Static VAR compensators provide solutions to two types of compensation problems normally encountered in practical power systems [Gyugyi et al., 1978]. The first is load compensation, where the requirements are usually to reduce or cancel the reactive power demand of large and fluctuating industrial loads, such as electric arc furnaces and rolling mills, and to balance the real power drawn from the ac supply lines. These types of heavy industrial loads are normally concentrated in one plant and served from one network terminal, and thus can be handled by a local compensator connected to the same terminal. The second type of compensation is related to voltage support of transmission lines at a given terminal in response to disturbances of both load and generation. The voltage support is achieved by rapid control of the SVC reactance and thus its reactive power output. The main objectives of dynamic VAR compensation are to increase the stability limit of the ac power system, to decrease terminal voltage fluctuations during load variations, and to limit overvoltages subsequent to large disturbances. SVCs are essentially thyristor-controlled reactive power devices.

The two fundamental thyristor-controlled reactive power device configurations are [Olwegard et al., 1981]:

- Thyristor-switched shunt capacitors (TSC): The idea is to split a **capacitor bank** into sufficiently small capacitor steps and switch those steps on and off individually. Figure 61.26(a) shows the concept of the TSC. It offers stepwise control, virtually no transients, and no harmonic generation. The average delay for executing a command from the regulator is half a cycle.
- Thyristor-switched shunt reactors (TCR): In this scheme the fundamental frequency current component through the reactor is controlled by delaying the closing of the thyristor switch with respect to the natural zero crossings of the current. Figure 61.26(b) shows the concept of the TCR. Harmonic currents are generated from the phase-angle-controlled reactor.

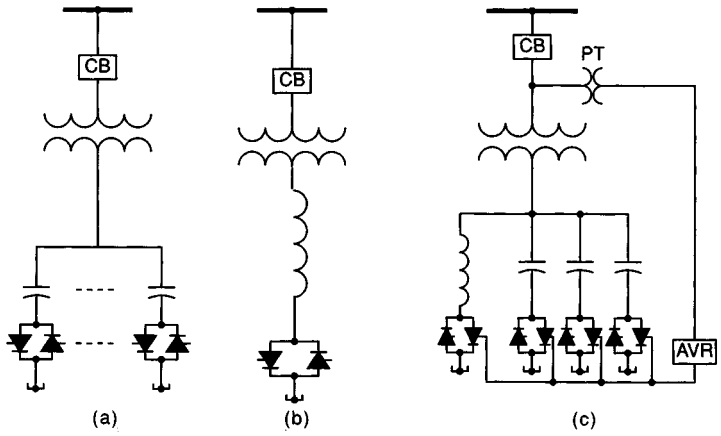

FIGURE 61.26 Basic static VAR compensator configurations. (a) Thyristor-switched shunt capacitors (TSC); (b) thyristor-switched shunt reactors (TCR); (c) combined TSC/TCR.

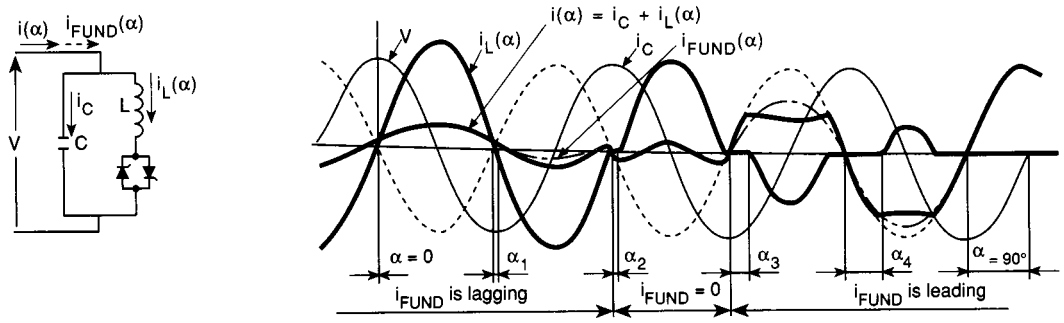

FIGURE 61.27 Basic fixed-capacitor, thyristor-controlled reactor-type compensator and associated waveforms.

The magnitude of the harmonics can be reduced using two methods. In the first, the reactor is split into smaller steps, while only one step is phase-angle controlled. The other reactor steps are either on or off. This decreases the magnitude of all harmonics. The second method involves the 12-pulse arrangement, where two identical connected thyristor-controlled reactors are used, one operated from a wye-connected secondary winding, the other from a delta-connected winding of a step-up transformer. TCR units are characterized by continuous control, and there is a maximum of one half-cycle delay for executing a command from the regulator.

In many applications, the arrangement of an SVC consists of a few large steps of thyristor-switched capacitor and one or two thyristor-controlled reactors, as shown in Fig. 61.26(c). The following are some practical schemes.

Fixed-Capacitor, Thyristor-Controlled Reactor (FC-TCR) Scheme

This scheme was originally developed for industrial applications, such as arc furnace "flicker" control [Gyugyi and Taylor, 1980]. It is essentially a TCR (controlled by a delay angle α) in parallel with a fixed capacitor. Figure 61.27 shows a basic fixed-capacitor, thyristor-controlled reactor-type compensator and associated waveforms. Figure 61.28 displays the steady-state reactive power versus terminal voltage characteristics of a static VAR compensator. In the figure, B_C is the imaginary part of the admittance of the capacitor C, and B_L is the imaginary part of the equivalent admittance of the reactor L at delay angle α. The relation between the output VARs and the applied voltage is linear over the voltage band of regulation. In practice, the fixed capacitor is usually replaced by a filter network that has the required capacitive reactance at the power system frequency but exhibits a low impedance at selected frequencies to absorb troublesome harmonics.

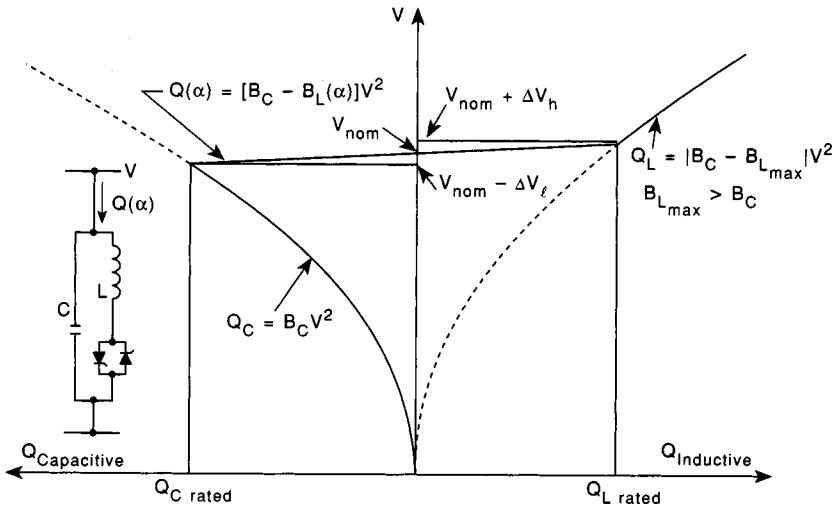

FIGURE 61.28 The steady-state reactive power versus terminal voltage characteristics of a static VAR compensator.

The behavior and response of the FC-TCR type of compensator under large disturbances is uncontrollable, at least during the first few cycles following the disturbance. The resulting voltage transients are essentially determined by the fixed capacitor and the power system impedance. This can lead to overvoltage and resonance problems.

At zero VAR demand, the capacitive and reactive VARs cancel out, but the capacitor bank's current is circulated through the reactor bank via the thyristor switch. As a result, this configuration suffers from no load (standby) losses. The losses decrease with increasing the capacitive VAR output and, conversely, increase with increasing the inductive VAR output.

Thyristor-Switched Capacitor, Thyristor-Controlled Reactor (TSC-TCR) Scheme

This hybrid compensator was developed specifically for utility applications to overcome the disadvantages of the FC-TCR compensators (behavior under large disturbances and loss characteristic). Figure 61.29 shows a basic circuit of this compensator. It consists in general of a thyristor-controlled reactor bank (or banks) and a number of capacitor banks, each in series with a solid-state switch, which is composed of either a reverse-parallel-connected thyristor pair or a thyristor in reverse parallel with a diode. The reactor's switch is composed of a reverse-parallel-connected thyristor pair that is capable of continuously controlling the current in the reactor from zero to maximum rated current.

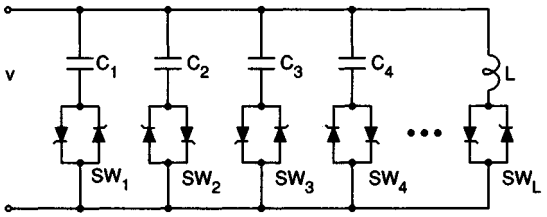

FIGURE 61.29 Basic thyristor-switched capacitor, thyristor-controlled reactor-type compensator.

The total capacitive range is divided into n operating intervals, where n is the number of capacitor banks in the compensator. In the first interval one capacitor bank is switched in, and at the same time the current in the TCR bank is adjusted so that the resultant VAR output from capacitor and reactor matches the VAR demand. In the ith interval the output is controllable in the range $[(i-1)\text{VAR}_{max}/n]$ to $(i\,\text{VAR}_{max}/n)$ by switching in the ith capacitor bank and using the TCR bank to absorb the surplus capacitive VARs. This scheme can be considered as a conventional FC-TCR, where the rating of the reactor bank is kept relatively small ($1/n$ times the maximum VAR output) and the value of the capacitor bank is changed in discrete steps so as to keep the operation of the reactor bank within its normal control range.

The losses of the TSC-TCR compensator at zero VARs output are inherently low, and they increase in proportion to the VAR output.

The mechanism by which SVCs introduce damping into the system can be explained as a result of the change in system voltage due to switching of a capacitor/reactor. The electrical power output of the generators is changed immediately due to the change in power transfer capability and the change in load power requirements.

Among the early applications of SVC for power system damping is the application to the Scandinavian system as discussed in Olwegard et al. [1981]. More recently, SVC control for damping of system oscillations based on local measurements has been proposed. The scheme uses phase-angle estimates based on voltage and power measurements at the SVC location as the control signal [see Lerch et al., 1991].

For a general mathematical model of an SVC and an analysis of its stabilizing effects, see Hammad [1986]. Representing the SVC in transient analysis programs is an important consideration [see Gole and Sood, 1990; Lefebvre and Gerin-Lajoie, 1992].

It is important to recognize that applying static VAR compensators to series-compensated ac transmission lines results in three distinct resonant modes [Larsen et al., 1990]:

- Shunt-capacitance resonance involves energy exchange between the shunt capacitance (line charging plus any power factor correction or SVCs) and the series inductance of the lines and the generator.
- Series-line resonance involves energy exchange between the series capacitor and the series inductance of the lines, transformers, and generators. The resonant frequency will depend on the level of series compensation.
- Shunt-reactor resonance involves energy exchange between shunt reactors at the intermediate substations of the line and the series capacitors.

The applications of SVCs are part of the broader area of flexible ac transmission systems (FACTS) [Hingorani, 1993]

Defining Terms

Capacitor bank: An assembly at one location of capacitors and all necessary accessories, such as switching equipment, protective equipment, and controls, required for a complete operating installation.

Reactor: A device whose primary purpose is to introduce reactance into a circuit. Inductive reactance is frequently abbreviated inductor.

Resonance: The enhancement of the response of a physical system to a periodic excitation when the excitation frequency is equal to a natural frequency of the system.

Shunt: A device having appreciable impedance connected in parallel across other devices or apparatus and diverting some of the current from it. Appreciable voltage exists across the shunted device or apparatus, and an appreciable current may exist in it.

Shunt reactor: A reactor intended for connection in shunt to an electric system to draw inductive current.

Subsynchronous resonance: An electric power system condition where the electric network exchanges energy with a turbine generator at one or more of the natural frequencies of the combined system below the synchronous frequency of the system.

Thyristor: A bistable semiconductor device comprising three or more junctions that can be switched from the off state to the on state, or vice versa, such switching occurring within at least one quadrant of the principal voltage-current characteristic.

Further Information

An excellent source of information on the application of capacitors on power systems is the Westinghouse *Transmission and Distribution* book, published in 1964. A most readable treatment of improving system stability by series capacitors is given by Kimbark's paper [1966]. Jancke et al. [1975] give a detailed discussion of experience with the 400-kV series-capacitor compensation installations on the Swedish system and aspects of the protection system. Hauer [1989] presents a discussion of practical stability controllers that manipulate series and/or shunt reactance.

An excellent summary of the state of the art in static VAR compensators is the record of the IEEE Working Group symposium conducted in 1987 on the subject (see IEEE Publication 87TH0187-5-PWR, Application of Static VAR Systems for System Dynamic Performance).

For state-of-the-art coverage of subsynchronous resonance and countermeasures, two symposia are available: IEEE Publication 79TH0059-6-PWR, State-of-the-Art Symposium—Turbine Generator Shaft Torsionals, and IEEE Publication 81TH0086-9-PWR, Symposium on Countermeasures for Subsynchronous Resonance.

61.5 Fault Analysis in Power Systems

Charles Gross

A **fault** in an electrical power system is the unintentional and undesirable creation of a conducting path (a *short circuit*) or a blockage of current (an *open circuit*). The short-circuit fault is typically the most common and is usually implied when most people use the term *fault*. We restrict our comments to the short-circuit fault.

The causes of faults include lightning, wind damage, trees falling across lines, vehicles colliding with towers or poles, birds shorting out lines, aircraft colliding with lines, vandalism, small animals entering switchgear, and line breaks due to excessive ice loading. Power system faults may be categorized as one of four types: single line-to-ground, line-to-line, double line-to-ground, and balanced three-phase. The first three types constitute severe unbalanced operating conditions.

It is important to determine the values of system voltages and currents during faulted conditions so that protective devices may be set to detect and minimize their harmful effects. The time constants of the associated transients are such that sinusoidal steady-state methods may still be used. The method of symmetrical components is particularly suited to fault analysis.

Our objective is to understand how symmetrical components may be applied specifically to the four general fault types mentioned and how the method can be extended to any unbalanced three-phase system problem.

Note that phase values are indicated by subscripts, *a, b, c;* sequence (symmetrical component) values are indicated by subscripts 0, 1, 2. The transformation is defined by

$$\begin{bmatrix} \overline{V}_a \\ \overline{V}_b \\ \overline{V}_c \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 \\ 1 & a^2 & a \\ 1 & a & a^2 \end{bmatrix} \begin{bmatrix} \overline{V}_0 \\ \overline{V}_1 \\ \overline{V}_2 \end{bmatrix} = [T] \begin{bmatrix} \overline{V}_a \\ \overline{V}_b \\ \overline{V}_c \end{bmatrix}$$

$$\begin{bmatrix} \overline{V}_0 \\ \overline{V}_1 \\ \overline{V}_2 \end{bmatrix} = \frac{1}{3} \begin{bmatrix} 1 & 1 & 1 \\ 1 & a & a^2 \\ 1 & a^2 & a \end{bmatrix} \begin{bmatrix} \overline{V}_0 \\ \overline{V}_1 \\ \overline{V}_2 \end{bmatrix} = [T]^{-1} \begin{bmatrix} \overline{V}_a \\ \overline{V}_b \\ \overline{V}_c \end{bmatrix}$$

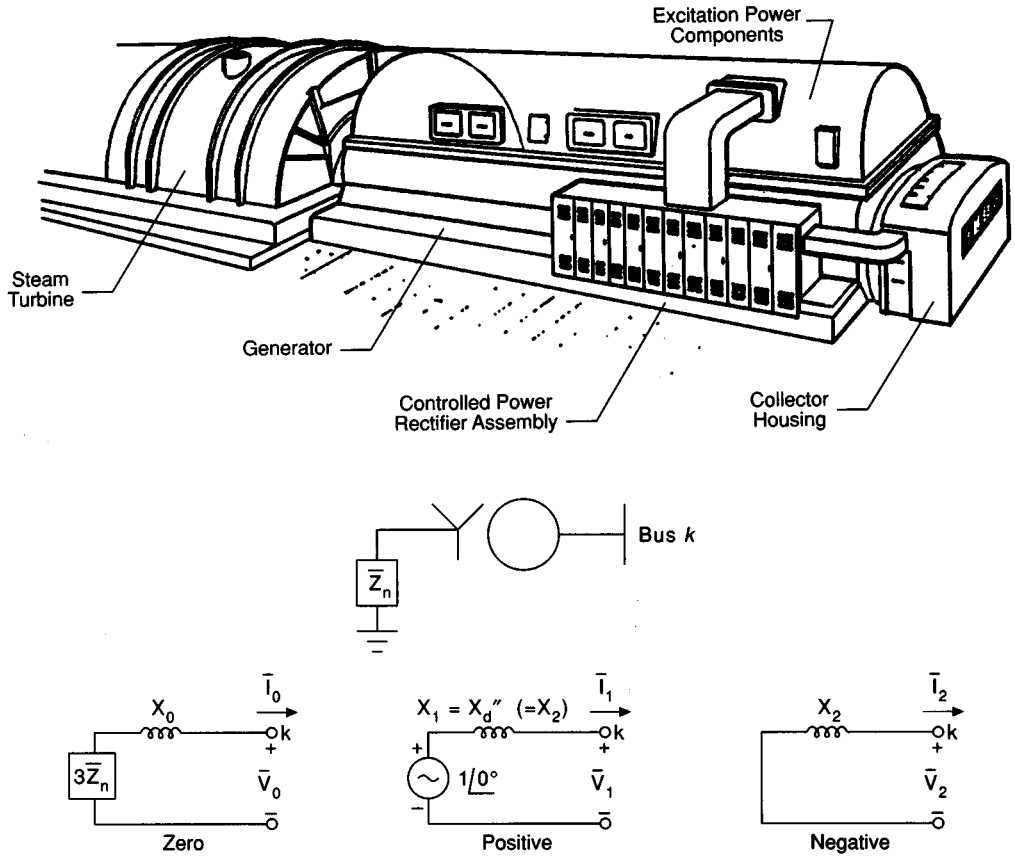

FIGURE 61.30 Generator sequence circuit models.

Simplifications in the System Model

Certain simplifications are possible and usually employed in fault analysis.

- Transformer magnetizing current and core loss will be neglected.
- Line shunt capacitance is neglected.
- Sinusoidal steady-state circuit analysis techniques are used. The so-called **dc offset** is accounted for by using correction factors.
- Prefault voltage is assumed to be $1\angle 0°$ per-unit. One per-unit voltage is at its nominal value prior to the application of a fault, which is reasonable. The selection of zero phase is arbitrary and convenient. Prefault load current is neglected.

For hand calculations, neglect series resistance is usually neglected (this approximation will not be necessary for a computer solution). Also, the only difference in the positive and negative sequence networks is introduced by the machine impedances. If we select the subtransient reactance X_d'' for the positive sequence reactance, the difference is slight (in fact, the two are identical for nonsalient machines). The simplification is important, since it reduces computer storage requirements by roughly one-third. Circuit models for generators, lines, and transformers are shown in Figs. 61.30, 61.31, and 61.32, respectively.

Our basic approach to the problem is to consider the general situation suggested in Fig. 61.33(a). The general terminals brought out are for purposes of external connections that will simulate faults. Note carefully the positive assignments of phase quantities. Particularly note that the currents flow *out of* the system. We can

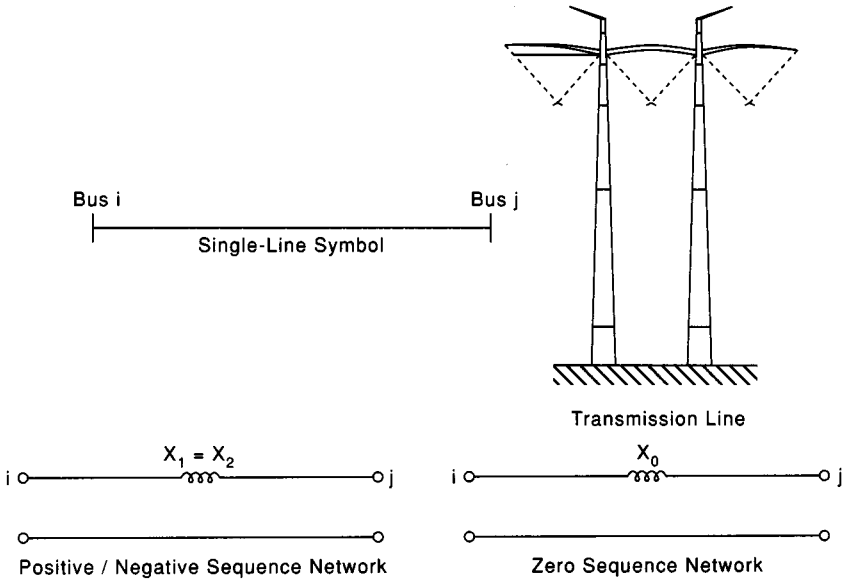

FIGURE 61.31 Line sequence circuit models.

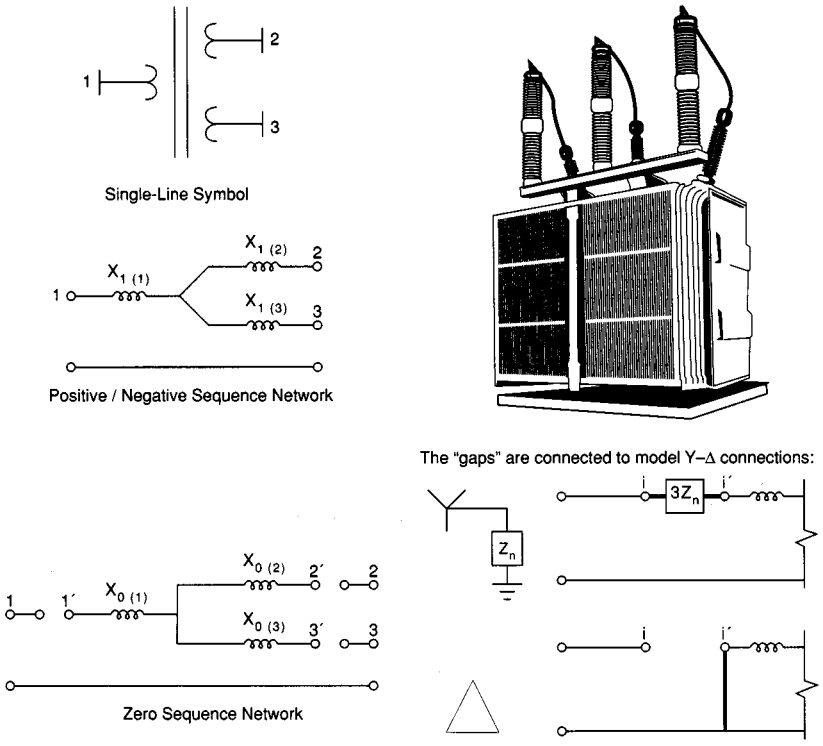

FIGURE 61.32 Transformer sequence circuit models.

construct general *sequence* equivalent circuits for the system, and such circuits are indicated in Fig. 61.33(b). The ports indicated correspond to the general three-phase entry port of Fig. 61.33(a). The positive sense of sequence values is compatible with that used for phase values.

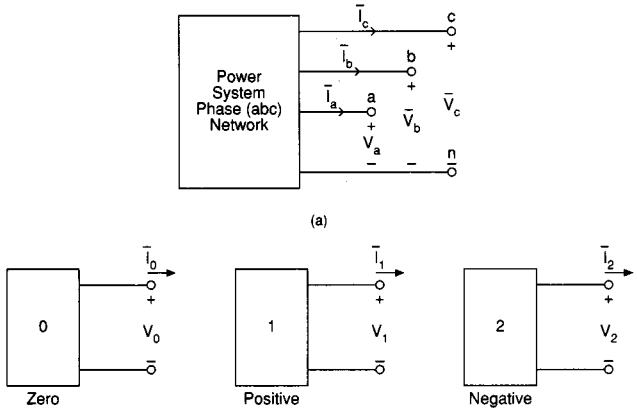

FIGURE 61.33 General fault port in an electric power system. (a) General fault port in phase (*abc*) coordinates; (b) corresponding fault ports in sequence (012) coordinates.

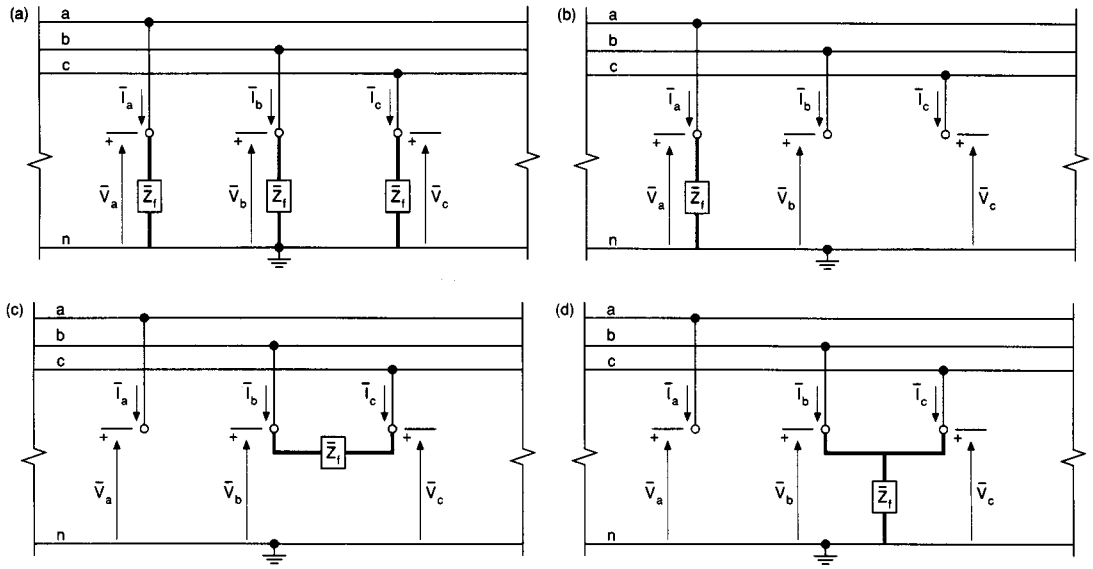

FIGURE 61.34 Fault types. (a) Three-phase fault; (b) single phase-to-ground fault; (c) phase-to-phase fault; (d) double phase-to-ground fault.

The Four Basic Fault Types

The Balanced Three-Phase Fault

Imagine the general three-phase access port terminated in a fault impedance ($\overline{Z}_f$) as shown in Fig. 61.34(a). The terminal conditions are

$$\begin{bmatrix} \overline{V}_a \\ \overline{V}_b \\ \overline{V}_c \end{bmatrix} = \begin{bmatrix} \overline{Z}_f & 0 & 0 \\ 0 & \overline{Z}_f & 0 \\ 0 & 0 & \overline{Z}_f \end{bmatrix} \begin{bmatrix} \overline{I}_a \\ \overline{I}_b \\ \overline{I}_c \end{bmatrix}$$

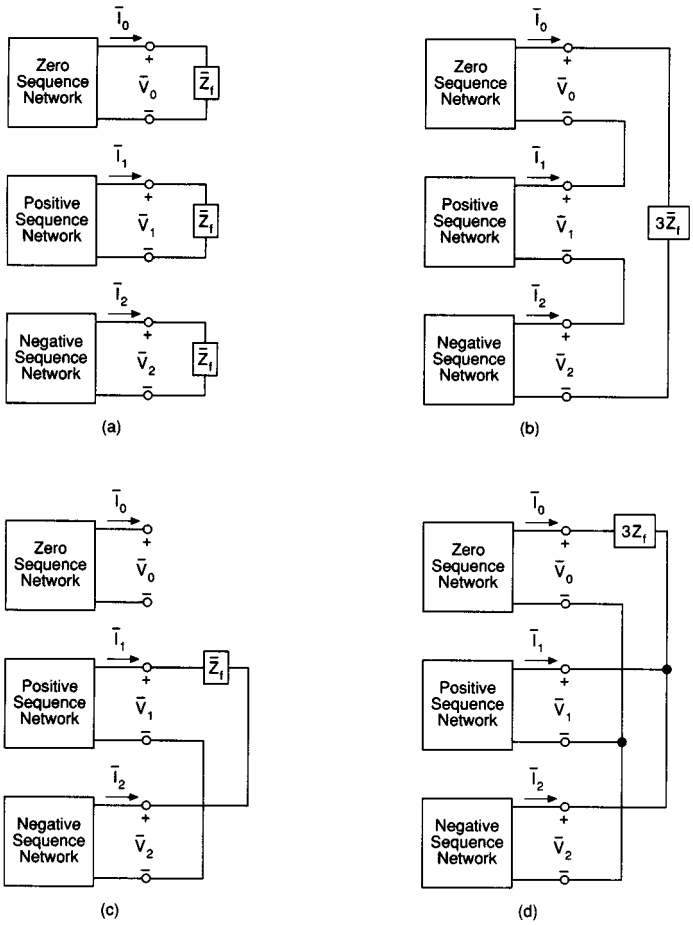

FIGURE 61.35 Sequence network terminations for fault types. (a) Balanced three-phase fault; (b) single phase-to-ground fault; (c) phase-to-phase fault; (d) double phase-to-ground fault.

Transforming to $[Z_{012}]$,

$$[Z_{012}] = [T]^{-1}\begin{bmatrix} \overline{Z}_f & 0 & 0 \\ 0 & \overline{Z}_f & 0 \\ 0 & 0 & \overline{Z}_f \end{bmatrix}[T] = \begin{bmatrix} \overline{Z}_f & 0 & 0 \\ 0 & \overline{Z}_f & 0 \\ 0 & 0 & \overline{Z}_f \end{bmatrix}$$

The corresponding network connections are given in Fig. 61.35(a). Since the zero and negative sequence networks are passive, only the positive sequence network is nontrivial.

$$\overline{V}_0 = \overline{V}_2 = 0 \tag{61.60}$$

$$\bar{I}_0 = \bar{I}_2 = 0 \tag{61.61}$$

$$\overline{V}_1 = \overline{Z}_f \bar{I}_1 \tag{61.62}$$

The Single Phase-to-Ground Fault

Imagine the general three-phase access port terminated as shown in Fig. 61.34(b). The terminal conditions are

$$\bar{I}_b = 0 \qquad \bar{I}_c = 0 \qquad \bar{V}_a = \bar{I}_a \bar{Z}_f$$

Therefore

$$\bar{I}_0 + a^2 \bar{I}_1 + a\bar{I}_2 = \bar{I}_0 + a\bar{I}_1 + a^2 \bar{I}_2 = 0$$

or

$$\bar{I}_1 = \bar{I}_2$$

Also

$$\bar{I}_b = \bar{I}_0 + a^2 \bar{I}_1 + a\bar{I}_2 = \bar{I}_0 + (a^2 + a)\bar{I}_1 = 0$$

or

$$\bar{I}_0 = \bar{I}_1 = \bar{I}_2 \tag{61.63}$$

Furthermore it is required that

$$\begin{aligned} \bar{V}_a &= \bar{Z}_f \bar{I}_a \\ \bar{V}_0 + \bar{V}_1 + \bar{V}_2 &= 3\bar{Z}_f \bar{I}_1 \end{aligned} \tag{61.64}$$

In general then, Eqs. (61.63) and (61.64) must be simultaneously satisfied. These conditions can be met by interconnecting the sequence networks as shown in Fig. 61.35(b).

The Phase-to-Phase Fault

Imagine the general three-phase access port terminated as shown in Fig. 61.34(c). The terminal conditions are such that we may write

$$\bar{I}_0 = 0 \qquad \bar{I}_b = -\bar{I}_c \qquad \bar{V}_b = \bar{Z}_f \bar{I}_b + \bar{V}_c$$

It follows that

$$\bar{I}_0 + \bar{I}_1 + \bar{I}_2 = 0 \tag{61.65}$$

$$\bar{I}_0 = 0 \tag{61.66}$$

$$\bar{I}_1 = -\bar{I}_2 \tag{61.67}$$

In general then, Eqs. (61.65), (61.66), and (61.67) must be simultaneously satisfied. The proper interconnection between sequence networks appears in Fig. 61.35(c).

The Double Phase-to-Ground Fault

Consider the general three-phase access port terminated as shown in Fig. 61.34(d). The terminal conditions indicate

$$\bar{I}_a = 0 \qquad \overline{V}_b = \overline{V}_c \qquad \overline{V}_b = (\bar{I}_b + \bar{I}_c)\overline{Z}_f$$

It follows that

$$\bar{I}_0 + \bar{I}_1 + \bar{I}_2 = \bar{0} \tag{61.68}$$

$$\overline{V}_1 = \overline{V}_2 \tag{61.69}$$

and

$$\overline{V}_0 - \overline{V}_1 = 3\overline{Z}_f \bar{I}_0 \tag{61.70}$$

For the general double phase-to-ground fault, Eqs. (61.68), (61.69), and (61.70) must be simultaneously satisfied. The sequence network interconnections appear in Fig. 61.35(d).

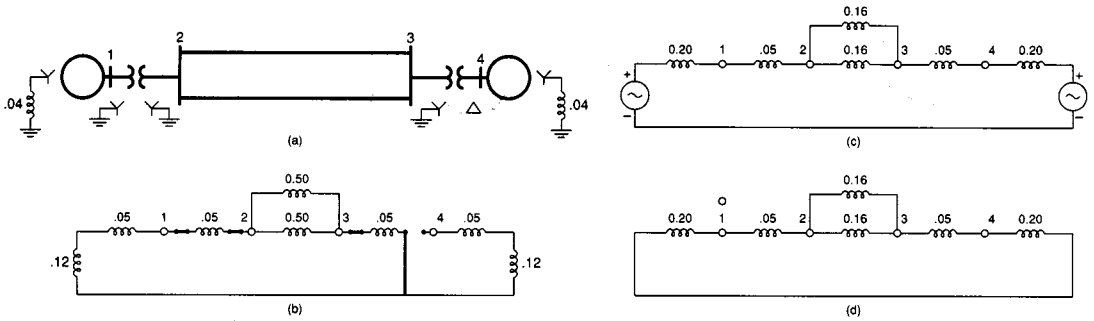

FIGURE 61.36 Example system. (a) Single-line diagram; (b) zero sequence network; (c) positive sequence network; (d) negative sequence network.

The single-line diagram and sequence networks are presented in Fig. 61.36.

Suppose bus 3 in the example system represents the fault location and $\bar{Z}_f = 0$. The positive sequence circuit can be reduced to its Thévenin equivalent at bus 3:

$$E_{T1} = 1.0\angle 0° \qquad \bar{Z}_{T1} = j0.1422$$

Similarly, the negative and zero sequence Thévenin elements are

$$\bar{E}_{T2} = 0 \qquad \bar{Z}_{T2} = j0.1422$$
$$\bar{E}_{T0} = 0 \qquad Z_{T0} = j0.0452$$

The network interconnections for the four fault types are shown in Fig. 61.37. For each of the fault types, compute the currents and voltages at the faulted bus.

Balanced Three-Phase Fault

The sequence networks are shown in Fig. 61.37(a). Obviously,

$$\bar{V}_0 = \bar{I}_0 = \bar{V}_2 = \bar{I}_2 = 0$$

$$\bar{I}_1 = \frac{1\angle 0°}{j0.1422} = -j7.032; \quad \text{also } \bar{V}_1 = 0$$

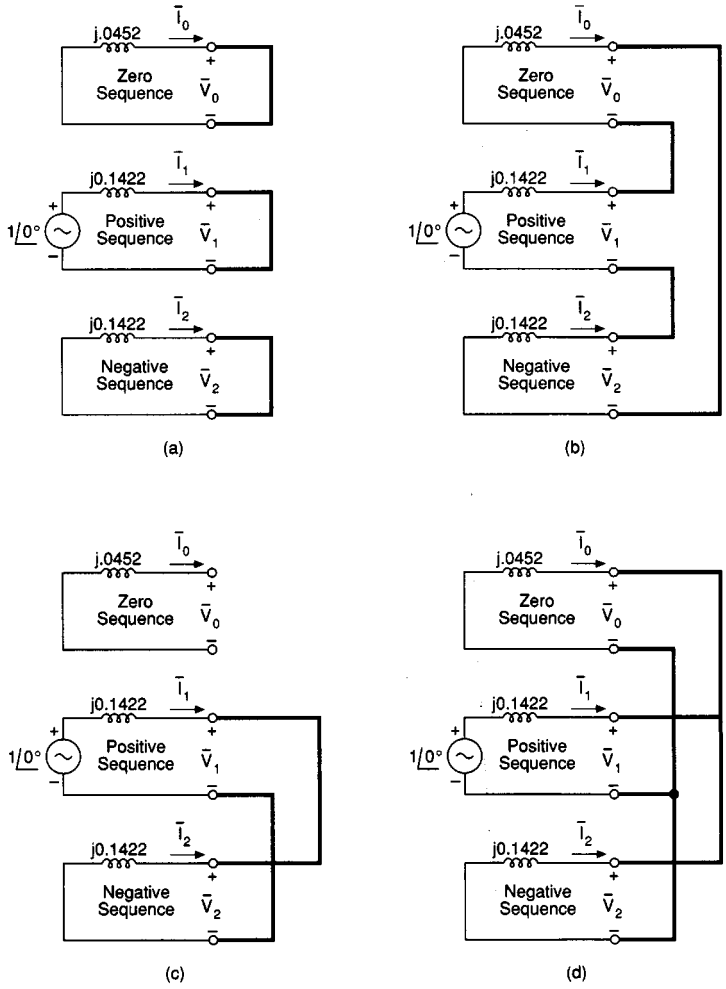

FIGURE 61.37 Example system faults at bus 3. (a) Balanced three-phase; (b) single phase-to-ground; (c) phase-to-phase; (d) double phase-to-ground.

To compute the phase values,

$$\begin{bmatrix} \bar{I}_a \\ \bar{I}_b \\ \bar{I}_c \end{bmatrix} = [T] \begin{bmatrix} \bar{I}_0 \\ \bar{I}_1 \\ \bar{I}_2 \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 \\ 1 & a^2 & a \\ 1 & a & a^2 \end{bmatrix} \begin{bmatrix} 0 \\ -j7.032 \\ 0 \end{bmatrix} = \begin{bmatrix} 7.032 \angle -90^\circ \\ 7.032 \angle 150^\circ \\ 7.032 \angle 30^\circ \end{bmatrix}$$

$$\begin{bmatrix} \bar{V}_a \\ \bar{V}_b \\ \bar{V}_c \end{bmatrix} = [T] \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

Single Phase-to-Ground Fault

The sequence networks are interconnected as shown in Fig. 61.37(b).

$$\bar{I}_0 = \bar{I}_1 = \bar{I}_2 = \frac{1\angle 0^\circ}{j0.0452 + j0.1422 + j0.1422} = -j3.034$$

$$\begin{bmatrix} \bar{I}_a \\ \bar{I}_b \\ \bar{I}_c \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 \\ 1 & a^2 & a \\ 1 & a & a^2 \end{bmatrix} \begin{bmatrix} -j3.034 \\ -j3.034 \\ -j3.034 \end{bmatrix} = \begin{bmatrix} -j9.102 \\ 0 \\ 0 \end{bmatrix}$$

The sequence voltages are

$$\begin{aligned} \overline{V}_0 &= -j0.0452(-j3.034) = -1371 \\ \overline{V}_1 &= 1.0 - j0.1422(-j3.034) = 0.5685 \\ \overline{V}_2 &= -j0.1422(-j3.034) = -0.4314 \end{aligned}$$

The phase voltages are

$$\begin{bmatrix} \overline{V}_a \\ \overline{V}_b \\ \overline{V}_c \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 \\ 1 & a^2 & a \\ 1 & a & a^2 \end{bmatrix} \begin{bmatrix} -0.1371 \\ 0.5685 \\ -0.4314 \end{bmatrix} = \begin{bmatrix} 0 \\ 0.8901\angle -103.4^\circ \\ 0.8901\angle -103.4^\circ \end{bmatrix}$$

Phase-to-phase and double phase-to-ground fault values are calculated from the appropriate networks [Figs. 61.37(c) and (d)]. Complete results are provided.

Further Considerations

Generators are not the only sources in the system. All rotating machines are capable of contributing to fault current, at least momentarily. Synchronous and induction motors will continue to rotate due to inertia and function as sources of fault current. The impedance used for such machines is usually the transient reactance X'_d or the subtransient X''_d, depending on protective equipment and speed of response. Frequently motors smaller than 50 hp are neglected. Connecting systems are modeled with their Thévenin equivalents.

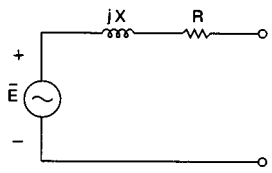

FIGURE 61.38 Positive sequence circuit looking back into faulted bus.

Although we have used ac circuit techniques to calculate faults, the problem is fundamentally transient since it involves sudden switching actions. Consider the so-called dc offset current. We model the system by determining its positive sequence Thévenin equivalent circuit, looking back into the positive sequence network at the fault, as shown in Fig. 61.38. The transient fault current is

$$i(t) = I_{ac}\sqrt{2}\cos(\omega t - \beta) + I_{dc}e^{-t/\tau}$$

This is a first-order approximation and strictly applies only to the three-phase or phase-to-phase fault. Ground faults would involve the zero sequence network also.

$$I_{ac} = \frac{E}{\sqrt{R^2 + X^2}} = \text{rms ac current}$$
$$I_{dc}(t) = I_{dc}e^{-t/\tau} = \text{dc offset current}$$

The maximum initial dc offset possible would be

$$\text{Max } I_{dc} = I_{max} = \sqrt{2}I_{ac}$$

The dc offset will exponentially decay with time constant τ, where

$$\tau = \frac{L}{R} = \frac{X}{\omega R}$$

The maximum dc offset current would be $I_{dc}(t)$

$$I_{dc}(t) = I_{dc}e^{-t/\tau} = \sqrt{2}I_{ac}e^{-t/\tau}$$

The *transient rms* current $I(t)$, accounting for both the ac and dc terms, would be

$$I(t) = \sqrt{I_{ac}^2 + I_{dc}^2(t)} = I_{ac}\sqrt{1 + 2e^{-2t/\tau}}$$

Define a multiplying factor k_i such that I_{ac} is to be multiplied by k_i to estimate the interrupting capacity of a breaker which operates in time T_{op}. Therefore,

$$k_i = \frac{I(T_{op})}{I_{ac}} = \sqrt{1 + 2e^{-2T_{op}/\tau}}$$

Observe that the maximum possible value for k_i is $\sqrt{3}$.

Example

In the circuit of Fig. 61.38, $E = 2400$ V, $X = 2\ \Omega$, $R = 0.1\ \Omega$, and $f = 60$ Hz. Compute k_i and determine the interrupting capacity for the circuit breaker if it is designed to operate in two cycles. The fault is applied at $t = 0$.

Solution

$$I_{ac} \cong \frac{2400}{2} = 1200 \text{ A}$$
$$T_{op} = \frac{2}{60} = 0.0333 \text{ s}$$
$$\tau = \frac{X}{\omega R} = \frac{2}{37.7} = 0.053$$
$$k_i = \sqrt{1 + 2e^{-2T_{op}/\tau}} = \sqrt{1 + 2e^{-0.0067/0.053}} = 1.252$$

Therefore

$$I = k_i I_{ac} = 1.252(1200) = 1503 \text{ A}$$

The Thévenin equivalent at the fault point is determined by normal sinusoidal steady-state methods, resulting in a first-order circuit as shown in Fig. 61.38. While this provides satisfactory results for the steady-state component I_{ac}, the *X/R* value so obtained can be in serious error when compared with the rate of decay of $I(t)$ as measured by oscillographs on an actual faulted system. The major reasons for the discrepancy are, first of all, that the system, for transient analysis purposes, is actually high-order, and second, the generators do not hold constant impedance as the transient decays.

Summary

Computation of fault currents in power systems is best done by computer. The major steps are summarized below:

- Collect, read in, and store machine, transformer, and line data in per-unit on common bases.
- Formulate the sequence impedance matrices.
- Define the faulted bus and Z_f. Specify type of fault to be analyzed.
- Compute the sequence voltages.
- Compute the sequence currents.
- Correct for wye-delta connections.
- Transform to phase currents and voltages.

For large systems, computer formulation of the sequence impedance matrices is required. Refer to Further Information for more detail. Zero sequence networks for lines in close proximity to each other (on a common right-of-way) will be mutually coupled. If we are willing to use the same values for positive and negative sequence machine impedances,

$$[Z_1] = [Z_2]$$

Therefore, it is unnecessary to store these values in separate arrays, simplifying the program and reducing the computer storage requirements significantly. The error introduced by this approximation is usually not important. The methods previously discussed neglect the prefault, or load, component of current; that is, the usual assumption is that currents throughout the system were zero prior to the fault. This is almost never strictly true; however, the error produced is small since the fault currents are generally much larger than the load currents. Also, the load currents and fault currents are out of phase with each other, making their sum more nearly equal to the larger components than would have been the case if the currents were in phase. In addition, selection of precise values for prefault currents is somewhat speculative, since there is no way of predicting what the loaded state of the system is when a fault occurs. When it is important to consider load currents, a power flow study is made to calculate currents throughout the system, and these values are superimposed on (added to) results from the fault study.

A term which has wide industrial use and acceptance is the *fault level* or **fault MVA** at a bus. It relates to the amount of current that can be expected to flow out of a bus into a three-phase fault. As such, it is an alternate way of providing positive sequence impedance information. Define

$$\begin{aligned}\text{Fault level in MVA at bus } i &= V_{i_{\text{pu nominal}}} I_{i_{\text{pu fault}}} S_{3\phi_{\text{base}}} \\ &= (1)\frac{1}{Z^1_{ii}} S_{3\phi_{\text{base}}} = \frac{S_{3\phi_{\text{base}}}}{Z^1_{ii}}\end{aligned}$$

Fault study results may be further refined by approximating the effect of dc offset.

The basic reason for making fault studies is to provide data that can be used to size and set protective devices. The role of such protective devices is to detect and remove faults to prevent or minimize damage to the power system.

Defining Terms

DC offset: The natural response component of the transient fault current, usually approximated with a first-order exponential expression.

Fault: An unintentional and undesirable conducting path in an electrical power system.

Fault MVA: At a specific location in a system, the initial symmetrical fault current multiplied by the prefault nominal line-to-neutral voltage (× 3 for a three-phase system).

Sequence (012) quantities: Symmetrical components computed from phase (*abc*) quantities. Can be voltages, currents, and/or impedances.

61.6 Protection

Arun G. Phadke

Fundamental Principles of Protection

Protective equipment—**relays**—is designed to respond to system abnormalities (faults) such as short circuits. When faults occur, the relays must signal the appropriate circuit breakers to trip and isolate the faulted equipment. The protection systems not only protect the faulty equipment from more serious damage, they also protect the power system from the consequences of having faults remain on the system for too long. In modern high-voltage systems, the potential for damage to the power system—rather than to the individual equipment—is often far more serious, and power system security considerations dictate the design of the protective system. The protective system consists of four major subsystems as shown in Fig. 61.39. The **transducers** (*T*)

are current and voltage transformers, which transform high voltages and currents to a more manageable level. In the United States, the most common standard for current transformers is a secondary current of 5 A (or less) for steady-state conditions. In Europe, and in some other foreign countries, a 1-A standard is also common. The voltage transformer standard is 69.3 V line-to-neutral or 120 V line-to-line on the transformer secondary side. Standardization of the secondary current and voltage ratings of the transducers has permitted independent development of the transducers and relays. The power handling capability of the transducers is expressed in terms of the volt-ampere burden, which they can supply without significant waveform distortion. In general, the transient response of the transducers is much more critical in relaying applications.

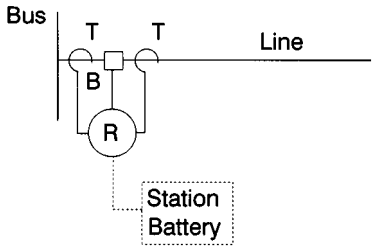

FIGURE 61.39 Elements of a protection system.

The second element of the protection system is the relay (*R*). This is the device that, using the current, voltage, and other inputs, can determine if a fault exists on the system, for which action on the part of the relay is needed. We will discuss relays in greater detail in the following. The third element of the protection chain is the circuit breaker (*B*), which does the actual job of interrupting the flow of current to the fault. Modern high-voltage circuit breakers are capable of interrupting currents of up to 100,000 A, against system voltages of up to 800,000 V, in about 15 to 30 ms. Lower-voltage circuit breakers are generally slower in operating speed. The last element of the protection chain is the station battery, which powers the relays and circuit breakers. The battery voltage has also been standardized at 125 V, although some other voltage levels may prevail in generating stations and in older substations.

The relays and circuit breakers must remove the faulted equipment from the system as quickly as possible. Also, if there are many alternative ways of deenergizing the faulty equipment, the protection system must choose a strategy that will remove from service the minimum amount of equipment. These ideas are embodied in the concepts of zones of protection, relay speed, and reliability of protection.

Zones of Protection

To make sure that a protection system removes the minimum amount of equipment from the power system during its operation, the power system is divided into zones of protection. Each zone has its associated protection system. A fault inside the zone causes the associated protection system to operate. A fault in any other zone must not cause an operation. A zone of protection usually covers one piece of equipment, such as a transmission line. The zone boundary is defined by the location of transducers (usually current transformers) and also by circuit breakers that will operate to isolate the zone. A set of zones of protection is shown in Fig. 61.40. Note that all zones are shown to overlap with their neighbors. This is to ensure that no point on the system is left unprotected. Occasionally, a circuit breaker may not exist at a zone boundary. In such cases, the tripping must be done at some other remote circuit breakers. For example, consider protection zone *A* in Fig. 61.40. A fault in that zone must be isolated by tripping circuit breakers *X* and *Y*. While the breaker *X* is near the transformer and can be tripped locally, *Y* is remote from the station, and some form of communication channel must be used to transfer the trip command to *Y*. Although most zones of protection have a precise extent, there are some zones that have a loosely defined reach. These are known as *open* zones and are most often encountered in transmission line protection.

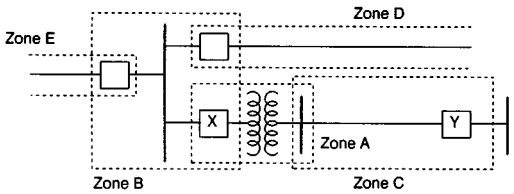

FIGURE 61.40 Zones of protection for a power system. Zones overlap; most zones are bounded by breakers.

Speed of Protection

The faster the operation of a protection function, the quicker is the prospect of removing a fault from the system. Thus, all protection systems are made as fast as possible. However, there are considerations that dictate

against making the protection faster than a minimum limit. Also, occasionally, it may be necessary to slow down a protection system in order to satisfy some specific system need. In general, the fastest protection available operates in about 5 to 10 ms after the inception of a fault [Thorp et al., 1979]. If the protection is made faster than this, it is likely to become "trigger happy" and operate falsely when it should not. When a protection system is intended as a backup system for some other protection, it is necessary to deliberately slow it down so that the primary protection may operate in its own time before the backup system will operate. This calls for a deliberate slowing of the backup protection. Depending upon the type of backup system being considered, the protection may sometimes be slowed down to operate in up to several seconds.

Reliability of Protection

In the field of relaying, **reliability** implies certain very specific concepts [Mason, 1956]. A reliable protection system has two attributes: *dependability* and *security*. A dependable relay is one that always operates for conditions for which it is designed to operate. A secure relay is one that will not operate for conditions for which it is not intended to operate. In modern power systems, the failure to operate when a fault occurs—lack of dependability—has very serious consequences for the power system. Therefore, most protective systems are made secure by duplicating relaying equipment, duplicating relaying functions, and providing several levels of backup protection. Thus modern systems tend to be very dependable, i.e., every fault is cleared, perhaps by more than one relay. As a consequence, security is somewhat degraded: modern protection systems will, occasionally, act and trip equipment falsely. Such occurrences are rare, but not uncommon. As power systems become leaner, i.e., they have insufficient margins of reserve generation and transmission, lack of security can be quite damaging. This has led to recent reevaluation of the proper balance between security and dependability of the protection systems.

Overcurrent Protection

The simplest fault detector is a sensor that measures the increase in current caused by the fault. The fuse is the simplest overcurrent protection; in fact, it is the complete protection chain—sensor, relay, and circuit breaker—in one package. Fuses are used in lower-voltage (distribution) circuits. They are difficult to set in high-voltage circuits, where load and fault currents may be of the same order of magnitude. Furthermore, they must be replaced when blown, which implies a long duration outage. They may also lead to system unbalances. However, when applicable, they are simple and inexpensive.

Inverse-Time Characteristic

Overcurrent relays sense the magnitude of the current in the circuit, and when it exceeds a preset value (known as the *pickup setting* of the relay), the relay closes its output contact, energizing the trip coil of the appropriate circuit breakers. The pickup setting must be set above the largest load current that the circuit may carry and must be smaller than the smallest fault current for which the relay must operate. A margin factor of 2 to 3 between the maximum load on the one hand and the minimum fault current on the other and the pickup setting of the relay is considered to be desirable. The overcurrent relays usually have an *inverse-time* characteristic as shown in Fig. 61.41. When the current exceeds the pickup setting, the relay operating time decreases in inverse proportion to the current magnitude. Besides this built-in feature in the relay mechanism, the relay also has a *time-dial* setting, which shifts the inverse-time curve vertically, allowing for more flexibility in setting the relays. The time dial has 11 discrete settings, usually labeled 1/2, 1, 2, . . ., 10, the lowest setting providing the fastest operation. The inverse-time characteristic offers an ideal relay for providing primary and backup protection in one package.

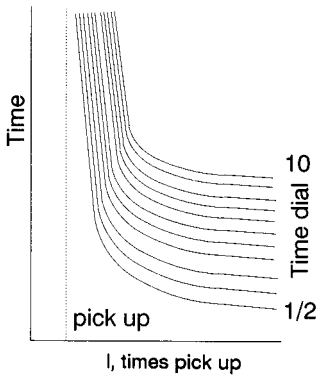

FIGURE 61.41 Inverse-time relay characteristic.

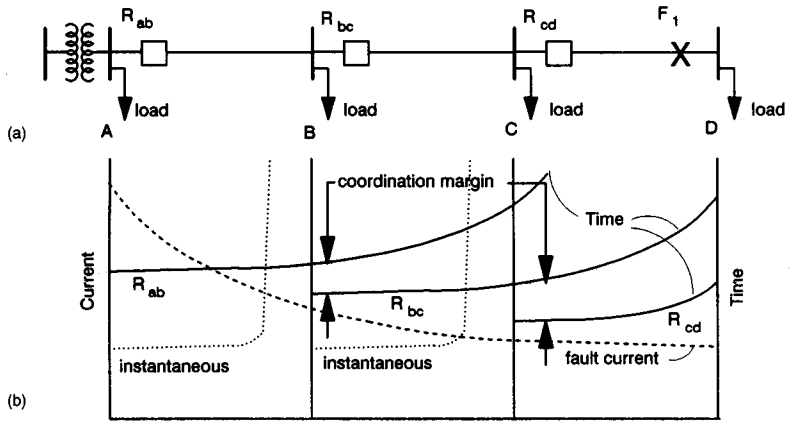

FIGURE 61.42 Coordination of inverse-time overcurrent and instantaneous relays for a radial system.

Coordination Principles

Consider the radial transmission system shown in Fig. 61.42. The transformer supplies power to the feeder, which has four loads at buses *A*, *B*, *C*, and *D*. For a fault at F_1, the relay R_{cd} must operate to open the circuit breaker B_{cd}. The relay R_{bc} is responsible for a zone of protection, which includes the entire zone of R_{cd}. This constitutes a remote backup for the protection at bus *C*. The backup relay (R_{bc}) must be slower than the primary relay (R_{cd}), its associated circuit breaker, with a safety margin. This delay in operating of the backup relay is known as the *coordination delay* and is usually about 0.3 s. In a similar fashion, R_{ab} backs up R_{bc}. The magnitude of the fault current varies as shown in Fig. 61.42(b), as the location of the fault is moved along the length of the feeder. We may plot the inverse time characteristic of the relay with the fault location as the abscissa, recalling that a smaller current magnitude gives rise to a longer operating time for the relay. The coordinating time delay between the primary and backup relays is also shown. It can be seen that, as we move from the far end of the feeder toward the source, the fault clearing time becomes progressively longer. The coordination is achieved by selecting relays with a time dial setting that will provide the proper separation in operating times.

The effect of cumulative coordination-time delays is slowest clearing of faults with the largest fault currents. This is not entirely satisfactory from the system point of view, and wherever possible, the inverse-time relays are supplemented by *instantaneous* overcurrent relays. These relays, as the name implies, have no intentional time delays and operate in less than one cycle. However, they cannot coordinate with the downstream relays and therefore must not operate ("see") for faults into the protection zone of the downstream relay. This criterion is not always possible to meet. However, whenever it can be met, instantaneous relays are used and provide a preferable compromise between fast fault clearing and coordinated backup protection.

Directional Overcurrent Relays

When power systems become meshed, as for most subtransmission and high-voltage transmission networks, inverse time overcurrent relays do not provide adequate protection under all conditions. The problem arises because the fault current can now be supplied from either end of the transmission line, and discrimination between faults inside and outside the zone of protection is not always possible. Consider the loop system shown in Fig. 61.43. Notice that in this system there must be a circuit breaker at each end of the line, as a fault on the line cannot be interrupted by opening one end alone. Zone *A* is the zone of protection for the line *A–D*. A fault at F_1 must be detected by the relays R_{ad} and R_{da}. The current through the circuit breaker B_{da} for the fault F_1 must be the determining quantity for the operation of the relay R_{da}. However, the impedances of the lines may be such that the current through the breaker B_{da} for the fault F_2 may be higher than the current for the fault F_1. Thus, if current magnitude alone is the criterion, the relay R_{da} would operate for fault F_2, as well as for the fault F_1. Of course, operation of R_{da} for F_2 is inappropriate, as it is outside its zone of protection, zone *A*. This

problem is solved by making the overcurrent relays directional. By this is meant that the relays will respond as overcurrent relays only if the fault is in the forward direction from the relays, i.e., in the direction in which their zone of protection extends. The directionality is provided by making the relay sensitive to the phase angle between the fault current and a reference quantity, such as the line voltage at the relay location. Other reference sources are also possible, including currents in the neutral of a transformer bank at the substation.

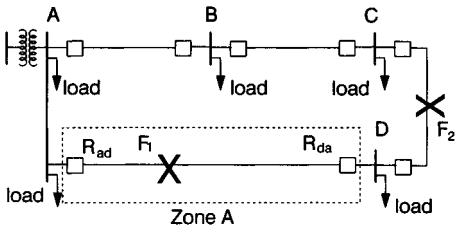

FIGURE 61.43 Protection of a loop (network) system with directional overcurrent relays.

Distance Protection

As the power networks become more complex, protection with directional overcurrent relays becomes even more difficult, if not impossible. Recall that the pickup setting of the relays must be set above the maximum load which the line is expected to carry. However, a network system has so many probable configurations due to various circuit breaker operations that the maximum load becomes difficult to define. For the same reason, the minimum fault current—the other defining parameter for the pickup setting—also becomes uncertain. Under these circumstances, the setting of the pickup of the overcurrent relays, and their reach, which will satisfy all the constraints, becomes impossible. Distance relays solve this problem.

Distance relays respond to a ratio of the voltage and current at the relay location. The ratio has the dimensions of an impedance, and the impedance between the relay location and fault point is proportional to the distance of the fault. As the zone boundary is related to the distance between the sending end and the receiving end of the transmission line, the distance to the fault forms an ideal relaying parameter. The distance is also a unique parameter in that it is independent of the current magnitude. It is thus free from most of the difficulties associated with the directional overcurrent relays mentioned above.

In a three-phase power system, 10 types of faults are possible: three single phase-to-ground faults, three phase-to-phase faults, three double phase-to-ground faults, and one three-phase fault. It turns out that relays responsive to the ratio of delta voltages and delta currents measure the correct distance to all multiphase faults. The delta quantities are defined as the difference between any two phase quantities; for example, $E_a - E_b$ is the delta voltage between a and b phases. Thus for a multiphase fault between phases x and y,

$$\frac{E_x - E_y}{I_x - I_y} = Z_1$$

where x and y can be a, b, or c and Z_1 is the positive sequence impedance between the relay location and the fault. For ground distance relays, the faulted phase voltage, and a compensated faulted phase current must be used

$$\frac{E_x}{I_x + mI_0} = Z_1$$

where m is a constant depending upon the line impedances and I_0 is the zero sequence current in the transmission line. A full complement of relays consists of three phase distance relays and three ground distance relays. As explained before, the phase relays are energized by the delta quantities, while the ground distance relays are energized by each of the phase voltages and the corresponding compensated phase currents. In many instances, ground distance protection is not preferred, and the time overcurrent relays may be used for ground fault protection.

Step-Distance Protection

The principle of distance measurement for faults is explained above. A relaying system utilizing that principle must take into account several features of the measurement principle and develop a complete protection scheme. Consider the system shown in Fig. 61.44. The distance relay R_{ab} must protect line AB, with its zone of protection as indicated by the dashed line. However, the distance calculation made by the relay is not precise enough for

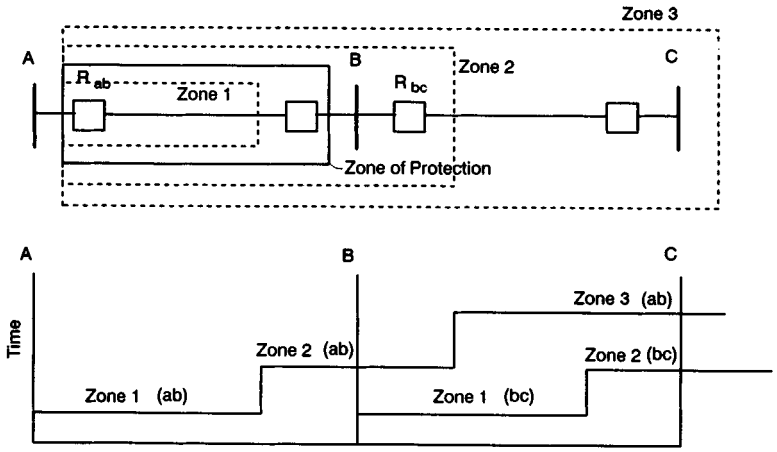

FIGURE 61.44 Zones of protection in a step-distance protection scheme. Zone 3 provides backup for the downstream line relays.

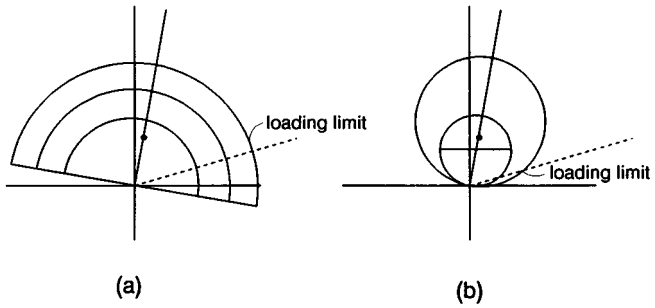

FIGURE 61.45 (a) Directional impedance characteristic. (b) Mho characteristic. Loadability limits as shown.

it to be able to distinguish between a fault just inside the zone and a fault just outside the zone, near bus *B*. This problem is solved by providing a two-zone scheme, such that if a fault is detected to be in zone 1, the relay trips instantaneously, and if the fault is detected to be inside zone 2, the relay trips with a time delay of about 0.3 s. Thus for faults near the zone boundary, the fault is cleared with this time delay, while for near faults, the clearing is instantaneous. This arrangement is referred to as a *step-distance* protection scheme, consisting of an underreaching zone (zone 1), and an overreaching zone (zone 2). The relays of the neighboring line (*BC*) can also be backed up by a third zone of the relay, which reaches beyond the zone of protection of relay R_{bc}. Zone 3 operation is delayed further to allow the zone 1 or zone 2 of R_{bc} to operate and clear the fault on line *BC*.

The distance relays may be further subdivided into categories depending upon the shape of their protection characteristics. The most commonly used relays have a directional distance, or a mho characteristic. The two characteristics are shown in Fig. 61.45. The directional impedance relay consists of two functions, a directional detection function and a distance measurement function. The mho characteristic is inherently directional, as the mho circle, by relay design, passes through the origin of the *RX* plane. Figure 61.45 also shows the multiple zones of the step distance protection.

