode voltage (positive value for forward biasing, negative value for reverse biasing), and C_{j0} is the zero bias depletion capacitance; A_j is the junction diode area:

$$C_{j0} = KA_j \tag{22.60}$$

K is a proportionality constant dependent on diode doping, and A_j is the diode area. C_j is voltage dependent. As V_D increases, C_j increases in a forward-biased diode in Fig. 22.19. For $V_0 = 0.7$ V and $V_D = -10$ V and $C_{j0} =$ 3 pF, the diode depletion capacitance is $C_j = 0.75$ pF. In Fig. 22.20 the small-signal model of the diode is shown. The total small-signal time constant τ_d is thus (by neglecting the bulk series diode resistance R_{BB})

$$\tau_d = r_d(C_d + C_j) = r_dC_d + r_dC_j = \tau_F + r_dC_j \tag{22.61}$$

τ_d is thus current dependent. At small I_D the r_dC_j product is predominant. For high-speed operation r_dC_j must be kept much smaller than τ_F. This is achieved by a large operating current I_D. The diode behaves to a first approximation as a frequency-dependent element. In the reverse operation, the diode behaves as a high ohmic resistor $R_p \approx V_R/I_G$ in parallel with the capacitor C_j. In forward small-signal operation, the diode behaves as a resistor r_d in parallel with the capacitors C_j and C_d (R_p is neglected). Thus, the diode is in a first approximation, a low-pass network.

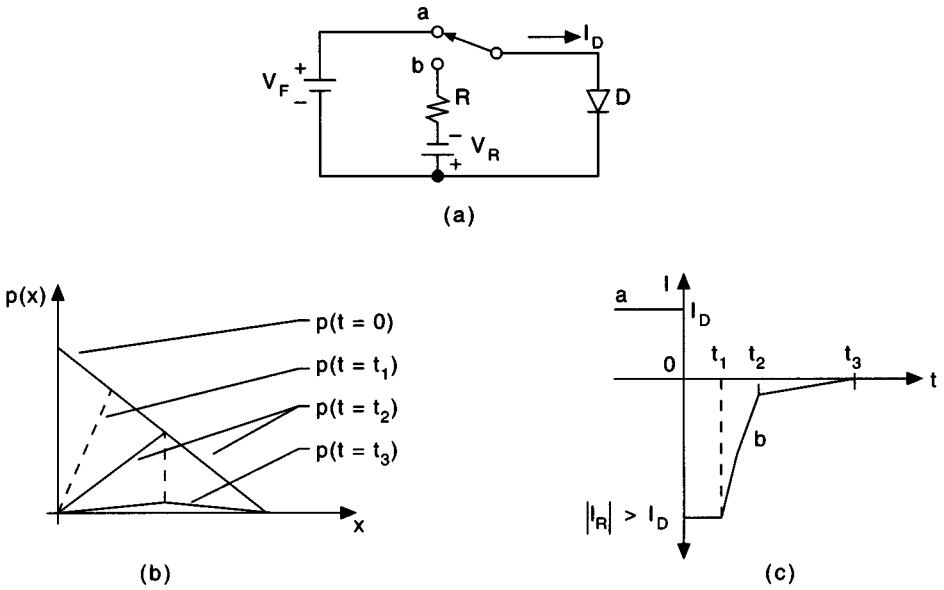

FIGURE 22.21 (a) Diode is switched from forward into reverse direction; (b) concentration of holes in the *n* region; (c) diode turns off in three time intervals.

Large-Signal Switching Behavior of a *pn*-Diode

When a forward-biased diode is switched from the forward into the reverse direction, the stored charge Q_d of **minority carriers** must first be removed. The charge of minority carriers in the forward-biased unsymmetrical diode is from Eqs. (22.55) and (22.58)

$$Q_d = I_D\tau_F = I_D W_n^2/2D_p \tag{22.62}$$

where $W_n << L_{pn}$ is assumed. τ_F is minimized by making W_n very small. Very low-lifetime τ_F is required for high-speed diodes. **Carrier lifetime** τ_F is reduced by adding a large concentration of recombination centers into the junction. This is common practice in the fabrication of high-speed computer diodes [Phillips, 1962]. The charge Q_d is stored mainly in the *n* region in the form of a concentration gradient of holes in Fig. 22.21(a). The diode is turned off by moving the switch from position (a) into position (b) [Fig. 22.21(a)]. The removal of carriers is done in three time intervals. During the time interval t_1, also called the recovery phase, a constant reverse current $|I_R| = V_R/R$ flows in the diode. During the time interval $t_2 - t_1$ the charge in the diode is reduced by about 1/2 of the original charge. During the third interval $t_3 - t_2$, the residual charge is removed.

If during the interval t_1, $|I_R| >> I_D$, then Q_d is reduced only by flow of reverse diffusion current; no holes arrive at the metal contact [Gugenbuehl et al., 1962], and

$$t_1 \approx \tau_F\,(I_D/|I_R|)^2 \tag{22.63}$$

During time interval $t_2 - t_1$, when $|I_R| = I_D$, in Fig. 22.21(b),

$$t_2 - t_1 \approx \tau_F I_D/|I_R| \tag{22.64}$$

The residual charge is removed during the time $t_3 - t_2 \approx 0.5\,\tau_F$.

Diode Reverse Breakdown

Avalanche breakdown occurs in a reverse-biased plane junction when the critical electric field E_{crt} at the junction within the depletion region reaches about $3 \cdot 10^5$ V/cm for junction doping densities of about 10^{15} to 10^{16} at/cm^3 [Gray and Meyer, 1984]. At this electric field E_{crt}, the minority carriers traveling (as reverse current) in the depletion region acquire sufficient energy to create new hole–electron pairs in collision with atoms. These energetic pairs are able to create new pairs, etc. This process is called the avalanche process and leads to a sudden increase of the reverse current I_R in a diode. The current is then limited only by the external circuitry. The avalanche current is not destructive as long as the local junction temperature does not create local hot spots, i.e., melting of material at the junction. Figure 22.22 shows a typical *I-V* characteristic for a junction diode in the avalanche breakdown. The effect of breakdown is seen by the large increase of the reverse current I_R when V_R reaches $-BV$. Here BV is the actual breakdown voltage. It was found that $I_{RA} = M\, I_R$, where I_{RA} is the avalanche reverse current at BV, M is the multiplication factor, and I_R is the reverse current not in the breakdown region. M is defined as

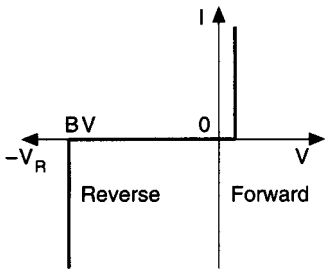

FIGURE 22.22 Reverse breakdown voltage of a diode at $-V_R = BV$.

$$M = 1/[1 - V_R/BV]^n \tag{22.65}$$

where $n = 3$ to 6. As $V_R = BV$, $M \rightarrow \infty$ and $I_{RA} \rightarrow \infty$. The above BV is valid for a strictly plane junction without any curvature. However, in a real planar diode as shown in Fig. 22.9, the *p*-diffusion has a curvature with a finite radius x_j. If the diode is doped unsymmetrically, thus $\sigma_p >> \sigma_n$, then the depletion area penetrates mostly into the *n* region. Because of the finite radius, the breakdown occurs at the radius x_j, rather than in a plane junction [Grove, 1967]. The breakdown voltage is significantly reduced due to the curvature. In very shallow planar diodes, the avalanche breakdown voltage BV can be much smaller than 10 V.

Zener and Avalanche Diodes

Zener diodes (ZD) and avalanche diodes are *pn*-diodes specially built to operate in reverse breakdown. They operate in the reverse direction; however, their operating mechanism is different. In a Zener diode the hole–electron pairs are generated by the electric field by direct transition of carriers from valence band into the conductance band. In an avalanche diode, the hole–electron pairs are generated by impact ionization due to high-energy holes and electrons.

Avalanche and Zener diodes are extensively used as voltage regulators and as overvoltage protection devices. T_C of Zener diodes is negative at $V_Z \leq 3.5$ to 4.5 V and is equal to zero at about $V_Z \approx 5$ V. T_C of a Zener diode operating above 5 V is in general positive. Above 10 V the *pn*-diodes operate as avalanche diodes with a strong positive temperature coefficient. The T_C of a Zener diode is more predictable than that of the avalanche diode. Temperature-compensated Zener diodes utilize the positive T_C of a 7-V Zener diode, which is compensated with a series-connected forward-biased diode with a negative T_C. The disadvantage of Zener diodes is a relatively large electronic noise.

Varactor Diodes

The varactor diode is an ordinary *pn*-diode that uses the voltage-dependent variable capacitance of the diode. The varactor diode is widely used as a voltage-dependent capacitor in electronically tuned radio receivers and in TV.

Tunnel Diodes

The tunnel diode is an ordinary *pn*-junction diode with very heavy doped *n* and *p* regions. Because the junction is very thin, a tunnel effect takes place. An electron can tunnel through the thin depletion layer from the

conduction band of the *n* region directly into the valence band of the *p* region. Tunnel diodes create a negative differential resistance in the forward direction, due to the tunnel effect. Tunnel diodes are used as mixers, oscillators, amplifiers, and detectors. They operate at very high frequencies in the gigahertz bands.

Photodiodes and Solar Cells

Photodiodes are ordinary *pn*-diodes that generate hole–electron pairs when exposed to light. A photocurrent flows across the junction, if the diode is reverse biased. Silicon *pn*-junctions are used to sense light at near-infrared and visible spectra around 0.9 μm. Other materials are used for different spectra.

Solar cells utilize the *pn*-junction to convert light energy into electrical energy. Hole–electron pairs are generated in the semiconductor material by light photons. The carriers are separated by the high electric field in the depletion region across the *pn*-junction.The electric field forces the holes into the *p* region and the electrons into the *n* region. This displacement of mobile charges creates a voltage difference between the two semiconductor regions. Electric power is generated in an external load connected between the terminals to the *p* and *n* regions. The conversion efficiency is relatively low, around 10 to 12%. With the use of new materials, an efficiency of about 30% has been reported. Efficiency up to 45% was achieved by using monochromatic light.

Schottky Barrier Diode

The Schottky barrier diode is a metal-semiconductor diode. Majority carriers carry the electric current. No minority carrier injection takes place. When the diode is forward biased, carriers are injected into the metal, where they reside as majority carriers at an energy level that is higher than the Fermi level in metals. The *I-V* characteristic is similar to conventional diodes. The barrier voltage is small, about 0.2 V for silicon. Since no minority carrier charge exists, the Schottky barrier diodes are very fast. They are used in high-speed electronic circuitry.

Defining Terms

Acceptor: Ionized, negative-charged immobile dopant atom (ion) in a *p*-type semiconductor after the release of a hole.

Avalanche breakdown: In the reverse-biased diode, hole–electron pairs are generated in the depletion region by ionization, thus by the lattice collision with energetic electrons and holes.

Bandgap energy: Energy difference between the conduction band and the valence band in a semiconductor.

Barrier voltage: A voltage which develops across the junction due to uncovered immobile ions on both sides of the junction. Ions are uncovered due to the diffusion of mobile carriers across the junction.

Boltzmann relation: Relates the density of particles in one region to that in an adjacent region, with the potential energy between both regions.

Carrier lifetime: Time an injected minority carrier travels before its recombination with a majority carrier.

Concentration gradient: Difference in carrier concentration.

Diffusion: Movement of free carriers in a semiconductor caused by the difference in carrier densities (concentration gradient). Also movement of dopands during fabrication of diffused diodes.

Diffusion capacitance: Change in charge of injected carriers corresponding to change in forward bias voltage in a diode.

Diffusion constant: Product of the thermal voltage and the mobility in a semiconductor.

Donor: Ionized, positive-charged immobile dopant atom (ion) in an *n*-type semiconductor after the release of an electron.

Drift: Movement of free carriers in a semiconductor due to the electric field.

Ideality factor: The factor determining the deviation from the ideal diode characteristic $m = 1$. At small and large currents $m \approx 2$.

Incremental model: Small-signal differential (incremental) semiconductor diode equivalent RC circuit of a diode, biased in a dc operating point.

Incremental resistance: Small-signal differential (incremental) resistance of a diode, biased in a dc operating point.

Junction capacitance: Change in charge of immobile ions in the depletion region of a diode corresponding to a change in reverse bias voltage on a diode.

Majority carriers: Holes are in majority in a *p*-type semiconductor; electrons are in majority in an *n*-type semiconductor.

Minority carriers: Electrons in a *p*-type semiconductor are in minority; holes are in majority. Similarly, holes are in minority in an *n*-type semiconductor and electrons are in majority.

Reverse breakdown: At the reverse breakdown voltage the diode can conduct a large current in the reverse direction.

Reverse generation-recombination current: Part of the reverse current in a diode caused by the generation of hole–electron pairs in the depletion region. This current is voltage dependent because the depletion region width is voltage dependent.

Reverse saturation current: Part of the reverse current in a diode which is caused by diffusion of minority carriers from the neutral regions to the depletion region. This current is almost independent of the reverse voltage.

Temperature coefficient: Relative variation $\Delta X/X$ of a value X over a temperature range, divided by the difference in temperature ΔT.

Zener breakdown: In the reverse-biased diode, hole–electron pairs are generated by a large electric field in the depletion region.

22.3 Electrical Equivalent Circuit Models and Device Simulators for Semiconductor Devices

Aicha Elshabini-Riad, F. W. Stephenson, and Imran A. Bhutta

In the past 15 years, the electronics industry has seen a tremendous surge in the development of new semiconductor materials, novel devices, and circuits. For the designer to bring these circuits or devices to the market in a timely fashion, he or she must have design tools capable of predicting the device behavior in a variety of circuit configurations and environmental conditions. Equivalent circuit models and semiconductor device simulators represent such design tools.

Overview of Equivalent Circuit Models

Circuit analysis is an important tool in circuit design. It saves considerable time, at the circuit design stage, by providing the designer with a tool for predicting the circuit behavior without actually processing the circuit.

An electronic circuit usually contains active devices, in addition to passive components. While the current and voltage behavior of passive devices is defined by simple relationships, the equivalent relationships in active devices are quite complicated in nature. Therefore, in order to analyze an active circuit, the devices are replaced by equivalent circuit models that give the same output characteristics as the active device itself. These models are made up of passive elements, voltage sources, and current sources. Equivalent circuit models provide the designer with reasonably accurate values for frequencies below 1 GHz for bipolar junction transistors (BJTs), and their use is quite popular in circuit analysis software. Some field-effect transistor (FET) models are accurate up to 10 GHz. As the analysis frequency increases, however, so does the model complexity. Since the equivalent circuit models are based on some fundamental equations describing the device behavior, they can also be used to predict the characteristics of the device itself.

When performing circuit analysis, two important factors that must be taken into account are the speed and accuracy of computation. Sometimes, the computation speed can be considerably improved by simplifying the equivalent circuit model, without significant loss in computation accuracy. For this reason, there are a number of equivalent circuit models, depending on the device application and related conditions. Equivalent circuit models have been developed for diodes, BJTs, and FETs. In this overview, the equivalent circuit models for BJT and FET devices are presented.

Most of the equivalent circuits for BJTs are based on the Ebers–Moll model [1954] or the Gummel–Poon model [1970]. The original Ebers–Moll model was a large signal, nonlinear dc model for BJTs. Since then, a number of improvements have been incorporated to make the model more accurate for various applications. In addition, an accurate model has been introduced by Gummel and Poon.

There are three main types of equivalent circuit models, depending on the device signal strength. On this basis, the models can be classified as follows:

1. Large-signal equivalent circuit model
2. Small-signal equivalent circuit model
3. DC equivalent circuit model

Use of the large-signal or small-signal model depends on the magnitude of the driving source. In applications where the driving currents or the driving voltages have large amplitudes, large-signal models are used. In circuits where the signal does not deviate much from the dc biasing point, small-signal models are more suitable. For dc conditions and very-low-frequency applications, dc equivalent circuit models are used. For dc and very-low-frequency analysis, the circuit element values can be assumed to be lumped, whereas in high-frequency analysis, incremental element values give much more precise results.

Large-Signal Equivalent Circuit Model

Depending on the frequency of operation, large-signal equivalent circuit models can be further classified as (1) high-frequency large-signal equivalent circuit model and (2) low-frequency large-signal equivalent circuit model.

High-Frequency Large-Signal Equivalent Circuit Model of a BJT. In this context, high-frequency denotes frequencies above 10 kHz. In the equivalent circuit model, the transistor is assumed to be composed of two back-to-back diodes. Two current-dependent current sources are added to model the current flowing through the reverse-biased base-collector junction and the forward-biased base-emitter junction. Two junction capacitances, C_{jE} and C_{jC}, model the fixed charges in the emitter-base space charge region and base-collector space charge region, respectively. Two diffusion capacitances, C_{DE} and C_{DC}, model the corresponding charge associated with mobile carriers, while the base resistance, r_b, represents the voltage drop in the base region. All the above circuit elements are very strong functions of operating frequency, signal strength, and bias voltage.

The high-frequency large-signal equivalent circuit model of an *npn* BJT is shown in Fig. 22.23, where the capacitances C_{jE}, C_{jC}, C_{DE}, C_{DC} are defined as follows:

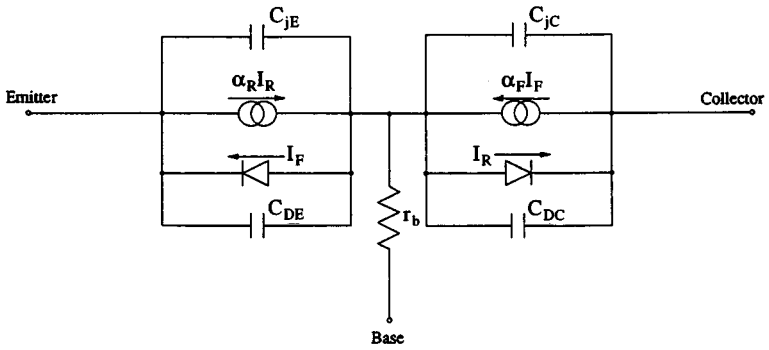

FIGURE 22.23 High-frequency large-signal equivalent circuit model of an *npn* BJT.

$$C_{jE}(V_{B'E'}) = \frac{C_{jEO}}{\left(1 - \dfrac{v_{B'E'}}{\phi_E}\right)^{m_E}} \tag{22.66}$$

$$C_{jC}(V_{B'C'}) = \frac{C_{jCO}}{\left(1 - \dfrac{v_{B'C'}}{\phi_C}\right)^{m_C}} \tag{22.67}$$

$$C_{DE} = \frac{\tau_F I_{CC}}{V_{B'E'}} \tag{22.68}$$

and

$$C_{DC} = \frac{\tau_R I_{EC}}{V_{B'E'}} \tag{22.69}$$

In these equations, $V_{B'E'}$ is the internal base-emitter voltage, C_{jEO} is the base-emitter junction capacitance at $V_{B'E'} = 0$, ϕ_E is the base-emitter barrier potential, and m_E is the base-emitter capacitance gradient factor. Similarly, $V_{B'C'}$ is the internal base-collector voltage, C_{jCO} is the base-collector junction capacitance at $V_{B'C'} = 0$, ϕ_C is the base-collector barrier potential, and m_C is the base-collector capacitance gradient factor. I_{CC} and I_{EC} denote the collector and emitter reference currents, respectively, while τ_F is the total forward transit time, and τ_R is the total reverse transit time. α_R and α_F are the large-signal reverse and forward current gains of a common base transistor, respectively.

This circuit can be made linear by replacing the forward-biased base-emitter diode with a low-value resistor, r_π, while the reverse-biased base-collector diode is replaced with a high-value resistor, r_μ. The junction and diffusion capacitors are lumped together to form C_π and C_μ, while the two current sources are lumped into one source ($g_{mF}V_F - g_{mR}V_R$), where g_{mF} and g_{mR} are the transistor forward and reverse transconductances, respectively. V_F and V_R are the voltages across the forward- and reverse-biased diodes, represented by r_π and r_μ, respectively. r_π is typically about 3 kΩ, while r_μ is more than a few megohms, and C_π is about 120 pF. The linear circuit representation is illustrated in Fig. 22.24.

The Gummel–Poon representation is very similar to the high-frequency large-signal linear circuit model of Fig. 22.24. However, the terms describing the elements are different and a little more involved.

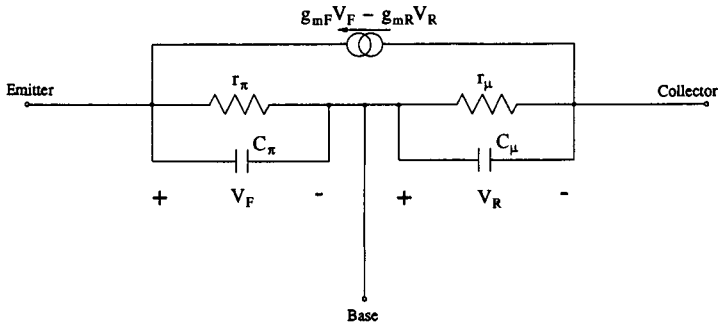

FIGURE 22.24 High-frequency large-signal equivalent circuit model (linear) of an *npn* BJT.

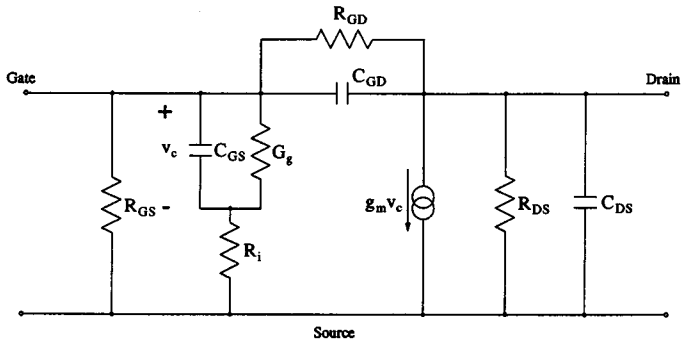

FIGURE 22.25 High-frequency large-signal equivalent circuit model of a FET.

High-Frequency Large-Signal Equivalent Circuit Model of a FET. In the high-frequency large-signal equivalent circuit model of a FET, the fixed charge stored between the gate and the source and between the gate and the drain is modeled by the gate-to-source and the gate-to-drain capacitances, C_{GS} and C_{GD}, respectively. The **mobile charges** between the drain and the source are modeled by the drain-to-source capacitance, C_{DS}. The voltage drop through the active channel is modeled by the drain-to-source resistance, R_{DS}. The current through the channel is modeled by a voltage-controlled current source. For large signals, the gate is sometimes driven into the forward region, and thus the conductance through the gate is modeled by the gate conductance, G_g. The conductance from the gate to the drain and from the gate to the source is modeled by the gate-to-drain and gate-to-source resistances, R_{GD} and R_{GS}, respectively. A variable resistor, R_i, is added to model the gate charging time such that the time constant given by R_iC_{GS} holds the following relationship

$$R_iC_{GS} = \text{constant} \tag{22.70}$$

For MOSFETs, typical element values are: C_{GS} and C_{GD} are in the range of 1–10 pF, C_{DS} is in the range of 0.1–1 pF, R_{DS} is in the range of 1–50 kΩ, R_{GD} is more than 10^{14} Ω, R_{GS} is more than 10^{10} Ω, and g_m is in the range of 0.1–20 mA/V.

Figure 22.25 illustrates the high-frequency large-signal equivalent model of a FET.

Low-Frequency Large-Signal Equivalent Circuit Model of a BJT. In this case, low frequency denotes frequencies below 10 kHz. The low-frequency large-signal equivalent circuit model of a BJT is based on its dc characteristics. Whereas at high frequencies one has to take incremental values to obtain accurate analysis, at low frequencies, the average of these incremental values yields the same level of accuracy in the analysis. Therefore, in low-frequency analysis, the circuit elements of the high-frequency model are replaced by their average values. The low-frequency large-signal equivalent circuit model is shown in Fig. 22.26.

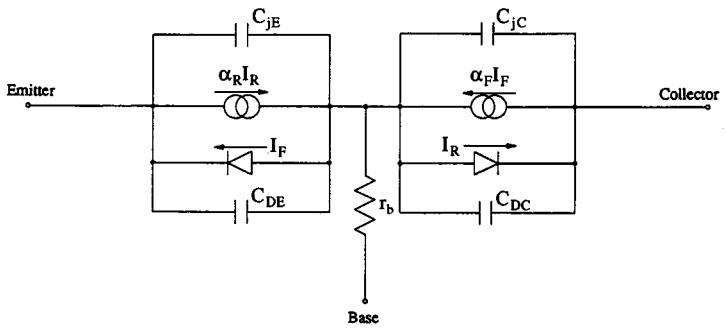

FIGURE 22.26 Low-frequency large-signal equivalent circuit model of an *npn* BJT.

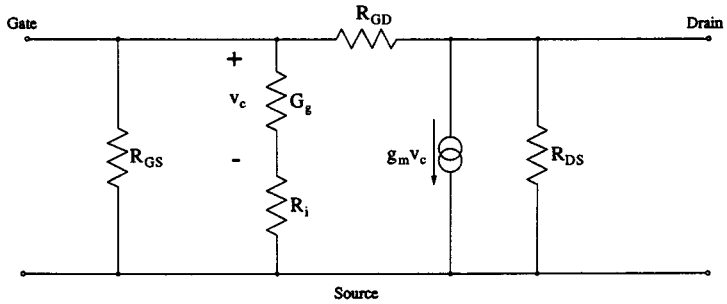

FIGURE 22.27 Low-frequency large-signal equivalent circuit model of a FET.

Low-Frequency Large-Signal Equivalent Circuit Model of a FET. Because of their high reactance values, the gate-to-source, gate-to-drain, and drain-to-source capacitances can be assumed to be open circuits at low frequencies. Therefore, the low-frequency large-signal model is similar to the high-frequency large-signal model, except that it has no capacitances. The resulting circuit describing low-frequency operation is shown in Fig. 22.27.

Small-Signal Equivalent Circuit Model

In a small-signal equivalent circuit model, the signal variations around the dc-bias operating point are very small. Just as for the large-signal model, there are two types of small-signal models, depending upon the operating frequency: (1) the high-frequency small-signal equivalent circuit model and (2) the low-frequency small-signal equivalent circuit model.

High-Frequency Small-Signal Equivalent Circuit Model of a BJT. The high-frequency small-signal equivalent circuit model of a BJT is quite similar to its high-frequency large-signal equivalent circuit model. In the small-signal model, however, in addition to the base resistance r_b, the emitter and collector resistances, r_e and r_c, respectively, are added to the circuit. The emitter resistance is usually very small because of high emitter doping used to obtain better emitter injection efficiency. Therefore, whereas at large signal strengths the effect of r_e is overshadowed by the base resistance, at small signal strengths this emitter resistance cannot be neglected. The collector resistance becomes important in the linear region, where the collector-emitter voltage is low. The high-frequency small-signal equivalent circuit model is shown in Fig. 22.28.

High-Frequency Small-Signal Equivalent Circuit Model of a FET. For small-signal operations, the signal strength is not large enough to forward bias the gate-to-semiconductor diode; hence, no current will flow from the gate to either the drain or the source. Therefore, the gate-to-source and gate-to-drain series resistances, R_{GS} and R_{GD}, can be neglected. Also, since there will be no current flow from the gate to the channel, the gate conductance, G_g, can also be neglected. Figure 22.29 illustrates the high-frequency small-signal equivalent circuit model of a FET.

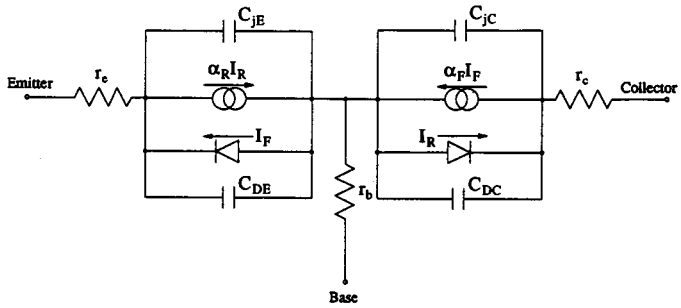

FIGURE 22.28 High-frequency small-signal equivalent circuit model of an *npn* BJT.

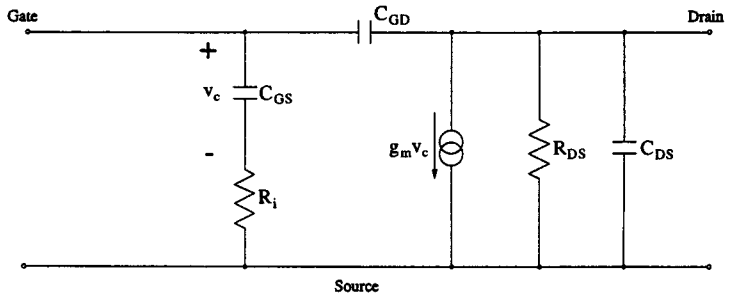

FIGURE 22.29 High-frequency small-signal equivalent circuit model of a FET.

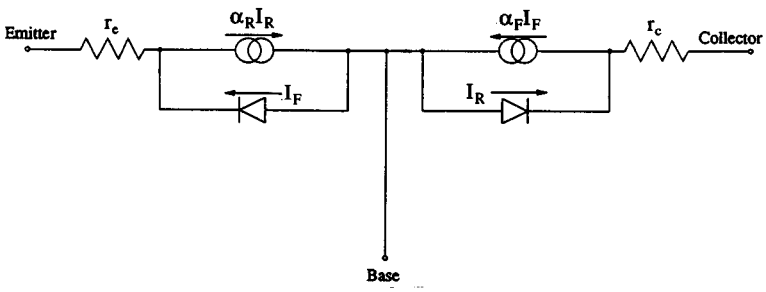

FIGURE 22.30 Low-frequency small-signal equivalent circuit model of an *npn* BJT.

Low-Frequency Small-Signal Equivalent Circuit Model of a BJT. As in the low-frequency large-signal model, the junction capacitances, C_{jC} and C_{jE}, and the diffusion capacitances, C_{DE} and C_{DC}, can be neglected. Furthermore, the base resistance, r_b, can also be neglected, because the voltage drop across the base is not significant and the variations in the base width caused by changes in the collector-base voltage are also very small. The low-frequency small-signal equivalent circuit model is shown in Fig. 22.30.

Low-Frequency Small-Signal Equivalent Circuit Model of a FET. Because the reactances associated with all the capacitances are very high, one can neglect the capacitances for low-frequency analysis. The gate conductance as well as the gate-to-source and gate-to-drain resistances can also be neglected in small-signal operation. The resulting low-frequency equivalent circuit model of a FET is shown in Fig. 22.31.

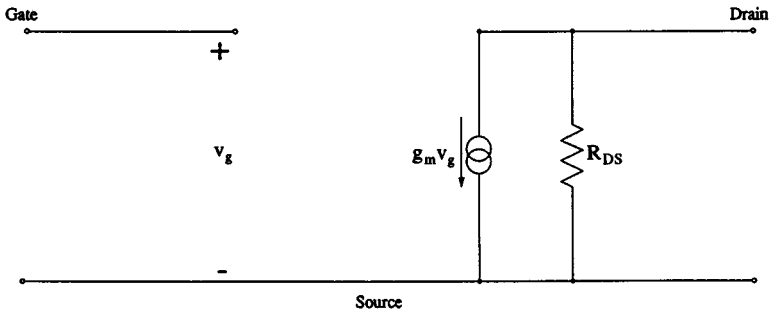

FIGURE 22.31 Low-frequency small-signal equivalent circuit model of a FET.

DC Equivalent Circuit Model

DC Equivalent Circuit Model of a BJT. The dc equivalent circuit model of a BJT is based on the original Ebers–Moll model. Such models are used when the transistor is operated at dc or in applications where the operating frequency is below 1 kHz.

There are two versions of the dc equivalent circuit model—the *injection version* and the *transport version*. The difference between the two versions lies in the choice of the reference current. In the *injection version*, the reference currents are I_F and I_R, the forward- and reverse-biased diode currents, respectively. In the *transport version*, the reference currents are the collector transport current, I_{CC}, and the emitter transport current, I_{CE}. These currents are of the form:

$$I_F = I_{ES}\left[\exp\left(\frac{qV_{BE}}{kT}\right) - 1\right] \tag{22.71}$$

$$I_R = I_{CS}\left[\exp\left(\frac{qV_{BC}}{kT}\right) - 1\right] \tag{22.72}$$

$$I_{CC} = I_S\left[\exp\left(\frac{qV_{BE}}{kT}\right) - 1\right] \tag{22.73}$$

and

$$I_{EC} = I_S\left[\exp\left(\frac{qV_{BC}}{kT}\right) - 1\right] \tag{22.74}$$

In these equations, I_{ES} and I_{CS} are the base-emitter saturation current and the base-collector saturation current, respectively. I_S denotes the saturation current.

In most computer simulations, the *transport version* is usually preferred because of the following conditions:

1. I_{CC} and I_{EC} are ideal over many decades.
2. I_S can specify both reference currents at any given voltage.

The dc equivalent circuit model of a BJT is shown in Fig. 22.32.

DC Equivalent Circuit Model of a FET. In the dc equivalent circuit model of a FET, the gate is considered isolated because the gate-semiconductor interface is formed as a reverse-biased diode and therefore is open circuited. All capacitances are also assumed to represent open circuits. R_{GS}, R_{GD}, and R_{DS} are neglected because

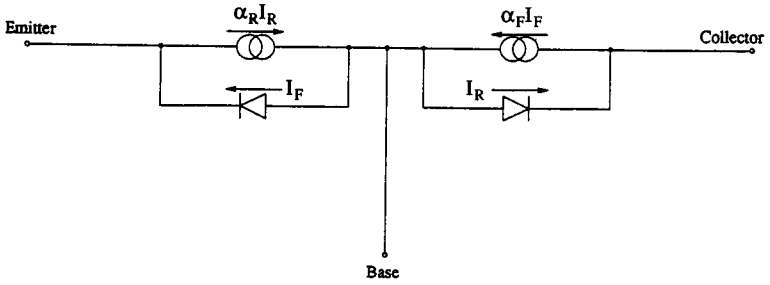

FIGURE 22.32 DC equivalent circuit model (injection version) of an *npn* BJT.

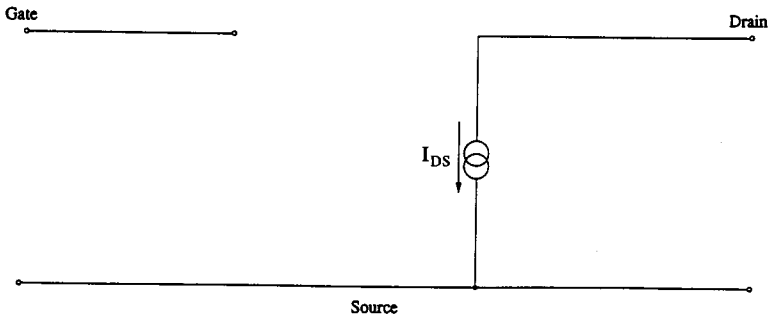

FIGURE 22.33 DC equivalent circuit model of a FET.

there is no conductance through the gate and, because this is a dc analysis, there are no charging effects associated with the gate. The dc equivalent circuit of a FET is illustrated in Fig. 22.33.

Commercially Available Packages

A number of circuit analysis software packages are commercially available, one of the most widely used being SPICE. In this package, the BJT models are a combination of the Gummel–Poon and the modified Ebers–Moll models. Figure 22.34 shows a common emitter transistor circuit and a SPICE input file containing the transistor model. Some other available packages are SLIC, SINC, SITCAP, and Saber.

Equivalent circuit models are basically used to replace the semiconductor device in an electronic circuit. These models are developed from an understanding of the device's current and voltage behavior for novel devices where internal device operation is not well understood. For such situations, the designer has another tool available, the semiconductor device simulator.

Overview of Semiconductor Device Simulators

Device simulators are based on the physics of semiconductor devices. The input to the simulator takes the form of information about the device under consideration such as material type, device, dimensions, doping concentrations, and operating conditions. Based on this information, the device simulator computes the electric field inside the device and thus predicts carrier concentrations in the different regions of the device. Device simulators can also predict transient behavior, including quantities such as current–voltage characteristics and frequency bandwidth. The three basic approaches to device simulation are (1) the classical approach, (2) the semiclassical approach, and (3) the quantum mechanical approach.

Device Simulators Based on the Classical Approach

The *classical approach* is based on the solution of Poisson's equation and the current continuity equations. The current consists of the drift and the diffusion current components.

Transistor model

FIGURE 22.34 Common emitter transistor circuit and SPICE circuit file.

Assumptions. The equations for the classical approach can be obtained by making the following approximations to the Boltzmann transport equation:

1. Carrier temperature is the same throughout the device and is assumed to be equal to the lattice temperature.
2. Quasi steady-state conditions exist.
3. Carrier **mean free path** must be smaller than the distance over which the **quasi-Fermi level** is changing by kT/q.
4. The impurity concentration is constant or varies very slowly along the mean free path of the carrier.
5. The energy band is parabolic.
6. The influence of the boundary conditions is negligible.

For general purposes, even with these assumptions and limitations, the models based on the classical approach give fairly accurate results. The model assumes that the driving force for the carriers is the quasi-Fermi potential gradient, which is also dependent upon the electric field value. Therefore, in some simulators, the quasi-Fermi level distributions are computed and the carrier distribution is estimated from this information.

Equations to Be Solved. With the assumption of a quasi-steady-state condition, the operating wavelength is much larger than the device dimensions. Hence, Maxwell's equations can be reduced to the more familiar Poisson's equation:

$$\nabla^2 \psi = -\frac{\rho}{\epsilon} \tag{22.75}$$

and, for a nonhomogeneous medium,

$$\nabla \cdot \epsilon \, (\nabla \psi) = -\rho \tag{22.76}$$

where ψ denotes the potential of the region under simulation, ϵ denotes the permittivity, and ρ denotes the charge enclosed by this region.

Also from Maxwell's equations, one can determine the current continuity equations for a homogeneous medium as:

$$\nabla \cdot J_n - q\left(\frac{\partial n}{\partial t}\right) = +qU \tag{22.77}$$

where

$$J_n = q\mu_n E + qD_n \nabla \cdot n \tag{22.78}$$

and

$$\nabla \cdot J_p + q\left(\frac{\partial p}{\partial t}\right) = -qU \tag{22.79}$$

where

$$J_p = q\mu_p pE - qD_p \nabla \cdot p \tag{22.80}$$

For nonhomogeneous media, the electric field term in the current expressions is modified to account for the nonuniform **density of states** and the bandgap variation [Lundstrom and Schuelke, 1983].

In the classical approach, the objective is to calculate the potential and the carrier distribution inside the device. Poisson's equation is solved to yield the potential distribution inside the device from which the electric field can be approximated. The electric field distribution is then used in the current continuity equations to obtain the carrier distribution and the current densities. The diffusion coefficients and carrier mobilities are usually field as well as spatially dependent.

The generation-recombination term U is usually specified by the Shockley–Read–Hall relationship [Yoshi et al., 1982]:

$$Rn = \frac{p\,n - n_{ie}^2}{\tau_p(n + n_t) + \tau_n(p + p_t)} \tag{22.81}$$

where p and n are the hole and electron concentrations, respectively, n_{ie} is the effective intrinsic carrier density, τ_p and τ_n are the hole and electron lifetimes, and p_t and n_t are the hole and electron trap densities, respectively.

The electron and hole mobilities are usually specified by the Scharfetter–Gummel empirical formula, as

$$\mu = \mu_0\left[1 + \frac{N}{(N/a) + b} + \frac{(E/c)^2}{(E/c) + d} + (E/e)^2\right]^{-1/2} \tag{22.82}$$

where N is the total ionized impurity concentration, E is the electric field, and a, b, c, d, and e are defined constants [Scharfetter and Gummel, 1969] that have different values for electrons and holes.

Boundary Conditions. Boundary conditions have a large effect on the final solution, and their specific choice is a very important issue. For ohmic contacts, infinite recombination velocities and space charge neutrality conditions are assumed. Therefore, for a p-type material, the ohmic boundary conditions take the form

$$\psi = V_{\text{appl}} + \frac{kT}{q} \ln\left(\frac{n_{ie}}{p}\right) \tag{22.83}$$

$$p = \left[\left(\frac{N_D^+ - N_A^-}{2}\right)^2 + n_{ie}^2\right]^{1/2} - \left(\frac{N_D^+ - N_A^-}{2}\right) \tag{22.84}$$

and

$$n = \frac{n_{ie}^2}{p} \tag{22.85}$$

where V_{appl} is the applied voltage, k is Boltzmann's constant, and N_D^+ and N_A^- are the donor and acceptor ionized impurity concentrations, respectively.

For **Schottky contacts**, the boundary conditions take the form

$$\psi = V_{\text{appl}} + \frac{E_G}{2} - \phi_B \tag{22.86}$$

and

$$n = n_{ie} \exp\left(\frac{(E_G/2) - \phi_B}{kT/q}\right) \tag{22.87}$$

where E_G is the semiconductor bandgap and ϕ_B is the barrier potential. For other boundaries with no current flow across them, the boundary conditions are of the form

$$\frac{\partial \psi}{\partial n} = \frac{\partial \varphi_n}{\partial n} = \frac{\partial \varphi_p}{\partial p} = 0 \tag{22.88}$$

where φ_n and φ_p are the electron and hole quasi-Fermi levels, respectively.

For field-effect devices, the potential under the gate may be obtained either by setting the gradient of the potential near the semiconductor-oxide interface equal to the gradient of potential inside the oxide [Kasai et al., 1982], or by solving Laplace's equation in the oxide layer, or by assuming a Dirichlet boundary condition at the oxide-gate interface and determining the potential at the semiconductor-oxide interface as:

$$\epsilon_{\text{Si}} \left.\frac{\partial \psi}{\partial y}\right|_{\text{Si}} = \epsilon_{\text{Ox}} \frac{\psi_G - \psi_S^\star(x,z)}{T(z)} \tag{22.89}$$

where ϵ_{Si} and ϵ_{Ox} are the permittivities of silicon and the oxide, respectively, ψ_G is the potential at the top of the gate, $\psi_S^*(x,z)$ is the potential of the gate near the interface, and T(z) is the thickness of the gate metal.