Loadability of Distance Relays

The load carried by a transmission line translates into an apparent impedance as seen by the relay, given by

$$Z_{\text{app}} = \frac{|E|^2}{P - jQ}$$

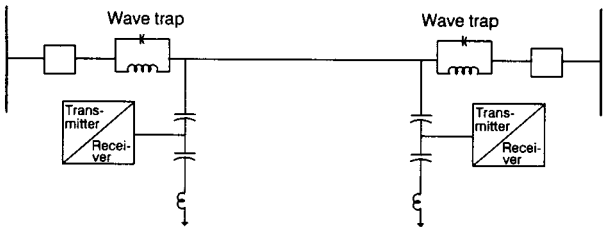

FIGURE 61.46 Carrier system for pilot protection of lines. Transmitter and receiver are connected to relays.

where $P–jQ$ is the load complex power and E is the voltage at the bus where a distance relay is connected. This impedance maps into the RX plane, as do all other apparent impedances, and hence the question arises whether this apparent load impedance could be mistaken for a fault by the distance relay. Clearly, this depends upon the shape of the distance relay characteristic employed. The loadability of a distance relay refers to the maximum load power (minimum apparent impedance) that the line can carry before a protective zone of a distance relay is penetrated by the apparent impedance. A typical load line is shown in Fig. 61.45. It is clear from this figure that the mho characteristic has a higher loadability than the directional impedance relay. In fact, other relay characteristics can be designed so that the loadability of a relay is increased even further.

Other Uses of Distance Relays

Although the primary use of distance relays is in protecting transmission lines, some other protection tasks can also be served by distance relays. For example, loss-of-field protection of generators is often based upon distance relays. Out-of-step relays and relays for protecting reactors may also be distance relays. Distance relays are also used in pilot protection schemes described next, and as backup relays for power apparatus.

Pilot Protection

Pilot protection of transmission lines uses communication channels (pilot channels) between the line terminals as an integral element of the protection system. In general, pilot schemes may be subdivided into categories according to the medium of communication used. For example, the pilot channels may be wire pilots, leased telephone circuits, dedicated telephone circuits, microwave channels, power line carriers, or fiber optic channels. Pilot protection schemes may also be categorized according to their function, such as a tripping pilot or a blocking pilot. In the former, the communication medium is used to send a tripping signal to a remote line terminal, while in the latter, the pilot channel is used to send a signal that prevents tripping at the remote terminal for faults outside the zone of protection of the relays. The power line carrier system is the most common system used in the United States. It uses a communication channel with a carrier signal frequency ranging between 30 and 300 kHz, the most common bands being around 100 kHz. The modulated carrier signal is coupled into one or more phases of the power line through coupling capacitors. In almost all cases, the capacitors of the capacitive-coupled voltage transformers are used for this function (see Fig. 61.46). The carrier signal is received at both the sending and the receiving ends of the transmission line by tuned receivers. The carrier signal is blocked from flowing into the rest of the power system by blocking filters, which are parallel resonant circuits, known as *wave traps*.

Coverage of 100% of Transmission Line

The step-distance scheme utilizes the zone 1 and zone 2 combination to protect 100% of the transmission line. The middle portion of the transmission line, which lies in zone 1 of relays at the two ends of the line, is protected at high speed from both ends. However, for faults in the remaining portion of the line, the near end clears the fault at high speed, i.e., in zone 1 time, while the remote end clears the fault in zone 2 time. In effect, such faults remain on the system for zone 2 time, which may be of the order 0.3 to 0.5 s. This becomes undesirable in modern power systems where the margin of stability may be quite limited. In any case, it is good protection practice to protect the entire line with high-speed clearing of all internal faults from both ends of the transmission line. Pilot protection accomplishes this task.

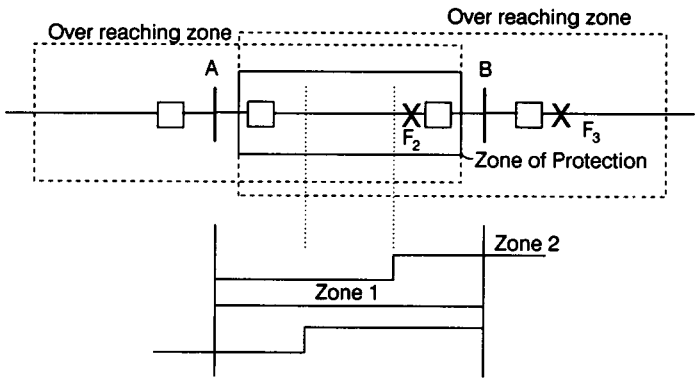

FIGURE 61.47 Pilot protection with overreaching zones of protection. This is most commonly used in a directional comparison blocking scheme.

Directional Comparison Blocking Scheme

Consider the fault at F_2 shown in Fig. 61.47. As discussed above, this fault will be cleared in zone 1 time by the step-distance relay at bus *B*, while the relay at bus *A* will clear the fault in zone 2 time. Since the relays at bus *B* can determine, with a high degree of certainty, that a fault such as F_2 is indeed inside the zone of protection of the relays, one could communicate this knowledge to terminal *A*, which can then cause the local circuit breaker to trip for the fault F_2. If the entire relaying and communication task can be accomplished quickly, 100% of the line can be protected at high speed. One of the most commonly used methods of achieving this function is to use overreaching zones of protection at both terminals, *and* if a fault is detected to be inside this zone, and if the remote terminal confirms that the fault is inside the zone of protection, then the local relay may be allowed to trip. In actual practice, the complement of this information is used to block the trip at the remote end. Thus, the remote end, terminal *B* in this case, detects faults that are outside the zone of protection and, for those faults, sends a signal which asks the relay at terminal *A* to block the tripping command. Thus, for a fault such as F_3, the relay at *A* will trip, unless the communication is received from terminal *B* that this particular fault is outside the zone of protection—as indeed fault F_3 happens to be. This mode, known as a blocking carrier, is preferred, since a loss of the carrier signal created by an internal fault, or due to causes that are unrelated to the fault, will not prevent the trip at the remote end. This is a highly dependable protection system, and precisely because of that it is somewhat less secure. Nevertheless, as discussed previously, most power systems require that a fault be removed as quickly as possible, even if in doing so for a few faults an unwarranted trip may result.

Other Pilot Protection Schemes

Several other types of pilot protection schemes are available. The choice of a specific scheme depends upon many factors. Some of these factors are importance of the line to the power system, the available communication medium, dependability of the communication medium, loading level of the transmission line, susceptibility of the system to transient stability oscillations, presence of series or shunt compensating devices, multiterminal lines, etc. A more complete discussion of all these issues will be found in the references [Westinghouse, 1982; Blackburn, 1987; Horowitz and Phadke, 1992].

Computer Relaying

Relaying with computers began to be discussed in technical literature in the mid-1960s. Initially, this was an academic exercise, as neither the computer speeds nor the computer costs could justify the use of computers for relaying. However, with the advent of high-performance microprocessors, computer relaying has become a very practical and attractive field of research and development. All major manufacturers of electric power equipment have computer relays to meet all the needs of power system engineers. Computer relaying is also being taught in several universities and has provided a very fertile field of research for graduate students.

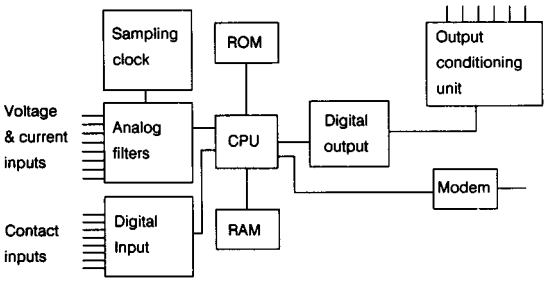

FIGURE 61.48 Block diagram of a computer relay architecture.

Computer relaying has also uncovered new ways of measuring power system parameters and may influence future development of power system monitoring and control functions.

Incentives for Computer Relaying

The acceptance of **computer relays** has been due to economic factors which have made microcomputers relatively inexpensive and computationally powerful. In addition to this economic advantage, the computer relays are also far more versatile. Through their self-diagnostic capability, they provide an assurance of availability. Thus, even if they should suffer the same (or even greater) number of failures in the field as traditional relays, their failures could be communicated to control centers and a maintenance crew called to repair the failures immediately. This type of diagnostic capability was lacking in traditional protection systems and often led to failures of relays, which went undetected for extended periods. Such hidden failures have been identified as one of the main sources of power system blackouts.

The computing power available with computer relays has also given rise to newer and better protection functions in several instances. Improved protection of transformers, multiterminal lines, fault location, and reclosing are a few of the protection functions where computer relaying is likely to have a significant impact. Very significant developments in the computer relaying field are likely to occur in the coming years.

Architecture for a Computer Relay

There are many ways of implementing computer-based relays. Figure 61.48 is a fairly typical block diagram of a computer relay architecture. The input signals consisting of voltage and currents and contact status are filtered to remove undesired frequency components and potentially damaging surges. These signals are sampled by the CPU under the control of a sampling clock. Typical sampling frequency used in a modern digital relay varies between 4 and 32 times the nominal power system frequency. The sampled data is processed by the CPU with a digital filtering algorithm, which estimates the appropriate relaying quantity. A typical relaying quantity may be the rms value of a current, the voltage or current phasor, or the apparent impedance. The estimated parameters are then compared with prestored relay characteristics, and the appropriate control action is initiated. The decision of the relay is communicated to the substation equipment, such as the circuit breaker, through the output ports. These outputs must also be filtered to block any surges from entering the relay through the output lines. In most cases, the relay can also communicate with the outside world through a modem. The data created by a fault is usually saved by the relaying computer and can be used for fault analysis or for sequence-of-event analysis following a power system disturbance. The user may interface with the relay through a keyboard, a control panel, or a communication port. In any case, provision must be made to enter relay settings in the relay and to save these settings in case the station power supply fails. Although the block diagram in Fig. 61.48 shows different individual subsystems, the actual hardware composition of the subsystems is dependent on the computer manufacturer. Thus, we may find several microprocessors in a given implementation, each controlling one or more subsystems. Also, the hardware technology is in a state of flux, and in a few years, we may see an entirely different realization of the computer relays.

Experience and Future Trends

Field experience with the computer relays has been excellent so far. The manufacturers of traditional relays have adopted this technology in a big way. As more experience is gained with the special requirements of computer relays, it is likely that other—nontraditional—relay manufacturers will enter the field.

It seems clear that in computer relaying, power system engineers have obtained a tool with exciting new possibilities. Computers, with the communication networks now being developed, can lead to improved monitoring, protection, and control of power systems. An entirely new field, adaptive relaying, has been introduced recently [Phadke and Horowitz, 1990]. The idea is that protection systems should adapt to changing conditions of the power networks. In doing so, protection systems become more sensitive and reliable. Another development, which can be traced to computer relaying, is that of synchronized phasor measurements in power systems [Phadke and Thorp, 1991]. The development of the Global Positioning System (GPS) satellites has made possible the synchronization of sampling clocks used by relays and other measuring devices across the power system. This technology is expected to have a major impact on static and dynamic state estimation and on control of the electric power networks.

Defining Terms

Computer relays: Relays that use digital computers as their logic elements.

Distance protection: Relaying principle based upon estimating fault location (distance) and providing a response based upon the distance to the fault.

Electromechanical relays: Relays that use electromechanical logic elements.

Pilot: A communication medium used by relays to help reach a reliable diagnosis of certain faults.

Relays: Devices that detect faults on power equipment and systems and take appropriate control actions to deenergize the faulty equipment.

Reliability: For relays, reliability implies *dependability*, i.e., certainty of operating when it is supposed to, and *security*, certainty of not operating when it is not supposed to.

Solid state relays: Relays that use solid state analog components in their logic elements.

Transducers: Current and voltage transformers that reduce high-magnitude signals to standardized low-magnitude signals which relays can use.

Further Information

In addition to the references provided, papers sponsored by the Power System Relaying Committee of the IEEE and published in the *IEEE Transactions on Power Delivery* contain a wealth of information about protective relaying practices and systems. Publications of CIGRÉ also contain papers on relaying, through their Study Committee 34 on protection. Relays and relaying systems usually follow standards, issued by IEEE in this country, and by such international bodies as the IEC in Europe. The field of computer relaying has been covered in *Computer Relaying for Power Systems*, by A.G. Phadke and J.S. Thorp (New York: Wiley, 1988).

61.7 Transient Operation of Power Systems

R. B. Gungor

Stable operations of power transmission systems have been a great concern of utilities since the beginning of early power distribution networks. The transient operation and the stability under transient operation are studied for existing systems, as well as the systems designed for future operations.

Power systems must be stable while operating normally at steady state for slow system changes under switching operations, as well as under emergency conditions, such as lightning strikes, loss of some generation, or loss of some transmission lines due to faults.

The tendency of a power system (or a part of it) to develop torques to maintain its stable operation is known as **stability**. The determination of the stability of a system then is based on the static and dynamic characteristics of its synchronous generators. Although large induction machines may contribute energy to the system during the *subtransient* period that lasts one or two cycles at the start of the **disturbance**, in general, induction machine loads are treated as static loads for **transient stability** calculations. This is one of the simplification considerations, among others.

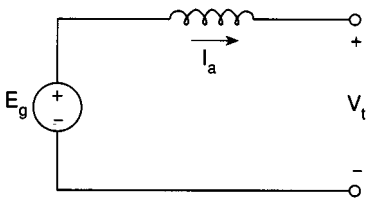

FIGURE 61.49 Per-phase model of an ideal synchronous generator.

The per-phase model of an ideal synchronous generator with nonlinearities and the stator resistance neglected is shown in Fig. 61.49, where E_g is the generated (excitation) voltage and X_s is the steady-state direct axis *synchronous reactance*. In the calculation of transient and subtransient currents, X_s is replaced by *transient reactance* X'_s and *subtransient reactance* X''_s, respectively.

Per-phase electrical power output of the generator for this model is given by Eq. (61.71).

$$P_e = \frac{E_g V_t}{X_s} \sin \delta = P_{\max} \sin \delta \tag{61.71}$$

where δ is the **power angle**, the angle between the generated voltage and the terminal voltage.

The simple power-angle relation of Eq. (61.71) can be used for real power flow between any two voltages separated by a reactance. For the synchronous machine, the total real power is three times the value calculated by Eq. (61.71), when voltages in volts and the reactance in ohms are used. On the other hand, Eq. (61.71) gives *per-unit* power when per-unit voltages and reactance are used.

Figure 61.50 shows a sketch of the power-angle relation of Eq. (61.71). Here the power P_1 is carried by the machine under δ_1, and P_2 under δ_2. For gradual changes in the output power up to $P_{\max}$ for $\delta = 90^\circ$, the machine will be stable. So we can define the **steady-state stability** limit as

$$\delta \leq 90^\circ \quad \frac{\partial P}{\partial \delta} > 0 \tag{61.72}$$

A sudden change in the load of the generator, e.g., from P_1 to P_2, will cause the rotor to slow down so that the power angle δ is increased to supply the additional power to the load. However, the deceleration of the rotor cannot stop instantaneously. Hence, although at δ_2 the developed power is sufficient to supply the load, the rotor will overshoot δ_2 until a large enough opposite torque is built up to stop deceleration. Now the excess energy will start accelerating the rotor to decrease δ. Depending on the inertia and damping, these oscillations will die out or the machine will become unstable and lose its synchronism to drop out of the system. This is the basic **transient operation** of a synchronous generator. Note that during this operation it may be possible for δ to become larger than 90° and the machine still stay stable. Thus $\delta = 90^\circ$ is not the transient stability limit.

Figure 61.51 shows typical power-angle versus time relations.

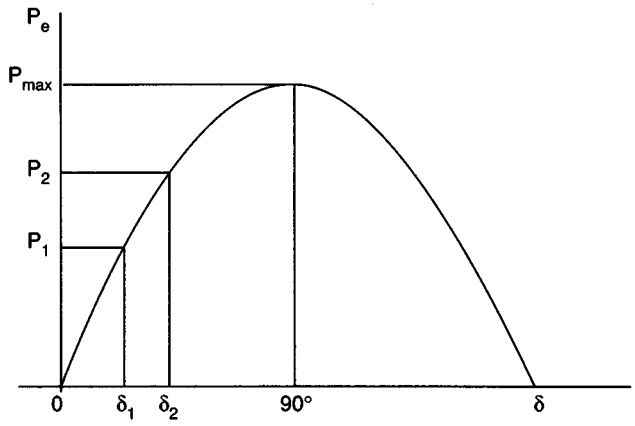

FIGURE 61.50 Power-angle characteristics of ideal synchronous generator.

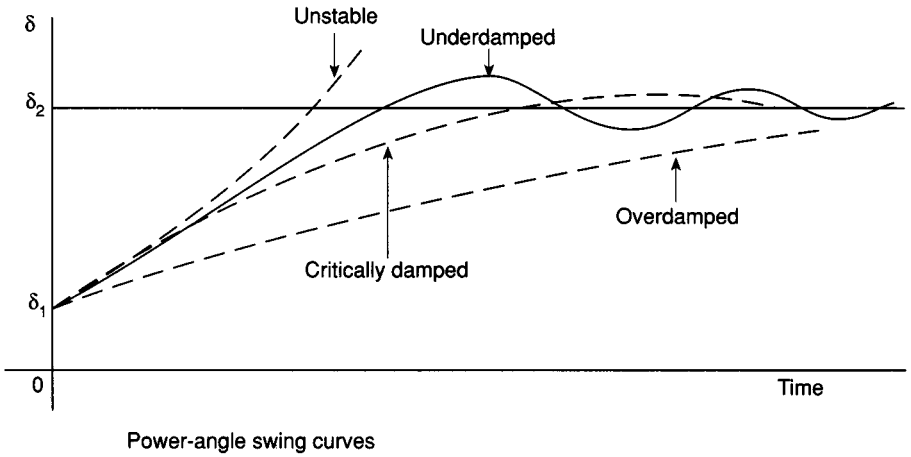

FIGURE 61.51 Typical power angle–time relations.

In the discussions to follow, the damping (stabilizing) effects of (1) the excitation systems; (2) the speed governors; and (3) the damper windings (copper squirrel-cage embedded into the poles of the synchronous generators) are omitted.

Stable Operation of Power Systems

Figure 61.52 shows an *N*-bus power system with *G* generators.

To study the stability of multimachine transmission systems, the resistances of the transmission lines and transformers are neglected and the reactive networks are reduced down to the generator internal voltages by dropping the loads and eliminating the load buses. One such reduced network is sketched in Fig. 61.53.

The power flow through the reactances of a reduced network are

$$P_{ij} = \frac{E_i E_j}{X_{ij}} \sin \delta_{ij} \qquad i, j = 1, 2, \ldots, G \tag{61.73}$$

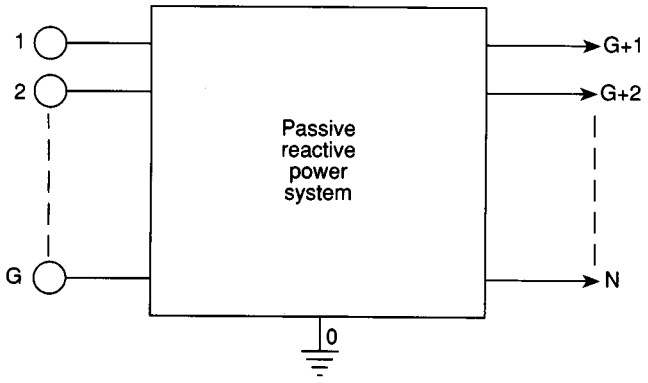

FIGURE 61.52 A multimachine reactive power system.

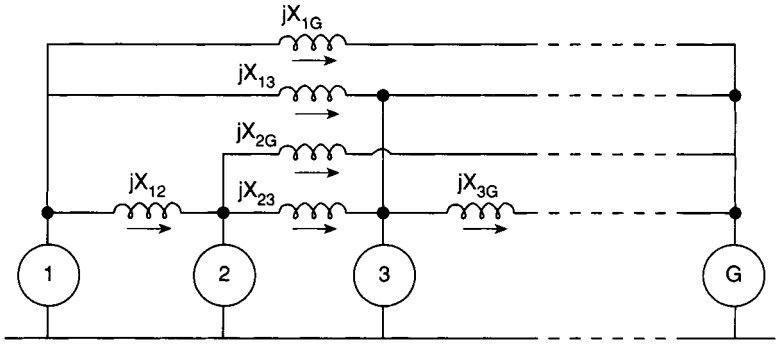

FIGURE 61.53 Multiport reduced reactive network.

The generator powers are

$$P_i = \sum_{k=1}^{G} P_{ik} \tag{61.74}$$

The system will stay stable for

$$\frac{\partial P_i}{\partial \delta_{ij}} > 0 \qquad i = 1, 2, \ldots, G \tag{61.75}$$

Equation (61.75) is observed for two machines at a time by considering all but two (say k and n) of the powers in Eq. (61.74) as constants. Since the variations of all powers but k and n are zero, we have

$$dP_i = \frac{\partial P_i}{\partial \delta_{i1}} d\delta_{i1} + \frac{\partial P_i}{\partial \delta_{i2}} d\delta_{i2} + \cdots + \frac{\partial P_i}{\partial \delta_{iG}} d\delta_{iG} = 0 \tag{61.76}$$

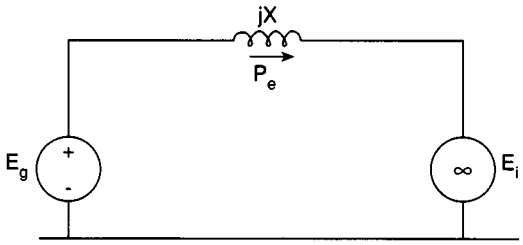

FIGURE 61.54 An ideal generator connected to an infinite bus.

These G-2 equations are simultaneously solved for G-2 $d\delta_{ij}$s, then these are substituted in dP_k and dP_n equations to calculate the partial derivatives of P_k and P_n with respect to δ_{kn} to see if Eqs. (61.75) for $i = k$ and $i = n$ are satisfied. Then the process is repeated for the remaining pairs.

Although the procedure outlined seems complicated, it is not too difficult to produce a computer algorithm for a given system.

To study the transient stability, dynamic operations of synchronous machines must be considered. An ideal generator connected to an infinite bus (an ideal source) through a reactance is sketched in Fig. 61.54.

The so-called *swing equation* relating the accelerating (or decelerating) power (difference between shaft power and electrical power as a function of δ) to the second derivative of the power angle is given in Eq. (61.77).

$$\begin{aligned} P_a &= P_s - P_e \\ M\frac{d^2\delta}{dt^2} &= P_s - \frac{E_g E_i}{X}\sin\delta \end{aligned} \tag{61.77}$$

where $M = HS/180f$ (MJ/electrical degree); H is the inertia constant (MJ/MVA); S is the machine rating (MVA); f is the frequency (Hz); P_s is the shaft power (MW).

For a system of G machines, a set of G swing equations as given in Eq. (61.78) must be solved simultaneously.

$$M_i\frac{d^2\delta_i}{dt^2} = P_{s_i} - P_{\max_i}\sin\delta_i \qquad i = 1, 2, \ldots, G \tag{61.78}$$

The swing equation of the single-machine system of Fig. 61.54 can be solved either graphically or analytically. For graphical integration, which is called *equal-area criterion,* we represent the machine by its subtransient reactance, assuming that electrical power can be calculated by Eq. (61.71), and during the transients the shaft power P_s remains constant. Then, using the power-angle curve(s), we sketch the locus of operating point on the curve(s) and equate the areas for stability. Figure 61.55 shows an example for which the shaft power of the machine is suddenly increased from the initial value of P_o to P_s.

The excess energy (area A_1) will start to accelerate the rotor to increase δ from δ_o to δ_m for which the area (A_2) above P_s equals the area below. These areas are

$$\begin{aligned} A_1 &= P_s(\delta_s - \delta_o) - \int_{\delta_o}^{\delta_s} P_{\max}\sin\delta\, d\delta \\ A_2 &= \int_{\delta_s}^{\delta_m} P_{\max}\sin\delta\, d\delta - P_s(\delta_m - \delta_s) \end{aligned} \tag{61.79}$$

Substituting, the values of P_o, P_s, δ_o, and δ_s, δ_m can be calculated.

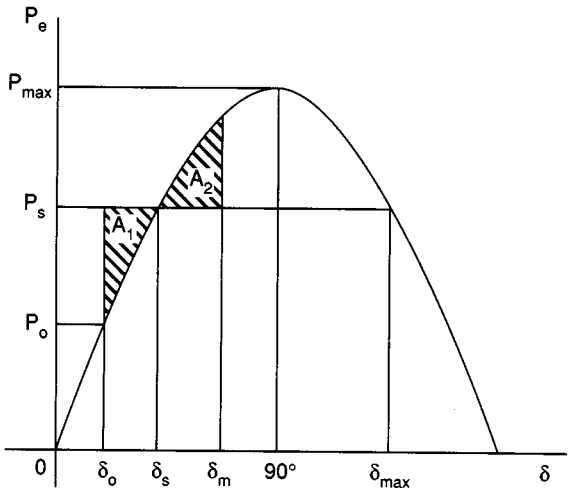

FIGURE 61.55 A sudden loading of a synchronous generator.

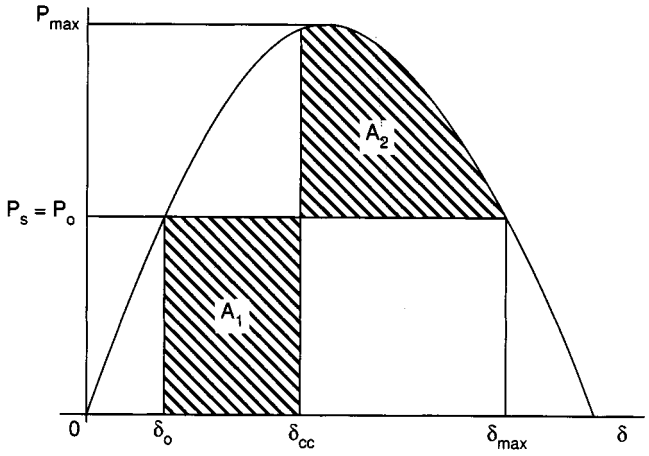

FIGURE 61.56 Critical clearing angle for stability.

Figure 61.56 illustrates another example, where a three-phase fault reduces the power transfer to infinite bus to zero. δ_{cc} is the **critical clearing angle** beyond which the machine will not stay stable.

The third example, shown in Fig. 61.57, indicates that the power transfers before, during, and after the fault are different. Here the system is stable as long as $\delta_m \leq \delta_{max}$.

For the analytical solution of the swing equation a *numerical integration* technique is used (Euler's method, modified Euler's method, Runge-Kutta method, etc.). The latter is most commonly used for computer algorithms.

The solution methods developed are based on various assumptions. As before, machines are represented by subtransient reactances, electrical powers can be calculated by Eq. (61.71), and the shaft power does not change during transients. In addition, the velocity increments are assumed to start at the beginning of time increments, and acceleration increments start at the middle of time increments; finally, an average acceleration can be used where acceleration is discontinuous (e.g., where circuit breakers open or close).

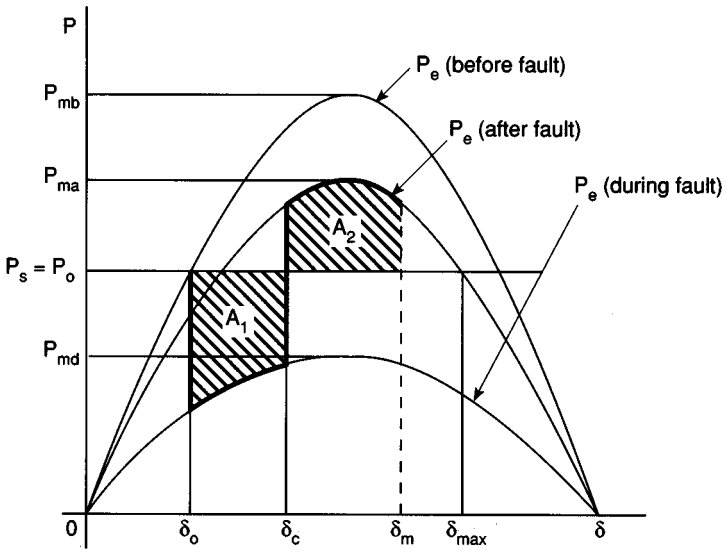

FIGURE 61.57 Power-angle relation for power transfer during fault.

Figure 61.58 shows a sketch of angle, velocity, and acceleration changes related to time as outlined above. Under these assumptions the next value of the angle δ can be obtained from the previous value as

$$\delta_{k+1} = \delta_k + \Delta_{k+1}\delta = \delta_k + \Delta_k\delta + \frac{(\Delta t)^2}{M} P_{ak} \tag{61.80}$$

where the accelerating power is

$$P_{ak} = P_s - P_{ek}$$

and

$$P_{ek} = P_{\max k} \sin \delta_k$$

For hand calculations a table, as shown in Table 61.5, can be set up for fast processing.

TABLE 61.5 Numerical Calculations of Swing Equations

n	t	P_{max}	P_e	P_{ak}	$\frac{(\Delta t)^2 P_a}{M}$	$\Delta_{k+1}\delta$	δ_k
0	0_-						
0	0_+						
0	0_{av}

3	$3\Delta t$						
4	$4\Delta t$						
5	$5\Delta t$						
6	$6\Delta t$						

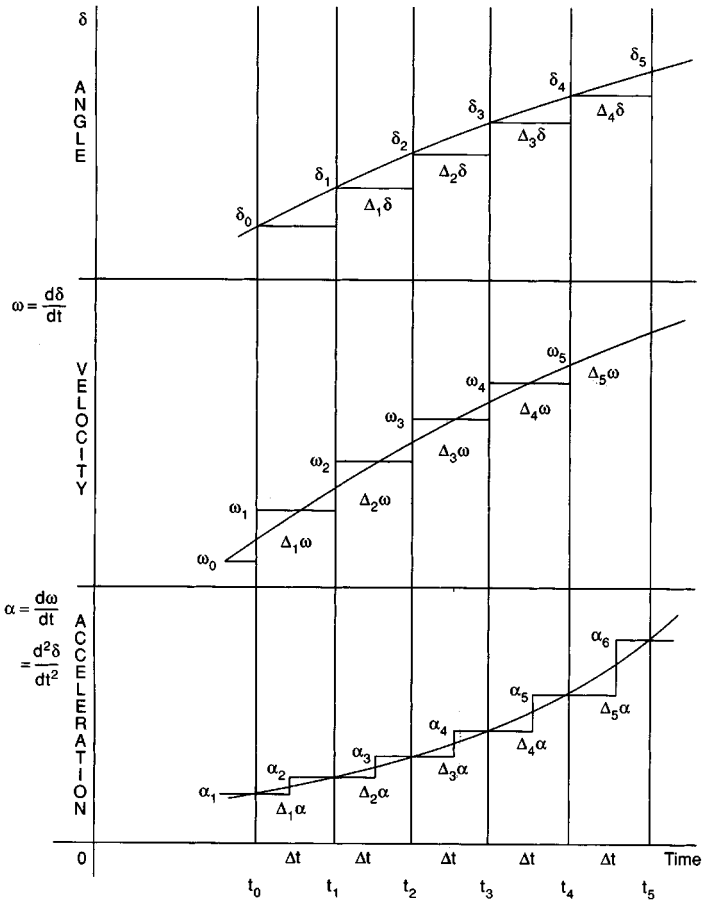

FIGURE 61.58 Incremental angle, velocity, and acceleration changes versus time.

Computer algorithms are developed by using the before-fault, during-fault, and after-fault Z_{BUS} matrix of the reactive network reduced to generator internal voltages with generators represented by their subtransient reactances. Each generator's swing curve is obtained by numerical integration of its power angle for a specified condition, then a set of swing curves is tabulated or graphed for observation of the transient stability. An example with partial calculated data and a line plot for such a study are included on the next page.

Defining Terms

Critical clearing angle: Power angle corresponding to the critical clearing time.

Critical clearing time: The maximum time at which a fault must be cleared for the system to stay transiently stable.

Disturbance (fault): A sudden change or a sequence of changes in the components or the formation of a power system.

Large disturbance: A disturbance for which the equations for dynamic operation cannot be linearized for analysis.

Power angle: The electrical angle between the generated and terminal voltages of a synchronous generator.

Small disturbance: A disturbance for which the equations for dynamic operation can be linearized for analysis.

Stability: The tendency of a power system (or a part of it) to develop torques to maintain its stable operation for a disturbance.

61.8 Planning

J. Duncan Glover

An electric utility transmission system performs three basic functions: delivers outputs from generators to the system, supplies power to the distribution system, and provides for power interchange with other utilities. The electric utility industry has developed planning principles and criteria to ensure that the transmission system reliably performs these basic functions.

The North American Electric Reliability Council (NERC) has provided definitions of the terms **reliability**, **adequacy**, and **security** (see Defining Terms at the end of this section).

System reliability may be viewed from two perspectives: short-term reliability and long-term reliability. The system operator is primarily concerned with real-time security aspects in the short term, that is, supplying steady, uninterrupted service under existing operating conditions and as they occur over the next few minutes, hours, days, or months. The transmission planning engineer, however, is concerned not only with security aspects in the short term but also adequacy and security aspects in the long term, as many as 25 or more years into the future.

The actual construction of a major transmission facility requires three to five years or more, depending largely on the siting and certification process. As such, the planning process requires up to ten years prior to operation of these facilities to ensure that they are available when required. The long lead times, environmental impacts, and high costs required for new transmission facilities require careful, near-optimal planning. Future changes in system operating conditions, such as changes in spatial load and generation patterns, create uncertainties that challenge the transmission planning engineer to select the best technical solution among several alternatives with due consideration of nontechnical factors. Transmission planning strives to maintain an optimal balance between system reliability, environmental impacts, and cost under future uncertainties.

Before transmission planning is started, long-term load forecasting and generation planning are completed. In long-term load forecasting, peak and off-peak loads in each area of the system under study are projected, year by year, from the present up to 25 years into the future. Such forecasts are based on present and past load trends, population growth patterns, and economic indicators. In generation planning, generation resources are selected with sufficient generation reserve margins to meet projected customer loads with adequate quality and reliability in an economic manner. New generating units both at new plant sites and at existing plants are selected, and construction schedules are established to ensure that new generation goes on-line in time to meet projected loads.

The results of long-term load forecasting and generation planning are used by transmission planning engineers to design the future transmission system so that it performs its basic functions. The following are selected during the transmission planning process.

- Routes for new lines
- Number of circuits for each route or right-of-way
- EHV versus HVDC lines
- Overhead versus underground line construction
- Types of towers for overhead lines
- Voltage levels

- Line ratings
- Shunt reactive and series capacitive line compensation
- Number and locations of substations
- Bus and circuit breaker configurations at substations
- Circuit breaker ratings
- Number, location, and ratings of bulk-power-system transformers
- Number, location, and ratings of voltage-regulating transformers and phase-shifting transformers
- Number, location, and ratings of static VAR systems, synchronous condensers, and shunt capacitor banks for voltage control
- Basic insulation levels (BILs)
- Surge arrester locations and ratings
- Protective relaying schemes
- Communications facilities
- Upgrades of existing circuits
- Reinforcements of system interconnections

Planning Tools

As electric utilities have grown in size and the number of interconnections has increased, making the above selections during the planning process has become increasingly complex. The increasing cost of additions and modifications has made it imperative that planning engineers consider a wide range of design options and perform detailed studies on the effects on the system of each option based on a number of assumptions: normal and emergency operating conditions, peak and off-peak loadings, and present and future years of operation. A large volume of network data must be collected and accurately handled. To assist the planning engineer, the following digital computer programs are used [Glover and Sarma, 1994]:

1. *Power-flow programs.* Power-flow (also called load-flow) programs compute voltage magnitudes, phase angles, and transmission line power flows for a power system network under steady-state operating conditions. Other output results, including transformer tap settings, equipment losses, and reactive power outputs of generators and other devices, are also computed. To do this, the locations, sizes, and operating characteristics of all loads and generation resources of the system are specified as inputs. Other inputs include the network configuration as well as ratings and other characteristics of transmission lines, transformers, and other equipment. Today's computers have sufficient storage and speed to compute in less than 1 min power-flow solutions for networks with more than 2000 buses and 2500 transmission lines. High-speed printers then print out the complete solution in tabular form for analysis by the planning engineer. Also available are interactive power-flow programs, whereby power-flow results are displayed on computer screens in the form of single-line diagrams; the engineer uses these to modify the network from a keyboard or with a mouse and can readily visualize the results. Spreadsheet analyses are also used. The computer's large storage and high-speed capabilities allow the engineer to run the many different cases necessary for planning.
2. *Transient stability programs.* Transient stability programs are used to study power systems under disturbance conditions to predict whether synchronous generators remain in synchronism and system stability is maintained. System disturbances can be caused by the sudden loss of a generator or a transmission line, by sudden load increases or decreases, and by short circuits and switching operations. The stability program combines power-flow equations and generator dynamic equations to compute the angular swings of machines during disturbances. The program also computes critical clearing times for network faults and allows the planning engineer to investigate the effects of various network modifications, machine parameters, disturbance types, and control schemes.
3. *Short-circuits programs.* Short-circuits programs compute three-phase and line-to-ground fault currents in power system networks in order to evaluate circuit breakers and relays that detect faults and

control circuit breakers. Minimum and maximum short-circuit currents are computed for each circuit breaker and relay location under various system operating conditions, such as lines or generating units out of service, in order to specify circuit breaker ratings and protective relay schemes.

4. *Transients programs.* Transients programs compute the magnitudes and shapes of transient overvoltages and currents that result from switching operations and lightning strikes. Planning engineers use the results of transients programs to specify BILs for transmission lines, transformers, and other equipment and to select surge arresters that protect equipment against transient overvoltages.

Research efforts aimed at developing computerized, automated transmission planning tools are ongoing. Examples and references are given in Back et al. [1989] and Smolleck et al. [1989]. Other programs for transmission planning include production-cost, investment-cost, relay-coordination, power-system database management, transformer thermal analysis, and transmission line design programs. Some of the vendors that offer software packages for transmission planning are given as follows:

- ABB Network Control Ltd., Switzerland
- CYME International, Burlington, Mass.
- EDSDA Micro Corporation, Bloomfield, Mich.
- Electric Power Consultants, Inc., Scotia, N.Y.
- Electrocon International, Inc., Ann Arbor, Mich.
- Power Technologies, Inc., Schenectady, N.Y.
- Operation Technology, Inc., Irvine, Calif.

Basic Planning Principles

The electric utility industry has established basic planning principles intended to provide a balance among all power system components so as not to place too much dependence on any one component or group of components. Transmission planning criteria are developed from these principles along with actual system operating history and reasonable contingencies. These planning principles are given as follows:

1. Maintain a balance among power system components based on size of load, size of generating units and power plants, the amount of power transfer on any transmission line or group of lines, and the strength of interconnections with other utilities. In particular:
   a. Avoid excessive generating capacity at one unit, at one plant, or in one area.
   b. Avoid excessive power transfer through any single transformer, through any transmission line, circuit, tower, or right-of-way, or though any substation.
   c. Provide interconnection capacity to neighboring utilities that is commensurate with the size of generating units, power plants, and system load.
2. Provide transmission capability with ample margin above that required for normal power transfer from generators to loads in order to maintain a high degree of flexibility in operation and to meet a wide range of contingencies.
3. Provide for power system operation such that all equipment loadings remain within design capabilities.
4. Utilize switching arrangements, associated relay schemes, and controls that permit:
   a. Effective operation and maintenance of equipment without excessive risk of uncontrolled power interruptions.
   b. Prompt removal and isolation of faulted components.
   c. Prompt restoration in the event of loss of any part of the system.

Equipment Ratings

Transmission system loading criteria used by planning engineers are based on equipment ratings. Both normal and various emergency ratings are specified. Emergency ratings are typically based on the time required for either emergency operator actions or equipment repair times. For example, up to 2 h may be required following a major event such as loss of a large generating unit or a critical transmission facility in order to bring other

generating resources on-line and to perform appropriate line-switching operations. The time to repair a failed transmission line typically varies from 2 to 10 days, depending on the type of line (overhead, underground cable in conduit, or pipe-type cable). The time required to replace a failed bulk-power-system transformer is typically 30 days. As such, ratings of each transmission line or transformer may include normal, 2-h emergency, 2- to 10-day emergency, and in some cases 30-day emergency ratings.

The rating of an overhead transmission line is based on the maximum temperature of the conductors. Conductor temperature affects the conductor sag between towers and the loss of conductor tensile strength due to annealing. If the temperature is too high, proscribed conductor-to-ground clearances [ANSI, 1993] may not be met, or the elastic limit of the conductor may be exceeded such that it cannot shrink to its original length when cooled. Conductor temperature depends on the current magnitude and its time duration, as well as on ambient temperature, wind velocity, solar radiation, and conductor surface conditions. Standard assumptions on ambient temperature, wind velocity, etc., are selected, often conservatively, to calculate overhead transmission line ratings [ANSI/IEEE Std. 738–85, 1985]. It is common practice to have summer and winter normal line ratings, based on seasonal ambient temperature differences. Also, in locations with higher prevailing winds, such as coastal areas, larger normal line ratings may be selected. Emergency line ratings typically vary from 110 to 120% of normal ratings. Recently, real-time monitoring of actual conductor temperatures along a transmission line has been used for on-line dynamic transmission line ratings [Henke and Sciacca, 1989].

Normal ratings of bulk-power-system transformers are determined by manufacturers' nameplate ratings. Nameplate ratings are based on the following ANSI/IEEE standard conditions: (1) continuous loading at nameplate output; (2) 30°C average ambient temperature (never exceeding 40°C); and (3) 110°C average hot-spot conductor temperature (never exceeding 120°C) for 65°C-average-winding-rise transformers [ANSI/IEEE C57.92-1981, 1990]. For 55°C-average-winding-rise transformers, the hot-spot temperature limit is 95°C average (never exceeding 105°C). The actual output that a bulk-power-system transformer can deliver at any time with normal life expectancy may be more or less than the nameplate rating, depending on the ambient temperature and actual temperature rise of the windings. Emergency transformer ratings typically vary from 130 to 150% of nameplate ratings.

Planning Criteria

Transmission system planning criteria have been developed from the above planning principles and equipment ratings as well as from actual system operating data, probable operating modes, and equipment failure rates. These criteria are used to plan and build the transmission network with adequate margins to ensure a reliable supply of power to customers under reasonable equipment-outage contingencies. The transmission system should perform its basic functions under a wide range of operating conditions. Transmission planning criteria include equipment loading criteria, transmission voltage criteria, stability criteria, and regional planning criteria.

Equipment Loading Criteria

Typical equipment loading criteria are given in Table 61.6. With no equipment outages, transmission equipment loadings should not exceed normal ratings for all realistic combinations of generation and interchange. Operation of all generating units including base-loaded and peaking units during peak load periods as well as operation of various combinations of generation and interchange during off-peak periods should be considered. Also, normal ratings should not be exceeded with all transmission lines and transformers in service and with any generating unit out of service.

With any single-contingency outage, emergency ratings should not be exceeded. One loading criterion is not to exceed 2-h emergency ratings when any transmission line or transformer is out of service. This gives time to perform switching operations and change generation levels, including use of peaking units, to return to normal loadings.

With some of the likely double-contingency outages, the transmission system should supply all system load without exceeding emergency ratings. One criterion is not to exceed 2- to 10-day emergency ratings when any line and any transformer are out of service or when any line and any generator are out of service. This gives time to repair the line. With the outage of any transformer and any generator, 30-day emergency ratings should not be exceeded, which gives time to install a spare transformer.

TABLE 61.6 Typical Transmission Equipment Loading Criteria

Equipment Out of Service	Rating Not to Be Exceeded	Comment
None	Normal	
Any generator	Normal	
Any line or any transformer	2-h emergency	Before switching.
Any line and any transformer*	2- to 10-day emergency	After switching required for both outages. Line repair time.
Any line and any generator*	2- to 10-day emergency	After switching required for both outages. Line repair time.
Any transformer and any generator*	30-day emergency	After switching required for both outages. Install spare transformer.

*Some utilities do not include double-contingency outages in transmission system loading criteria.

TABLE 61.7 Typical Minimum Transmission Voltage Criteria

	Planned Minimum Transmission Voltage at Substations, % of Nominal		
System Condition	Generator Station	EHV Station	HV Station
Normal	102	98	95–97.5
Single-contingency outage	100	96	92.5–95
Double-contingency outage*	98	94	92.5

*Some utilities do not include double-contingency outages in planned minimum transmission voltage criteria.

The loading criteria in Table 61.6 do not include all types of double-contingency outages. For example, the outage of a double-circuit transmission line or two transmission lines in the same right-of-way is not included. Also, the loss of two transformers in the same load area is not included. Under these double-contingency outages, it may be necessary to shed load at some locations during heavy load periods. Although experience has shown that these outages are relatively unlikely, their consequences should be evaluated in specific situations. Factors to be evaluated include the size of load served, the degree of risk, and the cost of reinforcement.

Specific loading criteria may also be required for equipment serving critical loads and critical load areas. One criterion is to maintain service to critical loads under a double-contingency outage with the prior outage of any generator.

Transmission Voltage Criteria

Transmission voltages should be maintained within suitable ranges for both normal and reasonable emergency conditions. Abnormal transmission voltages can cause damage or malfunction of transmission equipment such as circuit breakers or transformers and adversely affect many customers. Low transmission voltages tend to cause low distribution voltages, which in turn cause increased distribution losses as well as higher motor currents at customer loads and at power plant auxiliaries. Transmission voltage planning criteria are intended to be conservative.

Maximum planned transmission voltage is typically 105% of rated nominal voltage for both normal and reasonable emergency conditions. Typical minimum planned transmission voltages are given in Table 61.7. System conditions in Table 61.7 correspond to equipment out of service in Table 61.6. Single-contingency outages correspond to the loss of any line, any transformer, or any generator. Double-contingency outages correspond to the loss of any transmission line and transformer, any transmission line and generator, any transformer and generator, or any two generators.

Typical planned minimum voltage criteria shown in Table 61.7 for EHV (345 kV and higher) substations and for generator substations are selected to maintain adequate voltage levels at interconnections, at power plant auxiliary buses, and on the lower-voltage transmission systems. Typical planned minimum voltage criteria for lower HV (such as 138 kV, 230 kV) transmission substations vary from 95 to 97.5% of nominal voltage under normal system conditions to as low as 92.5% of nominal under double-contingency outages.

Equipment used to control transmission voltages includes voltage regulators at generating units (excitation control), tap-changing transformers, regulating transformers, synchronous condensers, shunt reactors, shunt capacitor banks, and static VAR devices. When upgrades are selected during the planning process to meet planned transmission voltage criteria, some of this equipment should be assumed out of service.

Stability Criteria

System stability is the ability of all synchronous generators in operation to stay in synchronism with each other while moving from one operating condition to another. Steady-state stability refers to small changes in operating conditions, such as normal load changes. Transient stability refers to larger, abrupt changes, such as the loss of the largest generator or a short circuit followed by circuit breakers opening, where synchronism or loss of synchronism occurs within a few seconds. Dynamic stability refers to longer time periods, from minutes up to a half hour following a large, abrupt change, where steam generators (boilers), automatic generation control, and system operator actions affect stability.

In the planning process, steady-state stability is evaluated via power-flow programs by the system's ability to meet equipment loading criteria and transmission voltage criteria under steady-state conditions. Transient stability is evaluated via stability programs by simulating system transient response for various types of disturbances, including short circuits and other abrupt network changes. The planning engineer designs the system to remain stable for the following typical disturbances:

1. With all transmission lines in service, a permanent three-phase fault (short circuit) occurs on any transmission line, on both transmission lines on any double-circuit tower, or at any bus; the fault is successfully cleared by primary relaying.
2. With any one transmission line out of service, a permanent three-phase fault occurs on any other transmission line; the fault is successfully cleared by primary relaying.
3. With all transmission lines in service, a permanent three-phase fault occurs on any transmission line; backup relaying clears the fault after a time delay, due to a circuit breaker failure.

Regional Planning Criteria

The North American Electric Reliability Council (NERC) defines nine geographical regions in North America, as shown in Fig. 61.59 [NERC, 1988]. Transmission planning studies are performed at two levels: (1) individual electric utility companies separately perform planning studies of their internal systems and (2) companies jointly participate in NERC committees or working groups to perform regional and interregional planning studies. The purpose of regional planning studies is to evaluate the transfer capabilities between interconnected utilities and the impact of severe disturbances.

One typical regional criterion is that the incremental power transfer capability, in addition to scheduled interchange, should provide a reasonable generation reserve margin under the following conditions: peak load, the most critical transmission line out of service, no component overloaded.

Another criterion is that severe disturbances to the interconnected transmission network should not result in system instability, widespread cascading outages, voltage collapse, or system blackouts. [NERC, 1988, 1989, and 1991]. Severe disturbances include the following:

1. With any three generating units or any combination of units up to 30% of system load out of service in an area, a sudden outage of any transmission line or any transformer occurs.
2. With any two generating units or any combination of units up to 20% of system load out of service in an area, a sudden outage of any generator or any double-circuit transmission line occurs.
3. With any transmission line or transformer out of service in an area, a sudden outage of any other transmission line or transformer occurs.
4. With any transmission line or transformer out of service in an area as well as any two generating units or any combination of units up to 20% of system load, a sudden outage of a transmission line occurs.
5. A sudden outage of all generating units at a power plant occurs.
6. A sudden outage of either a transmission substation or all transmission lines on a common right-of-way occurs.
7. A sudden outage of a large load or a major load center occurs.

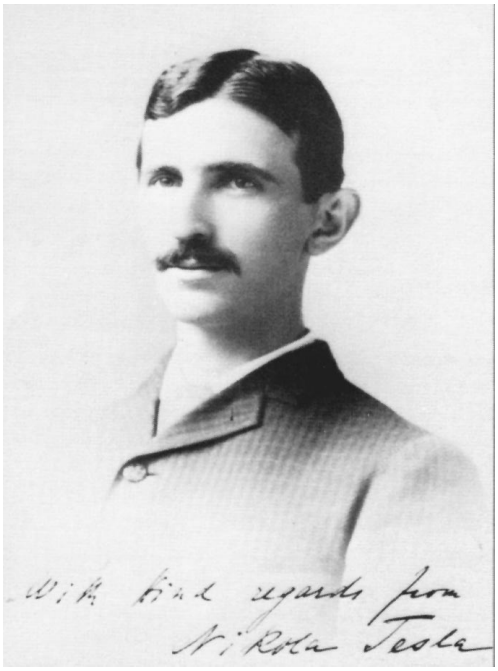
When evaluating the impacts of the above severe disturbances, regional planning studies should consider steady-state stability, transient stability, and dynamic stability. These studies should also consider the effects of three-phase faults and slow fault clearing due to improper relaying or failure of a circuit breaker to open, as well as the anticipated load range and various operating conditions.

Value-Based Transmission Planning

Recently some utilities have begun to use a value-of-service concept in transmission planning [EPRI, 1986]. This concept establishes a method of assigning a dollar value to various levels of reliability in order to balance reliability and cost. For each particular outage, the amount and dollar value of unserved energy are determined. Dollar value of unserved energy is based on rate surveys of various types of customers. If the cost of the transmission project required to eliminate the outage exceeds the value of service, then that project is given a lower priority. As such, reliability is quantified, and benefit-to-cost ratios are used to compare and prioritize planning options.

Nikola Tesla (1856–1943)

Nikola Tesla was born of Serbian parents in the village of Smiljan, in what is now Yugoslavia. He showed his technical brilliance early, but felt that his native country offered him only limited opportunities. In 1884 he emigrated to the United States and began working for Thomas Edison. He soon struck out on his own, however, for Edison had little use for Tesla's bold new ideas — in particular, his brilliant solution to the problems of applying alternating current in light and power systems. Tesla's polyphase ac system was brought to market by George Westinghouse, and after an acrimonious struggle with the Edison interests, which were wedded to the use of direct current (dc), the Tesla system became the standard in the twentieth century. Tesla's other inventions included the synchronous ac motor, devices for generating high voltage and high frequency currents, and contributions to radio technology. Tesla received the Edison Medal of the American Institute of Electrical Engineers in 1916. (Courtesy of the IEEE Center for the History of Electrical Engineering.)



Defining Terms

The North American Electric Reliability Council (NERC) defines *reliability* and the related terms *adequacy* and *security* as follows [NERC, 1988]:

Adequacy: The ability of the bulk-power electric system to supply the aggregate electric power and energy requirements of the consumers at all times, taking into account scheduled and unscheduled outages of system components.

Reliability: In a bulk-power electric system, reliability is the degree to which the performance of the elements of that system results in power being delivered to consumers within accepted standards and in the amount desired. The degree of reliability may be measured by the frequency, duration, and magnitude of adverse effects on consumer service.

Security: The ability of the bulk-power electric system to withstand sudden disturbances such as electric short circuits or unanticipated loss of system components.

Further Information

The North American Electric Reliability Council (NERC) was formed in 1968, in the aftermath of the November 9, 1965, northeast blackout, to promote the reliability of bulk-electric-power systems of North America. Transmission planning criteria presented here are partially based on NERC criteria as well as on specific criteria used by transmission planning departments from three electric utility companies: American Electric Power Service Corporation, Commonwealth Edison Company, and Pacific Gas & Electric Company. NERC's publications, developed by utility experts, have become standards for the industry. In most cases, these publications are available at no charge from NERC, Princeton, N.J.

62.2 Power Quality Monitoring
62.3 Power Quality Conditioning

Jos Arrillaga
University of Canterbury (New Zealand)

Ideally, power should be supplied without interruptions at constant frequency, constant voltage and with perfectly sinusoidal and, in the case of three-phase, symmetrical waveforms. Supply reliability constitutes a recognized independent topic, and is not usually discussed under power quality. The specific object of power quality is the "*pureness*" of the supply including voltage variations and waveform **distortion**.

Power system **disturbances** and the continually changing demand of consumers give rise to voltage variations. Deviation from the sinusoidal voltage supply can be due to transient phenomena or to the presence of non-linear components.

The power network is not only the main source of energy supply but also the conducting vehicle for possible interferences between consumers. This is a subject that comes under the general heading of electromagnetic compatibility (EMC).

EMC refers to the ability of electrical and electronic components, equipment, and systems to operate satisfactorily without causing interference to other equipment or systems, or without being affected by other operating systems in that electromagnetic environment.

EMC is often perceived as interference by electromagnetic radiation between the various elements of a system. The scope of EMC, however, is more general and it also includes conductive propagation and coupling by capacitance, inductance (self and mutual) encompassing the whole frequency spectrum.

A power quality problem is any occurrence manifested in voltage, current, or frequency deviation that results in failure or misoperation of equipment. The newness of the term reflects the newness of the concern. Decades ago, power quality was not a worry because it had no effect on most loads connected to electric distribution systems.

Therefore, power quality can also be defined as the ability of the electrical power system to transmit and deliver electrical energy to the consumers within the limits specified by EMC standards.

62.1 Power Quality Disturbances

Following standard criteria [IEC, 1993], the main deviations from a perfect supply are

- periodic waveform distortion (harmonics, interharmonics)
- voltage fluctuations, flicker
- short voltage interruptions, dips (sags), and increases (swells)
- three-phase unbalance
- transient overvoltages

The main causes, effects and possible control of these disturbances are considered in the following sections.

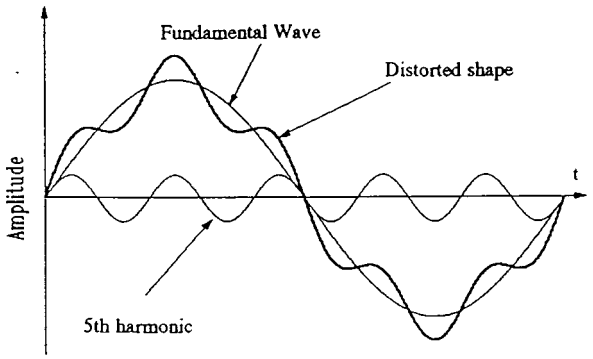

FIGURE 62.1 Example of a distorted sine wave.

Periodic Waveform Distortion

Harmonics are sinusoidal voltages or currents having frequencies that are whole multiples of the frequency at which the supply system is designed to operate (e.g., 50 Hz or 60 Hz). An illustration of fifth harmonic distortion is shown in Fig. 62.1. When the frequencies of these voltages and currents are not an integer of the fundamental they are termed interharmonics.

Both harmonic and interharmonic distortion is generally caused by equipment with non-linear voltage/current characteristics.

In general, distorting equipment produces harmonic currents that, in turn, cause harmonic voltage drops across the impedances of the network. Harmonic currents of the same frequency from different sources add vectorially.

The main detrimental effects of harmonics are [Arrillaga et al., 1985]

- maloperation of control devices, main signalling systems, and protective relays
- extra losses in capacitors, transformers, and rotating machines
- additional noise from motors and other apparatus
- telephone interference
- The presence of power factor correction capacitors and cable capacitance can cause shunt and series resonances in the network producing voltage amplification even at a remote point from the distorting load.

As well as the above, interharmonics can perturb **ripple control signals** and at sub-harmonic levels can cause flicker.

To keep the harmonic voltage content within the recommended levels, the main solutions in current use are

- the use of high pulse rectification (e.g., smelters and **HVdc** converters)
- passive filters, either tuned to individual frequencies or of the band-pass type
- active filters and conditioners

The harmonic sources can be grouped in three categories according to their origin, size, and predictability, i.e., small and predictable (domestic and residential), large and random (arc furnaces), and large and predictable (static converters).

Small Sources

The residential and commercial power system contains large numbers of single-phase converter-fed power supplies with capacitor output smoothing, such as TVs and PCs, as shown in Fig. 62.2. Although their individual rating is insignificant, there is little diversity in their operation and their combined effect produces considerable odd-harmonic distortion. The gas discharge lamps add to that effect as they produce the same harmonic components.

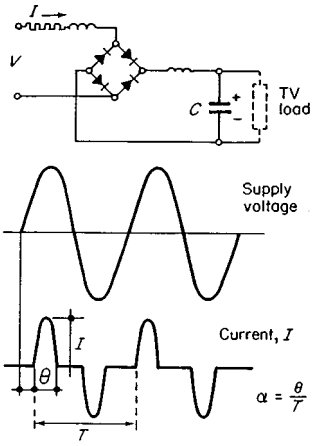

FIGURE 62.2 Single-phase bridge supply for a TV set.

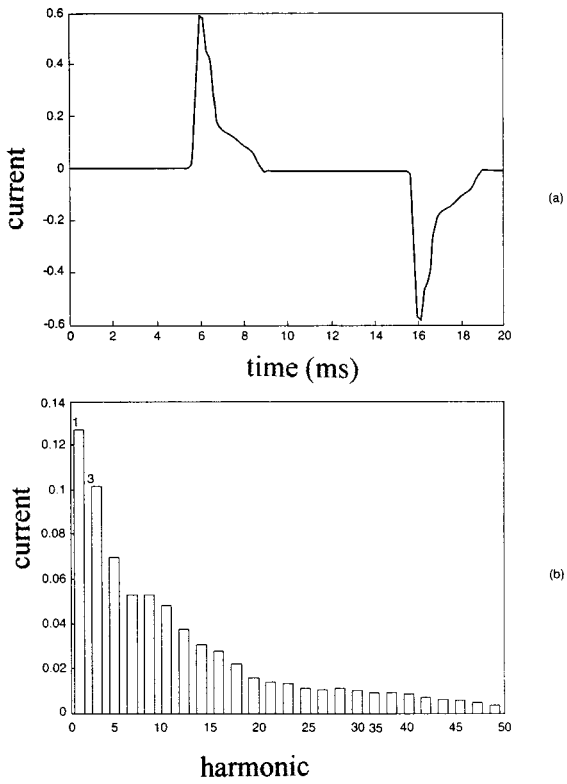

FIGURE 62.3 Current waveform (a) and harmonic spectrum (b) of a high efficiency lamp.

Figure 62.3 illustrates the current waveform and harmonic spectrum of a typical high efficiency lamp. The **total harmonic distortion (THD)** of such lamps can be between 50 and 150%.

Large and Random Sources

The most common and damaging load of this type is the arc furnace. Arc furnaces produce random variations of harmonic and interharmonic content which is uneconomical to eliminate by conventional filters.

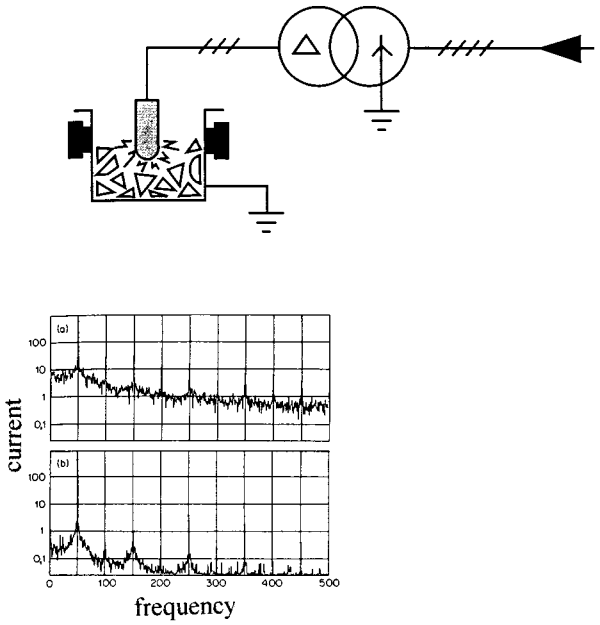

FIGURE 62.4 Typical frequency spectra of arc furnace operation. (a) During fusion; (b) during refining.

Figure 62.4 shows a snap-shot of the frequency spectra produced by an arc furnace during the melting and refining processes, respectively. These are greatly in excess of the recommended levels.

These loads also produce voltage fluctuations and flicker. Connection to the highest possible voltage level and the use of series reactances are among the measures currently taken to reduce their impact on power quality.

Static Converters

Large power converters, such as those found in smelters and HVdc transmission, are the main producers of harmonic current and considerable thought is given to their local elimination in their design.

The standard configuration for industrial and HVdc applications is the twelve-pulse converter, shown in Fig. 62.5. The "*characteristic*" harmonic currents for the configuration are of orders $12\,K \pm 1$ and their amplitudes are inversely proportional to the harmonic order, as shown by the spectrum of Fig. 62.6(b) which correspond to the time waveform of Fig. 62.6(a). These are, of course, maximum levels for ideal system conditions, i.e., with an infinite (zero impedance) ac system and a perfectly flat direct current (i.e., infinite smoothing reactance).

When the ac system is weak and the operation not perfectly symmetrical, **uncharacteristic harmonics** appear [Arrillaga, 1983].

While the characteristic harmonics of the large power converter are reduced by filters, it is not economical to reduce in that way the uncharacteristic harmonics and, therefore, even small injection of these harmonic currents can, via parallel resonant conditions, produce very large voltage distortion levels.

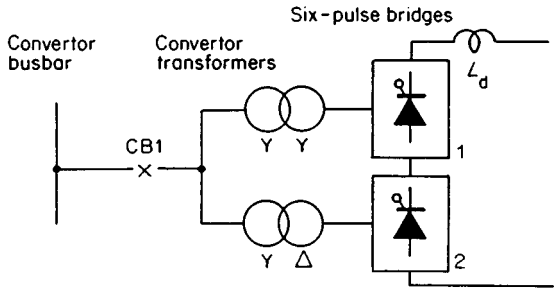

FIGURE 62.5 Twelve-pulse converter.

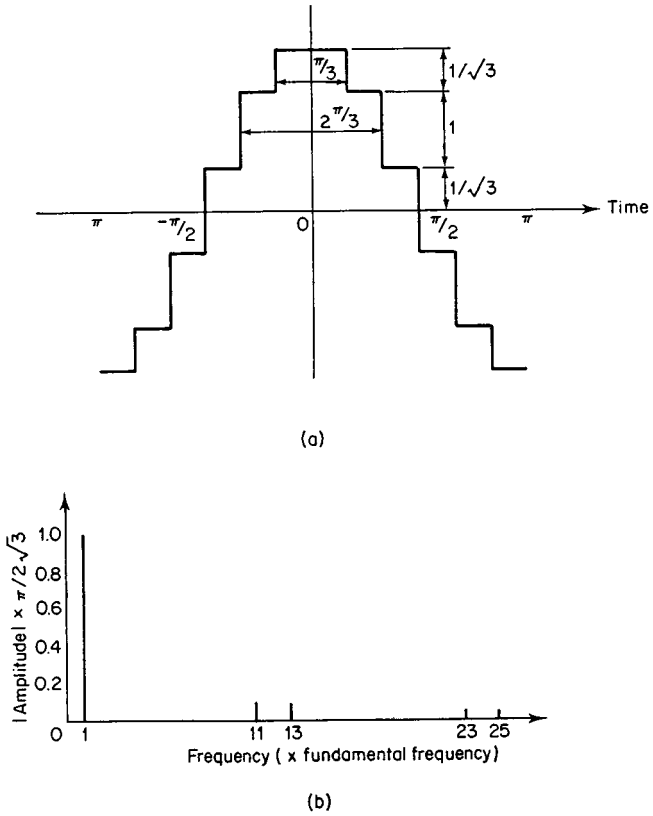

FIGURE 62.6 Twelve-pulse converter current. (a) Waveform; (b) spectrum.