Solution Methods. Two of the most popular methods of solving the above equations are finite difference method (FDM) and finite element method (FEM).

In FDM, the region under simulation is divided into rectangular or triangular areas for two-dimensional cases or into cubic or tetrahedron volumes in three-dimensional cases. Each corner or vertex is considered as a node. The differential equations are modified using finite difference approximations, and a set of equations is constructed in matrix form. The finite difference equations are solved iteratively at only these nodes. The most commonly used solvers are Gauss–Seidel/Jacobi (G-S/J) techniques or Newton's technique (NT) [Banks et al., 1983]. FDM has the disadvantage of requiring more nodes than the FEM for the same structure. A new variation of FDM, namely the finite boxes scheme [Franz et al., 1983], however, overcomes this problem by enabling local area refinement. The advantage of FDM is that its computational memory requirement is less than that required for FEM because of the band structure of the matrix.

In FEM, the region under simulation is divided into triangular and quadrilateral regions in two dimensions or into tetrahedra in three dimensions. The regions are placed to have the maximum number of vertices in areas where there is expected to be a large variation of composition or a large variation in the solution. The equations in FEM are modified by multiplying them with some shape function and integrating over the simulated region. In triangular meshes, the shape function is dependent on the area of the triangle and the spatial location of the node. The value of the spatial function is between 0 and 1. The solution at one node is the sum of all the solutions, resulting from the nearby nodes, multiplied by their respective shape functions. The number of nodes required to simulate a region is less than that in FDM; however, the memory requirement is greater.

Device Simulators Based on the Semiclassical Approach

The *semiclassical* approach is based upon the Boltzmann transport equation (BTE) [Engl, 1986] which can be written as:

$$\frac{df}{dt} = \frac{\partial f}{\partial t} + v \cdot \nabla_r \pm \frac{q}{(h/2\pi)} E \cdot \nabla_k f = \left(\frac{\partial f}{\partial t}\right)_{\text{coll}} \tag{22.90}$$

where f represents the carrier distribution in the volume under consideration at any time t, v is the group velocity, E is the electric field, and q and h are the electronic charge and Planck's constant, respectively.

BTE is a simplified form of the Liouville–Von Neumann equation for the density matrix. In this approach, the free flight between two consecutive collisions of the carrier is considered to be under the influence of the electric field, whereas different scattering mechanisms determine how and when the carrier will undergo a collision.

Assumptions. The assumptions for the semiclassical model can be summarized as follows:

1. Carrier-to-carrier interactions are considered to be very weak.
2. Particles cannot gain energy from the electric field during collision.
3. Scattering probability is independent of the electric field.
4. Magnetic field effects are neglected.
5. No electron-to-electron interaction occurs in the collision term.
6. Electric field varies very slowly, i.e., electric field is considered constant for a wave packet describing the particle's motion.
7. The electron and hole gas is not degenerate.
8. Band theory and effective-mass theorems apply to the semiconductor.

Equations to Be Solved. As a starting point, Poisson's equation is solved to obtain the electric field inside the device. Using the Monte Carlo technique (MCT), the BTE is solved to obtain the carrier distribution function, f. In the MCT, the path of one or more carriers, under the influence of external forces, is followed, and from

this information the carrier distribution function is determined. BTE can also be solved by the momentum and energy balance equations.

The carrier distribution function gives the carrier concentrations in the different regions of the device and can also be used to obtain the electron and hole currents, using the following expressions:

$$J_n = -q\int_k v f(r,k,t)d^3k \tag{22.91}$$

and

$$J_p = +q\int_k v f(r,k,t)d^3k \tag{22.92}$$

Device Simulators Based on the Quantum Mechanical Approach

The *quantum mechanical approach* is based on the solution of the Schrodinger wave equation (SWE), which, in its time-independent form, can be represented as

$$\frac{(h/2\pi)^2}{2m}\nabla^2\varphi_n + (E_n + qV)\ \varphi_n = 0 \tag{22.93}$$

where φ_n is the wave function corresponding to the subband n whose minimum energy is E_n, V is the potential of the region, m is the particle mass, and h and q are Planck's constant and the electronic charge, respectively.

Equations to Be Solved. In this approach, the potential distribution inside the device is calculated using Poisson's equation. This potential distribution is then used in the SWE to yield the electron wave vector, which in turn is used to calculate the carrier distribution, using the following expression:

$$n = \sum_n N_n \left|\varphi_n\right|^2 \tag{22.94}$$

where n is the electron concentration and N_n is the concentration of the subband n.

This carrier concentration is again used in Poisson's equation, and new values of φ_n, E_n, and n are calculated. This process is repeated until a self-consistent solution is obtained. The final wave vector is invoked to determine the scattering matrix, after which MCT is used to yield the carrier distribution and current densities.

Commercially Available Device Simulation Packages

The classical approach is the most commonly used procedure since it is the easiest to implement and, in most cases, the fastest technique. Simulators based on the classical approach are available in two-dimensional forms like FEDAS, HESPER, PISCES-II, PISCES-2B, MINIMOS, and BAMBI or three-dimensional forms like TRANAL, SIERRA, FIELDAY, DAVINCI, and CADDETH.

Large-dimension devices, where the carriers travel far from the boundaries, can be simulated based on a one-dimensional approach. Most currently used devices, however, do not fit into this category, and therefore one has to resort to either two- or three-dimensional simulators.

FEDAS (Field Effect Device Analysis System) is a two-dimensional device simulator that simulates MOSFETs, JFETs, and MESFETs by considering only those carriers that form the channel. The Poisson equation is solved everywhere except in the oxide region. Instead of carrying the potential calculation within the oxide region, the potential at the semiconductor-oxide interface is calculated by assuming a mixed boundary condition. FEDAS uses FDM to solve the set of linear equations. A three-dimensional variation of FEDAS is available for the simulation of small geometry MOSFETs.

HESPER (HEterostructure device Simulation Program to Estimate the performance Rigorously) is a two-dimensional device simulator that can be used to simulate heterostructure photodiodes, HBTs, and HEMTs. The simulation starts with the solution of Poisson's equation in which the electron and hole concentrations are described as functions of the composition (composition dependent). The recombination rate is given by the Shockley–Read–Hall relationship. Lifetimes of both types of carriers are assumed to be equal in this model.

PISCES-2B is a two-dimensional device simulator for simulation of diodes, BJTs, MOSFETs, JFETs, and MESFETs. Besides steady-state analysis, transient and ac small-signal analysis can also be performed.

Conclusion

The decision to use an equivalent circuit model or a device simulator depends upon the designer and the required accuracy of prediction. To save computational time, one should use as simple a model as accuracy will allow. At this time, however, the trend is toward developing quantum mechanical models that are more accurate, and with faster computers available, the computational time for these simulators has been considerably reduced.

Defining Terms

Density of states: The total number of charged carrier states per unit volume.
Fermi levels: The energy level at which there is a 50% probability of finding a charged carrier.
Mean free path: The distance traveled by the charged carrier between two collisions.
Mobile charge: The charge due to the free electrons and holes.
Quasi-Fermi levels: Energy levels that specify the carrier concentration inside a semiconductor under non-equilibrium conditions.
Schottky contact: A metal-to-semiconductor contact where, in order to align the Fermi levels on both sides of the junction, the energy band forms a barrier in the majority carrier path.

22.4 Electrical Characterization of Semiconductors

David C. Look

The huge electronics and computer industries exist primarily because of the unique electrical properties of semiconductor materials, such as Si and GaAs. These materials usually contain impurities and defects in their crystal lattices; such entities can act as **donors** and **acceptors**, and can strongly influence the electrical and optical properties of the charge carriers. Thus, it is extremely important to be able to measure the concentration and **mobility** of these carriers, and the concentrations and energies of the donors and acceptors. All of these quantities can, in principle, be determined by measurement and analysis of the temperature-dependent resistivity and Hall effect. On the simplest level, Hall-effect measurements require only a current source, a voltmeter, and a modest-sized magnet. However, the addition of temperature-control equipment and computer analysis produce a much more powerful instrument that can accurately measure concentrations over a range 10^4 to 10^{20} cm^{-3}. Many commercial instruments are available for such measurements; this chapter section reveals how to make full use of the versatility of the technique.

Theory

A phenomenological equation of motion for electrons of charge –e moving with velocity **v** in the presence of electric field **E** and magnetic field **B** is

$$m^*\dot{\mathbf{v}} = -e\left(\mathbf{E} + \mathbf{v} \times \mathbf{B}\right) - m^* \frac{\mathbf{v} - \mathbf{v}_{eq}}{\tau} \tag{22.95}$$

where m^* is the **effective mass**, $\mathbf{v}_{eq}$ is the velocity at equilibrium (steady state), and τ is the velocity (or momentum) **relaxation time** (i.e., the time in which oscillatory phase information is lost through collisions). Consider a rectangular sample, as shown in Fig. 22.35(a), with an external electric field $\mathbf{E}_{ex} = E_x\mathbf{x}$ and magnetic field $\mathbf{B} = B_z\mathbf{z}$. (Dimensions x and y are parallel to "ℓ" and "w," respectively, and z is perpendicular to both.) Then, if no current is allowed to flow in the y direction (i.e., $v_y = 0$), the steady-state condition $\dot{\mathbf{v}} = 0$ requires that $E_y = -v_xB_z$, and E_y is known as the Hall field. For electron concentration n, the current density is $j_x = nev_x$; thus, $E_y = -j_xB_z/en \equiv -j_xB_zR_H$, where $R_H = -1/en$, the **Hall coefficient**. Thus, simple measurements of the quantities E_y, j_x, and B_z yield a very important quantity: n.

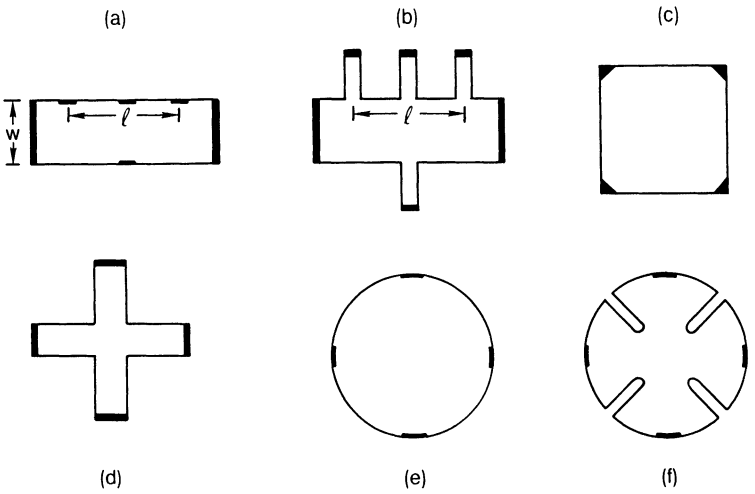

FIGURE 22.35 Various patterns commonly used for resistivity and Hall-effect measurements.

The above analysis assumes that all electrons are moving with the same velocity v (constant τ), which is not true in a semiconductor. A more detailed analysis, allowing for the energy $\mathcal{E}$ dependence of the electrons, gives

$$j_x = \frac{ne^2\langle\tau\rangle}{m^*}E_x \equiv -ne\mu_c E_x \tag{22.96}$$

$$R_H = \frac{E_y}{j_x B} = -\frac{1}{ne}\frac{\langle\tau^2\rangle}{\langle\tau\rangle^2} = -\frac{r}{en} \tag{22.97}$$

where

$$\langle\tau^n(\mathcal{E})\rangle = \frac{\int_0^\infty \tau^n(\mathcal{E})\mathcal{E}^{3/2}\frac{\partial f_0}{\partial\mathcal{E}}d\mathcal{E}}{\int_0^\infty \mathcal{E}^{3/2}\frac{\partial f_0}{\partial\mathcal{E}}d\mathcal{E}} \rightarrow \frac{\int_0^\infty \tau^n(\mathcal{E})\mathcal{E}^{3/2}e^{-\mathcal{E}/kT}d\mathcal{E}}{\int_0^\infty \mathcal{E}^{3/2}e^{-\mathcal{E}/kT}d\mathcal{E}} \tag{22.98}$$

This formulation is called the **relaxation-time approximation (RTA)** to the Boltzmann transport equation (BTE). Here, f_0 is the Fermi-Dirac **distribution function** and the second equality in Eq. (22.98) holds for non-degenerate electrons (i.e., those describable by Boltzmann statistics). The quantity $\mu_c = e\langle\tau\rangle/m^*$ is known as the conductivity **mobility,** since the quantity $ne\mu$ is just the conductivity σ. The **Hall mobility** is defined as $\mu_H = R_H\sigma = r\mu_c$, and the Hall concentration as $n_H = n/r = -1/eR_H$. Thus, a combined Hall effect and conductivity measurement gives n_H and μ_H, although one would prefer to know n, not n_H; fortunately, however, r is usually within 20% of unity, and is almost never as large as 2. In any case, r can often be calculated or measured so that an accurate value of n can usually be determined. It should also be mentioned that one way to evaluate the expressions in Eq. (22.98) is to define a new variable, $u = \mathcal{E}/kT$, and set u = 10 as the upper limit in the integrals.

The relaxation time, $\tau(\mathcal{E})$, depends on how the electrons interact with the **lattice vibrations,** as well as with extrinsic elements such as charged impurities and defects. For example, acoustical-mode lattice vibrations scatter electrons through the deformation potential (τ_{ac}) and piezoelectric potential (τ_{pe}); optical-mode vibrations through the polar potential (τ_{po}); ionized impurities and defects through the screened coulomb potential

(τ_{ii}); and charged **dislocations,** also through the coulomb potential (τ_{dis}). The strengths of these various scattering mechanisms depend on certain lattice parameters, such as dielectric constants and deformation potentials, and extrinsic factors, such as **donor**, **acceptor,** and dislocation concentrations, N_D, N_A, and N_{dis}, respectively [Rode, 1975; Wiley, 1975; Nag, 1980; Look, 1989; Look, 1998]. The total momentum scattering rate, or inverse **relaxation time,** is

$$\tau^{-1}(\mathcal{E}) = \tau_{ac}^{-1}(\mathcal{E}) + \tau_{pe}^{-1}(\mathcal{E}) + \tau_{po}^{-1}(\mathcal{E}) + \tau_{ii}^{-1}(\mathcal{E}) + \tau_{dis}^{-1}(\mathcal{E}) \tag{22.99}$$

and this expression is then used to determine $\langle\tau^n(\mathcal{E})\rangle$ via Eq. (22.98), and hence, $\mu_H = e\langle\tau^2\rangle/m^*\langle\tau\rangle$. Formulae for τ_{ac}, τ_{pe}, τ_{po}, τ_{ii}, and τ_{dis}, can be found in the literature, but are given below for completeness. For ionized impurity (or defect) scattering, in a non-degenerate, ***n*-type** material:

$$\tau_{ii}(\mathcal{E}) = \frac{2^{9/2}\pi\varepsilon_0^{\,2}(m^*)^{1/2}\mathcal{E}^{3/2}}{e^4(2N_A + n)\left[\ln(1+y) - y/(1+y)\right]} \tag{22.100}$$

where $y = 8\varepsilon_0 m^* kT\mathcal{E}/\hbar^2 e^2 n$. Here, ε_0 is the low-frequency (static) dielectric constant, k is Boltzmann's constant, and $\hbar$ is Planck's constant divided by 2π. [If the sample is ***p*-type**, let $(2N_A+n) \rightarrow (2N_D+p)$]. For acoustic-mode deformation-potential scattering:

$$\tau_{ac}(\mathcal{E}) = \frac{\pi\hbar^4\rho_d s^2 \mathcal{E}^{-1/2}}{2^{1/2} E_1^{\,2}(m^*)^{3/2} kT} \tag{22.101}$$

where ρ_d is the density, s is the speed of sound, and E_1 is the deformation potential. For acoustic-mode piezoelectric-potential scattering:

$$\tau_{p_e}(\mathcal{E}) = \frac{2^{3/2}\pi\hbar^2\varepsilon_0\mathcal{E}^{1/2}}{e^2P^2(m^*)^{1/2}kT} \tag{22.102}$$

where P is the piezoelectric coupling coefficient [$P = (h_{pz}^2/\rho s^2\varepsilon_0)^{1/2}$]. Finally, for polar optic-mode scattering, only a rough approximation can be given because the scattering is inelastic:

$$\tau_{po}(\mathcal{E}) = \frac{2^{3/2}\pi\hbar^2\left(e^{T_{po}/T} - 1\right)\left[0.762\mathcal{E}^{1/2} + 0.824(kT_{po})^{1/2} - 0.235(kT_{po})^{-1/2}\mathcal{E}\right]}{e^2 kT_{po}(m^*)^{1/2}\left(\varepsilon_\infty^{-1} - \varepsilon_0^{-1}\right)} \tag{22.103}$$

where T_{po} is the Debye temperature and ε_∞ is the high-frequency dielectric constant. This formula for $\tau_{po}(\mathcal{E})$ has the following property: if *only* p-o scattering existed, then an accurate BTE calculation of μ_H vs. T [Rode, 1975] would give results almost identical to those obtained by the RTA analysis described above, i.e., by setting $\mu_H = e\langle\tau^2\rangle/m^*\langle\tau\rangle$. However, when other scattering mechanisms are also important, then the RTA solution may not be as reliable. Fortunately, at low temperatures (e.g., below about 150K in GaN), p-o scattering weakens, and the RTA approach is quite accurate. This fact is important because we usually are interested in obtaining a good value of the acceptor concentration N_A from the μ_H vs. T fit, and N_A appears directly only in the ii-scattering formula Eq. (22.100), which is usually dominant at low temperatures.

Dislocation scattering in semiconductor materials is often ignored because it becomes significant only for dislocation densities $N_{dis} > 10^8$ cm^{-2} (note that this is an arreal, not volume, density). Such high densities are rare in most semiconductor devices, such as those fabricated from Si or GaAs, but are indeed quite common in devices based on GaN or other materials that involve mismatched substrates. In GaN grown on Al_2O_3 (sapphire), vertical threading dislocations, typically of concentration 10^{10} cm^{-2} or higher, emanate from the interface up to the surface, and horizontally moving electrons or holes experience a scattering characterized by

$$\tau_{dis}\left(\mathcal{E}\right) = \frac{\hbar^3 \varepsilon_0^{\,2} c^2}{N_{dis} m^* e^4} \frac{\left(1 + 8m^* \lambda^2 \mathcal{E}\right)^{3/2}}{\lambda^4} \tag{22.104}$$

where $\lambda = (\varepsilon_0 kT/e^2 n)^{1/2}$. For high-quality GaN/$Al_2O_3$, $N_{dis} \approx 10^8$ cm^{-2}; in the case of a sample discussed later in this chapter section, this value of N_{dis} drops the 300-K Hall mobility only a minor amount, from 915 to 885 cm^2/V s. However, if this same sample contained the usual concentration of dislocations found in GaN (about 10^{10} cm^{-2}), the mobility would drop to less than 100 cm^2/V s, a typical value found in many other samples.

Before going on, it should be mentioned that a very rough approximation of μ_H, which avoids the integrations of Eq. (22.98), can be obtained by setting $\mathcal{E} \approx kT$ and $\mu \approx e\tau/m^*$ in Eq. (22.99). The latter step (i.e., $\mu^{-1} = \mu_1^{-1} + \mu_2^{-1} + \mu_3^{-1} + \ldots$) is known as **Matthiessen's Rule.** However, with present-day computing power, even that available on PCs, it is not much more difficult to use the RTA analysis.

The fitting of μ_H vs. T data, described above, should be carried out in conjunction with the fitting of n vs. T, which is derived from the **charge-balance equation (CBE)**:

$$n + N_A = \frac{N_D}{1 + n/\phi_D} \tag{22.105}$$

where $\phi_D = (g_0/g_1) N_C' \exp(\alpha_D/k) T^{3/2} \exp(-E_{D0}/kT)$. Here, g_0/g_1 is a degeneracy factor, $N_C' = 2(2\pi m_n^* k)^{3/2}/h^3$, where h is Planck's constant, E_D is the **donor** energy, and E_{D0} and α_D are defined by $E_D = E_{D0} - \alpha_D T$. The above equation describes the simplest type of charge balance, in which the donor (called a single donor) has only one charge-state transition within a few kT of the Fermi energy. An example of such a donor is Si on a Ga site in GaN, for which $g_0 = 1$, and $g_1 = 2$. If there are multiple single donors, then equivalent terms are added on the right-hand side of Eq. (22.105); if there are double or triple donors, or more than one **acceptor,** proper variations of Eq. (22.105) can be found in the literature [Look, 1989].

For a ***p*-type** sample, the nearly equivalent equation is used:

$$p + N_D = \frac{N_A}{1 + p/\phi_A} \tag{22.106}$$

where $\phi_A = (g_1/g_0) N_V' \exp(\alpha_A/k) T^{3/2} \exp(-E_{A0}/kT)$, $N_V' = 2(2\pi m_p^* k)^{3/2}/h^3$, and $E_A = E_{A0} - \alpha_A T$.

Hall samples do not have to be rectangular, and other common shapes are given in Fig. 22.35(c)–(f); in fact, arbitrarily shaped specimens are discussed in the next section. However, the above analysis does assume that n and μ are homogeneous throughout the sample. If n and μ vary with depth (z) only, then the measured quantities are

$$\sigma_{sq} = \int_0^d \sigma(z)\,dz = e\int_0^d n(z)\mu(z)\,dz \tag{22.107}$$

$$R_{Hsq}\sigma_{sq}^{2} = \int_{0}^{d} n(z)\mu^{2}(z)dz \tag{22.108}$$

where d is the sample thickness and where the subscript "sq" denotes a sheet (arreal) quantity (cm^{-2}) rather than a volume quantity (cm^{-3}). If some of the carriers are holes, rather than electrons, then the sign of e for those carriers must be reversed. The general convention is that R_H is negative for electrons and positive for holes. In some cases, the hole and electron contributions to $R_{Hsq}\sigma_{sq}^{2}$ exactly balance at a given temperature, and this quantity vanishes.

Determination of Resistivity and Hall Coefficient

Consider the Hall-bar structure of Fig. 22.35(a) and suppose that current I is flowing along the long direction. Then, if V_c and V_H are the voltages measured along dimensions ℓ and w, respectively, and d is the thickness, one obtains $E_x = V_c/\ell$, $E_y = V_H/w$, $j_x = I/wd$, and

$$\sigma = \rho^{-1} = \frac{j_x}{E_x} = \frac{I\ell}{V_c wd} \tag{22.109}$$

$$R_H = \frac{E_y}{j_x B} = \frac{V_H d}{IB} \tag{22.110}$$

$$\mu_H = R\sigma = \frac{V_H \ell}{V_c wB} \tag{22.111}$$

$$n_H = (eR)^{-1} \tag{22.112}$$

In MKS units, I is in amps (A), V in volts (V), B in Tesla (T), and ℓ, w, and d in meters (m). By realizing that 1 T = 1 V–s m^{-2}, 1 A = 1 coulomb (C)/s, and 1 ohm (Ω) = 1 VA^{-1} then σ is in units of $\Omega^{-1}m^{-1}$, R_H in m^3C^{-1}, μ_H in $m^2V^{-1}s^{-1}$, and n_H in m^{-3}. However, it is more common to denote σ in $\Omega^{-1}cm^{-1}$, R_H in $cm^3\ C^{-1}$, μ_H in $cm^2\ V^{-1}s^{-1}$, and n_H in cm^{-3}, with obvious conversion factors (1 m = 10^2 cm). Because B is often quoted in Gauss (G), it is useful to note that 1 T = 10^4 G.

Clearly, the simple relationships given above will not hold for the nonrectangular shapes shown in Fig. 22.35(c)–(f), several of which are very popular. Fortunately, van der Pauw [1958] has solved the potential problem for a thin layer of arbitrary shape. One of the convenient features of the van der Pauw formulation is that no dimension need be measured for the calculation of sheet resistance or sheet carrier concentration, although a thickness must of course be known for volume resistivity and concentration. Basically, the validity of the van der Pauw method requires that the sample be flat, homogeneous, and isotropic, a singly connected domain (no holes), and have line electrodes on the periphery, projecting to point contacts on the surface, or else have true point contacts on the surface. The last requirement is the most difficult to satisfy, so that much work has gone into determining the effects of finite contact size.

Consider the arbitrarily shaped sample shown in Fig. 22.36(a). Here, a current I flows between contacts 1 and 2, and a voltage V_c is measured between contacts 3 and 4. Let $R_{ij,kl} \equiv V_{kl}/I_{ij}$, where the current enters contact i and leaves contact j, and $V_{kl} = V_k - V_l$. (These definitions, as well as the contact numbering, correspond to ASTM Standard F76.) The resistivity, ρ, with B = 0, is then calculated as follows:

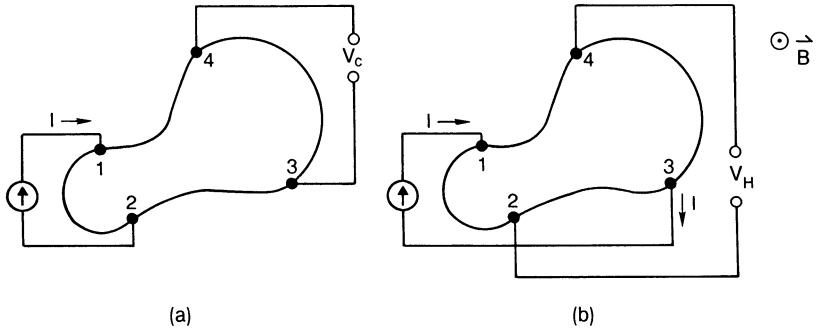

FIGURE 22.36 An arbitrary shape for van der Pauw measurements: (a) resistivity; (b) Hall effect.

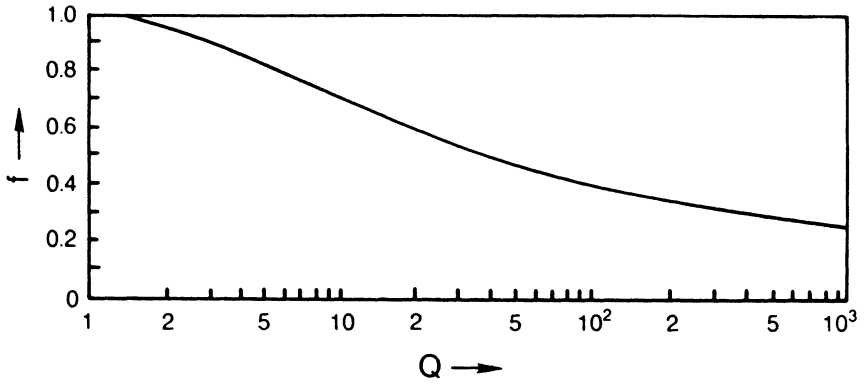

FIGURE 22.37 The resistivity-ratio function used to correct the van der Pauw results for asymmetric sample shape.

$$\rho = \frac{\pi d}{\ln(2)}\left[\frac{R_{21,34} + R_{32,41}}{2}\right] f \tag{22.113}$$

where f is determined from a transcendental equation:

$$\frac{Q-1}{Q+1} = \frac{f}{\ln(2)} \operatorname{arccosh}\left\{\frac{1}{2}\exp\left(\frac{\ln(2)}{f}\right)\right\} \tag{22.114}$$

Here, $Q = R_{21,34}/R_{32,41}$ if this ratio is greater than unity; otherwise, $Q = R_{32,41}/R_{21,34}$. A curve of f vs. Q, accurate to about 2%, is presented in Fig. 22.37 [van der Pauw, 1958]. Also useful is a somewhat simpler analytical procedure for determining f, due to Wasscher and reprinted in Weider [1979]. First, calculate α from

$$Q = \frac{\ln(1/2 - \alpha)}{\ln(1/2 + \alpha)} \tag{22.115}$$

and then calculate f from

$$f = \frac{\ln\left(1/4\right)}{\ln\left(1/2+\alpha\right)+\ln\left(1/2-\alpha\right)} \tag{22.116}$$

It is of course required that $-1/2 < \alpha < 1/2$, but this range of α covers $Q = 0$ to ∞. For example, a ratio $Q = 4.8$ gives a value $\alpha \approx 0.25$, and then $f \approx 0.83$. Thus, the ratio must be fairly large before ρ is appreciably reduced.

It is useful to further average ρ by including the remaining two contact permutations, and also reversing current for all four permutations. Then ρ becomes

$$\rho = \left[\pi d/\ln(2)\right]\left[\left(R_{21,34} - R_{12,34} + R_{32,41} - R_{23,41}\right)f_A + \left(R_{43,12} - R_{34,12} + R_{14,23} - R_{41,23}\right)f_B\right]/8 \tag{22.117}$$

where f_A and f_B are determined from Q_A and Q_B, respectively, by applying either Eq. (22.114) or Eq. (22.115). Here,

$$Q_A = \frac{R_{21,34} - R_{12,34}}{R_{32,41} - R_{23,41}} \tag{22.118}$$

$$Q_B = \frac{R_{43,12} - R_{34,12}}{R_{14,23} - R_{41,23}} \tag{22.119}$$

The **Hall mobility** is determined using the configuration of Fig. 22.36(b), in which the current and voltage contacts are crossed. The **Hall coefficient** becomes

$$R_H = \frac{d}{B}\left[\frac{R_{31,42} + R_{42,13}}{2}\right] \tag{22.120}$$

In general, to minimize magnetoresistive and other effects, it is useful to average over current and magnetic field polarities. Then,

$$\begin{aligned} R_H = \left(d/B\right)\Big[&R_{31,42}(+B) - R_{13,42}(+B) + R_{42,13}(+B) - R_{24,13}(+B) + R_{13,42}(-B) \\ &- R_{31,42}(-B) + R_{24,13}(-B) - R_{42,13}(-B)\Big]/8 \end{aligned} \tag{22.121}$$

Data Analysis

The primary quantities determined from Hall effect and conductivity measurements are the Hall carrier concentration (n_H or p_H) and **mobility** (μ_H). As already discussed, $n_H = -1/eR_H$, where R_H is given by Eq. (22.120) (for a van der Pauw configuration), and $\mu_H = R_H\sigma = R_H/\rho$, where ρ is given by Eq. (22.117). Although simple 300-K values of ρ, n_H, and μ_H are quite important and widely used, it is in temperature-dependent Hall (TDH) measurements that the real power of the Hall technique is demonstrated, because then the **donor** and **acceptor** concentrations and energies can be determined. The methodology is illustrated with a GaN example.

The GaN sample discussed here was a square (6 mm × 6 mm) layer grown on sapphire to a thickness of $d = 20$ μm. Small indium dots were soldered on the corners to provide ohmic contacts, and the Hall measurements were carried out in an apparatus similar to that illustrated in Fig. 22.38. Temperature control was achieved using a He exchange-gas dewar. The temperature dependencies of n_H and μ_H are shown in Figs. 22.39 and 22.40,

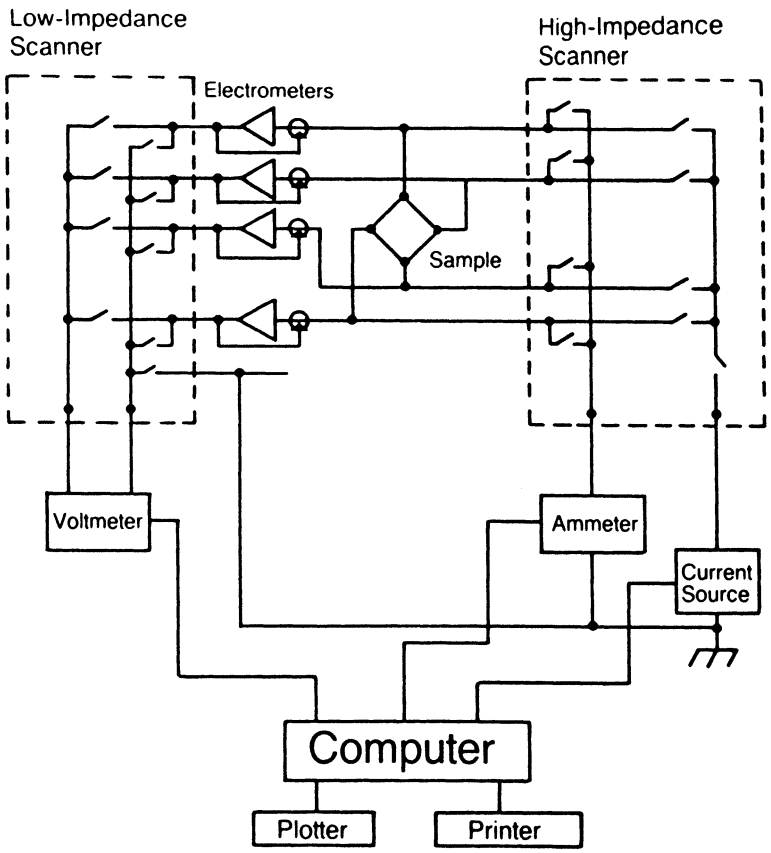

FIGURE 22.38 A schematic diagram of an automated, high-impedance Hall effect apparatus. All components are commercially available.

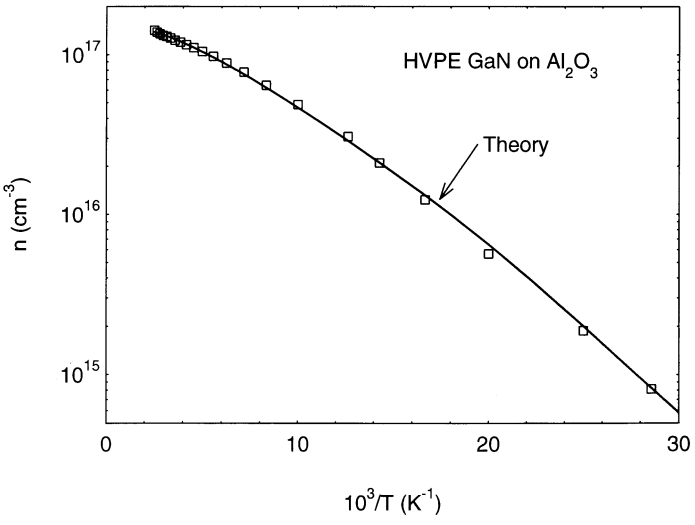

FIGURE 22.39 Hall concentration data (squares) and fit (solid line) vs. inverse temperature.

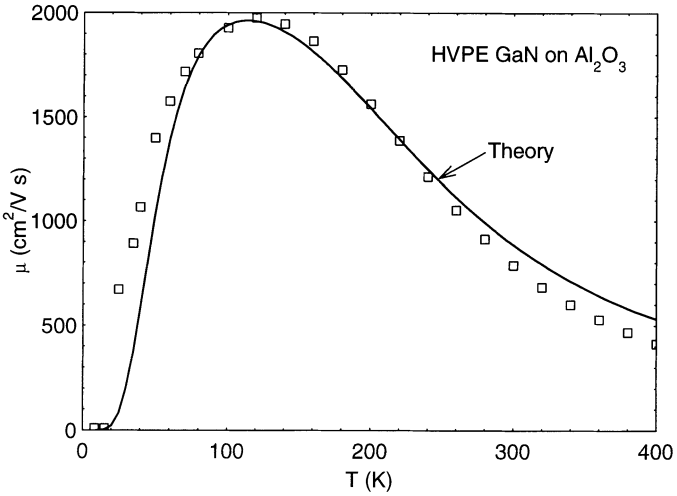

FIGURE 22.40 Hall mobility data (squares) and fit (solid line) vs. temperature.

respectively. The data in these figures have been corrected for a very thin, strongly ***n*-type** layer between the sapphire substrate and GaN layer, as discussed by Look and Molnar [1997].

The solid lines are fits of n_H and μ_H, carried out using MATHCAD software on a personal computer. In many cases, it is sufficient to simply assume $n = n_H$ (i.e., $r = 1$) in Eq. (22.105), but a more accurate answer can be obtained by using the following steps: (1) let $n = n_H = 1/eR_H$ at each T; (2) use Eq. (22.99), Eq. (22.98), and the expression $\mu_H = e\langle\tau^2\rangle/m^*\langle\tau\rangle$ to fit μ_H vs. T and get a value for N_A; (3) calculate $r = \langle\tau^2\rangle/\langle\tau\rangle^2$ at each T; (4) calculate a new $n = rn_H$ at each T; and (5) fit n vs. T with Eq. (22.105) to get values of N_D and E_D. Further iterations can be carried out if desired, but usually add little accuracy. The following parameters were taken from the literature: $P = 0.104$, $\varepsilon_0 = 10.4(8.8542 \times 10^{-12})$ F m^{-1}; $\varepsilon_\infty = 5.47(8.8542 \times 10^{-12})$ F m^{-1}; $T_{po} = 1044$ K; $m^* = 0.22(9.1095 \times 10^{-31})$ kG; $\rho_d = 6.10 \times 10^3$ kg m^{-3}; $s = 6.59 \times 10^3$ m s^{-1}; $g_0 = 1$; $g_1 = 2$; $\alpha_D = 0$; and $N_C' = 4.98 \times 10^{20}$ m^{-3}. The best value for E_1 was found to be 14 eV $= 2.24 \times 10^{-18}$ joules, although 9.2 eV is given by one literature source. The *fitted* parameters are: $N_D = 1.8 \times 10^{17}$ cm^{-3}, $N_A = 2 \times 10^{16}$ cm^{-3}, and $E_D = 18$ meV.

Sources of Error

Contact Size and Placement Effects

Much has been written about this subject over the past few decades [Look, 1989]. Indeed, it is possible to calculate errors due to contact size and placement for any of the structures shown in Fig. 22.35. For (a), (c), and (e), great care is necessary, while for (b), (d), and (f), large or misplaced contacts are not nearly as much of a problem. In general, a good rule of thumb is to keep contact size, and distance from the periphery, each below 10% of the smallest sample-edge dimension. For Hall-bar structures (a) and (b), in which the contacts cover the ends, the ratio $\ell/w > 3$ should be maintained.

Thermomagnetic Errors

Temperature gradients can set up spurious emfs that can modify the measured Hall voltage. Most of these effects, as well as misalignment of the Hall contacts in structure (b), can be averaged out by taking measurements at positive and negative values of both current and magnetic field, and then applying Eq. (22.117) and Eq. (22.121).

Conductive Substrates

If a thin film is grown on a conductive substrate, the substrate conductance may overwhelm the film conductance. If so, and if μ_{sub} and n_{sub} are known, then Eq. (22.107) and Eq. (22.108) can be reduced to a two-layer problem and used to extract μ_{bulk} and n_{bulk}. If the substrate and film are of different types (e.g., a ***p*-type** film

on an ***n*-type** substrate), then a current barrier (p/n junction) will be set up, and the measurement can possibly be made with no correction. However, in this case, the contacts must not overlap both layers.

Depletion Effects in Thin Films

Surface states as well as film/substrate interface states can deplete a thin film of a significant fraction of its charge carriers. Suppose these states lead to surface and interface potentials of ϕ_s and ϕ_i, respectively. Then, regions of width w_s and w_i will be depleted of their free carriers, where

$$w_{s(i)} = \left[\frac{2\varepsilon_0\phi_{s(i)}}{2\left(N_D - N_A\right)}\right]^{1/2} \tag{22.122}$$

It is assumed that $\phi_{s(i)} >> kT/e$, and that $e\phi_{s(i)} >> \mathcal{E}_C - \mathcal{E}_F$. The ***electrical* thickness** of the film will then be given by $d_{elec} = d - w_s - w_i$. Typical values of ϕ_s and ϕ_i are 1 V, so that if $N_D - N_A = 10^{17}$ cm^{-3}, then $w_s + w_i \approx 2000$ Å = 0.2 μm in GaN. Thus, if $d \approx 0.5$ μm, 40% of the electrons will be lost to surface and interface states, and $d_{elec} \approx$ 0.3 μm.

Inhomogeneity

A sample that is inhomogeneous in depth can be analyzed according to Eq. (22.107) and Eq. (22.108), as mentioned above. However, if a sample is *laterally* inhomogeneous, it is nearly always impossible to carry out an accurate analysis. One indication of such inhomogeneity is a resistivity ratio $Q >> 1$ (Fig. 22.37) in a *symmetric* sample, which would be expected to have $Q = 1$. The reader should be warned to *never* attempt an f-correction (Fig. 22.37) in such a case, because the f-correction is valid only for sample-shape asymmetry, not inhomogeneity.

Non-ohmic Contacts

In general, high contact resistances are not a severe problem as long as enough current can be passed to get measurable values of V_c and V_H. The reason is that the voltage measurement contacts carry very little current. However, in some cases, the contacts may set up a p/n junction and significantly distort the current flow. This situation falls under the "inhomogeneity" category, discussed above. Usually, contacts this bad show variations with current magnitude and polarity; thus, for the most reliable Hall measurements, it is a good idea to make sure the values are invariant with respect to the magnitudes and polarities of both current and magnetic field.

Defining Terms

Acceptor: An impurity or lattice defect that can "accept" one or more electrons from donors or the valence band; in the latter case, free holes are left to conduct current in the valence band.

Charge-balance equation (CBE): A mathematical relationship expressing the equality between positive and negative charges in a sample as a function of temperature.

Dislocation: A one-dimensional line defect in a solid, which often extends through the entire lattice. An *edge* dislocation is essentially an extra half-lattice plane inserted into the lattice.

Distribution function: A mathematical relationship describing the distribution of the electrons, as a function of temperature, among all the possible energy states in the lattice, including those arising from the conduction band, valence band, donors, and acceptors.

Donor: An impurity or lattice defect that can "donate" one or more electrons to acceptors or to the conduction band; in the latter case, free electrons are available to conduct current.

Effective mass: The *apparent* mass of an electron or hole with respect to acceleration in an electric field.

Electrical thickness: The "thickness" of a layer in which the current actually flows. In a thin sample, this dimension may be much less than the physical thickness of the sample because some of the charge carriers may be immobilized at surface and interface states.

Hall coefficient: The ratio between the Hall electric field E_y (a field that develops perpendicular to the plane formed by the current and magnetic field directions), and the current density j_x multiplied by the magnetic field strength B_z; i.e., $R_H = E_y/j_xB_z$. The Hall coefficient is closely related to the carrier concentration.

Hall mobility: The Hall coefficient multiplied by the conductivity. This mobility is often nearly equal to the conductivity mobility.

Lattice vibrations: The collective motions of atoms (often called phonons) in a crystal lattice. The phonons can interact with the charge carriers and reduce mobility.

Matthiessen's Rule: The approximation that the inverse of the total mobility is equal to the inverses of the individual components of the mobility; that is, $\mu^{-1} = \mu_1^{-1} + \mu_2^{-1} + \mu_3^{-1} + \ldots$, where μ_i^{-1} denotes the mobility that would result if only scattering mechanism i were present.

Mobility: The ease with which charge carriers move in a crystal lattice.

***n*-type:** The designation of a sample that has a conductivity primarily controlled by electrons.

***p*-type:** The designation of a sample that has a conductivity primarily controlled by holes.

Relaxation time: The time required to nullify a disturbance in the equilibrium energy or momentum distribution of the electrons and holes.

Relaxation time approximation (RTA): A relatively simple analytical solution of the Boltzmann transport equation that is valid for elastic (energy-conserving) scattering processes.

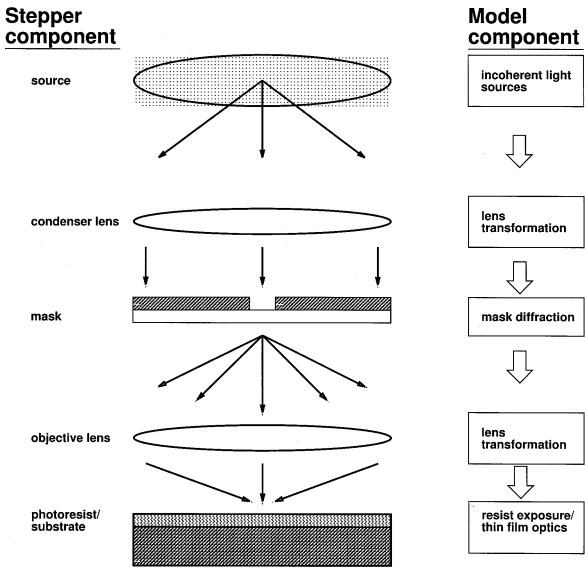

FIGURE 23.57 Optical image formation: each of the components of an imaging system affects the wavefront; between components, light follows free space propagation rules [Leon, 1998].

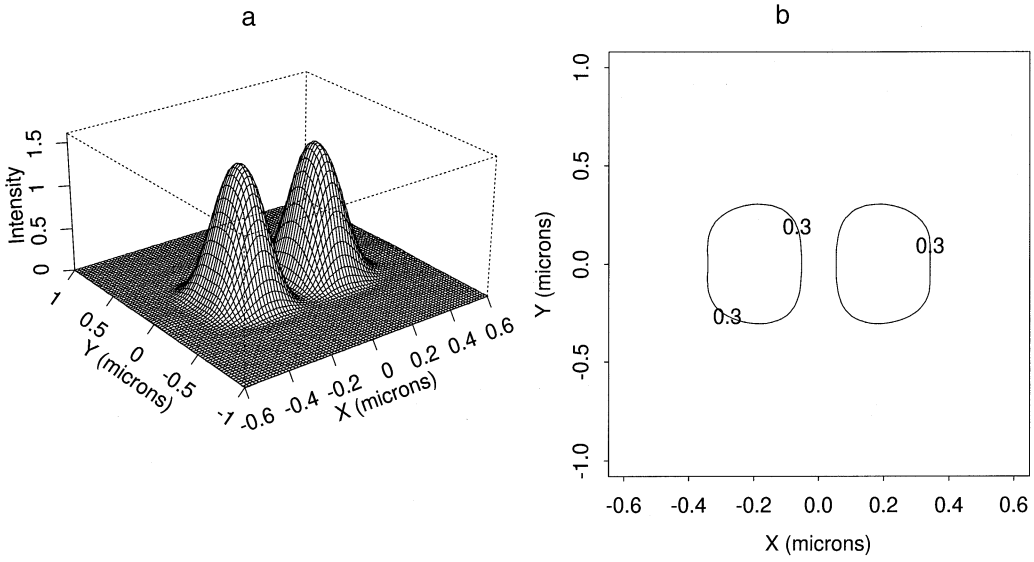

FIGURE 23.58 Aerial image: the light intensity at the resist surface due to imaging through two rectangles of size 0.28 × 0.6 μm separated by 0.12 μm [Watson, 1999] at an illumination wavelength of 248 nm. The half-wavelength feature spacing is well resolved.

Resist development is simulated based on a model introduced by Dill [1975]. The development process is treated as a surface-etching phenomenon, with the etch rate depending only on the local concentration of inhibitor. The evolution of the surface with development time can therefore be treated by the same evolution algorithms used in etching and deposition simulation.

As optical lithography is pushed to its limits in imaging ever smaller features using illumination wavelengths that are not easily reduced, simulation is playing an increasingly important role in the development of resolution-enhancement techniques such as **optical-proximity-correction (OPC)** features, **phase shift masks**, and **off axis** illumination.

Summary and Future Trends

Computer simulation of semiconductor processing has become a widely accepted technique to reduce the high cost and long turnaround time of fabrication trials. **Physically based models** of the classic process steps have been established and widely applied, while new processes such as chemical-mechanical polishing are begetting a new generation of models to simulate them. The increasing speed of computers and the improving understanding of fabrication processes, compared to the increasing cost of experiments in a multibillion dollar fabrication line, will continue to drive the development and refinement of accurate process simulation tools.

Defining Terms

Aerial image: The output of an optical simulator.

Device simulator: A computer simulation program that predicts the relation between current and voltage of an electron device based on its geometrical structure and its dopant atom distribution.

Empirical models: Models based primarily on fitting measured data without an analysis of the underlying phenomena.

Evolution simulator: A computer simulation tool for predicting the change in surface shape under the influence of surface motion rates.

Lithography simulator: A computer simulation tool for predicting the shape of resist features after exposure and development.

Monte Carlo models: Many physical systems can be modeled by following the trajectories of a representative number of individual particles under the applied forces. A random choice is made whenever statistically equally likely outcomes of events are possible.

Optical proximity correction: The modification of mask features in order to counteract undesired diffraction effects around small geometry features.

Off-axis illumination: The use of a non-point illumination source to improve lithographic resolution.

Optical simulator: A computer simulation tool for predicting light intensity at the surface of resist after passing through a projection lithography system.

Oxidation-enhanced diffusion (OED): The diffusion of dopants in the bulk of a wafer is enhanced when oxidation occurs at its surface.

Phase shift masks: The use of partially transmitting features on a mask to improve lithographic resolution.

Physically based models: Models based on fundamental physical and chemical principles.

Process simulator: A computer simulation program that predicts the outcome of the integrated circuit fabrication steps in terms of the geometrical structure and dopant distribution of the wafer.

Stokes flow: The flow of a liquid when body forces and inertial terms are negligible in comparison to viscous resistance.

Transient-enhanced diffusion (TED): The diffusion of dopants in the bulk of a wafer is very much enhanced following ion implantation.

Topography simulator: A computer simulation tool for predicting the net effect of a number of etching and deposition steps on the wafer topography.

24.1 Junction Field-Effect Transistors

Sidney Soclof

A junction field-effect transistor, or JFET, is a type of transistor in which the current flow through the device between the drain and source electrodes is controlled by the voltage applied to the gate electrode. A simple physical model of the JFET is shown in Fig. 24.1. In this JFET an *n*-type conducting channel exists between drain and source. The gate is a p^+ region that surrounds the *n*-type channel. The gate-to-channel *pn* junction is normally kept reverse-biased. As the reverse bias voltage between gate and channel increases, the depletion region width increases, as shown in Fig. 24.2. The depletion region extends mostly into the *n*-type channel because of the heavy doping on the p^+ side. The depletion region is depleted of mobile charge carriers and thus cannot contribute to the conduction of current between drain and source. Thus as the gate voltage increases, the cross-sectional areas of the *n*-type channel available for current flow decreases. This reduces the current flow between drain and source. As the gate voltage increases, the channel gets further constricted, and the current flow gets smaller. Finally when the depletion regions meet in the middle of the channel, as shown in Fig. 24.3, the channel is pinched off in its entirety between source and drain. At this point the current flow between drain and source is reduced to essentially zero. This voltage is called the **pinch-off voltage,** V_P. The pinch-off voltage is also represented by V_{GS} (off) as being the gate-to-source voltage that turns the drain-to-source current I_{DS} off. We have been considering here an *n*-channel JFET. The complementary device is the *p*-channel JFET that has an n^+ gate region surrounding a *p*-type channel. The operation of a *p*-channel JFET is the same as for an *n*-channel device, except the algebraic signs of all dc voltages and currents are reversed.

We have been considering the case for V_{DS} small compared to the pinch-off voltage such that the channel is essentially uniform from drain to source, as shown in Fig. 24.4(a). Now let's see what happens as V_{DS} increases. As an example let's assume an *n*-channel JFET with a pinch-off voltage of $V_P = -4$ V. We will see what happens

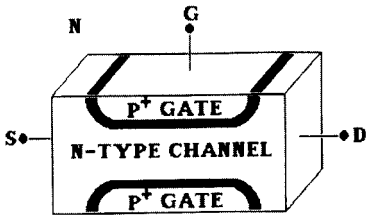

FIGURE 24.1

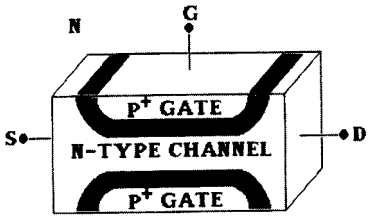

FIGURE 24.2

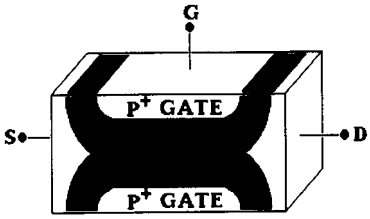

FIGURE 24.3

for the case of $V_{GS} = 0$ as V_{DS} increases. In Fig. 24.4(a) the situation is shown for the case of $V_{DS} = 0$ in which the JFET is fully "on" and there is a uniform channel from source to drain. This is at point A on the I_{DS} vs. V_{DS} curve of Fig. 24.5. The drain-to-source conductance is at its maximum value of g_{ds} (on), and the drain-to-source resistance is correspondingly at its minimum value of r_{ds} (on). Now let's consider the case of $V_{DS} = +1$ V, as shown in Fig. 24.4(b). The gate-to-channel bias voltage at the source end is still $V_{GS} = 0$. The gate-to-channel bias voltage at the drain end is $V_{GD} = V_{GS} - V_{DS} = -1$ V, so the depletion region will be wider at the drain end of the channel than at the source end. The channel will thus be narrower at the drain end than at the source end, and this will result in a decrease in the channel conductance g_{ds} and, correspondingly, an increase in the channel resistance r_{ds}. So the slope of the I_{DS} vs. V_{DS} curve that corresponds to the channel conductance will be smaller at $V_{DS} = 1$ V than it was at $V_{DS} = 0$, as shown at point B on the I_{DS} vs. V_{DS} curve of Fig. 24.5.

In Fig. 24.4(c) the situation for $V_{DS} = +2$ V is shown. The gate-to-channel bias voltage at the source end is still $V_{GS} = 0$, but the gate-to-channel bias voltage at the drain end is now $V_{GD} = V_{GS} - V_{DS} = -2$ V, so the depletion region will now be substantially wider at the drain end of the channel than at the source end. This leads to a further constriction of the channel at the drain end, and this will again result in a decrease in the channel conductance g_{ds} and, correspondingly, an increase in the channel resistance r_{ds}. So the slope of the I_{DS} vs. V_{DS} curve will be smaller at $V_{DS} = 2$ V than it was at $V_{DS} = 1$ V, as shown at point C on the I_{DS} vs. V_{DS} curve of Fig. 24.5.

In Fig. 24.4(d) the situation for $V_{DS} = +3$ V is shown, and this corresponds to point D on the I_{DS} vs. V_{DS} curve of Fig. 24.5.

When $V_{DS} = +4$ V, the gate-to-channel bias voltage will be $V_{GD} = V_{GS} - V_{DS} = 0 - 4$ V $= -4$ V $= V_P$. As a result the channel is now pinched off at the drain end but is still wide open at the source end since $V_{GS} = 0$, as shown in Fig. 24.4(e). It is very important to note that the channel is pinched off just for a very short distance at the drain end so that the drain-to-source current I_{DS} can still continue to flow. This is not at all the same situation as for the case of $V_{GS} = V_P$, where the channel is pinched off in its entirety, all the way from source to drain. When this happens, it is like having a big block of insulator the entire distance between source and drain, and I_{DS} is reduced to essentially zero. The situation for $V_{DS} = +4$ V $= -V_P$ is shown at point E on the I_{DS} vs. V_{DS} curve of Fig. 24.5.

For $V_{DS} > +4$ V, the current essentially saturates and doesn't increase much with further increases in V_{DS}. As V_{DS} increases above +4 V, the pinched-off region at the drain end of the channel gets wider, which increases r_{ds}. This increase in r_{ds} essentially counterbalances the increase in V_{DS} such that I_{DS} does not increase much. This region of the I_{DS} vs. V_{DS} curve in which the channel is pinched off at the drain end is called the **active region** and is also known as the *saturated region.* It is called the active region because when the JFET is to be used as an amplifier, it should be biased and operated in this region. The saturated value of drain current up in the active region for the case of $V_{GS} = 0$ is called the **drain saturation current,** I_{DSS} (the third subscript S

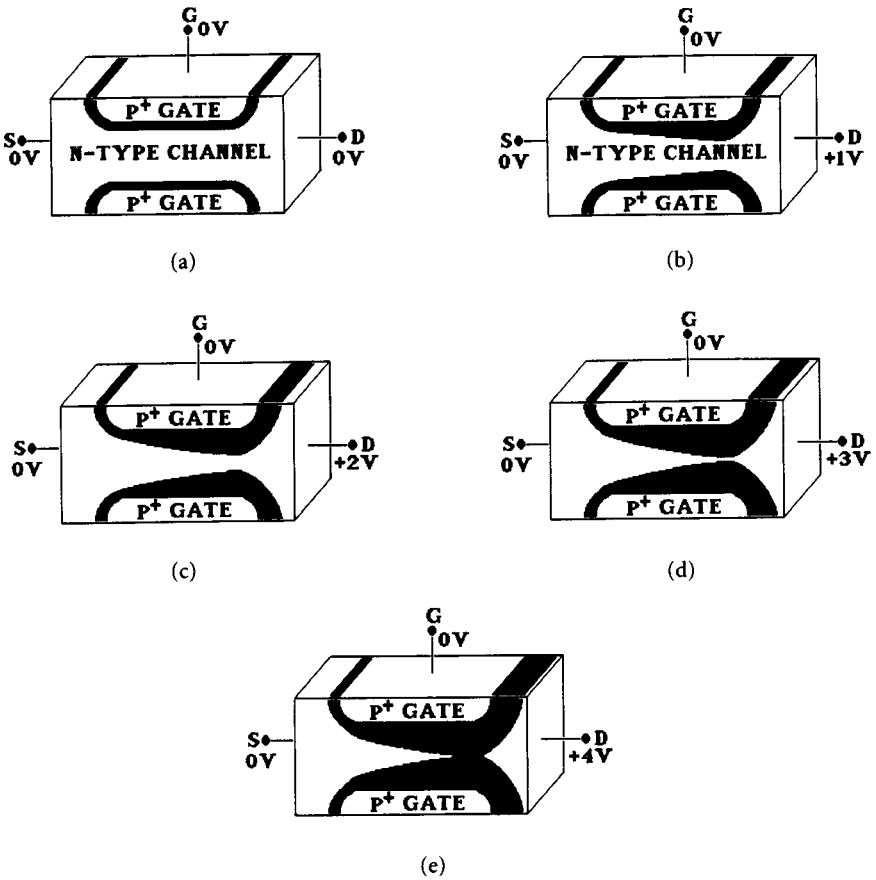

FIGURE 24.4

refers to I_{DS} under the condition of the gate *shorted* to the source). Since there is not really a true saturation of current in the active region, I_{DSS} is usually specified at some value of V_{DS}. For most JFETs, the values of I_{DSS} fall in the range of 1 to 30 mA.

The region below the active region where $V_{DS} < +4\text{ V} = -V_P$ has several names. It is called the **nonsaturated region**, the **triode region**, and the **ohmic region**. The term *triode region* apparently originates from the similarity of the shape of the curves to that of the vacuum tube triode. The term *ohmic region* is due to the variation of I_{DS} with V_{DS} as in Ohm's law, although this variation is nonlinear except for the region of V_{DS} that is small compared to the pinch-off voltage where I_{DS} will have an approximately linear variation with V_{DS}.

The upper limit of the active region is marked by the onset of the breakdown of the gate-to-channel *pn* junction. This will occur at the drain end at a voltage designated as BV_{DG}, or BV_{DS}, since $V_{GS} = 0$. This breakdown voltage is generally in the 30- to 150-V range for most JFETs.

So far we have looked at the I_{DS} vs. V_{DS} curve only for the case of $V_{GS} = 0$. In Fig. 24.6 a family of curves of I_{DS} vs. V_{DS} for various constant values of V_{GS} is presented. This is called the *drain characteristics*, also known as the *output characteristics*, since the output side of the JFET is usually the drain side. In the active region where I_{DS} is relatively independent of V_{DS}, a simple approximate equation relating I_{DS} to V_{GS} is the square-law *transfer equation* as given by $I_{DS} = I_{DSS}[1 - (V_{GS}/V_P)]^2$. When $V_{GS} = 0$, $I_{DS} = I_{DSS}$ as expected, and as $V_{GS} \rightarrow V_P$, $I_{DS} \rightarrow 0$. The lower boundary of the active region is controlled by the condition that the channel be pinched off at the drain end. To meet this condition

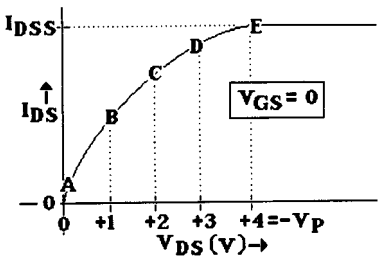

FIGURE 24.5

the basic requirement is that the gate-to-channel bias voltage at the drain end of the channel, V_{GD}, be greater than the pinch-off voltage V_P. For the example under consideration with $V_P = -4$ V, this means that $V_{GD} = V_{GS} - V_{DS}$ must be more negative than –4 V. Therefore, $V_{DS} - V_{GS} \geq +4$ V. Thus, for $V_{GS} = 0$, the active region will begin at $V_{DS} = +4$ V. When $V_{GS} = -1$ V, the active region will begin at $V_{DS} = +3$ V, for now $V_{GD} = -4$ V. When $V_{GS} = -2$ V, the active region begins at $V_{DS} = +2$ V, and when $V_{GS} = -3$ V, the active region begins at $V_{DS} = +1$ V. The dotted line in Fig. 24.6 marks the boundary between the nonsaturated and active regions.

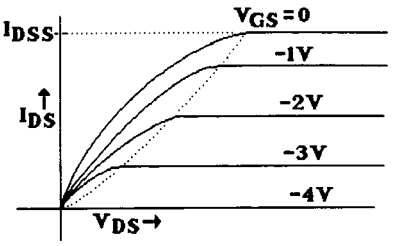

FIGURE 24.6

The upper boundary of the active region is marked by the onset of the avalanche breakdown of the gate-to-channel *pn* junction. When $V_{GS} = 0$, this occurs at $V_{DS} = BV_{DS} = BV_{DG}$. Since $V_{DG} = V_{DS} - V_{GS}$ and breakdown occurs when $V_{DG} = BV_{DG}$, as V_{GS} increases the breakdown voltage decreases, as given by $BV_{DG} = BV_{DS} - V_{GS}$. Thus $BV_{DS} = BV_{DG} + V_{GS}$. For example, if the gate-to-channel breakdown voltage is 50 V, the V_{DS} breakdown voltage will start off at 50 V when $V_{GS} = 0$ but decrease to 46 V when $V_{GS} = -4$ V.

In the nonsaturated region I_{DS} is a function of both V_{GS} and V_{DS}, and in the lower portion of the nonsaturated region where V_{DS} is small compared to V_P, I_{DS} becomes an approximately linear function of V_{DS}. This linear portion of the nonsaturated is called the *voltage-variable resistance* (VVR) region, for in this region the JFET acts like a linear resistance element between source and drain. The resistance is variable in that it is controlled by the gate voltage. This region and VVR application will be discussed in a later section. The JFET can also be operated in this region as a switch, and this will also be discussed in a later section.

JFET Biasing

Voltage Source Biasing

Now we will consider the biasing of JFETs for operation in the active region. The simplest biasing method is shown in Fig. 24.7, in which a voltage source V_{GG} is used to provide the quiescent gate-to-source bias voltage V_{GSQ}. In the active region the transfer equation for the JFET has been given as $I_{DS} = I_{DSS}[1 - (V_{GS}/V_P)]^2$, so for a quiescent drain current of I_{DSQ} the corresponding gate voltage will be given by $V_{GSQ} = V_P\,(1 - \sqrt{I_{DSQ}/I_{DSS}}$. For a Q point in the middle of the active region, we have that $I_{DSQ} = I_{DSS}/2$, so $V_{GSQ} = V_P\,(1 - \sqrt{1/2}) = 0.293\ V_P$.

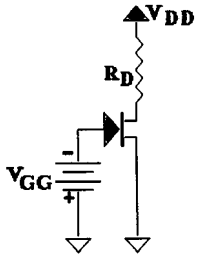

FIGURE 24.7 Voltage source biasing.

The voltage source method of biasing has several major drawbacks. Since V_P will have the opposite polarity of the drain supply voltage V_{DD}, the gate bias voltage will require a second power supply. For the case of an *n*-channel JFET, V_{DD} will come from a positive supply voltage and V_{GG} must come from a separate negative power supply voltage or battery. A second, and perhaps more serious, problem is the "open-loop" nature of this biasing method. The JFET parameters of I_{DDS} and V_P will exhibit very substantial unit-to-unit variations, often by as much as a 2:1 factor. There is also a significant temperature dependence of I_{DDS} and V_P. These variations will lead to major shifts in the position of the *Q* point and the resulting distortion of the signal. A much better biasing method is shown in Fig. 24.8.

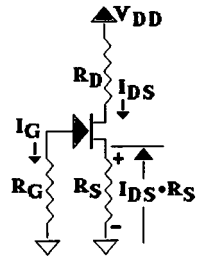

FIGURE 24.8 Self-biasing.

Self-Biasing

The biasing circuit of Fig. 24.8 is called a *self-biasing* circuit in that the gate-to-source voltage is derived from the voltage drop produced by the flow of drain current through the source biasing resistor R_S. It is a closed-loop system in that variations in the JFET parameters can be partially compensated for by the biasing circuit. The gate resistor R_G is used to provide a dc return path for the gate leakage current and is generally up in the megohm range.

The voltage drop across R_S is given by $V_S = I_{DS} \cdot R_S$. The voltage drop across the gate resistor R_G is $V_G = I_G \cdot R_G$. Since I_G is usually in the low nanoampere or even picoampere range, as long as R_G is not extremely large

the voltage drop across R_G can be neglected, so $V_G \cong 0$. Thus, we have that $V_{GS} = V_G - V_S \cong -V_S = -I_{DS} \cdot R_S$. For example, if $I_{DSS} = 10$ mA and $V_P = -4$ V, and for a Q point in the middle of the active region with $I_{DSQ} = I_{DSS}/2 = 5$ mA, we have that $V_{GSQ} = 0.293 V_P = -1.17$ V. Therefore the required value for the source biasing resistor is given by $R_S = -V_{GS}/I_{DSQ} = 1.17$ V/5 mA = 234 Ω. This produces a more stable quiescent point than voltage source biasing, and no separate negative power supply is required.

The closed-loop nature of this biasing circuit can be seen by noting that if changes in the JFET parameters were to cause I_{DS} to increase, the voltage drop across R_S would also increase. This will produce an increase in V_{GS} (in the negative direction for an *n*-channel JFET), which will act to reduce the increase in I_{DS}. Thus the net increase in I_{DS} will be less due to the feedback voltage drop produced by the flow of I_{DS} through R_S. The same basic action would, of course, occur for changes in the JFET parameters that would cause I_{DS} to decrease.

Bias Stability

Now let's examine the stability of the Q point. We will start again with the basic transfer equation as given by $I_{DS} = I_{DSS}[1 - (V_{GS}/V_P)]^2$. From this equation the change in the drain current, ΔI_{DS}, due to changes in I_{DSS}, V_{GS}, and V_P can be written as

$$\Delta I_{DS} = g_m \Delta V_{GS} - g_m \frac{V_{GS}}{V_P} \Delta V_P + \frac{I_{DS}}{I_{DSS}} \Delta I_{DSS}$$

Since $V_{GS} = -I_{DS} \cdot R_S$, $\Delta V_{GS} = -R_S \cdot \Delta I_{DS}$, we obtain that

$$\Delta I_{DS} = -g_m R_S \Delta I_{DS} - g_m \frac{V_{GS}}{V_P} \Delta V_P + \frac{I_{DS}}{I_{DSS}} \Delta I_{DSS}$$

Collecting terms in ΔI_{DS} on the left side gives

$$\Delta I_{DS}(1 + g_m R_S) = -g_m \frac{V_{GS}}{V_P} \Delta V_P + \frac{I_{DS}}{I_{DSS}} \Delta I_{DSS}$$

Now solving this for ΔI_{DS} yields

$$\Delta I_{DS} = \frac{-g_m (V_{GS}/V_P) \Delta V_P + \dfrac{I_{DS}}{I_{DSS}} \Delta I_{DSS}}{1 + g_m R_S}$$

From this we see that the shift in the quiescent drain current, ΔI_{DS}, is reduced by the presence of R_S by a factor of $1 + g_m R_S$.

If $I_{DS} = I_{DSS}/2$, then

$$g_m = \frac{2\sqrt{I_{DS} \cdot I_{DSS}}}{-V_P} = \frac{2\sqrt{I_{DS} \cdot 2I_{DS}}}{-V_P} = \frac{2\sqrt{2}\, I_{DS}}{-V_P}$$

Since $V_{GS} = 0.293 V_P$, the source biasing resistor will be $R_S = -V_{GS}/I_{DS} = -0.293\ V_P/I_{DS}$. Thus

$$g_m R_S = \frac{2\sqrt{2}\, I_{DS}}{-V_P} \times \frac{-0.293 V_P}{I_{DS}} = 2\sqrt{2} \times 0.293 = 0.83$$

so $1 + g_m R_S = 1.83$. Thus the sensitivity of I_{DS} due to changes in V_P and I_{DSS} is reduced by a factor of 1.83.

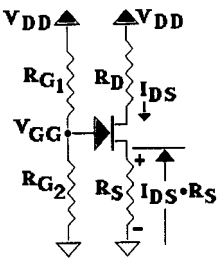

FIGURE 24.9

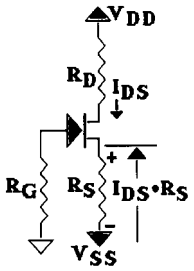

FIGURE 24.10

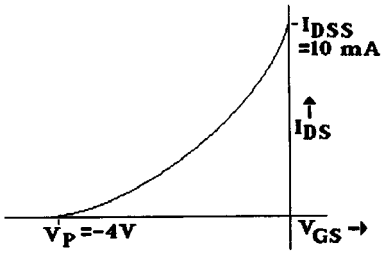

FIGURE 24.11 Transfer characteristic.

The equation for ΔI_{DS} can now be written in the following form for the fractional change in I_{DS}:

$$\frac{\Delta I_{DS}}{I_{DS}} = \frac{-0.83(\Delta V_P/V_P) + 1.41(\Delta I_{DSS}/I_{DSS})}{1.83}$$

so $\Delta I_{DS}/I_{DS} = -0.45\ (\Delta V_P/V_P) + 0.77\ (\Delta I_{DSS}/I_{DSS})$, and thus a 10% change in V_P will result in approximately a 4.5% change in I_{DS}, and a 10% change in I_{DSS} will result in an 8% change in I_{DS}. Thus, although the situation is improved with the self-biasing circuit using R_S, there will still be a substantial variation in the quiescent current with changes in the JFET parameters.

A further improvement in bias stability can be obtained by the use of the biasing methods of Figs. 24.9 and 24.10. In Fig. 24.9 a gate bias voltage V_{GG} is obtained from the V_{DD} supply voltage by means of the R_{G1}–R_{G2} voltage divider. The gate-to-source voltage is now $V_{GS} = V_G - V_S = V_{GG} - I_{DS}R_S$. So now for R_S we have $R_S = (V_{GG} - V_{GS})/I_{DS}$. Since V_{GS} is of opposite polarity to V_{GG}, this will result in a larger value for R_S than before. This in turn will result in a larger value for the $g_m R_S$ product and hence improved bias stability. If we continue with the preceding examples and now let $V_{GG} = V_{DD}/2 = +10$ V, we have that $R_S = (V_{GG} - V_{GS})/I_{DS} = [+10\text{V} - (-1.17\text{V})]/5\text{ mA} = 2.234\ \text{k}\Omega$, as compared to $R_S = 234\ \Omega$ that was obtained before. For g_m we have $g_m = 2\sqrt{I_{DS} \cdot I_{DSS}}/(-V_P) = 3.54$ mS, so $g_m R_S = 3.54\text{ mS} \cdot 2.234\ \text{k}\Omega = 7.90$. Since $1 + g_m R_S = 8.90$, we now have an improvement by a factor of 8.9 over the open-loop voltage source biasing and by a factor of 4.9 over the self-biasing method without the V_{GG} biasing of the gate.

Another biasing method that can lead to similar results is the method shown in Fig. 24.10. In this method the bottom end of the source biasing resistor goes to a negative supply voltage V_{SS} instead of to ground. The gate-to-source bias voltage is now given by $V_{GS} = V_G - V_S = 0 - (I_{DS} \cdot R_S + V_{SS})$ so that for R_S we now have $R_S = (-V_{GS} - V_{SS})/I_{DS}$. If $V_{SS} = -10$ V, and as before $I_{DS} = 5$ mA and $V_{GS} = -1.17$ V, we have $R_S = 11.7\text{ V}/5\text{ mA} = 2.34\ \text{k}\Omega$, and thus $g_m R_S = 7.9$ as in the preceding example. So this method does indeed lead to results similar to that for the R_S and V_{GG} combination biasing. With either of these two methods the change in I_{DS} due to a 10% change in V_P will be only 0.9%, and the change in I_{DS} due to a 10% change in I_{DSS} will be only 1.6%.

The biasing circuits under consideration here can be applied directly to the common-source (CS) amplifier configuration, and can also be used for the common-drain (CD), or source-follower, and common-gate (CG) JFET configurations.

Transfer Characteristics

Transfer Equation

Now we will consider the *transfer characteristics* of the JFET, which is a graph of the output current I_{DS} vs. the input voltage V_{GS} in the active region. In Fig. 24.11 a transfer characteristic curve for a JFET with $V_P = -4$ V and $I_{DSS} = +10$ mA is given. This is approximately a square-law relationship as given by $I_{DS} = I_{DSS}[1 - (V_{GS}/V_P)]^2$. This equation is not valid for V_{GS} beyond V_P (i.e., $V_{GS} < V_P$), for in this region the channel is pinched off and $I_{DS} \cong 0$.

At $V_{GS} = 0$, $I_{DS} = I_{DSS}$. This equation and the corresponding transfer curve can actually be extended up to the point where $V_{GS} \cong +0.5$ V. In the region where $0 < V_{GS} < +0.5$ V, the gate-to-channel *pn* junction is *forward-biased* and the depletion region width is reduced below the width under zero bias conditions. This reduction in the depletion region width leads to a corresponding expansion of the conducting channel and thus an increase in I_{DS} above I_{DSS}. As long as the gate-to-channel forward bias voltage is less than about 0.5 V, the *pn* junction will be essentially "off" and very little gate current will flow. If V_{GS} is increased much above +0.5 V, however, the gate-to-channel *pn* junction will turn "on" and there will be a substantial flow of gate voltage I_G. This gate current will load down the signal source and produce a voltage drop across the signal source resistance, as shown in Fig. 24.12. This voltage drop can cause V_{GS} to be much smaller than the signal source voltage V_{in}. As V_{in} increases, V_{GS} will ultimately level off at a forward bias voltage of about +0.7 V, and the signal source will lose control over V_{GS}, and hence over I_{DS}. This can result in severe distortion of the input signal in the form of clipping, and thus this situation should be avoided. Thus, although it is possible to increase I_{DS} above I_{DSS} by allowing the gate-to-channel junction to become forward-biased by a small amount ($\leq$0.5 V), the possible benefits are generally far outweighed by the risk of signal distortion. Therefore, JFETs are almost always operated with the gate-to-channel *pn* junction reverse-biased.

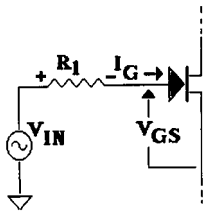

FIGURE 24.12 Effect of forward bias on V_{GS}.

Transfer Conductance

The slope of the transfer curve, dI_{DS}/dV_{GS}, is the *dynamic forward transfer conductance,* or *mutual transfer conductance,* g_m. We see that g_m starts off at zero when $V_{GS} = V_P$ and increases as I_{DS} increases, reaching a maximum when $I_{DS} = I_{DSS}$. Since $I_{DS} = I_{DSS}[1 - (V_{GS}/V_P)]^2$, g_m can be obtained as

$$g_m = \frac{dI_{DS}}{dV_{GS}} = 2I_{DSS}\frac{\left(1 - \dfrac{V_{GS}}{V_P}\right)}{-V_P}$$

Since

$$1 - \left(\frac{V_{GS}}{V_P}\right) = \sqrt{\frac{I_{DS}}{I_{DSS}}}$$

we have that

$$g_m = 2I_{DSS}\frac{\sqrt{I_{DS}/I_{DSS}}}{-V_P} = 2\frac{\sqrt{I_{DS} \cdot I_{DSS}}}{-V_P}$$

The maximum value of g_m is obtained when $V_{GS} = 0$ ($I_{DS} = I_{DSS}$) and is given by $g_m(V_{GS} = 0) = g_{m0} = 2I_{DS}/(-V_P)$.

Small-Signal AC Voltage Gain

Let's consider the CS amplifier circuit of Fig. 24.13. The input ac signal is applied between gate and source, and the output ac voltage is taken between drain and source. Thus the source electrode of this triode device is common to input and output, hence the designation of this JFET configuration as a CS amplifier.

A good choice of the dc operating point or quiescent point (Q point) for an amplifier is in the middle of the active region at $I_{DS} = I_{DSS}/2$. This allows for the maximum symmetrical drain current swing, from the quiescent level of $I_{DSQ} = I_{DSS}/2$, down to a minimum of $I_{DS} \cong 0$, and up to a maximum of $I_{DS} = I_{DSS}$. This choice for the Q point is also a good one from the standpoint of allowing for an adequate safety margin for the location

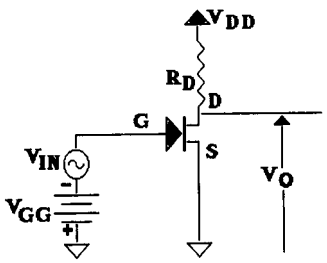

FIGURE 24.13 Common-source amplifier.

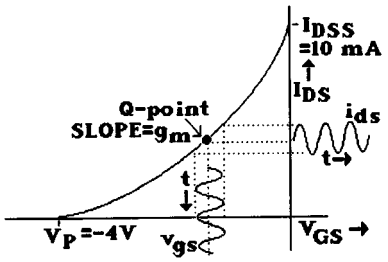

FIGURE 24.14 Transfer characteristic.

of the actual Q point due to the inevitable variations in device and component characteristics and values. This safety margin should keep the Q point well away from the extreme limits of the active region, and thus ensure operation of the JFET in the active region under most conditions. If $I_{DSS} = +10$ mA, then a good choice for the Q point would thus be around +5.0 mA. If $V_P = -4$ V, then

$$g_m = \frac{2\sqrt{I_{DS} \cdot I_{DSS}}}{-V_P} = \frac{2\sqrt{5\text{ mA} \cdot 10\text{ mA}}}{4\text{ V}} = 3.54\text{ mA/V} = 3.54\text{ mS}$$

If a small ac signal voltage v_{GS} is superimposed on the dc gate bias voltage V_{GS}, only a small segment of the transfer characteristic adjacent to the Q point will be traversed, as shown in Fig. 24.14. This small segment will be close to a straight line, and as a result the ac drain current i_{ds} will have a waveform close to that of the ac voltage applied to the gate. The ratio of i_{ds} to v_{GS} will be the slope of the transfer curve as given by $i_{ds}/v_{GS} \cong dI_{DS}/dV_{GS} = g_m$. Thus $i_{ds} \cong g_m v_{GS}$. If the net load driven by the drain of the JFET is the drain load resistor R_D, as shown in Fig. 24.13, then the ac drain current i_{ds} will produce an ac drain voltage of $v_{ds} = -i_{ds} \cdot R_D$. Since $i_{ds} = g_m v_{GS}$, this becomes $v_{ds} = -g_m v_{GS} \cdot R_D$. The ac small-signal voltage gain from gate to drain thus becomes $A_V = v_O/v_{\text{in}} = v_{ds}/v_{GS} = -g_m \cdot R_D$. The negative sign indicates signal inversion as is the case for a CS amplifier.

If the dc drain supply voltage is $V_{DD} = +20$ V, a quiescent drain-to-source voltage of $V_{DSQ} = V_{DD}/2 = +10$ V will result in the JFET being biased in the middle of the active region. Since $I_{DSQ} = +5$ mA in the example under consideration, the voltage drop across the drain load resistor R_D is 10 V. Thus $R_D = 10$ V/5 mA = 2 kΩ. The ac small-signal voltage gain A_V thus becomes $A_V = -g_m \cdot R_D = -3.54$ mS · 2 kΩ = –7.07. Note that the voltage gain is relatively modest as compared to the much larger voltage gains that can be obtained in a bipolar-junction transistor (BJT) common-emitter amplifier. This is due to the lower transfer conductance of both JFETs and MOSFETs (metal-oxide semiconductor field-effect transistors) as compared to BJTs. For a BJT the transfer conductance is given by $g_m = I_C/V_T$, where I_C is the quiescent collector current and $V_T = kT/q \cong 25$ mV is the thermal voltage. At $I_C = 5$ mA, $g_m = 5$ mA/25 mV = 200 mS, as compared to only 3.5 mS for the JFET in this example. With a net load of 2 kΩ, the BJT voltage gain will be –400 as compared to the JFET voltage gain of only 7.1. Thus FETs do have the disadvantage of a much lower transfer conductance, and therefore voltage gain, than BJTs operating under similar quiescent current levels, but they do have the major advantage of a much higher input impedance and a much lower input current. In the case of a JFET the input signal is applied to the *reverse-biased* gate-to-channel *pn* junction and thus sees a very high impedance. In the case of a common-emitter BJT amplifier, the input signal is applied to the *forward-biased* base-emitter junction, and the input impedance is given approximately by $r_{\text{in}} = r_{BE} \cong 1.5 \cdot \beta \cdot V_T/I_C$. If $I_C = 5$ mA and $\beta = 200$, for example, then $r_{\text{in}} \cong 1500\ \Omega$. This moderate input resistance value of 1.5 kΩ is certainly no problem if the signal source resistance is less than around 100 Ω. However, if the source resistance is above 1 kΩ, then there will be a substantial signal loss in the coupling of the signal from the signal source to the base of the transistor. If the source resistance is in the range of above 100 kΩ, and certainly if it is above 1 MΩ, then there will be severe signal attenuation due to the BJT input impedance, and the FET amplifier will probably offer a greater overall voltage gain. Indeed, when high-impedance signal sources are encountered, a multistage amplifier with a FET input stage followed by cascaded BJT stages is often used.

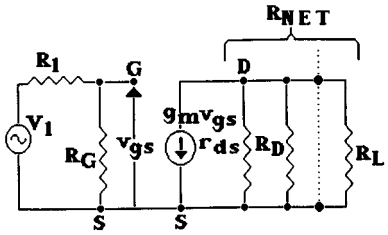

FIGURE 24.15 Effect of r_{ds} on R_{net}.

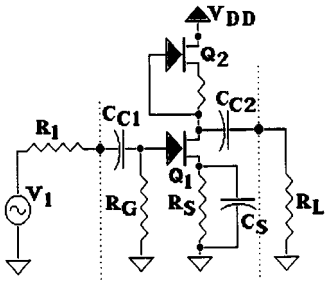

FIGURE 24.16 Active load circuit.

JFET Output Resistance

Dynamic Drain-to-Source Conductance

For the JFET in the active region the drain current I_{DS} is a strong function of the gate-to-source voltage V_{GS} but is relatively independent of the drain-to-source voltage V_{DS}. The transfer equation has previously been stated as $I_{DS} = I_{DSS}\,[1 - (V_{GS}/V_P)]^2$.