An example of uncharacteristic converter behavior is the presence of fundamental frequency on the dc side of the converter, often induced from ac transmission lines in the proximity of the dc line, which produces second harmonic and direct current on the ac side.

Even harmonics, particularly the second, are very disruptive to power electronic devices and are, therefore, heavily penalized in the regulations.

The flow of dc current in the ac system is even more distorting, the most immediate effect being asymmetrical saturation of the converters or other transformers with a considerable increase in even harmonics which, under certain conditions, can lead to **harmonic instabilities** [Chen et al., 1996].

Another common example is the appearance of triplen harmonics. Asymmetrical voltages, when using a common firing angle control for all the valves, result in current pulse width differences between the three phases which produce triplen harmonics. To prevent this effect, modern large power converters use the equidistant firing concept instead [Ainsworth, 1968]. However, this controller cannot eliminate second harmonic amplitude modulation of the dc current which, via the converter modulation process, returns third harmonic current of positive sequence. This current can flow through the converter transformer regardless of its connection and penetrate far into the ac system. Again, the presence of triplen harmonics is discouraged by stricter limits in the regulations.

Voltage Fluctuations and Flicker

This group includes two broad categories, i.e.,

- step voltage changes, regular or irregular in time, such as those produced by welding machines, rolling mills, mine winders, etc. [Figs. 62.7(a) and (b)].
- cyclic or random voltage changes produced by corresponding variations in the load impedance, the most typical case being the arc furnace load (Fig. 62.7(c)).

Generally, since voltage fluctuations have an amplitude not exceeding ±10%, most equipment is not affected by this type of disturbance. Their main disadvantage is flicker, or fluctuation of luminosity of an incandescent lamp. The important point is that it is impossible, in practice, to change the characteristics of the filament. The physiological discomfort associated with this phenomenon depends on the amplitude of the fluctuations, the rate of repetition for voltage changes, and the duration of the disturbance. There is, however, a perceptibility threshold below which flicker is not visible.

Flicker is mainly associated with the arc furnaces because they draw different amounts of current each power cycle. The upshot is a modulation of the system voltage magnitude in the vicinity of the furnace. The modulation frequency is in the band 0 to 30 Hz, which is in the range that can cause noticeable flicker of light bulbs.

The flicker effect is usually evaluated by means of a flickermeter (IEC Publication 868). Moreover, the amplitude of modulation basically depends on the ratio between the impedance of the disturbing installation and that of the supply network.

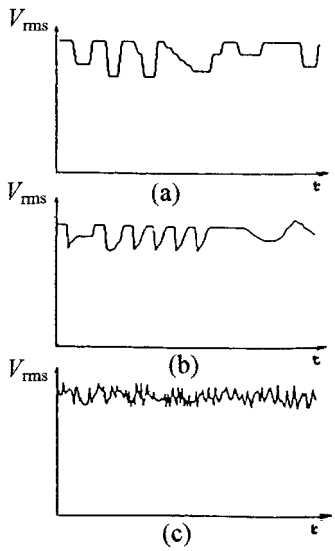

FIGURE 62.7 Voltage fluctuations.

Brief Interruptions, Sags, and Swells

Voltage Dips (SAGS)

A voltage dip is a sudden reduction (between 10 and 90%) of the voltage, at a point in the electrical system, such as that shown in Fig. 62.8, and lasting for 0.5 cycle to several seconds.

Dips with durations of less than half a cycle are regarded as transients.

A voltage dip may be caused by switching operations associated with temporary disconnection of supply, the flow of heavy current associated with the start of large motor loads or the flow of fault currents. These events may emanate from customers' systems or from the public supply network.

The main cause of momentary voltage dips is probably the lightning strike. In the majority of cases, the voltage drops to about 80% of its nominal value. In terms of duration, dips tend to cluster around three values: 4 cycles (the typical clearing time for faults), 30 cycles (the instantaneous reclosing time for breakers), and 120 cycles (the delayed reclosing time of breakers). The effect of a voltage dip on equipment depends on both its magnitude and its duration; in about 42% of the cases observed to date they are severe enough to exceed the tolerance standard adopted by computer manufacturers.

Possible effects are:

- extinction of discharge lamps
- incorrect operation of control devices
- speed variation or stopping of motors
- tripping of contactors
- computer system crash or measuring errors in instruments equipped with electronic devices
- commutation failure in HVdc converters [Arrillaga, 1983]

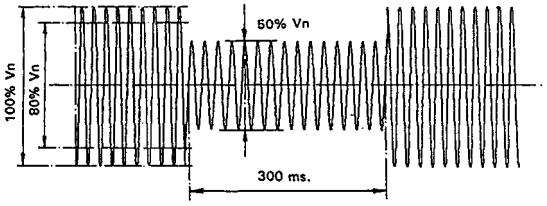

FIGURE 62.8 Voltage sag.

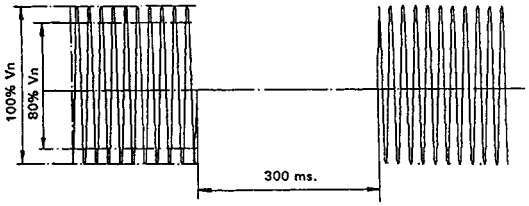

FIGURE 62.9 Voltage interruption.

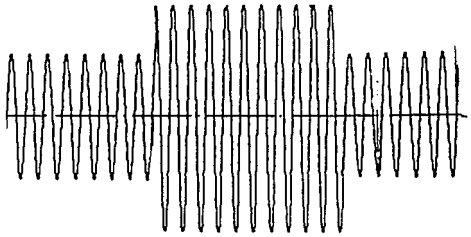

FIGURE 62.10 Voltage swell.

Brief Interruptions

Brief interruptions can be considered as voltage sags with 100% amplitude (see Fig. 62.9). The cause may be a blown fuse or breaker opening and the effect an expensive shutdown. For instance, a five-cycle interruption at a glass factory has been estimated as $200,000, and a major computer center reports that a 2-second outage can cost approximately $600,000. The main protection of the customer against such events is the installation of uninterruptible power supplies or power quality conditioners (discussed later).

Brief Voltage Increases (SWELLS)

Voltage swells, shown in Fig. 62.10, are brief increases in rms voltage that sometimes accompany voltage sags. They appear on the unfaulted phases of a three-phase circuit that has developed a single-phase short circuit. They also occur following load rejection.

Swells can upset electric controls and electric motor drives, particularly common adjustable-speed drives, which can trip because of their built-in protective circuitry. Swells may also stress delicate computer components and shorten their life.

Possible solutions to limit this problem are, as in the case of sags, the use of uninterruptible power supplies and conditioners.

Unbalances

Unbalance describes a situation, as shown in Fig. 62.11, in which the voltages of a three-phase voltage source are not identical in magnitude, or the phase differences between them are not 120 electrical degrees, or both. It affects motors and other devices that depend on a well-balanced three-phase voltage source.

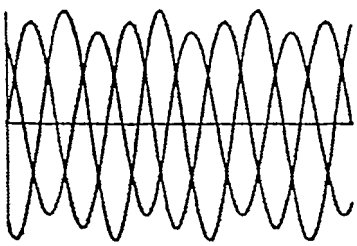

FIGURE 62.11 Voltage unbalance.

The degree of unbalances is usually defined by the proportion of negative and zero **sequence components**.

The main causes of unbalance are single-phase loads (such as electric railways) and untransposed overhead transmission lines.

A machine operating on an unbalanced supply will draw a current with a degree of unbalance several times that of the supply voltage. As a result, the three-phase currents may differ considerably and temperature rise in the machine will take place.

Motors and generators, particularly the large and more expensive ones, may be fitted with protection to detect extreme unbalance. If the supply unbalance is sufficient, the "*single-phasing*" protection may respond to the unbalanced currents and trip the machine.

Polyphase converters, in which the individual input phase voltages contribute in turn to the dc output, are also affected by an unbalanced supply, which causes an undesirable ripple component on the dc side, and non-characteristic harmonics on the ac side.

Transients

Voltage disturbances shorter than sags or swells are classified as transients and are caused by sudden changes in the power system [Greenwood, 1971]. They can be impulsive, generally caused by lightning and load switching, and oscillatory, usually due to capacitor-bank switching.

Capacitor switching can cause resonant oscillations leading to an overvoltage some three to four times the nominal rating, causing tripping or even damaging protective devices and equipment. Electronically based controls for industrial motors are particularly susceptible to these transients.

According to their duration, transient overvoltages can be divided into:

- switching surge (duration in the range of *ms*)
- impulse, spike (duration in the range of μs)

Surges are high-energy pulses arising from power system switching disturbances, either directly or as a result of resonating circuits associated with switching devices. They also occur during step load changes.

Impulses in microseconds, as shown in Fig. 62.12, result from direct or indirect lightning strokes, arcing, insulation breakdown, etc.

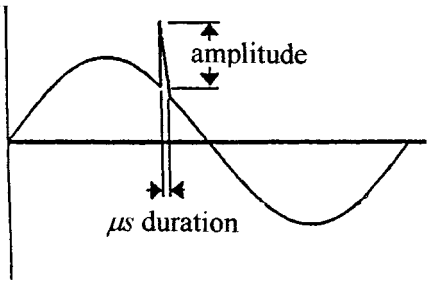

FIGURE 62.12 Impulse.

Protection against surges and impulses is normally achieved by surge-diverters and arc-gaps at high voltages and avalanche diodes at low voltages.

Faster transients in nanoseconds due to electrostatic discharges, an important category of EMC, are not normally discussed under Power Quality.

62.2 Power Quality Monitoring

Figure 62.13 illustrates the various components of a power quality detection system, i.e., voltage and current transducers, information transmission, instrumentation, and displays.

The most relevant information on power quality monitoring requirements can be found in the document IEC 1000-4.7. This document provides specific recommendations on monitoring accuracy in relation to the operating condition of the power system.

With reference to monitoring of individual frequencies, the maximum recommended relative errors for the magnitude and phase are 5% and 5°, respectively, under normal operating conditions and with constant voltage or current levels. However, such precision must be maintained for voltage variations of up to 20% (of nominal value) and 100% (peak value). For current measurements, the precision levels apply for overcurrents of up to 20% and peaks of 3 times rms value (on steady state) and 10 times the nominal current for a 1-sec duration.

Errors in the frequency response of current transformers occur due to capacitive effects, which are not significant in the harmonic region (say, up to the 50th harmonic), and also due to magnetizing currents. The

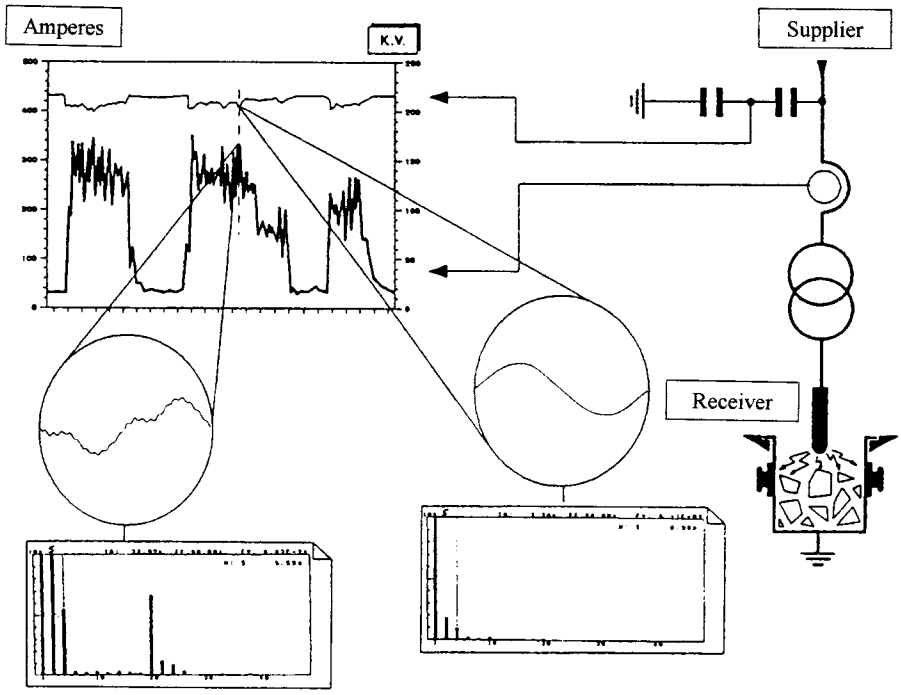

FIGURE 62.13 Power quality monitoring components.

latter can be minimized by reducing the current transformer load and improving the power factor; the ideal load being a short-circuited secondary with a *clamp* to monitor the current. Alternative transducers are being proposed for high frequency measurements using optical, magneto-optical, and Hall effect principles.

The iron-core voltage transformers respond well to harmonic frequencies for voltages up to 11 kV. Due to insulation capacitance, these transformers are not recommended for much higher voltages. The conventional capacitive voltage transformers (CVTs) are totally inadequate due to low frequency resonances between the capacitive divider and the output magnetic transformer; special portable capacitive dividers, without the output transformers, are normally used for such measurements. Again, alternative transducer principles, as for the current transformer, are being proposed for future schemes.

The signal transmission from the transducers to the control room passes through very noisy electromagnetic environments and the tendency is to use fiber optic cables, designed to carry either analog or digital samples of information in the time domain.

The time domain information is converted by signal or harmonic analyzers into the frequency domain; the instrumentation is also programmed to derive any required power quality indexes, such as THD (total harmonic distortion), EDV (equivalent distortion voltage), EDI (equivalent distortion current), etc.

The signal processing is performed by either analog or digital instrumentation, though the latter is gradually displacing the former. Most digital instruments in existence use the **FFT** (Fast Fourier Transform). The processing of information can be continuous or discontinuous depending on the characteristic of the signals under measurement with reference to waveform distortion. Document IEC 1000-4.7 lists the following types:

- quasi stationary harmonics
- fluctuating harmonics
- intermittent harmonics
- interharmonics

Only in the case of quasi stationary waveforms can the use of discontinuous monitoring be justified; examples of this type are the well-defined loads such as TV and PC sets.

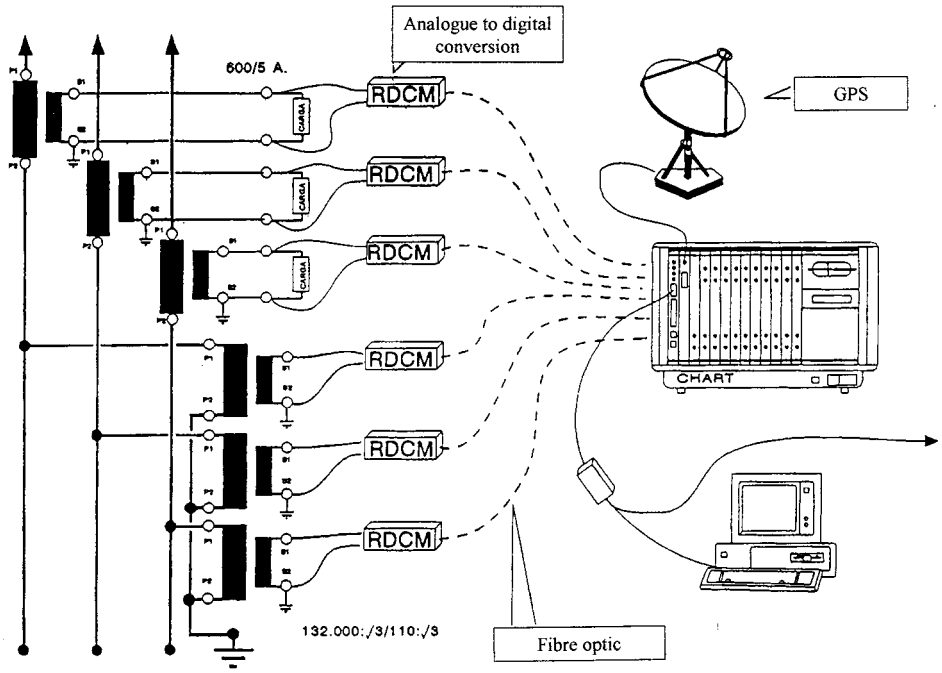

FIGURE 62.14 Simultaneous measurement of voltages and currents in a three-phase line.

In the remaining categories, it is necessary to perform real time continuous monitoring; examples of loads producing non-stationary distortion are arc furnaces and rolling mills.

Most of the instruments commercially available are not designed specifically for power system application, i.e., they are not multi-phase and cannot process continuous information. At the time of writing, the only system capable of multi-channel three-phase real time continuous monitoring is CHART [Miller and Dewe, 1992] which, although originally designed for harmonic monitoring, is capable of deriving continuous information of other power quality indexes such as flicker. It is based on the Intel Multi-bus II architecture and the RMX 386 operating system. An illustration of the system, shown in Fig. 62.14, includes remote data conversion modules, digital fiber optic transmission, **GPS** synchronization, central parallel processing, and ethernet-connected PCs for distant control and display.

62.3 Power Quality Conditioning

A common device in current use to ensure supply continuity for critical loads is the UPS or uninterruptible power supply. For brief interruptions, the UPS are of the static type, using batteries as the energy source and involving a rectifier/inverter system. A block diagram of a typical UPS is shown in Fig. 62.15 [Heydt, 1991].

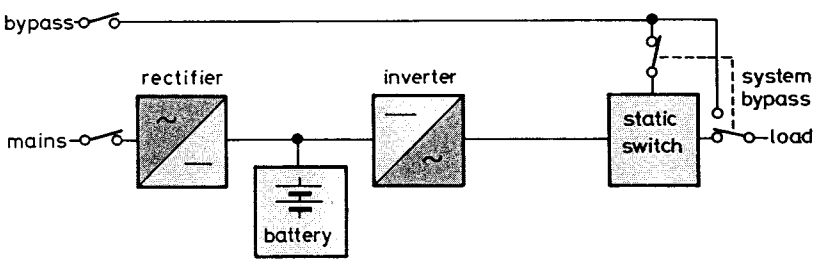

FIGURE 62.15 Uninterruptible power supply.

In the next few years power quality enhancements, in terms of reduced interruptions and voltage variations, can be expected by the application of power electronic controllers to utility distribution systems and/or at the supply end of many industrial and commercial customers.

Among the solutions already available are the solid state circuit breaker, the static condensers (or statcon), and the dynamic voltage restorer [Hingorani, 1995].

In a solid state circuit breaker, thyristors connected back-to-back form an ac switch module, several of which are, in turn, connected in series to acquire the required voltage rating. The breaker will interrupt the circuit at the first zero of the ac current. This means a delay of a few milliseconds, which should be acceptable for most applications.

Figure 62.16 shows a simplified illustration of a statcon which is made up of GTOs (Gate Turn Off) or similar devices such as insulated-gate bipolar transistors (IGBTs) or MOS-controlled thyristors (MCTs). The converter is driven by a dc storage device such as a dc capacitor, battery, or superconducting magnetic storage, and an ac transformer.. The dynamic voltage restorer, shown schematically in Fig. 62.17, turns a distorted waveform, including voltage dips, into the required waveform. The device injects the right amount of voltage by way of a series-connected transformer into the distribution feeder between the power supply side and load side.

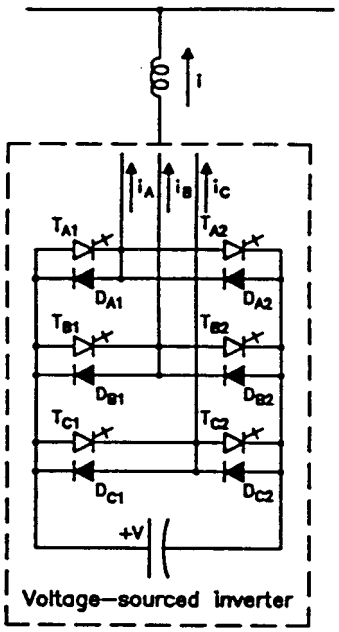

FIGURE 62.16 Static condenser.

The dynamic voltage restorer is similar to the statcon, with a transformer, converter, and storage, except that the transformer is connected in series with the busbar feeding the sensitive load. Compensation occurs in both directions, making up for the voltage dips and reducing the overvoltage. The response is very fast, occurring within a few milliseconds.

The capacity of the dc storage capacitor, in both the statcon and the dynamic voltage restorer, determines the duration of the correction provided for individual voltage dips. It can be a few cycles or seconds long. To enhance the load support capability, a storage battery with a booster electronic circuit can be connected in parallel with the capacitor.

Superconducting magnetic energy storage can be very effective to provide power for short periods. When the storage is not supporting the load, the converter will automatically charge the storage from the utility system, to be ready for the next event.

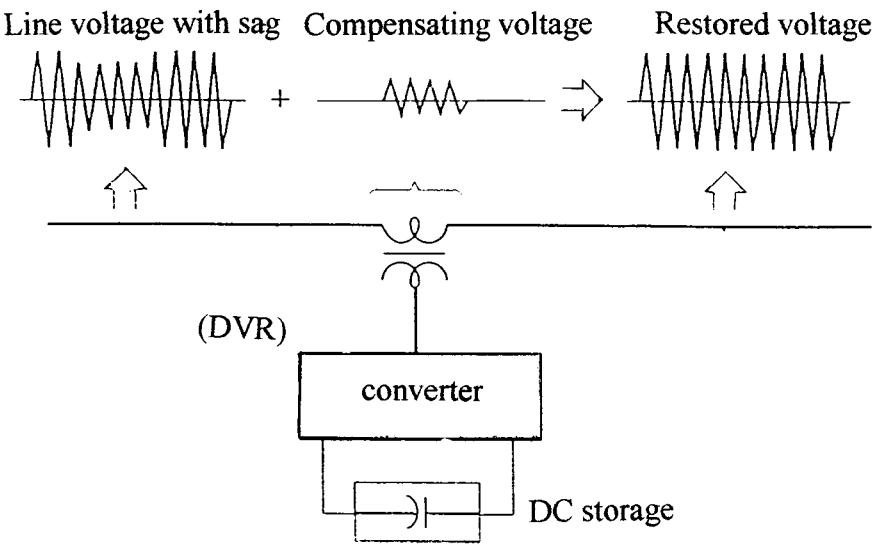

FIGURE 62.17 Dynamic voltage restorer.

Defining Terms

Distortion: Any deviation from a perfectly sinusoidal wave.
Disturbance: Any sudden change in the intended power, voltage, or current supply.
FFT (fast Fourier transform): Efficient computation of the discrete Fourier transform.
GPS (global positioning satellite): Used for time stamping and synchronization of multi-measurements at different geographical locations.
Harmonic instability: Extreme distortion of the voltage waveform at a particular frequency that causes inverter maloperation.
HVdc: High voltage direct current transmission.
Ripple control signal: A burst of pulses at a fixed non-harmonic frequency injected into the power system for the purpose of load management control.
Sequence components: Three symmetrical sets of voltages or currents equivalent to an asymmetrical three-phase unbalanced set.
THD (total harmonic distortions): The ratio of rms value of the harmonic content to the rms value of the generated frequency (in %).
Uncharacteristic harmonics: Static converter harmonics of orders different from $Pk \pm 1$ where P is the pulse number.

Further Information

Electric Power Quality by J. Heydt and *Power System Harmonics* by J. Arrillaga et al. are the only texts discussing the topic, though the latter is currently out of print. Two international conferences take place biennially specifically related to Power Quality; these are PQA (Power Quality: end use applications and perspectives) and the IEEE sponsored ICHQP (International Conference on Harmonics and Quality of Power).

Important information can also be found in the regular updates of the IEC and CENELEC standards, CIGRE, CIRED, UIC, and UNIPEDE documents and national guides such as the IEEE 519-1992.

Finally, the IEE and IEEE Journals on Power Transmission and Delivery, respectively, publish regularly important contributions in this area.

theory assumptions are both violated for the case when a loadflow does solve after discontinuous parameter change because the parameter variation is not continuous and smooth and the power system model may not be continuously differentiable at the point ($\mathbf{x}_0$, $\mathbf{p}_0$). The P-V curve, or Q-V curve, or eigenvalues and eigenvectors could be computed and used to assess proximity to voltage instability after each equipment outage or discontinuous parameter change when a loadflow solution exists to establish whether the solutions is stable or unstable at values of $\mathbf{p}$ above $\mathbf{p}_0$. The computation of the P-V curve, Q-V curve, or eigenvalues and eigenvectors requires significant computation and is not practical for screening thousands of contingencies for voltage instability or for assessing proximity to instability although they are used to assess stability and proximity to instability after a few selected contingencies. These methods also do not explicitly take into account the many discontinuities in the model and eigenvalues that occur for continuous parameter and discontinuous parameter changes. In many cases, the eigenvalue changes due to discontinuities is virtually all the change that occurs in an eigenvalue that approaches instability [IEEE, 1993] and the above methods have particular difficulty in such cases. The above methods cannot assess the agents that lose voltage instability for a particular event and cannot diagnose a cure when the loadflow has no solution for an equipment outage, wheeling or transaction combination, or both. These methods can provide a cure when a loadflow solution exists but its capabilities have not been compared to the f Security Assessment and Diagnosis proposed cure. The Voltage Stability
Security Assessment and Diagnosis (VSSAD) [Schlueter, 1998d] overcomes the above difficulties because:

1. It determines the number of discontinuities in any eigenvalue that have already occurred due to generator PV to load PQ bus type changes that are associated with an eigenvalue compared to the total number that are needed to produce voltage instability when the eigenvalue becomes negative. The eigenvalue is associated with a coherent bus group (voltage control area) [Schlueter, 1998a; f]. The subset of generators that experience PV-PQ bus type changes (reactive reserve basin) for computing a Q-V curve at any bus in that bus group are proven to capture the number of discontinuities in that eigenvalue [Schlueter, 1998a; f]. An eigenvalue approximation for the agent, composed of the test voltage control area where the Q-V current is computed and its reactive reserve basin, is used to theoretically justify the definitions of a voltage control area and the reactive reserve basin of an agent. The VSSAD agents are thus proven to capture eigenvalue structure of the loadflow jacobian evaluated at any operating point ($\mathbf{x}_0$, $\mathbf{p}_0$). The reactive reserve on generators in each voltage control area of a reactive reserve basin is proven to measure proximity to each of the remaining discontinuities in the eigenvalue required for bifurcation.
2. It can handle strictly discontinuous (equipment outage or large transfer or wheeling transaction changes) or continuous model or parameter change (load increase, transfer increases, and wheeling increases) whereas the above methods are restricted to continuous changes to assess stability or instability at a point $\mathbf{p}_0$.
3. It can simultaneously and quickly assess proximity to voltage instability for all agents where each has a bifurcating eigenvalue. Proximity to instability of any agent is measured by assessing (1) the percentage of voltage control areas containing generators in a reactive reserve basin with non-zero reserves, and (2) the percentage of base case reactive reserves remaining on reactive reserve basin voltage control areas that have not yet exhausted reserves [Schlueter, 1998b; f].
4. It can assess the cure for instability for contingencies that do not have a solution. The cure can be either (1) adding needed reactive reserve on specific generators to obtain a solution that is voltage stable, (2) adding reactive supply resources needed in one or more agents, or (3) the reduction in generation and load in one or more agents or between one or more agents to obtain a solution and assure that it is a stable solution. These cures can be obtained in an automated fashion [Schlueter, 1998b; f]. The diagnosis can also indicate if the lack of a solution is due to convergence difficulties or round-off error if the diagnosis indicates the contingency combination does not produce sufficient network reactive losses to cause instability or any agent.
5. It can provide operating constraints or security constraints on each agent's reactive reserve basin reserves that prevent voltage instability in an agent in a manner identical to how thermal constraints prevent thermal overload on a branch and voltage constraints prevent bus voltage limit violation at a bus [Schlueter, 1998c; f].

6. The reactive reserve basin operating constraints allow optimization that assures that correcting one voltage instability problem due to instability in one or more agents will not produce other voltage stability problems in the rest of the system [Schlueter, 1998c; f].
7. The reactive reserve basin constraints after an equipment outage and operating change combination allows optimization of transmission capacity that specifically corrects that particular equipment outage and transaction change induced voltage instability with minimum control change [Schlueter, 1998c; f].
8. It requires very little computation per contingency and can find multiple contingencies that cause voltage instability by simulating only a small percentage of the possible multiple contingencies [Schlueter, 1998d].

Kinds of Loadflow Instability

Two kinds of voltage instability have been associated with a loadflow model: loss of control voltage instability and clogging voltage instability [Schlueter, 1998d]. Loss of control voltage instability is caused by exhaustion of reactive power supply that produces loss of voltage control on some of the generators or synchronous condensers. Loss of voltage control on these reactive supply devices implies both lack of any further reactive supply from these devices and loss of control of voltage that will increase network reactive losses that absorb a portion of the flow of reactive power supply and prevent it from reaching the subregion needing that reactive supply. Loss of voltage control develops because of equipment outages (generator, transmission line, and transformer), operating condition changes (wheeling, interchange, and transfer transactions), and load/generation pattern changes. Loss of control voltage instability occurs in the subtransmission and transmission system [Schlueter, 1998d]. It produces either saddle node or singularity-induced bifurcation in a differential algebraic model. On the other hand, clogging develops because of increasing reactive power losses, and switching shunt capacitors and tap changers reaching their limits. These network reactive losses, due to increasing magnetic field and shunt capacitive supply withdrawal, can completely block reactive power supply from reaching the subregion with need [Schlueter, 1998d]. Clogging voltage instability can produce algebraic bifurcation in a differential algebraic model. The VSSAD method can diagnose whether the voltage instability occurs due to clogging or loss of control voltage instability for each equipment outage, transaction combination, or both that have no solution.

Theoretical Justification of the Diagnosis in VSSAD

A bifurcation subsystem analysis has been developed that theoretically justifies the diagnosis performed by [Schlueter, 1997; 1998a; b; d; f]. This bifurcation subsystem analysis for a loadflow model attempts to break the loadflow model into a subsystem model and external model

$$f\left(x_s, x_e, p\right) = \begin{bmatrix} f_s\left(x_s, x_e, p\right) \\ f_e\left(x_s, x_e, p\right) \end{bmatrix} = \begin{bmatrix} O_{n_1} \\ O_{n_2} \end{bmatrix} \tag{63.47}$$

and to break the state x into two components $x = \begin{bmatrix} x_s \\ x_e \end{bmatrix}$ where x_s is the dimension of $f_s(x_s, x_e, p) = O_{n_i}$.

The bifurcation occurs at $p^\star = p_o + \mu_o^\star \underline{n}$ when

$$\begin{bmatrix} \frac{\partial f_s}{\partial x_s}\left(x^\star, p^\star\right) & \frac{\partial f_s}{\partial x_e}\left(x^\star, p^\star\right) \\ \frac{\partial f_e}{\partial x_s}\left(x^\star, p^\star\right) & \frac{\partial f_e}{\partial x_e}\left(x^\star, p^\star\right) \end{bmatrix} \begin{bmatrix} u_i\left(p^\star\right) \\ w_i\left(p^\star\right) \end{bmatrix} = \lambda_i\left(p^\star\right) \begin{bmatrix} u_i(\\ w_i(\end{bmatrix} \tag{63.48}$$

The vector $\begin{bmatrix} u_i(p^*) \\ w_i(p^*) \end{bmatrix}$ is the right eigenvector of eigenvalue $\lambda_i(p^*) = 0$ at bifurcation point p^*. A bifurcation subsystem exists if two conditions hold:

$$\frac{\partial f_s}{\partial x_s}(x^*, p^*) \quad u_i(p^*) = 0 \tag{63.49}$$

$$\frac{\partial f_s}{\partial x_e}\frac{\partial f_e^{-1}}{\partial x_e}\frac{\partial f_e}{\partial x_s}u_i(p^*) = 0 \tag{63.50}$$

The first condition is called the bifurcation subsystem condition and the second is called the geometric decoupling condition. Finding a bifurcation subsystem for any bifurcation of the full system model requires finding the combination of correct dimension, correct subset of equations, and correct subset of variables such that the subsystem experiences the bifurcation (Eq. (63.49)) of the full system model (Eq. (63.48)) but also produces that bifurcation since the external model is completely uncoupled from the bifurcation subsystem in the direction of the right eigenvector (Eq. (63.50)). The right eigenvector is an approximation of the center manifold at bifurcation, and the center manifold is the subsystem that actually experiences the bifurcation and is obtained via a nonlinear transformation of the model. The expectation of finding a bifurcation subsystem for any loadflow bifurcation, noting the above requirements for identifying such a bifurcation subsystem, is that the difficulty in finding a bifurcation subsystem would be great even though one may exist for some bifurcations. The results in [Schlueter, 1998b; f] prove that one cannot only describe the bifurcation subsystem (where) for every clogging voltage instability and for every loss of control voltage instability, but also can theoretically establish diagnostic information on when, proximity, and cure for a specific bifurcation in a specific bifurcation subsystem for clogging or for loss of control voltage instability [Schlueter, 1998b; f].

The analysis establishes that:

1. The real power balance equations are a bifurcation subsystem for angle instability when the loadflow model is decoupled ($\frac{dP}{dV}$ and $\frac{dQ}{d\theta}$ are assumed null) [Schlueter, 1998b; f].
2. The reactive power balance equations are a bifurcation subsystem for voltage instability when the loadflow model is assumed decoupled [Schlueter, 1998b; f].
3. A voltage control area is the bifurcation subsystem (agent) for clogging voltage instability. The agent is vulnerable to voltage instability for loss of generation in the agent, line outage in the agent boundary, or increased real and reactive flow across the agent boundary based on analysis of the lower bound approximation of the eigenvalue associated with that agent. The cure for clogging voltage instability in this agent is to reduce the real and reactive flow across the boundary of the agent [Schlueter, 1998b; f].
4. A voltage control area and its associated reactive reserve basin are the bifurcation subsystem (agent) for loss of control voltage instability. The agent is vulnerable to voltage instability for loss of generation in the agent, line outages, transfer or wheeling transactions that reduce reactive reserve basin reserves based on analysis of the lower bound approximation of the eigenvalue associated with that agent. The cure for voltage instability in the agent is to add reactive reserves on the reactive reserve basin via capacitor insertion, generator voltage setpoint changes on reactive reserve basin generators, or reverse tap position changes on underload tap changers [Schlueter, 1998b; f].
5. The percentage of reserves unexhausted in the reactive reserve basin is theoretically justified as a proximity measure for clogging instability in any clogging voltage instability agent. The percentage of voltage control areas in a reactive reserve basin with unexhausted reactive reserve is theoretically justified as a proximity measure for each loss of control voltage instability agent [Schlueter, 1998b; f].
6. Exhaustion of reactive reserves in a particular locally most vulnerable agent's reactive reserve basin causes cascading exhaustion of reactive reserves and loss of control voltage instability in agents with successively

larger reactive reserve basins. This partially explains why voltage collapse occurs [Schlueter, 1998a; d; f] which is a cascading loss of stability in several agents.

The automated diagnostic procedures in VSSAD are thus theoretically justified via this bifurcation subsystem analysis.

Future Research

Research is needed to:

1. Develop improved nonlinear dynamic load models that are valid at any particular instant and that are valid when voltage decline is severe. The lack of accurate load models makes it difficult to accurately simulate the time behavior and/or assess the cause of the voltage instability. The lack of knowledge of what constitutes an accurate load model makes accurate postmortem simulation of a particular blackout a process of making trial and error assumptions on the load model structure to obtain as accurate a simulation as possible that conforms with time records of the event. Accurate predictive simulation of events that have not occurred is very difficult [Taylor, et al. 1998].
2. Explain (a) why each specific cascading sequence of bifurcations inevitably occurs in a differential algebraic model, and (b) the dynamic signature associated with each bifurcation sequence. Work is underway to explain why instability in generator and load dynamics can inevitably cause a singularity-induced bifurcation to occur. The time signature for singularity-induced bifurcation changes dependence on why it occurs is discussed in [Schlueter, 1998e; Liu, 1998].
3. Extend bifurcation subsystem analysis to the differential algebraic model and link the bifurcation subsystem in a differential algebraic model, to those obtained in the loadflow model. The bifurcation subsystems for different Hopf and saddle node bifurcations can explain why the subsystem experiences instability, as well as how to prevent instability as has been possible for bifurcation subsystems in the algebraic model. Knowledge of bifurcation subsystems in the algebraic model may assist in identifying bifurcation subsystems in the differential algebraic model.
4. Develop a protective or corrective control for voltage instability. A protective control would use constraints on the current operating condition for contingencies predicted to cause voltage instability if they occurred. These constraints on the current operation would prevent voltage instability if and when the contingency occurred. A corrective control would develop a control that correct the instability in the bifurcation subsystems experiencing instability only after the equipment outages or operating changes predicted to produce voltage instability have occurred. The implementation of the corrective control requires a regional 5-s updated data acquisition system and control implementation similar to that used in Electricité de France and elsewhere in Europe.

Defining Terms

Power system stability: The property of a power system that enables it to remain in a state of operating equilibrium under normal operating conditions and to converge to another acceptable state of equilibrium after being subjected to a disturbance. Instability occurs when the above is not true or when the system loses synchronism between generators and between generators and loads.

Small signal stability: The ability of the power system to maintain synchronism under small disturbances [Kundur, 1994].

Transient stability: The ability of a power system to maintain synchronism for a severe transient disturbance [Kundur, 1994].

Rotor angle stability: The ability of the generators in a power system to remain in synchronism after a severe transient disturbance [Kundur, 1994].

Voltage viability: The ability of a power system to maintain acceptable voltages at all buses in the system after being subjected to a disturbance. Loss of viability can occur if voltage at some bus or buses are below acceptable levels [Kundur, 1994]. Loss of viability is not voltage instability.

Voltage stability: The ability of the combined generation and transmission system to supply load after a disturbance, increased load, or change in system conditions without an uncontrollable and progressive decrease in voltage [Kundur, 1994]. Loss of voltage instability may stem from the attempt of load dynamics to restore power consumption beyond the capability of the combined transmission and generation system. Both small signal and transient voltage instability can occur.

Voltage collapse: An instability that produces a cascading (1) loss of stability in subsystems, and/or (2) outage of equipment due to relaying actions.

Bifurcation: A sudden change in system response from a smooth, continuous, slow change in parameters p.

Further Reading

There are several good books that discuss voltage stability. Kundur [1994] is the most complete in describing the modeling required to perform voltage stability as well as some of the algebraic model-based methods for assessing proximity to voltage instability. Van Cutsem and Vournas' book [1998] provides the only dynamical systems discussion of voltage instability and provides a picture of the various dynamics that play a role in producing voltage instability. Methods for analysis and simulation of the voltage instability dynamics are presented. This analysis and simulation is motivated by a thorough discussion of the network, generator, and load dynamics models and their impacts on voltage instability. Taylor [1994] provides a tutorial review of voltage stability, the modeling needed, and simulation tools required and how they can be used to perform a planning study on a particular utility or system.

The *IEEE Transactions on Power Systems* is a reference for the most recent papers on voltage viability and voltage instability problems. The *Journal of Electric Power Systems Research* and *Journal on Electric Machines and Power Systems* also contain excellent papers on voltage instability.

64.1 Transformer Construction

The Transformer Core

The core of the power TRANSFORMER is usually made of laminated cold-rolled magnetic steel that is grain oriented such that the rolling direction is the same as that of the flux lines. This type of core construction tends to reduce the eddy current and hysteresis losses. The eddy current loss P_e is proportional to the square of the product of the maximum flux density B_M (T), the frequency f (Hz), and thickness t (m) of the individual steel lamination.

$$P_e = K_e(B_M t f)^2 \quad \text{(W)} \tag{64.1}$$

K_e is dependent upon the core dimensions, the specific resistance of a lamination sheet, and the mass of the core. Also,

$$P_h = K_h f B_M^n \quad \text{(W)} \tag{64.2}$$

In Eq. (64.2), P_h is the hysteresis power loss, n is the Steinmetz constant $(1.5 < n < 2.5)$ and K_h is a constant dependent upon the nature of core material and varies from $3 \times 10^{-3} m$ to $20 \times 10^{-3} m$, where m = core mass in kilograms.

The core loss therefore is

$$P_e = P_e + P_h \tag{64.3}$$

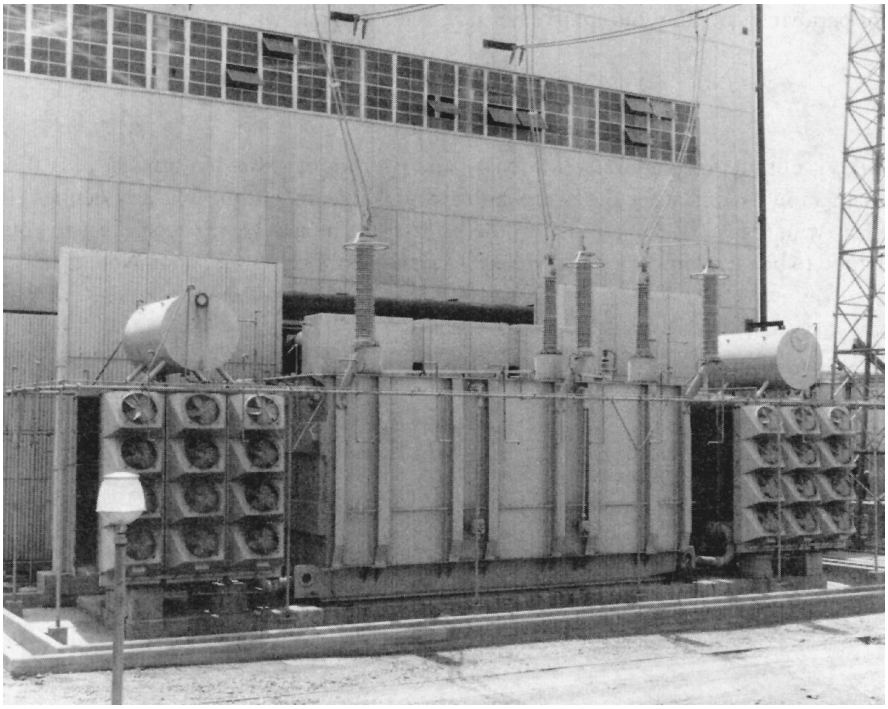

FIGURE 64.1 230kVY:17.1kVΔ 1153-MVA 3ϕ power transformer. (Photo courtesy of General Electric Company.)

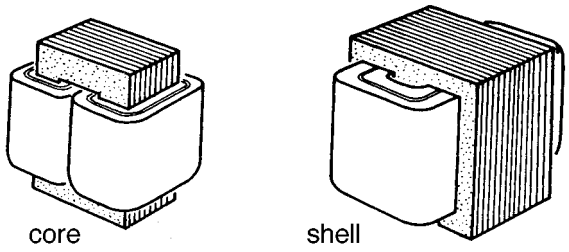
Core and Shell Types

Transformers are constructed in either a shell or a core structure. The shell-type transformer is one where the windings are completely surrounded by transformer steel in the plane of the coil. Core- type transformers are those that are not shell type. A power transformer is shown in Fig. 64.1.

Multiwinding transformers, as well as polyphase transformers, can be made in either shell- or core-type designs.



Transformer Windings

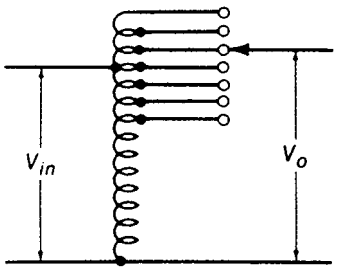
The windings of the power transformer may be either copper or aluminum. These conductors are usually made of conductors having a circular cross section; however, larger cross-sectional area conductors may require a rectangular cross section for efficient use of winding space.

The life of a transformer insulation system depends, to a large extent, upon its temperature. The total temperature is the sum of the ambient and the temperature rise. The temperature rise in a transformer is intrinsic to that transformer at a fixed load. The ambient temperature is controlled by the environment the transformer is subjected to. The better the cooling system that is provided for the transformer, the higher the "kVA" rating for the same ambient. For example, the kVA rating for a transformer can be increased with forced air (fan) cooling. Forced oil and water cooling systems are also used. Also, the duration of operating time at high temperature directly affects insulation life.

Other factors that affect transformer insulation life are vibration or mechanical stress, repetitive expansion and contraction, exposure to moisture and other contaminants, and electrical and mechanical stress due to overvoltage and short-circuit currents.

Paper insulation is laid between adjacent winding layers. The thickness of this insulation is dependent on the expected electric field stress. In large transformers oil ducts are provided using paper insulation to allow a path for cooling oil to flow between coil elements.

The short-circuit current in a transformer creates enormous forces on the turns of the windings. The short-circuit currents in a large transformer are typically 8 to 10 times larger than rated and in a small transformer are 20 to 25 times rated. The forces on the windings due to the short-circuit current vary as the square of the current, so whereas the forces at rated current may be only a few newtons, under short-circuit conditions these forces can be tens of thousands of newtons. These mechanical and thermal stresses on the windings must be taken into consideration during the design of the transformer. The current-carrying components must be clamped firmly to limit movement. The solid insulation material should be precompressed and formed to avoid its collapse due to the thermal expansion of the windings.



Taps

Power transformer windings typically have taps, as shown. The effect on transformer models is to change the turns ratio.

64.2 Power Transformer Modeling

The electric power **transformer** is a major power system component which provides the capability of reliably and efficiently changing (transforming) ac voltage and current at high power levels. Because electrical power is proportional to the product of voltage and current, for a specified power level, low current levels can exist only at high voltage, and vice versa.

The Three-Winding Ideal Transformer Equivalent Circuit

Consider the three coils wrapped on a common core as shown in Fig. 64.2(a). For an infinite core permeability (μ) and windings made of material of infinite conductivity (σ):

$$v_1 = N_1 \frac{d\phi}{dt} \quad v_2 = N_2 \frac{d\phi}{dt} \quad v_3 = N_3 \frac{d\phi}{dt} \tag{64.4}$$

where ϕ is the core flux. This produces:

$$\frac{v_1}{v_2} = \frac{N_1}{N_2} \quad \frac{v_2}{v_3} = \frac{N_2}{N_3} \quad \frac{v_3}{v_1} = \frac{N_3}{N_1} \tag{64.5}$$

For sinusoidal steady state performance:

$$\overline{V}_1 = \frac{N_1}{N_2}\overline{V}_2 \quad \overline{V}_2 = \frac{N_2}{N_3}\overline{V}_3 \quad \overline{V}_3 = \frac{N_3}{N_1}\overline{V}_1 \tag{64.6}$$

where $\overline{V}$, etc. are complex phasors.

The circuit symbol is shown in Fig. 64.2(b). Ampere's law requires that

$$\oint \hat{H} \cdot \hat{dl} = i_{\text{enclosed}} = 0 \tag{64.7}$$

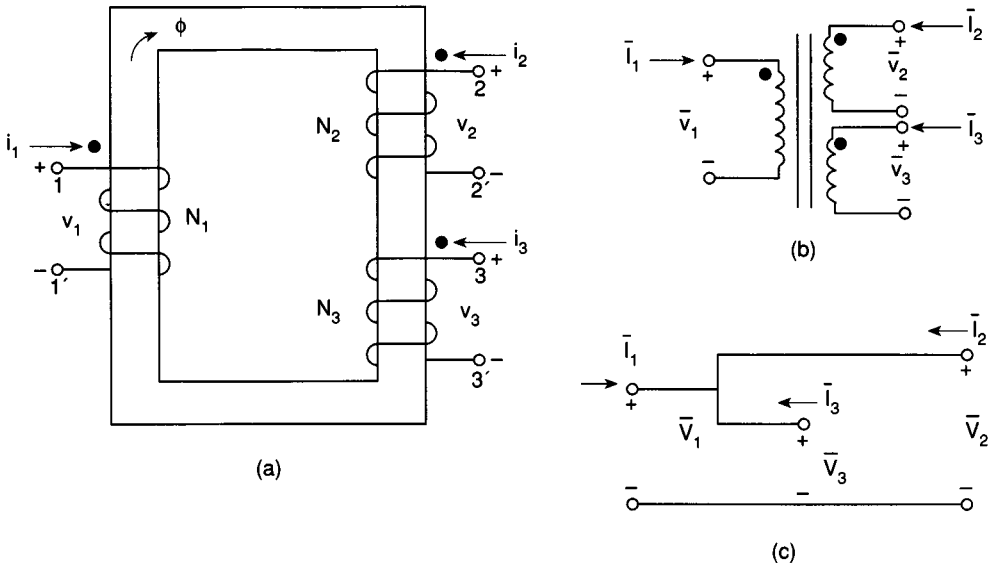


FIGURE 64.2 Ideal three-winding transformer. (a) Ideal three-winding transformer; (b) schematic symbol; (c) per-unit equivalent circuit.

$$0 = N_1 i_1 + N_2 i_2 + N_3 i_3 \tag{64.8}$$

Transform Eq. (64.8) into phasor notation:

$$N_1 \bar{I}_1 + N_2 \bar{I}_2 + N_3 \bar{I}_3 = 0 \tag{64.9}$$

Equations (64.6) and (64.9) are basic to understanding transformer operation. Consider Eq. (64.6). Also note that $-V_1$, $-V_2$, and $-V_3$ must be in phase, with dotted terminals defined positive. Now consider the total input complex power $-S$.

$$\bar{S} = \bar{V}_1 \bar{I}_1^{\star} + \bar{V}_2 \bar{I}_2^{\star} + \bar{V}_3 \bar{I}_3^{\star} = 0 \tag{64.10}$$

Hence, ideal transformers can absorb neither real nor reactive power.

It is customary to scale system quantities (*V, I, S, Z*) into dimensionless quantities called per-unit values. The basic per-unit scaling equation is

$$\text{Per-unit value} = \frac{\text{actual value}}{\text{base value}}$$

The base value always carries the same units as the actual value, forcing the per-unit value to be dimensionless. Base values normally selected arbitrarily are V_{base} and S_{base}. It follows that:

$$I_{\text{base}} = \frac{S_{\text{base}}}{V_{\text{base}}}$$

$$Z_{\text{base}} = \frac{V_{\text{base}}}{I_{\text{base}}} = \frac{V_{\text{base}}^2}{S_{\text{base}}}$$

When per-unit scaling is applied to transformers V_{base} is usually taken as V_{rated} as in each winding. S_{base} is common to all windings; for the two- winding case S_{base} is S_{rated}, since S_{rated} is common to both windings.

Per-unit scaling simplifies transformer circuit models. Select two primary base values, V_{1base} and S_{1base}. Base values for windings 2 and 3 are:

$$V_{2_{base}} = \frac{N_2}{N_1} V_{1_{base}} \qquad V_{3_{base}} = \frac{N_3}{N_1} V_{1_{base}} \tag{64.11}$$

and

$$S_{1_{base}} = S_{2_{base}} = S_{3_{base}} = S_{base} \tag{64.12}$$

By definition:

$$I_{1_{base}} = \frac{S_{base}}{V_{1_{base}}} \qquad I_{2_{base}} = \frac{S_{base}}{V_{2_{base}}} \qquad I_{3_{base}} = \frac{S_{base}}{V_{3_{base}}} \tag{64.13}$$

It follows that

$$I_{2_{base}} = \frac{N_1}{N_2} I_{1_{base}} \qquad I_{3_{base}} = \frac{N_1}{N_3} I_{1_{base}} \tag{64.14}$$

Thus, Eqs. (64.3) and (64.6) scaled into per-unit become:

$$\overline{V}_{1_{pu}} = \overline{V}_{2_{pu}} = \overline{V}_{3_{pu}} \tag{64.15}$$

$$\bar{I}_{1_{pu}} + \bar{I}_{2_{pu}} + \bar{I}_{3_{pu}} = 0 \tag{64.16}$$

The basic per-unit equivalent circuit is shown in Fig. 64.2(c). The extension to the *n*-winding case is clear.

A Practical Three-Winding Transformer Equivalent Circuit

The circuit of Fig. 64.2(c) is reasonable for some power system applications, since the core and windings of actual transformers are constructed of materials of high μ and σ, respectively, though of course not infinite. However, for other studies, discrepancies between the performance of actual and ideal transformers are too great to be overlooked. The circuit of Fig. 64.2(c) may be modified into that of Fig. 64.3 to account for the most important discrepancies. Note:

R_1,R_2,R_3 Since the winding conductors cannot be made of material of infinite conductivity, the windings must have some resistance.

X_1,X_2,X_3 Since the core permeability is not infinite, not all of the flux created by a given winding current will be confined to the core. The part that escapes the core and seeks out parallel paths in surrounding structures and air is referred to as *leakage* flux.

R_c,X_m Also, since the core permeability is not infinite, the magnetic field intensity inside the core is not zero. Therefore, some current flow is necessary to provide this small H. The path provided in the circuit for this "magnetizing" current is through X_m. The core has internal power losses, referred to as *core loss*, due to hystereses and eddy current phenomena. The effect is accounted for in the resistance R_c. Sometimes R_c and X_m are neglected.

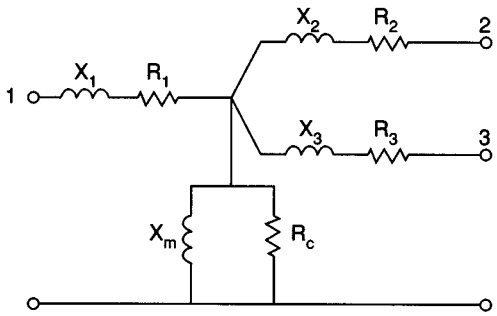

FIGURE 64.3 A practical equivalent circuit.

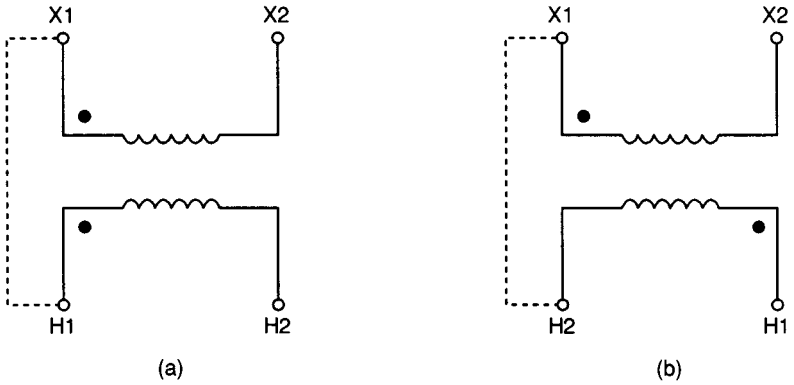

FIGURE 64.4 Transformer polarity terminology: (a) subtractive; (b) additive.

The circuit of Fig. 64.3 is a refinement on that of Fig. 64.2(c). The values R_1, R_2, R_3, X_1, X_2, X_3 are all small (less than 0.05 per-unit) and R_c, X_m, large (greater than 10 per-unit). The circuit of Fig. 64.3 requires that all values be in per-unit. Circuit data are available from the manufacturer or obtained from conventional tests. It must be noted that although the circuit of Fig. 64.3 is commonly used, it is not rigorously correct because it does not properly account for the mutual couplings between windings.

The terms **primary** and **secondary** refer to source and load sides, respectively (i.e., energy flows from primary to secondary). However, in many applications energy can flow either way, in which case the distinction is meaningless. Also, the presence of a third winding (tertiary) confuses the issue. The terms *step up* and *step down* refer to what the transformer does to the voltage from source to load. ANSI standards require that for a two-winding transformer the high-voltage and low-voltage terminals be marked as H1-H2 and X1-X2, respectively, with H1 and X1 markings having the same significance as *dots* for **polarity** markings. [Refer to ANSI C57 for comprehensive information.] *Additive* and *subtractive transformer polarity* refer to the physical positioning of high-voltage, low-voltage *dotted* terminals as shown in Fig. 64.4. If the dotted terminals are adjacent, then the transformer is said to be *subtractive*, because if these adjacent terminals (H1-X1) are connected together, the voltage between H2 and X2 is the *difference* between primary and secondary. Similarly, if adjacent terminals X1 and H2 are connected, the voltage (H1-X2) is the *sum* of primary and secondary values.

The Two-Winding Transformer

The device can be simplified to two windings. Common two-winding transformer circuit models are shown in Fig. 64.5.

$$\overline{Z}_e = \overline{Z}_1 + \overline{Z}_2 \tag{64.17}$$

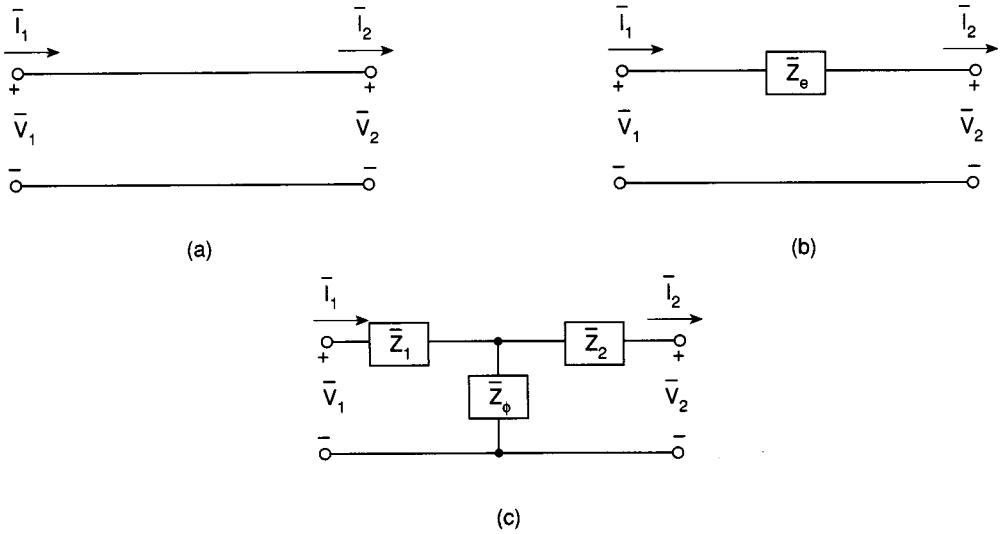

FIGURE 64.5 Two-winding transformer-equivalent circuits. All values in per-unit. (a) Ideal case; (b) no load current negligible; (c) precise model.

$$\bar{Z}_m = \frac{R_c(jX_m)}{R_c + jX_m} \tag{64.18}$$

Circuits (a) and (b) are appropriate when $-Z_m$ is large enough that magnetizing current and core loss is negligible.

64.3 Transformer Performance

There is a need to assess the quality of a particular transformer design. The most important measure for performance is the concept of efficiency, defined as follows:

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} \tag{64.19}$$

where P_{out} is output power in watts (kW, MW) and P_{in} is input power in watts (kW, MW).

The situation is clearest for the two-winding case where the output is clearly defined (i.e., the secondary winding), as is the input (i.e., the primary). Unless otherwise specified, the output is understood to be rated power at rated voltage at a user-specified power factor. Note that

$$\Sigma L = P_{\text{in}} - P_{\text{out}} = \text{sum of losses}$$

The transformer is frequently modeled with the circuit shown in Fig. 64.6. Transformer losses are made up of the following components:

Electrical losses:

$$I'^2_1 R_{\text{eq}} = I_1^2 R_1 + I_2^2 R_2 \tag{64.20a}$$

$$\text{Primary winding loss} = I_1^2 R_1 \tag{64.20b}$$

$$\text{Secondary winding loss} = I_2^2 R_2 \tag{64.20c}$$

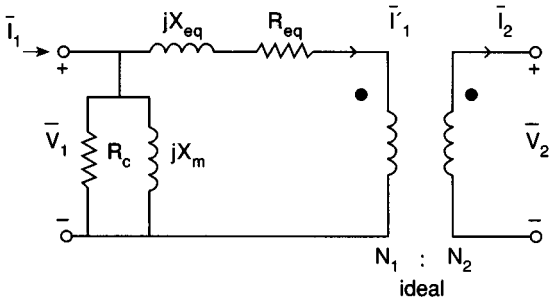

FIGURE 64.6 Transformer circuit model.

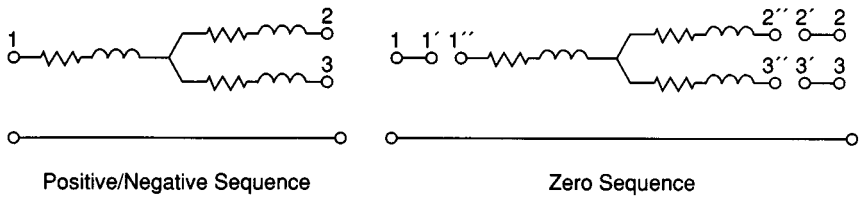

FIGURE 64.7 Sequence equivalent transformer circuits.

Magnetic (core) loss:

$$P_c = P_e + P_h = V_1^2/R_c \tag{64.21}$$

Core eddy current loss = P_e

Core hysterisis loss = P_h

Hence:

$$\Sigma L = I'^2_1 R_{eq} + V_1^2/R_c \tag{64.22}$$

A second concern is fluctuation of secondary voltage with load. A measure of this situation is called *voltage regulation*, which is defined as follows:

$$\text{Voltage Regulation (VR)} = \frac{V_{2NL} - V_{2FL}}{V_{2FL}} \tag{64.23}$$

where V_{2FL} = rated secondary voltage, with the transformer supplying rated load at a user-specified power factor, and V_{2NL} = secondary voltage with the load removed (set to zero), holding the primary voltage at the full load value.

A complete performance analysis of a 100 kVA 2400/240 V single-phase transformer is shown in Table 64.1.

64.4 Transformers in Three-Phase Connections

Transformers are frequently used in three-phase connections. For three identical three-winding transformers, nine windings must be accounted for. The three sets of windings may be individually connected in wye or delta in any combination. The symmetrical component transformation can be used to produce the sequence equivalent circuits shown in Fig. 64.7 which are essentially the circuits of Fig. 64.3 with R_c and X_m neglected.

The positive and negative sequence circuits are valid for both wye and delta connections. However, Y–Δ connections will produce a phase shift which is not accounted for in these circuits.

Reactive power	64.6 kvar	0.6456
Power factor	0.8091 lag	0.8091

Efficiency = 97.43%; voltage regulation = 5.77%.

The zero sequence circuit requires special modification to account for wye, delta connections. Consider winding 1:

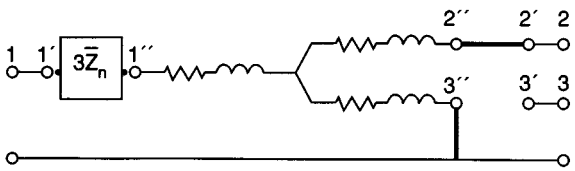
1. Solid grounded wye — short 1′ to 1″.
2. Ground wye through $-Z_n$ — connect 1′ to 1″ through $3-Z_n$.
3. Ungrounded wye — leave 1′ to 1″ open.
4. Delta — short 1″ to reference.

Winding sets 2 and 3 interconnections produce similar connection constraints at terminals 2′–2″ and 3′–3″, respectively.

Example. Three identical transformers are to be used in a three-phase system. They are connected at their terminals as follows:

Winding set 1 wye, grounded through $-Z_n$
Winding set 2 wye, solid ground
Winding set 3 delta

The zero sequence network is as shown.



Phase Shift in Y–Δ Connections

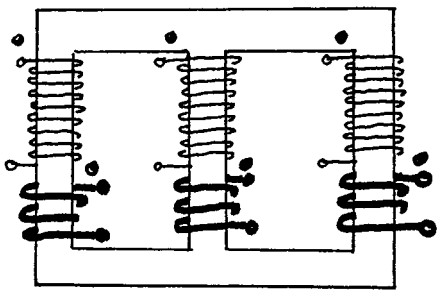
The positive and negative sequence networks presented in Fig. 64.7 are misleading in one important detail. For Y–Y or Δ–Δ connections, it is always possible to label the phases in such a way that there is no phase shift between corresponding primary and secondary quantities. However, for Y–Δ or Δ–Y connections, it is impossible to label the phases in such a way that no phase shift between corresponding quantities is introduced. ANSI standard C57.12.10.17.3.2 is as follows:

> *For either wye-delta or delta-wye connections, phases shall be labeled in such a way that positive sequence quantities on the high voltage side lead their corresponding positive sequence quantities on the low voltage side by 30°. The effect on negative sequence quantities may be the reverse, i.e., HV values* lag *LV values by 30°.*

This 30° phase shift is *not* accounted for in the sequence networks of Fig. 64.7. The effect only appears in the positive and negative sequence networks; the zero sequence network quantities are unaffected.