The drain current will, however, increase slowly with increasing V_{DS}. To take this dependence of I_{DS} on V_{DS} into account, the transfer equation can be modified to give

$$I_{DS} = I_{DSS}\left(1 - \frac{V_{GS}}{V_P}\right)^2\left(1 + \frac{V_{DS}}{V_A}\right)$$

where V_A is a constant called the *Early voltage* and is a parameter of the transistor with units of volts. The early voltage V_A is generally in the range of 30 to 300 V for most JFETs. The variation of the drain current with drain voltage is the result of the *channel length modulation effect* in which the channel length decreases as the drain voltage increases. This decrease in the channel length results in an increase in the drain current. In BJTs a similar effect is the *base width modulation effect.*

The *dynamic drain-to-source conductance* is defined as $g_{ds} = dI_{DS}/dV_{DS}$ and can be obtained from the modified transfer equation $I_{DS} = I_{DSS}\,[1 - (V_{GS}/V_P)]^2\,[1 + V_{DS}/V_A]$ as simply $g_{ds} = I_{DS}/V_A$. The reciprocal of g_{ds} is *dynamic drain-to-source resistance* r_{ds}, so $r_{ds} = 1/g_{ds} = V_A/I_{DS}$. If, for example, $V_A = 100$ V, we have that $r_{ds} = 100\text{ V}/I_{DS}$. At $I_{DS} = 1$ mA, $r_{ds} = 100$ V/1 mA = 100 kΩ, and at $I_{DS} = 10$ mA, $r_{ds} = 10$ kΩ.

Equivalent Circuit Model of CS Amplifier Stage

A small-signal equivalent circuit model of a CS FET amplifier stage is shown in Fig. 24.15. The ac small-signal voltage gain is given by $A_V = -g_m \cdot R_{net}$, where $R_{net} = [r_{ds} \| R_D \| RL]$ is the net load driven by the drain for the FET and includes the dynamic drain-to-source resistance r_{ds}. Since r_{ds} is generally much larger than $[R_D \| R_L]$, it will usually be the case that $R_{net} \cong [R_D \| R_L]$, and r_{ds} can be neglected. There are, however, some cases in which r_{ds} must be taken into account. This is especially true for the case in which an active load is used, as shown in Fig. 24.16. For this case $R_{net} = [r_{ds1} \| r_{ds2} \| R_L]$, and r_{ds} can be a limiting factor in determining the voltage gain.

Consider an example for the active load circuit of Fig. 24.16 for the case of identical JFETs with the same quiescent current. Assume that $R_L >> r_{ds}$ so that $R_{net} \cong [r_{ds1} \| r_{ds2}] = \text{VA}/(2I_{DSQ})$. Let $I_{DSQ} = I_{DSS}/2$, so $g_m = -2\sqrt{I_{DSS} \cdot I_{DSQ}}/(-V_P) = 2\sqrt{2}I_{DSQ}/(-V_P)$. The voltage gain is

$$A_V = -g_m \cdot R_{net} = \frac{2\sqrt{2}I_{DSQ}}{V_P} \times \frac{V_A}{2I_{DSQ}} = \sqrt{2}\,\frac{V_A}{V_P}$$

If $V_A = 100$ V and $V_P = -2$ V, we obtain $A_V = -70$, so we see that with active loads relatively large voltage gains can be obtained with FETs.

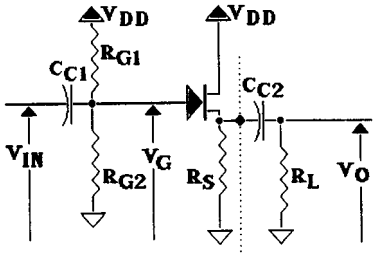

FIGURE 24.17 Source follower.

Another circuit in which the dynamic drain-to-source resistance r_{ds} is important is the constant-current source or current regulator diode. In this case the current regulation is directly proportional to the dynamic drain-to-source resistance.

Source Follower

Source-Follower Voltage Gain

We will now consider the CD JFET configuration, which is also known as the source follower. A basic CD circuit is shown in Fig. 24.17. The input signal is supplied to the gate of the JFET. The output is taken from the source of the JFET, and the drain is connected directly to the V_{DD} supply voltage, which is ac ground.

For the JFET in the active region we have that $i_{ds} = g_m v_{GS}$. For this CD circuit we also have that $v_{GS} = v_G - v_S$ and $v_S = i_{ds} R_{\text{net}}$, where $R_{\text{net}} = [R_S \| R_L]$ is the net load resistance driven by the transistor. Since $v_{GS} = i_{ds}/g_m$, we have that $i_{ds}/g_m = v_G - i_{ds} R_{\text{net}}$. Collecting terms in i_{ds} on the left side yields $i_{ds}[(1/g_m) + R_{\text{net}}] = v_G$, so

$$i_{ds} = \frac{v_G}{(1/g_m) + R_{\text{net}}} = \frac{g_m v_G}{1 + g_m R_{\text{net}}}$$

The output voltage is

$$v_O = v_S = i_{ds} R_{\text{net}} = \frac{g_m R_{\text{net}} v_G}{1 + g_m R_{\text{net}}}$$

and thus the ac small-signal voltage gain is

$$A_V = \frac{v_O}{v_G} = \frac{g_m R_{\text{net}}}{1 + g_m R_{\text{net}}}$$

Upon dividing through by g_m this can be rewritten as

$$A_V = \frac{R_{\text{net}}}{(1/g_m) + R_{\text{net}}}$$

From this we see that the voltage gain will be positive, and thus the source follower is a noninverting amplifier. We also note that A_V will always be less than unity, although for the usual case of $R_{\text{net}} >> 1/g_m$, the voltage gain will be close to unity.

The source follower can be represented as an amplifier with an open-circuit (i.e., no load) voltage transfer ratio of unity and an output resistance of $r_O = 1/g_m$. The equation for A_V can be expressed as $A_V = R_{\text{net}}/(R_{\text{net}} + r_O)$, which is the voltage division ratio of the $r_O = R_{\text{net}}$ circuit.

Source-Follower Examples

Let's consider an example of a JFET with I_{DSS} = 10 mA and V_P = –4 V. Let V_{DD} = +20 V and $I_{DSQ} = I_{DSS}/2$ = 5 mA. For $I_{DS} = I_{DSS}/2$ the value of V_{GS} is –1.17 V. To bias the JFET in the middle of the active region, we will let $V_{GQ} = V_{DD}/2$ = +10 V, so $V_{SQ} = V_{GQ} - V_{GS}$ = +10 V – (–1.17 V) = +11.17 V. Thus $R_S = V_{SQ}/I_{DSQ}$ = 11.17 V/5 mA = 2.23 kΩ.

The transfer conductance at I_{DS} = 5 mA is 3.54 mS so that $r_O = 1/g_m$ = 283 Ω. Since $g_m R_S$ = 7.9, good bias stability will be obtained. If $R_L >> R_S$, then $A_V \cong R_S/(r_O + R_S)$ = 2.23 kΩ/(283 Ω + 2.23 kΩ) = 0.887. If R_L = 1 kΩ, then R_{net} = 690 Ω, and A_V drops to 0.709, and if R_L = 300 Ω, R_{net} = 264 Ω and A_V is down to 0.483. A BJT emitter-follower circuit has the same equations for the voltage gain as the FET source follower. For the BJT case, $r_O = 1/g_m = V_T/I_O$ where V_T = thermal voltage = $kT/q \cong$ 25 mV and I_C is the quiescent collector current. For I_C = 5 mA, we get $r_O \cong$ 25 mV/5 mA = 5 Ω as compared to r_O = 283 Ω for the JFET case at the same quiescent current level. So the emitter follower does have a major advantage over the source follower since it has a much lower output resistance r_O and can thus drive very small load resistances with a voltage gain close to unity. For example, with R_L = 100 Ω, we get $A_V \cong$ 0.26 for the source follower as compared to $A_V \cong$ 0.95 for the emitter follower.

The FET source follower does, however, offer substantial advantages over the emitter follower of a much higher input resistance and a much lower input current. For the case in which a very high-impedance source, up in the megohm range, is to be coupled to a low-impedance load down in the range of 100 Ω or less, a good combination to consider is that of a cascaded FET source follower followed by a BJT emitter follower. This combination offers the very high input resistance of the source follower and the very low output resistance of the emitter follower.

For the source-follower circuit under consideration the input resistance will be $R_{in} = [R_{G1} \| R_{G2}]$ = 10 MΩ. If the JFET gate current is specified as 1 nA (max), and for good bias stability the change in gate voltage due to the gate current should not exceed $|V_P|/10$ = 0.4 V, the maximum allowable value for $[R_{G1} \| R_{G2}]$ is given by $I_G \cdot [R_{G1} \| R_{G2}] < 0.4$ V. Thus $[R_{G1} \| R_{G2}] < 0.4$ V/1 nA = 0.4 GΩ = 400 MΩ. Therefore R_{G1} and R_{G2} can each be allowed to be as large as 800 MΩ, and very large values for R_{in} can thus be obtained. At higher frequencies the input capacitance C_{in} must be considered, and C_{in} will ultimately limit the input impedance of the circuit. Since the input capacitance of the FET will be comparable to that of the BJT, the advantage of the FET source follower over the BJT emitter follower from the standpoint of input impedance will be obtained only at relatively low frequencies.

Source-Follower Frequency Response

The input capacitance of the source follower is given by $C_{in} = C_{GD} + (1 - A_V)C_{GS}$. Since A_V is close to unity, C_{in} will be approximately given by $C_{in} \cong C_{GD}$. The source-follower input capacitance can, however, be reduced below C_{GD} by a bootstrapping circuit in which the drain voltage is made to follow the gate voltage. Let's consider a representative example in which C_{GD} = 5 pF, and let the signal-source output resistance be R_1 = 100 kΩ. The input circuit is in the form of a simple *RC* low-pass network. The *RC* time constant is

$$\tau = [R \| R_{G1} \| R_{G2}] \cdot C_{in} \cong R_1 \cdot C_{in} \cong R_1 \cdot C_{GD}$$

Thus $\tau \cong$ 100 kΩ · 5 pF = 500 ns = 0.5 μs. The corresponding 3-dB or half-power frequency is $f_H = 1/(2\pi\tau)$ = 318 kHz. If R_1 = 1 MΩ, the 3-dB frequency will be down to about 30 kHz. Thus we see indeed the limitation on the frequency response that is due to the input capacitance.

Frequency and Time-Domain Response

Small-Signal CS Model for High-Frequency Response

We will now consider the frequency- and time-domain response of the JFET CS amplifier. In Fig. 24.18 an ac representation of a CS amplifier is shown, the dc biasing not being shown. In Fig. 24.19 the JFET small-signal ac equivalent circuit model is shown including the junction capacitances C_{GS} and C_{GD}. The gate-to-drain capacitance C_{GD} is a feedback capacitance in that it is connected between output (drain) and input (gate). Using

Miller's theorem for shunt feedback this feedback capacitance can be transformed into an equivalent input capacitance $C_{GD'} = (1 - A_V)C_{GD}$ and an equivalent output capacitance $C_{GD''} = (1 - 1/A_V)C_{GD}$, as shown in Fig. 24.20. The net input capacitance is now $C_{in} = C_{GS} + (1 - A_V)C_{GD}$ and the net output capacitance is $C_O = (1 - 1/A_V)C_{GD} + C_L$. Since the voltage gain A_V is given by $A_V = -g_m R_{net}$, where R_{net} represents the net load resistance, the equations for C_{in} and C_O can be written approximately as $C_{in} = C_{GS} + (1 + g_m R_{net})C_{GD}$ and $C_O = [1 + 1/(g_m R_{net})]C_{GD} + C_L$. Since usually $A_V = g_m R_{net} >> 1$, C_O can be written as $C_O \cong C_{GD} + C_L$. Note that the voltage gain given by $A_V = -g_m R_{net}$ is not valid in the higher frequency, where A_V will decrease with increasing frequency. Therefore the expressions for C_{in} and C_O will not be exact but will still be a useful approximation for the determination of the frequency- and time-domain responses. We also note that the contribution of C_{GD} to the input capacitance is increased by the Miller effect factor of $1 + g_m R_{net}$.

The circuit in Fig. 24.21 is in the form of two cascaded RC low-pass networks. The RC time constant on the input side is $\tau_1 = [R_1 \| R_G] \cdot C_{in} \cong R_1 \cdot C_{in}$, where R_1 is the signal-source resistance. The RC time constant on the output side is given by $\tau_2 = R_{net} \cdot C_O$. The corresponding breakpoint frequencies are

$$f_1 = \frac{1}{2\pi\tau_1} = \frac{1}{2\pi R_1 \cdot C_{in}}$$

and

$$f_2 = \frac{1}{2\pi\tau_2} = \frac{1}{2\pi R_{net} \cdot C_O}$$

The 3-dB or half-power frequency of this amplifier stage will be a function of f_1 and f_2. If these two breakpoint frequencies are separated by at least a decade (i.e., 10:1 ratio), the 3-dB frequency will be approximately equal to the lower of the two breakpoint frequencies. If the breakpoint frequencies are not well separated, then the 3-dB frequency can be obtained from the following approximate relationship: $(1/f_{3dB})^2 \cong (1/f_1)^2 + (1/f_2)^2$. The time-domain response as expressed in terms of the 10 to 90% rise time is related to the frequency-domain response by the approximate relationship that $t_{rise} \cong 0.35/f_{3dB}$.

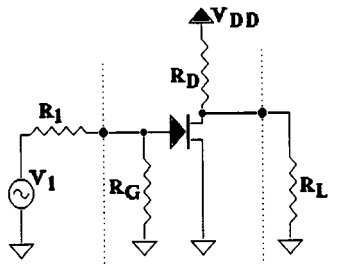

FIGURE 24.18 Common-source amplifier.

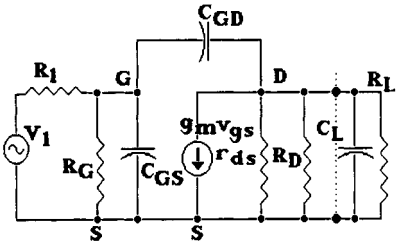

FIGURE 24.19 AC small-signal model.

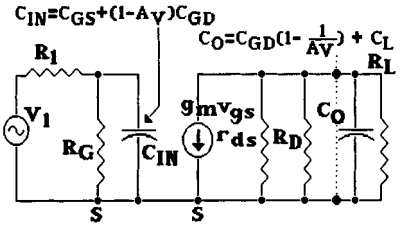

FIGURE 24.20

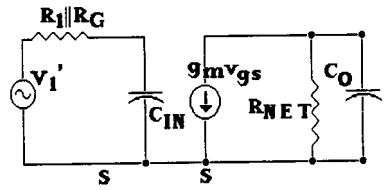

FIGURE 24.21

We will now consider a representative example. We will let $C_{GS} = 10$ pF and $C_{GD} = 5$ pF. We will assume that the net load driven by the drain of the transistors is $R_{net} = 2$ kΩ and $C_L = 10$ pF. The signal-source resistance $R_1 = 100$ Ω. The JFET will have $I_{DSS} = 10$ mA, $I_{DSQ} = I_{DSS}/2 = 5$ mA, and $V_P = -4$ V, so $g_m = 3.535$ mS. Thus the midfrequency gain is $A_V = -g_m R_{net} = -3.535$ mS · 2 kΩ = –7.07. Therefore we have that

$$C_{in} \cong C_{GS} + (1 + g_m R_{net})C_{GD} = 10 \text{ pF} + 8.07 \cdot 5 \text{ pF} = 50.4 \text{ pF}$$

and

$$C_O \cong C_{GD} + C_L = 15 \text{ pF}$$

Thus $\tau_1 = R_1 \cdot C_{in} = 100\ \Omega \cdot 50.4$ pF = 5040 ps = 5.04 ns, and $\tau_2 = R_{net} \cdot C_O = 2$ k$\Omega \cdot 15$ pF = 30 ns. The corresponding breakpoint frequencies are $f_1 = 1/(2\pi \cdot 5.04\text{ ns}) = 31.6$ MHz and $f_2 = 1/(2\pi \cdot 30\text{ ns}) = 5.3$ MHz. The 3-dB frequency of the amplifier can be obtained from $(1/f_{3dB})^2 \cong (1/f_1)^2 + (1/f_2)^2 = (1/31.6\text{ MHz})^2 + (1/5.3\text{ MHz})^2$, which gives $f_{3dB} \cong 5.2$ MHz. The 10 to 90% rise time can be obtained from $t_{rise} \cong 0.35/f_{3dB} = 0.35/5.2$ MHz = 67 ns.

In the preceding example the dominant time constant is the output circuit time constant of $\tau_2 = 30$ ns due to the combination of load resistance and output capacitance. If we now consider a signal-source resistance of 1 kΩ, the input circuit time constant will be $\tau_1 = R_1 \cdot C_{in} = 1000\ \Omega \cdot 50.4$ pF = 50.4 ns. The corresponding breakpoint frequencies are $f_1 = 1/(2\pi \cdot 50.4\text{ ns}) = 3.16$ MHz and $f_2 = 1/(2\pi \cdot 30\text{ ns}) = 5.3$ MHz. The 3-dB frequency is now $f_{3dB} \cong 2.7$ MHz, and the rise time is $t_{rise} \cong 129$ ns. If R_1 is further increased to 10 kΩ, we obtain $\tau_1 = R_1 \cdot C_{in} = 10$ k$\Omega \cdot 50.4$ pF = 504 ns, giving breakpoint frequencies of $f_1 = 1/(2\pi \cdot 504\text{ ns}) = 316$ kHz and $f_2 = 1/(2\pi \cdot 30\text{ ns}) = 5.3$ MHz. Now τ_1 is clearly the dominant time constant, the 3-dB frequency is now down to $f_{3dB} \cong f_1 = 316$ kHz, and the rise time is up to $t_{rise} \cong 1.1$ µs. Finally, for the case of $R_1 = 1$ MΩ, the 3-dB frequency will be only 3.16 kHz and the rise time will be 111 µs.

Use of Source Follower for Impedance Transformation

We see that large values of signal-source resistance can seriously limit the amplifier bandwidth and increase the rise time. In these cases, the use of an impedance transforming circuit such as an FET source follower or a BJT emitter follower can be very useful. Let's consider the use of a source follower as shown in Fig. 24.22. We will assume that both FETs are identical to the one in the preceding examples and are biased at $I_{DSQ} = 5$ mA. The source follower Q_1 will have an input capacitance of $C_{in} = C_{GD} + (1 - A_{V1})C_{GS} \cong C_{GD} = 5$ pF, since A_V will be very close to unity for a source follower that is driving a CS amplifier. The source-follower output resistance will be $r_O = 1/g_m = 1/3.535$ mS = 283 Ω. Let's again consider the case of $R_1 = 1$ MΩ. The time constant due to the combination of R_1 and the input capacitance of the source follower is $\tau_{SF} = 1$ M$\Omega \cdot 5$ pf = 5 µs. The time constant due to the combination of the source-follower output resistance r_O and the input capacitance of the CS stage is $\tau_1 = r_O \cdot C_{in} = 283\ \Omega \cdot 50.4$ pF = 14 ns, and the time constant of the output circuit is $\tau_2 = 30$ ns, as before. The breakpoint frequencies are $f_{SF} = 31.8$ kHz, $f_1 = 11$ MHz, and $f_2 = 5.3$ MHz. The 3-dB frequency of the system is now $f_{3dB} \cong f_{SF} = 31.8$ kHz, and the rise time is $t_{rise} \cong 11$ µs. The use of the source follower thus results in an improvement by a factor of 10:1 over the preceding circuit.

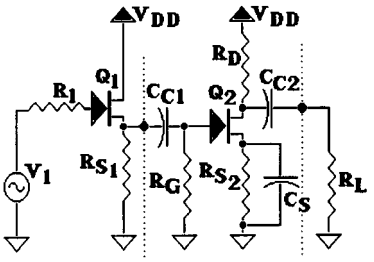

FIGURE 24.22

Voltage-Variable Resistor

Operation of a JFET as a Voltage-Variable Resistor

We will now consider the operation of a JFET as a voltage-variable resistor (VVR). A JFET can be used as a VVR in which the drain-to-source resistance r_{ds} of the JFET can be varied by variation of V_{GS}. For values of $V_{DS} << V_P$ the I_{DS} vs. V_{DS} characteristics are approximately linear, so the JFET looks like a resistor, the resistance value of which can be varied by the gate voltage as shown in Fig. 24.23.

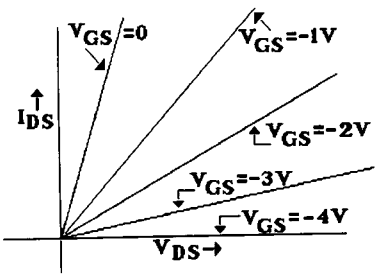

FIGURE 24.23

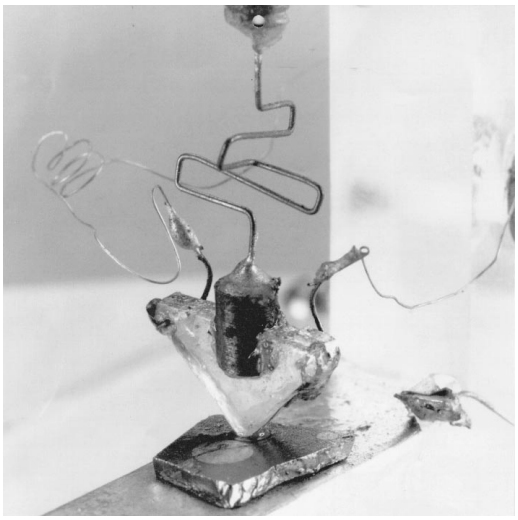
The channel conductance in the region where $V_{DS} << V_P$ is given by $g_{ds} = A\sigma/L = WH\sigma/L$, where the channel height H is given by $H = H_0 - 2W_D$. In this equation W_D is the depletion region width and H_0 is the value of H as $W_D \rightarrow 0$. The depletion region width is given by $W_D = K\sqrt{V_J} = K\sqrt{V_{GS} + \phi}$, where K is a constant, V_J is the junction voltage, and ϕ is the *pn*-junction contact potential (typically around 0.8 to 1.0 V). As V_{GS} increases, W_D increases and the channel height H decreases as given by $H = H_0 - 2K\sqrt{V_{GS} + \phi}$. When $V_{GS} = V_P$, the channel is completely pinched off, so $H = 0$ and thus $2K\sqrt{V_P + \phi} = H_0$. Therefore $2K = H_0/\sqrt{V_P + \phi}$, and thus

The Invention of the Transistor

In 1907, the American Telephone and Telegraph Company (AT&T) and the Western Electric Company combined their engineering departments and established the Bell Telephone Laboratory on West Street in New York City. By 1921, the laboratories constituted the largest industrial research organization in the country, occupying 400,000 square feet in a 13-story building in lower Manhattan and employing more than 1500 men and women. The organization was put on a more formal footing in 1925, when Frank B. Jewett was made President of Bell Telephone Laboratories, Inc. In the following decades, the labs distinguished themselves by contributions not only to communications technology, but to basic science as well. The awarding of the Nobel Prize in Physics to Clinton J. Davisson in 1937 was simply the most prominent recognition of the laboratories' scientific work.



The first point-contact transistor developed at Bell Labs in 1947 by John Bardeen, William Shockley, and Walter Brattain, had a thin gold foil along the sides of a polystyrene triangle. The foil was slit at the triangle's apex and was pressed against a piece of germanium by the metal piece at the top of the photo (Photo courtesy of AT&T Bell Laboratories.)

The true importance of the fusion of science and engineering in the industrial laboratory was made apparent to all in the years after World War II. In 1947, three Bell Labs physicist-engineers produced the single most significant electronic invention of the era—the transistor. John Bardeen, Walter Brattain, and William Shockley were consciously seeking to exploit new technology about the behavior of semiconducting materials when they devised a way to make a crystal of germanium do the work of a triode vacuum tube, the most basic of electronic components.

$$H = H_0 - H_0 \frac{\sqrt{V_{GS} + \phi}}{\sqrt{V_P + \phi}} = H_0 \left(1 - \frac{\sqrt{V_{GS} + \phi}}{\sqrt{V_P + \phi}} \right)$$

For g_{ds} we now have

$$g_{ds} = \frac{\sigma WH}{L} = \sigma \frac{WH_0}{L} \left(1 - \frac{\sqrt{V_{GS} + \phi}}{\sqrt{V_P + \phi}} \right)$$

When $V_{GS} = 0$, the channel is fully open or "on," and

$$g_{ds} = g_{ds}(\text{on}) = \sigma \frac{WH_0}{L} \left(1 - \frac{\sqrt{\phi}}{\sqrt{V_P + \phi}} \right)$$

AT&T Bell Laboratories

This photograph taken in 1948 is of the three Bell Labs physicist-engineers, John Bardeen, William Shockley, and Walter Brattain, who invented the first transistor. (Photo courtesy of AT&T Bell Laboratories.)

Their work built on the research of many before them, and much had to be done before the transistor and the solid-state devices that followed could become practical engineering tools, but in retrospect it is clear that the transistor gave the engineer the key to a whole new electronic world. (Courtesy of the IEEE Center for the History of Electrical Engineering.)

The drain-to-source conductance can now be expressed as

$$g_{ds} = g_{ds}(\text{on}) \frac{1 - \left(\sqrt{V_{GS} + \phi} \Big/ \sqrt{V_P + \phi}\right)}{1 - \left(\sqrt{\phi} \Big/ \sqrt{V_P + \phi}\right)}$$

The reciprocal quantity is the drain-to-source resistance r_{ds} as given by $r_{ds} = 1/g_{ds}$, and $r_{ds}(\text{on}) = 1/g_{ds}(\text{on})$, so

$$r_{ds} = r_{ds}(\text{on}) \frac{1 - \left(\sqrt{\phi} \Big/ \sqrt{V_P + \phi}\right)}{1 - \left(\sqrt{V_{GS} + \phi} \Big/ \sqrt{V_P + \phi}\right)}$$

As $V_{GS} \rightarrow 0$, $r_{ds} \rightarrow r_{ds}(\text{on})$, and as $V_{GS} \rightarrow V_P$, $r_{ds} \rightarrow \infty$. This latter condition corresponds to the channel being pinched off in its entirety all the way from source to drain. This is like having a big block of insulator (i.e., the depletion region) between source and drain. When $V_{GS} = 0$, r_{ds} is reduced to its minimum value of $r_{ds}(\text{on})$,

which for most JFETs is in the 20- to 400-Ω range. At the other extreme, when $V_{GS} > V_P$, the drain-to-source current I_{DS} is reduced to a very small value, generally down into the low nanoampere or even picoampere range. The corresponding value of r_{ds} is not really infinite but is very large, generally well up into the gigaohm (1000 MΩ) range. Thus by variation of V_{GS}, the drain-to-source resistance can be varied over a very wide range. As long as the gate-to-channel junction is reverse-biased, the gate current will be very small, generally down in the low nanoampere or even picoampere range, so the gate as a control electrode draws very little current. Since V_P is generally in the 2- to 5-V range for most JFETs, the V_{DS} values required to operate the JFET in the VVR range are generally <0.1 V. In Fig. 24.23 the VVR region of the JFET I_{DS} vs. V_{DS} characteristics is shown.

VVR Applications

Applications of VVRs include automatic gain control (AGC) circuits, electronic attenuators, electronically variable filters, and oscillator amplitude control circuits.

When using a JFET as a VVR, it is necessary to limit V_{DS} to values that are small compared to V_P to maintain good linearity. In addition V_{GS} should preferably not exceed 0.8 V_P for good linearity, control, and stability. This limitation corresponds to an r_{ds} resistance ratio of about 10:1. As V_{GS} approaches V_P, a small change in V_P can produce a large change in r_{ds}. Thus unit-to-unit variations in V_P as well as changes in V_P with temperature can result in large changes in r_{ds} as V_{GS} approaches V_P.

The drain-to-source resistance r_{ds} will have a temperature coefficient (TC) due to two causes: (1) the variation of the channel resistivity with temperature and (2) the temperature variation of V_P. The TC of the channel resistivity is positive, whereas the TC of V_P is negative due to the negative TC of the contact potential ϕ. The positive TC of the channel resistivity will contribute to a positive TC of r_{ds}. The negative TC of V_P will contribute to a negative TC of r_{ds}. At small values of V_{GS}, the dominant contribution to the TC is the positive TC of the channel resistivity, so r_{ds} will have a positive TC. As V_{GS} gets larger, the negative TC contribution of V_P becomes increasingly important, and there will be a value of V_{GS} at which the net TC of r_{ds} is zero, and above this value of V_{GS} the TC will be negative. The TC of r_{ds}(on) is typically +0.3%/°C for *n*-channel JFETs and +0.7%/°C for *p*-channel JFETs. For example, for a typical JFET with an r_{ds}(on) = 500 Ω at 25°C and V_P = 2.6 V, the zero TC point will occur at V_{GS} = 2.0 V. Any JFET can be used as a VVR, although there are JFETs that are specifically made for this application.

A simple example of a VVR application is the electronic gain control circuit of Fig. 24.24. The voltage gain is given by $A_V = 1 + (R_F/r_{ds})$. If, for example, R_F = 19 kΩ and r_{ds}(on) = 1 kΩ, then the maximum gain will be $A_{V\max} = 1 + [R_F/r_{ds}(\text{on})] = 20$. As V_{GS} approaches V_P, r_{ds} will increase and become very large such that $r_{ds} >> R_F$, so that A_V will decrease to a minimum value of close to unity. Thus the gain can be varied over a 20:1 ratio. Note that $V_{DS} \cong V_{\text{in}}$, so to minimize distortion the input signal amplitude should be small compared to V_P.

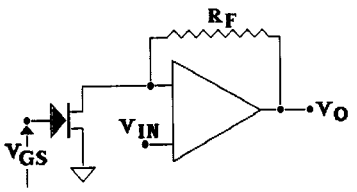


FIGURE 24.24 Electronic gain control.

Defining Terms

Active region: The region of JFET operation in which the channel is pinched off at the drain end but still open at the source end such that the drain-to-source current I_{DS} approximately saturates. The condition for this is that $|V_{GS}| < |V_P|$ and $|V_{DS}| > |V_P|$. The active region is also known as the saturated region.

Ohmic, nonsaturated, or triode region: The three terms all refer to the region of JFET operation in which a conducting channel exists all the way between source and drain. In this region the drain current varies with both V_{GS} and V_{DS}.

Drain saturation current, I_{DSS}: The drain-to-source current flow through the JFET under the conditions that $V_{GS} = 0$ and $|V_{DS}| > |V_P|$ such that the JFET is operating in the active or saturated region.

Pinch-off voltage, V_P: The voltage that when applied across the gate-to-channel *pn* junction will cause the conducting channel between drain and source to become pinched off. This is also represented as V_{GS} (off).

24.2 Bipolar Transistors

Joseph Watson

Modern amplifiers abound in the form of *integrated circuits* (ICs), which contain transistors, diodes, and other structures diffused into single-crystal *dice.* As an introduction to these ICs, it is convenient to examine sing-transistor amplifiers, which in fact are also widely used in their own right as *discrete* circuits — and indeed much more complicated discrete signal-conditioning circuits are frequently found following sensors of various sorts.

There are two basic forms of transistor, the *bipolar* family and the *field-effect* family, and both appear in ICs. They differ in their modes of operation but may be incorporated into circuits in quite similar ways. To understand elementary circuits, there is no need to become too familiar with the physics of transistors, but some basic facts about their electrical properties must be known.

Consider the bipolar transistor, of which there are two types, *npn* and *pnp.* Electrically, they differ only in terms of current direction and voltage polarity. Figure 24.25(a) illustrates the idealized structure of an *npn* transistor, and diagram (b) implies that it corresponds to a pair of diodes with three leads. This representation does *not* convey sufficient information about the actual operation of the transistor, but it does make the point that the flow of conventional current (positive to negative) is easy from the *base* to the *emitter,* since it passes through a *forward-biased diode,* but difficult from the *collector* to the *base,* because flow is prevented by a *reverse-biased diode.*

Figure 24.25(c) gives the standard symbol for the *npn* transistor, and diagram (d) defines the direction of current flow and the voltage polarities observed when the device is in operation. Finally, diagram (e) shows that for the *pnp* transistor, all these directions are reversed and the polarities are inverted.

For a transistor, there is a main current flow between the collector and the emitter, and a very much smaller current flow between the base and the emitter. So, the following relations may be written:

$$I_E = I_C + I_B \tag{24.1}$$

(Note that the arrow on the transistor symbol defines the emitter and the direction of current flow—*out* for the *npn* device, and *in* for the *pnp.*) Also

$$I_C / I_B = h_{FE} \tag{24.2}$$

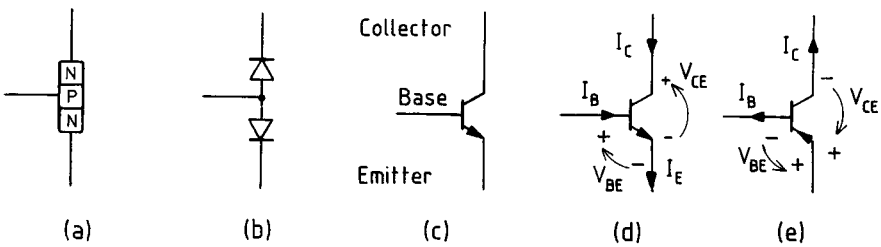

FIGURE 24.25 The bipolar transistor. (a) to (d) *npn* transistor; (e) *pnp* transistor.

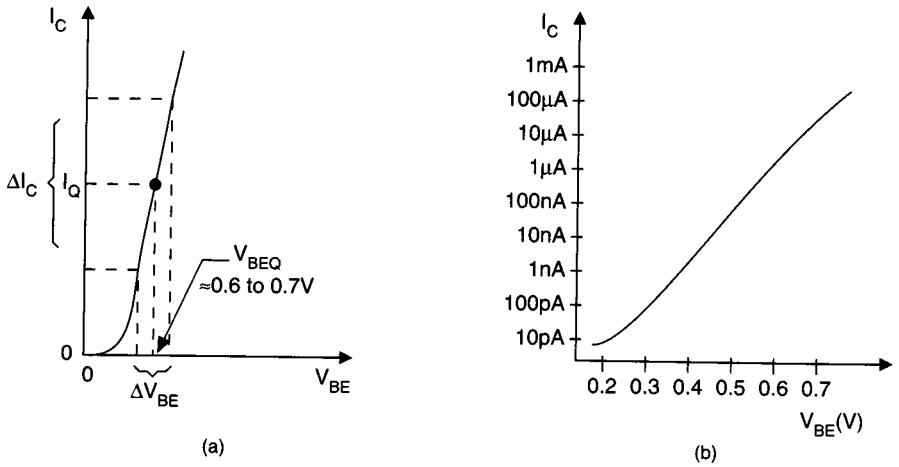

FIGURE 24.26 The transconductance curve for a transistor on (a) linear and (b) logarithmic axes.

Here, h_{FE} is called the *dc common-emitter current gain,* and because $I_C >> I_B$, then h_{FE} is large, typically 50 to 300. The implication of this may be seen immediately: if the small current I_B can be used to control the large current I_C, then the transistor may obviously be used as a current amplifier. [This is why Fig. 24.25(b) is inadequate—it completely neglects this all-important current-gain property of the transistor.] Furthermore, if a load resistance is connected into the collector circuit, it will become a voltage amplifier, too.

Unfortunately, h_{FE} is an ill-defined quantity and varies not only from transistor to transistor but also changes with temperature. The relationship between the base-emitter voltage V_{BE} and the collector current is much better defined and follows an exponential law closely over at least eight decades. This relationship is shown in both linear and logarithmic form in Fig. 24.26. Because the output current I_C is dependent upon the input voltage V_{BE}, the plot must be a transfer conductance or *transconductance* characteristic. The relevant law is

$$I_C = I_{ES}(e^{(q/kT)V_{BE}} - 1) \tag{24.3}$$

Here, I_{ES} is an extremely small leakage current internal to the transistor, q is the electronic charge, k is Boltzmann's constant, and T is the absolute temperature in kelvins. Usually, kT/q is called V_T and is about 26 mV at a room temperature of 25°C. This implies that for any value of V_{BE} over about 100 mV, then $\exp(V_{BE}/V_T) >> 1$, and for all normal operating conditions, Eq. (24.3) reduces to

$$I_C = I_{ES}e^{V_{BE}/V_T} \qquad \text{for } V_{BE} > 100 \text{ mV} \tag{24.4}$$

The term "normal operating conditions" is easily interpreted from Fig. 24.26(a), which shows that when V_{BE} has reached about 0.6 to 0.7 V, any small fluctuations in its value cause major fluctuations in I_C. This situation is illustrated by the dashed lines enclosing ΔV_{BE} and ΔI_C, and it implies that to use the transistor as an amplifier, working values of V_{BE} and I_C must be established, after which signals may be regarded as fluctuations around these values.

Under these *quiescent, operating,* or *working* conditions,

$$I_C = I_Q \qquad \text{and} \qquad V_{CE} = V_Q$$

and methods of defining these quiescent or operating conditions are called *biasing.*

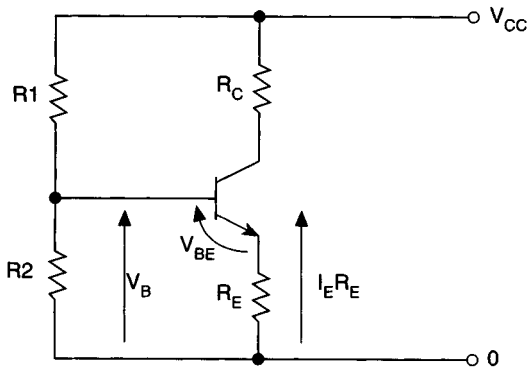

FIGURE 24.27 A transistor biasing circuit.

Biasing the Bipolar Transistor

A fairly obvious way to bias the transistor is to first establish a constant voltage V_B using a potential divider $R1$ and $R2$ as shown in the **biasing circuit** of Fig. 24.27. Here,

$$V_B \simeq \frac{V_{CC} R2}{R1 + R2}$$

if I_B is very small compared with the current through $R2$, which is usual. If it is not, this fact must be taken into account.

This voltage will be much greater than V_{BE} if a realistic power supply is used along with realistic values of $R1$ and $R2$. Hence, when the transistor is connected into the circuit, an emitter resistor must also be included so that

$$V_{BE} = V_B - I_E R_E \tag{24.5}$$

Now consider what happens when the power supply is connected. As V_B appears, a current I_B flows into the base and produces a much larger current $I_C = h_{FE} I_B$ in the collector. These currents add in the emitter to give

$$I_E = I_B + h_{FE} I_B = (1 + h_{FE}) I_B \simeq h_{FE} I_B \tag{24.6}$$

Clearly, I_E will build up until a fixed or quiescent value of base-emitter voltage V_{BEQ} appears. Should I_E try to build up further, V_{BE} will fall according to Eq. (24.5) and, hence, so will I_E. Conversely, should I_E not build up enough, V_{BE} will increase until it does so.

This is actually a case of current-derived negative feedback, and it successfully holds the collector current near the quiescent value I_Q. Furthermore, it does so in spite of different transistors with different values of h_{FE} being used and in spite of temperature variations. Actually, V_{BE} itself falls with temperature at about –2.2 mV/°C for constant I_C, and the circuit will compensate for this, too. The degree of success of the negative feedback in holding I_Q constant is called the *bias stability.*

This is one example of a **common-emitter** (CE) circuit, so-called because the emitter is the common terminal for both base and collector currents. The behavior of the transistor in such a circuit may be illustrated by superimposing a *load line* on the *output characteristics* of the transistor, as shown in Fig. 24.28.

If the collector current I_C is plotted against the collector-to-emitter voltage V_{CE}, a family of curves for various fixed values of V_{BE} or I_B results, as in Fig. 24.28. These curves show that as V_{CE} increases, I_C rises very rapidly and then turns over as it is limited by I_B. In the CE circuit, if I_B were reduced to zero, then I_C would also be

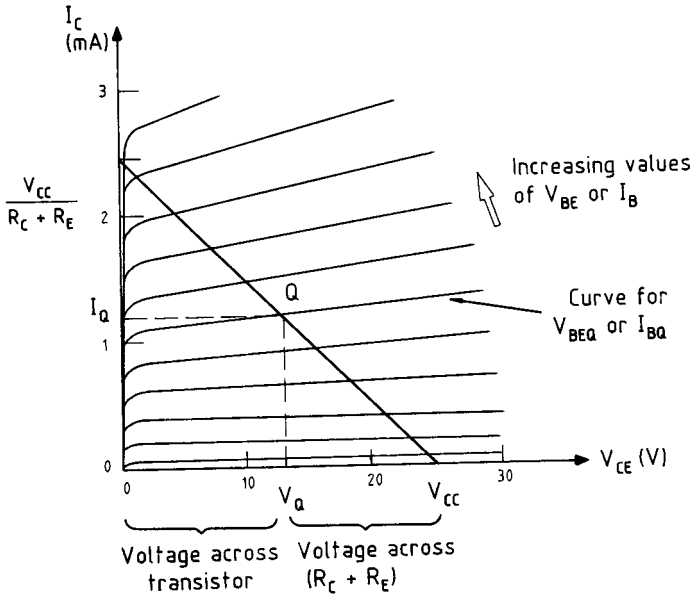

FIGURE 24.28 The load-line diagram.

zero (apart from a small leakage current I_{CE0}). Hence there would be no voltage drop in either R_C or R_E, and practically all of V_{CC} would appear across the transistor. That is, under *cut-off* conditions,

$$V_{CE} \rightarrow V_{CC} \qquad \text{for } I_B = 0 \tag{24.7}$$

Conversely, if I_B were large, I_C would be very large, almost all of V_{CC} would be dropped across $R_C + R_E$ and

$$I_C \rightarrow \frac{V_{CC}}{R_C + R_E} \qquad \text{for large } I_B \tag{24.8}$$

Actually, because the initial rise in I_C for the transistor is not quite vertical, there is always a small *saturation voltage* V_{CES} across the transistor under these conditions, where V_{CES} means the voltage across the transistor in the common-emitter mode when saturated. In this saturated condition $V_{CES} \simeq 0.3$ V for small silicon transistors. Both these conditions are shown in Fig. 24.28.

From the circuit of Fig. 24.27,

$$V_{CE} = V_{CC} - I_C(R_C + R_E) \tag{24.9a}$$

which may be rewritten as

$$I_C = -V_{CE}/(R_C + R_E) + V_{CC}/(R_C + R_E) \tag{24.9b}$$

This is the straight-line equation to the *dc load-line* (compare $y = mx + c$), showing that its slope is $-1/(R_C + R_E)$ and that it crosses the I_C axis at $V_{CC}/(R_C + R_E)$ as expected. The actual position of a point is determined by where this load line crosses the output characteristic in use, that is, by what value of V_{BE} or I_B is chosen. For example, the quiescent point for the transistor is where the load line crosses the output curve defined by $V_{BE} = V_{BEQ}$ (or $I_B = I_{BQ}$) to give $V_{CE} = V_Q$ and $I_C = I_Q$.

Note that because the transistor is *nonohmic* (that is, it does not obey Ohm's law), the voltage across it may only be determined by using the (ohmic) voltage drop across the resistors R_C and R_E according to Eq. (24.9). At the quiescent point this is

$$V_Q = V_{CC} - I_Q(R_C + R_E)$$

A design example will illustrate typical values involved with a small-transistor CE stage.

Example 1

A transistor is to be biased at a collector current of 1 mA when a 12-V power supply is applied. Using the circuit of Fig. 24.27, determine the values of $R1$, $R2$, and R_E if 3.4 V is to be dropped across R_E and if the current through $R2$ is to be 10 I_{BQ}. Assume that for the transistor used, $V_{BEQ} = 0.6$ V and $h_{FE} = 100$.

Solution. In this circuit $I_Q = 1$ mA $\simeq I_E$ (because $I_B << I_C$). Hence

$$R_E = \frac{V_{R_E}}{I_Q} = \frac{3.4}{1} = 3.4\ \text{k}\Omega$$

Also, $V_B = V_{RE} + V_{BE} = 3.4 + 0.6 = 4$ V. This gives

$$R2 = \frac{V_B}{10\ I_{BQ}}$$

where $I_{BQ} = I_Q/h_{FE} = 1/100 = 0.01$ mA, so

$$R2 = \frac{4}{10 \times 0.01} = 40\ \text{k}\Omega$$

Now $V_{R1} = V_{CC} - V_B = 12 - 4 = 8$ V, and the current through $R1$ is 10 $I_{BQ} + I_{BQ} = 11\ I_{BQ}$, so

$$R1 = \frac{V_{R1}}{I_{R1}} = \frac{8}{11 \times 0.01} = 72.7\ \text{k}\Omega$$

In the above design example, the base current I_{BQ} has been included in the current passing through $R1$. Had this not been done, $R1$ would have worked out at 80 kΩ. Usually, this difference is not very important because *discrete* (or individual) resistors are available only in a series of nominal values, and each of these is subject to a *tolerance,* including 10, 5, 2, and 1%.

In the present case, the following (5%) values could reasonably be chosen:

$$R_E = 3.3\ \text{k}\Omega \qquad R1 = 75\ \text{k}\Omega \qquad R2 = 39\ \text{k}\Omega$$

All this means that I_Q cannot be predetermined very accurately, but the circuit nevertheless settles down to a value close to the chosen one, and, most importantly, stays there almost irrespective of the transistor used and the ambient temperature encountered.

Having biased the transistor into an operating condition, it is possible to consider *small-signal operation.*

Small-Signal Operation

In the biasing circuit of Fig. 24.27, the collector resistor R_C had no discernible function, because it is simply the load resistor across which the signal output voltage is developed. However, it was included because it also drops a voltage due to the bias current flowing through it. This means that its value must not be so large that it robs the transistor of adequate operating voltage; that is, it must not be responsible for moving the operating point too far to the left in Fig. 24.28.

If the chosen bias current and voltage are I_Q and V_Q, then small signals are actually only fluctuations in these bias (or average) values that can be separated from them using coupling capacitors.

To inject an input signal to the base, causing V_{BE} and I_B to fluctuate by v_{be} and i_b, a signal source must be connected between the base and the common or zero line (also usually called ground or earth whether it is actually connected to ground or not!). However, most signal sources present a resistive path through themselves, which would shunt $R2$ and so change, or even destroy, the bias conditions. Hence, a coupling capacitor C_c must be included, as shown in Fig. 24.29, in series with a signal source represented by a Thévenin equivalent.

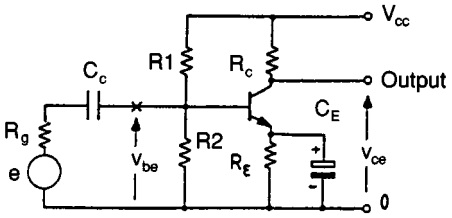

FIGURE 24.29 A complete common-emitter stage.

The emitter resistor R_E was included for biasing reasons (although there are other bias circuits that omit it), but for signal amplification purposes it must be shunted by a high-value capacitor C_E so that the signal current can flow down to ground without producing a signal voltage drop leading to negative feedback (as did the bias current). The value of C_E must be much greater than is apparent at first sight, and this point will be developed later; for the present, it will be assumed that it is large enough to constitute a short circuit at all the signal frequencies of interest. So, for ac signals R_E is short-circuited and only R_C acts as a load. This implies that a *signal* or *ac load line* comes into operation with a slope of $-1/R_C$, as shown in Fig. 24.30.

The ways in which the small-signal quantities fluctuate may now be examined. If v_{be} goes positive, this actually means that V_{BE} increases a little. This in turn implies that I_C increases by an amount i_c, so the voltage drop in R_C increases by v_{ce}. Keeping in mind that the top of R_C is held at a constant voltage, this means that the voltage at the bottom of R_C must fall by v_{ce}. This very important point shows that because v_{ce} falls as v_{be} rises, there is 180° phase shift through the stage. That is, the CE stage is an *inverting voltage amplifier.* However, because i_c increases into the collector as i_b increases into the base, it is also a *noninverting current amplifier.*

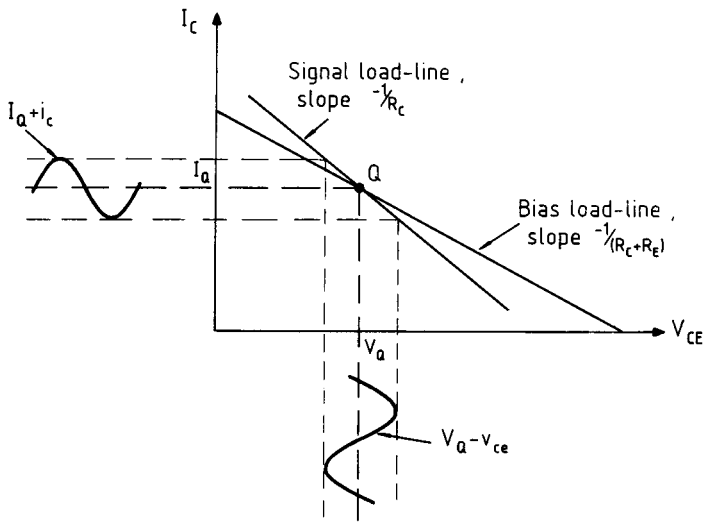

FIGURE 24.30 The signal or ac load line.

Now consider the amount by which v_{ce} changes with v_{be}, which is the *terminal voltage gain* of the stage. In Fig. 24.26, the slope of the transconductance curve at any point defines by how much I_C changes with a fluctuation in V_{BE}. That is, it gives the ratio i_c/v_{be} at any operating point Q. Equation (24.4) is

$$I_C = I_{ES} e^{V_{BE}/V_T}$$

so that

$$\frac{dI_C}{dV_{BE}} = \frac{1}{V_T} I_{ES} e^{V_{BE}/V_T}$$

or

$$\frac{i_c}{v_{be}} = \frac{I_C}{V_T} = g_m = \text{the transconductance} \tag{24.10}$$

Now the signal output voltage is

$$v_{ce} \simeq -i_c R_C$$

(Here, the approximation sign is because the collector-emitter path within the transistor does present a large resistance r_{ce} through which a very small part of i_c flows.)

The terminal voltage gain is therefore

$$A_v = \frac{v_{ce}}{v_{be}} \simeq \frac{-i_c R_C}{v_{be}} = -g_m R_C \tag{24.11}$$

where the negative sign implies signal inversion.

In practice, $V_T \simeq 26$ mV at room temperature, as has been mentioned, and this leads to a very simple numerical approximation. From Eq. (24.10) and using $I_C = I_Q$,

$$g_m = \frac{I_Q}{V_T} \simeq \frac{I_Q}{0.026} \simeq 39\, I_Q \qquad \text{mA/V}$$

if I_Q is in mA and at room temperature. This shows that irrespective of the transistor used, the transconductance may be approximated knowing only the quiescent collector current.

The magnitude and phase relationships between v_{ce} and i_c can easily be seen by including them on the signal load-line diagram as shown in Fig. 24.30, where the output characteristics of the transistor have been omitted for clarity. Sinusoidal output signals have been inserted, and either may be obtained from the other by following the signal load-line locus.

Now consider the small-signal current gain. Because the value of h_{FE} is not quite linear on the I_C/I_B graph, its slope too must be used for small-signal work. However, the departure from linearity is not great over normal working conditions, and the small-signal value h_{fe} is usually quite close to that of h_{FE}. Hence,

$$A_i = \frac{i_c}{i_b} \simeq h_{fe} \tag{24.12}$$

The small-signal or incremental input resistance to the base itself (to the right of point *X* in Fig. 24.29) may now be found:

$$R_{\text{in}} = \frac{v_{be}}{i_b} = \frac{v_{be}}{i_c}\frac{i_c}{i_b} \simeq \frac{h_{fe}}{g_m} \tag{24.13}$$

Three of the four main (midfrequency) parameters for the CE stage have now been derived, all from a rather primitive understanding of the transistor itself. The fourth, R_{out}, is the dynamic, incremental, or small-signal resistance of the transistor from collector to emitter, which is the slope of the output characteristic at the working point r_{ce}. Being associated with a reverse-biased (CB) junction, this is high—typically about 0.5 MΩ—so that the transistor acts as a current source feeding a comparatively low load resistance R_C. Summarizing, at mid frequency,

$$A_i \simeq h_{fe} \qquad A_v \simeq -g_m R_C \qquad R_{\text{in}} \simeq \frac{h_{fe}}{g_m} \qquad R_{\text{out}} \simeq r_{ce}$$

Example 2

Using the biasing values for *R*1, *R*2, and R_E already obtained in Example 1, calculate the value of R_C to give a terminal voltage gain of –150. Then determine the input resistance R_{in} if h_{fe} for the transistor is 10% higher than h_{FE}.

Solution. Because $I_Q = 1$ mA, $g_m \simeq 39 \times 1 = 39$ mA/V. Hence $A_v \simeq -g_m R_C$ or $-150 \simeq -39\, R_C$, giving

$$R_C = 150/39 \simeq 3.9\ \text{k}\Omega$$

(*Note:* This value *must* be checked to determine that it is reasonable insofar as biasing is concerned. In this case, it will drop $I_Q R_C = 1 \times 3.9 = 3.9$ V. Because $V_{RE} = 3.4$ V, this leaves 12 – 3.9 – 3.4 = 4.7 V across the transistor, which is reasonable.)

Finally,

$$R_{\text{in}} \simeq \frac{h_{fe}}{g_m} = \frac{110}{39} = 2.8\ \text{k}\Omega$$

A Small-Signal Equivalent Circuit

The conclusions reached above regarding the performance of the bipolar transistor are sufficient for the development of a basic equivalent circuit, or model, relevant *only* to small-signal operation. Taking the operating CE amplifier, this may be done by first "looking into" the base, shown as *b* in Fig. 24.31. Between this point and the actual active part of the base region *b′*, it is reasonable to suppose that the intervening (inactive) semiconductor material will present a small resistance $r_{bb'}$. This is called the *base spreading resistance*, and it is also shown in Fig. 24.31.

From *b′* to the emitter *e*, there will be a dynamic or incremental resistance given by

$$r_{b'e} = \frac{v_{b'e}}{i_b} = \frac{v_{b'e}}{i_c}\frac{i_c}{i_b} = \frac{h_{fe}}{g_m} \tag{24.14}$$

so that the full resistance from the base to the emitter must be

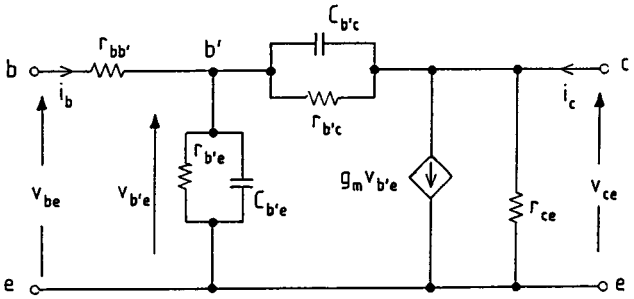

FIGURE 24.31 The hybrid-π small-signal transistor equivalent circuit or model.

$$R_{\text{in}} = r_{bb'} + r_{b'e} = r_{bb'} + \frac{h_{fe}}{g_m} \simeq \frac{h_{fe}}{g_m} \tag{24.15}$$

because $r_{bb'}$ is only about 10 to 100 Ω, which is small compared with $r_{b'e}$, this being several kilohms (as shown by the last example). It will now be understood why Eq. (24.13) gave $R_{\text{in}} \simeq h_{fe}/g_m$.

The reverse-biased junction that exists from b' to the collector ensures that the associated dynamic resistance $r_{b'c}$ will be very large indeed, which is fortunate, otherwise signal feedback from the output to the input would modify the gain characteristics of the amplifier. Typically, $r_{b'c}$ will be some tens of megohms.

However, because of transistor action, the dynamic resistance from collector to emitter, r_{ce}, will be smaller than $r_{b'c}$ and will typically be below a megohm. This "transistor action" may be represented by a current source from collector to emitter that is dependent upon either i_b or $v_{b'e}$. That is, it will be either $h_{fe}i_b$ or $g_m v_{b'e}$. The latter leads to the well-known hybrid-π model, and it is this which is shown in Fig. 24.31.

Where junctions or interfaces of any sort exist, there will always be distributed capacitances associated with them, and to make these easy to handle analytically, they may be "lumped" into single capacitances. In the present context, two lumped capacitances have been incorporated into the hybrid-π model, $C_{b'e}$ from base to emitter and $C_{b'c}$ from base to collector, respectively. These now complete the model, and it will be appreciated that they make it possible to analyze high-frequency performance. Typically, $C_{b'e}$ will be a few picofarads and will always be larger than $C_{b'c}$.

Figure 24.31 is the hybrid-π small-signal, dynamic, or incremental model for a bipolar transistor, and when external components are added and simplifications made, it makes possible the determination of the performance of an amplifier using that transistor not only at midfrequencies but at high and low frequencies, too.

Low-Frequency Performance

In Fig. 24.32 both a source and a load have been added to the hybrid-π equivalent circuit to model the complete CE stage of Fig. 24.29. Here, both $C_{b'e}$ and $C_{b'c}$ have been omitted because they are too small to affect the low-frequency performance, as has $r_{b'c}$ because it is large and so neither loads the source significantly compared to $r_{bb'} + r_{b'e}$ nor applies much feedback.

The signal source has been represented by a Thévenin equivalent that applies a signal via a coupling capacitor C_c. Note that this signal source has been returned to the emitter, which implies that the emitter resistor bypass capacitor C_E has been treated as a short circuit at all signal frequencies for the purposes of this analysis.

Because the top of biasing resistor $R1$ (Fig. 24.29) is taken to ground via the power supply insofar as the signal is concerned, it appears in parallel with $R2$, and the emitter is also grounded to the signal via C_E. That is, a composite biasing resistance to ground R_B appears:

$$R_B = \frac{R1 \cdot R2}{R1 + R2}$$

Finally, the collector load is taken to ground via the power supply and hence to the emitter via C_E.

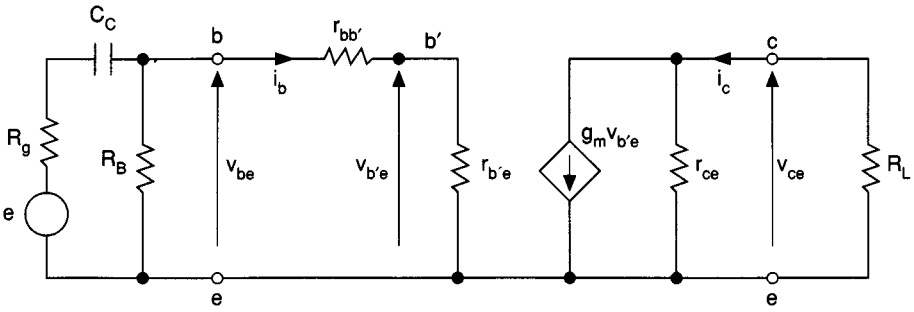

FIGURE 24.32 The loaded hybrid-π model for low frequencies.

Figure 24.32 shows that v_{be} is amplified independently of frequency, so the terminal voltage gain A_v may easily be determined:

$$A_v = \frac{v_{ce}}{v_{be}} = \frac{-i_c R_L}{v_{be}}$$

Now

$$v_{be} = \frac{v_{b'e}(r_{bb'} + r_{b'e})}{r_{b'e}} \simeq v_{b'e} \quad \text{and} \quad i_c = \frac{g_m v_{b'e} r_{ce}}{r_{ce} + R_L} \simeq g_m v_{b'e}$$

because $r_{b'e} >> r_{bb'}$ and $r_{ce} >> R_L$. So,

$$A_v \simeq -g_m R_L$$

which is as expected.

The model shows that v_{be} is amplified independently of frequency because there are no capacitances to its right, so an analysis of low-frequency response devolves down to determining v_{be} in terms of e. Here, part of e will appear across the capacitive reactance X_{Cc}, and the remainder is v_{be}. So, to make the concept of reactance valid, a sinusoidal signal E must be postulated, giving a sinusoidal value for $v_{be} = V_{be}$.

At midfrequencies, where the reactance of C_c is small, the signal input voltage is

$$V_{be}(f_m) = \frac{E \cdot R_{BP}}{R_g + R_{BP}} \tag{24.16}$$

where $R_{BP} = R_B R_{\text{in}}/(R_B + R_{\text{in}})$ and $R_{\text{in}} = r_{bb'} + r_{b'e}$ as before.

At low frequencies, where the reactance of C_c is significant,

$$V_{be}(f_{\text{low}}) = \frac{E \cdot R_{BP}}{\sqrt{(R_g + R_{BP})^2 + X_{C_c}^2}} \tag{24.17}$$

Dividing (24.16) by (24.17) gives

$$\frac{V_{be}(f_m)}{V_{be}(f_{\text{low}})} = \frac{\sqrt{(R_g + R_{BP})^2 + X_{C_c}^2}}{R_g + R_{BP}}$$

There will be a frequency f_L at which $|X_{Cc}| = R_g + R_{BP}$ given by

$$\frac{1}{2\pi f_L C_c} = R_g + R_{BP} \quad \text{or} \quad f_L = \frac{1}{2\pi C_c(R_g + R_{BP})} \tag{24.18}$$

At this frequency, $V_{be}(f_m)/V_{be}(f_L) = \sqrt{2}$ or $V_{be}(f_L)$ is 3 dB lower than $V_{be}(f_m)$.

Example 3

Using the circuit components of the previous examples along with a signal source having an internal resistance of $R_g = 5$ kΩ, find the value of a coupling capacitor that will define a low-frequency –3dB point at 42 Hz.

Solution. Using Eq. (24.18),

$$C_c = \frac{1}{2\pi(R_g + R_{BP})f_L}$$

where $R_{BP} = R1||R2||R_{\text{in}} = 75||39||2.8 = 2.5$ kΩ. That is,

$$C = \frac{10^6}{2\pi(5000 + 2500)(42)} \simeq 0.5\ \mu\text{F}$$

Since a single RC time constant is involved, the voltage gain of the CE stage will appear to fall at 6 dB/octave as the frequency is reduced because more and more of the signal is dropped across C_c. However, even if C_E is very large, it too will contribute to a fall in gain as it allows more and more of the output signal to be dropped across the $R_E||X_{CE}$ combination, this being applied also to the input loop, resulting in negative feedback. So, at very low frequencies, the gain roll-off will tend to 12 dB/octave. The question therefore arises of how large C_E should be, and this can be conveniently answered by considering a second basic form of transistor connection as follows.

The Emitter-Follower or Common-Collector (CC) Circuit

Suppose that R_C is short-circuited in the circuit of Fig. 24.29. This will not affect the biasing because the collector voltage may take any value (the output characteristic is nearly horizontal, as seen in Fig. 24.28). However, the small-signal output voltage ceases to exist because there is now no load resistor across which it can be developed, though the output current i_c will continue to flow as before.

If now C_E is removed, i_c flows entirely through R_E and develops a voltage which can be observed at the emitter $i_e R_E$ ($\simeq i_c R_E$). Consider the magnitude of this voltage. Figure 24.26(a) shows that for a normally operating transistor, the signal component of the base-emitter voltage ΔV_{BE} (or v_{be}) is very small indeed, whereas the constant component needed for biasing is normally about 0.6 to 0.7 V. That is, $v_{be} << V_{BE}$. This implies that the emitter voltage must always follow the base voltage but at a dc level about 0.6 to 0.7 V below it. So, if an output signal is taken from the emitter, it is almost the same as the input signal at the base. In other words, *the voltage gain of an* ***emitter follower*** *is almost unity.*

If this is the case, what is the use of the emitter follower? The answer is that because the signal *current gain* is unchanged at $i_e/i_b = (h_{fe} + 1) \simeq h_{fe}$, then the power gain must also be about h_{fe}. This means in turn that the output resistance must be the resistance "looking into" the transistor from the emitter, divided by h_{fe}. If the parallel combination of R_g and the bias resistors is R_G, then

$$R_{\text{out}(CC)} = \frac{R_G + r_{bb'} + r_{b'e}}{h_{fe}} \tag{24.19}$$

where $R_G = R_g||R1||R2$ (or $R_g||R_B$).

If a voltage generator with zero internal resistance ($R_g = 0$) were applied to the input, then this would become

$$R_{\text{out}(CC)} = \frac{r_{bb'} + r_{b'e}}{h_{fe}}$$

and if $r_{b'e} >> r_{bb'}$ (which is usual), then

$$R_{\text{out}(CC)} \simeq \frac{r_{b'e}}{h_{fe}} = \frac{1}{g_m} \tag{24.20}$$

Consider the numerical implications of this: if $I_C = 1$ mA, then $g_m \simeq 39$ mA/V (at room temperature), so $1/g_m \simeq 26\ \Omega$, which is a very low output resistance indeed. In fact, though it appears in parallel with R_E, it is unlikely that R_E will make any significant contribution because it is usually hundreds or thousands of ohms.

Example 4

Using the same bias resistors as for the CE examples, find the output resistance at the emitter of a CC stage.

Solution. The parallel resistances to the left of the base are

$$R_G = R_g||R1||R2 = 5||75||39 \approx 4.2\ \text{k}\Omega$$

Using Eq. (24.19),

$$R_{\text{out}} \approx \frac{R_G + r_{b'e}}{h_{fe}} = \frac{R_G}{h_{fe}} + \frac{1}{g_m} \qquad \text{(neglecting } r_{bb'}\text{)}$$

where $g_m \approx 39 I_C$, $I_Q = 1$ mA, and $h_{fe} = 110$, so

$$R_{\text{out}(CC)} \approx \frac{4200}{110} + \frac{1000}{39} \approx 63.8\ \Omega$$

From values like this, it is clear that the output of an emitter follower can be thought of as a good practical dependent voltage source of very low internal resistance.

The converse is also true: the input at the base presents a high resistance. This is simply because whereas much the same signal voltage appears at the base as at the emitter, the base signal current i_b is smaller than the emitter signal current i_e by a factor of $(h_{fe} + 1) \simeq h_{fe}$. Hence, the apparent resistance at the base must be at least $h_{fe} R_E$. To this must be added $r_{bb'} + r_{b'e}$ so that

$$R_{\text{in}(CC)} \simeq r_{bb'} + r_{b'e} + h_{fe} R_E \tag{24.21a}$$

Now h_{fe} is rarely less than about 100, so $h_{fe} R_E$ is usually predominant and

$$R_{\text{in}(CC)} \simeq h_{fe} R_E \tag{24.21b}$$

The emitter-follower circuit is therefore a *buffer stage* because it can accept a signal at a high resistance level without significant attenuation and reproduce it at a low resistance level and with *no phase shift* (except at high frequencies).

In this configuration, the unbypassed emitter resistor R_E is obviously in series with the input circuit as well as the output circuit. Hence, it is actually a feedback resistor and so may be given the alternative symbol R_F, as in Fig. 24.33. Because all the output signal voltage is fed back in series with the input, this represents 100% voltage-derived series negative feedback.

The hybrid-π model for the bipolar transistor may now be inserted into the emitter-follower circuit of Fig. 24.33, resulting in Fig. 24.34, from which the four midfrequency parameters may be obtained. As an example of the procedures involved, consider the derivation of the voltage gain expression.

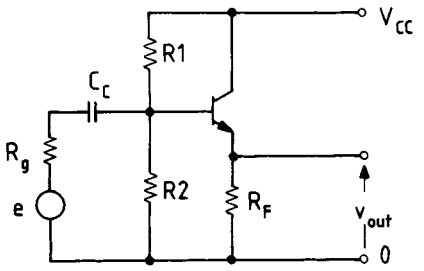

FIGURE 24.33 The emitter follower (or CC stage).

Summing signal currents at the emitter,

$$v_{\text{out}}\left(\frac{1}{R_F}+\frac{1}{r_{ce}}\right)=v_{b'e}\left(\frac{1}{r_{b'e}}+g_m\right)$$

Now $1/r_{ce} << 1/R_F$ and so may be neglected, and $v_{b'e} = v_{\text{in}} - v_{\text{out}}$, so

$$v_{\text{out}}\left(\frac{1}{R_F}\right)=(v_{\text{in}}-v_{\text{out}})\left(\frac{1}{r_{b'e}}+g_m\right)$$

or

$$v_{\text{out}}\left(\frac{1}{R_F}+\frac{1}{r_{b'e}}+g_m\right)=v_{\text{in}}\left(\frac{1}{r_{b'e}}+g_m\right)$$

giving

$$\begin{aligned}A_{v(CC)}&=\frac{v_{\text{out}}}{v_{\text{in}}}=\frac{1/r_{b'e}+g_m}{1/r_{b'e}+g_m+1/R_F}=\frac{1+g_m r_{b'e}}{1+g_m r_{b'e}+r_{b'e}/R_F}\\&\simeq\frac{g_m r_{b'e}}{g_m r_{b'e}+r_{b'e}/R_F}=\frac{g_m R_F}{g_m R_F+1}\end{aligned}\tag{24.22}$$

which is a little less than unity as expected.

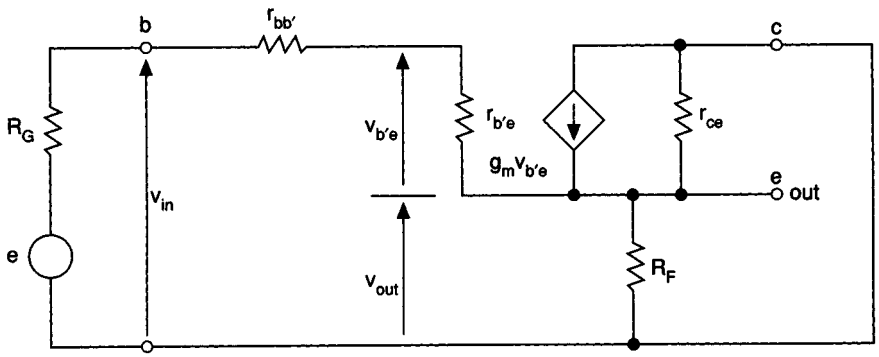

FIGURE 24.34 An emitter-follower equivalent circuit for low frequencies.

Similar derivations based on the equivalent circuit of Fig. 24.34 result in the other three basic midband operating parameters for the emitter follower, and all may be listed:

$$A_{i(CC)} \simeq h_{fe} \quad A_{v(CC)} \rightarrow +1$$
$$R_{\text{in}(CC)} \simeq r_{bb'} + r_{b'e} + h_{fe}R_F \simeq h_{fe}R_F$$

and

$$R_{\text{out}(CC)} \simeq \frac{R_G + r_{bb'} + r_{b'e}}{h_{fe}} \,||\, R_F \simeq \frac{R_G + r_{bb'} + r_{b'e}}{h_{fe}}$$
$$\simeq \frac{1}{g_m} \quad \text{if } R_g \rightarrow 0 \text{ and } r_{bb'} << r_{b'e}$$

The Common-Emitter Bypass Capacitor C_E

In a CE circuit such as that of Fig. 24.29, suppose C_c is large so that the low-frequency –3-dB point f_L is defined only by the parallel combination of the resistance at the emitter and C_E. It will now be seen why the emitter-follower work is relevant: the resistance appearing at the emitter of the CE stage is the same as the output resistance of the emitter-follower stage, and this will now appear in parallel with R_E. If this parallel resistance is renamed R_{emitter}, then, neglecting $r_{bb'}$,

$$R_{\text{emitter}} = R_{\text{out}(CC)} \,||\, R_E$$
$$\simeq \frac{R_G + r_{b'e}}{h_{fe}} \,||\, R_E$$
$$\simeq \frac{R_G + r_{b'e}}{h_{fe}}$$

and if C_E were to define f_L, then

$$f_L = \frac{1}{2\pi R_{\text{emitter}} C_E} \tag{24.23a}$$

For design purposes, C_E can be extracted for any given value of f_L:

$$C_E = \frac{1}{2\pi R_{\text{emitter}} f_L} \tag{24.23b}$$

Example 5

In Example 4, let C_c be large so that only C_E defines f_L at 42 Hz, and find the value of C_E.

Solution. In the emitter-follower example, where $R_g = 5$ kΩ, $R_{\text{out}(CC)}$ was found to be 63.8 Ω, and this is the same as R_{emitter} in the present case. Therefore,

$$C_E = \frac{10^6}{2\pi 63.8 \times 42} \simeq 60\ \mu\text{F}$$

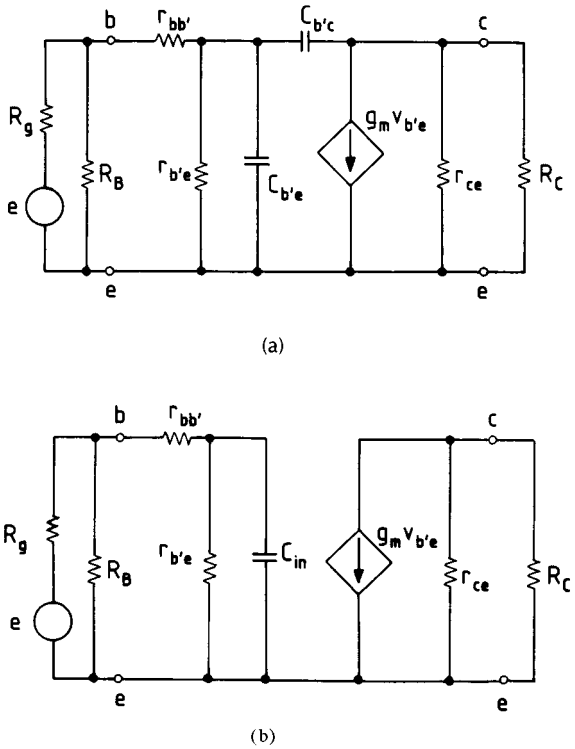

FIGURE 24.35 (a) The high-frequency hybrid-π model and (b) its simplification.

This is the value of C_E that would define f_L if C_c were large. However, if C_E is to act as a short circuit at this frequency, so allowing C_c to define f_L, then its value would have to be one or two orders of magnitude greater, that is, 600 to 6000 μF.

Summarizing, three possibilities exist:

1. If C_E is very large, C_c defines f_L and a 6-dB/octave roll-off results.
2. If C_c is large, C_E defines f_L and again a 6-dB/octave roll-off results.
3. If both C_c and C_E act together, a 12-dB/octave roll-off results.

In point of fact, at frequencies much less than f_L, both conditions (1) and (2) eventually produce 12-dB/octave roll-offs as the alternate "large" capacitors come into play at very low frequencies, but since the amplifier will not still have a useful gain at such frequencies, this is of little importance.

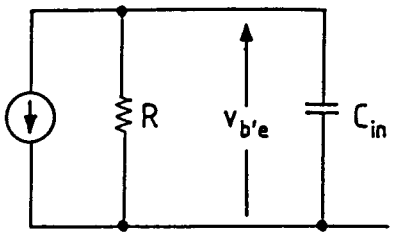
High-Frequency Response

Unlike the low-frequency response situation, the high-frequency response is governed by the small distributed capacitances inside the transistor structure, and these have been lumped together in the hybrid-π model of Fig. 24.31 as $C_{b'e}$ and $C_{b'c}$. At high frequencies, $r_{b'c}$ may be neglected in comparison with the reactance of $C_{b'c}$, so the model may be simplified as in Fig. 24.35(a). From this it will be seen that $C_{b'c}$ is a capacitance which appears from the output to the input so that it may be converted by the Miller Effect into a capacitance at the input of value:

$$C_{b'c}\,(1 - A_v) = C_{b'c}\,(1 + g_m R_C)$$

This will now add to $C_{b'e}$ to give C_{in}:

$$C_{\text{in}} = C_{b'e} + C_{b'c}\,(1 + g_m R_C) \tag{24.24}$$



$$R = \left(R_G + r_{bb'}\right) \| r_{b'e}$$

$$C_{in} = C_{b'e} + C_{b'c}\left(1 + g_m R_L\right)$$

FIGURE 24.36 Simplification of the input part of the high-frequency hybrid-π model.

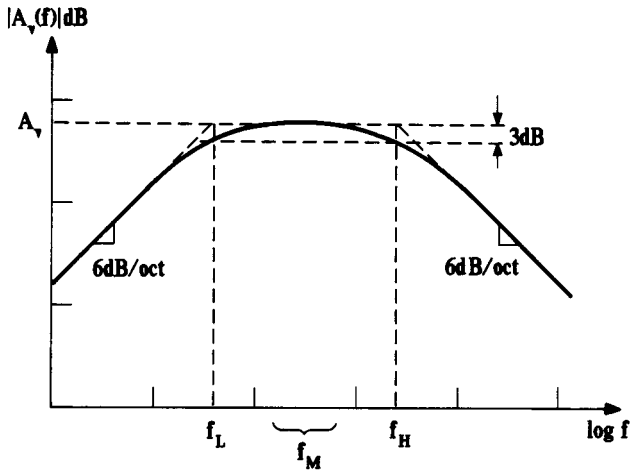


FIGURE 24.37 The complete frequency response.

This simplification is shown in Fig. 24.35(b), where C_{in} is seen to be shunted by the input parts of the model. These input parts may be reduced by sequential use of Thévenin–Norton transformations to result in Fig. 24.36, which is a simple parallel RC circuit driven by a current source. The actual value of this current source is immaterial—what matters is that the input signal to be amplified, $v_{b'e}$, will be progressively reduced as the frequency rises and the reactance of C_{in} falls.

Using a sinusoidal source, $V_{b'e}$ will be 3 dB down when $R = |X_{C_{in}}|$, which gives

$$R = \frac{1}{2\pi f_H C_{in}} \quad \text{or} \quad f_H = \frac{1}{2\pi R C_{in}} \tag{24.25}$$

where $R = (R_G + r_{bb'}) \| r_{b'e}$ from the circuit reduction.

Complete Response

Now that both the low- and high-frequency roll-offs have been related to single time constants (except when C_c and C_E act together), it is clear that the complete frequency response will look like Fig. 24.37, where the midband voltage gain is $A_v = -g_m R_C$.

Design Comments

The design of a simple single-transistor amplifier stage has now been covered in terms of both biasing and small-signal performance. These two concepts have been kept separate, but it will have been noticed that they

are bridged by the transconductance, because $g_m = (q/kT)I_Q$ ($\simeq 39I_Q$ at room temperature). That is, when I_Q has been determined, then the small-signal performance follows from expressions involving g_m.

In fact, once the quiescent voltage across the load resistor of a CE stage has been determined, the voltage gain follows from this irrespective of the values of I_Q and R_C.

If the quiescent voltage at the collector is V_{out}, then in dc biasing terms,

$$V_{RC} = I_Q R_C = (V_{CC} - V_{\text{out}})$$

and in small-signal terms,

$$A_v = -g_m R_C \cong -39 I_Q R_C \qquad \text{(at 25°C)}$$

$$= -39(V_{CC} - V_{\text{out}})$$

Thus, g_m really does act as a bridge between the bias and the small-signal conditions for the bipolar transistor amplifier stage.

Unfortunately, however, there are serious problems with such a stage from a practical viewpoint. For example, it cannot amplify down to dc because of the existence of C_c, and if a larger gain is needed, the cascading of such stages will present problems of phase shift and hence feedback stability. Furthermore, it cannot be produced in IC form because of the incorporation of large capacitances and somewhat critical and high-valued resistors. This leads to a reevaluation of the basic tenets of circuit design, and these may be summed up as follows: circuit design using *discrete* components is largely concerned with voltage drops across resistors (as has been seen), but the design of ICs depends extensively on *currents* and *current sources and sinks.*

Integrated Circuits

Monolithic ICs are fabricated on single chips of silicon or *dice* (the singular being *die*). This means that the active and passive structures on the chips are manufactured all at the same time, so it is easy to ensure that a large number of such structures are identical, or bear some fixed ratio to one another, but it is more difficult to establish precise values for such sets of structures. For example, a set of transistors may all exhibit almost the same values of h_{FE}, but the actual numerical value of h_{FE} may be subject to wider tolerances. Similarly, many pairs of resistors may bear a ratio n:1 to each other, but the actual values of these resistors are more difficult to define. So, in IC design, it is very desirable to exploit the close similarity of devices (or close ratios) rather than depend upon their having predictable absolute values. This approach has led to two ubiquitous circuit configurations, both of which depend upon device similarity: the **long-tailed pair or difference amplifier** (often called the *differential amplifier*), and the **current mirror**. This section will treat both, and the former is best introduced by considering the **degenerate common-emitter** stage.

The Degenerate Common-Emitter Stage

Consider two CE stages which are identical in every respect but which have no emitter resistor bypass capacitors, as shown in Fig. 24.38. Also, notice that in these diagrams, two power supply rails have been used, a positive one at V^+_{CC} and a negative one at V^-_{CC}. The reason for this latter, negative, rail is that the bases may be operated via signal sources referred to a common line or ground. (If, for example, V^+_{CC} and V^-_{CC} are obtained from batteries as shown, then the common line is simply the junction of the two batteries, as is also shown.) The absence of capacitors now means that amplification down to dc is possible.

It is now very easy to find the quiescent collector currents I_Q, because from a dc bias point of view the bases are connected to ground via resistances R_g, which will be taken as having low values so that they drop negligibly small voltages. Hence,

$$I_Q = \frac{|V^-_{CC}| - V_{BE}}{R_F} \tag{24.26}$$

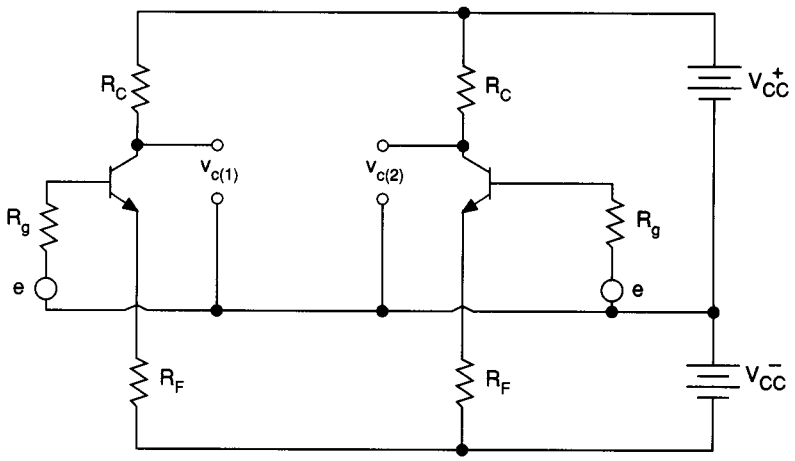

FIGURE 24.38 Two degenerate CE stages.

[For example, if industry-standard supplies of ±15 V are used, $V_{BE} = 0.6$ V, and for $R_F = 15$ kΩ, then $I_Q = (15 - 0.6)/15 = 0.96 \simeq 1$ mA.]

Now suppose that identical signals e are applied. At each collector, this will result in an output signal voltage v_c, where $v_c = -i_c R_C$. Also, at each emitter, the output signal voltage will be $v_e = i_e R_F \simeq i_c R_F$. That is,

$$\frac{v_c}{v_e} \simeq \frac{-i_c R_c}{i_c R_F} = -\frac{R_C}{R_F}$$

If the voltage gain from base to collector of a degenerate CE stage is $A_{v(dCE)}$ and the voltage gain from base to emitter is simply the emitter-follower gain $A_{v(CC)}$, then

$$v_c = A_{v(dCE)} e \qquad \text{and} \qquad v_e = A_{v(CC)} e$$

giving

$$\frac{A_{v(dCE)}}{A_{v(CC)}} \simeq -\frac{R_C}{R_F}$$

Now $A_{v(CC)}$ is known from Eq. (24.22) so that

$$A_{v(dCE)} \simeq -A_{v(CC)} \frac{R_C}{R_F} = -\frac{g_m R_C}{1 + g_m R_F} \simeq -\frac{R_C}{R_F} \tag{24.27}$$

Note that the input resistance to each base is as for the emitter-follower stage:

$$R_{\text{in}(dCE)} = r_{bb'} + r_{b'e} + h_{fe} R_F \simeq h_{fe} R_F$$

Now consider what happens if the emitters are connected together as in Fig. 24.39, where the two resistors R_F have now become R_X, where $R_X = \frac{1}{2} R_F$.