The Three-Phase Transformer

It is possible to construct a device (called a three-phase transformer) which allows the phase fluxes to share common magnetic return paths. Such designs allow considerable savings in core material, and corresponding economies in cost, size, and weight. Positive and negative sequence impedances are equal; however, the zero sequence impedance may be different. Otherwise the circuits of Fig. 64.7 apply as discussed previously.



Determining Per-Phase Equivalent Circuit Values for Power Transformers

One method of obtaining such data is through testing. Consider the problem of obtaining transformer equivalent circuit data from short-circuit tests. A numerical example will clarify per-unit scaling considerations.

FIGURE 64.8 Transformer circuit data from short-circuit tests. (a) Setup for transformer short-circuit tests; (b) transformer data; (c) short-circuit test data; (d) short-circuit impedance values in per-unit.

The short-circuit test circuit arrangement is shown in Fig. 64.8. The objective is to derive equivalent circuit data from the test data provided in Fig. 64.8. Note that measurements are made in winding "*i*", with winding "*j*" shorted, and winding "*k*" left open. The short circuit impedance, looking into winding "*i*" with the transformer so terminated is designated as Z_{ij}. The indices *i*, *j*, and *k*, can be 1, 2, or 3.

The impedance calculations are done in per-unit; base values are provided in Fig. 64.8(c). The transformer ratings of the transformer of Fig. 64.2(a) would conventionally be provided as follows:

3ϕ 3W Transformer
15kVY/115kVY/4.157kVΔ
100/100/20 MVA

where 3ϕ means that the transformer is a three-phase piece of equipment (as opposed to an interconnection of three single-phase devices). 3W means three three-phase windings (actually nine windings). Usually the schematic is supplied also. The 15 kV rating is the *line* (phase-to-phase) value; three-phase apparatus is always rated in *line* values. "Y" means winding No. 1 is internally wye connected. 115kVY means that 115 kV is the line voltage rating, and winding No. 2 is wye connected. In 4.157kVΔ, again, "4.157kV" is the line voltage rating, and winding No. 3 is delta connected. 100/100/20 MVA are the *total* (3ϕ) power ratings for the primary, secondary, and tertiary winding, respectively; three-phase apparatus is always rated in three-phase terms.

The per-unit bases for $S_{3\phi base}$ = 100 MVA are presented in Fig. 64.8(b). Calculating the short-circuit impedances from the test data in Fig. 64.8(c):

$$Z_{ij} = \frac{V_{i_{line}}/\sqrt{3}}{I_{i_{line}}}$$

$$R_{ij} = \frac{R_{3\phi}/3}{I^2_{1_{line}}}$$

$$X_{ij} = \sqrt{Z^2_{ij} - R^2_{ij}}$$

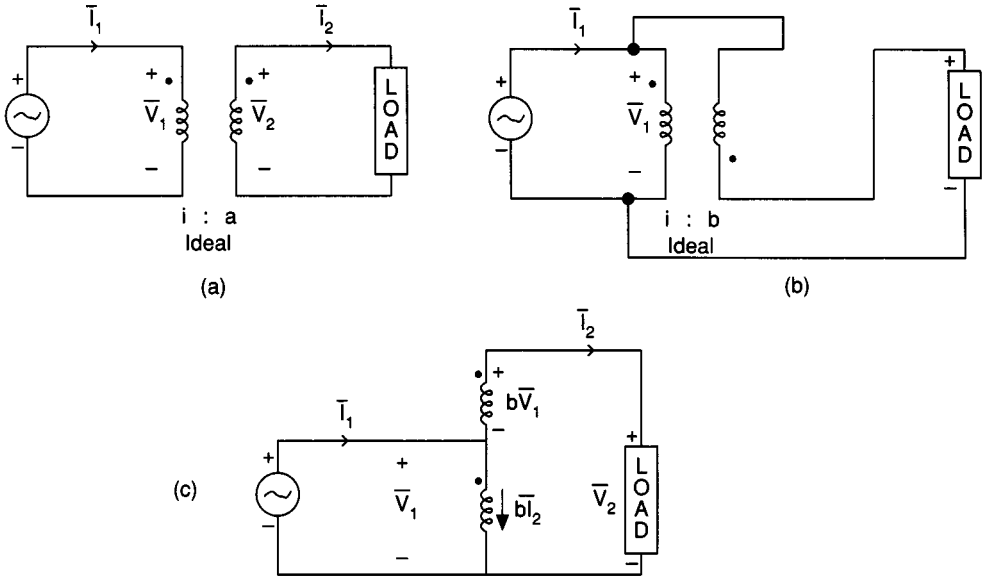

FIGURE 64.9 Autotransformer connection. (a) Conventional step-up connection; (b) autotransformer connection; (c) part (b) redrawn.

Now calculate the transformer impedances from the short-circuit impedances:

$$\bar{Z}_1 = \frac{1}{2}\left(\bar{Z}_{12} - \bar{Z}_{23} + \bar{Z}_{31}\right)$$

$$\bar{Z}_2 = \frac{1}{2}\left(\bar{Z}_{23} - \bar{Z}_{13} + \bar{Z}_{12}\right)$$

$$\bar{Z}_3 = \frac{1}{2}\left(\bar{Z}_{31} - \bar{Z}_{12} + \bar{Z}_{23}\right)$$

Results are shown in Fig. 64.8(d). Observe that the Y–Δ winding connections had no impact on the calculations.

Another detail deserves mention. Although the real and reactive parts of the short-circuit impedances ($-Z_{12}$, $-Z_{23}$, $--Z_{31}$) will always be positive, this is not true for the transformer impedances ($—Z_1$, $--Z_2$, $--Z_3$). One or more of these can be, and frequently is, negative for actual short-circuit data. Negative values underscore that the circuit of Fig. 64.7 is a *port equivalent* circuit, producing correct values at the winding terminals.

64.5 Autotransformers

Transformer windings, though magnetically coupled, are electrically isolated from each other. It is possible to enhance certain performance characteristics for transformers by electrically interconnecting primary and secondary windings. Such devices are called **autotransformers**. The benefits to be realized are lower cost, smaller size and weight, higher efficiency, and better voltage regulation. The basic connection is illustrated in Fig. 64.9. The issues will be demonstrated with an example.

Consider the conventional connection, shown in Fig. 64.9(a).

$$\bar{V}_2 = a\bar{V}_1$$

$$\bar{I}_2 = \frac{1}{a}\bar{I}_1$$

$$S_{\text{rating}} = V_1 I_1 = V_2 I_2 = S_{\text{load}}$$

Now for the autotransformer:

$$\overline{V}_2 = \overline{V}_1 + b\overline{V}_1 = (1 + b)\overline{V}_1$$
$$\bar{I}_1 = \bar{I}_2 + b\bar{I}_2 = (1 + b)\bar{I}_2$$

For the same effective ratio

$$1 + b = a$$

Therefore each winding rating is:

$$S_{\text{rated}} = S_{\text{load}}\left(\frac{b}{1+b}\right)$$

For example if $b = 1$ ($a = 2$)

$$S_{\text{rating}} = 1/2\ S_{\text{load}}$$

meaning that the transformer rating is only 50% of the load.

The principal advantage of the autotransformer is the increased power rating. Also, since the losses remain the same, expressed as a percentage of the new rating, they go down, and correspondingly, the efficiency goes up. The machine impedances in per unit drop for similar reasons. A disadvantage is the loss of electrical isolation between primary and secondary. Also, low impedance is not necessarily good, as we shall see when we study faults on power systems. Autotransformers are used in three-phase connections and in voltage control applications.

Defining Terms

Autotransformer: A transformer whose primary and secondary windings are electrically interconnected.
Polarity: Consideration of in-phase or out-of-phase relations of primary and secondary ac currents and voltages.
Primary: The source-side winding.
Secondary: The load-side winding.
Tap: An electrical terminal that permits access to a winding at a particular physical location.
Transformer: A device which converts ac voltage and current to different levels at essentially constant power and frequency.

65.1 Introduction

Distribution is the last section of the electrical power system. Figure 65.1 shows the major components of the electric power system. The power plants convert the energy stored in the fuel (coal, oil, gas, nuclear) or hydro into electric energy. The energy is supplied through step-up transformers to the electric network. To reduce energy transportation losses, step-up transformers increase the voltage and reduce the current. The high-voltage network, consisting of transmission lines, connects the power plants and high-voltage **substations** in parallel. The typical voltage of the high-voltage transmission network is between 240 and 765 kV. The high-voltage substations are located near the load centers, for example, outside a large town. This network permits load sharing among power plants and assures a high level of reliability. The failure of a line or power plant will not interrupt the energy supply.

The subtransmission system connects the high-voltage substations to the distribution substations. These stations are directly in the load centers. For example, in urban areas, the distance between the distribution stations is around 5 to 10 miles. The typical voltage of the subtransmission system is between 138 and 69 kV. In high load density areas, the subtransmission system uses a network configuration that is similar to the high-voltage network. In medium and low load density areas, the loop or radial connection is used. Figure 65.1 shows a typical radial connection.

The distribution system has two parts, primary and secondary. The primary distribution system consists of overhead lines or underground cables, which are called **feeders**. The feeders run along the streets and supply the distribution transformers that step the voltage down to the secondary level (120–480 V). The secondary distribution system contains overhead lines or underground cables supplying the consumers directly (houses, light industry, shops, etc.) by single- or three-phase power. Separate, dedicated primary feeders supply industrial customers requiring several megawatts of power. The subtransmission system directly supplies large factories consuming over 50 MW.

65.2 Primary Distribution System

The most frequently used voltages and wiring in the primary distribution system are listed in Table 65.1.

Primary distribution, in low load density areas, is a radial system. This is economical but yields low reliability. In large cities, where the load density is very high, a primary cable network is used. The distribution substations

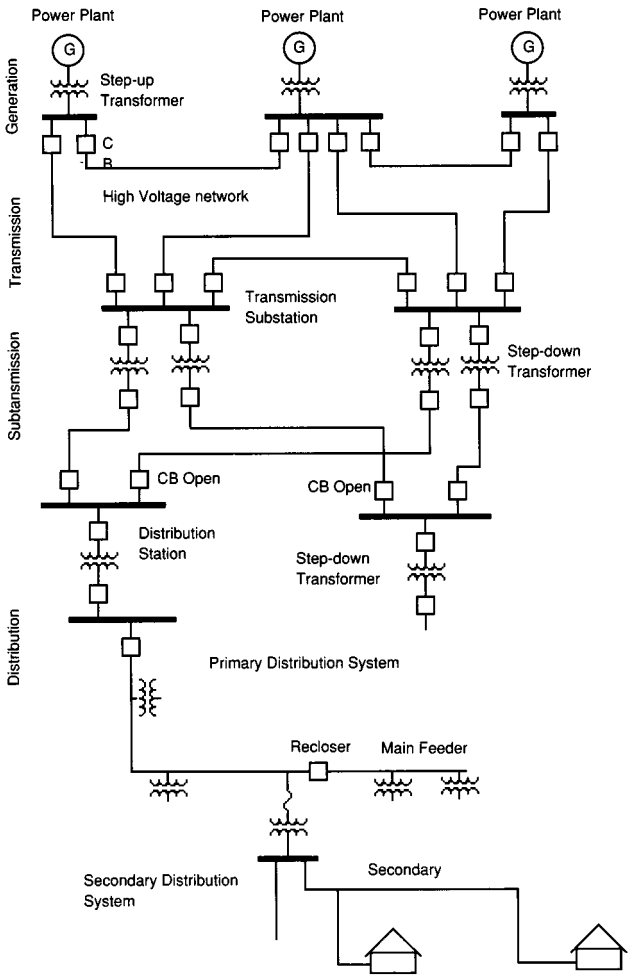

FIGURE 65.1 Electric energy system.

TABLE 65.1 Typical Primary Feeder Voltages (line-to-line)

Class, kV	Voltage, kV	Wiring
2.5	2.4	3-wire delta
5	4.16	4-wire Y
8.66	7.2	4-wire Y
15	12.47	3-wire delta/4-wire Y
25	22.9	4-wire Y
35	34.5	4-wire Y

are interconnected by the feeders (lines or cables). Circuit breakers (CBs) are installed at both ends of the feeder for short-circuit protection. The loads are connected directly to the feeders through fuses. The connection is similar to the one-line diagram of the high-voltage network shown in Fig. 65.1. The high cost of the network limits its application. A more economical and fairly reliable arrangement is the loop connection, when the main feeder is supplied from two independent distribution substations. These stations share the load. The problem with this connection is the circulating current that occurs when the two supply station voltages are different. The loop arrangement significantly improves system reliability.

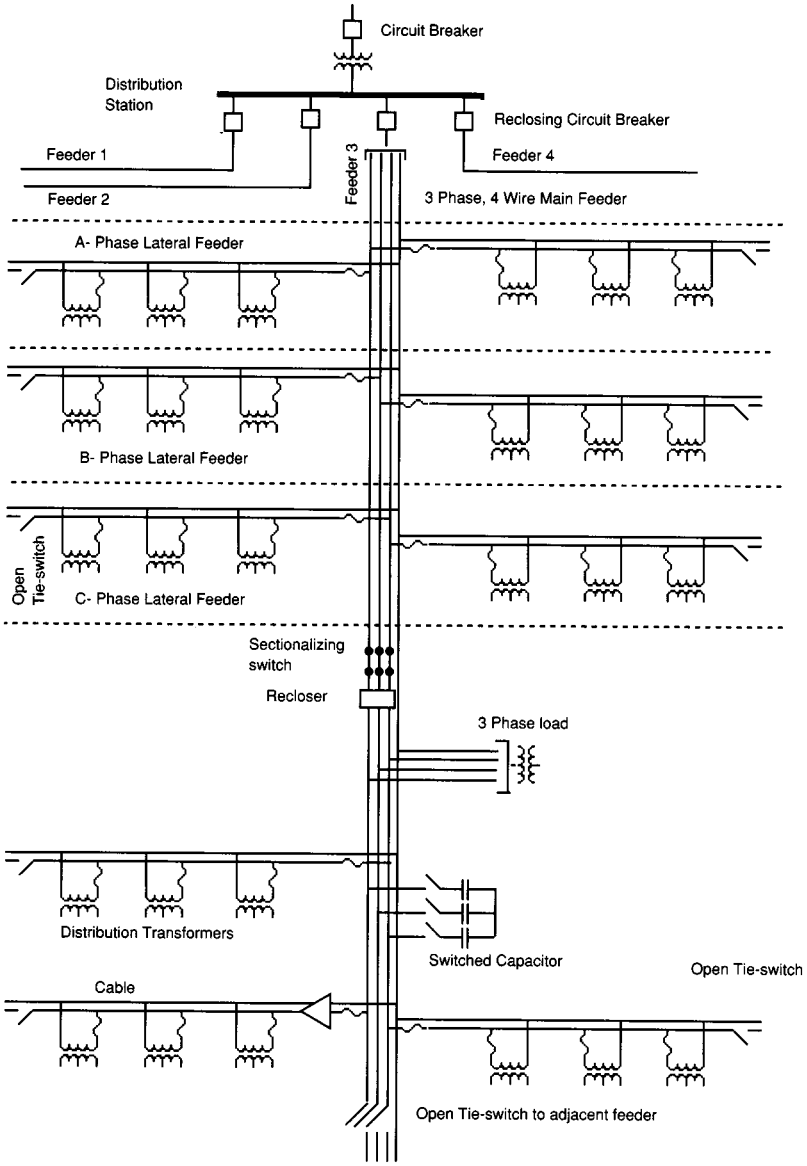

FIGURE 65.2 Radial primary distribution system.

The circulating current can be avoided by using the open-loop connection. This is a popular, frequently used circuit. Figure 65.2 shows a typical open-loop primary feeder. The distribution substation has four outgoing main feeders. Each feeder supplies a different load area and is protected by a reclosing CB.

The three-phase four-wire main feeders supply single-phase lateral feeders. A **recloser** and a sectionalizing switch divide the main feeder into two parts. The normally open tie-switch connects the feeder to the adjacent distribution substation. The fault between the CB and recloser opens the reclosing CB. The CB recloses after a few cycles. If the fault is not cleared, the opening and reclosing process is repeated two times. If the fault has not been cleared before the third reclosing, the CB remains open. Then the sectionalizing switch opens and the tie-switch closes. This energizes the feeder between the recloser and the tie-switch from the neighboring feeder. Similarly, the fault between the recloser and tie-switch activates the recloser. The recloser opens and recloses three times. If the fault is not cleared, the recloser remains open and separates the faulty part of the

feeder. This method is particularly effective in overhead lines where temporary faults are often caused by lightning, wind, and metal balloons.

A three-phase switched **capacitor bank** is rated two-thirds of the total average reactive load and installed two-thirds of the distance out on the feeder from the source. The capacitor bank improves the power factor and reduces voltage drop at heavy loads. However, at light loads, the capacitor is switched off to avoid overvoltages.

Some utilities use voltage regulators at the primary feeders. The voltage regulator is an autotransformer. The secondary coil of the transformer has 32 taps, and a switch connects the selected tap to the line to regulate the voltage. The problem with the **tap changer** is that the lifetime of the switch is limited. This permits only a few operations per day.

The lateral single-phase feeders are supplied from different phases to assure equal phase loading. Fuse cutouts protect the lateral feeders. These fuses are coordinated with the fuses protecting the distribution transformers. The fault in the distribution transformer melts the transformer fuse first. The lateral feeder fault operates the cutout fuse before the recloser or CB opens permanently.

A three-phase line supplies the larger loads. These loads are protected by CBs or high-power fuses.

Most primary feeders in rural areas are overhead lines using pole-mounted distribution transformers. The capacitor banks and the reclosing and sectionalizing switches are also pole-mounted. Overhead lines reduce the installation costs but reduce aesthetics.

In urban areas, an underground cable system is used. The switchgear and transformers are placed in underground vaults or ground-level cabinets. The underground system is not affected by weather and is highly reliable. Unfortunately, the initial cost of an underground cable is significantly higher than an overhead line with the same capacity. The high cost limits the underground system to high-density urban areas and housing developments. Flooding can be a problem.

65.3 Secondary Distribution System

The secondary distribution system provides electric energy to the customers through the distribution transformers and secondary cables. Table 65.2 shows the typical voltages and wiring arrangements.

In residential areas, the most commonly used is the single-phase three-wire 120/240-V radial system, where the lighting loads are supplied by the 120 V and the larger household appliances (air conditioner, range, oven, and heating) are connected to the 240-V lines. Depending on the location, either underground cables or overhead lines are used for this system.

In urban areas, with high-density mixed commercial and residential loads, the three-phase 208/120-V four-wire network system is used. This network assures higher reliability but has significantly higher costs. Underground cables are used by most secondary networks.

High-rise buildings are supplied by a three-phase four-wire 480/277-V spot network. The fluorescent lighting is connected to a 277-V and the motor loads are supplied by a 480-V source. A separate local 120-V system supplies the outlets in the various rooms. This 120-V radial system is supplied by small transformers from the 480-V network.

TABLE 65.2 Secondary Voltages and Connections

Class	Voltage	Connection	Application
1-phase	120/240	Three-wire	Residential
3-phase	208/120	Four-wire	Commercial/residential
3-phase	480/277	Four-wire	High-rise buildings
3-phase	380/220	Four-wire	General system, Europe
3-phase	120/240	Four-wire	Commercial
3-phase	240	Three-wire	Commercial/industrial
3-phase	480	Three-wire	Industrial
3-phase	240/480	Four-wire	Industrial

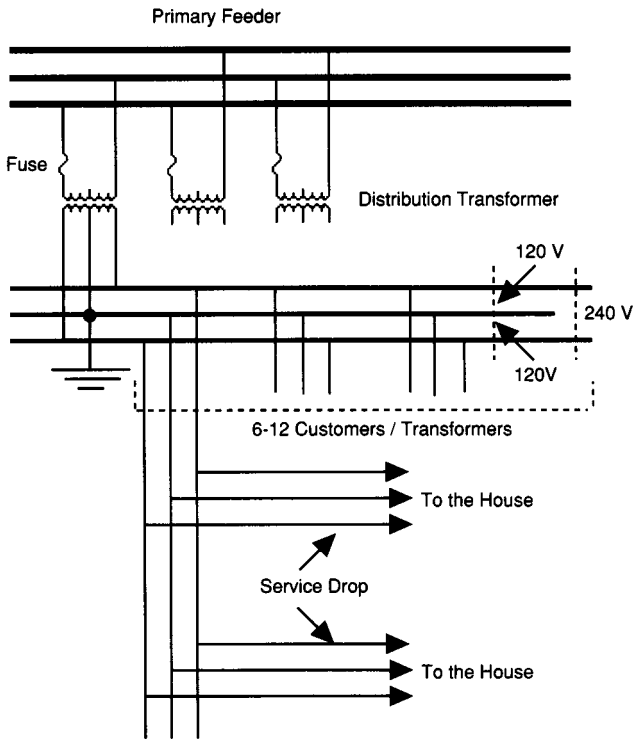

FIGURE 65.3 Typical 120/240-V radial secondary system.

65.4 Radial Distribution System

A typical overhead single-phase three-wire 120/240-V secondary system is shown in Fig. 65.3. The three distribution transformers are mounted on separate primary feeder poles and supplied from different phases. Each transformer supplies 6 to 12 houses. The transformers are protected by fuses. The secondary feeders and the service drops are not protected individually. The secondary feeder uses insulated No. 1/0 or 4/0 aluminum conductors. The average secondary length is from 200 to 600 ft. The typical load is from 15 to 30 W/ft.

The underground distribution system is used in modern suburban areas. The transformers are pad-mounted or placed in an underground vault. A typical 50-kVA transformer serves 5 to 6 houses, with each house supplied by an individual cable.

The connection of a typical house is shown in Fig. 65.4. The incoming secondary service drop supplies the kW and kWh meter. The modern, mostly electronic meters measure 15-min kW demand and the kWh energy consumption. It records the maximum power demand and energy consumption. The electrical utility maintains the distribution system up to the secondary terminals of the meter. The homeowner is responsible for the service panel and house wiring. The typical service panel is equipped with a main switch and circuit breaker. The main switch permits the deenergization of the house and protects against short circuits. The smaller loads are supplied by 120 V and the larger loads by 240 V. Each outgoing line is protected by a circuit breaker. The neutral has to be grounded at the service panel, just past the meter. The water pipe was used for grounding in older houses. In new houses a metal rod, driven in the earth, provides proper grounding. In addition, a separate bare wire is connected to the ground. The ground wire connects the metal parts of the appliances and service panel box together to protect against ground-fault-produced electric shocks.

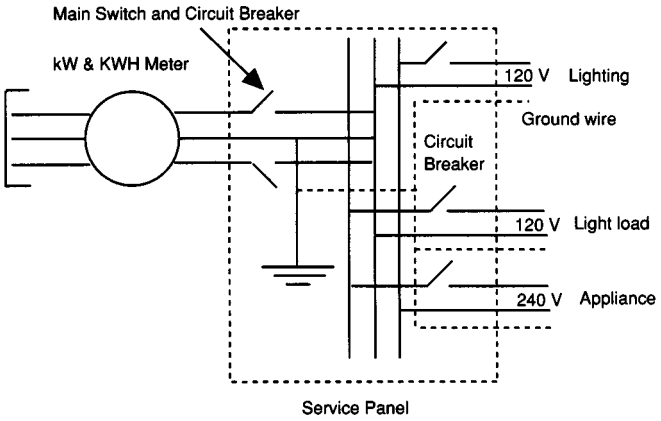

FIGURE 65.4 Residential electrical connection.

65.5 Secondary Networks

The secondary network is used in urban areas with high load density. Figure 65.5 shows a segment of a typical secondary network.

The secondary feeders form a mesh or grid that is supplied by transformers at the node points. The multiple supply assures higher reliability and better load sharing. The loads are connected directly to the low-voltage grid, without any protection equipment. The network is protected by fuses and network protector circuit breakers installed at the secondary transformers. A short circuit blows the fuses and limits the current. The network protectors automatically open on reverse current and reclose when the voltage on the primary feeder is restored after a fault.

65.6 Load Characteristics

The distribution system load varies during the day. The maximum load occurs in the early evening or late afternoon, and the minimum load occurs at night. The design of the distribution system requires both values, because the voltage drop is at the maximum during the peak load, and overvoltage may occur during the minimum load. The power companies continuously study the statistical variation of the load and can predict the expected loads on the primary feeders with high accuracy. The feeder design considers the expected peak load or maximum demand and the future load growth.

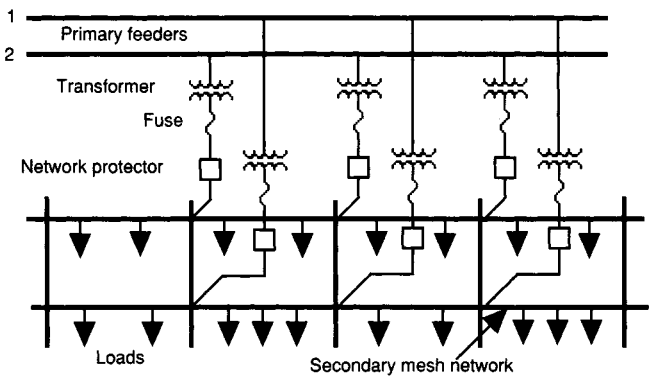

FIGURE 65.5 Typical segment of a secondary distribution network.

The economic conductor cross-section calculation requires the determination of average losses. The average loss is calculated by the loss factor (LSF), which is determined by statistical analyses of load variation.

$$\text{LSF} = \frac{\text{average loss}}{\text{loss at peak load}}$$

The average load is determined by the load factor (LF), which is the ratio of average load to peak load. The load factor for an area is determined by statistical analyses of the load variation in past years. The approximate relation between the loss factor and load factor is

$$\text{LSF} = 0.3\text{LF} + 0.7\text{LF}^2$$

This equation is useful because the load factor is measured continuously by utilities, and more accurate values are available for the load factor than for the loss factor. Typical values are given in Table 65.3.

TABLE 65.3 Typical Annual Load Factor Values

Type of Load	Load Factor
Residential	0.48
Commercial	0.66
Industrial	0.72

TABLE 65.4 Typical Demand Factors for Multifamily Dwellings

Number of Dwellings	Demand Factor, %
3 to 5	45
18 to 20	38
39 to 42	28
62 & over	23

The connected load or demand can be estimated accurately in residential and industrial areas. The connected load or demand is the sum of continuous ratings of apparatus connected to the system. However, not all equipment is used simultaneously. The actual load in a system is significantly lower than the connected load. The demand factor is used to estimate the actual or maximum demand. The demand factor (DF) is defined by

$$\text{DF} = \frac{\text{maximum demand}}{\text{total connected demand}}$$

The demand factor depends on the number of customers and the type of load. Typical demand factor values are given in Table 65.4.

65.7 Voltage Regulation

The voltage supplied to each customer should be within the ±5% limit, which, at 120 V, corresponds to 114 and 126-V. Figure 65.6 shows a typical voltage profile for a feeder at light and heavy load conditions. The figure shows that at heavy load, the voltage at the end of the line will be less than the allowable minimum voltage. However, at the light load condition the voltage supplied to each customer will be within the allowable limit. Calculation of the voltage profile, voltage drop, and feeder loss is one of the major tasks in distribution system design. The concept of voltage drop and loss calculation is demonstrated using the feeder shown in Fig. 65.6.

To calculate the voltage drop, the feeder is divided into sections. The sections are determined by the loads. Assuming a single-phase system, the load current is calculated by Eq. (65.1):

$$|I_i| = \frac{P_i}{V \cos \varphi_i}, \qquad I_i = |I_i| (\cos \varphi_i + \sin \varphi_i) \tag{65.1}$$

where P is the power of the load, V is the rated voltage, and φ is the power factor.

The section current is the sum of the load currents. Equation (65.2) gives the section current between load i and $i - 1$:

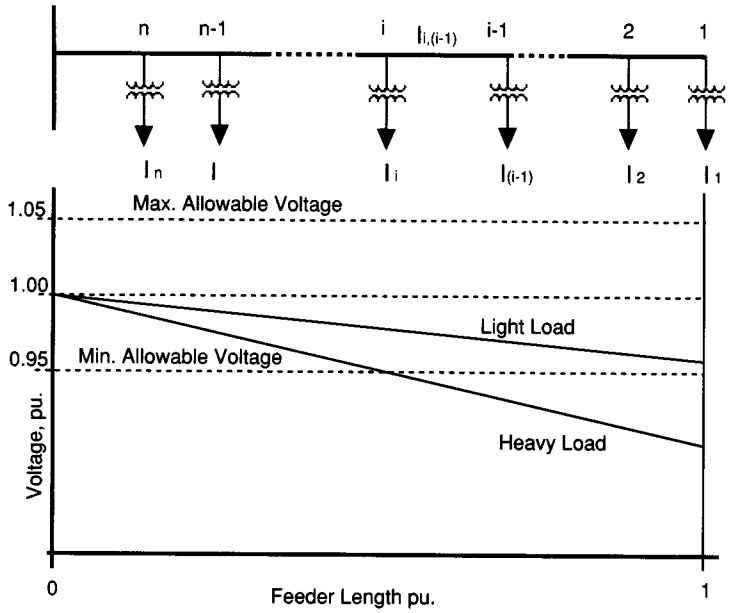

FIGURE 65.6 Feeder voltage profile.

$$I_{(i,\,i-1)} = \sum_{1}^{i-1} I_i \tag{65.2}$$

The electrical parameters of the overhead feeders are the resistance and reactance, which are given in Ω/mi. The underground feeders have significant capacitance in addition to the reactance and resistance. The capacitance is given in μF/mi. The actual values for overhead lines can be calculated using the conductor diameter and phase-to-phase and phase-to-ground distances [Fink and Beaty, 1978]. The residential underground system generally uses single-conductor cables with polyethylene insulation. The older systems use rubber insulation with neoprene jacket. Circuit parameters should be obtained from manufacturers. The distribution feeders are short transmission lines. Even the primary feeders are only a few miles long. This permits the calculation of the section resistance and reactance by multiplying the Ω/mi values by the length of the section. The length of the section in a single-phase two-wire system is two times the actual length. In a balanced three-phase system, it is the simple length. In a single-phase three-wire system the voltage drop on the neutral conductor must be calculated. Further information may be obtained from Pansini [1991].

Equation (65.3) gives the voltage drop, with a good approximation, for section i, $(i-1)$. The total voltage drop is the sum of the sections voltage drops.

$$e_{i,(i-1)} = \left|I_{i,(i-1)}\right|(R_{i,(i-1)} \cos \varphi_{i,(i-1)} + X_{i,(i-1)} \sin \varphi_{i,(i-1)}) \tag{65.3}$$

Equation (65.4) gives the losses on the line:

$$\text{Loss}_i = \sum_{1}^{i-1} (I_{i,(i-1)})^2 R_{i,(i-1)} \tag{65.4}$$

The presented calculation method describes the basic concept of feeder design; more details can be found in the literature.

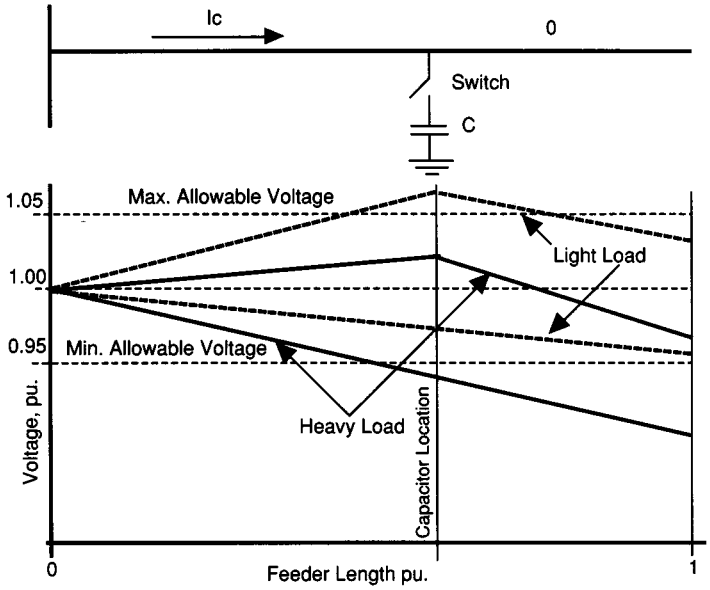

FIGURE 65.7 Capacitor effect on voltage profile.

65.8 Capacitors and Voltage Regulators

The voltage drop can be reduced by the application of a shunt capacitor. As shown in Fig. 65.7, a properly selected and located shunt capacitor assures that the voltage supplied to each of the customers will be within the allowable limit at the heavy load condition. However, at light load, the same capacitor will increase the voltage above the allowable limit. Most capacitors in the distribution system use switches. The capacitor is switched off during the night when the load is light and switched on when the load is heavy. The most frequent use of capacitors is on the primary feeders. In an overhead system, three-phase capacitor banks with vacuum switches are installed on the poles. Residential underground systems require less shunt capacitance for voltage control due to the reduced reactance. Even so, shunt capacitors are used for power factor correction and loss reduction.

The optimum number, size, and location of capacitor banks on a feeder is determined by detailed computer analyses. The concept of optimization includes the minimization of the operation, installation, and investment costs. The most important factor that affects the selection is the distribution and power factor of loads. In residential areas, the load is uniformly distributed. In this case the optimum location of the capacitor bank is around two-thirds of the length of the feeder.

The effect of capacitor bank can be studied by adding the capacitor current to the load current. The capacitor current flows between the supply and the capacitor as shown in Fig. 65.7. Its value can be calculated from Eq. (65.5) for a single-phase system:

$$I_c = j\omega CV, \qquad \omega = 2\pi f \tag{65.5}$$

where *C is the capacitance, f is the frequency (60 Hz), and V is the voltage to ground.*

The capacitive current is added to the inductive load current, reducing the total current, the voltage drop, and losses. The voltage drop and loss can be calculated from Eqs. (65.2) to (65.5).

The voltage regulator is a tap-changing transformer, which is located, in most cases, at the supply end of the feeder. The tap changer increases the supply voltage, which in turn increases the voltage above the allowable minimum at the last load. The tap changer transformer has two windings. The excitation winding is connected in parallel. The regulating winding is connected in series with the feeder. The latter has taps and a tap changer

switch. The switch changes the tap position according to the required voltage. The tap changing requires the short interruption of load current. The frequent current interruptions reduce the lifetime of the tap changer switch. This problem limits the number of tap changer operations to between one to three per day.

Defining Terms

Capacitor bank: Consists of capacitors connected in parallel. Each capacitor is placed in a metal can and equipped with bushings.

Feeder: Overhead lines or cables which are used to distribute the load to the customers. They interconnect the distribution substations with the loads.

Recloser: A circuit breaker which is designed to interrupt short-circuit current and reclose the circuit after interruption.

Substation: A junction point in the electric network. The incoming and outgoing lines are connected to a busbar through circuit breakers.

Tap changer: A transformer. One of the windings is equipped with taps. The usual number of taps is 32. Each tap provides a 1% voltage regulation. A special circuit breaker is used to change the tap position.

66.1 Generators

Chen-Ching Liu, Khoi Tien Vu, and Yixin Yu

Electric generators are devices that convert energy from a mechanical form to an electrical form. This process, known as electromechanical energy conversion, involves magnetic fields that act as an intermediate *medium.* There are two types of generators: alternating current (ac) and direct current (dc). This section explains how these devices work and how they are modeled in analytical or numerical studies.

The input to the machine can be derived from a number of energy sources. For example, in the generation of large-scale electric power, coal can produce steam that drives the shaft of the machine. Typically, for such a thermal process, only about 1/3 of the raw energy (i.e., from coal) is converted into mechanical energy. The final step of the energy conversion is quite efficient, with an efficiency close to 100%.

The generator's operation is based on Faraday's law of electromagnetic induction. In brief, if a coil (or winding) is linked to a varying magnetic field, then an electromotive force, or voltage, emf, is induced across the coil. Thus, generators have two essential parts: one creates a magnetic field, and the other where the emf's are induced. The magnetic field is typically generated by electromagnets (thus, the field intensity can be adjusted for control purposes), whose windings are referred to as field windings or **field circuits**. The coils where the emf's are induced are called *armature* windings or **armature circuits**. One of these two components is stationary (stator), and the other is a rotational part (rotor) driven by an external torque. Conceptually, it is immaterial which of the two components is to rotate because, in either case, the armature circuits always "see" a varying magnetic field. However, practical considerations lead to the common design that for ac generators, the field windings are mounted on the rotor and the armature windings on the stator. In contrast, for dc generators, the field windings are on the stator and armature on the rotor.

AC Generators

Today, most electric power is produced by synchronous generators. Synchronous generators rotate at a constant speed, called **synchronous speed**. This speed is dictated by the operating frequency of the system and the machine structure. There are also ac generators that do not necessarily rotate at a fixed speed such as those

found in windmills (induction generators); these generators, however, account for only a very small percentage of today's generated power.

Synchronous Generators

Principle of Operation. For an illustration of the steady-state operation, refer to Fig. 66.1 which shows a cross section of an ac machine. The rotor consists of a winding wrapped around a steel body. A dc current is made to flow in the rotor winding (or field winding), and this results in a magnetic field (rotor field). When the rotor is made to rotate at a constant speed, the three stationary windings aa', bb', and cc' experience a periodically varying magnetic field. Thus, emf's are induced across these windings in accordance with Faraday's law. These emf's are ac and periodic; each period corresponds to one revolution of the rotor. Thus, for 60-Hz electricity, the rotor of Fig. 66.1 has to rotate at 3600 revolutions per minute (rpm); this is the synchronous speed of the given machine. Because the windings aa', bb', and cc' are displaced equally in space from each other (by 120 degrees), their emf waveforms are displaced in time by 1/3 of a period. In other words, the machine of Fig. 66.1 is capable of generating three-phase electricity. This machine has two poles since its rotor field resembles that of a bar magnet with a north pole and a south pole.

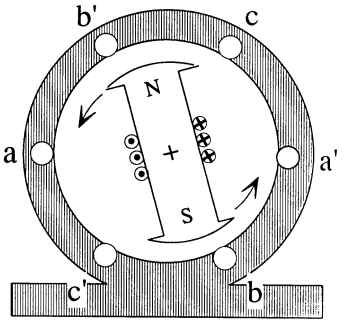

FIGURE 66.1 Cross section of a simple two-pole synchronous machine. The rotor body is salient. Current in rotor winding: ⊗ into the page, ⊙ out of the page.

When the stator windings are connected to an external (electrical) system to form a closed circuit, the steady-state currents in these windings are also periodic. These currents create magnetic fields of their own. Each of these fields is pulsating with time because the associated current is ac; however, the combination of the three fields is a **revolving field**. This revolving field arises from the space displacements of the windings and the phase differences of their currents. This combined magnetic field has two poles and rotates at the same speed and direction as the rotor. In summary, for a loaded synchronous (ac) generator operating in a steady state, there are two fields rotating at the same speed: one is due to the rotor winding and the other due to the stator windings. It is important to observe that the armature circuits are in fact exposed to two rotating fields, one of which, the armature field, is caused by and in fact tends to counter the effect of the other, the rotor field. The result is that the induced emf in the armature can be reduced when compared with an unloaded machine (i.e., open-circuited stator windings). This phenomenon is referred to as **armature reaction**.

It is possible to build a machine with p poles, where $p = 4, 6, 8, \ldots$ (even numbers). For example, the cross-sectional view of a four-pole machine is given in Fig. 66.2. For the specified direction of the (dc) current in the rotor windings, the rotor field has two pairs of north and south poles arranged as shown. The emf induced in a stator winding completes one period for every pair of north and south poles sweeping by; thus, each revolution of the rotor corresponds to two periods of the stator emf's. If the machine is to operate at 60 Hz then the rotor needs to rotate at 1800 rpm. In general, a p-pole machine operating at 60 Hz has a rotor speed of $3600/(p/2)$ rpm. That is, the lower the number of poles is, the higher the rotor speed has to be. In practice, the number of poles is dictated by the mechanical system (prime mover) that drives the rotor. Steam turbines operate best at a high speed; thus, two- or four-pole machines are suitable. Machines driven by hydro turbines usually have more poles.

Usually, the stator windings are arranged so that the resulting armature field has the same number of poles as the rotor field. In practice, there are many possible ways to arrange these windings; the essential idea, however, can be understood via the simple arrangement shown in Fig. 66.2. Each phase consists of a pair of windings (thus occupies four slots on the stator structure), e.g., those for phase a are labeled a_1a_1' and a_2a_2'. Geometry suggests that, at any time instant, equal emf's are induced across the windings of the same phase. If the individual windings are connected in series as shown in Fig. 66.2, their emf's add up to form the phase voltage.

Mathematical/Circuit Models. There are various models for synchronous machines, depending on how much detail one needs in an analysis. In the simplest model, the machine is equivalent to a constant voltage source in series with an impedance. In more complex models, numerous nonlinear differential equations are involved.

Steady-state model. When a machine is in a steady state, the model requires no differential equations. The representation, however, depends on the rotor structure: whether the rotor is cylindrical (round) or salient.

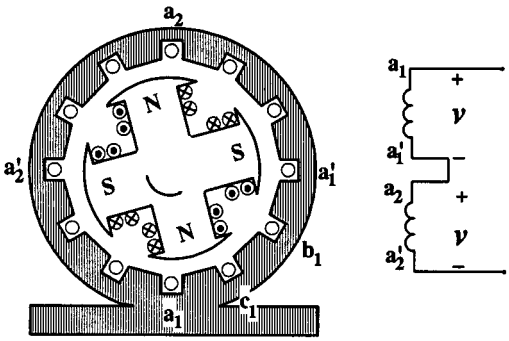

FIGURE 66.2 *Left,* cross section of a four-pole synchronous machine. Rotor has a salient pole structure. *Right,* schematic diagram for phase *a* windings.

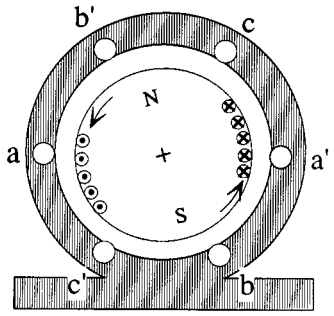

FIGURE 66.3 Cross section of a two-pole round-rotor synchronous machine.

The rotors depicted in Figs. 66.1 and 66.2 are salient since the poles are protruding from the shaft. Such structures are mechanically weak, since at a high speed (3600 rpm and 1800 rpm, respectively) the centrifugal force becomes a serious problem. Practically, for high-speed turbines, round-rotor (or cylindrical-rotor) structures are preferred. The cross section of a two-pole, round-rotor machine is depicted in Fig. 66.3. From a practical viewpoint, salient rotors are easier to build because each pole and its winding can be manufactured separately and then mounted on the rotor shaft. For round rotors, slots need to be reserved in the rotor where the windings can be placed.

The mathematical model for round-rotor machines is much simpler than that for salient-rotor ones. This stems from the fact that the rotor body has a permeability much higher than that of the air. In a steady state, the stator field and the rotor body are at a standstill relative to each other. (They rotate at the same speed as discussed earlier.) If the rotor is salient, it is easier to establish the magnetic flux lines along the direction of the rotor body (when viewed from the cross section). Therefore, for the same set of stator currents, different positions of the rotor alter the stator field in different ways; this implies that the induced emf's are different. If the rotor is round, then the relative position of the rotor structure does not affect the stator field. Hence, the associated mathematical model is simplified.

In the following, the steady-state models of the round-rotor and salient-rotor generators are explained.

Refer to Fig. 66.3 which shows a two-pole round-rotor machine. Without loss of generality, one can select phase *a* (i.e., winding aa') for the development of a mathematical model of the machine. As mentioned previously, the (armature or stator) winding of phase *a* is exposed to two magnetic fields: rotor field and stator field.

1. Rotor field. Its flux as seen by winding aa' varies with the rotor position; the flux linkage is largest when the N–S axis is perpendicular to the winding surface and minimum (zero) when this axis aligns with the surface. Thus, one can express the flux due to the rotor field as seen by winding aa' as $\lambda_1 = L(\theta)I_F$ where θ is to denote the angular position of the N–S axis (of the rotor field) relative to the surface of aa', I_F is the rotor current (a dc current), and L is a periodic function of θ.
2. Stator field. Its flux as seen by winding aa' is a combination of three individual fields which are due to currents in the stator windings, i_a, i_b, and i_c. This flux can be expressed as $\lambda_2 = L_s i_a + L_m i_b + L_m i_c$, where L_s (L_m) is the self (mutual) inductance. Because the rotor is round, L_s and L_m are not dependent on θ, the relative position of the rotor and the winding. Typically, the sum of the stator currents $i_a + i_b + i_c$ is near zero; thus, one can write $\lambda_2 = (L_s - L_m)i_a$.

The total flux seen by winding aa' is $\lambda = \lambda_1 - \lambda_2 = L(\theta)I_F - (L_s - L_m)i_a$, where the minus sign in $\lambda_1 - \lambda_2$ is due to the fact that the stator field opposes the rotor field. The induced emf across the winding aa' is $d\lambda/dt$, the time derivative of λ:

$$e_a = \frac{d\lambda}{dt} = \frac{dL}{dt} I_F - (L_s - L_m)\frac{di_a}{dt} \triangleq e_F - (L_s - L_m)\frac{di_a}{dt}$$

The time-varying quantities are normally sinusoidal, and for practical purposes, can be represented by phasors. Thus the above expression becomes:

$$\bar{E}_a = \bar{E}_F - (L_s - L_m)j\omega_0 \bar{I}_a \triangleq \bar{E}_F - jX_s\bar{I}_a$$

where ω_0 is the angular speed (rad/s) of the rotor in a steady state. This equation can be modeled as a voltage source $-E_F$ behind a reactance jX_s, as shown in Fig. 66.4; this reactance is usually referred to as *synchronous reactance*. The resistor R_a in the diagram represents the winding resistance, and V_t is the voltage measured across the winding.

As mentioned, the theory for salient-rotor machines is more complicated. In the equation $\lambda_2 = L_s i_a + L_m i_b + L_m i_c$, the terms L_s and L_m are now dependent on the (relative) position of the rotor. For example (refer to Fig. 66.1), L_s is maximum when the rotor is in a vertical position and minimum when the rotor is 90° away.

In the derivation of the mathematical/circuit model for salient-rotor machines, the stator field B_2 can be resolved into two components; when the rotor is viewed from a cross section, one component aligns along the rotor and the other is perpendicular to the rotor (Fig. 66.5). The component B_d, which directly opposes the rotor field, is said to belong to the *direct axis*; the other component, B_q, is weaker and belongs to the *quadrature axis*. The model for a salient-rotor machine consists of two circuits, direct-axis circuit and quadrature-axis circuit, each similar to Fig. 66.4. Any quantity of interest, such as I_a, the current in winding aa', is made up of two components, one from each circuit. The round-rotor machine can be viewed as a special case of the salient-pole theory where the corresponding parameters of the d-axis and q-axis circuits are equal.

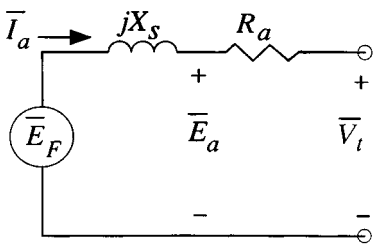

FIGURE 66.4 Per-phase equivalent circuit of round-rotor synchronous machines. $-E_F$ is the internal voltage (phasor form) and V_t is the terminal volt-

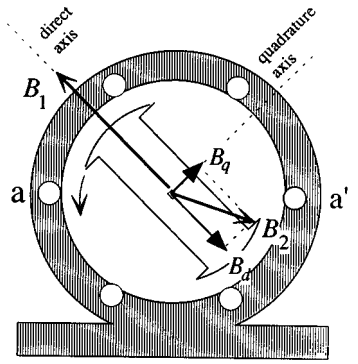

FIGURE 66.5 In the salient-pole theory, the stator field (represented by a single vector B_2) is decomposed into B_d and B_q. Note that $|B_d| > |B_q|$.

Dynamic models. When a power system is in a steady state (i.e., operated at an equilibrium), the electrical output of each generator is equal to the power applied to the rotor shaft. (Various losses have been neglected without affecting the essential ideas provided in this discussion.) Disturbances occur frequently in power systems, however. Examples of disturbances are load changes, short circuits, and equipment outages. A disturbance results in a mismatch between the power input and output of generators, and therefore the rotors depart from their synchronous-speed operation. Intuitively, the impact is more severe for machines closer to the disturbance. When a system is perturbed, there are several possibilities for its subsequent behavior. If the disturbance is small, the machines may soon reach a new steady speed, which is close to or identical to their synchronous speed, in which case the system is said to be stable. It may also happen that some machines speed up while others slow down. In a more complicated situation, a rotor may oscillate about its synchronous speed. This results in an unstable case. An unstable situation can result in abnormal changes in system frequency and voltage and, unless properly controlled, may lead to damage to machines (e.g., broken shafts). To study these phenomena, dynamic models are required. Details of a dynamic model depend on a number of factors such as location of disturbance and time duration of interest. An overview of dynamic generator models is given here. In essence, there are two aspects that need be modeled: electromechanical and electromagnetic.

1. *Electromechanical equations.* Electromechanical equations are to model the effect of input–output imbalance on the rotor speed (and therefore on the operating frequency). The rotor of each machine can be described by the so-called **swing equation**,

$$M\frac{d^2\theta}{dt^2} + D\frac{d\theta}{dt} = P_{\text{in}} - P_{\text{out}}$$

where θ denotes the rotor position relative to a certain rotating frame, M the inertia of rotor, and D damping. The term $d\theta/dt$ represents the angular velocity and $d^2\theta/dt^2$ is the angular acceleration of the rotor. The preceding differential equation is derived from Newton's law for rotational motions and, in some respects, resembles the dynamical equation of a swinging pendulum (with $P_{\text{in}} \sim$ driving torque, and $P_{\text{out}} \sim$ restoring torque). The term P_{in}, which drives the rotor shaft, can be considered constant in many cases. The term P_{out}, the power sent out to the system, may behave in a very complicated way. Qualitatively, P_{out} tends to increase (respectively, decrease) as the rotor position moves forward (respectively, backward) relative to the synchronous rotating frame. However, such a stable operation can take place only when the system is capable of absorbing (respectively, providing) the extra power. In a multimachine system, conflict might arise when various machines compete with each other in sending out more (or sending out less) electrical power; as a result, the stabilizing effect might be reduced or even lost.

2. *Electromagnetic equations.* The (nonlinear) electromagnetic equations are derived from Faraday's law of electromagnetic induction—induced emf's are proportional to the rate of change of the magnetic fluxes. A general form is as follows:

$$\begin{cases} e_d = \dfrac{d}{dt}\lambda_d + \lambda_q\dfrac{d}{dt}\theta - ri_d \\ e_q = \dfrac{d}{dt}\lambda_q + \lambda_d\dfrac{d}{dt}\theta - ri_q \end{cases} \tag{66.1}$$

where

$$\begin{cases} \lambda_d = G(s)i_F - X_d(s)i_d \\ \lambda_q = -X_q(s)i_q \end{cases} \tag{66.2}$$

The true terminal voltage, e.g., e_a for phase a, can be obtained by combining the direct-axis and quadrature-axis components e_d and e_q, respectively, which are given in Eq. (66.1). On each line of Eq. (66.1), the induced emf is the combination of two sources: the first is the rate of change of the flux on the same axis [$(d/dt)\lambda_d$ on the first line, $(d/dt)\lambda_q$ on the second]; the second comes into effect only when a disturbance makes the rotor and stator fields depart from each other [given by $(d/dt)\theta$]. The third term in the voltage equation represents the ohmic loss associated with the stator winding.

Equation (66.2) expresses the fluxes in terms of relevant currents: flux is equal to inductance times current, with inductances $G(s)$, $X_d(s)$, $X_q(s)$ given in an operational form (s denotes the derivative operator).

Figure 66.6 gives a general view of the input–output state description of machine's dynamic model, the state variables of which appear in Eqs. (66.1) and (66.2).

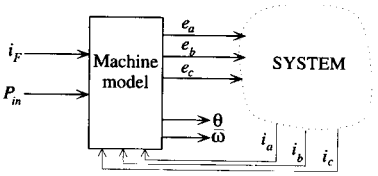

FIGURE 66.6 A block diagram depicting a qualitative relationship among various electrical and mechanical quantities of a synchronous machine. e_a, e_b, e_c are phase voltages; i_a, i_b, i_c phase currents; i_F rotor field current; θ relative position of rotor; ω deviation of rotor speed from synchronous speed; P_{in} mechanical power input. The state variables appear in Eqs. (66.1) and (66.2).

3. *Miscellaneous.* In addition to the basic components of a synchronous generator (rotor, stator, and their windings), there are auxiliary devices which help maintain the machine's operation within acceptable limits. Three such devices are mentioned here: governor, damper windings, and excitation control system.

- Governor. This is to control the mechanical power input P_{in}. The control is via a feedback loop where the speed of the rotor is constantly monitored. For instance, if this speed falls behind the synchronous speed, the input is insufficient and has to be increased. This is done by opening up the valve to increase the steam for turbogenerators or the flow of water through the penstock for hydrogenerators. Governors are mechanical systems and therefore have some significant time lags (many seconds) compared to other electromagnetic phenomena associated with the machine. If the time duration of interest is short, the effect of governor can be ignored in the study; that is, P_{in} is treated as a constant.
- Damper windings (armortisseur windings). These are special conducting bars buried in notches on the rotor surface, and the rotor resembles that of a squirrel-cage-rotor induction machine (see Section 66.2). The damper windings provide an additional stabilizing force for the machine when it is perturbed from an equilibrium. As long as the machine is in a steady state, the stator field rotates at the same speed as the rotor, and no currents are induced in the damper windings. That is, these windings exhibit no effect on a steady-state machine. However, when the speeds of the stator field and the rotor become different (because of a disturbance), currents are induced in the damper windings in such a way as to keep, according to Lenz's law, the two speeds from separating.
- Excitation control system. Modern excitation systems are very fast and quite efficient. An excitation control system is a feedback loop that aims at keeping the voltage at machine terminals at a set level. To explain the main feature of the excitation system, it is sufficient to consider Fig. 66.4. Assume that a disturbance occurs in the system, and as a result, the machine's terminal voltage V_t drops. The excitation system boosts the internal voltage E_F; this action can increase the voltage V_t and also tends to increase the reactive power output.

From a system viewpoint, the two controllers of excitation and governor rely on local information (machine's terminal voltage and rotor speed). In other words, they are decentralized controls. For large-scale systems, such designs do not always guarantee a desired stable behavior since the effect of interconnection is not taken into account in detail.

Synchronous Machine Parameters. When a disturbance, such as a short circuit at the machine terminals, takes place, the dynamics of a synchronous machine will be observed before a new steady state is reached. Such a process typically takes a few seconds and can be divided into subprocesses. The damper windings (armortisseur) exhibit their effect only during the first few cycles when the difference in speed between the rotor and the perturbed stator field is significant. This period is referred to as *subtransient.* The next and longer period, which is between the subtransient and the new steady state, is called *transient.*

Various parameters associated with the subprocesses can be visualized from an equivalent circuit. The *d*-axis and *q*-axis (dynamic) equivalent circuits of a synchronous generator consist of resistors, inductors, and voltage sources. In the subtransient period, the equivalent of the damper windings needs to be considered. In the transient period, this equivalent can be ignored. When the new steady state is reached, the current in the rotor winding becomes a constant (dc); thus, one can further ignore the equivalent inductance of this winding. This approximate method results in three equivalent circuits, listed in order of complexity: subtransient, transient, and steady state. For each circuit, one can define parameters such as (effective) reactance and time constant. For example, the *d*-axis circuit for the transient period has an effective reactance X'_d and a time constant T'_{do} (computed from the *R-L* circuit) when open circuited. The parameters of a synchronous machine can be computed from experimental data and are used in numerical studies. Typical values for these parameters are given in Table 66.1.

References on synchronous generators are numerous because of the historical importance of these machines in large-scale electric energy production. [Sarma, 1979] includes a derivation of the steady-state and dynamic models, dynamic performance, excitation, and trends in development of large generators. [Chapman, 1991]

TABLE 66.1 Typical Synchronous Generator Parameters[a]

Parameter	Symbol	Round Rotor	Salient-Pole Rotor with Damper Windings
Synchronous reactance			
d-axis	X_d	1.0–2.5	1.0–2.0
q-axis	X_q	1.0–2.5	0.6–1.2
Transient reactance			
d-axis	X'_d	0.2–0.35	0.2–0.45
q-axis	X'_q	0.5–1.0	0.25–0.8
Subtransient reactance			
d-axis	X''_d	0.1–0.25	0.15–0.25
q-axis	X''_q	0.1–0.25	0.2–0.8
Time constants			
Transient			
Stator winding open-circuited	T'_{do}	4.5–13	3.0–8.0
Stator winding short-circuited	T'_d	1.0–1.5	1.5–2.0
Subtransient			
Stator winding short-circuited	T''_d	0.03–0.1	0.03–0.1

[a] Reactances are per unit, i.e., normalized quantities. Time constants are in seconds.

and [McPherson, 1981] are among the basic sources of reference in electric machinery, where many practical aspects are given. An introductory discussion of power system stability as related to synchronous generators can be found in [Bergen, 1986]. A number of handbooks that include subjects on ac as well as dc generators are also available in [Laughton and Say, 1985; Fink and Beaty, 1987; and Chang, 1982].

Superconducting Generators

The demand for electricity has increased steadily over the years. To satisfy the increasing demand, there has been a trend in the development of generators with very high power rating. This has been achieved, to a great extent, by improvement in materials and cooling techniques. Cooling is necessary because the loss dissipated as heat poses a serious problem for winding insulation. The progress in machine design based on conventional methods appears to reach a point where further increases in power ratings are becoming difficult. An alternative method involves the use of superconductivity.

In a superconducting generator, the field winding is kept at a very low temperature so that it stays superconductive. An obvious advantage to this is that no resistive loss can take place in this winding, and therefore a very large current can flow. A large field current yields a very strong magnetic field, and this means that many issues considered important in the conventional design may no longer be critical. For example, the conventional design makes use of iron core for armature windings to achieve an appropriate level of magnetic flux for these windings; iron cores, however, contribute to heat loss—because of the effects of hysteresis and eddy currents—and therefore require appropriate designs for winding insulation. With the new design, there is no need for iron cores since the magnetic field can be made very strong; the absence of iron allows a simpler winding insulation, thereby accommodating additional armature windings.

There is, however, a limit to the field current increase. It is known that superconductivity and diamagnetism are closely related; that is, if a material is in the superconducting state, no magnetic lines of force can enter its interior. Increasing the current produces more and more magnetic lines of force, and this can continue until the dense magnetic field can penetrate the material. When this happens, the material fails to stay superconductive, and therefore resistive loss can take place. In other words, a material can stay superconductive until a certain *critical field strength* is reached. The critical field strength is dependent on the material and its temperature.

A typical superconducting design of an ac generator, as in the conventional design, has the field winding mounted on the rotor and armature winding on the stator. The main differences between the two designs lie in the way cooling is done. The rotor has an inner body which is to support a winding cooled to a very low temperature by means of liquid helium. The liquid helium is fed to the winding along the rotor axis. To maintain the low temperature, thermal insulation is needed, and this can be achieved by means of a vacuum space and a radiation shield. The outer body of the rotor shields the rotor's winding from being penetrated by the armature fields so that the superconducting state will not be destroyed. The stator structure is made of nonmagnetic material, which must be mechanically strong. The stator windings (armature) are not superconducting and are typically cooled by water. The immediate surroundings of the machine must be shielded from the strong magnetic fields; this requirement, though not necessary for the machine's operation, can be satisfied by the use of a copper or laminated iron screen.

From a circuit viewpoint, superconducting machines have smaller internal impedance relative to the conventional ones (refer to equivalent circuit shown in Fig. 66.4). Recall that the reactance jX_s stems from the fact that the armature circuits give rise to a magnetic field that tends to counter the effect of the rotor winding. In the conventional design, such a magnetic field is enhanced because iron core is used for the rotor and stator structures; thus jX_s is large. In the superconducting design, the core is basically air; thus, jX_s is smaller. The difference is generally a ratio of 5:1 in magnitude. An implication is that, at the same level of output current I_a and terminal voltage V_t, it requires of the superconducting generator a smaller induced emf E_F or, equivalently, a smaller field current.

It is expected that the use of superconductivity adds another 0.4% to the efficiency of generators. This improvement might seem insignificant (compared to an already achieved figure of 98% by the conventional design) but proves considerable in the long run. It is estimated that given a frame size and weight, a superconducting generator's capacity is three times that of a conventional one. However, the new concept has to deal with such practical issues as reliability, availability, and costs before it can be put into large-scale operation.

[Bumby, 1983] provides more details on superconducting electric machines with issues such as design, performance, and application of such machines.

Induction Generators

Conceptually, a three-phase induction machine is similar to a synchronous machine, but the former has a much simpler rotor circuit. A typical design of the rotor is the squirrel-cage structure, where conducting bars are embedded in the rotor body and shorted out at the ends. When a set of three-phase currents (waveforms of equal amplitude, displaced in time by one-third of a period) is applied to the stator winding, a rotating magnetic field is produced. (See the discussion of a revolving magnetic field for synchronous generators in the section "Principle of Operation".) Currents are therefore induced in the bars, and their resulting magnetic field interacts with the stator field to make the rotor rotate in the same direction. In this case, the machine acts as a motor since, in order for the rotor to rotate, energy is drawn from the electric power source. When the machine acts as a motor, its rotor can never achieve the same speed as the rotating field (this is the synchronous speed) for that would imply no induced currents in the rotor bars. If an external mechanical torque is applied to the rotor to drive it beyond the synchronous speed, however, then electric energy is pumped to the power grid, and the machine will act as a generator.

An advantage of induction generators is their simplicity (no separate field circuit) and flexibility in speed. These features make induction machines attractive for applications such as windmills.

A disadvantage of induction generators is that they are highly inductive. Because the current and voltage have very large phase shifts, delivering a moderate amount of power requires an unnecessarily high current on the power line. This current can be reduced by connecting capacitors at the terminals of the machine. Capacitors have negative reactance; thus, the machine's inductive reactance can be compensated. Such a scheme is known as capacitive compensation. It is ideal to have a compensation in which the capacitor and equivalent inductor completely cancel the effect of each other. In windmill applications, for example, this faces a great challenge because the varying speed of the rotor (as a result of wind speed) implies a varying equivalent inductor. Fortunately, strategies for ideal compensation have been designed and put to commercial use.

In [Chapman, 1991], an analysis of induction generators and the effect of capacitive compensation on machine's performance are given.

DC Generators

To obtain dc electricity, one may prefer an available ac source with an electronic rectifier circuit. Another possibility is to generate dc electricity directly. Although the latter method is becoming obsolete, it is still important to understand how a dc generator works. This section provides a brief discussion of the basic issues associated with dc generators.

Principle of Operation

As in the case of ac generators, a basic design will be used to explain the essential ideas behind the operation of dc generators. Figure 66.7 is a schematic diagram showing an end of a simple dc machine.

The stator of the simple machine is a permanent magnet with two poles labeled N and S. The rotor is a cylindrical body and has two (insulated) conductors embedded in its surface. At one end of the rotor, as illustrated in Fig. 66.7, the two conductors are connected to a pair of copper segments; these semicircular segments, shown in the diagram, are mounted on the shaft of the rotor. Hence, they rotate together with the rotor. At the other end of the rotor, the two conductors are joined to form a coil.

Assume that an external torque is applied to the shaft so that the rotor rotates at a certain speed. The rotor winding formed by the two conductors experiences a periodically varying magnetic field, and hence an emf is induced across the winding. Note that this voltage periodically alternates in sign, and thus, the situation is conceptually the same as the one encountered in ac generators. To make the machine act as a dc source, viewed from the terminals, some form of rectification needs be introduced. This function is made possible with the use of copper segments and brushes.

According to Fig. 66.7, each copper segment comes into contact with one brush half of the time during each rotor revolution. The placement of the (stationary) brushes guarantees that one brush always has positive potential relative to the other. For the chosen direction of rotation, the brush with higher potential is the one directly beneath the N-pole. (Should the rotor rotate in the reverse direction, the opposite is true.) Thus, the brushes can serve as the terminals of the dc source. In electric machinery, the rectifying action of the copper segments and brushes is referred to as **commutation**, and the machine is called a commutating machine.