The two quiescent emitter currents now combine to give $I_X = 2I_E \simeq 2I_C$, and otherwise the circuit currents and voltages remain undisturbed. So, if the two input signals are identical, then the two output signals will also

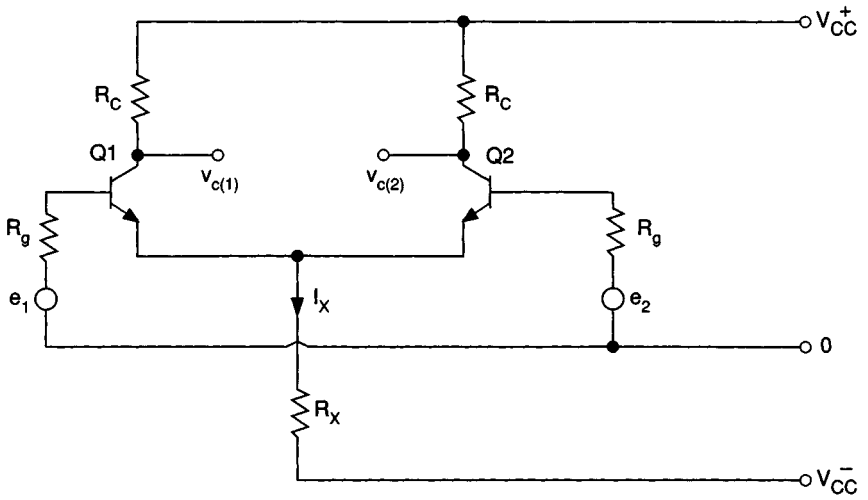

FIGURE 24.39 The difference amplifier.

be identical. This circuit is now called a *difference amplifier,* and the reason will become obvious as soon as the two input signals differ.

The Difference Amplifier

In Fig. 24.39, if $e_1 = e_2$, these are called common-mode input signals, $e_{in(CM)}$, and they will be amplified by $-R_C/R_F$ as for the degenerate CE stage. However, if $e_1 \neq e_2$, then $e_1 - e_2 = e_{in}$, the difference input signal. The following definitions now apply:

$$\frac{e_1 + e_2}{2} = e_{in(CM)} \quad \text{the common mode component}$$

and

$$\frac{\pm(e_1 - e_2)}{2} = e_{in(diff)} \quad \text{the difference component, or } \tfrac{1}{2} e_{in}$$

Hence, $e_1 = e_{in(CM)} + e_{in(diff)}$ and $e_2 = e_{in(CM)} - e_{in(diff)}$.

Consider the progress of a signal current driven by $e_1 - e_2$ and entering the base of $Q1$. It will first pass through R_g, then into the resistance R_{in} at the base of $Q1$, and will arrive at the emitter of $Q2$. Here, if R_X is large, most of this signal current will pass into the resistance presented by the $Q2$ emitter and eventually out of the $Q2$ base via another R_g to ground. The total series resistance is therefore

$$R_g + R_{in} = R_g + r_{bb'} + r_{b'e} + h_{fe} R_{emitter(2)}$$

But

$$R_{emitter(2)} = \frac{R_g + r_{bb'} + r_{b'e}}{h_{fe}}$$

so

$$R_g + R_{in} = 2(R_g + r_{bb'} + r_{b'e})$$

which is the resistance between the two signal sources. Hence,

$$i_{b(1)} = -i_{b(2)} = \frac{e_1 - e_2}{2(R_g + r_{bb'} + r_{b'e})}$$

giving

$$v_{c(1)} = -v_{c(2)} = \frac{h_{fe}R_C(e_1 - e_2)}{2(R_g + r_{bb'} + r_{b'e})}$$

so that the overall difference voltage gain to each collector is

$$A_{ov} = \frac{v_c}{e_1 - e_2} = \frac{\pm h_{fe}R_C}{2(R_g + r_{bb'} + r_{b'e})} \tag{24.28a}$$

If the voltage gain with the input signal measured between the actual bases is needed, R_g may be removed to give

$$A_v = \frac{\pm h_{fe}R_C}{2(r_{bb'} + r_{b'e})} \tag{24.28b}$$

Finally, if the output signal is measured between the collectors (which will be twice that at each collector because they are in antiphase), the difference-in–to–difference-out voltage gain will be

$$A_{v(\text{diff})} = \frac{h_{fe}R_C}{r_{bb'} + r_{b'e}} \simeq \frac{h_{fe}R_C}{r_{b'e}} = g_m R_C \tag{24.28c}$$

which is the same as for a single CE stage.

Note that this is considerably larger than the gain for a common-mode input signal; that is, the difference stage amplifies difference signals well but largely rejects common-mode signals. This common-mode rejection property is very useful, for often, small signals appear across leads, both of which may contain identical electrical noise. So, the difference stage tends to reject the noise while still amplifying the signal. Furthermore, the difference stage has the advantage that it needs no coupling or bypass capacitors and so will amplify frequencies down to zero (dc). Also, it is very stable biaswise and lends itself perfectly to realization on a monolithic IC.

To make the above derivation valid, the long-tail resistance R_X should be as large as possible so that most of the signal current enters the emitter of $Q2$. However, R_X must also carry the quiescent current, which would produce a very high quiescent voltage drop and so require a very high value of V_{CC-}. To overcome this, another transistor structure may be used within a configuration known as a current mirror.

The Current Mirror

The two transistors in Fig. 24.40 are assumed to be identical, and $Q1$ has its base and collector connected so that it acts simply as a diode (formed by the base-emitter junction). The current through it is therefore

$$I = \frac{V_{CC} - V_{BE}}{R} \tag{24.29}$$

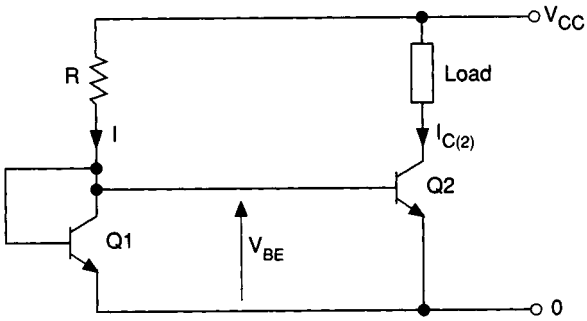

FIGURE 24.40 The current mirror.

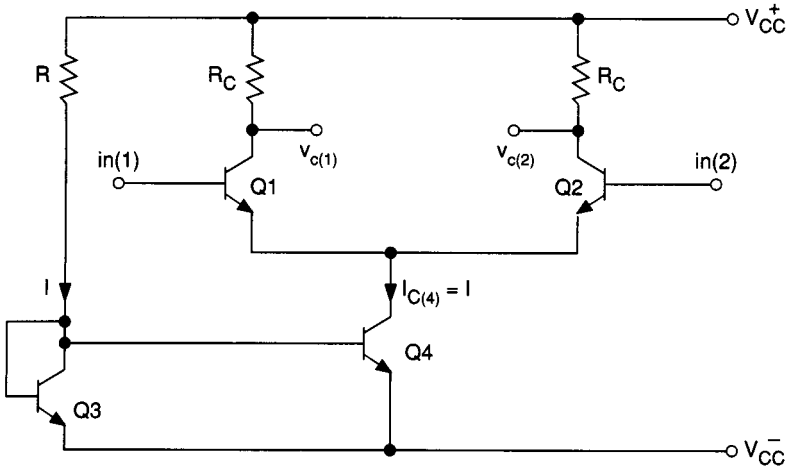

FIGURE 24.41 Current mirror biasing.

The voltage drop V_{BE} so produced is applied to $Q2$ as shown so that it is forced to carry the same collector current I; that is, it mirrors the current in $Q1$.

The transistor $Q2$ is now a device that carries a dc $I_{C(2)} = I$ but presents a large incremental resistance r_{ce} at its collector. This is exactly what is required by the difference amplifier pair, so it may be used in place of R_X.

The Difference Stage with Current Mirror Biasing

Figure 24.41 shows a complete difference stage complete with a current mirror substituting for the long-tail resistor R_X, where the emitter quiescent currents combine to give I_X:

$$I_X = \frac{V_{CC^+} + |V_{CC^-}| - V_{BE(3)}}{R} = I \tag{24.30}$$

This quiescent or bias current is very stable, because the change in $V_{BE(3)}$ due to temperature variations is exactly matched by that required by $Q4$ to produce the same current. The difference gain will be as discussed above, but the common-mode gain will be extremely low because of the high incremental resistance r_{ce} presented by the long-tail transistor.

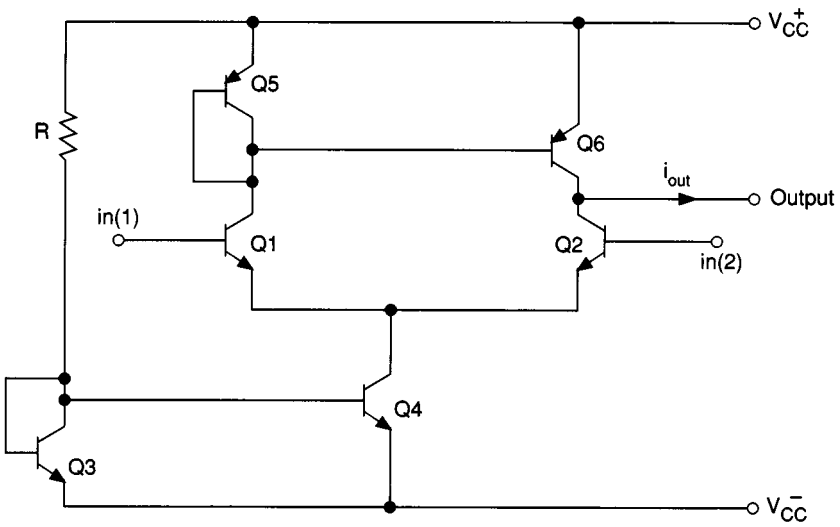

FIGURE 24.42 A complete difference amplifier stage.

The Current Mirror as a Load

A second current mirror may be used as a load for the difference amplifier, as shown in Fig. 24.42. This must utilize *pnp* transistor structures so that the *Q*6 collector loads the *Q*2 collector with a large incremental resistance $r_{ce}(6)$, making for an extremely high voltage gain. Furthermore, *Q*5 and *Q*6 combine the signal output currents of both *Q*1 and *Q*2 to perform a double-ended–to–single-ended conversion as follows. Taking signal currents,

$$i_{\text{out}} = i_c(6) - i_c(2)$$

But

$$i_c(6) = i_c(5)$$

by current mirror action, and

$$i_c(5) = i_c(1)$$

so

$$i_c(6) = i_c(1)$$

Also,

$$i_c(2) = -i_c(1)$$

by difference amplifier action, so

$$i_{\text{out}} = i_c(1) + i_c(1) = 2i_c(1) \tag{24.31}$$

Thus, both sides of the long-tailed pair are used to provide an output current that may then be applied to further stages to form a complete amplifier. Also, because no capacitors and only one resistor are needed, it is an easy circuit for monolithic integration on a single die.

Summary

It has been shown how a limited knowledge of bipolar operation can lead to properly biased amplifier stages using discrete transistors. An equivalent circuit—the hybrid-π model—was then derived, again from limited information, which made possible the analysis of such stages, and some purely practical design results were favorably compared with its predictions. Finally, the tenets of this equivalent circuit were used to evaluate the performance of the difference amplifier and current mirror circuits, which are the cornerstones of modern electronic circuit design in a very wide variety of its manifestations. These circuits are, in fact, the classic transconductance and translinear elements that are ubiquitous in modern IC signal conditioning and function networks.

It should be recognized that there are many models other than the one introduced here, from the simple but very common *h*-parameter version to complex and comprehensive versions developed for computer-aided design (CAD) methods. However, the present elementary approach has been from a design rather than an analytical direction, for it is obvious that powerful modern computer-oriented methods such as the SPICE variants become useful only when a basic circuit configuration has been established, and at the time of writing, this is still the province of the human designer.

Defining Terms

Biasing circuit: A circuit that holds a transistor in an operating condition ready to receive signals.

Common emitter: A basic transistor amplifier stage whose emitter is common to both input and output loops. It amplifies voltage, current, and hence power.

Current mirror: An arrangement of two (or more) transistors such that a defined current passing into one is mirrored in another at a high resistance level.

Degenerate common emitter: A combination of the common-emitter and emitter-follower stages with a very well-defined gain.

Difference amplifier or long-tailed pair: An arrangement of two transistors that amplifies difference signals but rejects common-mode signals. It is often called a differential pair.

Emitter follower or common collector: A basic transistor amplifier stage whose collector is common to both input and output loops. Its voltage gain is near unity, but it amplifies current and hence power. It is a high-input resistance, low-output resistance, or buffer, circuit.

24.3 The Metal-Oxide Semiconductor Field-Effect Transistor (MOSFET)

John R. Brews

The MOSFET is a transistor that uses a control electrode, the **gate**, to capacitively modulate the conductance of a surface **channel** joining two end contacts, the **source** and the **drain**. The gate is separated from the semiconductor **body** underlying the gate by a thin *gate insulator,* usually silicon dioxide. The surface channel is formed at the interface between the semiconductor body and the gate insulator (see Fig. 24.43).

The MOSFET can be understood by contrast with other field-effect devices, like the *JFET,* or junction field-effect transistor, and the *MESFET,* or metal semiconductor field-effect transistor [Hollis and Murphy, 1990]. These other transistors modulate the conductance of a *majority-carrier* path between two *ohmic* contacts by capacitive control of its cross section. (Majority carriers are those in greatest abundance in a field-free semiconductor, electrons in *n*-type material and holes in *p*-type material.) This modulation of the cross section can take place at any point along the length of the channel, so the gate electrode can be positioned anywhere and need not extend the entire length of the channel.

Analogous to these field-effect devices is the *buried-channel, depletion-mode,* or *normally on* MOSFET, which contains a surface layer of the same doping type as the source and drain (opposite type to the semiconductor body of the device). As a result, it has a built-in or normally on channel from source to drain with a conductance that is reduced when the gate depletes the majority carriers.

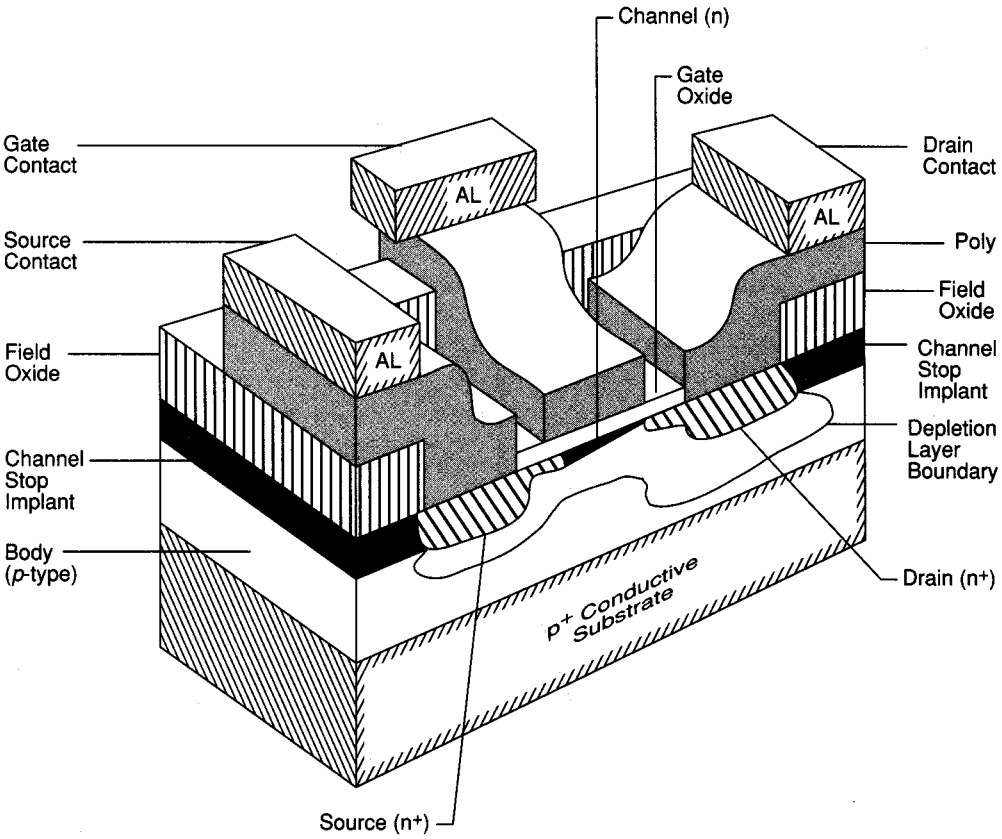

FIGURE 24.43 A high-performance *n*-channel MOSFET. The device is isolated from its neighbors by a surrounding thick *field oxide* under which is a heavily doped *channel stop* implant intended to suppress accidental channel formation that could couple the device to its neighbors. The drain contacts are placed over the field oxide to reduce the capacitance to the body, a parasitic that slows response times. These structural details are described later. (*Source:* After Brews, 1990.)

In contrast, the true MOSFET is an *enhancement-mode* or *normally off* device. The device is normally off because the body forms *pn* junctions with both the source and the drain, so no majority-carrier current can flow between them. Instead, *minority-carrier* current can flow, provided minority carriers are available. As discussed later, for gate biases that are sufficiently attractive, above **threshold**, minority carriers are drawn into a surface channel, forming a conducting path from source to drain. The gate and channel then form two sides of a capacitor separated by the gate insulator. As additional attractive charges are placed on the gate side, the channel side of the capacitor draws a balancing charge of minority carriers from the source and the drain. The more charges on the gate, the more populated the channel, and the larger the conductance. Because the gate *creates* the channel, to ensure electrical continuity the gate must extend over the entire length of the separation between source and drain.

The MOSFET channel is created by attraction to the gate and relies upon the insulating layer between the channel and the gate to prevent leakage of minority carriers to the gate. As a result, MOSFETs can be made only in material systems that provide very good gate insulators, and the best system known is the silicon–silicon dioxide combination. This requirement for a good gate insulator is not so important for JFETs and MESFETs, where the role of the gate is to *push away* majority carriers rather than to attract minority carriers. Thus, in GaAs systems where good insulators are incompatible with other device or fabricational requirements, MESFETs are used.

A more recent development in GaAs systems is the heterostructure field-effect transistor, or HFET [Pearton and Shaw, 1990], made up of layers of varying compositions of Al, Ga, and As or In, Ga, P, and As. These devices are made using molecular beam epitaxy or by organometallic vapor phase epitaxy, expensive methods still being refined for manufacture. HFETs include a variety of structures, the best known of which is the modulation doped FET, or MODFET. HFETs are field-effect devices, not MOSFETs, because the gate simply modulates the carrier density in a preexistent channel between ohmic contacts. The channel is formed spontaneously, regardless of the quality of the gate insulator as a condition of equilibrium between the layers, just as a depletion layer is formed in a *pn* junction. The resulting channel is created very near to the gate electrode, resulting in gate control as effective as in a MOSFET.

The silicon-based MOSFET has been successful primarily because the silicon–silicon dioxide system provides a stable interface with low trap densities, and because the oxide is impermeable to many environmental contaminants, has a high breakdown strength, and is easy to grow uniformly and reproducibly [Nicollian and Brews, 1982]. These attributes allow easy fabrication using lithographic processes, resulting in integrated circuits (ICs), with very small devices, very large device counts, and very high reliability at low cost. Because the importance of the MOSFET lies in this relationship to high-density manufacture, an emphasis of this article is to describe the issues involved in continuing miniaturization.

An additional advantage of the MOSFET is that it can be made using either electrons or holes as channel carrier. Using both types of devices in so-called complementary MOS (CMOS) technology allows circuits that draw no *dc* power if current paths include at least one series connection of both types of device because, in steady state, only one or the other type conducts, not both at once. Of course, in exercising the circuit, power is drawn during switching of the devices. This flexibility in choosing *n*- or *p*-channel devices has enabled large circuits to be made that use low power levels. Hence, complex systems can be manufactured without expensive packaging or cooling requirements.

Current-Voltage Characteristics

The derivation of the current-voltage characteristics of the MOSFET can be found in several sources [Annaratone, 1986; Brews, 1981; Pierret, 1990]. Here a qualitative discussion is provided.

Strong-Inversion Characteristics

In Fig. 24.44 the source-drain current I_D is plotted versus drain-to-source voltage V_D (the I-V curves for the MOSFET). At low V_D the current increases approximately linearly with increased V_D, behaving like a simple resistor with a resistance that is controlled by the gate voltage V_G: as the gate voltage is made more attractive for channel carriers, the channel becomes stronger, more carriers are contained in the channel, and its resistance R_{ch} drops. Hence, at larger V_G the current is larger.

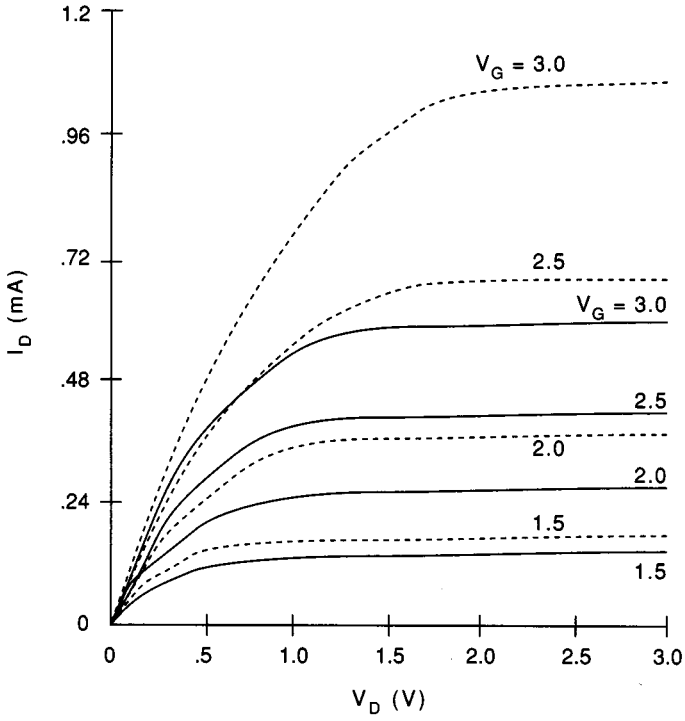

FIGURE 24.44 Drain current I_D versus drain voltage V_D for various choices of gate bias V_G. The dashed-line curves are for a long-channel device for which the current in saturation increases quadratically with gate bias. The solid-line curves are for a *short-channel* device that is approaching *velocity saturation* and thus exhibits a more linear increase in saturation current with gate bias, as discussed in the text.

At large V_D the curves flatten out, and the current is less sensitive to drain bias. The MOSFET is said to be in *saturation*. There are different reasons for this behavior, depending upon the field along the channel caused by the drain voltage. If the source-drain separation is short, near or below a micrometer, the usual drain voltage is sufficient to create fields along the channel of more than a few $\times 10^4$ V/cm. In this case the carrier energy is sufficient for carriers to lose energy by causing vibrations of the silicon atoms composing the crystal (optical phonon emission). Consequently, the carrier velocity does not increase much with increased field, saturating at a value $\upsilon_{sat} \approx 10^7$ cm/s in silicon MOSFETs. Because the carriers do not move faster with increased V_D, the current also saturates.

For longer devices the current-voltage curves saturate for a different reason. Consider the potential along the insulator-channel interface, the surface potential. Whatever the surface potential is at the source end of the channel, it varies from the source end to a value larger at the drain end by V_D because the drain potential is V_D higher than the source. The gate, on the other hand, is at the same potential everywhere. Thus, the difference in potential between the gate and the source is larger than that between the gate and the drain. Correspondingly, the oxide field at the source is larger than that at the drain, and as a result less charge can be supported at the drain. This reduction in attractive power of the gate reduces the number of carriers in the channel at the drain end, increasing channel resistance. In short, we have $I_D \approx V_D / R_{ch}$, but the channel resistance $R_{ch} = R_{ch}(V_D)$ is increasing with V_D. As a result, the current-voltage curves do not continue along the initial straight line, but bend over and saturate.

Another difference between the current-voltage curves for short devices and those for long devices is the dependence on gate voltage. For long devices, the current level in saturation, $I_{D,sat}$, increases quadratically with gate bias. The reason is that the number of carriers in the channel is proportional to $V_G - V_{TH}$ (where V_{TH} is the *threshold voltage*), as is discussed later, the channel resistance $R_{ch} \propto 1/(V_G - V_{TH})$, and the drain bias in saturation is approximately V_G. Thus, $I_{D,sat} = V_D/R_{ch} \propto (V_G - V_{TH})^2$, and we have quadratic dependence. When

the carrier velocity is saturated, however, the dependence of the current on drain bias is suppressed because the speed of the carriers is fixed at υ_{sat}, and $I_{D,sat} \propto \upsilon_{sat}/R_{ch} \propto (V_G - V_{TH})\,\upsilon_{sat}$, a linear gate-voltage dependence. As a result, the current available from a short device is not as large as would be expected if we assumed it behaved like a long device.

Subthreshold Characteristics

Quite different current-voltage behavior is seen in **subthreshold**, that is, for gate biases so low that the channel is in *weak inversion*. In this case the number of carriers in the channel is so small that their charge does not affect the potential, and channel carriers simply must adapt to the potential set up by the electrodes and the dopant ions. Likewise, in subthreshold any flow of current is so small that it causes no potential drop along the interface, which becomes an equipotential.

As there is no lateral field to move the channel carriers, they move by diffusion only, driven by a gradient in carrier density set up because the drain is effective in reducing the carrier density at the drain end of the channel. In subthreshold the current is then independent of drain bias once this bias exceeds a few tens of millivolts, enough to reduce the carrier density at the drain end of the channel to near zero.

In short devices, however, the source and drain are close enough together to begin to share control of the potential with the gate. If this effect is too strong, a drain-voltage dependence of the subthreshold characteristic then occurs, which is undesirable because it increases the MOSFET off current, and can cause a drain-bias dependent threshold voltage.

Although for a well-designed device there is no drain-voltage dependence in subthreshold, gate-bias dependence is exponential. The surface is lowered in energy relative to the semiconductor body by the action of the gate. If this *surface potential* is ϕ_S below that of the body, the carrier density is enhanced by a Boltzmann factor $\exp(q\phi_S/kT)$ relative to the body concentration, where kT/q = the thermal voltage ≈ 25 mV at 290 K. As ϕ_S is roughly proportional to V_G, this exponential dependence on ϕ_S leads to an exponential dependence upon V_G for the carrier density and, hence, for the current in subthreshold.

Important Device Parameters

A number of MOSFET parameters are important to the performance of a MOSFET. In this subsection some of these parameters are discussed, particularly from the viewpoint of digital ICs.

Threshold Voltage

The threshold voltage is vaguely defined as the gate voltage V_{TH} at which the channel begins to form. At this voltage devices begin to switch from "off" to "on," and circuits depend on a voltage swing that straddles this value. Thus, threshold voltage helps in deciding the necessary supply voltage for circuit operation, and also it helps in determining the leakage or "off" current that flows when the device is in the off state.

Threshold voltage is controlled by oxide thickness d and by body doping. To control the body doping, ion implantation is used so that the dopant-ion density is not simply a uniform extension of the bulk, background level N_B ions/unit volume but has superposed upon it an implanted-ion density. To estimate the threshold voltage, we need a picture of what happens in the semiconductor under the gate as the gate voltage is changed from its off level toward threshold.

If we imagine changing the gate bias from its off condition toward threshold, at first the result is to repel majority carriers, forming a surface *depletion layer* (refer to Fig. 24.43). In the depletion layer there are almost no carriers present, but there are dopant ions. In *n*-type material these dopant ions are positive donor impurities that cannot move under fields because they are locked in the silicon lattice, where they have been deliberately introduced to replace silicon atoms. In *p*-type material these dopant ions are negative acceptors. Thus, each charge added to the gate electrode to bring the gate voltage closer to threshold causes an increase in the depletion-layer width sufficient to balance the gate charge by an equal but opposite charge of dopant ions in the silicon depletion layer.

This expansion of the depletion layer continues to balance the addition of gate charge until threshold is reached. Then this charge response changes: above threshold any additional gate charge is balanced by an increasingly strong inversion layer or channel. The border between a depletion-layer and an inversion-layer response, threshold, should occur when

$$\frac{dqN_{\text{inv}}}{d\phi_S} = \frac{dQ_D}{d\phi_S} \tag{24.32}$$

where $d\phi_S$ is the small change in surface potential that corresponds to our incremental change in gate charge, qN_{inv} is the inversion-layer charge/unit area, and Q_D is the depletion-layer charge/unit area. According to Eq. (24.32), the two types of response are equal at threshold, so one is larger than the other on either side of this condition. To be more quantitative, the rate of increase in qN_{inv} is exponential; that is, its rate of change is proportional to qN_{inv}, so as qN_{inv} increases, so does the left side of Eq. (24.32). On the other hand, Q_D has a square-root dependence on ϕ_S, which means its rate of change becomes smaller as Q_D increases. Thus, as surface potential is increased, the left side of Eq. (24.32) increases proportional to qN_{inv} until, at threshold, Eq. (24.32) is satisfied. Then, beyond threshold, the exponential increase in qN_{inv} with ϕ_S swamps Q_D, making change in qN_{inv} the dominant response. Likewise, below threshold, the exponential decrease in qN_{inv} with decreasing ϕ_S makes qN_{inv} negligible and change in Q_D becomes the dominant response. The abruptness of this change in behavior is the reason for the term *threshold* to describe MOSFET switching.

To use Eq. (24.32) to find a formula for threshold voltage, we need expressions for N_{inv} and Q_D. Assuming the interface is held at a lower energy than the bulk due to the charge on the gate, the minority-carrier density at the interface is larger than in the bulk semiconductor, even below threshold. Below threshold and even up to the threshold of Eq. (24.32), the number of charges in the channel/unit area N_{inv} is given for *n*-channel devices approximately by [Brews, 1981]:

$$N_{\text{inv}} \approx d_{\text{INV}} \frac{n_i^2}{N_B} e^{q(\phi_S - V_S)/kT} \tag{24.33}$$

where the various symbols are defined as follows: n_i = intrinsic carrier density/unit volume $\approx 10^{10}/\text{cm}^3$ in silicon at 290 K, and V_S = body reverse bias, if any. The first factor, d_{INV}, is an effective depth of minority carriers from the interface given by

$$d_{\text{INV}} = \frac{\varepsilon_s kT/q}{Q_D} \tag{24.34}$$

where Q_D = depletion-layer charge/unit area due to charged dopant ions in the region where there are no carriers and ε_s is the dielectric permittivity of the semiconductor.

Equation (24.33) expresses the net minority-carrier density/unit area as the product of the bulk minority-carrier density/unit volume, n_i^2/N_B, with the depth of the minority-carrier distribution d_{INV} multiplied in turn by the customary Boltzmann factor $\exp[q(\phi_S - V_S)/kT]$ expressing the enhancement of the interface density over the bulk due to lower energy at the interface. The depth d_{INV} is related to the carrier distribution near the interface using the approximation (valid in *weak inversion*) that the minority-carrier density decays exponentially with distance from the oxide-silicon surface. In this approximation, d_{INV} is the *centroid* of the minority-carrier density. For example, for a uniform bulk doping of 10^{16} dopant ions/cm^3 at 290 K, using Eq. (24.33) and the surface potential at threshold from Eq. (24.38) below ($\phi_{TH} = 0.69$ V), there are $Q_D/q = 3 \times 10^{11}$ charges/cm^2 in the depletion layer at threshold. This Q_D corresponds to a $d_{\text{INV}} = 5.4$ nm and a carrier density at threshold of $N_{\text{inv}} = 5.4 \times 10^9$ charges/cm^2.

The next step in using the definition of threshold, Eq. (24.32), is to introduce the depletion-layer charge/unit area Q_D. For the ion-implanted case, Q_D is made up of two terms [Brews, 1981]:

$$Q_D = qN_B L_B \left\{ 2\left[q\phi_{TH}/(kT) - m_1 - 1 \right] \right\}^{1/2} + qD_I \tag{24.35}$$

where the first term is Q_B, the depletion-layer charge from bulk dopant atoms in the depletion layer with a width that has been reduced by the first moment of the implant, namely, m_1 given in terms of the centroid of the implant x_C by

$$m_1 = \frac{D_I x_C}{N_B L_B^2} \tag{24.36}$$

The second term is the additional charge due to the implanted-ion density within the depletion layer, D_I ions per unit area. The Debye length L_B is defined as

$$L_B^2 \equiv \frac{kT}{q} \frac{\varepsilon_s}{qN_B} \tag{24.37}$$

where ε_s is the dielectric permittivity of the semiconductor. The Debye length is a measure of how deeply a variation of surface potential penetrates into the body when $D_I = 0$ and the depletion layer is of zero width.

Approximating qN_{inv} by Eq. (24.33) and Q_D by Eq. (24.35), Eq. (24.32) determines the surface potential at threshold, ϕ_{TH}, to be

$$\phi_{TH} = 2\frac{kT}{q}\ln\frac{N_B}{n_i} + \frac{kT}{q}\ln\left(1 + \frac{qD_I}{Q_B}\right) \tag{24.38}$$

where the new symbols are defined as follows: Q_B = depletion-layer charge/unit area due to bulk body dopant N_B in the depletion layer, and qD_I = depletion-layer charge/unit area due to implanted ions in the depletion layer between the inversion-layer edge and the depletion-layer edge. Because even a small increase in ϕ_S above ϕ_{TH} causes a large increase in qN_{inv}, which can balance a rather large change in gate charge or gate voltage, ϕ_S does not increase much as $V_G - V_{TH}$ increases. Nonetheless, in strong inversion $N_{\text{inv}} \approx 10^{12}$ charges/cm^2, so in strong inversion ϕ_S will be about 10 kT/q larger than ϕ_{TH}.

Equation (24.38) indicates for uniform doping (no implant, $D_I = 0$) that threshold occurs approximately for $\phi_S = \phi_{TH} = 2(kT/q)\ln(N_B/n_i) \equiv 2\phi_B$, but for the nonuniformly doped case a larger surface potential is needed, assuming the case of a normal implant where D_I is positive, increasing the dopant density. The implant increases the required surface potential because the field at the surface is larger, narrowing the inversion layer, and reducing the channel strength for $\phi_S = 2\phi_B$. Hence, a somewhat larger surface potential is needed to increase qN_{inv} to the point that Eq. (24.32) is satisfied. Equation (24.38) would not apply if a significant fraction of the implant were confined to lie within the inversion layer itself. However, no realistic implant can be confined within a distance comparable to an inversion-layer thickness (a few tens of nanometers), so Eq. (24.38) covers practical cases.

With the surface potential ϕ_{TH} known, the potential on the gate at threshold Φ_{TH} can be found if we know the oxide field F_{ox} by simply adding the potential drop across the semiconductor to that across the oxide. That is, $\Phi_{TH} = \phi_{TH} + F_{\text{ox}}\, d$, with d = oxide thickness and F_{ox} given by Gauss's law as

$$\varepsilon_{\text{ox}} F_{\text{ox}} = Q_D \tag{24.39}$$

There are two more complications in finding the threshold voltage. First, the *gate voltage* V_{TH} usually differs from the gate potential Φ_{TH} at threshold because of a work-function difference between the body and the gate material. This difference causes a spontaneous charge exchange between the two materials as soon as the MOSFET is placed in a circuit allowing charge transfer to occur. Thus, even before any *voltage* is applied to the device, a *potential* difference exists between the gate and the body due to spontaneous charge transfer. The

second complication affecting threshold voltage is the existence of charges in the insulator and at the insulator-semiconductor interface. These nonideal contributions to the overall charge balance are due to traps and fixed charges incorporated during the device processing.

Ordinarily interface-trap charge is negligible ($<10^{10}$/cm^2 in silicon MOSFETs), and the other nonideal effects upon threshold voltage are accounted for by introducing the *flatband voltage* V_{FB}, which corrects the gate bias for these contributions. Then, using Eq. (24.39) with $F_{ox} = (V_{TH} - V_{FB} - \phi_{TH})/d$ we find

$$V_{TH} = V_{FB} + \phi_{TH} + Q_D \frac{d}{\varepsilon_{ox}} \tag{24.40}$$

which determines V_{TH} even for the nonuniformly doped case, using Eq. (24.38) for ϕ_{TH} and Q_D at threshold from Eq. (24.35). If interface-trap charge/unit area is not negligible, then terms in the interface-trap charge/unit area Q_{IT} must be added to Q_D in Eq. (24.40).

From Eqs. (24.35) and (24.38), the threshold voltage depends upon the implanted dopant-ion profile only through two parameters, the net charge introduced by the implant in the region between the inversion layer and the depletion-layer edge qD_p and the centroid of this portion of the implanted charge x_C. As a result, a variety of implants can result in the same threshold, ranging from the extreme of a δ-function spike implant of dose D_I/unit area located at the centroid x_O to a box-type rectangular distribution with the same dose and centroid, namely, a rectangular distribution of width $x_W = 2x_C$ and volume density D_I/x_W. (Of course, x_W must be no larger than the depletion-layer width at threshold for this equivalence to hold true, and x_C must not lie within the inversion layer.) This weak dependence on the details of the profile leaves flexibility to satisfy other requirements, such as control of off current.

As already said, for gate biases $V_G > V_{TH}$ any gate charge above the threshold value is balanced mainly by inversion-layer charge. Thus, the additional oxide field, given by $(V_G - V_{TH})/d$, is related by Gauss's law to the inversion-layer carrier density approximately by

$$\varepsilon_{ox} \frac{V_G - V_{TH}}{d} \approx qN_{inv} \tag{24.41}$$

which shows that channel strength above threshold is proportional to $V_G - V_{TH}$, an approximation often used in this article. Thus, the switch in balancing gate charge from the depletion layer to the inversion layer causes N_{inv} to switch from an exponential gate-voltage dependence in subthreshold to a linear dependence above threshold.

For circuit analysis Eq. (24.41) is a convenient *definition* of V_{TH} because it fits current-voltage curves. If this definition is chosen instead of the charge-balance definition of Eq. (24.32), then Eqs. (24.32) and (24.38) result in an *approximation* to ϕ_{TH}.

Driving Ability and $I_{D,sat}$

The driving ability of the MOSFET is proportional to the current it can provide at a given gate bias. One might anticipate that the larger this current, the faster the circuit. Here this current is used to find some response times governing MOSFET circuits.

MOSFET current is dependent upon the carrier density in the channel, or upon $V_G - V_{TH}$, see Eq. (24.41). For a long-channel device, driving ability depends also on channel length. The shorter the channel length, L, the greater the driving ability, because the channel resistance is directly proportional to the channel length. Although it is an oversimplification, let us suppose that the MOSFET is primarily in saturation during the driving of its load. This simplification will allow a clear discussion of the issues involved in making faster MOSFET's without complicated mathematics. Assuming the MOSFET to be saturated over most of the switching period, driving ability is proportional to current in saturation, or to

$$I_{D,sat} = \frac{\varepsilon_{ox} Z\mu}{2dL} \left(V_G - V_{TH}\right)^2 \tag{24.42}$$

where the factor of two results from the saturating behavior of the *I-V* curves at large drain biases and Z is the width of the channel normal to the direction of current flow. Evidently, for long devices driving ability is quadratic in $V_G - V_{TH}$, and inversely proportional to d.

The result of Eq. (24.42) holds for long devices. For short-channel devices, as explained for Fig. 24.44, the larger fields exerted by the drain electrode cause *velocity saturation* and, as a result, $I_{D,\text{sat}}$ is given roughly by [Einspruch and Gildenblat, 1989]

$$I_{D,\text{sat}} \approx \frac{\varepsilon_{\text{ox}} Z \upsilon_{\text{sat}}}{d} \frac{(V_G - V_{TH})^2}{V_G - V_{TH} + F_{\text{sat}} L} \tag{24.43}$$

where υ_{sat} is the carrier saturation velocity, about 10^7 cm/s for silicon at 290 K, F_{sat} is the field at which velocity saturation sets in, about 5×10^4 V/cm for electrons and not well established as $\gtrsim 10^5$ V/cm for holes in silicon MOSFETs. For Eq. (24.43) to agree with Eq. (24.42) at long L, we need $\mu \approx 2\upsilon_{\text{sat}}/F_{\text{sat}} \approx 400$ cm^2(V·s) for electrons in silicon MOSFETs, which is only roughly correct. Nonetheless, we can see that for devices in the submicron channel length regime, $I_{D,\text{sat}}$ tends to become independent of channel length L and becomes more linear with $V_G - V_{TH}$ and less quadratic (see Fig. 24.44). Equation (24.43) shows that velocity saturation is significant when $V_G/L \gtrsim F_{\text{sat}}$ for example, when $L \lesssim 0.5$ μm if $V_G - V_{TH} = 2.5$ V.

To relate $I_{D,\text{sat}}$ to a gate response time, τ_G, consider one MOSFET driving an identical MOSFET as load capacitance. Then the current from Eq. (24.43) charges this capacitance to a voltage V_G in a gate response time τ_G given by [Shoji, 1988]

$$\begin{aligned} \tau_G &= \frac{C_G V_G}{I_{D,\text{sat}}} \\ &= \frac{L}{\upsilon_{\text{sat}}} \left(1 + \frac{C_{\text{par}}}{C_{\text{ox}}}\right) \frac{V_G (V_G - V_{TH} + F_{\text{sat}} L)}{(V_G - V_{TH})^2} \end{aligned} \tag{24.44}$$

where C_G is the MOSFET gate capacitance $C_G = C_{\text{ox}} + C_{\text{par}}$, with $C_{\text{ox}} = \varepsilon_{\text{ox}} ZL/d$ the MOSFET oxide capacitance, and C_{par} the parasitic component of the gate capacitance [Chen, 1990]. The parasitic capacitance C_{par} is due mainly to overlap of the gate electrode over the source and drain and partly to fringing-field and channel-edge capacitances. For short-channel lengths, C_{par} is a significant part of C_G, and keeping C_{par} under control as L is reduced is an objective of gate-drain alignment technology. Typically, $V_{TH} \approx V_G/4$, so

$$\tau_G \approx \left(\frac{L}{\upsilon_{\text{sat}}}\right)\left(1 + \frac{C_{\text{par}}}{C_{\text{ox}}}\right)\left(1.3 + 1.8 \frac{F_{\text{sat}} L}{V_G}\right) \tag{24.45}$$

Thus, on an intrinsic level, the gate response time is closely related to the transit time of an electron from source to drain, which is L/υ_{sat} in velocity saturation. At shorter L, a linear reduction in delay with L is predicted, while for longer devices the improvement can be quadratic in L, depending upon how V_G is scaled as L is reduced.