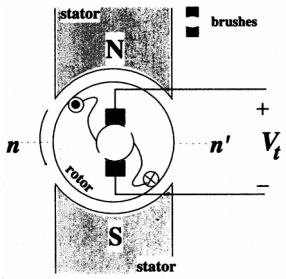

FIGURE 66.7 A basic two-pole dc generator. V_t is the voltage across the machine terminals. ⊗# and ⊙# indicate the direction of currents (into or out of the page) that would flow if a closed circuit is made.

A qualitative sketch of V_t, the voltage across terminals of an unloaded simple dc generator, as a function of time is given in Fig. 66.8. Note that this voltage is not a constant. A unidirectional current can flow when a resistor is connected across the terminals of the machine.

The pulsating voltage waveform generated by the simple dc machine usually cannot meet the requirement of practical applications. An improvement can be made with more pairs of conductors. These conductors are placed in slots that are made equidistant on the rotor surface. Each pair of conductors can generate a voltage waveform similar to the one in Fig. 66.8, but there are time shifts among these waveforms due to the spatial displacement among the conductor pairs. For instance, when an individual voltage is minimum (zero), other voltages are not. If these voltage waveforms are added, the result is a near constant voltage waveform. This improvement of the dc waveform requires many pairs of the copper segments and a pair of brushes.

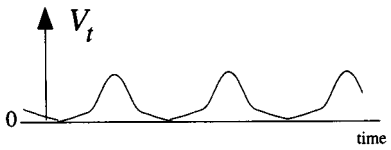

FIGURE 66.8 Open-circuited terminal voltage of the simple dc generator.

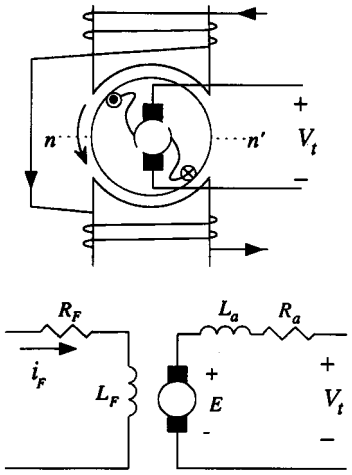

FIGURE 66.9 A simple two-pole dc generator with a stator winding to produce a magnetic field. *Top*, main components of the machine; *bottom*, coupled-circuit representation; the circuit on the left represents the field winding; the induced emf E is controlled by i_F.

When the generator is connected to an electrical load, load currents flow through the rotor conductors. Therefore, a magnetic field is set up in addition to that of the permanent magnet. This additional field generally weakens the magnetic flux seen by the rotor conductors. A direct consequence is that the induced emf's are less than those in an unloaded machine. Similar to the case of ac generators, this phenomenon is referred to as armature reaction, or flux-weakening effect.

The use of brushes in the design of dc generators can cause a serious problem in practice. Each time a brush comes into contact with two adjacent copper segments, the corresponding conductors are short-circuited. For a loaded generator, such an event occurs when the currents in these conductors are not zero, resulting in flashover at the brushes. This means that the life span of the brushes can be drastically reduced and that frequent maintenance is needed. A number of design techniques have been developed to mitigate this problem.

Mathematical/Circuit Model

The (no-load) terminal voltage V_t of a dc generator depends on several factors. First, it depends on the construction of the machine (e.g., the number of conductors). Second, the voltage magnitude depends on the magnetic field of the stator: the stronger the field is, the higher the voltage becomes. Third, since the induced emf is proportional to the rate of change of the magnetic flux (Faraday's law), the terminals have higher voltage with a higher machine speed. One can write

$$V_{t(\text{no load})} = K\lambda n$$

where K is a constant representing the first factor, λ is magnetic flux, and n is rotor speed. The foregoing equation provides some insights into the voltage control of dc generators. Among the three terms, it is impractical to modify K, which is determined by the machine design. Changing n over a wide range may not be feasible since this is limited by what drives the rotor. Changing the magnetic flux λ can be done if the permanent magnet is replaced by an electromagnet, and this is how the voltage control is done in practice. The control of λ is made possible by adjusting the current fed to this electromagnet. Figure 66.9 shows the modified design of the simple dc generator. The stator winding is called the *field winding*, which produces excitation for the machine. The current in the field winding is adjusted by means of a variable resistor connected in series with this winding. It is also possible to use two field windings in order to have more flexibility in control.

The use of field winding(s) on the stator of the dc machine leads to a number of methods to produce the magnetic field. Depending on how the field winding(s) and the rotor winding are connected, one may have

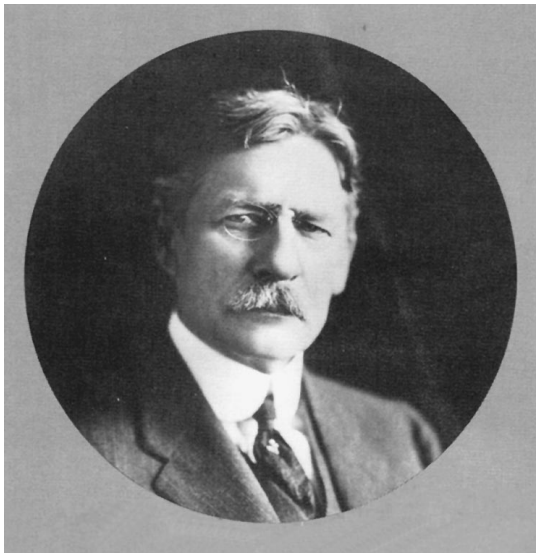
TABLE 66.2 Excitation Methods and Voltage Current Characteristics for DC Generators

Excitation Methods	Characteristics
Separate	
	For low currents, the curve is nearly a straight line. As load current increases, the armature reaction becomes more severe and contributes to the nonlinear drop.	
Series	
	At no load, there is no field current, and voltage is due to the residual flux of the stator core. The voltage rises rapidly over the range of low currents, but the resistive drop soon becomes dominant.	
Shunt	
	Voltage buildup depends on the residual flux. The shunt field resistance must be less than a critical value.	
Compounded	
	There are two field windings. Depending on how they are set up, one may have *cumulative* if the two fields are additive, *differential* if the two fields are subtractive.	*Cumulative:* An increase in load current increases the resistive drop, yet creates more flux. At high currents, however, resistive drop becomes dominant. *Differential:* An increase in load current not only increases the resistive drop, but also reduces the net flux. Voltage drops drastically.

shunt excitation, series excitation, etc. Each connection yields a different terminal characteristic. The possible connections and the resulting current–voltage characteristics are given in Table 66.2.

[Chapman, 1991] and [Fink and Beaty, 1987] provide more detailed discussions of dc generators. Specifically, [Chapman, 1991] shows how the characteristics are derived for various excitation methods.

Frank Julian Sprague (1857–1934)



Frank Sprague was a true entrepreneur in the new field of electrical technology. After a brief stint on Thomas Edison's staff, Sprague went out on his own, founding Sprague Electric Railway and Motor Company in 1884. In 1887, Sprague equipped the first modern trolley railway in the United States. Sprague's successful construction of a streetcar system for Richmond, Virginia, in 1888 was the beginning of the great electric railway boom. Sprague followed this system with 100 other such systems, both in America and Europe, during the next two years. In less than 15 years, more than 20,000 miles (32,000 km) of electric street railway were built.

In addition to his work in railroads, Sprague's diverse talents led to his development of electric elevators, an ac induction smelting furnace, miniature electric power units for use in small appliances, and as a member of the U.S. Naval Consulting Board during World War I, he developed fuses and air and depth bombs. Sprague was awarded the AIEE's Edison Medal in 1910. (Courtesy of the IEEE Center for the History of Electrical Engineering.)

Defining Terms

Armature circuit: A winding where the load current is carried.

Armature reaction: The phenomenon in which the magnetic field due to currents in the armature circuit counters the effect of the field circuit.

Commutation: A mechanical technique in which rectification can be achieved in dc machines.

Field circuit: A set of windings that produces a magnetic field so that the electromagnetic induction can take place in electric machines.

Revolving fields: A magnetic field created by multiphase currents on spatially displaced windings in rotating machines; the field revolves in the air gap.

Swing equation: A nonlinear differential equation describing the rotor dynamics of an ac synchronous machine.

Synchronous speed: A characteristic speed of synchronous and induction machines with a revolving field; it is determined by the rotor structure and the line frequency.

Further Information

Several handbooks, e.g., *Electrical Engineer's Reference Book* and *Standard Handbook for Electrical Engineers,* give more details on the machine design. [Bumby, 1983] covers the subject of superconducting generators. Some textbooks in the area of rotating machines are listed as [Sarma, 1979; Chapman, 1991; McPherson, 1981].

The quarterly journal *IEEE Transactions on Energy Conversion* covers the field of rotating machinery and power generation. Another IEEE quarterly journal, *IEEE Transactions on Power Systems,* is devoted to the general aspects of power system engineering and power engineering education.

The bimonthly journal *Electric Machines and Power Systems,* published by Hemisphere Publishing Corporation, covers the broad field of electromechanics, electric machines, and power systems.

66.2 Motors

Donald Galler

Electric motors are the most commonly used prime mover in industry. The classification of the types of ac and dc motors commonly used in industrial applications is shown in Fig. 66.10.

Motor Applications

DC Motors

Permanent magnet (PM) field motors occupy the low end of the horsepower (hp) range and are commercially available up to about 10 hp. Below 1 hp they are used for servo applications, such as in machine tools, for robotics, and in high-performance computer peripherals.

Wound field motors are used above about 10 hp and represent the highest horsepower range of **dc motor** application. They are commercially available up to several hundred horsepower and are commonly used in traction, hoisting, and other applications where a wide range of speed control is needed. The shunt wound dc motor is commonly found in industrial applications such as grinding and machine tools and in elevator and hoist applications. Compound wound motors have both a series and shunt field component to provide specific torque-speed characteristics. Propulsion motors for transit vehicles are usually compound wound dc motors.

AC Motors

Single-phase ac motors occupy the low end of the horsepower spectrum and are offered commercially up to about 5 hp. Single-phase **synchronous motors** are only used below about 1/10 of a horsepower. Typical applications are timing and motion control, where low torque is required at fixed speeds. Single-phase **induction motors** are used for operating household appliances and machinery from about 1/3 to 5 hp.

Polyphase ac motors are primarily three-phase and are by far the largest electric prime mover in all of industry. They are offered in ranges from 5 up to 50,000 hp and account for a large percentage of the total motor industry in the world. In number of units, the three-phase **squirrel cage induction motor** is the most common. It is commercially available from 1 hp up to several thousand horsepower and can be used on

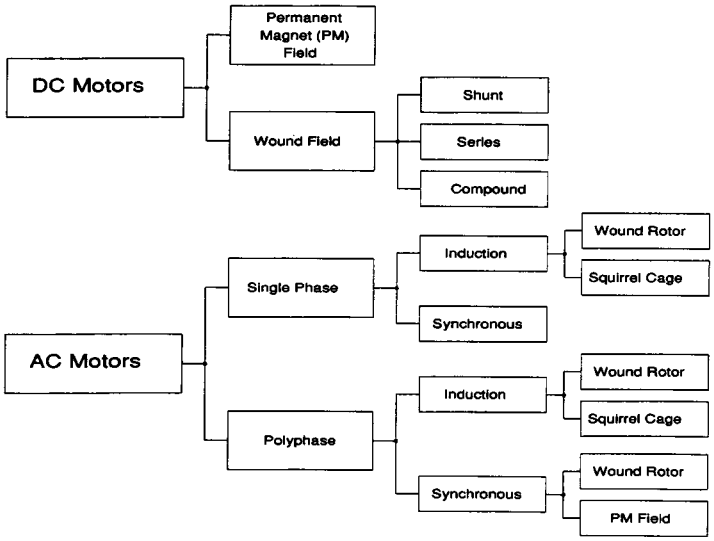

FIGURE 66.10 Classification of ac and dc motors for industrial applications.

conventional ac power or in conjunction with adjustable speed ac drives. Fans, pumps, and material handling are the most common applications.

When the torque-speed characteristics of a conventional ac induction motor need to be modified, the **wound rotor induction motor** is used. These motors replace the squirrel cage rotor with a wound rotor and slip rings. External resistors are used to adjust the torque-speed characteristics for speed control in such applications as ac cranes, hoists, and elevators.

Three-phase synchronous motors can be purchased with PM fields up to about 5 hp and are used for applications such as processing lines and transporting film and sheet materials at precise speeds.

In the horsepower range above about 10,000 hp, three-phase synchronous motors with wound fields are used rather than large squirrel cage induction motors. Starting current and other characteristics can be controlled by the external field exciter. Three-phase synchronous motors with wound fields are available up to about 50,000 hp.

Motor Analysis

DC Motor Analysis

The **separately excited dc motor** is the simplest of all dc motors and is the one most commonly found in industrial applications. The equivalent circuit is shown in Fig. 66.11. An adjustable dc voltage V is applied to the motor terminals. This voltage is impressed across the series combination of the armature resistance R_a and the back emf V_a generated by the armature. The field is energized with a separate dc power supply, usually at 300 or 500 V dc.

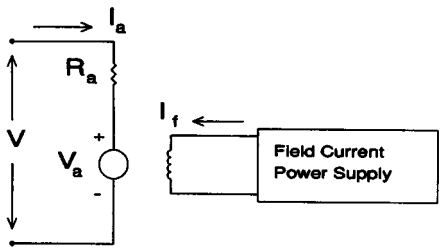

FIGURE 66.11 Equivalent circuit of separately excited dc motor.

The terminal voltage is given as

$$V = I_a R_a + V_a \tag{66.3}$$

The torque in steady state is

$$T = K_t I_a \Phi \tag{66.4}$$

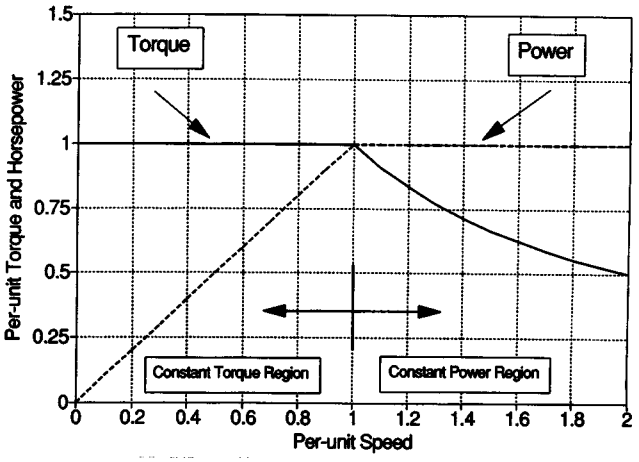

FIGURE 66.12 Torque-speed capability for the separately excited dc motor.

and the generated armature voltage is

$$V = K_a \omega \Phi \tag{66.5}$$

where Φ is the magnitude of the flux produced by the field winding and is proportional to the field current I_f. The torque constant K_t and the armature constant K_a are numerically equal in a consistent set of units. ω is the shaft speed in radians/second.

Solving the three equations gives the steady-state speed as

$$\omega = \frac{V - T(R_a / K_t \Phi)}{K_a \Phi} \tag{66.6}$$

The input power and output power are

$$P_{\text{in}} = I_a V \tag{66.7}$$

$$P_{\text{out}} = \omega T = I_a V - I_a^2 R_a \tag{66.8}$$

The efficiency (neglecting power loss in the field) is

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} = \frac{\omega T}{I_a V} \tag{66.9}$$

A simplified torque-speed curve is shown in Fig. 66.12. The torque capability is constant up to the base speed of the motor while the armature and field currents are held constant. The speed is controlled by armature voltage in this range. Operation above base speed is accomplished by reducing the field current. This is called *field weakening*. The motor operates at constant power in this range, and the torque reduces with increasing speed.

Synchronous Motor Analysis

Synchronous motor analysis may be conducted using either a round rotor or salient pole model for the motor. The round rotor model is used in the following discussion. The equivalent circuit is shown in Fig. 66.13. The model consists of two ac voltages V_1 and V_2 connected by an impedance $Z = R + jX$. Analysis is facilitated by use of the phasor diagram shown in Fig. 66.14. The power delivered through the impedance to the load is

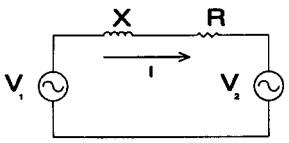

FIGURE 66.13 Per-phase equivalent circuit model for the synchonous motor (round rotor model).

$$P_2 = V_2 I \cos \phi_2 \tag{66.10}$$

where ϕ_2 is the phase angle of I with respect to V_2. The phasor current

$$I = \frac{V_1 - V_2}{Z} \tag{66.11}$$

is expressed in polar form as

$$\begin{aligned} I &= \frac{V_1 \angle \delta - V_2 \angle 0^\circ}{Z \angle \phi_2} \\ &= \frac{V_1}{Z} \delta - \angle \phi - \frac{V_2}{Z} \angle -\phi_z \end{aligned} \tag{66.12}$$

The equations make use of the fact that the three-phase operation is symmetrical and uses a "per-phase" equivalent circuit. This will also be true for the induction motor, which is analyzed in the following section.

The real part of I is

$$I \cos \phi_2 = \frac{V_1}{Z} \cos(\delta - \phi_z) - \frac{V_2}{Z} \cos(-\phi_z) \tag{66.13}$$

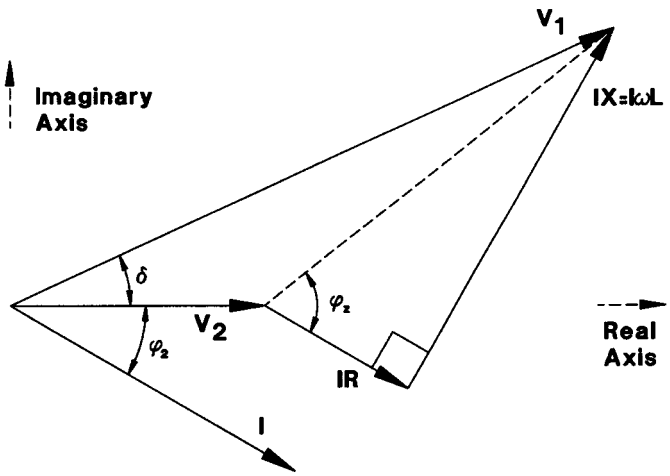

FIGURE 66.14 Phasor diagram for the ac synchronous motor (round rotor model).

Using Eq. (66.13) in Eq. (66.10) gives

$$P_2 = \frac{V_1 V_2}{Z} \cos(\delta - \phi_z) - \frac{V_2^2 R}{Z^2} \tag{66.14}$$

Letting $\alpha = 90° - \phi_z = \arctan R/X$ gives the output power as

$$P_2 = \frac{V_1 V_2}{Z} \sin(\delta + \alpha) - \frac{V_2^2 R}{Z^2} \tag{66.15}$$

and the input power as

$$P_1 = \frac{V_1 V_2}{Z} \sin(\delta - \alpha) + \frac{V_1^2 R}{Z^2} \tag{66.16}$$

Usually R is neglected and

$$P_1 = P_2 = \frac{V_1 V_2}{X} \sin \delta \tag{66.17}$$

which shows that the power is maximum when $\delta = 90°$ and is

$$P_{\text{MAX}} = \frac{V_1 V_2}{X} \tag{66.18}$$

The current can be found from Eqs. (66.15) and (66.16) since the only loss occurs in R. Setting

$$I^2 R = P_2 - P_1 \tag{66.19}$$

and solving for I gives

$$I = \sqrt{(P_2 - P_1)/R} \tag{66.20}$$

which is the input line current.

The power factor is

$$\cos \theta = \frac{P_1}{V_1 I} \tag{66.21}$$

and $\theta = \delta + \phi_2$ as shown in Fig. 66.14.

All the foregoing values are per-phase values. The total input power is

$$P_{\text{in}} = 3P_1 \tag{66.22}$$

The mechanical output power is

$$\begin{aligned} P_{\text{out}} &= T\omega \\ &= 3 \cdot P_2 \end{aligned} \tag{66.23}$$

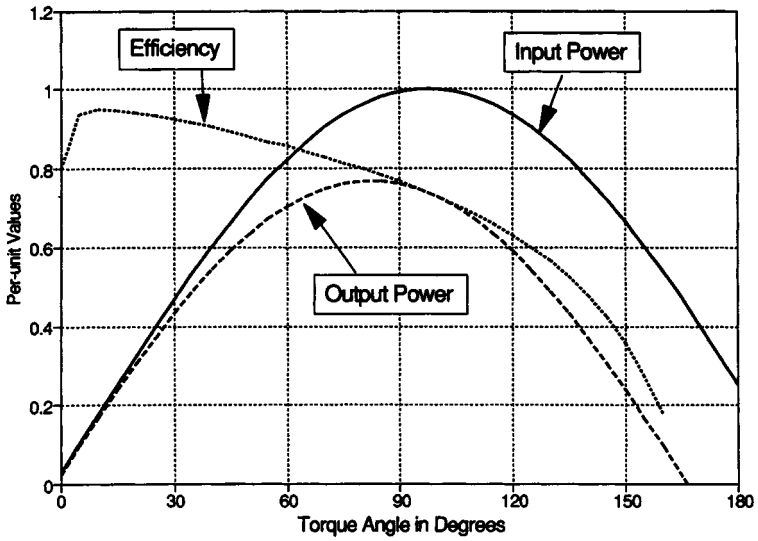

FIGURE 66.15 Synchronous motor performance.

and the torque is

$$T = 3 \cdot P_{\text{out}} / \omega \tag{66.24}$$

where ω is the rotational speed of the motor expressed in radians per second.

Synchronous motor operation is determined by the torque angle δ and is illustrated in Fig. 66.15 for a typical motor. Input power, output power, and current are shown on a per-unit basis. Torque is not shown but is related to output power only by a constant.

Induction Motor Analysis

The characteristic algebraic equations for the steady-state power, torque, and efficiency of the ac induction motor are derived from the per-phase equivalent circuit of Fig. 66.16. All voltages and currents are in sinusoidal steady state. The derivation of the equations can be simplified by defining the complex motor impedance as

$$Z_m = \frac{\alpha}{\zeta} + j\frac{\beta}{\zeta} \tag{66.25}$$

By defining the following constants as

$$\begin{aligned} M_1 &= R_1 R_2^2 \\ M_2 &= R_2 L_m{}^2 \\ M_3 &= L_2 + L_m \\ M_4 &= L_1 + L_m \\ M_5 &= R_1 M_3^2 + M_2 \end{aligned} \tag{66.26}$$

the terms of Eq. (66.25) become

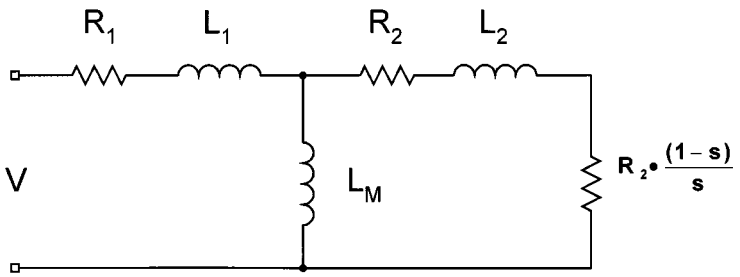

FIGURE 66.16 Equivalent circuit of ac induction motor.

$$\zeta = R_2^2 + \omega_s^2 M_3^2 \tag{66.27}$$

$$\alpha = \zeta R_1 + (\omega_m + \omega_s)\omega_s M_2 \tag{66.28}$$

$$\beta = (\omega_m + \omega_s)\,[\zeta L_1 + L_M R_2^2 + \omega_s^2 M_3 L_2 L_m] \tag{66.29}$$

The angular velocity ω_s is the slip frequency and is defined as follows:

$$\omega_s = \omega_f - \omega_m \tag{66.30}$$

where ω_f is the frequency applied to the **stator** and

$$\omega_m = \omega / N_p \tag{66.31}$$

is the **rotor** angular velocity in terms of an equivalent stator frequency. N_p is the number of stator pole pairs. The average mechanical output power of the motor is the power in the resistance $R_2\,\omega_m/\omega_s$ and is given as

$$P_{\text{out}} = \frac{3V^2\zeta\omega_m\omega_s M_2}{\alpha^2 + \beta^2} \tag{66.32}$$

where V is the rms line-neutral voltage. Since

$$\begin{aligned} T &= \frac{P_{\text{out}}}{\omega} \\ &= \frac{P_{\text{out}} N_p}{\omega_m} \end{aligned} \tag{66.33}$$

the torque becomes

$$T = \frac{3V^2\zeta N_p\omega_s M_2}{\alpha^2 + \beta^2} \tag{66.34}$$

The motor efficiency is defined as

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} \tag{66.35}$$

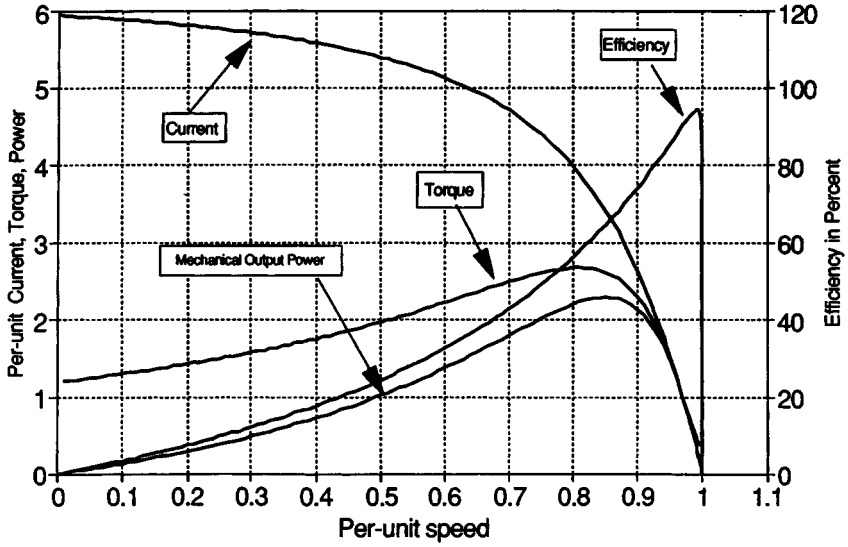

FIGURE 66.17 Induction motor operating characteristics, fixed voltage, and frequency.

where the input power is

$$P_{\text{in}} = \frac{3V_f^2 \cos\theta}{|Z_m|} = \frac{3V_f^2\,\alpha}{|Z_m|^2\,\zeta} \tag{66.36}$$

Using Eqs. (66.32) and (66.36), the efficiency becomes

$$\eta = \frac{\omega_m \omega_s M_2}{\alpha} \tag{66.37}$$

Typical performance characteristics of the induction motor are shown in Fig. 66.17.

Classical analysis represents all the motor expressions in terms of the slip, *s*, which is defined as

$$s = \frac{\omega_f - \omega_m}{\omega_f} \tag{66.38}$$

where ω_m is the equivalent mechanical frequency of the rotor, $\omega_m = \omega / N_p$, and ω_f is the angular velocity of the stator field in radians/second.

In this format, the output power is

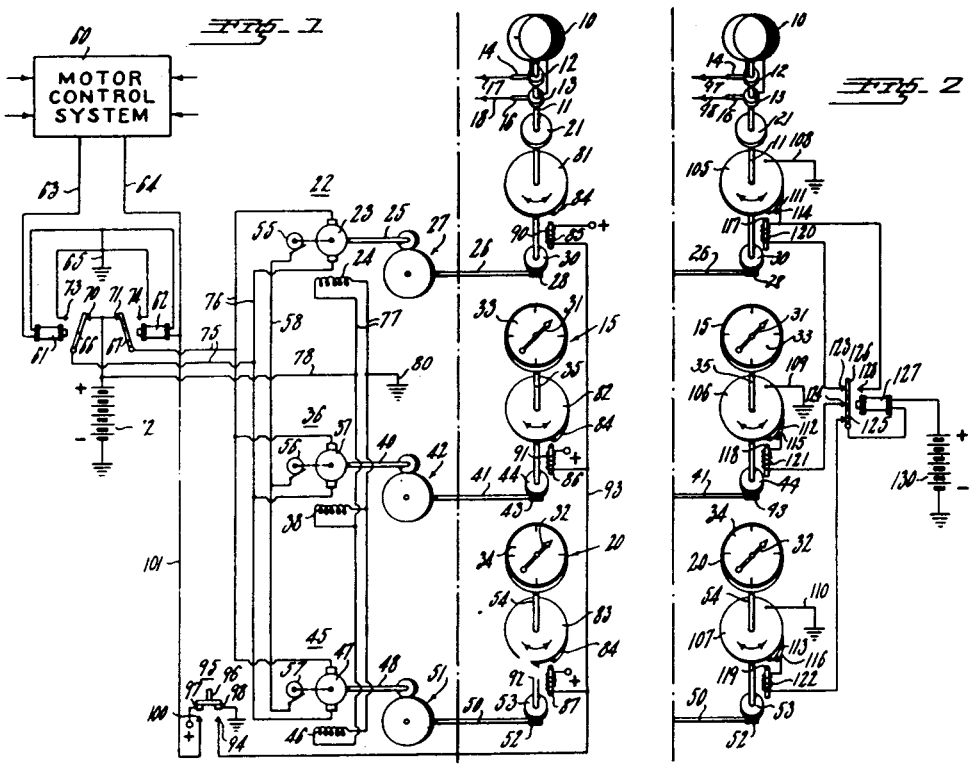
$$P = I_2^2 R_2 \cdot \frac{(1 - s)}{s} \tag{66.39}$$

Automatic Motor Synchronization Control

William P. Lear
Patented July 2, 1946
#2,403,098

Lear described a system for synchronizing instrumentation throughout an aircraft using DC servo motors instead of mechanical linkages that loaded down the master instrument. Its greater application came in using it to control and maintain altitude and heading by synchronizing the aircraft's control surfaces and using the servos to adjust them. This "autopilot" helped reduce pilot fatigue on long flights and was one of the developments that made commercial air practical during the 1950s and beyond. The servo control principles described are still used in automated air and sea navigation today.

Lear is perhaps best known for his development of small corporate jet aircraft known as Learjets in the 1960s. He patented the first practical car radio in the 1930s that launched today's giant Motorola Company. He also developed the eight-track tape system for autos in the 1960s and before his death in 1978, he designed the Lear fan, a high speed propeller aircraft made entirely from composites. (Copyright © 1995, DewRay Products, Inc. Used with permission.)



The maximum torque, T_m, occurs at a slip of

$$S_m = \frac{R_2}{\sqrt{R_1^2 + \left(X_1 + X_2\right)^2}} \tag{66.40}$$

where X_1 and X_2 are the stator and rotor reactances corresponding to L_1 and L_2. If R_1 and X are neglected, the torque can be expressed as

$$T = 2T_m \cdot \frac{ss_m}{s^2 + s_m^2} \tag{66.41}$$

but this expression loses accuracy if $s < 0.1$ where most practical operation takes place. Another expression,

$$T = 2T_m \cdot \frac{ss_m}{s^2 + s_m\left(1 + sR_1/R_2\right)^2} \cdot \left(\left(1 + \left(1 + s_m R_1/R_2\right)^2\right)\right)$$

may be used and is useful over the whole slip range. The full equation set of the previous discussion should be used where variable frequency and variable voltage operation is used, such as in adjustable speed drives. These equations are accurate for all regions of motor and generator operation.

ACand DC Motor Terms

General Terms

ω: Shaft angular velocity in radians/second
P_{out}: Electrical output power
P_{in}: Electrical input power
η: Efficiency
T: Shaft torque

DC Motor Terms

I_a: Armature current
I_f: Field current
V_a: Back emf generated by armature
V: Motor terminal voltage
R_a: Armature resistance
K_t: Torque constant
K_a: Armature constant
Φ: Field flux

AC Induction Motor Terms

L_1: Stator winding inductance
R_1: Stator winding resistance
L_2: Rotor winding inductance
R_2: Rotor winding resistance
L_M: Magnetizing inductance
N_p: Number of pole pairs in stator winding
ω_f: Frequency of voltage applied to stator
ω_m: Rotor equivalent mechanical frequency
ω_s: Slip frequency, $\omega_s = \omega_f - \omega_m$
s: Slip $s = (\omega_f - \omega_m)/\omega_f$
T_M: Maximum torque
s_M: Slip at maximum torque

AC Synchronous Motor Terms

V_1: Terminal voltage
V_2: Back emf generated by rotor
R: Rotor circuit resistance
X: Rotor circuit reactance
Z: Rotor circuit impedance $Z = R + jX$
δ: Torque angle (between V_1 and V_2)
ϕ_2: Angle between I and V_2
ϕ_Z: Rotor circuit reactance angle $\phi_z = \tan^{-1} X/R$
α: $90° - \phi_z$
θ: Power factor angle $\theta = \delta + \phi_2$

Defining Terms

DC motor: A dc motor consists of a stationary active part, usually called the field structure, and a moving active part, usually called the armature. Both the field and armature carry dc.

Induction motor: An ac motor in which a primary winding on the stator is connected to the power source and polyphase secondary winding on the rotor carries induced current.

Permanent magnet dc motor: A dc motor in which the field flux is supplied by permanent magnets instead of a wound field.

Rotor: The rotating member of a motor including the shaft. It is commonly called the armature on most dc motors.

Separately excited dc motor: A dc motor in which the field current is derived from a circuit which is independent of the armature.

Squirrel cage induction motor: An induction motor in which the secondary circuit (on the rotor) consists of bars, short-circuited by end rings. This forms a squirrel cage conductor structure which is disposed in slots in the rotor core.

Stator: The portion of a motor that includes and supports the stationary active parts. The stator includes the stationary portions of the magnetic circuit and the associated windings and leads.

Synchronous motor: An ac motor in which the average speed of normal operation is exactly proportional to the frequency to which it is connected. A synchronous motor generally has rotating field poles which are excited by dc.

Wound rotor induction motor: An induction motor in which the secondary circuit consists of a polyphase winding or coils connected through a suitable circuit. When provided with slip rings, the term *slip-ring induction motor* is used.

Further Information

The theory of ac motor drive operation is covered in the collection of papers edited by Bimal K. Bose, *Adjustable Speed AC Drive Systems* (IEEE, 1981). A good general text is *Electric Machinery,* by Fitzgerald, Kingsley, and Umans. The analysis of synchronous machines is covered in the book *Alternating Current Machines,* by M.G. Say (Wiley, 1984). *Three-Phase Electrical Machines — Computer Simulation* by J. R. Smith (Wiley, 1993) covers computer modeling and simulation techniques.

66.3 Small Electric Motors

Elias G. Strangas

Introduction

Small electrical machines carry a substantial load in residential environments, but also in industrial environments, where they are mostly used to control processes.

In order to adapt to the limitations of the power available, the cost requirements, and the widely varying operating requirements, small motors are available in a great variety of designs. Some of the small motors require electronics in order to start and operate, while others can start and run directly connected to the supply line.

AC motors that can start directly from the line are mostly of the induction type. Universal motors are also used extensively for small AC powered, handheld tools. They can either run directly from the line or have their speed adjusted through electronics.

Stepping motors of many varying designs require electronics to operate. They are used primarily to position a tool or a component and are seldom used to provide steady rotating motion.

Besides these motors, permanent magnet AC motors are replacing rapidly both DC and induction motors for accurate speed and position control, but also to decrease size and increase efficiency. They require power and control electronics to start and run.

Single Phase Induction Motors

To produce rotation, a multi-phase stator winding is often used in an AC motor, supplied from a symmetric and balanced system of currents. The magnetomotive force of these windings interacts with the magnetic field of the rotor (induced or applied) to produce a torque. In three-phase induction motors, the rotor field is created by currents that are induced due to the relative speed of the rotor and the synchronously rotating stator field.

In an induction motor that is supplied by a single-phase stator current, it is not as clear how a rotating magnetomotive force can be created and a torque be produced. Two different concepts will be used to generate torque.

The first, conceptually simpler design concept, involves the generation of a second current which flows in a second winding of the stator. This auxiliary winding is spatially displaced on the stator. This brings the motor design close to the multi-phase principle. The current in the auxiliary winding has to be out of phase with the current in the main winding, and this is accomplished through the use of increased resistance in it or a capacitor in series with it. A motor can operate in this fashion over its entire speed range.

Once the motor is rotating, the second design concept allows that one of the phases, the auxiliary one, be disconnected. The current in the remaining main winding alone produces only a pulsating flux, which can be analyzed as the sum of two rotating fields of equal amplitude but opposite direction. These fields, as seen from the moving rotor, rotate at different speeds, hence inducing in it currents of different frequency and amplitude. If the speed of the rotor is w_r, the applied frequency to the stator is f and the number of pole pairs in the motor is p, the frequencies of the currents induced in the rotor are $pw_r - f$ and $pw_r + f$. These unequal currents in turn produce unequal torques in the two directions, with a nonzero net torque.

The various designs of single-phase induction motors result from the variety of ways that the two phases are generated and by whether the auxiliary phase remains energized after starting.

Shaded Pole Motors

These motors are simple, reliable, and inefficient. The stator winding is not distributed on the rotor surface, but rather it is concentrated on salient poles. The auxiliary winding, which has to produce flux out of phase with the main winding, is nothing but a hardwired shorted turn around a portion of the main pole as Fig. 66.18.

Because of the shorted turn, the flux out of the shaded part of the pole lags behind the flux out of the main pole. The motor always rotates from the main to the shaded pole, and it is not possible to change directions.

Shaded pole motors are inefficient and have high starting and running current and low starting torque. They are used where reliability and cost are important, while their small size makes unimportant the overall effect of their disadvantages, e.g., small fans. Their size ranges from 0.002 to 0.1 hp.

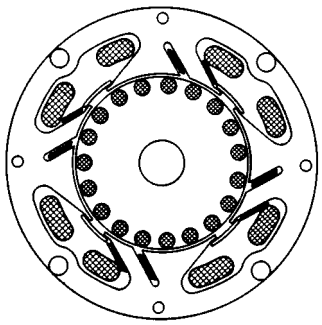

FIGURE 66.18 A shaded pole motor with tapered poles and magnetic wedges. (*Source:* C. G. Veinott and J. E. Martin, *Fractional and Subfractional Horsepower Electric Motors,* New York: McGraw-Hill, 1986. With permission.)

Resistance Split-Phase Motors

These motors have an auxiliary winding which simply has higher resistance than the main winding and is displaced spatially on the stator by about 90°. Both windings are distributed on the stator surface and are connected to the line voltage, but the different time constants between them makes the

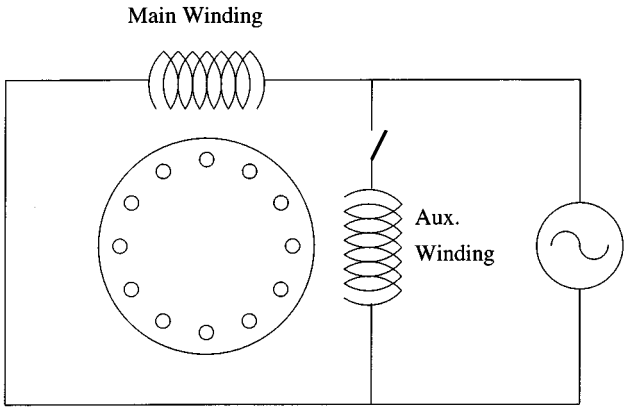

FIGURE 66.19 Connections of a resistive, split-phase motor.

current in the auxiliary winding lead that of the main. This arrangement results in a nonzero, but relatively low starting torque and high starting current.

The use of the auxiliary winding is limited only to starting—the motor runs more efficiently without it, as a single phase motor described earlier. A switch, activated by speed (centrifugal) or by stator temperature, disconnects the auxiliary winding shortly after starting. Figure 66.19 represents schematically the connections of this type of motor.

These motors represent an improvement in efficiency and starting torque over shaded pole motors, at the expense of increased cost and lower reliability. They are built to larger sizes, but their application is limited by the high starting current.

Capacitor Motors

Another way to generate a phase angle of current in the auxiliary winding is to include a capacitor in series with it. The capacitor can be disconnected after starting in a capacitor start motor. Their operation is similar to that of the resistance split-phase motor, but they have better starting characteristics and are made as large as 5 hp. Figure 66.20 shows schematically the wiring diagram of the capacitor start motor.

To optimize both starting and running, different values of the capacitor are used. One value of the capacitor is calculated to minimize starting current and maximize starting torque, while the other is designed to maximize efficiency at the operating point. A centrifugal switch handles the changeover. Such motors are built for up to 10 hp, and their cost is relatively high because of the switch and two capacitors. Figure 66.21 shows schematically the wiring diagram of the capacitor start and run motor.

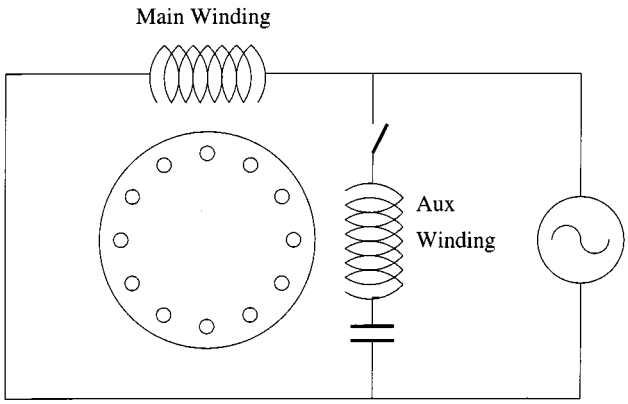

FIGURE 66.20 Conenctions of a capacitor start motor.

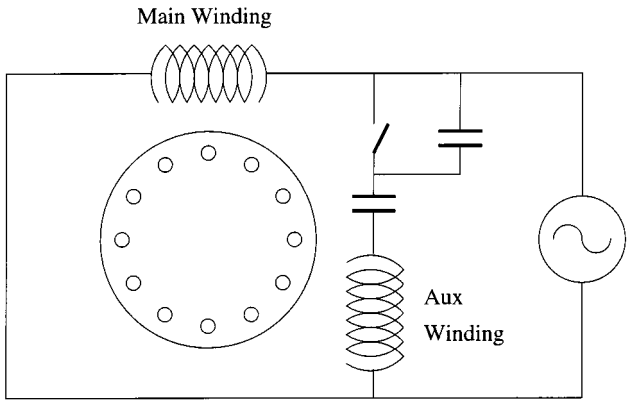

FIGURE 66.21 Connections of a capacitor-start, capacitor-run motor.

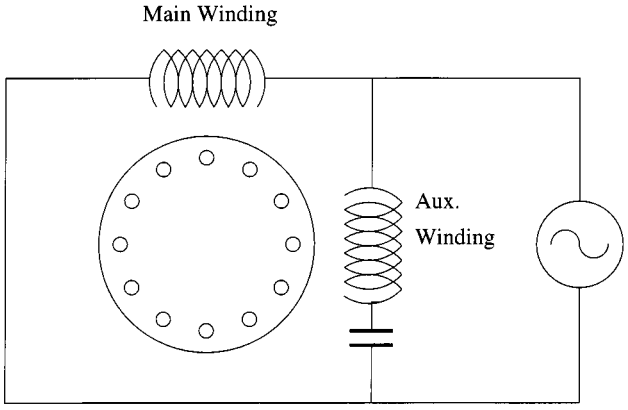

FIGURE 66.22 Connections of a permanent split capacitor motor.

A permanent split capacitor motor uses the same capacitor throughout the speed range of the motor. Its value requires a compromise between the values of the two-capacitor motors. The result is a motor design optimized for a particular application, e.g., a compressor or a fan. Figure 66.22 shows schematically the wiring diagram of the permanent split capacitor motor.

Universal Motors

These motors can be supplied from either DC or AC. Their design is essentially similar to a DC motor with series windings. When operated as AC motors, supplied say by a 60 Hz source, the current in the armature and the field windings reverses 120 times per second. As the torque is roughly proportional to both armature and field currents, connecting these windings in series guarantees that the current reverses in both at the same time, retaining the unidirectional torque. Figure 66.23 shows a schematic diagram of the connections of universal motors.

They can run at speeds up to 20,000 rpm, thus being very compact for a given horsepower. Their most popular applications include portable drills, food mixers, and fans.

Universal motors supplied from AC lend themselves easily to variable speed applications. A potentiometer, placed across the line voltage, controls the firing of a TRIAC thus varying the effective value of the voltage at the motor.

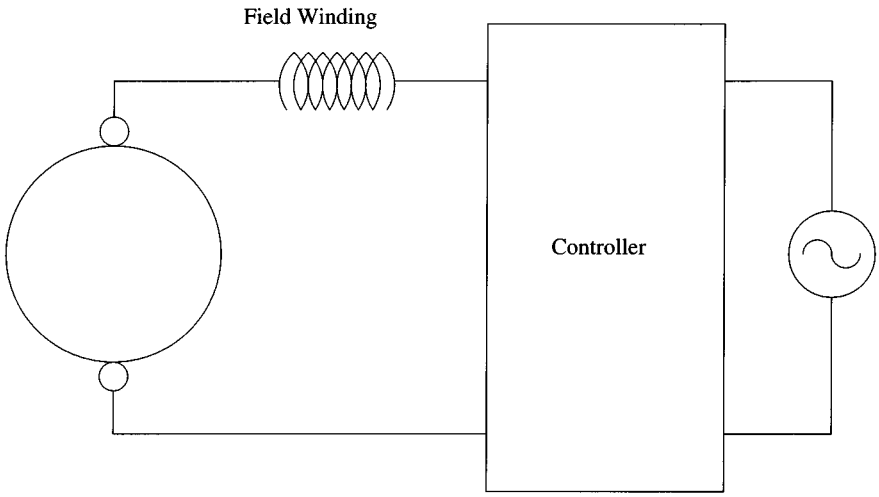

FIGURE 66.23 Connections of a universal motor.

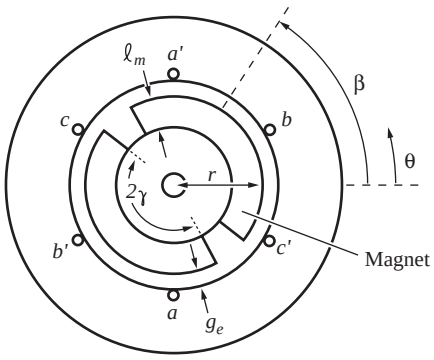

FIGURE 66.24 Surface mounted magnets on a Permanent Magnet AC motor.

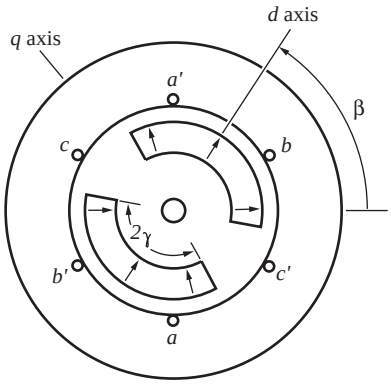

FIGURE 66.25 Inset (interior) magnets on a permanent magnet AC motor.

Permanent Magnet AC Motors

When compared to induction motors, permanent magnet motors have higher steady state torque for the same size and better efficiency. They carry a polyphase winding in the stator, which can be either rectangular or sinusoidally distributed. The rotor has a steel core, with permanent magnets mounted on it or inset. These magnets can be made from a variety of materials, such as rare earth, ceramic, etc.

Figure 66.24 shows a schematic of the cross-section of a motor with surface mounted magnets, and Fig. 66.25 shows a schematic of a motor with inset magnets.

The stator windings are supplied by a DC source through power electronic switches that constitute an inverter. Which switches are to be conducting at any time is determined by a controller, which in turn uses as inputs a speed or torque command and a measurement or an estimate of the rotor position. Figure 66.26 shows a schematic of the motor cross-section and of the inverter.

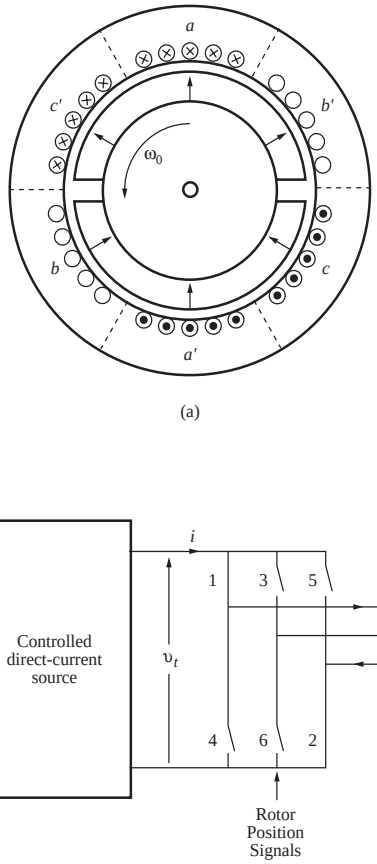

FIGURE 66.26 Permanent magnet AC motor and inverter.

When the stator windings are rectangular and are energized based only on the rotor position, the resulting set of PM motor, inverter, and controller is called a brushless DC motor. The developed torque is proportional to the airgap flux, B_g, and the stator current, I_s.

$$T = kB_g I_s$$

Due to the rotor speed, w_0 a voltage, e, (back emf) is induced to the stator windings.

$$e = kB_g w_0$$

Stepping Motors

These motors convert a series of power pulses to a corresponding series of equal angular movements. These pulses can be delivered at a variable rate, allowing the accurate positioning of the rotor without feedback. They can develop torque up to 15 Nm and can handle 1500 to 2500 pulses per second. They have zero steady state error in positioning and high torque density. An important characteristic of stepping motors is that when one phase is activated they do not develop a rotating but rather a holding torque, which makes them retain accurately their position, even under load.

Stepping motors are conceptually derived either from a variable reluctance motor or from a permanent magnet synchronous motor.

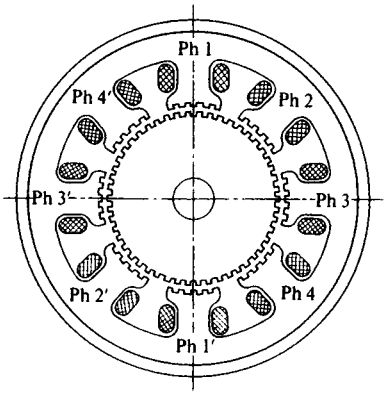

FIGURE 66.27 Cross-sectional view of a four-phase variable reluctance motor. Number of rotor teeth 50, step number 200, step angle 1.8°. (*Source:* Oxford University Press, 1989. With permission.)

One design of stepping motors, based on the doubly salient switched reluctance motor, uses a large number of teeth in the rotor (typically 45) to create saliency, as shown in Fig. 66.27. In this design, when the rotor teeth are aligned in say Phase 1, they are misaligned in Phases 2 and 3. A pulse of current in Phase 2 will cause a rotation so that the alignment will occur at Phase 2. If, instead, a pulse to Phase 3 is given, the rotor will move the same distance in the opposite rotation.

The angle corresponding to a pulse is small, typically 3° to 5°, resulting from alternatively exciting one stator phase at a time.

A permanent magnet stepping motor uses permanent magnets in the rotor. Figure 66.28 shows the steps in the motion of a four-phase PM stepping motor.

Hybrid stepping motors come in a variety of designs. One, shown in Fig. 66.29, consists of two rotors mounted on the same shaft, displaced by one half tooth. The permanent magnet is placed axially between the rotors, and the magnetic flux flows radially at the air gaps, closing through the stator circuit. Torque is created by the interaction of two magnetic fields, that due to the magnets and that due to the stator currents. This design allows a finer step angle control and higher torque, as well as smoother torque during a step.

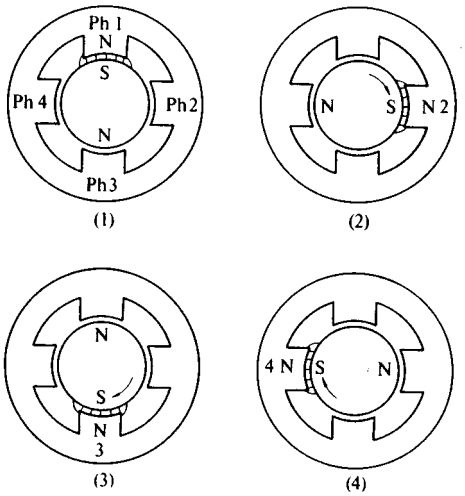

FIGURE 66.28 Steps in the operation of a permanent magnet stepping motor. (*Source:* T. Kenjo, *Stepping Motors and Their Microprocessor Controls,* Oxford University Press, 1989. With permission.)

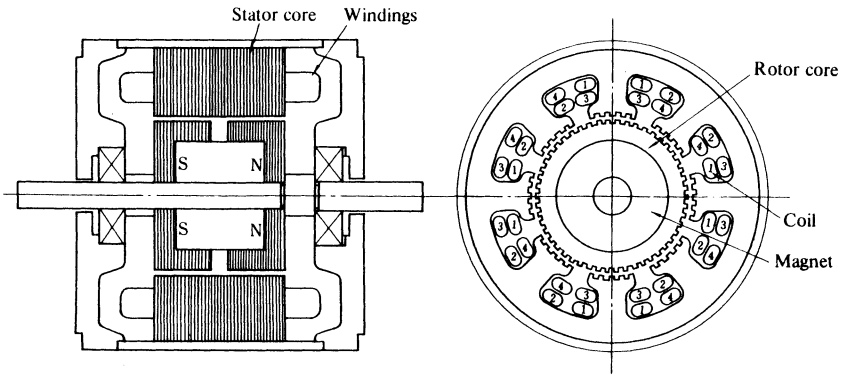

FIGURE 66.29 Construction of a hybrid stepping motor. (*Source:* Oxford University Press, 1989. With permission.)

Fundamental to the operation of stepping motors is the utilization of power electronic switches, and of a circuit providing the timing and duration of the pulses. A characteristic of a specific stepping motor is the maximum frequency it can operate at starting or running without load.

As the frequency of the pulses to a running motor is increased, eventually the motor loses synchronism. The relation between the frictional load torque and maximum pulse frequency is called the pull-out characteristic.

Further Information

There is an abundance of books and literature on small electrical motors. *IEEE Transactions on Industry Applications, Power Electronics, Power Delivery and Industrial Electronics* all have articles on the subject. In addition, IEE and other publications and conference records can provide the reader with specific and useful information.

Electrical Machines and Drives [Slemon, 1992] is one of the many excellent textbooks on the subject. *Stepping Motors and their Microprocessor Controls* [Kenjo, 1984] has a thorough discussion of stepping motors, while *Fractional and Subfractional Horsepower Electric Motors* [Veinott and Martin, 1986] covers small AC and DC motors. *Brushless Permanent-Magnet and Reluctance Motor Drives* [Miller, 1989] and *Permanent Magnet, Reluctance and Self-Synchronous Motors* [Nasar et al., 1993] reflect the increased interest in reluctance and brushless DC motors, and provide information on their theory of operation, design and control. Finally, *Fractional Horsepower Electric Motors* [Miller and Miller, 1984] gives a lot of practical information about the application of small motors.

66.4 Simulation of Electric Machinery

Chee-Mun Ong

Simulation has been an option when the physical system is too large or expensive to experiment with or simply not available. Today, with powerful simulation packages, simulation is becoming a popular option for conducting studies and for learning, especially when well-established models are available. **Modeling** refers to the process

of analysis and synthesis to determine a suitable mathematical description that captures the relevant dynamical characteristics and simulation to the techniques of setting up and experimenting with the model.

Models of three-phase synchronous and induction machines for studying electromechanical and low-frequency electrical transients are well established because of the importance of generator and load behavior in stability and fault studies. Electric machines, however, do interact with other connected components over a wide range of frequencies, from fractions of Hertz for electromechanical phenomena to millions of Hertz for electromagnetic phenomena.

Reduced models suitable for limited frequency ranges are often preferred over complex models because of the relative ease in usage — as in determining the values of model parameter and in implementing a simulation. In practice, reduced models that portray essential behavior over a limited frequency range are obtained by making judicious approximations. Hence, one has to be aware of the assumptions and limitations when deciding on the level of modeling details of other components in the simulation and when interpreting the simulation results.

Basics in Modeling

Most machine models for electromechanical transient studies are derived from a lumped-parameter circuit representation of the machine's windings. Such lumped-parameter circuit representations are adequate for low-frequency electromechanical phenomena. They are suited for dynamical studies, often times to determine the machine's performance and control behavior or to learn about the nature of interactions from electromechanical oscillations. Studies of interactions occurring at higher frequencies, such as surge or traveling waves studies, may require a distributed-parameter circuit representation of the machine windings.

A lumped-parameter model for dynamical studies typically will include the voltage equations of the windings, derived using a coupled circuit approach, and an expression for the developed electromagnetic torque. The latter is obtained from an expression of the developed electromagnetic power by considering the input power expression and allowing for losses and magnetic energy storage terms. The expression for the developed electromagnetic torque is obtained by dividing that for developed electromagnetic power by the rotor mechanical speed. The rotor speed, in turn, is determined by an equation of the rotor's dynamics that equates the rotor's inertia torque to its acceleration torque.

For example, in a reduced order model of a separately excited dc machine that ignores the details of commutation action and only portrays the average values of voltage, current, and power, the armature winding can be represented as an equivalent winding whose axis is determined by the position of the commutator brushes. The induced voltage in the armature, E_a, due to field flux can be expressed as $k_a\omega\phi$, k_a being a machine constant; ω, the rotor speed; and ϕ the flux per pole. When armature reaction is ignored, ϕ will be the flux produced by the field winding. (See Fig. 66.30).

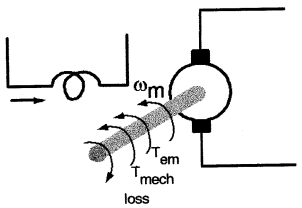

FIGURE 66.30 dc machine.

Using motoring convention, the voltage equations of the armature and field windings with axes that are at right angles to each other can be expressed as

$$V_a = E_a + R_a I_a + L_{aq}\frac{dI_a}{dt} \quad \text{V}$$
$$v_f = R_f i_f + L_f \frac{di_f}{dt} \tag{66.42}$$

where V_a is the terminal voltage of the armature winding, R_a its effective resistance including brush drops, L_{aq} its inductance, v_f the applied field voltage, R_f and L_f, the field circuit resistance and inductance. For motoring, positive I_a will flow into the positive terminal of V_a, as power flows from the external voltage source into the armature winding. Like the physical device, the model is capable of motoring and generating, and the transition from one mode to the other will take place naturally.

Equating the acceleration torque of the rotor to its inertia torque, one obtains:

$$T_{em} - T_{loss} + T_{mech} = J\frac{d\omega_m}{dt} \quad \text{N-m} \tag{66.43}$$

where T_{em} is the electromagnetic torque developed by the machine; T_{loss}, the equivalent torque representing friction and windage and stray load losses; and T_{mech}, the externally applied mechanical torque on the shaft in the direction of rotation. As shown in Fig. 66.30, T_{em} is positive for motoring and negative for generating; T_{mech} is negative for motoring and positive for generating.

Like the derivation of E_a, the developed torque, T_{em}, can be shown to be equal to $k_a\phi I_a$ by considering first the total power flow into the windings, that is,

$$\begin{aligned} V_a I_a &= E_a I_a + R_a I_a^2 + \frac{d\left(L_{aq} I_a^2/2\right)}{dt} \quad \text{W} \\ v_f i_f &= R_f i_f^2 + \frac{d\left(L_f i_f^2/2\right)}{dt} \end{aligned} \tag{66.44}$$

Summing the input powers to both windings, dropping the resistive losses and magnetic energy storage terms, and equating the remaining term to developed power, one will obtain the following relationships from which an expression of the developed torque can be written.

$$T_{em}\omega_m = P_{em} = E_a I_a \quad \text{W} \tag{66.45}$$

Figure 66.31 shows the flowchart for a simple dc machine simulation. The required inputs are V_a, v_f, and T_{mech}. Solving the windings' voltage equations with the required inputs, we can obtain the winding currents, I_a and i_f. The magnetizing curve block contains open-circuit test data of the machine to translate i_f to $k_a\phi$ or the ratio of the open-circuit armature voltage to some fixed speed, that is E_a/ω_{mo}. The simulation yields the output of the two winding currents, the field flux, the developed torque, and the rotor speed.

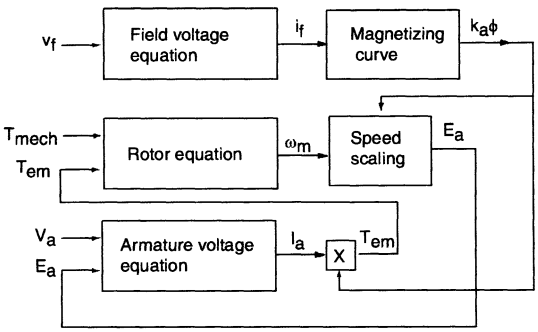

FIGURE 66.31 dc machine simulation flowchart.

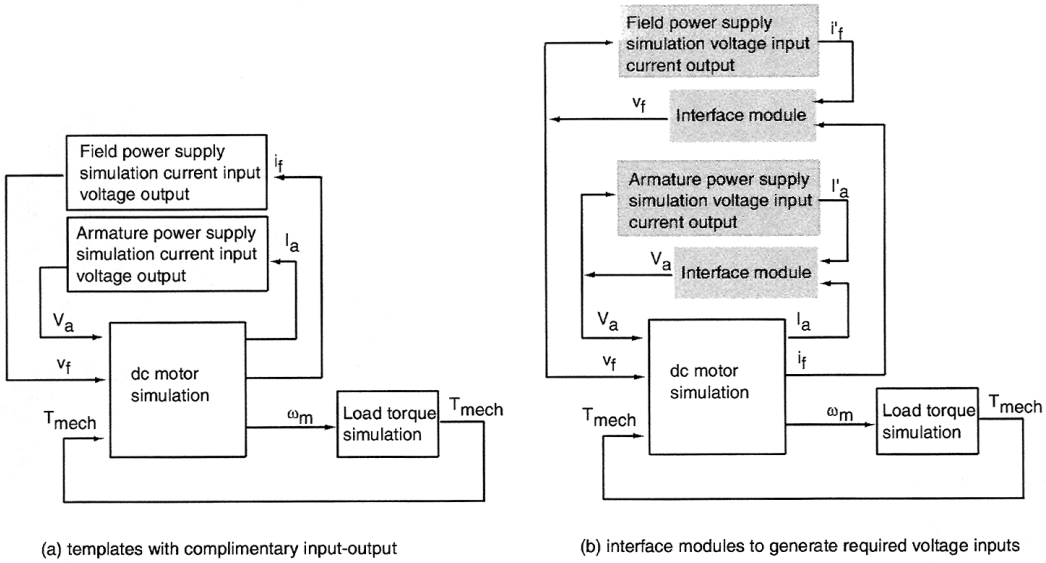
Modular Approach

Simulation of larger systems consisting of electric machines can be assembled directly from basic equations of the individual components and their connections. On a higher level of integration, it will be more convenient and advantageous to utilize templates of subsystems to construct the full system in a modular manner. Subsystem templates once verified can be reused with confidence for studies that are within the scope of the models implemented. The tasks of constructing and debugging a simulation using the modular approach can be much easier than building the same simulation from elementary representations.

Proper considerations to matching inputs to outputs of the connected templates are required when using templates. Take, for example, a template of the above dc motor simulation. Such a template will require inputs of V_a, v_f, and T_{mech} to produce outputs of I_a, i_f, flux, and rotor speed. On the mechanical side, the motor template has to be interfaced to the simulation of the mechanical prime mover or load for its remaining input of T_{mech}. In the case of a simple load, the load torque, T_{mech}, could be constant or some simple function of rotor speed, as shown in Fig. 66.32. On the electrical side, the motor template has to be interfaced to the templates of the power supplies to the armature and field windings for its inputs of V_a and v_f. These voltages can come from



(a) templates with complimentary input-output

(b) interface modules to generate required voltage inputs

FIGURE 66.32 Interface for dc motor simulation.

the simulations of the power supply circuits if they provide outputs of these voltages. If not, as in the case where the templates of the power supply circuits also require voltages V_a and v_f as their inputs, the interconnection of the motor and power supply circuits templates will require an interface module with current as input and voltage as output as shown in Fig. 66.32(b).

In practice, the interface module can be of physical or fictitious origin — the latter essentially a convenient but acceptable approximation. Referring again to Fig. 66.32 of the power supply connected to the motor, examples of an interface module of physical origin would be where shunt filtering capacitors or bleeding resistors are actually present at the terminals of the motor windings. Written with current as input and voltage as output, the equations for simulating the shunt capacitor and the shunt bleeding resistor are

$$V = \frac{1}{C}\int i\,dt \quad V = Ri \tag{66.46}$$

where i is the net current flowing into the branch in both cases.

But if the actual system does not have elements with equations that can be written to accept current as input and voltage as output, shunt R and C of fictitious origin can be inserted at the cost of some loss in accuracy to fulfill the necessary interface requirement. For good accuracy, the current in the introduced fictitious branch element should be kept very small relative to the currents of the actual branches by using very large R or very small C. In practice, loop instability in analog computation and numerical stiffness in digital computation will determine the lower bound on how small an error can be attained. In spite of the small error introduced, this technique can be very useful, as evident from trying to use the above dc motor simulation to simulate an open-circuit operation of the motor. While it is possible to reformulate the equations to handle the open-circuit condition, the equations as given with voltage input and current output can be used for the open-circuit condition if one is willing to accept a small inaccuracy of introducing a very large resistor to approximate the open-circuit. On the other hand, the simulation of short-circuit operation with the above **model** can be easily implemented using a V_a of zero.

Mathematical Transformations

Mathematical transformations are used in the analysis and simulation of three-phase systems, mostly to decouple variables. For example, the transformations to symmetrical components or $\alpha\beta 0$ components are used

in the analysis of unbalanced three-phase network analysis. Transformations to decouple variables, to facilitate the solution of difficult equations with time-varying coefficients, or to refer variables from one frame of reference to another are employed in the analysis and simulation of three-phase ac machines.

For example, in the analysis and simulation of a three-phase synchronous machine with a salient pole rotor, transformation of stator quantities onto a frame of reference attached to the asymmetrical rotor results in a much simpler model. In this rotor reference model, the inductances are not dependent on rotor position and, in steady-state operation, the stator voltages and currents are not time varying.

Park's transformation decouples and rotates the stator variables of a synchronous machine onto a dq reference frame that is fixed to the rotor. The positive d-axis of the dq frame is aligned with the magnetic axis of the field winding, that of the positive q-axis is ahead in the direction of rotation or lead the positive d-axis by $\pi/2$. Defined in this manner, the internal excitation voltage given by $E_f = \omega L_{af} i_f$ is in the direction of the positive q-axis. Park's original dq0 transformation [1929] was expressed in terms of the angle, θ_d, between the rotor's d-axis and the axis of the stator's a-phase winding.

The so-called qd0 transformation in more recent publications is Park's transformation expressed in terms of the angle, θ_q, between the rotor's q-axis and the axis of the stator's a-phase winding. The row order of components in the qd0 transformation matrix from top of bottom is q-, d-, and then 0. As evident from Fig. 66.33, the angle θ_q is equal to $\theta_d + \pi/2$. The transformation from abc variables to a qd0 reference frame is accomplished with

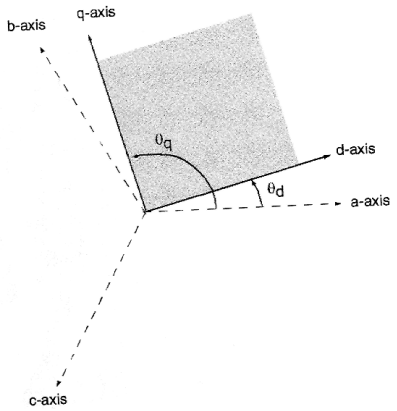


FIGURE 66.33 qd0 transformation.

$$[\mathbf{f}_{qd0}] = [\mathbf{T}_{qd0}(\theta_q)][\mathbf{f}_{abc}] \tag{66.47}$$

where **f** can be voltage, current, or flux, and

$$\left[\mathbf{T}_{qd0}\left(\theta_q\right)\right] = \frac{2}{3}\begin{bmatrix} \cos\theta_q & \cos\left(\theta_q - \frac{2\pi}{3}\right) & \cos\left(\theta_q + \frac{2\pi}{3}\right) \\ \sin\theta_q & \sin\left(\theta_q - \frac{2\pi}{3}\right) & \sin\left(\theta_q + \frac{2\pi}{3}\right) \\ \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \end{bmatrix} \tag{66.48}$$

Transforming back from qd0 to abc is accomplished by premultiplying both sides of Eq. (66.47) with the inverse

$$\left[\mathbf{T}_{qd0}\left(\theta_q\right)\right]^{-1} = \begin{bmatrix} \cos\theta_q & \sin\theta_q & 1 \\ \cos\left(\theta_q - \frac{2\pi}{3}\right) & \sin\left(\theta_q - \frac{2\pi}{3}\right) & 1 \\ \cos\left(\theta_q + \frac{2\pi}{3}\right) & \sin\left(\theta_q + \frac{2\pi}{3}\right) & 1 \end{bmatrix} \tag{66.49}$$

The angle θ_q can be determined from

$$\theta_d\left(t\right) = \int_0^t \omega\left(t\right)dt + \theta_q\left(0\right) \quad \text{rad} \tag{66.50}$$

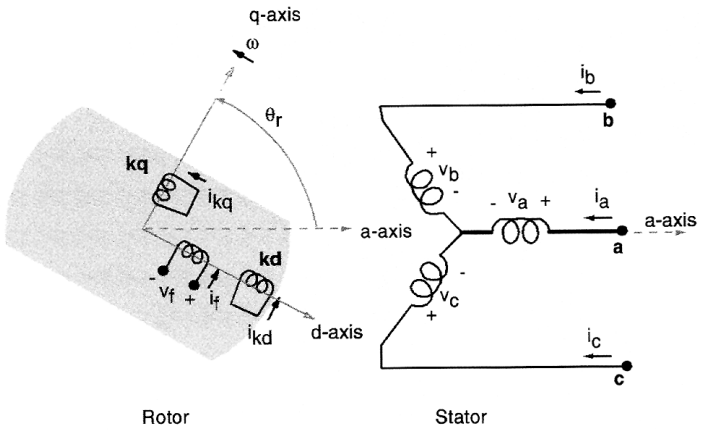

FIGURE 66.34 Circuit representation of idealized synchronous machine.

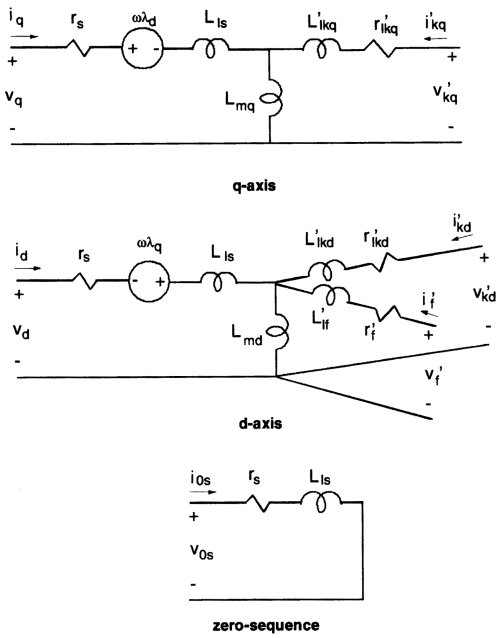

FIGURE 66.35 Equivalent qd0 circuits of synchronous machine.

where $\omega(t)$ is the rotational speed of the qd reference frame and $\theta_q(0)$, the initial value of θ_q at $t = 0$. In the case of the rotor's qd reference frame, $\omega(t)$ is equal to the rotor's speed in electrical radians (per second), that is, $\omega(t) = \omega_r(t)$.

Figure 66.34 shows a circuit representation of an idealized synchronous machine with damper windings, *kd* and *kq*, and field winding, *f*, on the rotor. The equivalent circuit representation and equations of the machine in its own rotor qd0 reference frame and in motor convention are shown in Fig. 66.35 and Table 66.3, respectively.

Base Quantities

Oftentimes, the machine equations are expressed in terms of the flux linkages per second, ψ, and reactances, x, instead of λ and L. These are related simply by the base or rated value of angular frequency, ω_b, that is,

$$\psi = \omega_b \lambda \quad \text{and} \quad x = \omega_b L \tag{66.51}$$

TABLE 66.3 qd0 Model of Synchronous Machine

Voltage equations

$$v_q = r_s i_q + \frac{d\lambda_q}{dt} + \lambda_d \frac{d\theta_r}{dt} \qquad v'_f = r'_f i'_f + \frac{d\lambda_f}{dt}$$
$$v_d = r_s i_d + \frac{d\lambda_d}{dt} - \lambda_q \frac{d\theta_r}{dt} \qquad v'_{kd} = r'_{kd} i'_{kd} + \frac{d\lambda'_{kd}}{dt}$$
$$v_0 = r_s i_0 + \frac{d\lambda_0}{dt} \qquad v'_{kq} = r'_{kq} i'_{kq} + \frac{d\lambda'_{kq}}{dt}$$

Flux linkage equations

$$\lambda_q = L_q i_q + L_{mq} i'_{kq} \qquad \lambda'_f = L_{md} i_d + L_{md} i'_{kd} + L'_{ff} i'_f$$
$$\lambda_d = L_d i_d + L_{md} i'_f + L_{md} i'_{kd} \qquad \lambda'_{kd} = L_{md} i_d + L_{md} i'_f + L'_{kdkd} i'_{kd}$$
$$\lambda_0 = L_{ls} i_0 \qquad \lambda'_{kq} = L_{mq} i_q + L'_{kqkq} i'_{kq}$$

Torque equation

$$T_{em} = \frac{3}{2}\frac{P}{2}\left(\lambda_d i_q - \lambda_q i_d\right) \quad \text{N-m}$$

where $\omega_b = 2\pi f_{rated}$ electrical radian per second, f_{rated} being the rated frequency in Hertz of the machine. When dealing with complex waveforms, it is logical to use peak rather than the rms value as the base value. The base quantities with peak rather rms value of a P-pole, three-phase induction machines with rated line-to-line rms voltage, V_{rated}, and rated volt-ampere, S_{rated}, area as follows:

base voltage, $V_b = \sqrt{2/3}V_{rated}$ base volt-ampere, $S_b = S_{rated}$ base current, $I_b = 2S_b/3V_b$
base impedance, $Z_b = V_b/I_b$ base torque, $T_b = S_b/\omega_{bm}$ base speed, $\omega_{bm} = 2\omega_b/P$

Simulation of Synchronous Machines

Table 66.4 shows the main steps in a simulation of a three-phase synchronous machine with T_{mech}, v_f, and *abc* stator voltages as input. The rotor's speed and angle, $\omega_r(t)$ and δ, are determined by the rotor's equation of motion.

$$T_{em} + T_{mech} - T_{damp} = J\frac{d\omega_{rm}(t)}{dt} \quad \text{N-m} \tag{66.52}$$

The developed torque, T_{em}, is positive for motoring operation and negative for generating operation.

The rotor angle, δ, is defined as the angle of the q_r axis of the rotor with respect to the q_e axis of the synchronously **rotating reference frame,** that is,

$$\begin{aligned}\delta(t) &= \theta_r(t) - \theta_e(t) \quad \text{elect. rad} \\ &= \int_0^t \left(\omega_r(t) - \omega_e\right)dt + \theta_r(0) - \theta_e(0)\end{aligned} \tag{66.53}$$

Since the synchronous speed, ω_e, is a constant,

$$\frac{d\left(\omega_r(t) - \omega_e\right)}{dt} = \frac{d\omega_r(t)}{dt} \tag{66.54}$$

TABLE 66.4 Simulation of Synchronous Machine

Transform input stator *abc* voltages to the qd reference frame attached to the rotor using $[\mathbf{v}_{qd0}] = [\mathbf{T}_{qd0}(\theta_r)][\mathbf{v}_{abc}]$ where $\theta_r(t) = \int_0^t \omega_r(t)dt + \theta_r(0)$. The currents or flux linkages of the cut set of three inductors in both the q- and d-axis circuits of Fig. 66.35, are not independent. Using the winding flux linkages per second as states, the mutual flux linkages per second are expressed as

$$\psi_{mq} = \omega_b L_{mq}\left(i_q + i'_{kq}\right) = x_{MQ}\left(\frac{\psi_q}{x_{ls}} + \frac{\psi'_{kq}}{x'_{lkq}}\right) \quad \psi_{md} = \omega_b L_{md}\left(i_d + i'_{kd} + i'_f\right) = x_{MD}\left(\frac{\psi_d}{x_{ls}} + \frac{\psi'_{kd}}{x'_{lkd}} + \frac{\psi'_f}{x'_{lf}}\right)$$

where

$$\frac{1}{x_{MQ}} = \frac{1}{x_{mq}} + \frac{1}{x'_{lkq}} + \frac{1}{x_{ls}} \quad \frac{1}{x_{MD}} = \frac{1}{x_{md}} + \frac{1}{x'_{lkd}} + \frac{1}{x'_{lf}} + \frac{1}{x_{ls}}$$

Solve winding flux linkages using the following integral form of the winding voltage equations:

$$\psi_q = \omega_b \int \left(v_q - \frac{\omega_r}{\omega_b}\psi_d + \frac{r_s}{x_{ls}}\left(\psi_{mq} - \psi_q\right)\right)dt \qquad \psi'_{kq} = \frac{\omega_b r'_{kq}}{x'_{lkq}} \int \left(\psi_{mq} - \psi'_{kq}\right)dt$$

$$\psi_d = \omega_b \int \left(v_d + \frac{\omega_r}{\omega_b}\psi_q + \frac{r_s}{x_{ls}}\left(\psi_{md} - \psi_d\right)\right)dt \qquad \psi'_{kd} = \frac{\omega_b r'_{kd}}{x'_{lkd}} \int \left(\psi_{md} - \psi'_{kd}\right)dt$$

$$\psi_0 = \omega_b \int \left(v_0 - \frac{r_s}{x_{ls}}\psi_0\right)dt \qquad \psi'_f = \frac{\omega_b r'_f}{x_{md}} \int \left(E_f + \frac{x_{md}}{x'_{lf}}\left(\psi_{md} - \psi'_f\right)\right)dt$$

where $E_f = x_{md}\frac{v'_f}{\tau_f}$, and

$$\psi_q = x_{ls} i_q + \psi_{mq} \qquad \psi_d = x_{ls} i_d + \psi_{md} \qquad \psi_0 = x_{ls} i_0$$

$$\psi'_f = x'_{lf} i'_f + \psi_{md} \qquad \psi'_{kd} = x'_{lkd} i'_{kd} + \psi_{md} \qquad \psi'_{kq} = x'_{lkq} i'_{kq} + \psi_{mq}$$

Determine qd0 winding currents from winding flux linkages.

$$i_q = \frac{\psi_q - \psi_{mq}}{x_{ls}} \qquad i_d = \frac{\psi_d - \psi_{md}}{x_{ls}} \qquad i_0 = \frac{\psi_0}{x_{ls}}$$

$$i'_{kd} = \frac{\psi'_{kd} - \psi_{md}}{x'_{lkd}} \qquad i'_{kq} = \frac{\psi'_{kq} - \psi_{mq}}{x'_{lkq}} \qquad i'_f = \frac{\psi'_f - \psi_{md}}{x'_{lf}}$$

Transform qd0 currents to *abc* using $[\mathbf{i}_{abc}] = [\mathbf{T}_{qd0}^{-1}(\theta_r)][\mathbf{i}_{qd0}]$.

Using $(2/P)\,\omega_r(t)$ in place of $\omega_{rm}(t)$ and Eq. (66.54) to replace $d\omega_r(t)/dt$, Eq. (66.52) can be rewritten in terms of the slip speed:

$$\omega_r(t) - \omega_e = \frac{P}{2J}\int_0^t \left(T_{em} + T_{mech} - T_{damp}\right)dt \quad \text{elect. rad/s} \tag{66.55}$$

The angles $\theta_r(t)$ and $\theta_e(t)$ are the respective angles of the q_r and q_e axes of the rotor and synchronously **rotating reference frames** measured with respect to the stationary axis of the a-phase stator winding. Note that δ is the angle between the q_r axis of the rotor and the q_e axis of the reference synchronously rotating frame. For multi-machine systems, the rotor angles of the machines could all be referred to a common synchronously rotating reference frame at some bus or to the q_r axis of the rotor of a chosen reference machine.

A flowchart showing the main blocks for the above simulation is given in Fig. 66.36. As shown, the input voltages and output currents are in abc phase quantities. For some studies, the representation of the supply

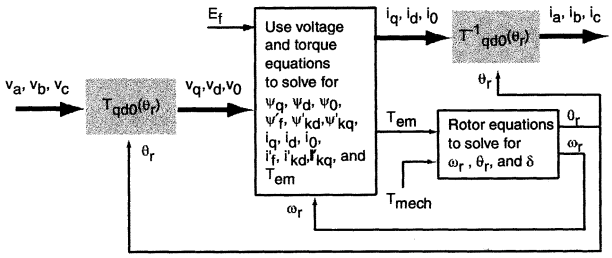

FIGURE 66.36 Block diagram of synchronous machine simulation.

network connected to the machine may not be in phase variables. For example, in linearized analysis, and also in transient stability of power systems, the network representation is usually in a synchronously **rotating reference frame.** In linearized analysis, the small-signal representation of the system is obtained by making small perturbations about an operating point. When the machines are in their respective rotor qd0 reference frames and the power network is in a synchronously rotating qd0 reference frame, the qd0 variables of the network and machines are in steady-state; thus linearized analysis about an operating point can be performed.

In transient stability, the main interest is the stability of the system after some large disturbances. The **models** employed are to portray the transient behavior of the power flows in the network and the electromechanical response of the machines. When dealing with large networks, the fast electromagnetic transients of the network are usually ignored and a static network representation is used. At each new time step of the **dynamic simulation**, an update of the network condition can be obtained by solving the phasor equations of the static network along with power or current injections from the machines. Because the phasor quantities of the network can be expressed as qd components of a synchronously rotating qd0 reference [Ong, 1998], the exchange of voltage variables between network and machine at the bus will require a rotational transformation given below

$$\begin{bmatrix} v_q \\ v_d \\ v_0 \end{bmatrix} = \begin{bmatrix} \cos\delta & -\sin\delta & 0 \\ \sin\delta & \cos\delta & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} v_q^e \\ v_d^e \\ v_0 \end{bmatrix} \tag{66.56}$$

where δ is the rotor angle of the q_r of the machines qd0 rotor reference frame measured with respect to the q_e axis of the network's synchronously rotating reference frame. The above transformation is also applicable to the exchange of current variables between network and machine.

Other synchronous machine models, besides that given in Table 66.3, are used in power system analysis. Typically, when the network is large and the phenomenon of interest is somewhat localized in nature, machines further away from the action can be represented by simpler models to save computation time. On the other hand, certain phenomena may require an even more sophisticated model than that given in Table 66.3. Canay [1993] described refinements in both the rotor circuit representation and the method of parameter determination to obtain a closer fit of the rotor variables. For studying shaft torsion, the damper circuit representation should not be ignored. In transient stability studies, machines beyond the first two neighborhoods of the disturbance can be represented by progressively simpler models with distance from the disturbance. Ignoring just the $p\psi_q$ and $p\psi_d$ terms and also setting $\omega = \omega_e$ in the stator equations will yield a so-called subtransient model of two orders less than the above given model. Further simplification by setting $p\psi'_{kq}$ and $p\psi'_{kd}$ to zero or omitting the damper winding equations will yield a so-called transient model of another two orders less. Finally, setting $p\psi'_f$ to zero and holding field flux linkage constant yields the constant field flux linkage model.

Significant savings in computing time can also be made by neglecting the subtransient and transient saliency of the machine. When rotor saliency is ignored, the effective stator impedances along the rotor's q_r and d_r axes are equal. In other words, the stator impedance in the synchronously rotating reference frame of the network will not be a function of rotor angle. Because its value need not be updated with the rotor angle at each time step of the dynamic simulation, the constant stator impedance of this model can be absorbed into the network's admittance or impedance representation.

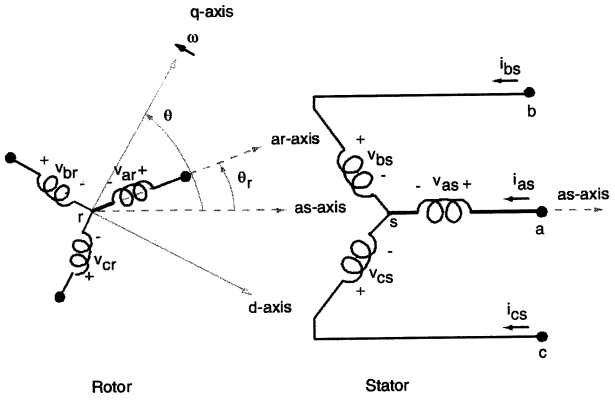

FIGURE 66.37 Circuit representation of induction machine.

Three-Phase Induction Machines

Figure 66.37 shows a circuit representation of a symmetrical three-phase induction machine with uniform airgap. The axes of the qd0 reference frames are assumed to be rotating at an arbitrary angular speed of ω. The angles $\theta(t)$ and $\theta_r(t)$, in electrical radians, can be determined from

$$\theta(t) = \int_0^t \omega(t)dt + \theta(0) \quad \theta_r(t) = \int_0^t \omega_r dt + \theta_r(0) \tag{66.57}$$

where $\theta(0)$ and $\theta_r(0)$ are their respective initial values at time $t = 0$.

As before, the voltage equations of the stator and rotor windings can be written using the coupled circuit approach. Corresponding voltage equations in the arbitrary qd0 reference frame can be obtained by applying the transformation $T_{qd0}(\theta)$ to the stator variables and the transformation $T_{qd0}(\theta - \theta_r)$ to the rotor variables. The equations of a symmetrical induction machine in the arbitrary reference frame in terms of the flux linkages per second and reactances are summarized in Table 66.5.

Seldom is there a need to simulate an induction machine in the arbitrary **rotating reference frame.** Induction machine loads are often simulated on the network's synchronously rotating reference frame in power system studies. However, in transient studies of adjustable speed drives, it is usually more convenient to simulate the induction machine and its converter on a stationary reference frame. Equations of the machine in the stationary and synchronously rotating reference frames can be obtained by setting the speed of the arbitrary reference frame, ω, to zero and ω_e, respectively.

Often the stator windings are connected to the supply by a three-wire connection, as shown in Fig. 66.38. With a three-wire connection, the stator zero-sequence current, i_{0s}, or $(i_{as} + i_{bs} + i_{cs})/3$, is zero by physical constraint, irrespective of whether the phase currents are balanced or not. The phase currents could be unbalanced, as in single-phasing operation. The stator neutral is free-floating. Its voltage, v_{sg}, measured with respect to some ground point g, need not be zero. Where the applied voltages are non-sinusoidal, as in the case when the supply is from a bridge inverter, v_{sg} is not zero.

In general, the input stator phase voltages, v_{ag}, v_{bg}, and v_{cg}, for the simulation of the induction machine can be established from the following relationships:

$$v_{as} = v_{ag} - v_{sg} \quad v_{bs} = v_{bg} - v_{sg} \quad v_{cs} = v_{cg} - v_{sg} \tag{66.58}$$

When point *s* is solidly connected to point, *g*, v_{sg} will be zero. Otherwise, if R_{sg} and L_{sg} are the resistance and inductance of the connection between points *s* and *g*, v_{sg} can be determined from

TABLE 66.5 Model of induction machine in arbitrary qdo

Voltage equations

$$v_{qs} = \frac{p}{\omega_b}\psi_{qs} + \frac{\omega}{\omega_b}\psi_{ds} + r_s i_{qs} \qquad v'_{qr} = \frac{p}{\omega_b}\psi'_{qr} + \left(\frac{\omega - \omega_r}{\omega_b}\right)\psi'_{dr} + r'_r i'_{qr}$$

$$v_{ds} = \frac{p}{\omega_b}\psi_{ds} - \frac{\omega}{\omega_b}\psi_{qs} + r_s i_{ds} \qquad v'_{dr} = \frac{p}{\omega_b}\psi'_{dr} - \left(\frac{\omega - \omega_r}{\omega_b}\right)\psi'_{qr} + r'_r i'_{dr}$$

$$v_{0s} = \frac{p}{\omega_b}\psi_{0s} + r_s i_{0s} \qquad v'_{0r} = \frac{p}{\omega_b}\psi'_{0r} + r'_r i'_{0r}$$

Flux linkage equations

$$\begin{bmatrix} \psi_{qs} \\ \psi_{ds} \\ \psi_{0s} \\ \psi'_{qr} \\ \psi'_{dr} \\ \psi'_{0r} \end{bmatrix} = \begin{bmatrix} x_{ls} + x_m & 0 & 0 & x_m & 0 & 0 \\ 0 & x_{ls} + x_m & 0 & 0 & x_m & 0 \\ 0 & 0 & x_{ls} & 0 & 0 & 0 \\ x_m & 0 & 0 & x'_{lr} + x_m & 0 & 0 \\ 0 & x_m & 0 & 0 & x'_{lr} + x_m & 0 \\ 0 & 0 & 0 & 0 & 0 & x'_{lr} \end{bmatrix} \begin{bmatrix} i_{qs} \\ i_{ds} \\ i_{0s} \\ i'_{qr} \\ i'_{dr} \\ i'_{0r} \end{bmatrix}$$

Torque equation

$$T_{em} = \frac{3}{2}\frac{P}{2\omega_r}\left[\frac{\omega}{\omega_b}\left(\psi_{ds} i_{qs} - \psi_{qs} i_{ds}\right) + \frac{\omega - \omega_r}{\omega_b}\left(\psi'_{dr} i'_{qr} - \psi'_{qr} i'_{dr}\right)\right] \quad \text{N-m}$$

$$= \frac{3}{2}\frac{P}{2\omega_b}\left(\psi'_{qr} i'_{dr} - \psi'_{dr} i'_{qr}\right) = \frac{3}{2}\frac{P}{2\omega_b}\left(\psi_{ds} i_{qs} - \psi_{qs} i_{ds}\right) = \frac{3}{2}\frac{P}{2\omega_b} x_m\left(i'_{dr} i_{qs} - i'_{qr} i_{ds}\right)$$

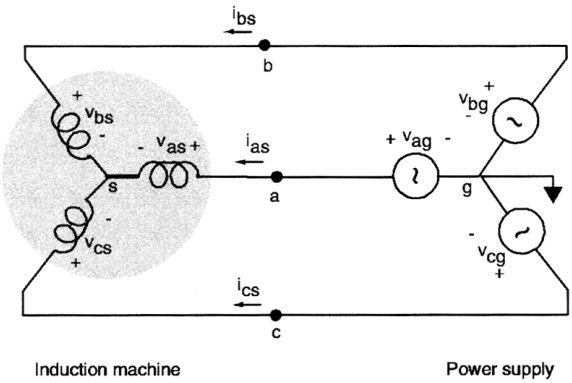

FIGURE 66.38 Three-wire power supply connection.

$$v_{sg} = R_{sg}\left(i_{as} + i_{bs} + {}_{cs}\right) + L_{sg}\frac{d}{dt}\left(i_{as} + i_{bs} + i_{cs}\right) = 3\left(R_{sg} + L_{sg}\frac{d}{dt}\right)i_{0s} \tag{66.59}$$

Where the stator windings' neutral is free-floating, v_{sg} can be determined from an open-circuit approximation of the form shown in Eq. (66.46).

Defining Terms

Model of an electric machine: Differential algebraic equations describing the dynamic behavior of the electric machine.

Dynamic simulation: Setting up of a model capable of portraying certain dynamic behavior of the real device and performing experiments on the model.

Rotating reference frame: A rotating qd plane. For example, a synchronously rotating reference frame is a qd plane that is rotating at synchronous speed as defined by the fundamental excitation frequency.

Further Information

The above chapter section has briefly described some of the techniques of the coupled-circuit approach and qd0 transformation in modeling, and the treatment of interface and floating neutral conditions in implementing a simulation. For more information on modeling and implementation of machine simulations, see [Ong, 1998].

Some techniques of modeling permanent magnet machines are described in [Rahman and Little, 1984; Ong, 1998].

Problems concerning effects of local saturation, anisotropic magnetic properties, and eddy-currents in machines require detailed modeling of the field region. Two- and three-dimensional models of the field region can be solved using finite-element [Salon, 1995] and boundary-element [Shen, 1995] techniques. Although the field models are not as amenable as the circuit models for use in large system studies, they have been successfully integrated with lumped circuit element models in dynamic simulations [Demerdash and Alhamadi, 1995; Preston et al., 1988].

67.1 Introduction

Energy management is the process of monitoring, coordinating, and controlling the generation, transmission, and distribution of electrical energy. The physical plant to be managed includes generating plants that produce energy fed through transformers to the high-voltage transmission network (grid), interconnecting generating plants and load centers. Transmission lines terminate at substations that perform switching, voltage transformation, measurement, and control. Substations at load centers transform to subtransmission and distribution levels. These lower-voltage circuits typically operate radially, i.e., no normally closed paths between substations through subtransmission or distribution circuits. (Underground cable networks in large cities are an exception.)

Since transmission systems provide negligible energy storage, supply and demand must be balanced by either generation or load. Production is controlled by turbine governors at generating plants, and automatic generation control is performed by control center computers remote from generating plants. Load management, sometimes called demand-side management, extends remote supervision and control to subtransmission and distribution circuits, including control of residential, commercial, and industrial loads.

Events such as lightning strikes, short circuits, equipment failure, or accidents may cause a system fault. Protective relays actuate rapid, local control through operation of circuit breakers before operators can respond. The goal is to maximize safety, minimize damage, and continue to supply load with the least inconvenience to customers. Data acquisition provides operators and computer control systems with status and measurement information needed to supervise overall operations. **Security** control analyzes the consequences of faults to establish operating conditions that are both robust and economical.

Energy management is performed at control centers (see Fig. 67.1), typically called system control centers, by computer systems called *energy management systems* (EMS). Data acquisition and remote control is performed by computer systems called *supervisory control and data acquisition* (SCADA) systems. These latter systems may be installed at a variety of sites including system control centers. An EMS typically includes a SCADA "front-end" through which it communicates with generating plants, substations, and other remote devices.

Figure 67.2 illustrates the **applications** layer of modern EMS as well as the underlying layers on which it is built: the operating system, a database manager, and a utilities/services layer.

FIGURE 67.1 Central dispatch operation arena of Entergy Corporation's Beaumont Control Center (Beaumont, Texas) which includes a modern EMS.

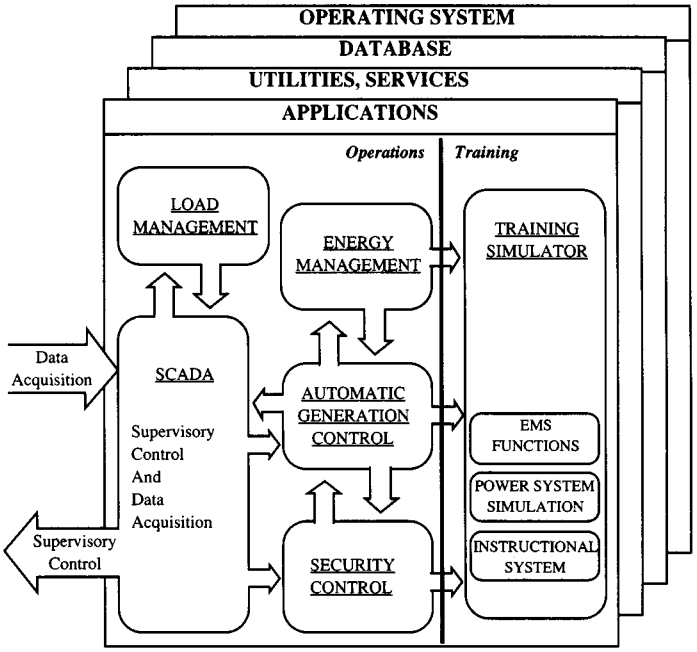

FIGURE 67.2 Layers of a modern EMS.

67.2 Power System Data Acquisition and Control

A SCADA system consists of a master station that communicates with **remote terminal units** (RTUs) for the purpose of allowing operators to observe and control physical plants. Generating plants and transmission substations certainly justify RTUs, and their installation is becoming more common in distribution substations as costs decrease. RTUs transmit device status and measurements to, and receive control commands and setpoint data from, the master station. Communication is generally via dedicated circuits operating in the range of 600 to 4800 bits/s with the RTU responding to periodic requests initiated from the master station (polling) every 2 to 10 s, depending on the criticality of the data.

The traditional functions of SCADA systems are summarized:

- Data acquisition: Provides telemetered measurements and status information to operator.
- Supervisory control: Allows operator to remotely control devices, e.g., open and close circuit breakers. A "select before operate" procedure is used for greater safety.
- Tagging: Identifies a device as subject to specific operating restrictions and prevents unauthorized operation.

- Alarms: Informs operator of unplanned events and undesirable operating conditions. Alarms are sorted by criticality, area of responsibility, and chronology. Acknowledgment may be required.
- Logging: Logs all operator entry, all alarms, and selected information.
- Load shed: Provides both automatic and operator-initiated tripping of load in response to system emergencies.
- Trending: Plots measurements on selected time scales.

Since the master station is critical to power system operations, its functions are generally distributed among several computer systems depending on specific design. A dual computer system configured in primary and standby modes is most common. SCADA functions are listed below without stating which computer has specific responsibility.

- Manage communication circuit configuration
- Downline load RTU files
- Maintain scan tables and perform polling
- Check and correct message errors
- Convert to engineering units
- Detect status and measurement changes
- Monitor abnormal and out-of-limit conditions
- Log and time-tag sequence of events
- Detect and annunciate alarms
- Respond to operator requests to:
  - Display information
  - Enter data
  - Execute control action
  - Acknowledge alarms
- Transmit control action to RTUs
- Inhibit unauthorized actions
- Maintain historical files
- Log events and prepare reports
- Perform load shedding

67.3 Automatic Generation Control

Automatic generation control (AGC) consists of two major and several minor functions that operate on-line in real time to adjust the generation against load at minimum cost. The major functions are load frequency control and economic **dispatch,** each of which is described below. The minor functions are reserve monitoring, which assures enough reserve on the system, **interchange** scheduling, which initiates and completes scheduled interchanges, and other similar monitoring and recording functions.

Load Frequency Control

Load frequency control (LFC) has to achieve three primary objectives which are stated below in priority order:

1. To maintain frequency at the scheduled value
2. To maintain net power interchanges with neighboring control areas at the scheduled values
3. To maintain power allocation among units at economically desired values

The first and second objectives are met by monitoring an error signal, called *area control error* (ACE), which is a combination of net interchange error and frequency error and represents the power imbalance between

generation and load at any instant. This ACE must be filtered or smoothed such that excessive and random changes in ACE are not translated into control action. Since these excessive changes are different for different systems, the filter parameters have to be tuned specifically for each control area. The filtered ACE is then used to obtain the proportional plus integral control signal. This control signal is modified by limiters, deadbands, and gain constants that are tuned to the particular system. This control signal is then divided among the generating units under control by using participation factors to obtain *unit control errors* (UCE).

These participation factors may be proportional to the inverse of the second derivative of the cost of unit generation so that the units would be loaded according to their costs, thus meeting the third objective. However, cost may not be the only consideration because the different units may have different response rates and it may be necessary to move the faster generators more to obtain an acceptable response. The UCEs are then sent to the various units under control and the generating units monitored to see that the corrections take place. This control action is repeated every 2 to 6 s.

In spite of the integral control, errors in frequency and net interchange do tend to accumulate over time. These time errors and accumulated interchange errors have to be corrected by adjusting the controller settings according to procedures agreed upon by the whole interconnection. These accumulated errors as well as ACE serve as performance measures for LFC.

The main philosophy in the design of LFC is that each system should follow its own load very closely during normal operation, while during emergencies each system should contribute according to its relative size in the interconnection without regard to the locality of the emergency. Thus, the most important factor in obtaining good control of a system is its inherent capability of following its own load. This is guaranteed if the system has adequate regulation margin as well as adequate response capability. Systems that have mainly thermal generation often have difficulty in keeping up with the load because of the slow response of the units.

The design of the controller itself is an important factor, and proper tuning of the controller parameters is needed to obtain "good" control without "excessive" movement of units. Tuning is system-specific, and although system simulations are often used as aids, most of the parameter adjustments are made in the field using heuristic procedures.

Economic Dispatch

Since all the generating units that are on-line have different costs of generation, it is necessary to find the generation levels of each of these units that would meet the load at the minimum cost. This has to take into account the fact that the cost of generation in one generator is not proportional to its generation level but is a nonlinear function of it. In addition, since the system is geographically spread out, the transmission losses are dependent on the generation pattern and must be considered in obtaining the optimum pattern.

Certain other factors have to be considered when obtaining the optimum generation pattern. One is that the generation pattern provide adequate reserve margins. This is often done by constraining the generation level to a lower boundary than the generating capability. A more difficult set of constraints to consider are the transmission limits. Under certain real-time conditions it is possible that the most economic pattern may not be feasible because of unacceptable line flows or voltage conditions. The present-day economic dispatch (ED) algorithm cannot handle these security constraints. However, alternative methods based on optimal power flows have been suggested but have not yet been used for real-time dispatch.

The minimum cost dispatch occurs when the incremental cost of all the generators is equal. The cost functions of the generators are nonlinear and discontinuous. For the equal marginal cost algorithm to work it is necessary for them to be convex. These incremental cost curves are often represented as monotonically increasing piecewise-linear functions. A binary search for the optimal marginal cost is conducted by summing all the generation at a certain marginal cost and comparing it with the total power demand. If the demand is higher, a higher marginal cost is needed, and vice versa. This algorithm produces the ideal setpoints for all the generators for that particular demand, and this calculation is done every few minutes as the demand changes.

The losses in the power system are a function of the generation pattern, and they are taken into account by multiplying the generator incremental costs by the appropriate penalty factors. The penalty factor for each generator is a reflection of the sensitivity of that generator to system losses, and these sensitivities can be obtained from the transmission loss factors (Section 67.6).

This ED algorithm generally applies to only thermal generation units that have cost characteristics of the type discussed here. The hydro units have to be dispatched with different considerations. Although there is no cost for the water, the amount of water available is limited over a period, and the displacement of fossil fuel by this water determines its worth. Thus, if the water usage limitation over a period is known, say from a previously computed hydro optimization, the water worth can be used to dispatch the hydro units.

LFC and the ED functions both operate automatically in real time but with vastly different time periods. Both adjust generation levels, but LFC does it every few seconds to follow the load variation, while ED does it every few minutes to assure minimal cost. Conflicting control action is avoided by coordinating the control errors. If the unit control errors from LFC and ED are in the same direction, there is no conflict. Otherwise, a logic is set to either follow load (permissive control) or follow economics (mandatory control).

Reserve Monitoring

Maintaining enough reserve capacity is required in case generation is lost. Explicit formulas are followed to determine the spinning (already synchronized) and ready (10 min) reserves required. The availability can be assured by the operator manually, or, as mentioned previously, the ED can also reduce the upper dispatchable limits of the generators to keep such generation available.

Interchange Transaction Scheduling

The contractual exchange of power between utilities has to be taken into account by the LFC and ED functions. This is done by calculating the net interchange (sum of all the buy and sale agreements) and adding this to the generation needed in both the LFC and ED. Since most interchanges begin and end on the hour, the net interchange is ramped from one level to the new over a 10- or 20-min period straddling the hour. The programs achieve this automatically from the list of scheduled transactions.

67.4 Load Management

SCADA, with its relatively expensive RTUs installed at distribution substations, can provide status and measurements for distribution feeders at the substation. Distribution automation equipment is now available to measure and control at locations dispersed along distribution circuits. This equipment can monitor sectionalizing devices (switches, interruptors, fuses), operate switches for circuit reconfiguration, control voltage, read customers' meters, implement time-dependent pricing (on-peak, off-peak rates), and switch customer equipment to manage load. This equipment requires significantly increased functionality at distribution control centers.

Distribution control center functionality varies widely from company to company, and the following list is evolving rapidly.

- Data acquisition: Acquires data and gives the operator control over specific devices in the field. Includes data processing, quality checking, and storage.
- Feeder switch control: Provides remote control of feeder switches.
- Tagging and alarms: Provides features similar to SCADA.
- Diagrams and maps: Retrieves and displays distribution maps and drawings. Supports device selection from these displays. Overlays telemetered and operator-entered data on displays.
- Preparation of switching orders: Provides templates and information to facilitate preparation of instructions necessary to disconnect, isolate, reconnect, and reenergize equipment.
- Switching instructions: Guides operator through execution of previously prepared switching orders.
- Trouble analysis: Correlates data sources to assess scope of trouble reports and possible dispatch of work crews.
- Fault location: Analyzes available information to determine scope and location of fault.
- Service restoration: Determines the combination of remote control actions which will maximize restoration of service. Assists operator to dispatch work crews.

- Circuit continuity analysis: Analyzes circuit topology and device status to show electrically connected circuit segments (either energized or deenergized).
- Power factor and voltage control: Combines substation and feeder data with predetermined operating parameters to control distribution circuit power factor and voltage levels.
- Electrical circuit analysis: Performs circuit analysis, single-phase or three-phase, balanced or unbalanced.
- Load management: Controls customer loads directly through appliance switching (e.g., water heaters) and indirectly through voltage control.
- Meter reading: Reads customers' meters for billing, peak demand studies, time of use tariffs. Provides remote connect/disconnect.

67.5 Energy Management

Generation control and ED minimize the current cost of energy production and transmission within the range of available controls. Energy management is a supervisory layer responsible for economically scheduling production and transmission on a global basis and over time intervals consistent with cost optimization. For example, water stored in reservoirs of hydro plants is a resource that may be more valuable in the future and should, therefore, not be used now even though the cost of hydro energy is currently lower than thermal generation. The global consideration arises from the ability to buy and sell energy through the interconnected power system; it may be more economical to buy than to produce from plants under direct control. Energy accounting processes transaction information and energy measurements recorded during actual operation as the basis of payment for energy sales and purchases.

Energy management includes the following functions:

- System load forecast: Forecasts system energy demand each hour for a specified forecast period of 1 to 7 days.
- Unit commitment: Determines start-up and shut-down times for most economical operation of thermal generating units for each hour of a specified period of 1 to 7 days.
- Fuel scheduling: Determines the most economical choice of fuel consistent with plant requirements, fuel purchase contracts, and stockpiled fuel.
- Hydro-thermal scheduling: Determines the optimum schedule of thermal and hydro energy production for each hour of a study period up to 7 days while ensuring that hydro and thermal constraints are not violated.
- Transaction evaluation: Determines the optimal incremental and production costs for exchange (purchase and sale) of additional blocks of energy with neighboring companies.
- Transmission loss minimization: Recommends controller actions to be taken in order to minimize overall power system network losses.
- Security constrained dispatch: Determines optimal outputs of generating units to minimize production cost while ensuring that a network security constraint is not violated.
- Production cost calculation: Calculates actual and economical production costs for each generating unit on an hourly basis.

67.6 Security Control

Power systems are designed to survive all probable contingencies. A contingency is defined as an event that causes one or more important components such as transmission lines, generators, and transformers to be unexpectedly removed from service. Survival means the system stabilizes and continues to operate at acceptable voltage and frequency levels without loss of load. Operations must deal with a vast number of possible conditions experienced by the system, many of which are not anticipated in planning. Instead of dealing with the impossible task of analyzing all possible system states, security control starts with a specific state: the current state if executing the real-time network sequence; a postulated state if executing a study sequence. Sequence means sequential execution of programs that perform the following steps:

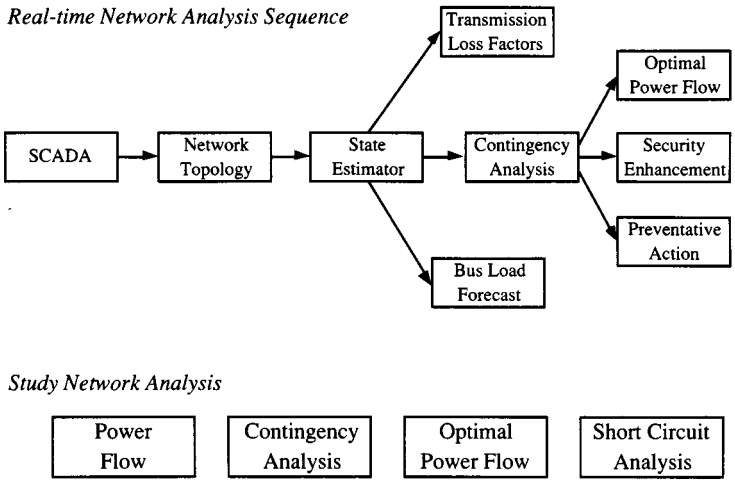

FIGURE 67.3 Real-time and study network analysis sequences.

1. Determine the state of the system based on either current or postulated conditions.
2. Process a list of contingencies to determine the consequences of each contingency on the system in its specified state.
3. Determine preventive or corrective action for those contingencies which represent unacceptable risk.

Real-time and study network analysis sequences are diagramed in Fig. 67.3.

Security control requires topological processing to build network models and uses large-scale ac network analysis to determine system conditions. The required applications are grouped as a network subsystem which typically includes the following functions:

- Topology processor: Processes real-time status measurements to determine an electrical connectivity (bus) model of the power system network.
- State estimator: Uses real-time status and analog measurements to determine the "best" estimate of the state of the power system. It uses a redundant set of measurements; calculates voltages, phase angles, and power flows for all components in the system; and reports overload conditions.
- Power flow: Determines the steady-state conditions of the power system network for a specified generation and load pattern. Calculates voltages, phase angles, and flows across the entire system.
- Contingency analysis: Assesses the impact of a set of contingencies on the state of the power system and identifies potentially harmful contingencies that cause operating limit violations.
- Optimal power flow: Recommends controller actions to optimize a specified objective function (such as system operating cost or losses) subject to a set of power system operating constraints.
- Security enhancement: Recommends corrective control actions to be taken to alleviate an existing or potential overload in the system while ensuring minimal operational cost.
- Preventive action: Recommends control actions to be taken in a "preventive" mode before a contingency occurs to preclude an overload situation if the contingency were to occur.
- Bus load forecasting: Uses real-time measurements to adaptively forecast loads for the electrical connectivity (bus) model of the power system network.
- Transmission loss factors: Determines incremental loss sensitivities for generating units; calculates the impact on losses if the output of a unit were to be increased by 1 MW.
- Short-circuit analysis: Determines fault currents for single-phase and three-phase faults for fault locations across the entire power system network.

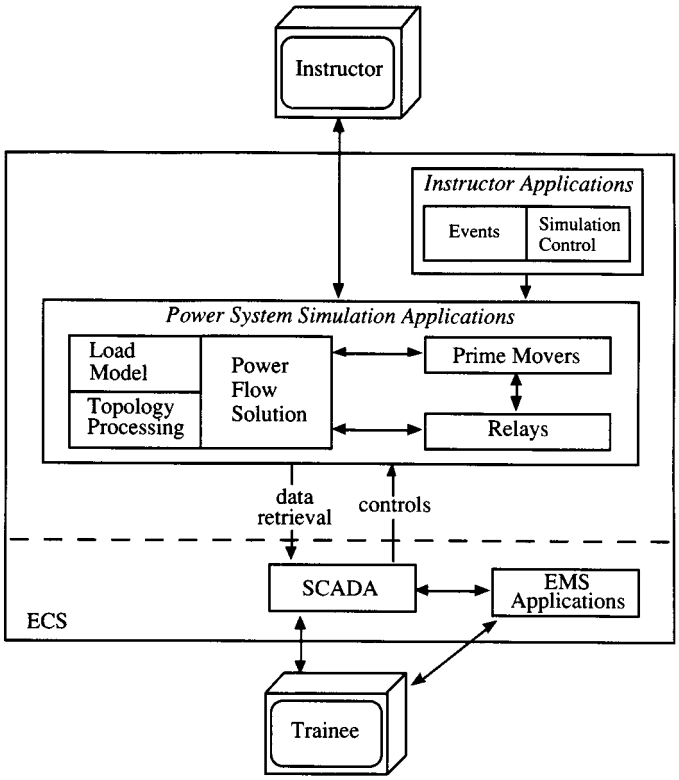

FIGURE 67.4 OTS block diagram.

67.7 Operator Training Simulator

Training simulators were originally created as generic systems for introducing operators to the electrical and dynamic behavior of power systems. Today, they model actual power systems with reasonable fidelity and are integrated with EMS to provide a realistic environment for operators and dispatchers to practice normal, every-day operating tasks and procedures as well as experience emergency operating situations. The various training activities can be safely and conveniently practiced with the simulator responding in a manner similar to the actual power system.

An operator training simulator (OTS) can be used in an investigatory manner to recreate past actual operational scenarios and to formulate system restoration procedures. Scenarios can be created, saved, and reused. The OTS can be used to evaluate the functionality and performance of new real-time EMS functions and also for tuning AGC in an off-line, secure environment.

The OTS has three main subsystems (Fig. 67.4).

Energy Control System

The energy control system (ECS) emulates normal EMS functions and is the only part of the OTS with which the trainee interacts. It consists of the supervisory control and data acquisition (SCADA) system, generation control system, and all other EMS functions.

Power System Dynamic Simulation

This subsystem simulates the dynamic behavior of the power system. System frequency is simulated using the "long-term dynamics" system model, where frequency of all units is assumed to be the same. The prime-mover dynamics are represented by models of the units, turbines, governors, boilers, and boiler auxiliaries. The network

flows and states (bus voltages and angles, topology, transformer taps, etc.) are calculated at periodic intervals. Relays are modeled, and they emulate the behavior of the actual devices in the field.

Instructional System

This subsystem includes the capabilities to start, stop, restart, and control the simulation. It also includes making savecases, retrieving savecases, reinitializing to a new time, and initializing to a specific real-time situation.

It is also used to define event schedules. Events are associated with both the power system simulation and the ECS functions. Events may be deterministic (occur at a predefined time), conditional (based on a predefined set of power system conditions being met), or probabilistic (occur at random).

Defining Terms

Application: A software function within the energy management system which allows the operator to perform a specific set of tasks to meet a specific set of objectives.

Dispatch: The allocation of generation requirement to the various generating units that are available.

Distribution system: That part of the power system network which is connected to, and responsible for, the final delivery of power to the customer; typically the part of the network that operates at 33 kV and below, to 120 V.

Interchange or transaction: A negotiated purchase or sale of power between two companies.

Remote terminal unit (RTU): Hardware that gathers system-wide real-time data from various locations within substations and generating plants for telemetry to the energy management system.

Security: The ability of the power system to sustain and survive planned and unplanned events without violating operational constraints.

68.1 Introduction

Power system software can be grouped in many different ways, e.g., functionality, computer platform, etc. but here it is grouped by end user. There are four major groups of end users for the software:

- major utilities
- small utilities, and industry consumers of electricity
- consultants
- universities

Large comprehensive program packages are required by utilities. They are complex, with many different functions and must have very easy input/output (IO). They serve the needs of a single electrical system and may be tailor-made for the customer. They can be integrated with the electrical system using SCADA (Supervisory Control And Data Acquisition). It is not within the scope of this chapter to discuss the merits of these programs. Suffice to say that the component programs used in these packages usually have the same generic/development roots as the programs used by the other three end user groups.

The programs used by the other three groups have usually been initially created in the universities. They start life as research programs and later are used for teaching and/or consultancy programs. Where the consultant is also an academic, then the programs may well retain their crude research style IO. However, if they are to be used by others who are not so familiar with the algorithms, then usually they are modified to make them more user friendly. Once this is achieved, the programs become commercial and are used by consultants, industry, and utilities. These are the types of programs that are now so commonly seen in the engineering journals quite often bundled together in a generic package.

68.2 Early Analysis Programs

Two of the earliest programs to be developed for power system analysis were the fault and load flow (power flow) programs. Both were originally produced in the late 1950s. Many programs in use today are either based on these two types of program or have one or the other embedded in them.

Load Flow (Power Flow)

The need to know the flow patterns and voltage profiles in a network was the driving force behind the development of load flow programs.

Although the network is linear, load flow analysis is iterative because of nodal (busbar) constraints. At most busbars the active and reactive powers being delivered to customers are known but the voltage level is not. As far as the load flow analysis is concerned, these busbars are referred to as PQ buses. The generators are scheduled to deliver a specific active power to the system and usually the voltage magnitude of the generator terminals is fixed by automatic voltage regulation. These busbars are known as PV buses.

As losses in the system cannot be determined before the load flow solution, one generator busbar only has its voltage magnitude specified. In order to give the required two specifications per node, this bus also has its voltage angle defined to some arbitrary value, usually zero. This busbar is known as the slack bus. The slack bus is a mathematical requirement for the program and has no exact equivalent in reality. However, in operating practice, the total load plus the losses are not known. When a system is not in power balance, i.e., when the input power does not equal the load power plus losses, the imbalance modifies the rotational energy stored in the system. The system frequency thus rises if the input power is too large and falls if the input power is too little. Usually a generating station and probably one machine is given the task of keeping the frequency constant by varying the input power. This control of the power entering a node can be seen to be similar to the slack bus.

The algorithms first adopted had the advantages of simple programming and minimum storage but were slow to converge requiring many iterations. The introduction of ordered elimination, which gives implicit inversion of the network matrix, and sparsity programming techniques, which reduces storage requirements, allowed much better algorithms to be used. The Newton-Raphson method gave convergence to the solution in only a few iterations. Using Newtonian methods of specifying the problem, a Jacobian matrix containing the partial derivatives of the system at each node can be constructed. The solution by this method has quadratic convergence. This method was followed quite quickly by the Fast Decoupled Newton-Raphson method. This exploited the fact that under normal operating conditions, and providing that the network is predominately reactive, the voltage angles are not affected by reactive power flow and voltage magnitudes are not effected by real power flow. The Fast Decoupled method requires more iterations to converge but each iteration uses less computational effort than the Newton Raphson method. A further advantage of this method is the robustness of the algorithm.

Further refinements can be added to a load flow program to make it give more realistic results. Transformer on-load tap changers, voltage limits, active and reactive power limits, plus control of the voltage magnitudes at buses other than the local bus help to bring the results close to reality. Application of these limits can slow down convergence.

The problem of obtaining an accurate, load flow solution, with a guaranteed and fast convergence has resulted in more technical papers than any other analysis topic. This is understandable when it is realized that the load flow solution is required during the running of many other types of power system analyses. While improvements have been made, there has been no major breakthrough in performance. It is doubtful if such an achievement is possible as the time required to prepare the data and process the results represents a significant part of the overall time of the analysis.

Fault Analysis

A fault analysis program derives from the need to adequately rate switchgear and other busbar equipment for the maximum possible fault current that could flow through them.

Initially only three-phase faults were considered and it was assumed that all busbars were operating at unity per unit voltage prior to the fault occurring. The load current flowing prior to the fault was also neglected.

By using the results of a load flow prior to performing the fault analysis, the load currents can be added to the fault currents allowing a more accurate determination of the total currents flowing in the system.

Unbalanced faults can be included by using symmetrical components. The negative sequence network is similar to the positive sequence network but the zero sequence network can be quite different primarily because of ground impedance and transformer winding configurations.

Transient Stability

After a disturbance, due usually to a network fault, the synchronous machine's electrical loading changes and the machines speed up (under very light loading conditions they can slow down). Each machine will react differently depending on its proximity to the fault, its initial loading and its time constants. This means that the angular positions of the rotors relative to each other change. If any angle exceeds a certain threshold (usually between 140° and 160°) the machine will no longer be able to maintain synchronism. This almost always results in its removal from service.

Early work on transient stability had concentrated on the reaction of one synchronous machine coupled to a very large system through a transmission line. The large system can be assumed to be infinite with respect to the single machine and hence can be modeled as a pure voltage source. The synchronous machine is modeled by the three phase windings of the stator plus windings on the rotor representing the field winding and the eddy current paths. These are resolved into two axes, one in line with the direct axis of the rotor and the other in line with the quadrature axis situated 90° (electrical) from the direct axis. The field winding is on the direct axis. Equations can be developed which determine the voltage in any winding depending on the current flows in all the other windings. A full set of differential equations can be produced which allows the response of the machine to various electrical disturbances to be found. The variables must include rotor angle and rotor speed which can be evaluated from a knowledge of the power from the turbine into, and power to the system out of the machine. The great disadvantage with this type of analysis is that the rotor position is constantly changing as it rotates. As most of the equations involve trigonometrical functions relating to stator and rotor windings, the matrices must be constantly reevaluated. In the most severe cases of network faults the results, once the dc transients decay, are balanced. Further, on removal of the fault the network is considered to be balanced. There is thus much computational effort involved in obtaining detailed information for each of the three phases which is of little value to the power system engineer. By contrast, this type of analysis is very important to machine designers. However, programs have been written for multi-machine systems using this method.

Several power system catastrophes in the U.S. and Europe in the 1960s gave a major boost to developing transient stability programs. What was required was a simpler and more efficient method of representing the machines in large power systems.

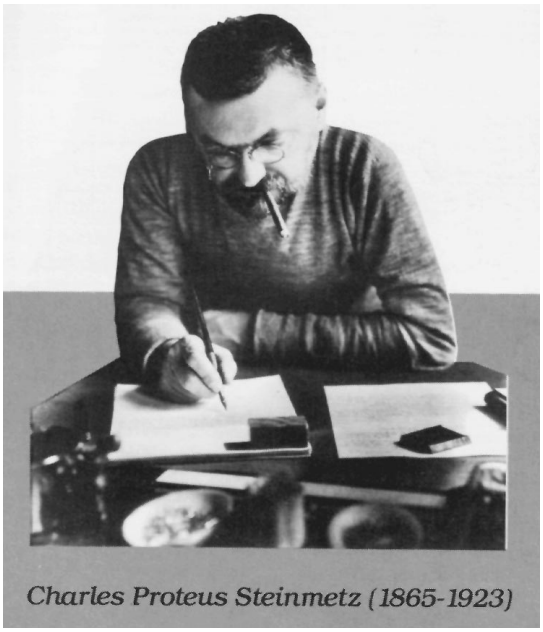
Initially, transient stability programs all ran in the time domain. A set of differential equations is developed to describe the dynamic behavior of the synchronous machines. These are linked together by algebraic equations for the network and any other part of the system that has a very fast response, i.e., an insignificant time constant, relative to the synchronous machines. All the machine equations are written in the direct and quadrature axes of the rotor so that they are constant regardless of the rotor position. The network is written in the real and imaginary axes similar to that used by the load flow and faults programs. The transposition between these axes only requires knowledge of the rotor angle relative to the synchronously rotating frame of reference of the network.

Later work involved looking at the response of the system, not to major disturbances but to the build-up of oscillations due to small disturbances and poorly set control systems. As the time involved for these disturbances to occur can be large, time domain solutions are not suitable and frequency domain models of the system were produced. Lyapunov functions have also been used, but good models have been difficult to produce. However, they are now of sufficiently good quality to compete with time domain models where quick estimates of stability are needed such as in the day to day operation of a system.

Charles Proteus Steinmetz (1865–1923)

Charles Steinmetz (1865–1923) came to the United States in 1889 from Breslau, Germany, where he was a student at the University of Breslau. He joined the inventor Rudolf Eickemeyer in building electric apparatus at Yonkers, New York, and at age 27 he formulated the law of hysteresis, which made it possible to reduce the loss of efficiency in electrical apparatus. When Eickemeyer's firm was bought by General Electric, Steinmetz joined the new company, beginning a 31-year relationship that ended only with his death.

His improvements in methods of making calculations of current in alternating current circuits revolutionized power engineering, and his theory of electrical transients stood as another important contribution. In the midst of his GE career, Steinmetz was also a professor at Union College and a vocal champion of civic and political causes. (Courtesy of the IEEE Center for the History of Electrical Engineering.)



Charles Proteus Steinmetz (1865-1923)

Fast Transients

While the transient stability program assumed a fast transient response was equivalent to an instantaneous response and only concentrated on the slower response of the synchronous machines, the requirement to model the fast transient response of traveling waves on transmission lines brought about the development of programs that treated variables with large time constants as if they were constants and modeled the variables with very small time constants by differential equations.

The program is based on the equations governing voltage and current wave propagation along a lossless line. Attenuation is then included using suitable lumped resistances. A major feature of the method is that inductance and capacitance can both be represented by resistance in parallel with a current source. This allows a purely resistive network to be formed.

Whereas, with the most other programs, source code was treated as intellectual property, the development of the fast transient program was done by many different researchers who pooled their ideas and programs. An electromagnetic transient program developed quickly and it probably became the first power systems analysis tool to be used for many different purposes throughout the world. From this base, numerous commercial packages have been developed.

In parallel with the development of electromagnetic transient programs, several state variable programs were produced to examine the fast transient behavior of parts of the electrical system, such as ac transmission lines and HVdc transmission systems. As these programs were specifically designed for the purpose they were intended, it gave them certain advantages over the general purpose electromagnetic transient program.

Reliability

Of constant concern to the operators of power systems is the reliability of equipment. This has become more important as systems are run harder. In the past, reliability was ensured by building in reserve equipment which was either connected in parallel with other similar devices or could be easily connected in the event of a failure. Not only that, knowledge of the capabilities of materials has increased so that equipment can be built with a more certain level of reliability.

However, reliability of a system is governed by the reliability of all the parts and their configuration. Much work has been done on the determination of the reliability of power systems but work is still being done to fully model power system components and integrate them into system reliability models.

The information that is obtained from reliability analysis is very much governed by the nature of the system. The accepted breakdown of a power system containing generation, transmission, and distribution is into three hierarchical levels. The first level is for the generation facilities alone, the second level contains generation and transmission, while the third level contains generation, transmission, and distribution facilities. Much of the early work was focused on the generation facilities. The reasons for this was that, first, more information was available about the generation; second, the size of the problem was smaller; and, third, the emphasis of power systems was placed in generation. With the onset of deregulation, distribution and customer requirements are now considered paramount.

At the generation and transmission levels, the loss of load expectation and frequency and duration evaluation are prime reliability indicators. A power system component may well have several derated states along with the fully operational and non-operational states. Recursive techniques are available to construct the system models and they can include multi-state components.

The usual method for evaluating reliability indices at the distribution level, such as the average interruption duration per customer per year, is an analytical approach based on a failure modes assessment and the use of equations for series and parallel networks.

Economic Dispatch and Unit Commitment

Many programs are devoted to power system operational problems and the minimization of the cost of production and delivery of energy is of great importance. Two types of program which deal with this problem are economic dispatch and unit commitment.

Economic dispatch uses optimization techniques to determine the level of power each generator (unit) must supply to the system in order to meet the demand. Each unit must have its generating costs, which will be nonlinear functions of energy, defined along with the units operational maximum and minimum power limits. The transmission losses of the system must also be taken into account to ensure an overall minimum cost.

Unit commitment calculates the necessary generating units that should be connected (committed) at any time in order to supply the demand and losses plus allow sufficient reserve capability to withstand a load increase or accidental loss of a generating unit. Several operating restrictions must be taken into account when determining which machines to commit or decommit. These include maximum and minimum running times for a unit and the time needed to commit a unit. Fuel availability constraints must also be considered. For example, there may be limited fuel reserves such as coal stocks or water in the dam. Other fuel constraints may be minimum water flows below the dam or agreements to purchase minimum amounts of fuel. Determining unit commitment for a specific time cannot be evaluated without consideration of the past operational configuration or the future operating demands.

68.3 The Second Generation of Programs

It is not the intention to suggest that only the above programs were being produced initially. However, most of the other programs remained as either research tools or one-off analysis programs. The advent of the PC gave a universal platform on which most users and programs could come together. This process was further assisted when windowing reduced the need for such a high level of computer literacy on the part of users. For

example, electromagnetic transient program's generality, which made it so successful, is also a handicap and it requires good programming skill to utilize it fully. This has lead to several commercial programs that are loosely based on the methods of analysis first used in by the electromagnetic transient program. They have the advantage of a much improved user interface.

Not all software is run on PCs. Apart from the Macintosh, which has a similar capability to a PC but which is less popular with engineers, more powerful workstations are available usually based on the Unix operating system. Mini computers and mainframe computers are also still in general use in universities and industry even though it had been thought that they would be totally superseded.

Hardware and software for power system operation and control required at utility control centers is usually sold as a total package. These systems, although excellent, can only be alluded to here as the information is proprietary. The justification for a particular configuration requires input from many diverse groups within the utility.

Graphics

Two areas of improvement that stand out in this second wave of generally available programs are both associated with the graphical capabilities of computers. A good diagram can be more easily understood than many pages of text or tables.