The gate response time is not the only delay in device switching, because the drain-body *pn* junction also must charge or discharge for the MOSFET to change state [Shoji, 1988]. Hence, we must also consider a drain response time τ_D. Following Eq. (24.44), we suppose that the drain capacitance C_D is charged by the supply voltage through a MOSFET in saturation so that

$$\tau_D = \frac{C_D V_G}{I_{D,\text{sat}}} = \frac{C_D}{C_G} \tau_G \tag{24.46}$$

Equation (24.46) suggests that τ_D will show a similar improvement to τ_G as L is reduced, provided that C_D/C_G does not increase as L is reduced. However, $C_{ox} \propto L/d$, and the major component of C_{par}, namely, the overlap capacitance contribution, leads to $C_{par} \propto L_{ovlp}/d$ where L_{ovlp} is roughly three times the length of overlap of the gate over the source or drain [Chen, 1990]. Then $C_G \propto (L + L_{ovlp})/d$ and, to keep the C_D/C_G ratio from increasing as L is reduced, either C_D or oxide-thickness d must be reduced along with L.

Clever design can reduce C_D. For example, various *raised-drain* designs reduce the drain-to-body capacitance by separating much of the drain area from the body using a thick oxide layer. The contribution to drain capacitance stemming from the sidewall depletion-layer width next to the channel region is more difficult to handle, because the sidewall depletion layer is deliberately reduced during miniaturization to avoid *short-channel* effects, that is, drain influence upon the channel in competition with gate control. As a result this sidewall contribution to the drain capacitance tends to increase with miniaturization unless junction depth can be shrunk.

Equations (24.45) and (24.46) predict reduction of response times by reduction in channel length L. Decreasing oxide thickness leads to no improvement in τ_G, but Eq. (24.46) shows a possibility of improvement in τ_D, because C_D is independent of d while C_G increases as d decreases. The *ring oscillator*, a closed loop of an odd number of inverters, is a test circuit whose performance depends primarily on τ_G and τ_D. Gate delay/stage for ring oscillators is found to be near 12 ps/stage at 0.1 μm channel length, and 60 ps/stage at 0.5 μm.

For circuits, interconnection capacitances and fan-out (multiple MOSFET loads) will increase response times beyond the device response time, even when parasitics are taken into account. Thus, we are led to consider interconnection delay, τ_{INT}. Although a lumped model suggests, as with Eq. (24.46), that $\tau_{INT} \approx (C_{INT}/C_G)\,\tau_G$, the length of interconnections requires a *distributed* model. Interconnection delay is then

$$\tau_{INT} = \frac{R_{INT}C_{INT}}{2} + R_{INT}C_G + \left(1 + \frac{C_{INT}}{C_G}\right)\tau_G \tag{24.47}$$

where the new symbols are R_{INT} = interconnection resistance, C_{INT} = interconnection capacitance, and we have assumed that the interconnection joins a MOSFET driver in saturation to a MOSFET load C_G. For small R_{INT}, τ_{INT} is dominated by the last term, which resembles Eqs. (24.44) and (24.46). However, unlike the ratio C_D/C_G in Eq. (24.46), it is difficult to reduce or even maintain the ratio C_{INT}/C_G in Eq. (24.47) as L is reduced. Remember, $C_G \propto Z\,(L + L_{ovlp})/d$. Reduction of L therefore tends to increase C_{INT}/C_G, especially because interconnect cross sections cannot be reduced without impractical increases in R_{INT}. What is worse, along with reduction in L, chip sizes usually increase, making line lengths longer, increasing R_{INT} even at constant cross section. As a result, interconnection delay becomes a major problem as L is reduced. The obvious way to keep C_{INT}/C_G under control is to increase the device width Z so that $C_G \propto Z\,(L + L_{ovlp})/d$ remains constant as L is reduced. A better way is to cascade drivers of increasing Z [Chen, 1990; Shoji, 1988]. Either solution requires extra area, however, reducing the packing density that is a major objective in decreasing L in the first place. An alternative is to reduce the oxide thickness d, a major technology objective today.

Transconductance

Another important device parameter is the small-signal transconductance g_m [Sedra and Smith, 1991; Haznedar, 1991], which determines the amount of output current swing at the drain that results from a given input voltage variation at the gate, that is, the small-signal gain:

$$g_m = \left.\frac{\partial I_D}{\partial V_G}\right|_{V_D=\text{const}} \tag{24.48}$$

Using the chain rule of differentiation, the transconductance in saturation can be related to the small-signal *transition* or *unity-gain frequency*, which determines at how high a frequency ω the small-signal current gain $|\imath_{out}/\imath_{in}| = g_m/(\omega C_G)$ drops to unity. Using the chain rule,

$$g_m = \frac{\partial I_{D,\text{sat}}}{\partial Q_G}\frac{\partial Q_G}{\partial V_G} = \omega_T C_G \tag{24.49}$$

where C_G is the oxide capacitance of the device, $C_G = \partial Q_G/\partial V_G|V_D$ with Q_G = the charge on the gate electrode. The frequency ω_T is a measure of the small-signal, high-frequency speed of the device, neglecting parasitic resistances. Using Eq. (24.43) in Eq. (24.49) we find that the transition frequency also is related to the transit time L/υ_{sat} of Eq. (24.45), so that both the digital and small-signal circuit speeds are related to this parameter.

Output Resistance and Drain Conductance

For small-signal circuits the output resistance r_o of the MOSFET [Sedra and Smith, 1991] is important in limiting the gain of amplifiers. This resistance is related to the small-signal drain conductance g_D in saturation by

$$r_o = \frac{1}{g_D} = \frac{\partial V_D}{\partial I_{D,\text{sat}}}\bigg|_{V_G = \text{const}} \tag{24.50}$$

If the MOSFET is used alone as a simple amplifier with a load line set by a resistor R_L, the gain becomes

$$\left|\frac{\upsilon_o}{\upsilon_{\text{in}}}\right| = g_m \frac{R_L r_o}{R_L + r_o} \le g_m R_L \tag{24.51}$$

showing how gain is reduced if r_o is reduced to a value approaching R_L.

As devices are miniaturized, r_o is decreased, g_D increased, due to several factors. At moderate drain biases, the main factor is channel-length modulation, the reduction of the channel length with increasing drain voltage that results when the depletion region around the drain expands toward the source, causing L to become drain-bias dependent. At larger drain biases, a second factor is drain control of the inversion-layer charge density, which can compete with gate control in short devices. This is the same mechanism discussed later in the context of subthreshold behavior. At rather high drain bias, carrier multiplication further lowers r_o.

In a digital inverter, a lower r_o widens the voltage swing needed to cause a transition in output voltage. This widening increases power loss due to current spiking during the transition, and reduces noise margins [Annaratone, 1986]. It is not, however, a first-order concern in device miniaturization for digital applications. Because small-signal circuits are more sensitive to r_o than digital circuits, MOSFETs designed for small-signal applications cannot be made as small as those for digital applications.

Limitations upon Miniaturization

A major factor in the success of the MOSFET has been its compatibility with processing useful down to very small dimensions. Today channel lengths (source-to-drain spacings) of 0.5 μm are manufacturable, and further reduction to 0.1 μm has been achieved for limited numbers of devices in test circuits such as ring oscillators. In this section some of the limits that must be considered in miniaturization are outlined [Brews, 1990].

Subthreshold Control

When a MOSFET is in the "off" condition, that is, when the MOSFET is in *subthreshold,* the off current drawn with the drain at supply voltage must not be too large in order to avoid power consumption and discharge of ostensibly isolated nodes [Shoji, 1988]. In small devices, however, the source and drain are closely spaced, so there exists a danger of direct interaction of the drain with the source, rather than an interaction mediated by the gate and channel. In an extreme case, the drain may draw current directly from the source, even though the gate is "off" (*punchthrough*). A less extreme but also undesirable case occurs when the drain and gate jointly control the carrier density in the channel (*drain-induced barrier lowering*, or drain control of threshold voltage).

In such a case, the on–off behavior of the MOSFET is not controlled by the gate alone, and switching can occur over a range of gate voltages dependent on the drain voltage. Reliable circuit design under these circumstances is very complicated, and testing for design errors is prohibitive. Hence, in designing MOSFETs, a drain-bias independent subthreshold behavior is necessary.

A measure of the range of influence of the source and drain is the depletion-layer width of the associated *pn* junctions. The depletion layer of such a junction is the region in which all carriers have been depleted, or pushed away, due to the potential drop across the junction. This potential drop includes the applied bias across the junction and a spontaneous *built-in* potential drop induced by spontaneous charge exchange when *p* and *n* regions are brought into contact. The depletion-layer width W of an abrupt junction is related to potential drop V and dopant-ion concentration/unit volume N by

$$W = \left(\frac{2\varepsilon_s V}{qN} \right)^{1/2} \tag{24.52}$$

To avoid subthreshold problems, a commonly used rule of thumb is to make sure that the channel length is longer than a minimum length $L_{\min}$ related to the junction depth r_j, the oxide thickness d, and the depletion-layer widths W_S and W_D of the source and drain by [Brews, 1990]

$$L_{\min} = A[r_j d(W_S + W_D)^2]^{1/3} \tag{24.53}$$

where the empirical constant $A = 0.88\ \text{nm}^{-1/3}$ if r_j, W_S, and W_D are in micrometers and d is in nanometers.

Equation (24.53) shows that smaller devices require shallower junctions (smaller r_j), thinner oxides (smaller d), or smaller depletion-layer widths (smaller voltage levels or heavier doping). These requirements introduce side effects that are difficult to control. For example, if the oxide is made thinner while voltages are not reduced proportionately, then oxide fields increase, requiring better oxides. If junction depths are reduced, better control of processing is required, and the junction resistance is increased due to smaller cross sections. To control this resistance, various *self-aligned contact* schemes have been developed to bring the source and drain contacts closer to the gate [Brews, 1990; Einspruch and Gildenblat, 1989], reducing the resistance of these connections. If depletion-layer widths are reduced by increasing the dopant-ion density the *driving ability* of the MOSFET suffers because the threshold voltage increases. That is, Q_D increases in Eq. (24.40), reducing $V_G - V_{TH}$. Thus, for devices that are not velocity-saturated, that is, devices where $V_G/L \lesssim F_{\text{sat}}$, increasing V_{TH} results in slower circuits.

As secondary consequences of increasing dopant-ion density, channel conductance is further reduced due to the combined effects of increased scattering of electrons from the dopant atoms and increased oxide fields that pin carriers in the inversion layer closer to the insulator–semiconductor interface, increasing scattering at the interface. These effects also reduce driving ability, although for shorter devices they are important only in the linear region (that is, below saturation), assuming that mobility μ is more strongly affected than saturation velocity υ_{sat}.

Hot-Electron Effects

Another limit upon how small a MOSFET can be made is a direct result of the larger fields in small devices. Let us digress to consider why proportionately larger voltages, and thus larger fields, are used in smaller devices. First, according to Eq. (24.45), τ_G is shortened if voltages are increased, at least so long as $V_G/L \lesssim F_{\text{sat}}$ 5×10^4 V/cm. If τ_G is shortened this way, then so are τ_D and τ_{INT}, Eqs. (24.46) and (24.47). Thus, faster response is gained by increasing voltages into the velocity saturation region. Second, the fabricational control of smaller devices has not improved proportionately as L has shrunk, so there is a larger percentage variation in device parameters with smaller devices. Thus, disproportionately larger voltages are needed to ensure that all devices operate in the circuit, to overcome this increased fabricational "noise." Thus, to increase speed and to cope with fabricational variations, fields go up in smaller devices.

As a result of these larger fields along the channel direction, a small fraction of the channel carriers have enough energy to enter the insulating layer near the drain. In silicon-based *p*-channel MOSFETs, energetic holes can become trapped in the oxide, leading to a positive oxide charge near the drain that reduces the strength of the channel, degrading device behavior. In *n*-channel MOSFETs, energetic electrons entering the oxide create interface traps and oxide wear-out, eventually leading to gate-to-drain shorts [Pimbley et al., 1989].

To cope with these problems "drain-engineering" has been tried, the most common solution being the *lightly doped drain* [Chen, 1990; Einspruch and Gildenblat, 1989; Pimbley et al., 1989]. In this design, a lightly doped extension of the drain is inserted between the channel and the drain proper. To keep the field moderate and reduce any peaks in the field, the lightly doped drain extension is designed to spread the drain-to-channel voltage drop as evenly as possible. The aim is to smooth out the field at a value close to F_{sat} so that energetic carriers are kept to a minimum. The expense of this solution is an increase in drain resistance and a decreased gain. To increase packing density, this lightly doped drain extension can be stacked vertically alongside the gate, rather than laterally under the gate, to control the overall device area.

Thin Oxides

According to Eq. (24.53), thinner oxides allow shorter devices and therefore higher packing densities for devices. In addition, driving ability is increased, shortening response times for capacitive loads, and output resistance and transconductance are increased. There are some basic limitations upon how thin the oxide can be made. For instance, there is a maximum oxide field that the insulator can withstand. It is thought that the intrinsic breakdown voltage of SiO_2 is of the order of 10^7 V/cm, a field that can support $\approx 2 \times 10^{13}$ charges/cm^2, a large enough value to make this field limitation secondary. Unfortunately, as they are presently manufactured, the intrinsic breakdown of MOSFET oxides is much less likely to limit fields than defect-related leakage or breakdown, and control of these defects has limited reduction of oxide thicknesses in manufacture to about 5 nm to date.

If defect-related problems could be avoided, the thinnest useful oxide would probably be about 3 nm, limited by direct tunneling of channel carriers to the gate. This tunneling limit is not well established, and also is subject to oxide-defect enhancement due to tunneling through intermediate defect levels. Thus, the manufacture of thin oxides is a very active area of exploration.

Dopant-Ion Control

As devices are made smaller, the precise positioning of dopant inside the device is critical. At high temperatures during processing, dopant ions can move. For example, source and drain dopants can enter the channel region, causing position dependence of threshold voltage. Similar problems occur in isolation structures that separate one device from another [Pimbley et al., 1989; Einspruch and Gildenblat, 1989; Wolf, 1995].

To control these thermal effects, process sequences are carefully designed to limit high-temperature steps. This design effort is shortened and improved by the use of computer modeling of the processes. Dopant-ion movement is complex, however, and its theory is made more difficult by the growing trend to use *rapid thermal processing* that involves short-time heat treatments. As a result, dopant response is not steady state, but transient. Computer models of transient response are primitive, forcing further advance in small-device design to be more empirical.

Other Limitations

Besides limitations directly related to the MOSFET, there are some broader difficulties in using MOSFETs of smaller dimension in chips involving even greater numbers of devices. Already mentioned is the increased delay due to interconnections that are lengthening due to increasing chip area and increasing complexity of connection. The capacitive loading of MOSFETs that must drive signals down these lines can slow circuit response, requiring extra circuitry to compensate. Another limitation is the need to isolate devices from each other [Brews, 1990; Chen 1990; Einspruch and Gildenblat, 1989; Pimbley et al., 1989; Wolf, 1995], so their actions remain uncoupled by parasitics. As isolation structures are reduced in size to increase device densities, new parasitics are discovered. A developing solution to this problem is the manufacture of circuits on insulating substrates, silicon-on-insulator technology [Colinge, 1991]. To succeed, this approach must deal with new problems, such as the electrical quality of the underlying silicon–insulator interface and the defect densities in the silicon layer on top of this insulator.

Defining Terms

Channel: The conducting region in a MOSFET between source and drain. In an *enhancement*-mode (or normally off) MOSFET, the channel is an inversion layer formed by attraction of minority carriers toward the gate. These carriers form a thin conducting layer that is prevented from reaching the gate by a thin *gate-oxide* isulating layer when the gate bias exceeds *threshold*. In a *buried-channel*, or *depletion-mode* (or normally on) MOSFET, the channel is present even at zero gate bias, and the gate serves to increase the channel resistance when its bias is nonzero. Thus, this device is based on majority-carrier modulation, like a MESFET.

Gate: The control electrode of a MOSFET. The voltage on the gate capacitively modulates the resistance of the connecting channel between the source and drain.

Source, drain: The two output contacts of a MOSFET, usually formed as *pn* junctions with the *substrate* or *body* of the device.

Strong inversion: The range of gate biases corresponding to the "on" condition of the MOSFET. At a fixed gate bias in this region, for low drain-to-source biases the MOSFET behaves as a simple gate-controlled resistor. At larger drain biases, the channel resistance can increase with drain bias, even to the point that the current *saturates*, or becomes independent of drain bias.

Substrate or body: The portion of the MOSFET that lies between the *source* and *drain* and under the *gate*. The gate is separated from the body by a thin *gate insulator*, usually silicon dioxide. The gate modulates the conductivity of the body, providing a gate-controlled resistance between the source and drain. The body is sometimes *dc*-biased to adjust overall circuit operation. In some circuits the body voltage can swing up and down as a result of input signals, leading to "body-effect" or "back-gate bias" effects that must be controlled for reliable circuit response.

Subthreshold: The range of gate biases corresponding to the "off" condition of the MOSFET. In this regime the MOSFET is not perfectly "off" but conducts a leakage current that must be controlled to avoid circuit errors and power consumption.

Threshold: The gate bias of a MOSFET that marks the boundary between "on" and "off" conditions.

25.1 Integrated Circuit Technology

Joe E. Brewer

Integrated circuit (IC) technology, the cornerstone of the modern electronics industry, is subject to rapid change. Electronic engineers, especially those engaged in research and development, can benefit from an understanding of the structure and pattern of growth of the technology.

Technology Perspective

A solid state IC is a group of interconnected circuit elements formed on or within a continuous substrate. While an integrated circuit may be based on many different material systems, silicon is by far the dominant material. More than 98% of contemporary electronic devices are based on silicon technology. On the order of 85% of silicon ICs are complementary metal oxide semiconductor (CMOS) devices.

From an economic standpoint the most important metric for an IC is the "level of functional integration." Since the invention of the IC by Jack Kilby in 1958, the level of integration has steadily increased. The pleasant result is that cost and physical size per function reduce continuously, and we enjoy a flow of new, affordable information processing products that pervade all aspects of our day-to-day lives. The historical rate of increase is a doubling of functional content per chip every 18 months.

For engineers who work with products that use semiconductor devices, the challenge is to anticipate and make use of these enhanced capabilities in a timely manner. It is not an overstatement to say that survival in the marketplace depends on rapid "design-in" and deployment.

For engineers who work in the semiconductor industry, or in its myriad of supporting industries, the challenge is to maintain this relentless growth. The entire industry is marching to a drumbeat. The cost of technology development and the investment in plant and equipment have risen to billions of dollars. Companies that lag behind face a serious loss of market share and, possibly, dire economic consequences.

Technology Generations

The concept of a technology generation emerged from analysis of historical records, was clearly defined by Gordon Moore in the 1960s, and codified as Moore's law. The current version of the law is that succeeding generations will support a four times increase in circuit complexity, and that new generations emerge at approximately 3-year intervals. The associated observations are that linear dimensions of device features change by a factor of 0.7, and the economically viable die size grows by a factor of 1.6.

Minimum feature size stated in microns (micrometers) is the term used most frequently to label a technology generation. "Feature" refers to a geometric object in the mask set such as a linewidth or a gate length. The "minimum feature" is the smallest dimension that can be reliably used to form the entity.

Figure 25.1 displays the technology evolution sequence. In the diagram succeeding generations are numbered using the current generation as the "0" reference. Because this material was written in 1996, the "0" generation is the 0.35 μm minimum feature size technology that began volume production in 1995.

An individual device generation has been observed to have a reasonably well-defined life cycle which covers about 17 years. The first year of volume manufacture is the reference point for a generation, but its lifetime actually extends further in both directions. As shown in Fig. 25.2, one can think of the stages of maturity as ranging over a linear scale which measures years to production in both the plus and minus directions. The 17-year life cycle of a single generation, with new generations being introduced at 3-year intervals, means that at any given time up to six generations are being worked on. This tends to blur the significance of research news and company announcements unless the reader is sensitive to the technology overlap in time.

To visualize this situation, consider Fig. 25.3. The top row lists calendar years. The second row shows how the life cycle of the 0.35 μm generation relates to the calendar. The third row shows the life cycle of the 0.25 μm generation vs. the calendar. Looking down any column corresponding to a specific calendar year, one can see which generations are active and identify their respective life cycle year.

FIGURE 25.3 Time overlap of semiconductor technology generations.

One should not interpret the 17-year life cycle as meaning that no work is being performed that is relevant to a generation before the 17-year period begins. For example, many organizations are conducting experiments directed at transistors with gate lengths smaller than 0.1 μm. This author's interpretation is that when basic research efforts have explored technology boundary conditions, the conditions are ripe for a specific generation to begin to coalesce as a unique entity. When a body of research begins to seek compatible materials and processes to enable design and production at the target feature size, the generation life cycle begins. This is a rather diffused activity at first, and it becomes more focused as the cycle proceeds.

National Technology Roadmap for Semiconductors

The National Technology Roadmap for Semiconductors (NTRS) is an almost 200-page volume distributed by the Semiconductor Industry Association (SIA). Focused on mainstream leading edge technology, the roadmap provides a common vision for the industry. It enables a degree of cooperative precompetitive research and development among the fiercely competitive semiconductor device manufacturers. It is a dynamic document which will be revised and reissued to reflect learning on an as-needed basis.

The NTRS is compiled by engineers and scientists from all sectors of the U.S. IC technology base. Industry, academia, and government organizations participate in its formulation. Key leaders are the Semiconductor Research Corporation (SRC) and SEMATECH industry consortia. The roadmap effort is directed by the Roadmap Coordinating Group (RCG) of the SIA.

The starting assumption of the NTRS is that Moore's law will continue to describe the growth of the technology. The overall roadmap comprises many individual roadmaps which address defined critical areas of semiconductor research, development, engineering, and manufacturing. In each area, needs and potential solutions for each technology generation are reviewed. Of course, this process is more definitive for the early generations because knowledge is more complete and the range of alternatives is restricted.

The NTRS document provides a convenient summary table which presents some of the salient characteristics of the six technology generations ranging from 1995 to 2010. That summary is reproduced (with minor variations in format) as Table 25.1.

The NTRS is available from the SIA, 181 Metro Drive, Suite 450, San Jose, CA 95110, telephone 408-436-6600, fax 408-436-6646. The document can also be accessed via the SEMATECH home page at <http://www.sematech.org>.

Information concerning the IC life cycle can be found in Larrabee, G. B. and Chatterjee, P. "DRAM Manufacturing in the 90's — Part 1: The History Lesson" and "Part 2: The Roadmap," Semiconductor International, pp. 84–92, May 1991.

25.2 Layout, Placement, and Routing

Mehdi R. Zargham and Spyros Tragoudas

Very large scale integrated (VLSI) electronics presents a challenge, not only to those involved in the development of fabrication technology, but also to computer scientists, computer engineers, and electrical engineers. The ways in which digital systems are structured, the procedures used to design them, the trade-offs between hardware and software, and the design of computational algorithms will all be greatly affected by the coming changes in integrated electronics.

A VLSI chip can today contain millions of transistors and is expected to contain more than 100 million transistors in the year 2000. One of the main factors contributing to this increase is the effort that has been invested in the development of computer-aided design (CAD) systems for VLSI design. The VLSI CAD systems are able to simplify the design process by hiding the low-level circuit theory and device physics details from the designer, and allowing him or her to concentrate on the functionality of the design and on ways of optimizing it.

A VLSI CAD system supports descriptions of hardware at many levels of abstraction, such as system, subsystem, register, gate, circuit, and layout levels. It allows designers to design a hardware device at an abstract level and progressively work down to the layout level. A layout is a complete geometric representation (a set of rectangles) from which the latest fabrication technologies directly produce reliable, working chips. A VLSI

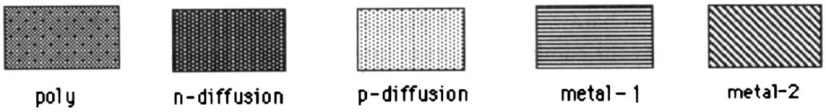

FIGURE 25.4 Different layers.

CAD system also supports verification, synthesis, and testing of the design. Using a CAD system, the designer can make sure that all of the parts work before actually implementing the design.

A variety of VLSI CAD systems are commercially available that perform all or some of the levels of abstraction of design. Most of these systems support a *layout editor* for designing a circuit **layout.** A layout-editor is software that provides commands for drawing lines and boxes, copying objects, moving objects, erasing unwanted objects, and so on. The output of such an editor is a design file that describes the layout. Usually, the design file is represented in a standard format, called Caltech Intermediate Form (CIF), which is accepted by the fabrication industry.

What Is Layout?

For a specific circuit, a layout specifies the position and dimension of the different layers of materials as they would be laid on the silicon wafer. However, the layout description is only a symbolic representation, which simplifies the description of the actual fabrication process. For example, the layout representation does not explicitly indicate the thickness of the layers, thickness of oxide coating, amount of ionization in the transistors channels, etc., but these factors are implicitly understood in the fabrication process. Some of the main layers used in any layout description are *n*-diffusion, *p*-diffusion, poly, metal-1, and metal-2. Each of these layers is represented by a polygon of a particular color or pattern. As an example, Fig. 25.4 presents a specific pattern for each layer that will be used through the rest of this section.

As is shown in Fig. 25.5, an *n*-diffusion layer crossing a poly layer implies an nMOS transistor, and a *p*-diffusion crossing poly implies a pMOS transistor.

Note that the widths of diffusion and poly are represented with a scalable parameter called *lambda.* These measurements, referred to as *design rules,* are introduced to prevent errors on the chip, such as preventing thin lines from opening (disconnecting) and short circuiting.

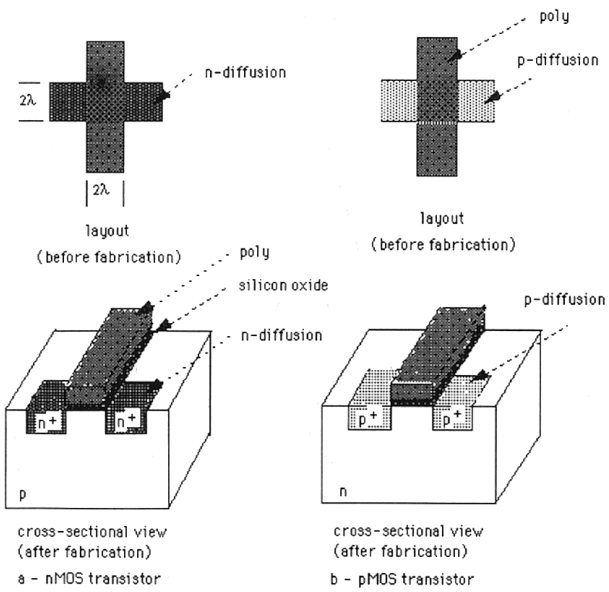

FIGURE 25.5 Layout and fabrication of MOS transistors.

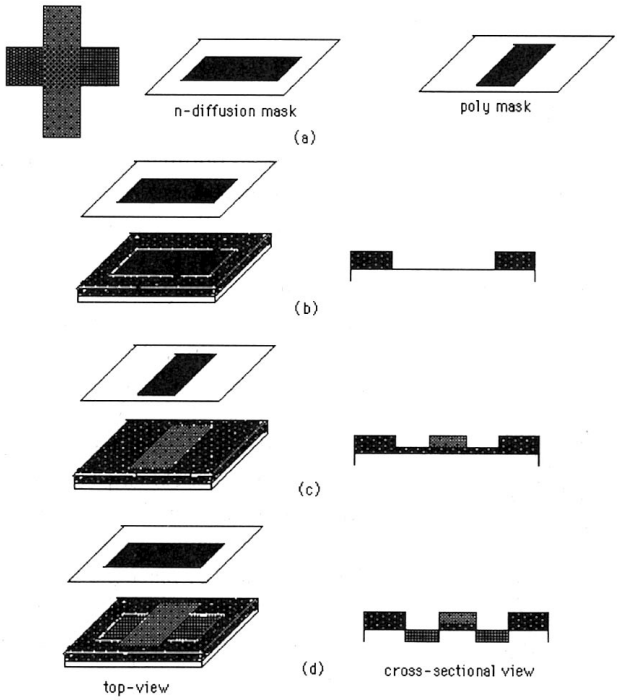

FIGURE 25.6 Fabrication steps for an nMOS transistor.

Implementing the design rules based on lambda makes the design process independent of the fabrication process. This allows the design to be rescaled as the fabrication process improves.

Metal layers are used as wires for connections between the components. This is because metal has the lowest propagation delay compared to the other layers. However, sometimes a poly layer is also used for short wires in order to reduce the complexity of the wire routing. Any wire can cross another wire without getting electrically affected as long as they are in different layers. Two different layers can be electrically connected together using *contacts.* The fabrication process of the contacts depends on types of the layers that are to be connected. Therefore, a layout editor supports different types of contacts by using different patterns.

From the circuit layout, the actual chip is fabricated. Based on the layers in the layout, various layers of materials, one on top of the others, are laid down on a silicon wafer. Typically, the processing of laying down each of these materials involves several steps, such as masking, oxide coating, lithography and etching [Mead and Conway, 1980]. For example, as shown in Fig. 25.6(a), for fabricating an nMOS transistor, first two masks, one for poly and one for *n*-diffusion, are obtained from the circuit layout. Next, the *n*-diffusion mask is used to create a layer of silicon oxide on the wafer [see Fig. 25.6(b)]. The wafer will be covered with a thin layer of oxide in places where the transistors are supposed to be placed as opposed to a thick layer in other places. The poly mask is used to place a layer of polysilicon on top of the oxide layer to define the gate terminals of the transistor [see Fig. 25.6(c)]. Finally, the *n*-diffusion regions are made to form the source and drain terminals of the transistor [see Fig. 25.6(d)].

To better illustrate the concept of layout design, the design of an inverter in the CMOS technology is shown in Fig. 25.7. An inverter produces an output voltage that is the logical inverse of its input. Considering the circuit diagram of Fig. 25.7(a), when the input is 1, the lower nMOS is on, but the upper pMOS is off. Thus, the output becomes 0 by becoming connected to the ground through the nMOS. On the other hand, if the input is 0, the pMOS is on and the nMOS is off, so the output must find a charge-up path through the pMOS to the supply and therefore becomes 1. Figure 25.7(b) represents a layout for such an inverter. As can be seen from this figure, the problem of a layout design is essentially reduced to drawing and painting a set of polygons. Layout editors provide commands for drawing such polygons. The commands are usually entered at the keyboard or with a mouse and, in some menu-driven packages, can be selected as options from a pull-down menu.

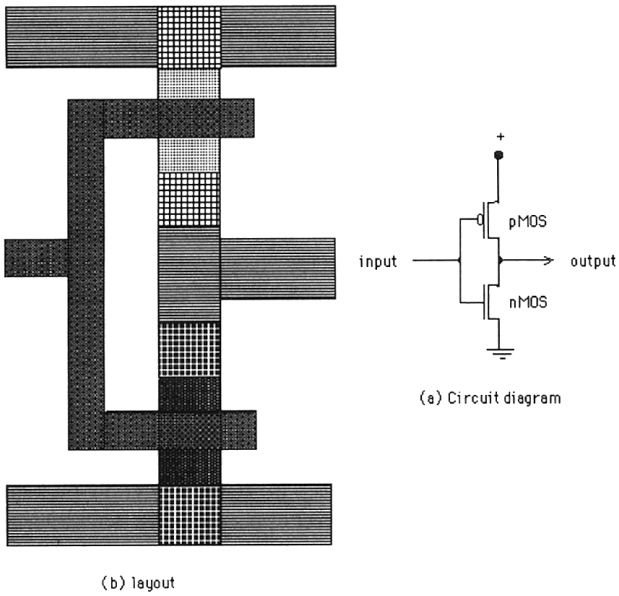

FIGURE 25.7 An inverter.

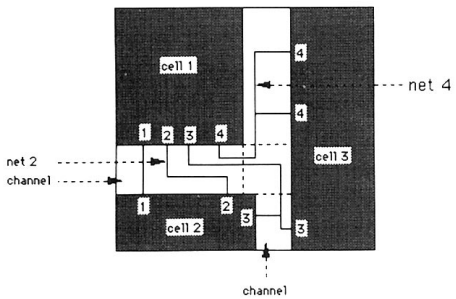

FIGURE 25.8 Placement and routing.,

In addition to the drawing commands, often a layout system provides tools for minimizing the overall area of the layout (i.e., size of the chip). Today a VLSI chip consists of a lot of individual cells, with each one laid out separately. A cell can be an inverter, a NAND gate, a multiplier, a memory unit, etc. The designer can make the layout of a cell and then store it in a file called the *cell library*. Later, each time the designer wants to design a circuit that requires the stored cell, he or she simply copies the layout from the cell library. A layout may consist of many cells. Most of the layout systems provide routines, called **floorplanning, placement** and **routing** routines, for placing the cells and then interconnecting them with wires in such a way that minimizes the layout area. As an example, Fig. 25.8 presents the placement of three cells. The area between the cells is used for routing. The entire routing surface is divided into a set of rectangular routing areas called channels. The sides of each channel consist of a set of terminals. A wire that connects the terminals with the same ID is called a net. The router finds a location for the wire segments of each net within the channel. The following sections classify various types of placement and routing techniques and provide an overview of the main steps of some of these techniques.

Floorplanning Techniques

The floorplanning problem in Computer Aided Design of Integrated Circuits is similar to that in Architecture and the goal is to find a location for each cell based on proximity (layout adjacency) criteria to other cells. We

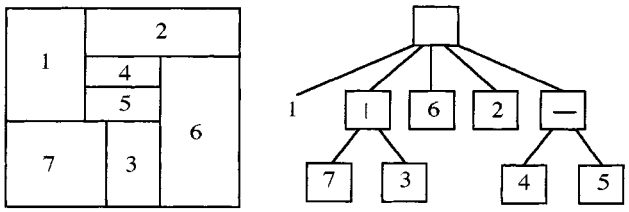

FIGURE 25.9 A hierarchical floorplan and its associated tree. The root node has degree 5. The internal node labeled with | indicates a vertical slicing. The internal node labeled with — indicates a horizontal slicing.

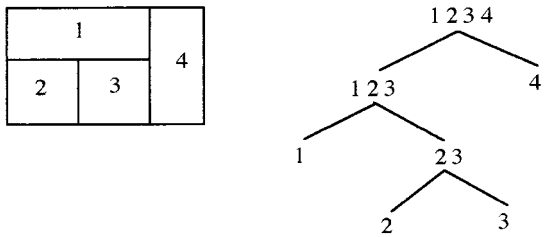

FIGURE 25.10 A sliceable floorplan and its associated binary tree.

consider rectangular floorplans whose boundaries are rectangles. It is desirable to obtain a floorplan that minimizes the overall area of the layout.

An important goal in floorplanning is the cell sizing problem where the goal is to determine the dimensions of variable cells whose area is invariant. All cells are assumed to be rectangular, and in the cell sizing problem the goal is to determine the width and height of each cell subject to predetermined upper and lower bounds on their ratio, and to their product being equal to its area, so that the final floorplan has optimal area.

One of the early approaches in floorplanning is the hierarchical, where recursive bipartition or partition into more than two parts is recursively employed and a floorplan tree is constructed. The tree simply reflects the hierarchical construction of the floorplan. Figure 25.9 shows a hierarchical floorplan and its associated tree. The partitioning problem and related algorithms are discussed extensively later in this section.

Many early hierarchical floorplanning tools insist that the floorplan be sliceable. A sliceable floorplan is recursively defined as follows: (a) a cell or (b) a floorplan that can be bipartitioned into two sliceable floorplans with either a horizontal or vertical line. Figure 25.10 shows a sliceable floorplan whose tree is binary.

Many tools that produce sliceable floorplans are still in use because of their simplicity. In particular, many problems arising in sliceable floorplanning are solvable optimally in polynomial time [Sarrafzadeh and Wong, 1996]. Unfortunately, sliceable floorplans are rarely optimal (in terms of their area), and they often result in layouts with very difficult routing phases. (Routing is discussed later in this section.) Figure 25.11 shows a compact floorplan that is not sliceable.

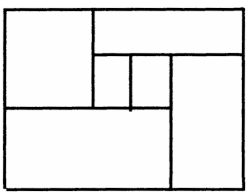

FIGURE 25.11 A compact layout that is not sliceable.

Hierarchical tools that produce nonsliceable floorplans have also been proposed [Sarrafzadeh and Wong, 1996]. The major problem in the development of such tools is that we are often facing problems that are intractable and thus we have to rely on heuristics in order to obtain fast solutions. For example, the cell sizing problem can be tackled optimally in sliceable floorplans [Otten, 1983 and Stockmeyer, 1983] but the problem is intractable for general nonsliceable floorplans.

A second approach to floorplanning is the rectangular dual graph. The idea here is to use duality arguments and express the cell adjacency constraints in terms of a graph, and then use an algorithm to translate the graph into a rectangular floorplan. A rectangular dual graph of a rectangular floorplan is a planar graph G = (V,E), where V is the set of cells and E is the set of edges, and an edge (C_1,C_2) is in E if and only if cells C_1 and C_2 are adjacent in the floorplan. See Fig. 25.12 for a rectangular floorplan and its rectangular dual graph G.

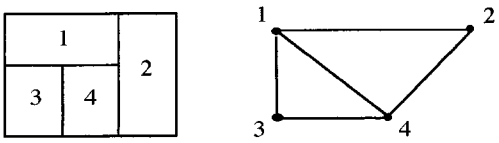

FIGURE 25.12 A rectangular floorplan and its associated dual planer graph.

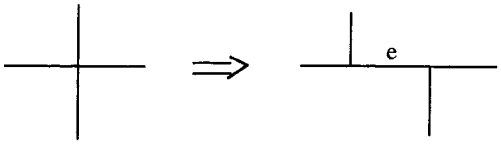

FIGURE 25.13 A cross junction can be replaced by 2 T-junctions.

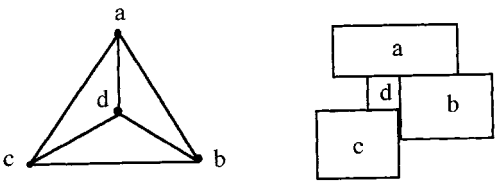

FIGURE 25.14 For a cycle of size 3 that is not a face we cannot satisfy all constraints.

Let us assume that the floorplan does not contain cross junctions. Figure 25.13 shows a cross junction. This restriction does not significantly increase the area of a floorplan because, as Fig. 25.13 shows, a cross junction can be replaced by two T-junctions by simply adding a short edge e.

It has been shown that in the absence of cross junctions the dual graph is planar triangulated (PT), and every T-junction corresponds to a triangulated face of the dual PT graph. Unfortunately, not all PT graphs have a rectangular floorplan. For example, in the graph of Fig. 25.14 we cannot satisfy the adjacency requirements of edges (a,b), (b,c) and (c,a) at the same time. Note that the later edges form a cycle of length three that is not a face. It has been shown that a PT graph has a rectangular floorplan if and only if it does not contain such cycles of length three. Moreover, a linear time algorithm to obtain such a floorplan has been presented [Sarrafzadeh and Wong, 1996]. The rectangular dual graph approach is a new method for floorplanning, and many floorplanning problems, such as the sizing problem, have not been tackled yet.

Rectangular floorplans can be obtained using simulated annealing and genetic algorithms. Both techniques are used to solve general optimization problems for which the solution space is not well understood. The approaches are easy to implement, but the algorithms have many parameters which require empirical adjustments, and the results are usually unpredictable.

A final approach to floorplanning, which unfortunately requires substantial computational resources and results to an intractable problem, is to formulate the problem as a mixed-integer linear programming (LP). Consider the following definitions:

W_i,H_i,R_i : width, height and area of cell C_i
X_i,Y_i : coordinates of lower left corner of cell C_i
X,Y : the width and height of the final floorplan
A_i,B_i : lower and upper bound for the ratio W_i/H_i of cell C_i
P_{ij}, Q_{ij} : variables that take 0/1 values for each pair of cells C_i and C_j

The goal is to find X_i,Y_i,W_i, and H_i for each cell so that all constraints are satisfied and XY is minimized. The latter is a nonlinear constraint. However, we can fix the width W and minimize the height of the floorplan as follows:

$$\min Y$$
$$X_i + W_i \le W$$
$$Y \ge Y_i + H_i$$

The complete mixed-integer LP formulation is [Sutanthavibul et al., 1991]:

$$\min Y$$
$$X_i, Y_i, W_i \ge 0$$
$$P_{ij}, Q_{ij} = 0 \text{ or } 1$$
$$X_i + W_i \le W$$
$$Y \ge Y_i + H_i$$
$$X_i + W_i \le X_j + W(P_{ij} + Q_{ij})$$
$$X_j + W_j \le X_i + W(1 - P_{ij} + Q_{ij})$$
$$Y_i + H_i \le Y_j + H(1 + P_{ij} - Q_{ij})$$
$$Y_j + H_j \le Y_i + H(2 - P_{ij} - Q_{ij})$$

When H_i appears in the above equations, it must be replaced (using first-order approximation techniques) by $H_i = D_i W_i + E_i$ where D_i and E_i are defined below:

$$W_{min} = \sqrt{R_i A_i}$$

$$W_{max} = \sqrt{R_i B_i}$$

$$H_{min} = \sqrt{R_i / B_i}$$

$$H_{max} = \sqrt{R_i / A_i}$$

$$D_i = (H_{max} - H_{min})/(W_{min} - W_{max})$$

$$E_i = H_{max} - D_i W_{min}$$

The unknown variables are X_i, Y_i, W_i, P_{ij}, and Q_{ij}. All other variables are known. The equations can then be fed into an LP solver to find a minimum cost solution for the unknowns.

Placement Techniques

Placement is a restricted version of floorplanning where all cells have fixed dimension. The objective of a placement routine is to determine an optimal position on the chip for a set of cells in a way that the total occupied area and total estimated length of connections are minimized. Given that the main cause of delay in a chip is the length of the connections, providing shorter connections becomes an important objective in placing a set of cells. The placement should be such that no cells overlap and enough space is left to complete all the connections.