The ability to produce graphical output of the results of an analysis has made the use of computers in all engineering fields, not just power system analysis, much easier. Tabulated results are never easy to interpret. They are also often given to a greater degree of accuracy than the input data warrants. A graph of the results, where appropriate, can make the results very easy to interpret and if there is also an ability to graph any variable with any other, or two if three dimensions can be utilized, then new and possibly significant information can be quickly assimilated.

New packages became available for business and engineering which were based on either the spreadsheet or database principle. These also had the ability to produce graphical output. It was no longer essential to know a programming language to do even quite complex engineering analysis. The programming was usually inefficient and obtaining results was more laborious, e.g., each iteration had to be started by hand. But, as engineers had to use these packages for other work, they became very convenient tools.

A word of caution here—be careful that the results are graphed in an appropriate manner. Most spreadsheet packages have very limited x-axis (horizontal) manipulation. Provided the x-axis data comes in regular steps, the results are acceptable. However, we have seen instances where very distorted graphs have been presented because of this problem.

Apart from the graphical interpretation of results, there are now several good packages that allow the analyst to enter the data graphically. It is a great advantage to be able to develop a one-line, or three-phase, diagram of a network directly with the computer. All the relevant system components can be included. Parameter data still require entry in a more orthodox manner but by merely clicking on a component, a data form for that component can be made available. The chances of omitting a component are greatly reduced with this type of data entry. Further, the same system diagram can be used to show the results of some analyses.

An extension of the network diagram input is to make the diagram relate to the actual topography. In these cases, the actual routes of transmission lines are shown and can be superimposed on computer generated geographical maps. The lines in these cases have their lengths automatically established and, if the line characteristics are known, the line parameters can be calculated.

These topographical diagrams are an invaluable aid for power reticulation problems, for example, the minimum route length of reticulation given all the points of supply and the route constraints. Other optimization algorithms include determination of line sizes and switching operations.

The analysis techniques can be either linear or nonlinear. If successful, the nonlinear algorithm is more accurate but these techniques suffer from larger data storage requirements, greater computational time, and possible divergence. There are various possible optimization techniques that can and have been applied to this problem. There is no definitive answer and each type of problem may require a different choice.

The capability chart represents a method of graphically displaying power system performance. These charts are drawn on the complex power plane and define the real and reactive power that may be supplied from a

point in the system during steady state operation. The power available is depicted as a region on the plane and the boundaries of the region represent the critical operating limits of the system. The best known example of a capability chart is the operating chart of a synchronous machine. The power available from the generator is restricted by limiting values of the rotor current, stator current, turbine power (if a generator), and synchronous stability limits. Capability charts have been produced for transmission lines and HVdc converters.

Where the capability chart is extended to cover more than one power system component, the two-dimensional capability chart associated with a single busbar can be regarded as being a single slice of an overall $2n$ dimensional capability chart for the n busbars that make up a general power system. If the system is small, a contour plotting approach can be used to gradually trace out the locus on the complex power plane. A load flow algorithm is used to iteratively solve the operating equations at each point on the contour, without having to resort to an explicit closed form solution.

The good contour behavior near the operating region has allowed a faster method to be adopted. A seed load flow solution, corresponding to the nominal system state, is obtained to begin drawing the chart. A region growing process is then used to locate the region in which all constrained variables are less than 10% beyond their limits. This process is similar to a technique used in computer vision systems to recognize shapes of objects. The region grows by investigating the six nearest lattice vertices to any unconstrained vertex. Linear interpolation along the edges between vertices is then used to estimate the points of intersection between the contour and the lattice. This method has a second advantage in that it can detect holes and islands in the chart. However, it should be noted that these regions are purely speculative and have not been found in practice.

Protection

The need to analyze protection schemes has resulted in the development of protection coordination programs. Protection schemes can be divided into two major groupings: unit and non-unit schemes.

The first group contains schemes that protect a specific area of the system, i.e., a transformer, transmission line, generator, or busbar. The most obvious example of unit protection schemes is based on Kirchhoff's current law—the sum of the currents entering an area of the system must be zero. Any deviation from this must indicate an abnormal current path. In these schemes, the effects of any disturbance or operating condition outside the area of interest are totally ignored and the protection must be designed to be stable above the maximum possible fault current that could flow through the protected area. Schemes can be made to extend across all sides of a transformer to account for the different currents at different voltage levels. Any analysis of these schemes are thus of more concern to the protection equipment manufacturers.

The non-unit schemes, while also intended to protect specific areas, have no fixed boundaries. As well as protecting their own designated areas, the protective zones can overlap into other areas. While this can be very beneficial for backup purposes, there can be a tendency for too great an area to be isolated if a fault is detected by different non-unit schemes. The most simple of these schemes measures current and incorporates an inverse time characteristic into the protection operation to allow protection nearer to the fault to operate first. While this is relatively straightforward for radial schemes, in networks, where the current paths can be quite different depending on operating and maintenance strategies, protection can be difficult to set and optimum settings are probably impossible to achieve. It is in these areas where protection software has become useful to manufacturers, consultants, and utilities.

The very nature of protection schemes has changed from electromechanical devices, through electronic equivalents of the old devices, to highly sophisticated system analyzers. They are computers in their own right and thus can be developed almost entirely by computer analysis techniques.

Other Uses for Load Flow Analysis

It has already been demonstrated that load flow analysis is necessary in determining the economic operation of the power system and it can also be used in the production of capability charts. Many other types of analyses require load flow to be embedded in the program.

As a follow on from the basic load flow analysis, where significant unbalanced load or unbalanced transmission causes problems, a three-phase load flow may be required to study their effects. These programs require each phase to be represented separately and mutual coupling between phases to be taken into account. Transformer winding connections must be correctly represented and the mutual coupling between transmission lines on the same tower or on the same right-of-way must also be included.

Motor starting can be evaluated using a transient stability program but in many cases this level of analysis is unnecessary. The voltage dip associated with motor start up can be determined very precisely by a conventional load flow program with a motor starting module.

Optimal power system operation requires the best use of resources subject to a number of constraints over any specified time period. The problem consists of minimizing a scalar objective function (normally a cost criterion) through the optimal control of a vector of control parameters. This is subject to the equality constraints of the load flow equations, inequality constraints on the control parameters, and inequality constraints of dependent variables and dependent functions. The programs to do this analysis are usually referred to as optimal power flow (OPF) programs.

Often optimal operation conflicts with the security requirements of the system. Load flow studies are used to assess security (security assessment). This can be viewed as two separate functions. First, there is a need to detect any operating limit violations through continuous monitoring of the branch flows and nodal voltages. Second, there is a need to determine the effects of branch outages (contingency analysis). To reduce this to a manageable level, the list of contingencies is reduced by judicial elimination of most of the cases that are not expected to cause violations. From this the possible overloading of equipment can be forecast. The program should be designed to accommodate the condition where generation cannot meet the load because of network islanding.

The conflicting requirements of system optimization and security require that they be considered together. The more recent versions of OPF interface with contingency analysis and the computational requirements are enormous.

Extensions to Transient Stability Analysis

Transient stability programs have been extended to include many other system components, including FACTS (flexible ac transmission systems) and dc converters.

FACTS may be either shunt or branch devices. Shunt devices usually attempt to control busbar voltage by varying their shunt susceptance. The device is therefore relatively simple to implement in a time domain program. Series devices may be associated with transformers. Stability improvement is achieved by injecting a quadrature component of voltage derived from the other two phases rather than by a tap changer which injects a direct component of voltage. Fast acting power electronics can inject either or a combination of both direct and quadrature voltage to help maintain voltage levels and improve stability margins.

Dc converters for HVdc links and rectifier loads have received much attention. The converter controls are very fast acting and therefore a quasi steady state (QSS) model can be considered accurate. That is, the model of the converter terminals contains no dynamic equations and in effect the link behaves as if it was in steady state for every time solution of the ac system. While this may be so some time after a fault has been removed, during and just after a fault the converters may well suffer from commutation failure or fire through. These events cannot be predicted or modeled with a QSS model. In this case, an appropriate method of analysis is to combine a state variable model of the converter, which can model the firing of the individual valves, with a conventional multi-machine transient stability program containing a QSS model. During the period of maximum disturbance, the two models can operate together. Information about the overall system response is passed to the state variable model at regular intervals. Similarly the results from the detailed converter model are passed to the multi machine model overriding its own QSS model. As the disturbance reduces, the results from the two different converter models converge and it is then only necessary to run the computationally inexpensive QSS model within the multi machine transient stability program.

Voltage Collapse

Steady state analysis of the problem of voltage instability and voltage collapse are often based on load flow analysis programs. However, time solutions can provide further insight into the problem.

A transient stability program can be extended to include induction machines which are associated with many of the voltage collapse problems. In these studies, it is the stability of the motors that are examined rather than the stability of the synchronous machines. The asynchronous nature of the induction machine means that rotor angle is not a concern, but instead the capability of the machines to recover after a fault has depressed the voltage and allowed the machines to slow down. The re-accelerating machines draw more reactive current which can hold the terminal voltage down below that necessary to allow recovery. Similarly starting a machine will depress the voltage which affects other induction machines which further lowers the voltage.

However, voltage collapse can also be due to longer term problems. Transient stability programs then need to take into account controls that are usually ignored. These include automatic transformer tap adjustment and generator excitation limiters which control the long-term reactive power output to keep the field currents within their rated values.

The equipment that can contribute to voltage collapse must also be more carefully modeled. Simple impedance models for loads ($P = P_oV^2$; $Q = Q_oV^2$) are no longer adequate. An improvement can be obtained by replacing the (mathematical) power 2 in the equations by more suitable values. Along with the induction machine models, the load characteristics can be further refined by including saturation effects.

SCADA

SCADA (Supervisory Control And Data Acquisition) has been an integral part of system control for many years. A control center now has much real time information available so that human and computer decisions about system operation can be made with a high degree of confidence.

In order to achieve high quality input data, algorithms have been developed to estimate the state of a system based on the available on-line data (state estimation). These methods are based on weighted least squares techniques to find the best state vector to fit the scatter of data. This becomes a major problem when conflicting information is received. However, as more data becomes available, the reliability of the estimate can be improved.

Power Quality

One form of poor power quality which has received a large amount of attention is the high level of harmonics that can exist and there are numerous harmonic analysis programs now available.

Recently, the harmonic levels of both currents and voltages have increased considerably due to the increasing use of non-linear loads such as arc furnaces, HVdc converters, FACTS equipment, dc motor drives, and ac motor speed control. Moreover, commercial sector loads now contain often unacceptable levels of harmonics due to widespread use of equipment with rectifier-fed power supplies with capacitor output smoothing (e.g., computer power supplies and fluorescent lighting). The need to conserve energy has resulted in energy efficient designs that exacerbate the generation of harmonics. Although each source only contributes a very small level of harmonics, due to their small power ratings, widespread use of small non-linear devices may create harmonic problems which are more difficult to remedy than one large harmonic source.

Harmonic analysis algorithms vary greatly in their algorithms and features; however, almost all use the frequency domain. The most common technique is the direct method (also known as current injection method). Spectral analysis of the current waveform of the non-linear components is performed and entered into the program. The network data is used to assemble a system admittance matrix for each frequency of interest. This set of linear equations is solved for each frequency to determine the node voltages and, hence, current flow throughout the system. This method assumes the non-linear component is an ideal harmonic current source. The next more advanced technique is to model the relationship between the harmonic currents injected by a component to its terminal voltage waveform. This then requires an iterative algorithm, which does require

excursion into the time domain for modeling this interaction. When the fundamental (load flow) is also included, thus simulating the interaction between fundamental and harmonic frequencies, it is termed a harmonic power flow. The most advanced technique, which is still only a research tool, is the harmonic domain. In this iterative technique one Jacobian is built-up that represents all harmonic frequencies. This allows coupling between harmonics, which occurs, for example, in salient synchronous machines, to be represented.

There are many other features that need to be considered, such as whether the algorithm uses symmetrical components or phase coordinates, or whether it is single- or three-phase. Data entry for single-phase typically requires the electrical parameters, whereas three-phase analysis normally requires the physical geometry of the overhead transmission lines and cables and conductor details so that a transmission line parameter program or cable parameter program can calculate the line or cable electrical parameters.

The communication link between the monitoring point and the control center can now be very sophisticated and can utilize satellites. This technology has led to the development of systems to analyze the power quality of a system. Harmonic measurement and analysis has now reached a high level of maturity. Many different pieces of information can be monitored and the results over time stored in a database. Algorithms based on the fast Fourier transform can then be used to convert this data from the time domain to the frequency domain. Computing techniques coupled with fast and often parallel computing allows this information to be displayed in real time. By utilizing the time stamping capability of the global positioning system (GPS), information gathered at remote sites can be linked together. Using the GPS time stamp, samples taken exactly simultaneously can be feed to a harmonic state estimator which can even determine the position and magnitude of harmonics entering the system as well as the harmonic voltages and currents at points not monitored (provided enough initial monitoring points exist).

One of the most important features of harmonic analysis software is the ability to display the results graphically. The refined capabilities of present three-dimensional graphics packages has simplified the analysis considerably.

Finite Element Analysis

Finite element analysis is not normally used by power system engineers although it is a common tool of high voltage and electrical machine engineers. It is necessary, for example, where accurate machine representation is required. For example, in a unit connected HVdc terminal the generators are closely coupled to the rectifier bridges. The ac system at the rectifier end is isolated from all but its generator. There is no need for costly filters to reduce harmonics. Models of the synchronous machine suitable for a transient stability study can be obtained from actual machine tests. For fast transient analysis, a three-phase generator model can be used but it will not account for harmonics. A finite element model of the generator provides the means of allowing real time effects such as harmonics and saturation to be directly included. Any geometric irregularities in the generator can be accounted for and the studies can be done at the design stage rather than having to rely on measurements or extrapolation from manufactured machines to obtain circuit parameters. There is no reliance on estimated machine parameters. The disadvantages are the cost and time to run a simulation and it is not suitable at present to integrate with existing transient stability programs as it requires a high degree of expertise. As the finite element model is in this case used in a time simulation, part of the air gap is left unmeshed in the model. At each time step the rotor is placed in the desired position and the missing elements in the air gap region formed using the nodes on each side of the gap.

Grounding

The safe grounding of power system equipment is very important, especially as the short circuit capability of power systems continues to grow. Programs have been developed to evaluate and design grounding systems in areas containing major power equipment, such as substations and to evaluate the effects of fault current on remote, separately grounded equipment.

The connection to ground may consist of a ground mat of buried conductors, electrodes (earth rods), or both. The shape and dimensions of the electrodes, their locations, and the layout of an ground mat, plus the resistivity of the ground at different levels must be specified in order to evaluate the ground resistance. A grid of buried conductors and electrodes is usually considered to be all at the same potential. Where grid sections are joined by buried or aerial links, these links can have resistance allowing the grid sections to have different potentials. It is usual to consider a buried link as capable of radiating current into the soil.

Various methods of representing the fault current are available. The current can be fixed or it can be determined from the short circuit MVA and the busbar voltage. A more complex fault path may need to be constructed for faults remote from the site being analyzed.

From the analysis, the surface potential over the affected area can be evaluated and, from that, step and touch potentials calculated. Three-dimensional graphics of the surface potentials are very useful in highlighting problem areas.

Other Programs

There are too many other programs available to be discussed. For example, neither automatic generator control nor load forecasting have been included. However, an example of a small program that can stand alone or fit into other programs is given here.

In order to obtain the electrical parameters of overhead transmission lines and underground cables, utility programs have been developed. Transmission line parameter programs use the physical geometry of the conductors, the conductor type, and ground resistivity to calculate the electrical parameters of the line. Cable parameter programs use the physical dimensions of the cable, its construction, and its position in the ground. The results of these programs are usually fed directly to network analysis programs such as load flow or faults. The danger of errors introduced during transfer are thus minimized. This is particularly true for three-phase analyses due to the volume of data involved.

68.4 Further Development of Programs

Recently there has been a shift in emphasis in the types of program being constructed. Deregulation (a misnomer of grand proportions) is making financial considerations a prime operating constraint. New programs are now being developed which assist in the buying and selling of energy through the electrical system.

Following on from the solution of the economic dispatch, "time of use" pricing has been introduced into some power system operations. Under this system, the price of electricity at a given time reflects the marginal cost of generation at that time. As the marginal generator changes over time, so does the price of electricity.

The next stage is to price electricity not only on time but also on the place of use (nodal pricing). Thus, the cost of transportation of the energy from the producer to the user is included in the price. This can be a serious problem at present when power is exchanged between utilities. It will become increasingly common as the individual electricity producers and users set up contractual agreements for supply and use. A major problem at present is the lack of common agreement as to whether nodal pricing is the most appropriate mechanism for a deregulated wholesale electricity market. Clarification will occur as the structure of the industry changes.

Nodal pricing also takes into account other commercial and financial factors. These include the pricing of both generation and transmission constraints, the setting of a basis for transmission constraint hedges and for the economic dispatch of generation. The programs must be designed to give both the suppliers and consumers of energy the full opportunity costs of the operation of the power system.

Inherent in nodal pricing must be such factors as marginal cost pricing, short run price, and whether the price is *ex ante* (before) or *ex post* (after) the event. Thus far, the programming effort has concentrated on real power pricing but the cost of reactive power should also eventually be included.

The changes in the operation of power systems, which are occurring throughout the world at present, will inevitably force changes to many of the programs in use today and, as shown above, new programs will emerge.

These programs are an example of direct transfer of university programs to major utilities. However, because the number of organizations involved in the industry is increasing, these and other programs will become more generally available.

Program Suites

As more users become involved with a program, its quirks become less acceptable and it must become easy to use, i.e., user friendly. Second, with the availability of many different types of program, it became important to be able to transfer the results of one program to the input of another. If the user has access to the source code, this can often be done relatively quickly by generating an output file in a suitable format for the input of the second program. There has, therefore, been a great deal of attention devoted to creating common formats for data transfer as well as producing programs with easy data entry formats and good result processing capabilities.

Many good "front end" programs are now available which allow the user to quickly write an analysis program and utilize the built in IO features of the package. There are also several good general mathematical packages available. Much research work can now be done using tools such as these. The researcher is freed from the chore of developing algorithms and IO routines by using these standard packages. Not only that, extra software is being developed which can turn these general packages into specialist packages. It may well be that before long all software will be made to run on sophisticated developments of these types of package and the stand alone program will fall into oblivion.

68.5 Conclusions

There are many more programs available than can be discussed here. Those that have been discussed are not necessarily more significant than those omitted. There are programs to help you with almost every power system problem you have and new software is constantly becoming available to solve the latest problems.

Make sure that programs you use are designed to do the job you require. Some programs make assumptions which give satisfactory results in most cases but may not be adequate for your particular case. No matter how sophisticated and friendly the program may appear, it is the algorithm and processing of data which are the most important parts. As programs become more complex and integrated, new errors (regressions) can be introduced. Wherever possible check the answers and always make sure they feel right.

Further Information

There are several publications that can keep engineers up to date with the latest developments in power system analysis. The *IEEE Spectrum* (U.S.) and the *IEE Review* (U.K.) are the two most well respected, general interest, English language journals that report on the latest development in electrical engineering. The *Power Engineering Journal* produced by the IEE regularly runs tutorial papers, many of which are of direct concern to power systems analysts. However, for magazine-style coverage of the developments in power system analysis, the *IEEE Computer Applications in Power* is in the authors' opinion, the most useful.

Finally, a few text books that provide a much greater insight into the programs discussed in the chapter have been included below.

The IRIDIUM system is a satellite-based, wireless personal communications network designed to permit any type of telephone transmission—voice, data, fax, or paging—to reach its destination anywhere on earth. The IRIDIUM constellation will consist of 66 interconnected satellites like the one shown above.

Each IRIDIUM satellite, weighing approximately 689 kg (1,500 lb), will orbit above the earth at an altitude of 420 nautical miles and communicate directly with subscriber equipment. Each of the satellites will function like extremely tall cellular towers and will project tightly focused beams over the ground. The low-earth orbit of IRIDIUM satellites as well as recent advances in microelectronics make it possible to communicate with a handheld phone.

The IRIDIUM system was conceived in 1987 by engineers at Motorola's Satellite Communications Division. It is being financed by a private international consortium of telecommunications and industrial companies and is expected to begin operation in 1998. (Photo courtesy of Motorola.)

ELECTRICAL TECHNOLOGY has been involved in aiding communication between a sender and a receiver of information since the advent of the electrical telegraph. The evolution of electrical communications technology has been influenced by both advances in devices for processing and transmitting electrical signals, as well as the growth and variety of communications applications that have become essential to modern society. A large fraction of electrical engineers are involved with some aspect of communications, as evidenced by the size of the IEEE Communications Society, which is second only to the Computer Society. In fact, communication between computers makes up a large part of communication system traffic, and communication technology is playing an increasing role *within* computers as they employ multiple processors and processors that are geographically distributed.

This section presents an overview of a variety of communication systems that have been developed to overcome the constraints of physical communication channels by exploiting the capabilities of the electronic and optoelectronic devices that are described elsewhere in this handbook. As a reflection of the dual influences of electrotechnology and user applications, some of the following chapters have application themes (broadcasting, satellite and aerospace, personal and office, and telemetry), while the rest have themes related to systems techniques (digital, optical, network, information theory, phase-locked loop, and computer-aided design).

The conventional radio station is a prototype of a broadcasting system in which a single transmitter sends the same message to multiple receivers. Chapter 69 reviews the basic notions of modulation needed to match the transmitted signal to the propagation and noise characteristics of the transmission medium and outlines recent developments in systems for high-definition television (HDTV) and digital audio broadcasting (DAB).

The chapter on digital techniques emphasizes the coding techniques used to detect and correct transmission errors (which are inevitable even if systems can be designed to reduce their frequency of occurrence). Since the rate of pulse transmission over a channel can be maximized by having an accurate model for the channel, such systems are improved by continually readjusting the channel model as the characteristics change with time. This chapter also discusses adaptive equalizers that match electrical pulse shapes to changing channels.

The development of fiber-optic cables and efficient solid-state lasers has revolutionized telephone communications. Chapter 71 describes some of the related developments in signal design and transmission for optical systems that carry voice, video, and computer data messages.

Traditional telephone switching has evolved into a huge field of telecommunication networks, with the advent of new media such as fiber-optic cables and satellites and the rapidly growing digital traffic such as that between computers, and supporting e-mail and the World Wide Web. Chapter 72 describes switching and transmission protocols and other standards that are being developed to coordinate the design of equipment that sends and receives messages over the networks.

The chapter on information theory uses that term in a broad sense to describe mathematical models and techniques for describing and simplifying both deterministic and random signals. These techniques can be used for efficient communication by removing inessential information and by showing how a receiver can distinguish useful information from noise disturbances.

Satellite and aerospace applications, described in Chapter 74, provide dramatic examples of challenging communication environments where, due to equipment weight limitations and great distances, signals are weak compared to the associated noise, and propagation characteristics are nonlinear.

Personal and office innovations related to communication systems are as dramatic to the ordinary citizen as those in entertainment applications such as HDTV and digital audio. Chapter 75 describes how facsimile systems, which are especially useful for rapid transmission of graphical information, exploit standardized techniques for compressing black-and-white images. Also presented are new developments in modulation techniques and propagation modeling that have been stimulated by mobile telephone and wireless network applications.

Phase-locked loops are presented in Chapter 76 as good examples of electronic systems that are able to detect weak signals whose characteristics change with time in environments where there is strong interference from noise and from competing transmitters.

Telemetry systems are dedicated to collection and transmission of data from many sensors, often in hostile or distant environments. Chapter 77 describes how constraints on equipment size, weight and power often lead to novel methods for data multiplexing and transmission.

This section concludes with a chapter on computer-aided design methods that are being exploited to design communication systems more rapidly and effectively. Many of the problems, such as best location of a large number of nodes in a network where the construction costs and performance measures are a complex function of design parameters, are best solved by a designer who works interactively with computer algorithms.

Nomenclature

69.1 Modulation and Demodulation

Richard C. Dorf and Zhen Wan

Modulation is the process of impressing the source information onto a bandpass signal with a carrier frequency f_c. This bandpass signal is called the modulated signal $s(t)$, and the baseband source signal is called the modulating signal $m(t)$. The modulated signal could be represented by

$$s(t) = \text{Re}\{g(t)e^{j\omega ct}\} \tag{69.1}$$

or, equivalently,

$$s(t) = R(t)\cos[\omega_c t + \theta(t)] \tag{69.2}$$

and

$$s(t) = x(t)\cos\omega_c t - y(t)\sin\omega_c t \tag{69.3}$$

where $\omega_c = 2\pi f_c$. The complex envelope is

$$g(t) = R(t)e^{j\theta(t)} = x(t) + jy(t) \tag{69.4}$$

and $g(t)$ is a function of the modulating signal $m(t)$. That is,

$$g(t) = g[m(t)]$$

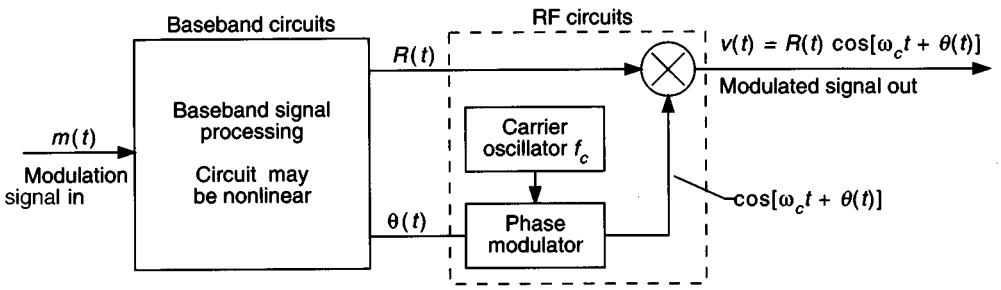

FIGURE 69.1 Generalized transmitter using the AM-PM generation technique.

Thus $g[\cdot]$ performs a mapping operation on $m(t)$. The particular relationship that is chosen for $g(t)$ in terms of $m(t)$ defines the type of modulation used.

In Table 69.1, examples of the mapping function $g(m)$ are given for the following types of modulation:

- AM: amplitude modulation
- DSB-SC: double-sideband suppressed-carrier modulation
- PM: phase modulation
- FM: frequency modulation
- SSB-AM-SC: single-sideband AM suppressed-carrier modulation
- SSB-PM: single-sideband PM
- SSB-FM: single-sideband FM
- SSB-EV: single-sideband envelope-detectable modulation
- SSB-SQ: single-sideband square-law-detectable modulation
- QM: quadrature modulation

Modulation

In Table 69.1, a generalized approach may be taken to obtain universal transmitter models that may be reduced to those used for a particular modulation type. We also see that there are equivalent models which correspond to different circuit configurations, yet they may be used to produce the same type of modulated signal at their outputs. It is up to communication engineers to select an implementation method that will optimize performance, yet retain low cost based on the state of the art in circuit development.

There are two canonical forms for the generalized transmitter. Figure 69.1 is an AM-PM type circuit as described in Eq. (69.2). In this figure, the baseband signal processing circuit generates $R(t)$ and $\theta(t)$ from $m(t)$. The R and θ are functions of the modulating signal $m(t)$ as given in Table 69.1 for the particular modulation type desired.

Figure 69.2 illustrates the second canonical form for the generalized transmitter. This uses in-phase and quadrature-phase (IQ) processing. Similarly, the formulas relating $x(t)$ and $y(t)$ are shown in Table 69.1, and the baseband signal processing may be implemented by using either analog hardware or digital hardware with software. The remainder of the canonical form utilizes radio frequency (RF) circuits as indicated.

Any type of signal modulation (AM, FM, SSB, QPSK, etc.) may be generated by using either of these two canonical forms. Both of these forms conveniently separate baseband processing from RF processing.

Superheterodyne Technique

Most receivers employ the **superheterodyne receiving** technique (see Fig. 69.3). This technique consists of either down-converting or up-converting the input signal to some convenient frequency band, called the *intermediate frequency* (IF) band, and then extracting the information (or modulation) by using the appropriate detector. This basic receiver structure is used for the reception of all types of bandpass signals, such as television, FM, AM, satellite, and radar signals.

TABLE 69.1 Complex Envelope Functions for Various Types of Modulation

Type of Modulation	Mapping Functions $g[m]$	Corresponding Quadrature Modulation $x(t)$	Corresponding Quadrature Modulation $y(t)$	Corresponding Amplitude and Phase Modulation $R(t)$	Corresponding Amplitude and Phase Modulation $\theta(t)$	Linearity	Remarks
AM	$1 + m(t)$	$1 + m(t)$	0	$\lvert 1 + m(t)\rvert$	$\begin{cases} 0, & m(t) > -1 \\ 180°, & m(t) < -1 \end{cases}$	L[b]	$m(t) > -1$ required for envelope detection.
DSB-SC	$m(t)$	$m(t)$	0	$\lvert m(t)\rvert$	$\begin{cases} 0, & m(t) > 0 \\ 180°, & m(t) < 0 \end{cases}$	L	Coherent detection required.
PM	$e^{jD_p m(t)}$	$\cos[D_p m(t)]$	$\sin[D_p m(t)]$	1	$D_p m(t)$	NL	D_p is the phase deviation constant (radian/volts).
FM	$e^{jDf\int_{-\infty}^{t} m(\sigma)d\sigma}$	$\cos\left[D_f \int_{-\infty}^{t} m(\sigma)d\sigma\right]$	$\sin\left[D_f \int_{-\infty}^{t} m(\sigma)d\sigma\right]$	1	$D_f \int_{-\infty}^{t} m(\sigma)d\sigma$	NL	D_f is the frequency deviation constant (radian/volt-sec).
SSB-AM-SC[a]	$m(t) \pm j\hat{m}(t)$	$m(t)$	$\pm\, \hat{m}(t)$	$\sqrt{[m(t)^2 + [\hat{m}(t)]^2}$	$\tan^{-1}[\pm\, \hat{m}(t)/m(t)]$	L	Coherent detection required.
SSB-PM[a]	$e^{jD_p[m(t)\pm j\hat{m}(t)]}$	$e^{\mp D_p \hat{m}(t)}\cos[D_p m(t)]$	$e^{\mp D_p \hat{m}(t)}\sin[D_p m(t)]$	$e^{\mp D_p \hat{m}(t)}$	$D_p m(t)$	NL	
SSB-FM[a]	$e^{jDf\int_{-\infty}^{t}[m(\sigma)\pm j\hat{m}(\sigma)]d\sigma}$	$e^{\mp D_f \int_{-\infty}^{t} \hat{m}(\sigma)d\sigma}\cos\left[D_f \int_{-\infty}^{t} m(\sigma)d\sigma\right]$	$e^{\mp D_f \int_{-\infty}^{t} \hat{m}(\sigma)d\sigma}\sin\left[D_f \int_{-\infty}^{t} m(\sigma)d\sigma\right]$	$e^{\mp D_f \int_{-\infty}^{t} \hat{m}(\sigma)d\sigma}$	$D_f \int_{-\infty}^{t} m(\sigma)d\sigma$	NL	
SSB-EV[a]	$e^{\{\ln[1 + m(t)]\pm j\hat{\ln}[1 + m(t)]\}}$	$[1 + m(t)]\cos\{\hat{\ln}[1 + m(t)]\}$	$\pm[1 + m(t)]\sin\{\hat{\ln}[1 + m(t)]\}$	$1 + m(t)$	$\pm\hat{\ln}[1 + m(t)]$	NL	$m(t) > -1$ is required so that the ln will have a real value.
SSB-SQ[a]	$e^{(1/2)\{\ln[1 + m(t)]\pm j\hat{\ln}[1 + m(t)]\}}$	$\sqrt{1 + m(t)}\cos\left\{\frac{1}{2}\hat{\ln}[1 = m(t)]\right\}$	$\pm\sqrt{1 + m(t)}\sin\left\{\frac{1}{2}\hat{\ln}[1 + m(t)]\right\}$	$\sqrt{1 + m(t)}$	$\pm\frac{1}{2}\hat{\ln}[1 + m(t)]$	NL	$m(t) > -1$ is required so that the ln will have a real value.
QM	$m_1(t) + jm_2(t)$	$m_1(t)$	$m_2(t)$	$\sqrt{m_1^2(t) + m_2^2(t)}$	$\tan^{-1}[m_2(t)/m_1(t)]$	L	Used in NTSC color television: requires coherent detection.

L = linear, NL = nonlinear, [ˆ.] is the Hilbert transform (i.e., –90° phase-shifted version) of [·]. The Hilbert transform is $\hat{x}(t) \triangleq x(t) * \frac{1}{\pi t} = \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{x(\lambda)}{t - \lambda}\, d\lambda$

[a]Use upper signs for upper sideband signals and lower signs for lower sideband signals.

[b]In the strict sense, AM signals are not linear because the carrier term does not satisfy the linearity (superposition) condition.

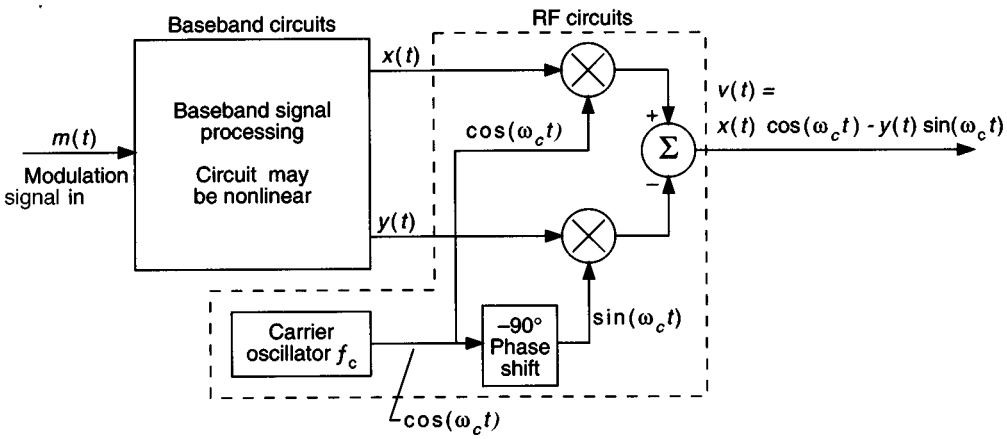

FIGURE 69.2 Generalized transmitter using the quadrature generation technique.

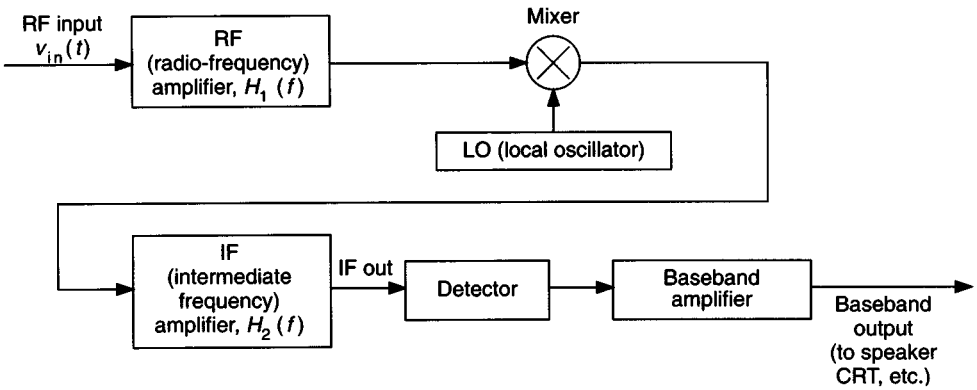

FIGURE 69.3 Superheterodyne receiver.

If the complex envelope $g(t)$ is desired for generalized signal detection or for optimum reception in digital systems, the $x(t)$ and $y(t)$ quadrature components, where $x(t) + jy(t) = g(t)$, may be obtained by using quadrature product detectors, as illustrated in Fig. 69.4. $x(t)$ and $y(t)$ could be fed into a signal processor to extract the modulation information. Disregarding the effects of noise, the signal processor could recover $m(t)$ from $x(t)$ and $y(t)$ (and, consequently, demodulate the IF signal) by using the inverse of the complex envelope generation functions given in Table 69.1.

The generalized modulation techniques are shown in Table 69.1. In digital communication systems, discrete modulation techniques are usually used to modulate the source information signal. Discrete modulation includes:

- PCM = pulse-code modulation
- DM = differential modulation
- DPCM = differential pulse-code modulation
- FSK = frequency-shift keying
- PSK = phase-shift keying
- DPSK = differential phase-shift keying
- MPSK = *M*-ary phase-shift keying
- QAM = quadrature amplitude modulation

1024	10	$20B$	65.0	60.2

[a] B is the absolute bandwidth of the input analog signal.

Pulse-Code Modulation

PCM is essentially analog-to-digital conversion of a special type, where the information contained in the instantaneous samples of an analog signal is represented by digital words in a serial bit stream. The PCM signal is generated by carrying out three basic operations: sampling, quantizing, and encoding (see Fig. 69.5). The sampling operation generates a flat-top pulse amplitude modulation (PAM) signal. The quantizing converts the actual sampled value into the nearest of the M amplitude levels. The PCM signal is obtained from the quantized PAM signal by encoding each quantized sample value into a digital word.

Frequency-Shift Keying

The FSK signal can be characterized as one of two different types. One type is called *discontinuous-phase* FSK since $\theta(t)$ is discontinuous at the switching times. The discontinuous-phase FSK signal is represented by

$$s(t) = \begin{cases} A_c \cos(\omega_1 t + \theta_1) \text{ for } t \text{ in time interval when a binary 1 is sent} \\ A_c \cos(\omega_2 t + \theta_2) \text{ for } t \text{ in time interval when a binary 0 is sent} \end{cases} \quad (69.5)$$

Radio Distance and Direction Indicator

Luis W. Alvarez
Patented August 30, 1949
#2,480,208

An excerpt from Luis Alvarez's patent application:

This invention relates to a communications system and more particularly to a system for presenting in panoramic form the location and disposition of objects as they might be seen from the air. In particular, the system hereinafter described is a radar or radio echo detection system presenting objects and targets principally on the ground lying in the path of flight of an airplane.

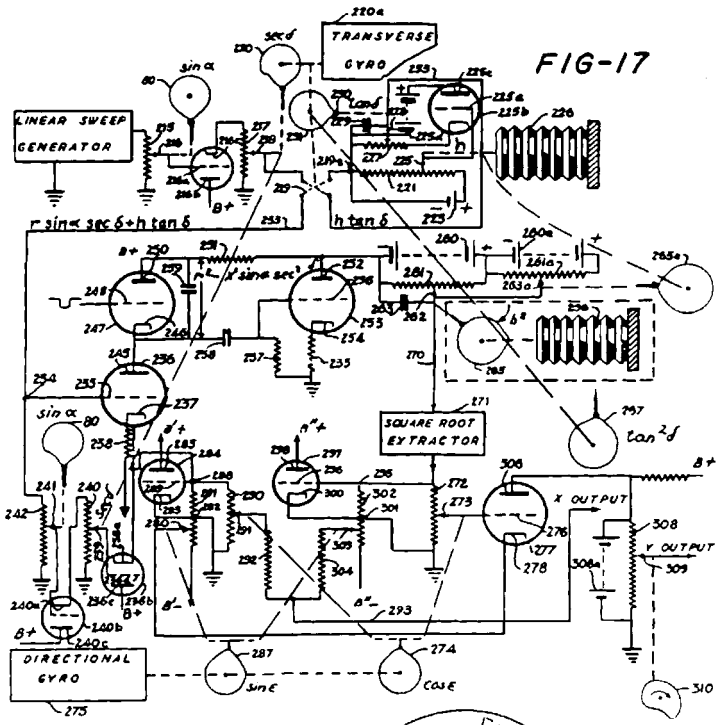

FIG-17

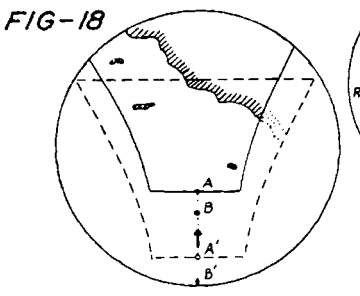

FIG-18

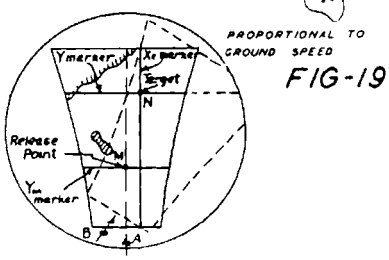

FIG-19

Ground radar systems were already known and used by the military. These involved a highly directional antenna alternately coupled to a transmitter and receiver with the antenna swept in a radial fashion. The display consisted of a cathode ray tube with targets represented by radial sweeps from the center of the screen. Dr. Alvarez took on the special problem of panoramic presentation of ground targets from aircraft. He solved the computation and display problems associated with the hyperbolic shape of the radar beams as transmitted and received from a moving aircraft. He also described handling pitch, roll, yaw, and other disturbances. (Copyright © 1995, DewRay Products, Inc. Used with permission.)

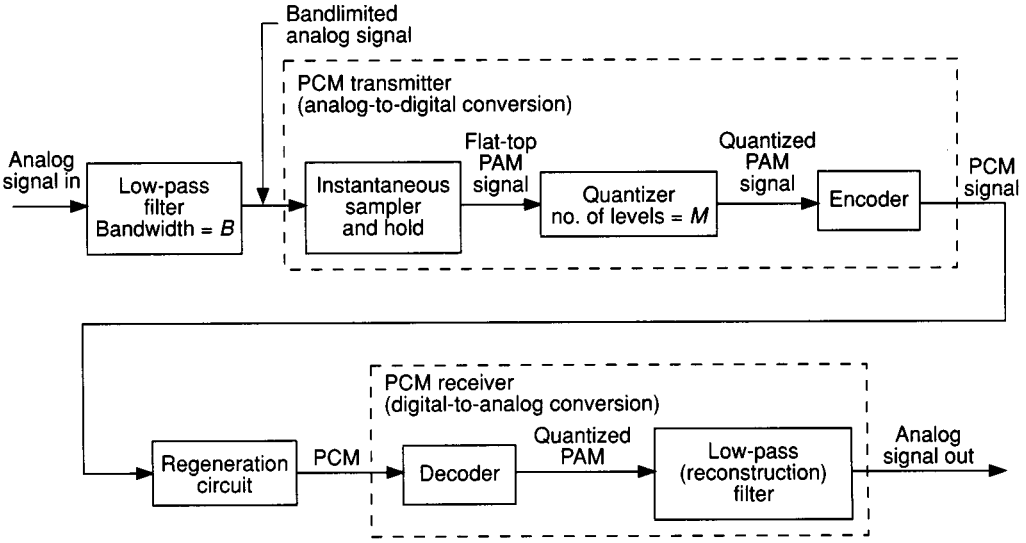

FIGURE 69.5 A PCM transmission system.

where f_1 is called the mark (binary 1) frequency and f_2 is called the space (binary 0) frequency. The other type is continuous-phase FSK. The continuous-phase FSK signal is generated by feeding the data signal into a frequency modulator, as shown in Fig. 69.6(b). This FSK signal is represented by

$$s(t) = A_c \cos\left[\omega_c t + D_f \int_{-\infty}^{t} m(\lambda)d\lambda\right]$$

or

$$s(t) = \mathrm{Re}\{g(t)e^{j\omega ct}\} \tag{69.6}$$

where

$$g(t) = A_c e^{j\theta(t)} \tag{69.7}$$

$$\theta(t) = D_f \int_{-\infty}^{t} m(\lambda)d\lambda \quad \text{for FSK} \tag{69.8}$$

Detection of FSK is illustrated in Fig. 69.7.

M-ary Phase-Shift Keying

If the transmitter is a PM transmitter with an *M*-level digital modulation signal, MPSK is generated at the transmitter output. A plot of the permitted values of the complex envelope, $g(t) = A_c e^{j\theta(t)}$, would contain *M* points, one value of *g* (a complex number in general) for each of the *M* multilevel values, corresponding to the *M* phases that θ is permitted to have.

MPSK can also be generated using two quadrature carriers modulated by the *x* and *y* components of the complex envelope (instead of using a phase modulator)

$$g(t) = A_c e^{j\theta(t)} = x(t) + jy(t) \tag{69.9}$$

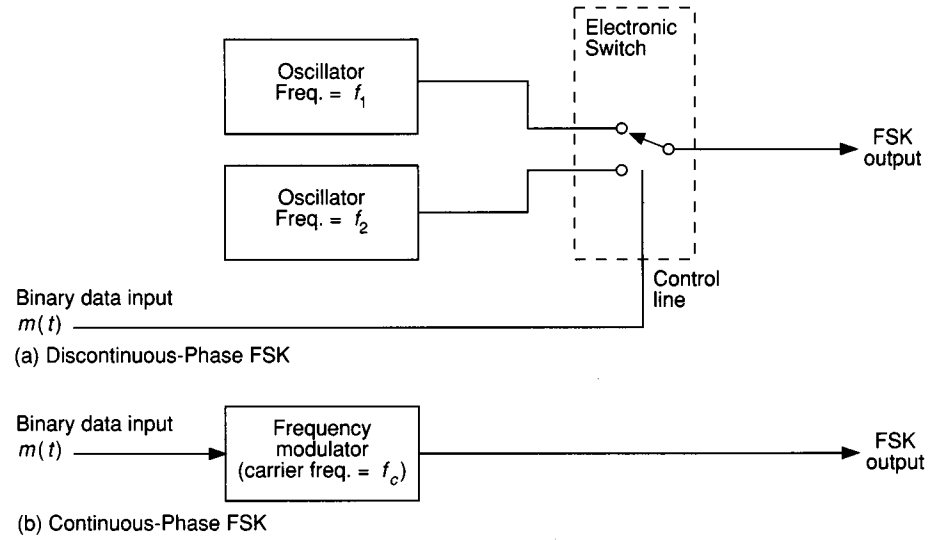

FIGURE 69.6 Generation of FSK.

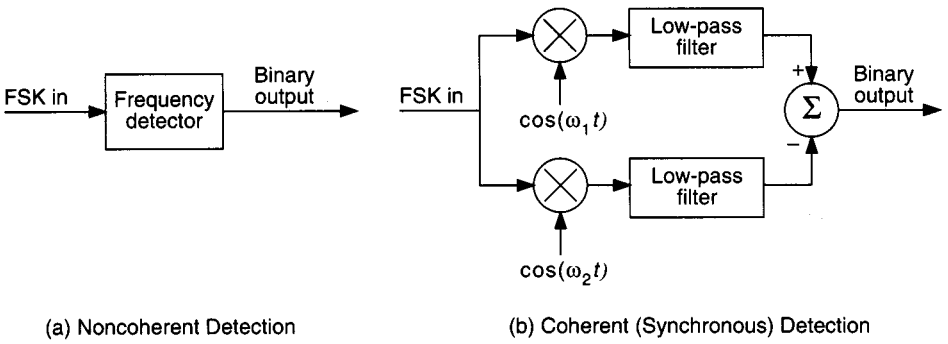

FIGURE 69.7 Detection of FSK.

where the permitted values of x and y are

$$x_i = A_c \cos \theta_i \tag{69.10}$$

$$y_i = A_c \sin \theta_i \tag{69.11}$$

for the permitted phase angles θ_i, $i = 1, 2, ..., M$, of the MPSK signal. This is illustrated by Fig. 69.8, where the signal processing circuit implements Eqs. (69.10) and (69.11).

MPSK, where $M = 4$, is called quadrature-phase-shift-keyed (QPSK) signaling.

Quadrature Amplitude Modulation

Quadrature carrier signaling is called quadrature amplitude modulation (QAM). In general, QAM signal constellations are not restricted to having permitted signaling points only on a circle (of radius A_c, as was the case for MPSK). The general QAM signal is

$$s(t) = x(t) \cos \omega_c t - y(t) \sin \omega_c t \tag{69.12}$$

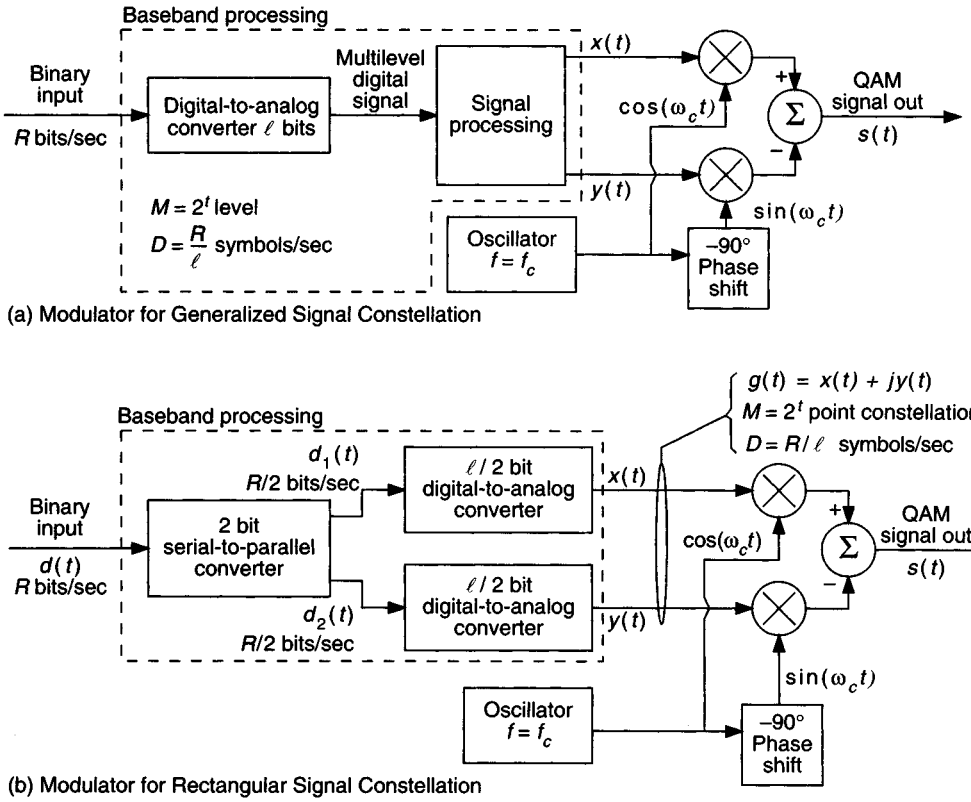

FIGURE 69.8 Generation of QAM signals.

The generation of QAM signals is shown in Fig. 69.8. The spectral efficiency for QAM signaling is shown in Table 69.3.

Defining Terms

Modulation: The process of impressing the source information onto a bandpass signal with a carrier frequency f_c. It can be expressed as

$$s(t) = \mathrm{Re}\{g(t)\ e^{j\omega ct}\}$$

where $g(t)$ is a function of the modulating signal $m(t)$. That is,

$$g(t) = g[m(t)]$$

$g[\cdot]$ performs a mapping operation on $m(t)$. The particular relationship that is chosen for $g(t)$ in terms of $m(t)$ defines the type of modulation used.

Superheterodyne receiver: Most receivers employ the superheterodyne receiving technique, which consists of either down-converting or up-converting the input signal to some convenient frequency band, called the intermediate frequency band, and then extracting the information (or modulation) by using an appropriate detector. This basic receiver structure is used for the reception of all types of bandpass signals, such as television, FM, AM, satellite, and radar signals.

69.2 Radio Broadcasting

Jefferson F. Lindsey III and Dennis F. Doelitzsch

Standard Broadcasting (Amplitude Modulation)

Standard broadcasting refers to the transmission of voice and music received by the general public in the 535- to 1705-kHz frequency band. Amplitude modulation is used to provide service ranging from that needed for small communities to higher-power broadcast stations needed for larger regional areas. The ***primary service***

The Revolutionary Technology of Radio

The beginning of the present century saw the birth of several technologies that were to be revolutionary in their impact. The most exciting of these was radio or, as it was generally called at the time, "wireless". No other technology would seem to obliterate the barriers of distance in human communication or to bring individuals together with such immediacy and spontaneity. And seldom had there emerged an activity that seemed so mysterious and almost magical to most of the population.

Radio was mysterious not only to the layman, but also to many engineers and technically informed individuals. The mystery lay largely in radio's application of principles and phenomena only recently identified by physicists and engineers working at the frontiers of their specialties. The existence of electromagnetic waves that traveled like light had been predicted by the brilliant physicist James Clerk Maxwell in the 1860s and proven by the young German Heinrich Hertz in the 1880s. The possible use of these waves for communicating through space without wires occurred to many; however, the first practical steps to making radio useful are generally attributed to Oliver Lodge in England, Guglielmo Marconi in Italy, and Aleksandr Popov in Russia. Marconi's broadcast of Morse code across the Atlantic in 1901 first showed the world just what enormous potential radio had for changing the whole concept of long-distance communication. The next few years saw feverish activity everywhere as men tried to translate the achievements of the pioneers into the foundations of a practical technology.

By 1912, radio technology had attracted a small number of dedicated individuals who identified their own future with the progress of their chosen field. Some of these had organized themselves into small, localized societies, but it was clear to many that a broader vision was needed if radio practitioners were to achieve the recognition and respect of technical professionals. It was with such a vision in mind that representatives of two of these local societies met in New York City in May 1912 to form the Institute of Radio Engineers. The IRE was to be an international society dedicated to the highest professional standards and to the advancement of the theory and practice of radio technology.

The importance of radio lay not simply in its expansion of the means of human communication over distances, but also in its exploitation and expansion of very novel scientific and technical capabilities. As the century progressed, radio would give rise to the 20th century's most revolutionary technology of all — electronics. (Courtesy of the IEEE Center for the History of Electrical Engineering.)

area is defined as the area in which the groundwave signal is not subject to objectionable interference or objectionable fading. The ***secondary service*** *area* refers to an area serviced by skywaves and not subject to objectionable interference. *Intermittent service area* refers to an area receiving service from either a groundwave or a skywave but beyond the primary service area and subject to some interference and fading.

Frequency Allocations

The carrier frequencies for standard broadcasting in the United States (referred to internationally as medium-wave broadcasting) are designated in the Federal Communications Commission (FCC) Rules and Regulations, Vol. III, Part 73. A total of 117 carrier frequencies are allocated from 540 to 1700 kHz in 10-kHz intervals. Each carrier frequency is required by the FCC rules to deviate no more than ±20 Hz from the allocated frequency, to minimize heterodyning from two or more interfering stations. Double-sideband full-carrier modulation, commonly called *amplitude modulation* (AM), is used in standard broadcasting for sound transmission. Typical modulation frequencies for voice and music range from 50 Hz to 10 kHz. Each channel is generally thought of as 10 kHz in width, and thus the frequency band is designated from 535 to 1705 kHz; however, when the modulation frequency exceeds 5 kHz, the radio frequency bandwidth of the channel exceeds 10 kHz and

adjacent channel interference may occur. To improve the high-frequency performance of transmission and to compensate for the high-frequency roll-off of many consumer receivers, FCC rules require that stations boost the high-frequency amplitude of transmitted audio using preemphasis techniques. In addition stations may also use multiplexing to transmit stereophonic programming. The FCC adopted Motorola's C-QUAM compatible quadrature amplitude modulation in 1994. Approximately 700 AM stations transmit in stereo.

Channel and Station Classifications

In standard broadcast (AM), stations are classified according to their operating power, protection from interference, and hours of operation. A Class A station operates with 10 to 50 kW of power servicing a large area with primary, secondary, and intermittent coverage and is protected from interference both day and night. These stations are called "clear channel" stations because the channel is cleared of nighttime interference over a major portion of the country. Class B stations operate full time with transmitter powers of 0.25 to 50 kW and are designed to render primary service only over a principal center of population and the rural area contiguous thereto. While nearly all Class A stations operate with 50 kW, most Class B stations must restrict their power to 5 kW or less to avoid interfering with other stations. Class B stations operating in the 1605 to 1705 kHz band are restricted to a power level of 10 kW daytime and 1 kW nighttime. Class C stations operate on six designated channels (1230, 1240, 1340, 1400, 1450, and 1490) with a maximum power of 1 kW or less full time and render primarily local service to smaller communities. Class D stations operate on Class A or B frequencies with Class B transmitter powers during daytime, but nighttime operation, if permitted at all, must be at low power (less than 0.25 kW) with no protection from interference.

Although Class A stations cover large areas at night, approximately in a 1220-km (750-mi) radius, the nighttime coverage of Class B, C, and D stations is limited by interference from other stations, electrical devices, and atmospheric conditions to a relatively small area. Class C stations, for example, have an interference-free nighttime coverage radius of approximately 8 to 16 km. As a result, there may be large differences in the area that the station covers daytime versus nighttime. With over 5200 AM stations licensed for operation by the FCC, interference, both day and night, is a factor that significantly limits the service which stations may provide. In the absence of interference, a daytime signal strength of 2 mV/m is required for reception in populated areas of more than 2500, while a signal of 0.5 mV/m is generally acceptable in less populated areas. Secondary nighttime service is provided in areas receiving a 0.5-mV/m signal 50% or more of the time without objectionable interference. Table 69.4 indicates the daytime contour overlap limits. However, it should be noted that these limits apply to new stations and modifications to existing stations. Nearly every station on the air was allocated prior to the implementation of these rules when the interference criteria were less restrictive.

Field Strength

The field strength produced by a standard broadcast station is a key factor in determining the primary and secondary service areas and interference limitations of possible future radio stations. The field strength limitations are specified as field intensities by the FCC with the units volts per meter; however, measuring devices may read volts or decibels referenced to 1 mW (dBm), and a conversion may be needed to obtain the field intensity. The power received may be measured in dBm and converted to watts. Voltage readings may be converted to watts by squaring the root mean square (rms) voltage and dividing by the field strength meter input resistance, which is typically on the order of 50 or 75 Ω. Additional factors needed to determine **electric field intensity** are the power gain and losses of the field strength receiving antenna system. Once the power gain and losses are known, the effective area with loss compensation of the field strength receiver antenna may be obtained as

$$A_{\text{eff}} = G \frac{\lambda^2}{4\pi} L \tag{69.14}$$

where A_{eff} = effective area including loss compensation, m^2; G = power gain of field strength antenna, W/W; λ = wavelength, m; and L = mismatch loss and cable loss factor, W/W.

From this calculation, the power density in watts per square meter may be obtained by dividing the received power by the effective area, and the electric field intensity may be calculated as

TABLE 69.4 Protected Service Signal Intensities for Standard Broadcasting (AM)

Class of Station	Power (kW)	Class of Channel Used	Signal Strength Contour of Area Protected from Objectionable Interference* (μV/m)		Permissible Interfering Signal	
			Day†	Night	Day†	Night‡
A	10–50	Clear	SC 100 AC 500	SC 500 50% SW AC 500 GW	SC 5 AC 250	SC 25 AC 250
B	0.25–50	Clear Regional	500	2000†	25 AC 250	25 250
C	0.25–1	Local	500	Not precise§	SC 25	Not precise
D	0.25–50	Clear Regional	500	Not precise	SC 25 AC 250	Not precise

*When a station is already limited by interference from other stations to a contour of higher value than that normally protected for its class, this higher-value contour shall be the established protection standard for such station. Changes proposed by Class A and B stations shall be required to comply with the following restrictions. Those interferers that contribute to another station's RSS using the 50% exclusion method are required to reduce their contribution to that RSS by 10%. Those lesser interferers that contribute to a station's RSS using the 25% exclusion method but do not contribute to that station's RSS using the 50% exclusion method may make changes not to exceed their present contribution. Interferers not included in a station's RSS using the 25% exclusion method are permitted to increase radiation as long as the 25% exclusion threshold is not equaled or exceeded. In no case will a reduction be required that would result in a contributing value that is below the pertinent value specified in the table.

†Groundwave.

‡Skywave field strength for 10% or more of the time. For Alaska, Class SC is limited to 5 μV/m.

§During nighttime hours, Class C stations in the contiguous 48 states may treat all Class B stations assigned to 1230, 1240, 1340, 1400, 1450, and 1490 kHz in Alaska, Hawaii, Puerto Rico and the U.S. Virgin Islands as if they were Class C stations.

Note: SC = same channel; AC = adjacent channel; SW = skywave; GW = groundwave; RSS = root of sum squares.

Source: FCC Rules and Regulations, Revised 1991; vol. III, pt. 73.182(a).

$$E = \sqrt{\mathcal{P} Z_{fs}} \tag{69.15}$$

where E = electric field intensity, V/m; $\mathcal{P}$ = power density, W/m^2; and $Z_{fs} = 120\pi\ \Omega$, impedance of free space.

The protected service contours and permissible interference contours for standard broadcast stations shown in Table 69.4, along with a knowledge of the field strength of existing broadcast stations, may be used in determining the potential for establishing new standard broadcast stations.

Propagation

One of the major factors in the determination of field strength is the propagation characteristic that is described by the change in electric field intensity with an increase in distance from the broadcast station antenna. This variation depends on a number of factors including frequency, distance, surface dielectric constant, surface loss tangent, polarization, local topography, and time of day. Generally speaking, groundwave propagation occurs at shorter ranges both during day and night periods. Skywave propagation permits longer ranges and occurs during night periods, and thus some stations must either reduce power or cease to operate at night to avoid causing interference. Propagation curves in the broadcast industry are frequently referred to a reference level of 100 mV/m at 1 km; however, a more general expression of groundwave propagation may be obtained by using the Bremmer series [Bremmer, 1949]. A typical groundwave propagation curve for electric field strength as a function of distance is shown in Fig. 69.9 for an operating frequency of 770–810 kHz. The ground conductivity varies from 0.1 to 5000 mS/m, and the ground relative dielectric constant is 15.

The **effective radiated power** (ERP) refers to the effective power output from the antenna in a specified direction and includes the transmitter power output, transmission line losses, and antenna power gain. The ERP in most cases exceeds the transmitter output power, since that antenna power gain is normally 2 or more. For a hypothetical perfect isotropic radiator with a power gain of 1, the ERP is found to be

$$\text{ERP} = \frac{E^2 r^2}{30} \tag{69.16}$$

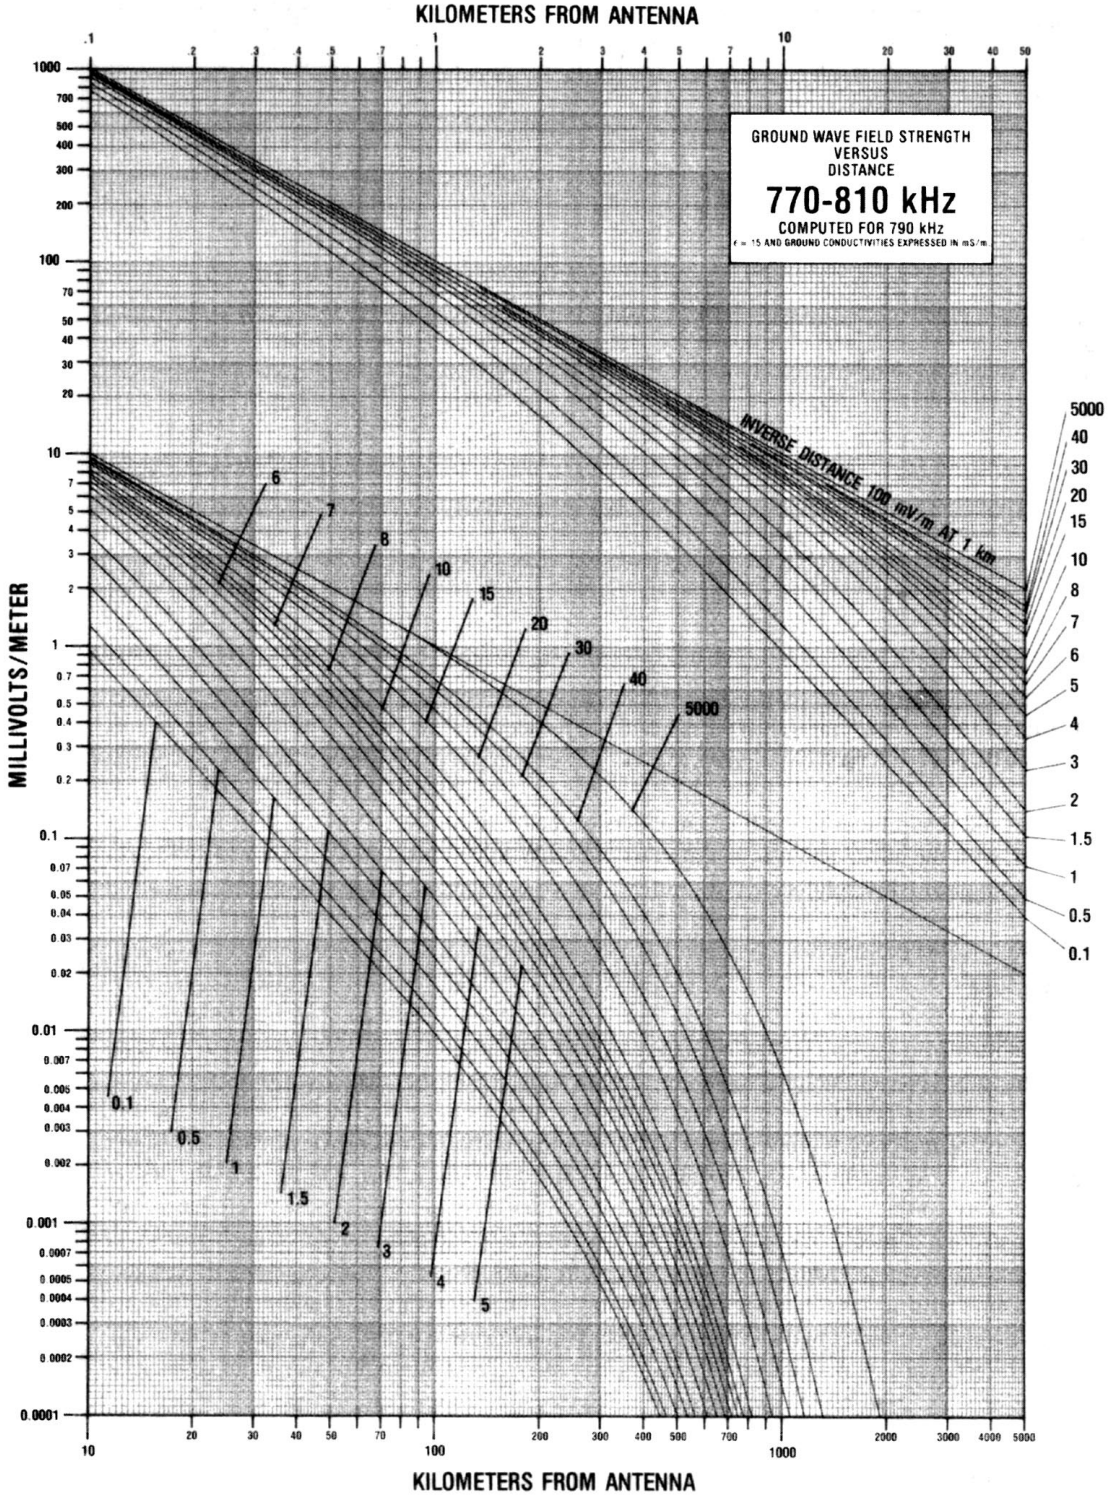

FIGURE 69.9 Typical groundwave propagation for standard AM broadcasting. (*Source:* 1986 National Association of Broadcasters.)