All exact methods known for determining an optimal solution require a computing effort that increases exponentially with number of cells. To overcome this problem, many heuristics have been proposed [Preas and Lorenzetti, 1988]. There are basically three strategies of heuristics for solving the placement problem, namely, *constructive, partitioning,* and *iterative* methods. Constructive methods create placement in an incremental manner where a complete placement is only available when the method terminates. They often start by placing a *seed* (a seed can be a single cell or a group of cells) on the chip and then continuously placing other cells based on some heuristics such as size of cells, connectivity between the cells, design condition for connection lengths, or size of chip. This process continues until all the cells are placed on the chip. Partitioning methods divide the cells into two or more partitions so that the number of connections that cross the partition boundaries

is minimized. The process of dividing is continued until the number of cells per partition becomes less than a certain small number. Iterative methods seek to improve an initial placement by repeatedly modifying it. Improvement might be made by transforming one cell to a new position or switching positions of two or more cells. After a change is made to the current placement configuration based on some cost function, a decision is made to see whether to accept the new configuration. This process continues until an optimal (in most cases a near optimal) solution is obtained. Often the constructive methods are used to create initial placement on which an iterative method subsequently improves.

Constructive Method

In most of the constructive methods, at each step an unplaced cell is selected and then located in the proper area. There are different strategies for selecting a cell from the collection of unplaced cells [Wimer and Koren, 1988]. One strategy is to select the cell that is most strongly connected to already placed cells. For each unplaced cell, we find the total of its connections to all of the already placed cells. Then we select the unplaced cell that has the maximum number of connections. As an example consider the cells in Fig. 25.15. Assume that cells c_1 and c_2 are already placed on the chip. In Fig. 25.16 we see that cell c_5 has been selected as the next cell to be placed. This is because cell c_5 has the largest number of connections (i.e., three) to cells c_1 and c_2.

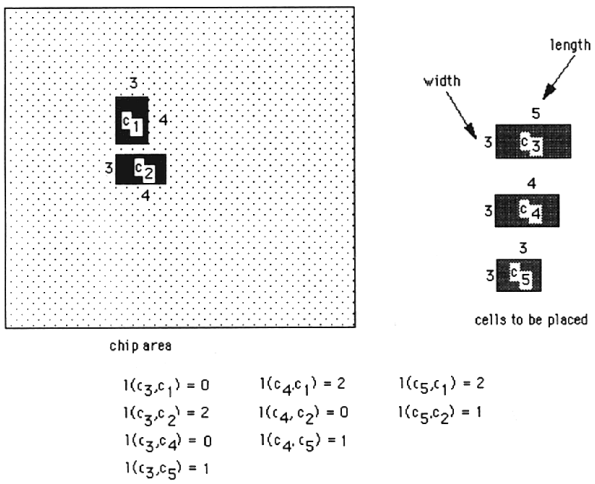

FIGURE 25.15 Initial configuration.

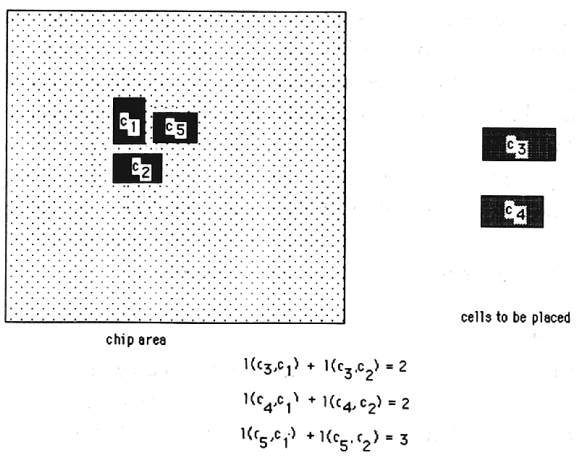

FIGURE 25.16 Selection based on the number of connections.

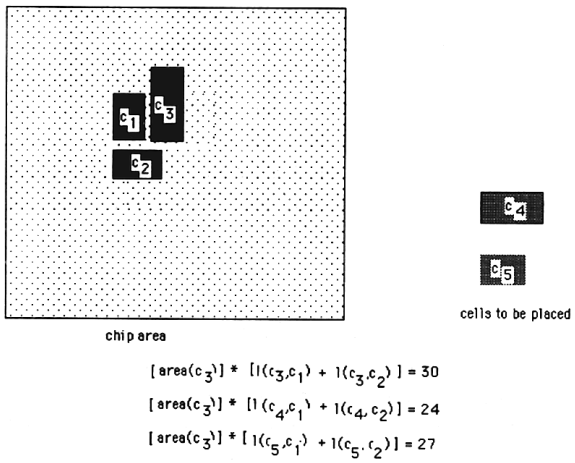

FIGURE 25.17 Selection based on the number of connections and area.

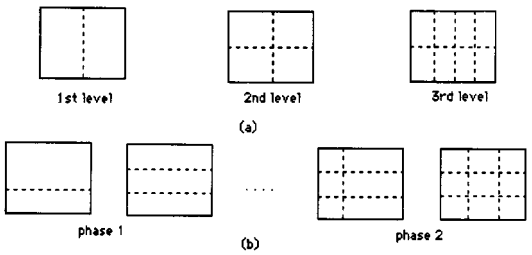

FIGURE 25.18 Partitioning.

The foregoing strategy does not consider area as a factor and thus results in fragmentation of the available free area; this may make it difficult to place some of the large unplaced cells later. This problem can be overcome, however, by considering the product of the number of connections and the area of the cell as a criteria for the selection. Figure 25.17 presents an example of such a strategy. Cell c_3 is selected as the next choice since the product of its area and its connections to c_1 and c_2 combine to associate with the maximum value.

Partitioning Method

The approaches for the partitioning method can be classified as quadratic and sliced bisection. In both approaches the layout is divided into two subareas, A and B, each having a size within a predefined range. Each cell is assigned to one of these subareas. This assignment is such that the number of interconnections between the two subareas is minimal. For example, Fig. 25.18 presents successive steps for the quadratic and sliced-bisection methods. As shown in Fig. 25.18(a), in the first step of the quadratic method the layout area is divided into two almost equal parts; in the second step the layout is further divided into four almost equal parts in the opposite direction. This process continues until each subarea contains only one cell. Similar to the quadratic method, the sliced-bisection also divides the layout area into several subareas.

The sliced-bisection method has two phases. In the first phase, the layout area is iteratively divided into a certain number of almost equal subareas in the same direction. In this way, we end up with a set of slices [see Fig. 25.18(b)]. Similarly, the second phase divides the area into a certain number of subareas; however, the slicing is done in the opposite direction.

Several heuristics have been proposed for each of the preceding partitioning methods. Here, for example, we emphasize the work of Fiduccia–Mattheyses [Fiduccia and Mattheyses, 1982], which uses the quadratic method. For simplicity, their algorithm is only explained for one step of this method. Initially the set of cells is randomly divided into two sets, A and B. Each set represents a subarea of the layout and has size equal to the area it represents. A cell is selected from one of these sets to be moved to the other set. The selection of the

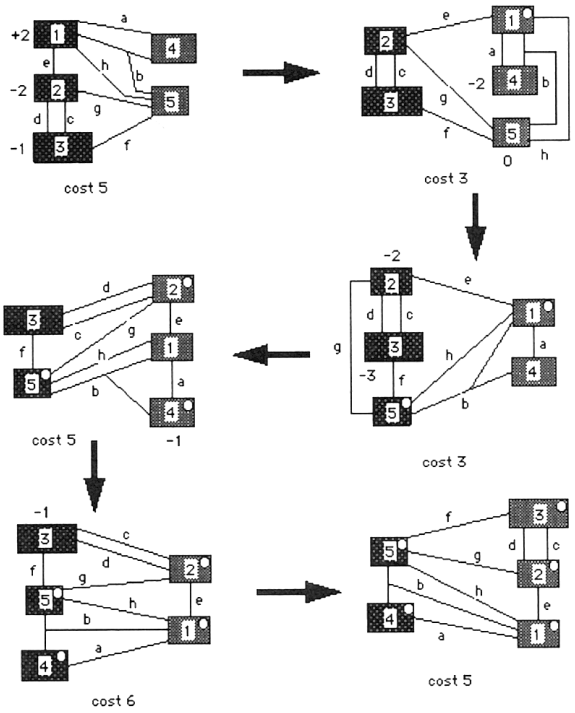

FIGURE 25.19 Illustration of a pass.

cell depends on three criteria. The cell should be free, i.e., the cell must have a minimum gain among the gains of all other free cells. A cell c has gain g if the number of interconnections between the cells of the two sets decreases by g units when c is moved from its current set to the other. Finally, the selected set's move should not violate a predefined balancing criterion that guarantees that the sizes of the two sets are almost equal. After moving the selected cell from its current set to the complementary set, it is no longer free. A new partition, which corresponds to the new instance of the two sets A and B, is created. The cost of a partition is defined as the number of interconnections between cells in the two sets of the partition. The Fiduccia–Mattheyses algorithm keeps track of the best partition encountered so far, i.e., the partition with the minimum cost. The algorithm will move the selected cell to the complementary set even if its gain is negative. In this case, the new partition is worse than the previous one, but the move can eventually lead to better partitions.

This process of generating new partitions and keeping track of the best encountered partition is repeated until no free cells are left. At this point of the process, which is called a pass, the algorithm returns the best partition and terminates. To obtain better partitions, the algorithm can be modified such that more passes occur. This can easily be done by selecting the best partition of a pass as the initial partition of the next pass. In this partition, however, all cells are free. The modified algorithm terminates whenever a new pass returns a partition that is no better than the partition returned by the previous pass. This way, the number of passes generated will never be more than the number of the interconnections in the circuit and the algorithm always terminates.

The balancing criterion in the Fiduccia–Mattheyses algorithm is easily maintained when the cells have uniform areas. The only way a pass can be implemented to satisfy the criterion is to start with a random initial partition in which the two sets differ by one cell, each time select the cell of maximum gain from the larger sized set, move the cell and generate a new partition, and repeat until no free cells are left.

In the example of Fig. 25.19, the areas of the cells are nonuniform. However, the assigned cell areas ensure that the previously described operation occurs so that the balancing criterion is satisfied. (The cell areas are omitted in this figure, but they correspond to the ones given in Fig. 25.15.) Figure 23.19 illustrates a pass of the Fiduccia–Mattheyses algorithm. During this pass, six different partitions are generated, i.e., the initial partition and five additional ones. Note that according to the description of the pass, the number of additional partitions equals the number of cells in the circuit.

Each partition consists of the cells of the circuit (colored according to the set to which they belong and labeled with an integer), the gain value associated with each free cell in the set from which the selected cell will be moved (this value can be a negative number), and the nets (labeled with letters). In the figure a cell that is no longer free is distinguished by an empty circle placed inside the rectangle that represents that cell.

The initial partition has cost 5 since nets *a*, *b*, *h*, *g*, *f* connect the cells in the two sets. Then the algorithm selects cell 1, which has the maximum gain. The new partition has cost 3 (nets *e*, *g*, *f*), and cell 1 is no longer free. The final partition has no free cells. The best partition in this pass has cost 3.

Iterative Method

Many iterative techniques have been proposed. Here, we emphasize one of these techniques called simulated annealing. Simulated annealing, as proposed by Kirkpatrick et al. [1983], makes the connection between statistical mechanics and combinatorial optimization problems. The main advantage with simulated annealing is its hill-climbing ability, which allows it to back out of inferior local solutions and find better solutions.

Sechen has applied simulated annealing to the placement problem and has obtained good solutions [Sechen, 1990]. The method basically involves the following steps:

BEGIN

1. Find an initial configuration by placing the cells randomly. Set the initial temperature, *T*, and the maximum number of iterations.
2. Calculate the cost of the initial configuration.
   A general form of the cost function may be: $Cost = c_1 * Area\ of\ layout + c_2 * Total\ interconnection\ length$ where c_1 and c_2 are tuning factors.
3. While (stopping criterion is not satisfied)
   {587
   a. For (maximum number of iteration)
      {
      1.Transform the old configuration into a new configuration.
      This transformation can be in the form of exchange of positions of two randomly selected cells or change of position of a randomly selected cell.
      2.Calculate the cost of the new configuration.
      3.If (new cost < old cost) accept the iteration, else check if the new iteration could be accepted with the probability: e ($|$new cost – old cost$|$ / *T*). There are also other options for the probability function.
      }
   b. Update the temperature.
      }

END

The parameter *T* is called *temperature;* it is initially set to a very large value, so that the probability of accepting "uphill" moves is very close to 1, that it is slowly decreasing toward zero, according to a rule called the cooling schedule. Usually, the new reduced temperature is calculated as follows:

$$\text{New temperature} = (\text{cooling rate}) \times (\text{Old temperature})$$

Using a faster cooling rate can result in getting stuck at local minima; however, a cooling rate that is too slow can pass over the possible global minima. In general, the cooling rate is taken from approximately 0.80 to 0.95.

Usually, the stopping criterion for the while-loop is implemented by recording the cost function's value at the end of each temperature stage of the annealing process. The stopping criterion is satisfied when the cost function's value has not changed for a number of consecutive stages.

Though simulated annealing is not the ultimate solution to placement problems, it gives very good results compared to the other popular techniques. The long execution time of this algorithm is its major disadvantage. Although a great deal of research has been done in improving this technique, substantial improvements have not been achieved.

Routing Techniques

Given a collection of cells placed on a chip, the routing problem is to connect the terminals (or ports) of these cells for a specific design requirement. The routing problem is often divided into three subproblems: global, detailed, and specialized routers. The global router considers the overall routing region in order to distribute the nets over the channels based on their capacities while keeping the length of each net as short as possible. For every channel that a net passes through, the net's id is placed on the sides of the channel. Once the terminals of each channel are determined, the detailed router connects all the terminals with the same id by a set of wire segments. (A wire segment is a piece of material described by a layer, two end-points, and a width.) The specialized router is designed to solve a specific problem such as routing of power and ground wires. These wires require special attention for two reasons: 1) they are usually routed in one layer in order to reduce the parasitic capacitance of contacts, and 2) they are usually wider than other wires (signal and data) since they carry more current.

Detailed routers further divide into general-purpose and restricted routers. The general-purpose routers impose very few constraints on the routing problem and operate on a single connection at a time. Since these routers work on the entire design in a serial fashion, the size of the problems they can attempt is limited. On the other hand, the restricted routers require some constraints on the routing problem, such as empty rectangular areas with all of the pins on the periphery. Because of their limited scope, these routers can do a better job of modeling the contention of nets for the routing resources and therefore can be viewed as routing the nets in parallel.

To reduce the complexity of restricted routers, this type of router often uses a rectangular grid on which trunks (horizontal wire segments) and branches (vertical wire segments) are placed on different layers. In other words, the layers supported by the technology are divided into two groups, horizontal and vertical. This is known as the Manhattan model. On the other hand, in a non-Manhattan model, the assignment of a layer to a vertical or horizontal direction is not enforced. Given the freedom of direction, assignment to layers reduces the channel width and vias in many cases; the latter model usually produces a better result than the former.

In the literature, many different techniques have been proposed for restricted routers. In general these techniques can be grouped into four different approaches: 1) algorithms (such as left-edge, maze, greedy, hierarchical); 2) expert systems; 3) neural networks; and 4) genetic algorithms [Zobrist, 1994; Sarrafzadeh, 1996; and Lengauer, 1990]. As an example, we consider here only one of the techniques, called a maze router which is widely known. The maze router can be used as a global router and/or detailed router. It finds the shortest rectilinear path by propagating a wavefront from a source point toward a destination point [Lee, 1969]. Considering the routing surface as a rectangular array of cells, the algorithm starts by marking the source cell as visited. In successive steps, it visits all the unvisited neighbors of visited cells. This continues until the destination cell is visited. For example, consider the cell configuration given in Fig. 25.20.

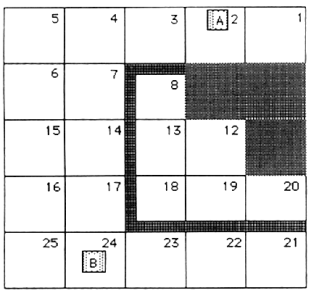

FIGURE 25.20 Initial configuration.

We would like to find a minimal-crossing path from source cell A (cell 2) to destination cell B (cell 24). (The minimal-crossing path is defined as a path that crosses over the fewest number of existing paths.) The algorithm begins by assigning the start cell 2 to a list, denoted as L, i.e., L consists of the single entry {2}. For each entry in L, its immediate neighbors (which are not blocked) will be added to an auxiliary list L′. (The auxiliary cell list L′ is provided for momentary storage of names of cells.) Therefore, list L′ contains entries {1,3}. To these cells a chain coordinate and a weight are assigned, as denoted in Fig. 25.21. For example, in cell 3, we have the pair (0, →), meaning that the chain coordinate is toward right and the cell weight is 0. The weight for a cell represents the number of wires that should be crossed in order to reach that cell from the source cell. The cells with minimum weight in list L′ are appended

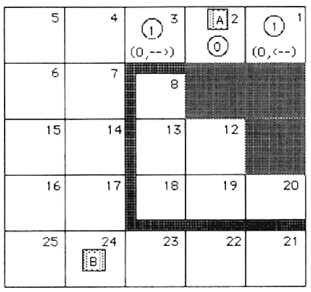

FIGURE 25.21 First step.

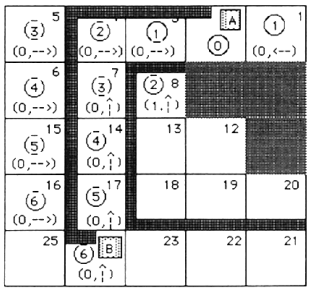

FIGURE 25.22 Final step.

to list L. Thus, cells 1 and 3 are appended to list L. Moreover, cell 2 is erased from list L. Appending the immediate neighbors of the cells in L to L′, we find that list L′ now contains entries 4 and 8. Note that cell 8 has a weight of 1; this is because a wire must be crossed in order to reach to this cell. Again the cells with minimum weight in list L′ are appended to list L, and cell 3 and cell 1 are erased from L. Now L contains entry {4}. The above procedure is repeated until it reaches to the final cell B. Then a solution is found by tracing the chain coordinated from cell B to cell A as shown in Fig. 25.22.

The importance of Lee's algorithm is that it always finds the shortest path between two points. Since it routes one net at a time, however, there is a possibility of having some nets unrouted at the end of the routing process. The other weak points of this technique are the requirements of a large memory space and long execution time. For this reason, the maze router is often used as a side router for the routing of critical nets and/or routing of leftover unrouted nets.

Defining Terms

Floorplanning: A floorplan routine determines an approximate position for each cell so that the total area is minimized.

Layout: Specifies the position and dimension of the different layers of materials as they would be layed on the silicon wafer.

Placement: A placement routine determines an optimal position on the chip for a set of cells with fixed dimensions in a way that the total occupied area and the total estimated length of connections are minimized.

Routing: Given a collection of cells placed on a chip, the routing routine connects the terminals of these cells for a specific design requirement.

25.3 Application-Specific Integrated Circuits

S. K. Tewksbury

Introduction

Present-day silicon very large scale integration complementary metal-oxide semiconductor (**VLSI CMOS**) technologies can place and interconnect several million transistors (representing over a million gates) on a single integrated circuit (**IC**) approximately 1 cm square. Provided with such a vast number of gates, a digital system designer can implement very sophisticated and complex system functions (including full systems) on a single IC. However, efficient design (including optimized performance) of such functions using all these gates is a complex puzzle of immense complexity. If this technology were to have been provided to the world overnight, it is doubtful that designers could in fact make use of this vast amount of logic on an IC.

However, this technology instead has evolved over a long period of time (about three decades), starting with only a few gates per IC, with the number of gates per IC doubling consistently about every 18 months (a progression referred to as Moore's Law), and evolving to the present high gate densities per IC. Projections [The National Technology Roadmap for Semiconductors, 1994] of this evolution over the next 15 years, as shown in Table 25.2, promise continued dramatic advances in the amount of logic and memory which will be provided on individual ICs. Paralleling the technology evolution, computer-aided design (**CAD**) tools and electronics design automation (**EDA**) tools [Rubin, 1987; Sherwani, 1993; Hill and Peterson, 1993; Banerjee, 1994] have evolved to assist designers of the increasingly complex ICs. With these CAD tools, today's design teams effectively have an army of very "experienced" designers embedded in the tools, capable of applying the knowledge gained over the long and steady history of IC evolution. This prior experience captured in CAD/EDA tools includes the ability to convert a high-level description [Camposano and Wolf, 1991; Gajski et al., 1992] of a specific function (e.g., ALU, register, control unit, microcontroller, etc.) into an efficient physical implementation of that function.

Figure 25.23 is a photomicrograph of a contemporary, high-performance VLSI application-specific IC (**ASIC**) circuit, the ADSP-1060 (SHARC) digital signal processor (DSP) from Analog Devices, Inc. The right two thirds of the IC is 4 Mbit of SRAM, providing considerable on-chip memory. The DSP is on the left third of the IC. A 0.5-μm CMOS technology with two levels of metal was used, with a total of about 20 million transistors on the IC. The IC provides 120 MFLOP of performance.

Adapted from *The National Technology Roadmap for Semiconductors,* Semiconductor Industry Association, San Jose, Calif., 1994.

This section summarizes the design process, the gate-level physical design, and several issues which have become particularly important with today's VLSI technologies, with a focus on ASICs. An important and growing issue is that of testing, including built-in testing, design for testability, and related topics (see e.g., Jha and Kundu [1990] and Parker [1992]). This is a broad topic, beyond the scope of this section.

Primary Steps of VLSI ASIC Design

The VLSI IC design process consists of a sequence of well-defined steps [Preas and Lorenzetti, 1988; Hill et al., 1989; DeMicheli, 1994a and b] related to the definition of the functions to be designed; organization of the circuit blocks implementing these logic functions within the area of the IC; verification and simulation at several stages of design (e.g., behavioral simulation, gate-level simulation, circuit simulation [White and Sangiovanni-Vincentelli, 1987; Lee et al., 1993], etc.); routing of physical interconnections among the blocks, and final detailed placement and transistor-level layout of the VLSI circuit. This process can also be used hierarchically to design one of the blocks making up the overall IC, representing that circuit block in terms of simpler blocks. This establishes the "top-down" hierarchical approach, extendable to successively lower-level elements of the overall design.

These general steps are illustrated in Fig. 25.24(a), roughly showing the basic steps taken. A representative example [Lipman, 1995] of a contemporary design approach is illustrated in Fig. 25.24(b). Design approaches are continually changing and Fig. 25.24(b) is merely one of several current design sequences. Below, we summarize the general steps highlighted in Fig. 25.24(a).

A. *Behavioral Specification of Function:* The behavioral specification is essentially a description of the function expected to be performed by the IC. The design can be represented by schematic capture, with the designer representing the design using block diagrams. High-level description languages (**HDLs**) such as VHDL [Armstrong, 1989; Lipsett et al., 1990; Mazor and Langstraat, 1992] and Verilog [Thomas and Moorby, 1991] are increasingly used to provide a detailed specification of the function in a manner which is largely independent of the physical design of the function. VHDL and Verilog are "hardware description languages," representing designs from a variety of viewpoints including behavioral descriptions, structural descriptions, and logical descriptions. Figure 25.25(a) illustrates the specification of the overall function in terms of subfunctions (A(s), B(s), …, E(s)) as well as expansion of one subfunction (C(s)) into still simpler functions (c1, c2, c3, …, c6).

B. *Verification of Function's Behavior:* It is important to verify that the behavior specification of today's complex ICs properly represents the behavior desired. In the case of HDL languages, there may be software "debugging" of the "program" until the desired behavior is obtained, much as programming languages need to be debugged until correct operation is obtained. Early verification is important since any errors in the specification of the function will lead to an IC which is faulty as a result of the design, rather than of physical defects.

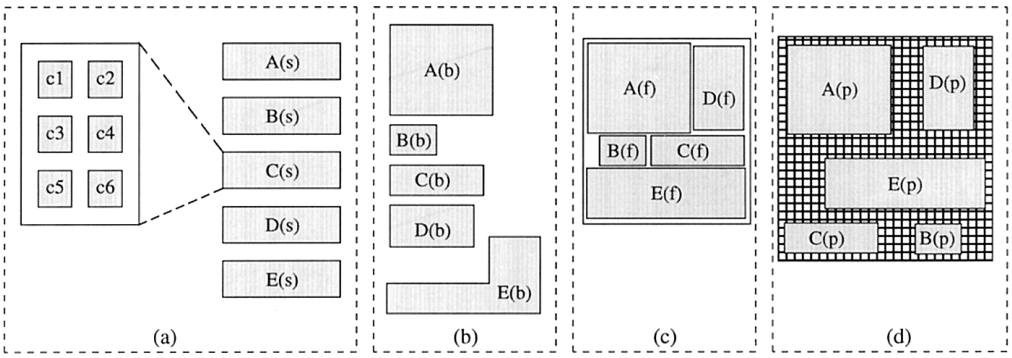

FIGURE 25.25 Circuit stages of design. (a) Initial specification (e.g., HDL, schematic, etc.) of ASIC function in terms of functions, with the next lower level description of function C illustrated. (b) Estimated size of physical blocks implementing functions. (c) Floorplanning to organize blocks on an IC. (d) Placement and routing of interconnections among blocks.

C. *Mapping of Logical Function into Physical Blocks:* Next, the logical functions, e.g., A(s), B(s), …, E(s) in Fig. 25.25(a), are converted into physical circuit blocks, e.g., blocks A(b), B(b), …, E(b) in Fig. 25.25(b). Each physical block represents a logic function as a set of interconnected gates. Although details of the physical layout are not known at this point, the estimated area and aspect ratio (ratio of height to width) of each circuit block is needed to organize these blocks within the area of the IC.

D. *Floorplanning:* Next, the individual circuit blocks must be compactly arranged to fit within the minimum area. Floorplanning establishes this organization, as illustrated in Fig. 25.25(c). At this stage, routing of interconnections among blocks has not been performed, perhaps requiring modifications to the floor plan after routing. During floor planning, the design of a logic function in terms of a block function can be modified to achieve shapes which better match the available IC area. For example, the block E(b) in Fig. 25.25(b) has been redesigned to provide a different geometric shape for block E(f) in the floor plan in Fig. 25.25(c).

E. *Verification/Simulation of Function Performance:* Given the floorplan, it is possible to estimate the average length of interconnections among the blocks (with the actual length not known until after interconnection routing in step F below. Signal timing throughout the IC is estimated, allowing verification that the various circuit blocks interact within timing margins.

F. *Placement and Routing:* When an acceptable floorplan has been established, the next step is to complete the routing of interconnections among the various blocks of the design. As interconnections are routed, the overall IC area expands to provide the area for the wiring, with the possibility that the original floorplan (which ignored interconnections) is not optimal. Placement [Shahookar and Mazumder, 1991] considers various rearrangements of the circuit blocks, without changing their internal design but allowing rotations, etc. For example, the arrangement of some of the blocks in Fig. 25.25(c) have been changed in the arrangement in Fig. 25.25(d).

G. *Verification/Simulation of Performance:* Following placement and routing, the detailed layout of the circuit blocks and interconnections has been established and more accurate simulations of signal timing and circuit behavior can be performed, verifying that the circuit behaves as desired with the interblock interconnections in place.

H. *Physical Design at Transistor/Cell Level:* As the above steps are completed, the design is moving closer toward a full definition of the ASIC circuit in terms of a set of physical masks precisely specifying placement of all the transistors and interconnections. In this step, that process is completed.

I. *Verification/Simulation of Performance:* Before fabricating the masks and proceeding with manufacture of the ASIC circuit, a final verification of the ASIC is normally performed. Figure 25.24(b) represents this step as "golden simulation," a process based on detailed and accurate simulation tools, tuned to the process of the foundry and providing the final verification of desired performance.

Increasing Impact of Interconnection Delays on Design

In earlier generations of VLSI technology (with larger transistors and wider interconnection lines/spacings), delays through the low-level logic gates greatly dominated delays along interconnection lines. This was largely the result of the lower resistance of the larger cross-section interconnections. Under these conditions, a single pass through a design sequence such as shown in Fig. 25.24 was often adequate. In particular, the placement of blocks on the ICs, although impacting the lengths of interconnections among blocks, did not have a major impact on performance since the gate delays within the blocks were substantially larger than interconnection delays between blocks. Under such conditions, the steps of floorplanning and of placement and routing focused on such objectives as minimum overall area and minimum interconnection area.

However, as feature sizes have decreased below about 0.5 μm, this condition has changed and current VLSI technology has interconnection delays substantially larger than logic delays. The increasing importance of interconnection delays is driven by several effects. The smaller feature size leads to interconnections with a higher resistance R^* per unit length and with a higher capacitance C^* per unit area (the capacitance increase also reflecting additional metal layers and coupling capacitances). For interconnection lines among high-level blocks (spanning the IC), the result is a larger RC time constant ($R^*LC \times {}^*L$), with L the line length. While interconnect delays are increasing, gate delays are decreasing. Figure 25.26 illustrates the general behavior on technology scaling to smaller features. A logic function F in a previous-generation technology requires a smaller physical area and has a higher speed in a later, scaled technology (i.e., a technology with feature sizes decreased). Although the intrablock line lengths decrease (relaxing the impact within the block of higher R^*C^*), the interblock lines continue to have lengths proportional to the overall IC size (which is increasing), with the larger R^*C^* leading to increased RC delays on such interconnections.

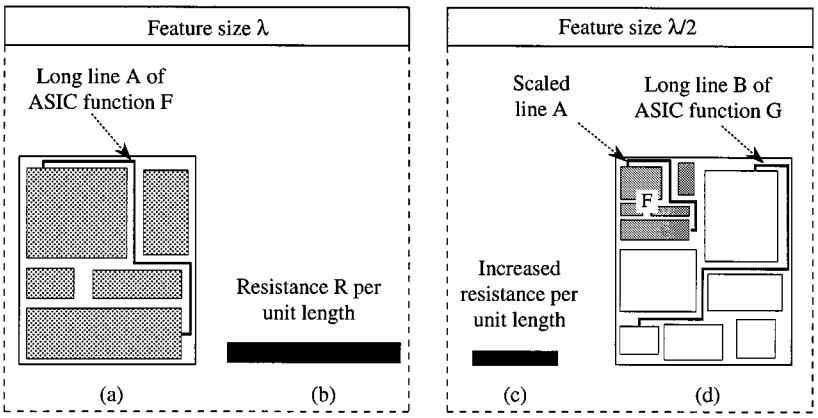

FIGURE 25.26 Interconnect lengths under scaling of feature size. (a) Initial VLSI ASIC function F with line A extending across IC. (b) Interconnection cross section with resistance R^* per unit length. (c) Interconnection cross section, in scaled technology, with increased resistance per unit length. (d) VLSI ASIC function G in scaled technology containing function F but reduced in size (including interconnection A) and containing a long line B extending across the IC.

As the interconnection delays have become increasingly dominant, the design process has evolved into an iterative process through the design steps, as illustrated by the back-and-forward annotation arrows in Fig. 25.24(a). Initial estimates of delays in step B need to be refined through back-annotation of interconnection delay parameters obtained after floorplanning and/or after placement and routing to reflect the actual interconnection characteristics, perhaps requiring changes in the initial specification of the desired function in terms of logical and physical blocks. This iterative process moving between the logical design and the physical design of an ASIC has been problematic since often the logical design is performed by the company developing the ASIC, whereas the physical design is performed by the company (the "foundry") fabricating the ASIC. CAD tools are an important vehicle for coordination of the interface between the designer and the foundry.

General Transistor Level Design of CMOS Circuits

The previous section has emphasized the CAD tools and general design steps involved in designing an ASIC. A top-down approach was emphasized, with the designer addressing successively more-detailed portions of the overall design through a hierarchical organization of the overall description of the function. However, the design process also presumes a considerable understanding of the bottom-up principles through which the overall IC function will eventually appear as a fully detailed specification of the transistor and interconnection structures throughout the overall IC [Dillinger, 1988; Weste and Eshraghian, 1993; Wolf, 1994; Rabaey, 1996; Kang and Leblebici, 1996].

Figure 25.27 illustrates the transistor-level description of a simple three-input, NAND gate. VLSI ASIC logic circuits are dominated by this general structure, with the **PMOS transistors** (making up the pull-up section) connected to the supply voltage V_{dd} and the **NMOS transistors** (making up the pull-down section) connected to the ground return *GND*. When the logic function generates a logic "1" output, the pull-up section is shorted through its PMOS transistors to *Vdd* leading to a high output voltage while the pull-down section is open, with no connection of *GND* to the output. When generating a logic "0" output, the pull-down section is shorted to *GND* while the pull-up section is open (no path to V_{dd}). Since the output is either a 1 or a 0, only one of the sections (pull-up or pull-down) is shorted, with no dc current flowing directly from V_{dd} to *GND* through the logic circuit pull-up and pull-down sections.

The PMOS transistors used in the pull-up section are fabricated with P-type source and drain regions on N-type substrates. The NMOS transistors used in the pull-down section, on the other hand, are fabricated with N-type source and drain regions on P-type substrates. Since a given silicon wafer is either N-type or P-type, a deep, opposite doping-type region must be placed in the silicon wafer for those transistors needing a substrate of the opposite type. The shaded regions in Fig. 25.27(a) represent the "substrate types" within which the

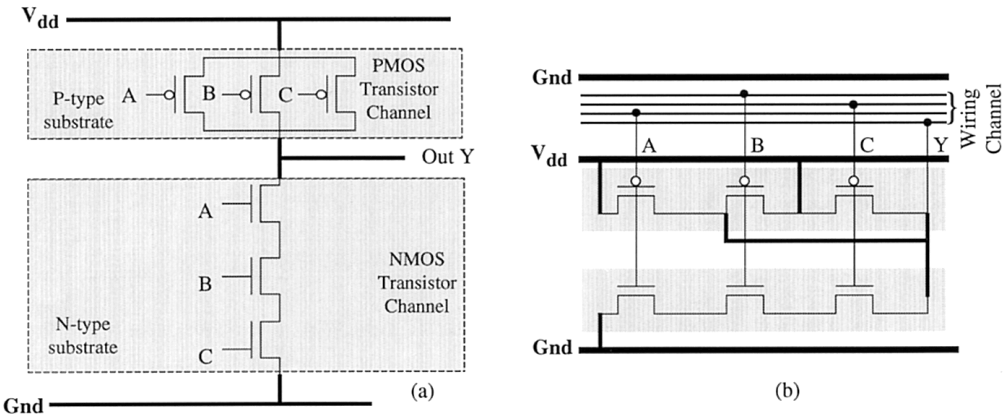

FIGURE 25.27 Transistor representation of three-input NAND gate. (a) Transistor representation without regard to layout. (b) Transistor representation using parallel rows of PMOS and NMOS transistors, with interconnections connected from a wiring channel.

transistors are fabricated. A deep doping of the desired substrate type is provided, with transistors fabricated within such deep, substrate doping "wells." To allow tight packing of transistors, large substrate doping wells are used, with a large number of transistors placed in each well.

Each logic cell must be connected to power (V_{dd}) and ground (*Gnd*), requiring that external power and ground connections to the IC be routed (on continuous metal lines to avoid resistive voltage drops) to each logic cell on the IC. Early IC technologies provided only a single level of metallization on which to route power and ground and an interdigitated layout, illustrated in Fig. 25.28(a), was adopted. Given this power and ground layout approach, channels of pull-up sections and channels of pull-down sections were placed between the power and ground interconnections, as illustrated in Fig. 25.28(b).

Bottom-up IC design is also hierarchical, with the designer completing detailed layout of a specific logic function (e.g., a binary adder), placing that detailed layout (a *cell*) in a library of physical designs and then reusing that library cell when other instantiations of the cell are required elsewhere in the IC. Figure 25.29 illustrates this cell-based approach, with cells of common height but varying width placed in rows between the power and ground lines. The straight power and ground lines shown in Fig. 25.29 allow tight packing of adjacent rows.

To achieve tight packing of cells within a row, adjacent cells (Fig. 25.29) are abutted against each other. Since metal interconnections are used within cells (and most basic cells are reused throughout the design), it is generally not possible to route intercell metal interconnections over cells. This constraint can be relaxed, as shown in Fig. 25.30(b), when additional metal layers are available, restricting a subset of the layers for intracell use and allowing over-the-cell routing [Sherwani et al., 1995] with the other layers.

When metal intercell interconnections cannot be safely routed over cells, interconnection channels must be provided between rows of logic cells, leading to the ***wiring channels*** above and/or below rows of logic cells as shown in Fig. 25.29. In this approach, all connections to and from a logic cell are fed from the top and/or bottom wiring channel. The width of the wiring channel is adjusted to provide space for the number of intercell interconnections required in the channel. Special cells providing through-cell routing can be used to support short interconnections between adjacent rows of cells. Given this layout style at the lowest level of cells, larger functions can be readily constructed, as illustrated in Fig. 25.30(a). Figure 25.29(b) illustrates interconnections (provided in the polysilicon layer under the metal layers) to the logic cells from the wiring channel. For classical CMOS logic cells, the same set of input signals are applied to both the pull-up and pull-down sections, as in the example in Fig. 25.27(b). By organizing the sequence of transistors along the pull-up and pull-down sections properly, inputs can extend vertically between a PMOS transistor in the pull-up section and a corresponding NMOS transistor in the pull-down section. Algorithms to determine the appropriate ordering of transistors evolved early in CAD tools.

ASIC Technologies

Drawing on the discussion above, the primary ASIC technologies (gate arrays, sea-of-gate arrays, standard cell ASICs, ASICs with "megacells," and field-programmable gate arrays) can be easily summarized. For comparison, full custom VLSI is briefly described first.

Full Custom Design

In *full custom design,* custom logic cells are designed, starting at the lowest level (i.e., transistor-based cell design) and extending to higher levels (e.g., combinations of cells for higher-level functions) to create the overall IC function. Figure 25.31(a) illustrates the general layout at the cell level. The designer can exploit new cell designs

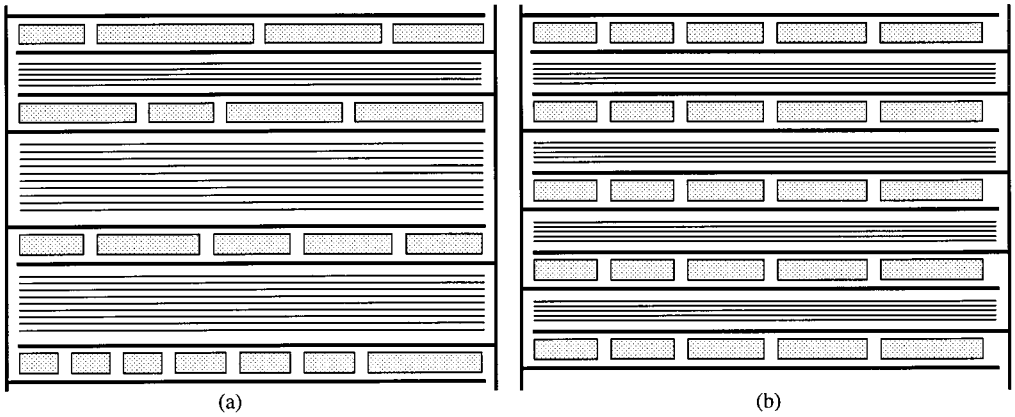

FIGURE 25.31 (a) Full custom layout (with custom cells) or standard cell ASIC layout (using library cells). (b) Gate array layout, with fixed width wiring channels (in prefabricated, up to metallization, wafers).

which improve the performance of the specific function being designed, can provide interconnections through wiring areas between logic cells to create compact functions, can use the full variety of CMOS circuit designs (e.g., dynamic logic, pass-transistor logic, etc.), can use cells previously developed privately for earlier ICs, and can use cells from a standard library provided by the foundry.

Standard Cell ASIC Technology

Consider a full custom circuit design completed using only predefined logic cells from a foundry-provided specific library and physical design processes provided by standard EDA/CAD tools. This approach, *standard cell design* [Heinbuch, 1987, *SCMOS Standard Cell Library,* 1989], is one of the primary ASIC technologies. A critical issue impacting standard cell ASIC design is the quality of the standard cell library provided by the foundry. By providing a rich set of library cells, the coordination between the logical design and the physical design is substantially more effective. Figure 25.31(a) also illustrates the general standard cell approach, using standard library cells of design-specified height (according to cells used), design-specified width logic rows, and varying width of the wiring channel to accommodate the number of interconnection wires determined during place and route.

Gate Array ASIC Technology

The *gate array technology* [Hollis, 1987] is based on partially prefabricated (up to but not including the final metallization layer) wafers with simple gate cells. Such *noncustomized* wafers are stockpiled and the ASIC designer specifies the final metallization layer added to *customize* the gate array. Gate array cells draw on the general cell design shown earlier, Fig. 25.27(b). Figure 25.32 illustrates representative non-customized transistor-level cells although different foundries use different physical layouts) with the dashed lines representing metal layers (including power and ground) added during the final metallization process.

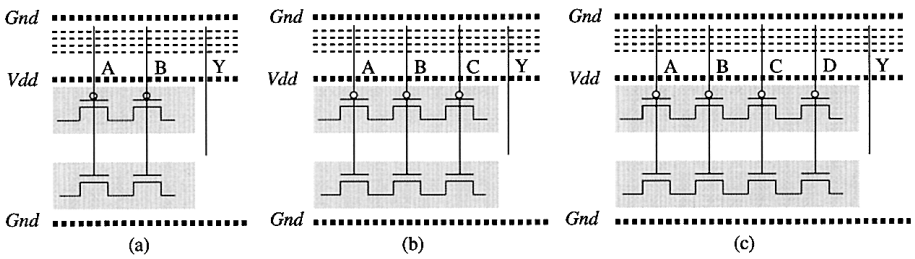

FIGURE 25.32 Basic noncustomized gate array cells (two input, three and four input examples). The dashed lines represent the power and ground lines, as well as interconnections in the wiring channel, which are placed on the IC during customization.