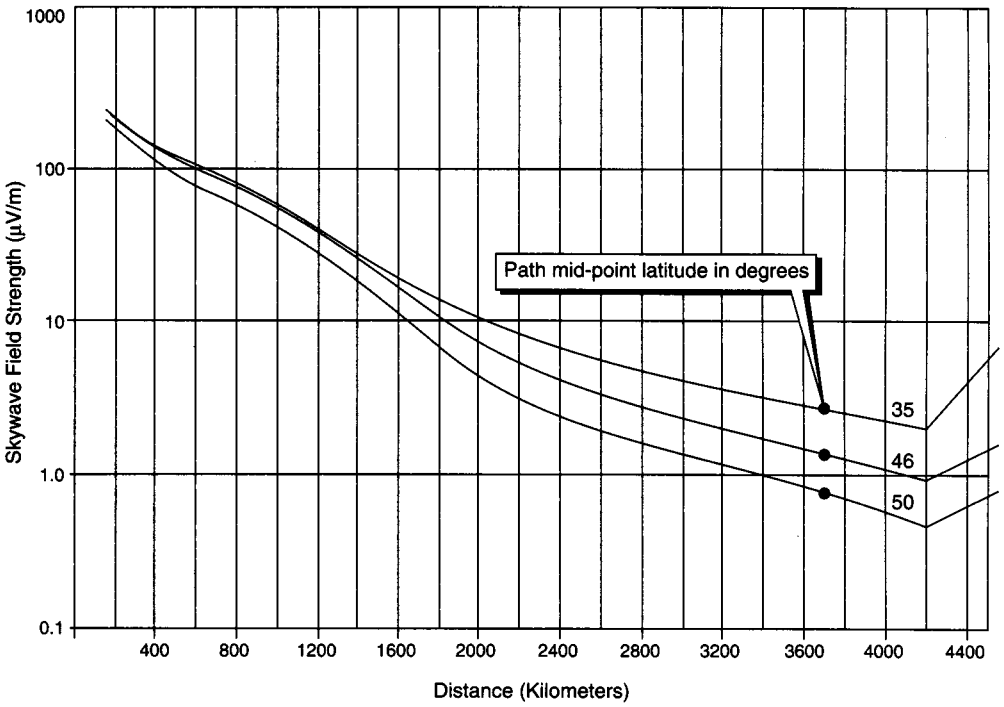

FIGURE 69.10 Skywave propagation for standard AM broadcasting. (*Source:* FCC Rules and Regulations, 1982, vol. III, pt. 73.190, fig. 2.)

where E is the electric field intensity, V/m, and r is the distance, m. For a distance of 1 km (1000 m), the ERP required to produce a field intensity of 100 mV/m is found to be 333.3 W. Since the field intensity is proportional to the square root of the power, field intensities may be determined at other powers.

Skywave propagation necessarily involves some fading and less predictable field intensities and is most appropriately described in terms of statistics or the percentage of time a particular field strength level is found. Figure 69.10 shows skywave propagation for a 100-mV/m field strength at a distance of 1 km for midpoint path latitudes of 35 to 50 degrees.

Transmitters

Standards that cover AM broadcast transmitters are given in the Electronic Industry Association (EIA) Standard TR-101A, "Electrical Performance Standard for Standard Broadcast Transmitters." Parameters and methods for measurement include the following: carrier output rating, carrier power output capability, carrier frequency range, carrier frequency stability, carrier shift, carrier noise level, magnitude of radio frequency (RF)harmonics, normal load, transmitter output circuit adjustment facilities, RF and audio interface definitions, modulation capability, audio input level for 100% modulation, audio frequency response, audio frequency harmonic distortion, rated power supply, power supply variation, operating temperature characteristics, and power input.

Standard AM broadcast transmitters range in power output from 5 W up to 50 kW units. While solid-state devices are used for many models (especially the lower-powered units), several manufacturers still retain tubes in the final amplifiers of their high-powered models. This is changing, however, with the introduction in recent years of 50-kW fully transistorized models. A block diagram of a typical 1-kW solid-state transmitter is shown in Fig. 69.11.

Antenna Systems

The antenna system for a standard AM broadcast station typically consists of a quarter-wave vertical tower, a ground system of 120 or more quarter-wave radials buried a few inches underground, and an antenna tuning

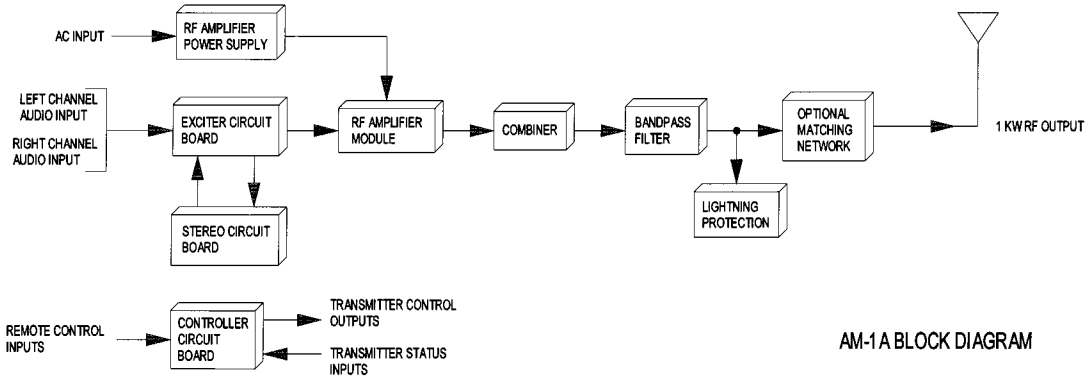

FIGURE 69.11 Block diagram of typical 1-kW solid-state AM transmitter. (*Source:* Broadcast Electronics Inc., Quincy, Ill. Reprinted with permission.)

unit to "match" the complex impedance of the antenna system to the characteristic impedance of the transmitter and transmission line so that maximum transfer of power may occur. Typical heights for AM broadcast towers range from 150 to 500 ft. When the radiated signal must be modified to prevent interference to other stations or to provide better service in a particular direction, additional towers may be combined in a phased array to produce the desired field intensity contours. For example, if a station power increase would cause interference with existing stations, a directional array could be designed that would tailor the coverage to protect the existing stations while allowing increases in other directions. The protection requirements can generally be met with arrays consisting of 4 towers or less, but complex arrays have been constructed consisting of 12 or more towers to meet stringent requirements at a particular location. An example of a directional antenna pattern is shown in Fig. 69.12. This pattern provides major coverage to the southwest and restricts radiation (and thus interference) towards the northeast.

Frequency Modulation

Frequency-modulation (FM) broadcasting refers to the transmission of voice and music received by the general public in the 88- to 108-MHz frequency band. FM is used to provide higher-fidelity reception than is available with standard broadcast AM. In 1961 stereophonic broadcasting was introduced with the addition of a double-sideband suppressed carrier for transmission of a left-minus-right difference signal. The left-plus-right sum channel is sent with use of normal FM. Some FM broadcast systems also include a **subsidiary communications authorization (SCA)** subcarrier for private commercial uses. FM broadcast is typically limited to line-of-sight ranges. As a result, FM coverage is localized to a range of 75 mi (120 km) depending on the antenna height and ERP.

Frequency Allocations

The 100 carrier frequencies for FM broadcast range from 88.1 to 107.9 MHz and are equally spaced every 200 kHz. The channels from 88.1 to 91.9 MHz are reserved for educational and noncommercial broadcasting and those from 92.1 to 107.9 MHz for commercial broadcasting. Each channel has a 200-kHz bandwidth. The maximum frequency swing under normal conditions is ±75 kHz. Stations operating with an SCA may under certain conditions exceed this level, but in no event may exceed a frequency swing of ±82.5 kHz. The carrier frequency is required to be maintained within ±2000 Hz. The frequencies used for FM broadcasting generally limit the coverage to the line-of-sight or a slightly greater distance. The actual coverage area is determined by the ERP of the station and the height of the transmitting antenna above the average terrain in the area. Either increasing the power or raising the antenna will increase the coverage area.

Station Classifications

In FM broadcast, stations are classified according to their maximum allowable ERP and the transmitting antenna height above average terrain in their service area. Class A stations provide primary service to a radius of about

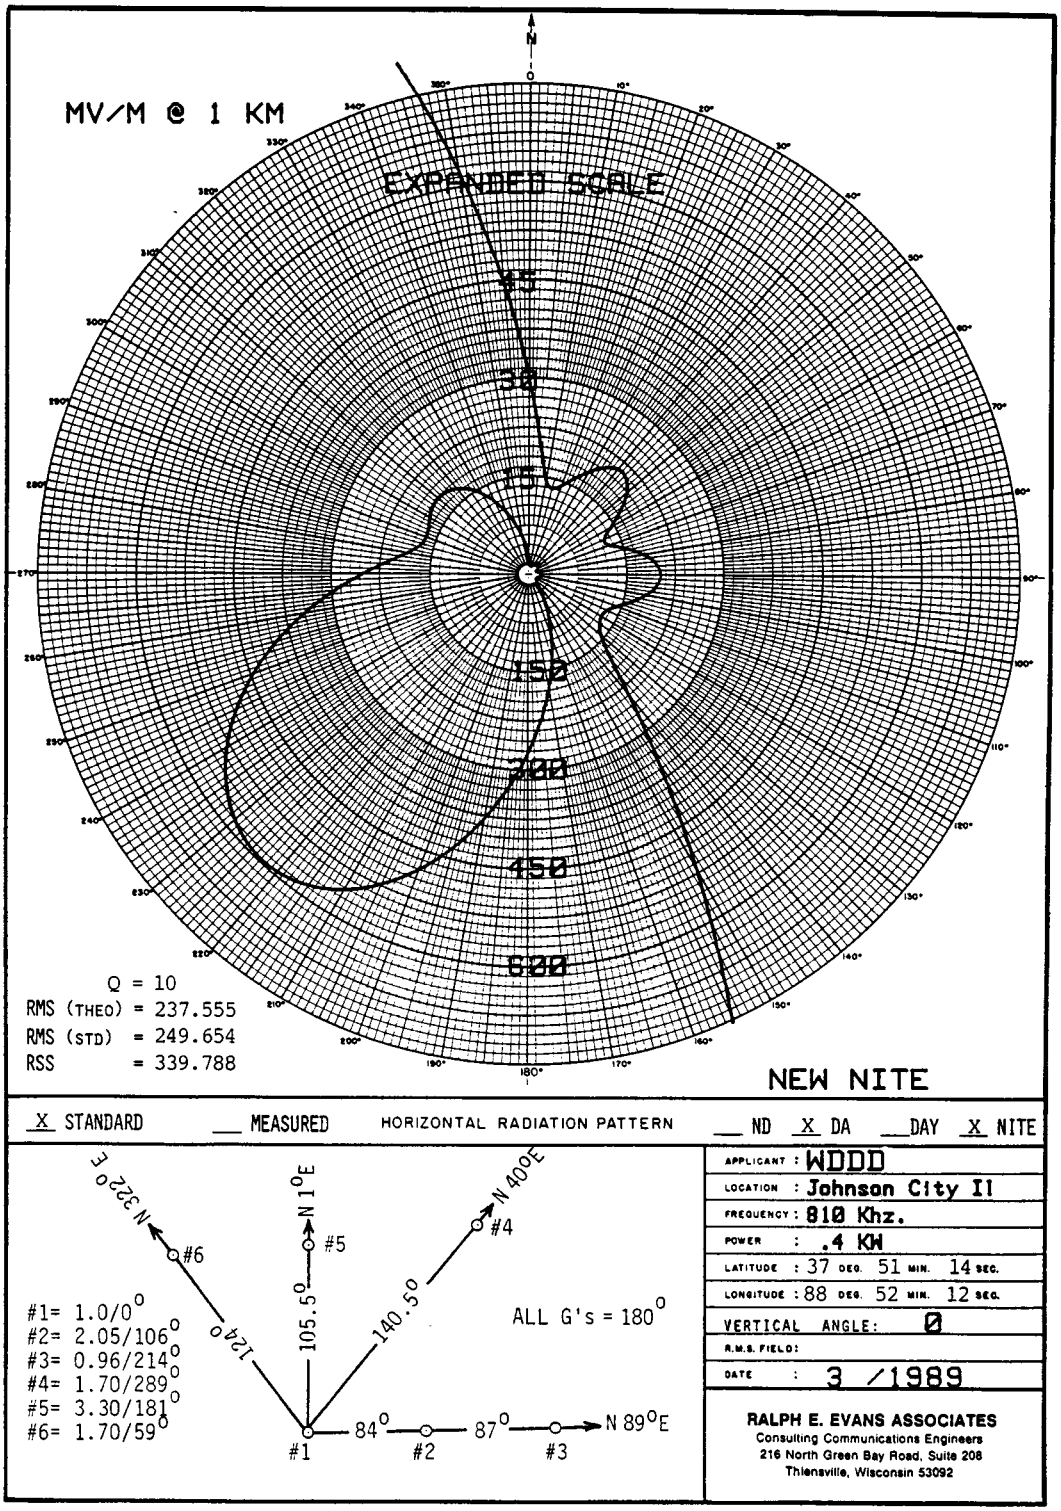

FIGURE 69.12 Directional AM antenna pattern for a six-element array. (*Source:* WDDD-AM, Marion, Ill., and Ralph Evans Associates.)

TABLE 69.5 FM Station Classifications, Powers, and Tower Heights

Station Class	Maximum ERP	HAAT, m (ft)	Distance, km
A	6 kW (7.8 dBk)	100 (328)	28
B1	25 kW (14.0 dBk)	100 (328)	39
B	50 kW (17.0 dBk)	150 (492)	52
C3	25 kW (14.0 dBk)	100 (328)	39
C2	50 kW (17.0 dBk)	150 (492)	52
C1	100 kW (20.0 dBk)	299 (981)	72
C	100 kW (20.0 dBk)	600 (1968)	92

28 km with 6000 W of ERP at a maximum height of 100 m. The most powerful class, Class C, operates with maximums of 100,000 W of ERP and heights up to 600 m with a primary coverage radius of over 92 km. The powers and heights above average terrain (HAAT) for all of the classes are shown in Table 69.5. All classes may operate at antenna heights above those specified but must reduce the ERP accordingly. Stations may not exceed the maximum power specified, even if antenna height is reduced. The classification of the station determines the allowable distance to other co-channel and adjacent channel stations.

Field Strength and Propagation

The field strength produced by an FM broadcast station depends on the ERP, antenna heights, local terrain, tropospheric scattering conditions, and other factors. From a statistical point of view, however, an estimate of the field intensity may be obtained from Fig. 69.13. A factor in the determination of new licenses for FM broadcast is the separation between allocated co-channel and adjacent channel stations, the class of station, and the antenna heights. The spacings are given in Table 69.6. The primary coverage of all classes of stations (except B and B1, which are 0.5 mV/m and 0.7 mV/m, respectively) is the 1.0 mV/m contour. The distance to the primary contour, as well as to the "city grade" or 3.16 mV/m contour may be estimated using Fig. 69.13. Although FM broadcast propagation is generally thought of as line-of-sight, larger ERPs along with the effects of diffraction, refraction, and tropospheric scatter allow coverage slightly greater than line-of-sight.

Transmitters

FM broadcast transmitters typically range in power output from 10 W to 50 kW. A block diagram of a dual FM transmitter is shown in Fig. 69.14. This system consists of two 25-kW transmitters that are operated in parallel and that provide increased reliability in the event of a failure in either the exciter or transmitter power amplifier. The highest-powered solid-state transmitters are currently 10 kW, but manufacturers are developing new devices that will make higher-power solid-state transmitters both cost-efficient and reliable.

Antenna Systems

FM broadcast antenna systems are required to have a horizontally polarized component. Most antenna systems, however, are circularly polarized, having both horizontal and vertical components. The antenna system, which usually consists of several individual radiating bays fed as a phased array, has a radiation characteristic that concentrates the transmitted energy in the horizontal plane toward the population to be served, minimizing the radiation out into space and down toward the ground. Thus, the ERP towards the horizon is increased with gains up to 10 dB. This means that a 5-kW transmitter coupled to an antenna system with a 10-dB gain would have an ERP of 50 kW. Directional antennas may be employed to avoid interference with other stations or to meet spacing requirements. Figure 69.15 is a plot of the horizontal and vertical components of a typical nondirectional circularly polarized FM broadcast antenna showing the effect upon the pattern caused by the supporting tower.

Preemphasis

Preemphasis is employed in an FM broadcast transmitter to improve the received signal-to-noise ratio. The preemphasis upper-frequency limit shown is based on a time constant of 75 μs as required by the FCC for FM

broadcast transmitters. Audio frequencies from 50 to 2120 Hz are transmitted with normal FM, whereas audio frequencies from 2120 Hz to 15 kHz are emphasized with a larger modulation index. There is significant signal-to-noise improvement when the receiver is equipped with a matching deemphasis circuit.

FM Spectrum

The monophonic system was initially developed to allow sound transmissions for audio frequencies from 50 to 15,000 Hz to be contained within a ±75-kHz RF bandwidth. With the development of FM stereo, the original FM signal (consisting of a left-plus-right channel) is transmitted in a smaller bandwidth to be compatible with a monophonic FM receiver, and a left-minus-right channel is frequency-multiplexed on a subcarrier of 38-kHz using double-sideband suppressed carrier. An unmodulated 19-kHz subcarrier is derived from the 38-kHz subcarrier to provide a synchronous demodulation reference for the stereophonic receiver. The synchronous detector at 38 kHz recovers the left-minus-right channel information, which is then combined with the left-plus-right channel information in sum and difference combiners to produce the original left-channel and right-channel signals. In addition stations may utilize an SCA in a variety of ways, such as paging, data transmission, specialized foreign language programs, radio reading services, utility load management, and background music. An FM stereo station may utilize multiplex subcarriers within the range of 53 to 99 kHz with up to 20% modulation of the main carrier using any form of modulation. The only requirement is that the station does not exceed its occupied bandwidth limitations.

Defining Terms

Effective radiated power: Refers to the effective power output from an antenna in a specified direction and includes transmitter output power, transmission line loss and antenna power gain.

Electric field intensity: Measure of signal strength in volts per meter used to determine channel allocation criteria and interference considerations.

Primary service: Refers to areas in which the groundwave signal is not subject to objectionable interference or objectionable fading.

SCA: Subsidiary communications authorization for paging, data transmission, specialized foreign language programs, radio readings services, utility load management and background music using multiplexed subcarriers from 53–99 kHz in connection with broadcast FM.

Secondary service: Refers to areas serviced by skywaves and not subject to objectionable interference.

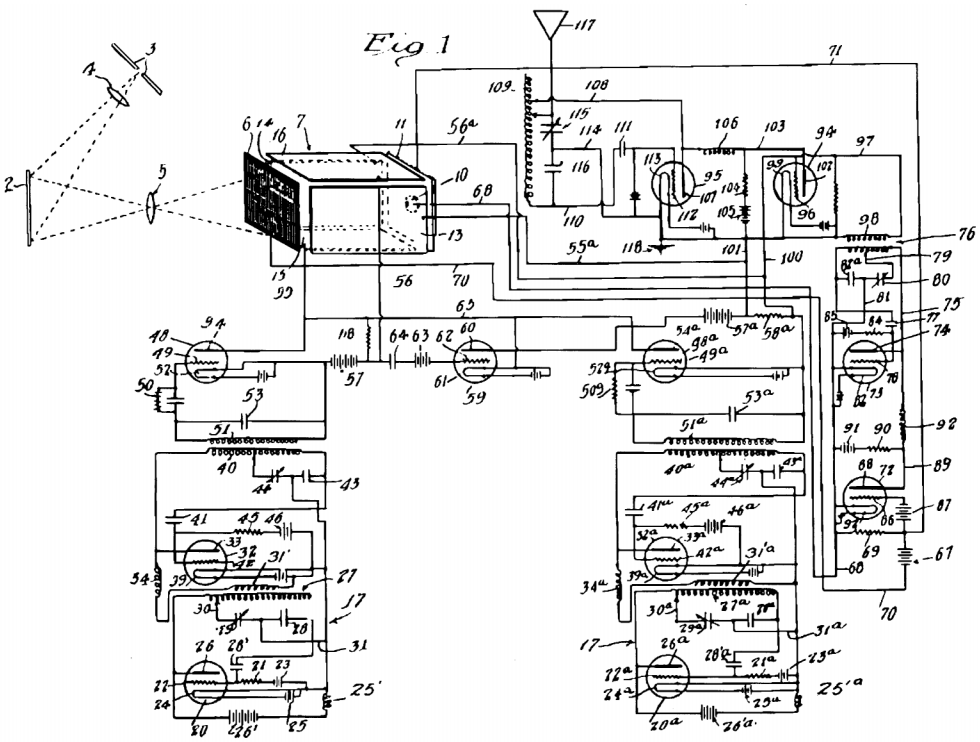
69.3 Television Systems

Jerry Whitaker

The technology of television is based on the conversion of light rays from still or moving scenes and pictures into electronic signals for transmission or storage, and subsequent reconversion into visual images on a screen. A similar function is provided in the production of motion picture film; however, where film records the brightness variations of a complete scene on a single frame in a short exposure no longer than a fraction of a second, the elements of a television picture must be scanned one piece at a time. In the television system, a scene is dissected into a **frame** composed of a mosaic of *picture elements* (pixels). A **pixel** is defined as the smallest area of a television image that can be transmitted within the parameters of the system. This process is accomplished by:

- Analyzing the image with a photoelectric device in a sequence of *horizontal* ***scans*** from the top to the bottom of the image to produce an electric signal in which the brightness and color values of the individual picture elements are represented as voltage levels of a video waveform
- Transmitting the values of the picture elements in sequence as voltage levels of a video signal
- Reproducing the image of the original scene in a video signal display of parallel scanning lines on a viewing screen



Television System

Philo T. Farnsworth
Patented August 26, 1930
#1,773,980

An excerpt from Philo Farnsworth's patent application:

In the process and apparatus of the present invention, light from all portions of the object whose image is to be transmitted, is focused at one time upon a light sensitive plate of a photo-electrical cell to thereby develop an electronic discharge from said plate, in which each portion of the cross-section of such electronic discharge will correspond in electrical intensity with the intensity of light imposed on that portion of the sensitive plate from which the electrical discharge originated. Such a discharge is herein termed an electrical image.

Up to this time, the television process attempted to transmit an image converted to an electrical signal by scanning with mechanically moving apparatus during the brief time period the human eye would retain a picture. Such equipment could not move at sufficient speed to provide full-shaded images to the viewer. At the age of 20, Farnsworth succeeded in producing the first all-electronic television image. It took more that two decades to be adopted for consumer use, but it is easy to see how important this invention has become in today's society.

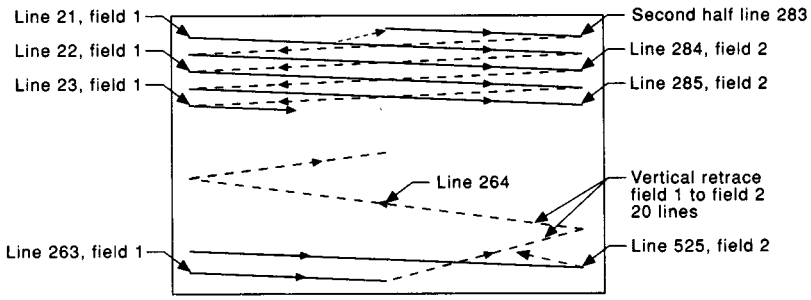


FIGURE 69.16 The interlaced scanning pattern (raster) of the television image. (*Source:* Electronic Industries Association.)

Scanning Lines and Fields

The image pattern of electrical charges on a camera tube target or CCD, corresponding to the brightness levels of a scene, are converted to a video signal in a sequential order of picture elements in the scanning process. At the end of each horizontal line sweep, the video signal is *blanked* while the beam returns rapidly to the left side of the scene to start scanning the next line. This process continues until the image has been scanned from top to bottom to complete one ***field*** *scan.*

After completion of this first field scan, at the midpoint of the last line, the beam again is blanked as it returns to the top center of the target where the process is repeated to provide a second field scan. The spot size of the beam as it impinges upon the target must be fine enough to leave unscanned areas between lines for the second scan. The pattern of scanning lines covering the area of the target, or the screen of a picture display, is called a **raster.**

Interlaced Scanning Fields

Because of the half-line offset for the start of the beam return to the top of the raster and for the start of the second field, the lines of the second field lie in-between the lines of the first field. Thus, the lines of the two are **interlaced.** The two interlaced fields constitute a single television *frame.* Figure 69.16 shows a frame scan with interlacing of the lines of two fields.

Reproduction of the camera image on a cathode ray tube (CRT) or solid-state display is accomplished by an identical operation, with the scanning beam modulated in density by the video signal applied to an element of the electron gun or control element, in the case of a solid-state display device. This control voltage to the display varies the brightness of each picture element on the screen.

Blanking of the scanning beam during the return trace is provided for in the video signal by a "blacker-than-black" pulse waveform. In addition, in most receivers and monitors another blanking pulse is generated from the horizontal and vertical scanning circuits and applied to the display system to ensure a black screen during scanning retrace. The retrace lines are shown as diagonal dashed lines in Fig. 69.16.

The interlaced scanning format, standardized for monochrome and compatible color, was chosen primarily for two partially related and equally important reasons:

- To eliminate viewer perception of the intermittent presentation of images, known as *flicker*
- To reduce video bandwidth requirements for an acceptable flicker threshold level

Perception of flicker is dependent primarily upon two conditions:

- The brightness level of an image
- The relative area of an image in a picture

The 30-Hz transmission rate for a full 525-line television frame is comparable to the highly successful 24-frame-per-second rate of motion-picture film. However, at the higher brightness levels produced on television screens, if all 483 lines (525 less blanking) of a television image were to be presented sequentially as single

frames, viewers would observe a disturbing flicker in picture areas of high brightness. For a comparison, motion-picture theaters on average produce a screen brightness of 10 to 25 ft·L (footlambert), whereas a direct-view CRT may have a highlight brightness of 50 to 80 ft·L. It should be noted also that motion-picture projectors flash twice per frame to reduce the flicker effect.

Through the use of interlaced scanning, single field images with one-half the vertical resolution capability of the 525-line system are provided at the high flicker-perception threshold rate of 60 Hz. Higher resolution of the full 483 lines of vertical detail is provided at the lower flicker-perception threshold rate of 30 Hz. The result is a relatively flickerless picture display at a screen brightness of well over 50 to 75 ft·L, more than double that of motion-picture film projection. Both 60-Hz fields and 30-Hz frames have the same horizontal resolution capability.

The second advantage of interlaced scanning, compared to progressive scanning, where the frame is constructed in one pass over the display face (rather than in two through interlace), is a reduction in video bandwidth for an equivalent flicker threshold level. Progressive scanning of 525 lines would have to be completed in 1/60 s to achieve an equivalent level of flicker perception. This would require a line scan to be completed in half the time of an interlaced scan. The bandwidth then would double for an equivalent number of pixels per line.

The standards adopted by the Federal Communications Commission (FCC) for monochrome television in the United States specified a system of 525 lines per frame, transmitted at a frame rate of 30 Hz, with each frame composed of two interlaced fields of horizontal lines. Initially in the development of television transmission standards, the 60-Hz power line waveform was chosen as a convenient reference for vertical scan. Furthermore, in the event of coupling of power line hum into the video signal or scanning/deflection circuits, the visible effects would be stationary and less objectionable than moving **hum bars** or distortion of horizontal-scanning geometry. In the United Kingdom and much of Europe, a 50-Hz interlaced system was chosen for many of the same reasons. With improvements in television receivers, the power line reference was replaced with a stable crystal oscillator, rendering the initial reason for the frame rate a moot point.

The existing 525-line monochrome standards were retained for color in the recommendations of the National Television System Committee (NTSC) for compatible color television in the early 1950s. The NTSC system, adopted in 1953 by the FCC, specifies a scanning system of 525 horizontal lines per frame, with each frame consisting of two interlaced fields of 262.5 lines at a field rate of 59.94 Hz. Forty-two of the 525 lines in each frame are blanked as black picture signals and reserved for transmission of the vertical scanning synchronizing signal. This results in 483 visible lines of picture information. Because the vertical blanking interval represents a significant amount of the total transmitted waveform, the television industry has sought ways to carry additional data during the blanking interval. Such applications include closed captioning and system test signals.

Synchronizing Video Signals

In monochrome television transmission, two basic synchronizing signals are provided to control the timing of picture-scanning deflection:

- Horizontal sync pulses at the line rate.
- Vertical sync pulses at the field rate in the form of an interval of wide horizontal sync pulses at the field rate. Included in the interval are **equalizing pulses** at twice the line rate to preserve interlace in each frame between the even and odd fields (offset by a half line).

In color transmissions, a third synchronizing signal is added during horizontal scan blanking to provide a frequency and phase reference for color signal encoding circuits in cameras and decoding circuits in receivers. These synchronizing and reference signals are combined with the picture video signal to form a **composite video** waveform.

The scanning and color-decoding circuits in receivers must follow the frequency and phase of the synchronizing signals to produce a stable and geometrically accurate image of the proper color **hue** and **saturation.** Any change in timing of successive vertical scans can impair the interlace of the even and odd fields in a frame. Small errors in horizontal scan timing of lines in a field can result in a loss of resolution in vertical line structures. Periodic errors over several lines that may be out of the range of the horizontal scan automatic frequency control circuit in the receiver will be evident as jagged vertical lines.

TABLE 69.7 Frequency Allocations for TV Channels 2 through 83 in the U.S.

Channel Designation	Frequency Band, MHz	Channel Designation	Frequency Band, MHz	Channel Designation	Frequency Band, MHz
2	54–60	30	566–572	58	734–740
3	60–66	31	572–578	59	740–746
4	66–72	32	578–584	60	746–752
5	76–82	33	584–590	61	752–758
6	82–88	34	590–596	62	758–764
7	174–180	35	596–602	63	764–770
8	180–186	36	602–608	64	770–776
9	186–192	37	608–614	65	776–782
10	192–198	38	614–620	66	782–788
11	198–204	39	620–626	67	788–794
12	204–210	40	626–632	68	794–800
13	210–216	41	632–638	69	800–806
14	470–476	42	638–644	70	806–812
15	476–482	43	644–650	71	812–818
16	482–488	44	650–656	72	818–824
17	488–494	45	656–662	73	824–830
18	494–500	46	662–668	74	830–836

28	554–560	56	722–728		
29	560–566	57	728–734		

Television Industry Standards

There are three primary color transmission standards in use today:

- *NTSC* (National Television Systems Committee): Used in the United States, Canada, Central America, most of South America, and Japan. In addition, NTSC is used in various countries or possessions heavily influenced by the United States.
- *PAL* (Phase Alternation each Line): Used in England, most countries and possessions influenced by the British Commonwealth, many western European countries and China. Variation exists in PAL systems.
- *SECAM* (Sequential Color with [Avec] Memory): Used in France, countries and possessions influenced by France, the USSR (generally the former Soviet Bloc nations), and other areas influenced by Russia.

The three standards are incompatible for a variety of reasons (see Benson and Whitaker, 1991).

Television transmitters in the United States operate in three frequency bands:

- Low-band VHF (very high frequency), channels 2 through 6
- High-band VHF, channels 7 through 13
- UHF (ultra-high frequency), channels 14 through 83 (UHF channels 70 through 83 currently are assigned to mobile radio services)

Table 69.7 shows the frequency allocations for channels 2 through 83. Because of the wide variety of operating parameters for television stations outside the United States, this section will focus primarily on TV transmission as it relates to the Unites States.

Maximum power output limits are specified by the FCC for each type of service. The maximum **effective radiated power** (ERP) for low-band VHF is 100 kW; for high-band VHF it is 316 kW; and for UHF it is 5 MW. The ERP of a station is a function of transmitter power output (TPO) and antenna gain. ERP is determined by multiplying these two quantities together and subtracting transmission line loss.

The second major factor that affects the coverage area of a TV station is antenna height, known in the broadcast industry as *height above average terrain* (HAAT). HAAT takes into consideration the effects of the geography in the vicinity of the transmitting tower. The maximum HAAT permitted by the FCC for a low- or high-band VHF station is 1000 ft (305 m) east of the Mississippi River and 2000 ft (610 m) west of the Mississippi. UHF stations are permitted to operate with a maximum HAAT of 2000 ft (610 m) anywhere in the United States (including Alaska and Hawaii).

The ratio of visual output power to **aural** output power can vary from one installation to another; however, the aural is typically operated at between 10 and 20% of the visual power. This difference is the result of the reception characteristics of the two signals. Much greater signal strength is required at the consumer's receiver to recover the visual portion of the transmission than the aural portion. The aural power output is intended to be sufficient for good reception at the fringe of the station's coverage area but not beyond. It is of no use for a consumer to be able to receive a TV station's audio signal but not the video.

In addition to high power stations, two classifications of low-power TV stations have been established by the FCC to meet certain community needs: They are:

- ***Translator:*** A low-power system that rebroadcasts the signal of another station on a different channel. Translators are designed to provide "fill-in" coverage for a station that cannot reach a particular community because of the local terrain. Translators operating in the VHF band are limited to 100 W power output (ERP), and UHF translators are limited to 1 kW.
- ***Low-Power Television (LPTV):*** A service established by the FCC designed to meet the special needs of particular communities. LPTV stations operating on VHF frequencies are limited to 100 W ERP, and UHF stations are limited to 1 kW. LPTV stations originate their own programming and can be assigned by the FCC to any channel, as long as sufficient protection against interference to a full-power station is afforded.

Composite Video

The composite video waveform is shown in Fig. 69.17. The actual radiated signal is inverted, with modulation extending from the synchronizing pulses at maximum carrier level (100%) to reference picture white at 7.5%. Because an increase in the amplitude of the radiated signal corresponds to a decrease in picture brightness, the polarity of modulation is termed *negative*. The term *composite* is used to denote a video signal that contains:

- Picture luminance and chrominance information
- Timing information for synchronization of scanning and color signal processing circuits

The negative-going portion of the waveform shown in Fig. 69.17 is used to transmit information for synchronization of scanning circuits. The positive-going portion of the amplitude range is used to transmit luminance information representing brightness and, for color pictures, chrominance.

At the completion of each line scan in a receiver or monitor, a horizontal synchronizing (***H****-sync*) pulse in the composite video signal triggers the scanning circuits to return the beam rapidly to the left of the screen for the start of the next line scan. During the return time, a horizontal blanking signal at a level lower than that corresponding to the blackest portion of the scene is added to avoid the visibility of the retrace lines. In a similar manner, after completion of each field, a vertical blanking signal blanks out the retrace portion of the scanning beam as it returns to the top of the picture to start the scan of the next field. The small-level difference between video reference black and blanking level is called **setup.** Setup is used as a guard band to ensure separation of the synchronizing and video-information functions and adequate blanking of the scanning retrace lines on receivers.

The waveforms of Fig. 69.18 show the various reference levels of video and sync in the composite signal. The unit of measurement for video level was specified initially by the Institute of Radio Engineers (IRE). These ***IRE*** *units* are still used to quantify video signal levels. The primary IRE values are given in Table 69.8.

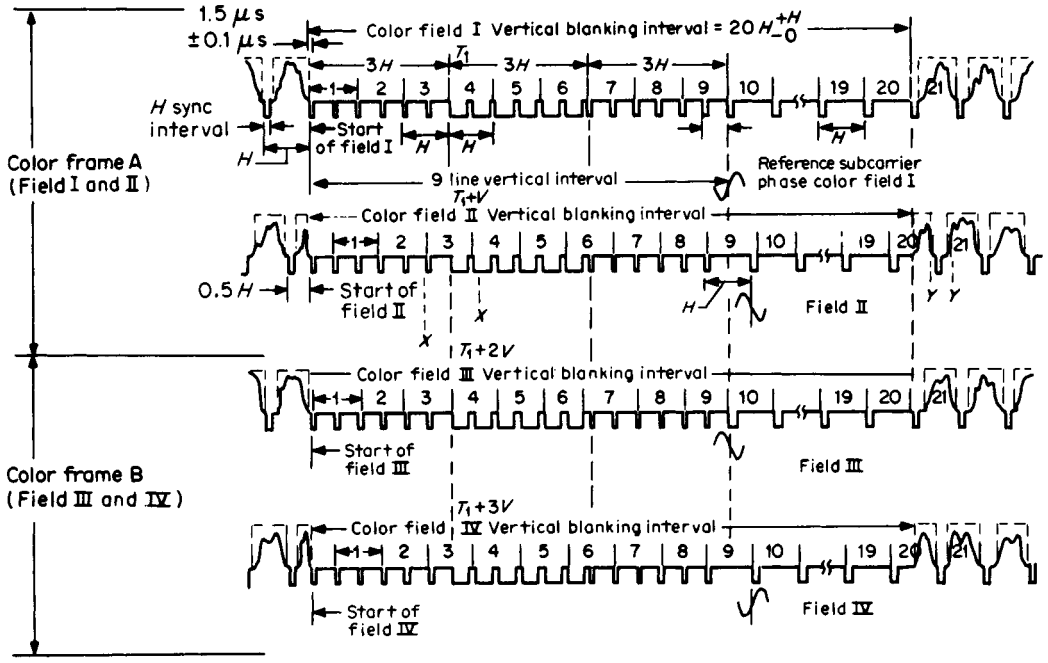

FIGURE 69.17 The principal components of the NTSC color television waveform. (*Source:* Electronic Industries Association.)

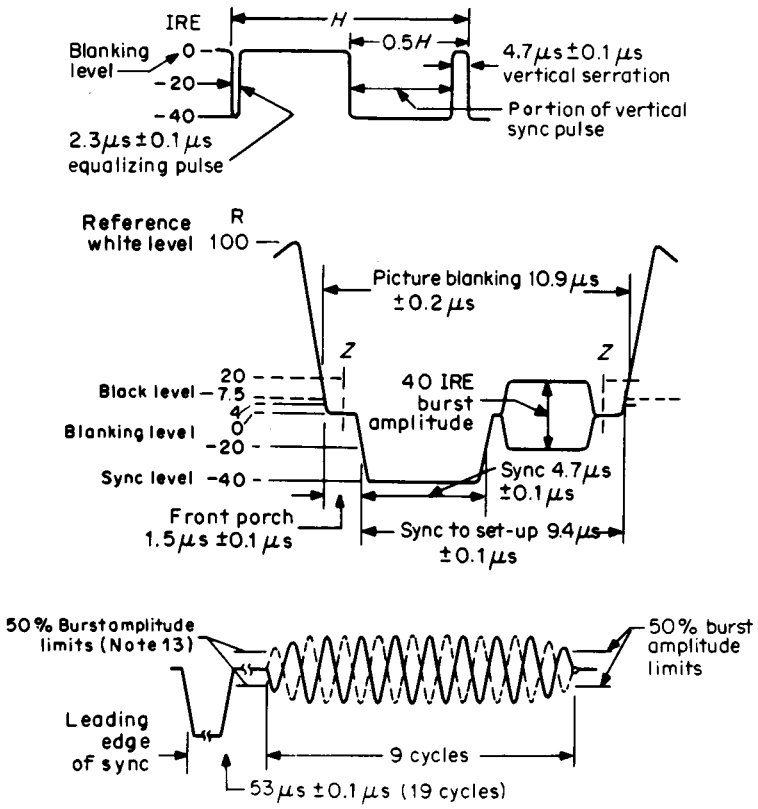

FIGURE 69.18 Sync pulse widths for the NTSC color system. (*Source:* Electronic Industries Association.)

Color Signal Encoding

To facilitate an orderly introduction of color television broadcasting in the United States and other countries with existing monochrome services, it was essential that the new transmissions be compatible. In other words, color pictures would provide acceptable quality on unmodified monochrome receivers. In addition, because of the limited availability of the RF spectrum, another related requirement was the need to fit approximately 2-MHz bandwidth of color information into the 4.2-MHz video bandwidth of the existing 6-MHz broadcasting channels with little or no modification of existing transmitters. This is accomplished by using the band-sharing color signal system developed by the NTSC and by taking advantage of the fundamental characteristics of the eye regarding color sensitivity and resolution.

The video-signal spectrum generated by scanning an image consists of energy concentrated near harmonics of the 15,734-Hz line scanning frequency. Additional lower-amplitude sideband components exist at multiples of 60 Hz (the field scan frequency) from each line scan harmonic. Substantially no energy exists halfway between the line scan harmonics, that is, at odd harmonics of one half line frequency. Thus, these blank spaces in the spectrum are available for the transmission of a signal for carrying color information and its sideband. In addition, a signal modulated with color information injected at this frequency is of relatively low visibility in the reproduced image because the odd harmonics are of opposite phase on successive scanning lines and in successive frames, requiring four fields to repeat. Furthermore, the visibility of the color video signal is reduced further by the use of a subcarrier frequency near the cutoff of the video bandpass.

TABLE 69.8 Video and Sync Levels in IRE Units

Signal Level	IRE Level
Reference white	100
Blanking level width measurement	20
Color burst sine wave peak	+20 to –20
Reference black	7.5
Blanking	0
Sync pulse width measurement	–20
Sync level	–40

In the NTSC system, color is conveyed using two elements:

- A luminance signal
- A chrominance signal

The luminance signal is derived from components of the three primary colors — red, green, and blue — in the proportions for *reference white*, E_y, as follows:

$$E_y = 0.3E_R + 0.59E_G + 0.11E_B$$

These transmitted values equal unity for white and thus result in the reproduction of colors on monochrome receivers at the proper luminance level. This is known as the *constant-luminance* principle.

The color signal consists of two chrominance components, *I* and *Q*, transmitted as amplitude-modulated sidebands of two 3.579545-MHz subcarriers in quadrature. The subcarriers are suppressed, leaving only the sidebands in the color signal. Suppression of the carriers permits demodulation of the color signal as two separate color signals in a receiver by reinsertion of a carrier of the phase corresponding to the desired color signal (**synchronous demodulation**).

I and *Q* signals are composed of red, green, and blue primary color components produced by color cameras and other signal generators. The phase relationship among the *I* and *Q* signals, the derived primary and complementary colors, and the color synchronizing burst can be shown graphically on a **vectorscope** display. The horizontal and vertical sweep signals on a vectorscope are produced from R-Y and B-Y subcarrier sine waves in quadrature, producing a circular display. The chrominance signal controls the intensity of the display. A vectorscope display of an Electronic Industries Association (EIA) standard color bar signal is shown in Fig. 69.19.

Color-Signal Decoding

Each of the two chroma signal carriers can be recovered individually by means of synchronous detection. A reference subcarrier of the same phase as the desired chroma signal is applied as a gate to a balanced demodulator. Only the modulation of the signal in the same phase as the reference will be present in the output. A

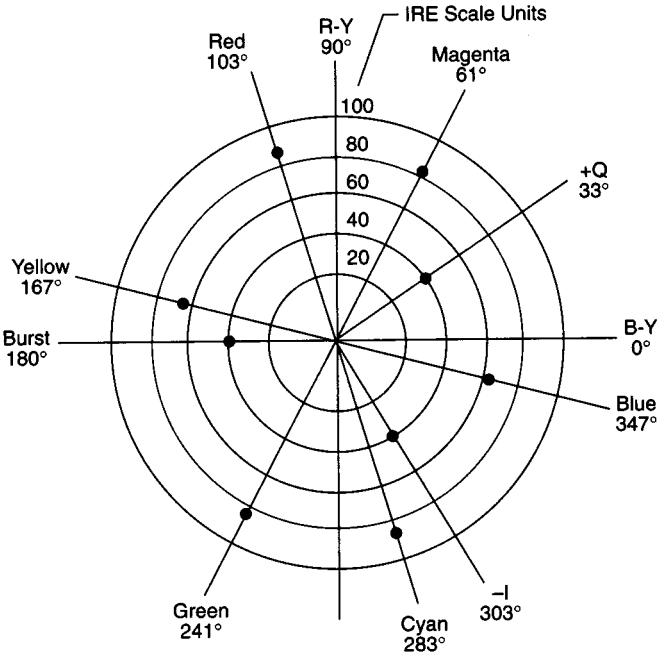

FIGURE 69.19 Vectorscope representation for chroma and vector amplitude relationships in the NTSC system. (*Source:* Electronic Industries Association.)

low-pass filter may be added to remove second harmonic components of the chroma signal generated in the process.

Transmission Equipment

Television transmitters are classified in terms of their operating band, power level, type of final amplifier stage, and cooling method. The transmitter is divided into two basic subsystems:

- The *visual* section, which accepts the video input, amplitude modulates an RF carrier, and amplifies the signal to feed the antenna system
- The *aural* section, which accepts the audio input, frequency modulates a separate RF carrier and amplifies the signal to feed the antenna system

The visual and aural signals are combined to feed a single radiating system.

Transmitter Design Considerations

Each manufacturer has a particular philosophy with regard to the design and construction of a broadcast TV transmitter. Some generalizations can, however, be made with respect to basic system design.

When the power output of a TV transmitter is discussed, the visual section is the primary consideration. Output power refers to the *peak power* of the visual section of the transmitter (*peak of sync*). The FCC-licensed ERP is equal to the transmitter power output minus feedline losses times the power gain of the antenna.

A low-band VHF station can achieve its maximum 100-kW power output through a wide range of transmitter and antenna combinations. A 35-kW transmitter coupled with a gain-of-4 antenna would work, as would a 10-kW transmitter feeding an antenna with a gain of 12. Reasonable pairings for a high-band VHF station would range from a transmitter with a power output of 50 kW feeding an antenna with a gain of 8, to a 30-kW transmitter connected to a gain-of-12 antenna. These combinations assume reasonable feedline losses. To reach the exact power level, minor adjustments are made to the power output of the transmitter, usually by a front panel power trim control.

UHF stations that want to achieve their maximum licensed power output are faced with installing a very high-power transmitter. Typical pairings include a transmitter rated for 220 kW and an antenna with a gain of 25, or a 110-kW transmitter and a gain-of-50 antenna. In the latter case, the antenna could pose a significant problem. UHF antennas with gains in the region of 50 are possible, but not advisable for most installations because of the coverage problems that can result. High-gain antennas have a narrow vertical radiation pattern that can reduce a station's coverage in areas near the transmitter site.

At first examination, it might seem reasonable and economical to achieve licensed ERP using the lowest transmitter power output possible and highest antenna gain. Other factors, however, come into play that make the most obvious solution not always the best solution. Factors that limit the use of high-gain antennas include:

- The effects of high-gain designs on coverage area and signal penetration
- Limitations on antenna size because of tower restrictions, such as available vertical space, weight, and windloading
- The cost of the antenna

The amount of output power required of a transmitter will have a fundamental effect on system design. Power levels dictate whether the unit will be of solid-state or vacuum-tube design; whether air, water, or vapor cooling must be used; the type of power supply required; the sophistication of the high-voltage control and supervisory circuitry; and many other parameters.

Solid-state devices are generally used for VHF transmitters below 35 kW and for low-power UHF transmitters (below 10 kW). Tetrodes may also be used in these ranges. As solid-state technology advances, the power levels possible in a reasonable transmitter design steadily increase. In the realm of high power UHF transmitters, the **klystron** is a common power output device. Klystrons use an *electron bunching* technique to generate high power (55 kW from a single tube is not uncommon) at microwave frequencies. The klystron, however, is relatively inefficient in its basic form. A stock klystron with no efficiency-optimizing circuitry might be only 40 to 50% efficient, depending on the type of device used. Various schemes have been devised to improve klystron efficiency, the best known of which is **beam pulsing.** Two types of pulsing are in common used:

- *Mod-anode pulsing*, a technique designed to reduce power consumption of the klystron during the color burst and video portion of the signal (and thereby improve overall system efficiency)
- *Annular control electrode* (ACE) pulsing, which accomplishes basically the same thing by incorporating the pulsing signal into a low-voltage stage of the transmitter, rather than a high-voltage stage (as with mod-anode pulsing).

Still another approach to improving UHF transmitter efficiency involves entirely new classes of vacuum tubes: the **Klystrode** (also known as the *inductive output tube,* IOT) and the **multistage depressed collector (MSDC) klystron.** (The Klystrode is a registered trademark of Varian.) The IOT is a device that essentially combines the cathode/grid structure of the tetrode with the drift tube/collector structure of the klystron. The MSDC klystron incorporates a collector assembly that operates at progressively lower voltage levels. The net effect for the MSDC is to recover energy from the electron stream rather than dissipating the energy as heat.

Elements of the Transmitter

A television transmitter can be divided into four major subsystems:

- The exciter
- Intermediate power amplifier (IPA)
- Power amplifier (PA)
- High-voltage power supply

Figure 69.20 shows the audio, video, and RF paths for a typical television transmitter.

The modulated visual intermediate frequency (IF) signal is band-shaped in a vestigial sideband filter, typically a surface-acoustic-wave (SAW) filter. Envelope-delay correction is not required for the SAW filter because of the uniform delay characteristics of the device. Envelope-delay compensation may, however, be needed for other parts of the transmitter. The SAW filter provides many benefits to transmitter designers and operators.

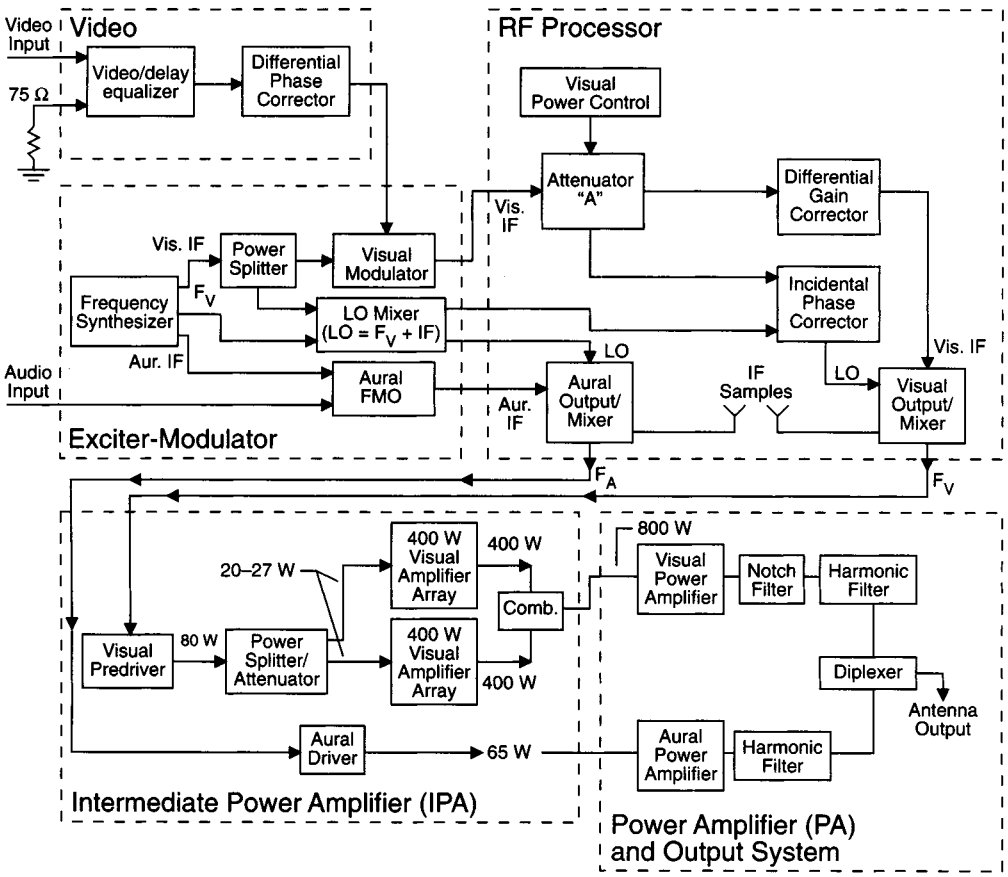

FIGURE 69.20 Simplified block diagram of a VHF television transmitter.

A SAW filter requires no adjustments and is stable with respect to temperature and time. A *color-notch filter* is required at the output of the transmitter because imperfect linearity of the IPA and PA stages introduces unwanted modulation products.

The power amplifier raises the output energy of the transmitter to the desired RF operating level. Tetrodes in television service are operated in the class B mode to obtain reasonable efficiency while maintaining a linear transfer characteristic. Class B amplifiers, when operated in tuned circuits, provide linear performance because of the flywheel effect of the resonance circuit. This allows a single tube to be used instead of two in push-pull fashion. The bias point of the linear amplifier is chosen so that the transfer characteristic at low modulation levels matches that at higher modulation levels. The plate (anode) circuit of a tetrode PA is usually built around a coaxial resonant cavity, which provides a stable and reliable tank circuit.

Solid state transmitters typically incorporate a massively parallel design to achieve the necessary power levels. So-called power blocks of 1 kW or greater are combined as required to meet the target transmitter power output. Most designs use MOSFETs running in a class D (or higher) switching mode. Any one of several combiner schemes may be used to couple the power blocks to the load. Depending on the design, high-reliability features may be incorporated into the transmitter, including automatic disconnection of failed power blocks and hot-changing of defective modules.

UHF transmitters using a klystron in the final output stage must operate class A, the most linear but also most inefficient operating mode for a vacuum tube. Two types of klystrons have traditionally been used: *integral cavity* and *external cavity* devices. The basic theory of operation is identical for each tube, but the mechanical approach is radically different. In the **integral cavity klystron,** the cavities are built into the device to form a

single unit. In the **external cavity klystron,** the cavities are outside the vacuum envelope and are bolted around the tube when the klystron is installed in the transmitter. A number of factors come into play in a discussion of the relative merits of integral vs. external cavity designs. Primary considerations include operating efficiency, purchase price, and life expectancy.

Transmitters based on IOT or MSDC klystron final tubes have much in common with traditional klystron-based systems. There are, however, a number of significant differences, including:

- Low-level video waveform precorrection circuitry
- Drive power requirements
- Power supply demands and complexity
- Fault/arc suppression and protection
- Cooling system design and complexity
- Overall system efficiency

The transmitter block diagram of Fig. 69.20 shows separate visual and aural PA stages. This configuration is normally used for high-power transmitters. Low-power designs often use a combined mode (*common amplification*) in which the aural and visual signals are added prior to the PA. This approach offers a simplified system but at the cost of additional precorrection of the input video signal.

PA stages often are configured so that the circuitry of the visual and aural amplifiers is identical, providing backup protection in the event of a visual PA failure. The aural PA can then be reconfigured to amplify both the aural and the visual signals at reduced power.

The aural output stage of a television transmitter is similar in basic design to a frequency modulated (FM) broadcast transmitter. Tetrode output devices generally operate class C; solid-state devices operate in one of many possible switching modes for high efficiency. The aural PA for a UHF transmitter may use a klystron, IOT, MSDC, tetrode, or a group of solid-state power blocks.

Harmonic filters are employed to attenuate out-of-band radiation of the aural and visual signals to ensure compliance with FCC requirements. Filter designs vary depending upon the manufacturer; however, most are of coaxial construction utilizing L and C components housed within a prepackaged assembly. Stub filters are also used, typically adjusted to provide maximum attenuation at the second harmonic of the operating frequency of the visual carrier and the aural carrier.

The filtered visual and aural outputs are fed to a hybrid diplexer where the two signals are combined to feed the antenna. For installations that require dual-antenna feedlines, a hybrid combiner with quadrature-phased outputs is used. Depending upon the design and operating power, the color-notch filter, aural and visual harmonic filters, and diplexer may be combined into a single mechanical unit.

Antenna System

Broadcasting is accomplished by the emission of coherent electromagnetic waves in free space from one or more radiating-antenna elements that are excited by modulated RF currents. Although, by definition, the radiated energy is composed of mutually dependent magnetic and electric vector fields, conventional practice in television engineering is to measure and specify radiation characteristics in terms of the electric field only.

The field vectors may be polarized horizontally, vertically, or circularly. Television broadcasting, however, has used horizontal polarization for the majority of installations worldwide. More recently interest in the advantages of circular polarization has resulted in an increase in this form of transmission, particularly for VHF channels. Both horizontal and circular polarization designs are suitable for tower-top or side-mounted installations. The latter option is dictated primarily by the existence of a previously installed tower-top antenna. On the other hand, in metropolitan areas where several antennas must be located on the same structure, either a stacking or candelabra-type arrangement is feasible. Another approach to TV transmission involves combining the RF outputs of two or more stations and feeding a single wideband antenna. This approach is expensive and requires considerable engineering analysis to produce a combiner system that will not degrade the performance of either transmission system.

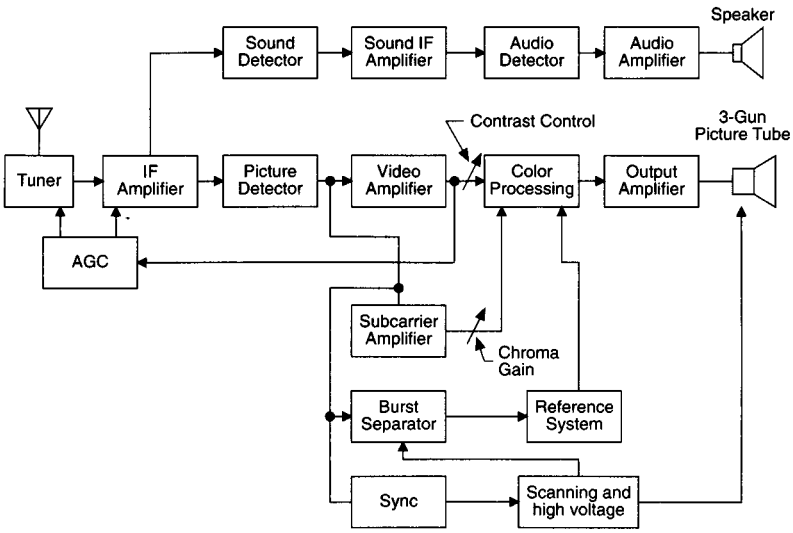

FIGURE 69.21 Simplified schematic block diagram of a color television receiver.

Television Reception

The broadcast channels in the United States are 6 MHz wide for transmission on conventional 525-line standards. The minimum signal level at which a television receiver will provide usable pictures and sound is called the *sensitivity level*. The FCC has set up two standard signal level classifications, Grades A and B, for the purpose of licensing television stations and allocating coverage areas. Grade A refers to urban areas relatively near the transmitting tower; Grade B use ranges from suburban to rural and other fringe areas a number of miles from the transmitting antenna.

Many sizes and form factors of receivers are manufactured. Portable personal types include pocket-sized or hand-held models with picture sizes of 2 to 4 in. diagonal for monochrome and 5 to 6 in. for color. Large screen sizes are available in monochrome where low cost and light weight are prime requirements. However, except where portability is important, the majority of television program viewing is in color. The 19- and 27-in. sizes dominate the market.

Television receiver functions may be broken down into several interconnected blocks. With the increasing use of large-scale integrated circuits, the isolation of functions has become less obvious in the design of receivers. The typical functional configuration of a receiver using a trigun picture tube is shown in Fig. 69.21.

Display Systems

Color video displays may be classified under the following categories:

- Direct-view CRT
- Large-screen display, optically projected from a CRT
- Large-screen display, projected from a modulated light beam
- Large-area display of individually driven light-emitting CRTs or incandescent picture elements
- Flat-panel matrix of transmissive or reflective picture elements
- Flat-panel matrix of light-emitting picture elements

The CRT remains the dominant type of display for both consumer and professional 525-/625-line television applications. The Eidophor and light-valve systems using a modulated light source have found wide application for presentations to large audiences in theater environments, particularly where high screen brightness is required. Matrix-driven flat-panel displays are used in increasing numbers for small-screen personal television receivers and for portable projector units. Video and data projectors using LCD technology have gained wide acceptance.

Cathode Ray Tube Display

The direct-view CRT is the dominant display device in television. The attributes offered by CRTs include the following:

- High brightness
- High resolution
- Excellent gray-scale reproduction
- Low cost compared to other types of displays

From the standpoint of television receiver manufacturing simplicity and low cost, packaging of the display device as a single component is attractive. The tube itself is composed of only three basic parts: an electron gun, an envelope, and a shadow-mask phosphor screen. The luminance efficiency of the electron optical system and the phosphor screen is high. A peak beam current of under 1 μA in a 25-in. tube will produce a highlight brightness of up to 100 ft·L. The major drawback is the power required to drive the horizontal sweep circuit and the high accelerating voltage necessary for the electron beam. This requirement is partially offset through generation of the screen potential and other lower voltages by rectification of the scanning flyback voltage.

As consumer demands drive manufacturers to produce larger picture sizes, the weight and depth of the CRT and the higher power and voltage requirements become serious limitations. These are reflected in sharply increasing receiver costs. To withstand the atmospheric pressures on the evacuated glass envelope, CRT weight increases exponentially with the viewable diagonal. Nevertheless, manufacturers have continued to meet the demand for increased screen sizes with larger direct-view tubes. Improved versions of both tridot delta and in-line guns have been produced. The tridot gun provides small spot size at the expense of critical convergence adjustments for uniform resolution over the full-tube faceplate. In-line guns permit the use of a self-converging deflection yoke that will maintain dynamic horizontal convergence over the full face of the tube without the need for correction waveforms. The downside is slightly reduced resolution.

Defining Terms

Aural: The sound portion of a television signal.

Beam pulsing: A method used to control the power output of a klystron in order to improve the operating efficiency of the device.

Blanking: The portion of a television signal that is used to blank the screen during the horizontal and vertical retrace periods.

Composite video: A single video signal that contains luminance, color, and synchronization information. NTSC, PAL, and SECAM are all examples of composite video formats.

Effective radiated power: The power supplied to an antenna multiplied by the relative gain of the antenna in a given direction.

Equalizing pulses: In an encoded video signal, a series of 2X line frequency pulses occurring during vertical blanking, before and after the vertical synchronizing pulse. Different numbers of equalizing pulses are inserted into different fields to ensure that each field begins and ends at the right time to produce proper interlace. The 2X line rate also serves to maintain horizontal synchronization during vertical blanking.

External cavity klystron: A klystron device in which the resonant cavities are located outside the vacuum envelope of the tube.

Field: One of the two (or more) equal parts of information into which a frame is divided in interlace video scanning. In the NTSC system, the information for one picture is divided into two fields. Each field contains one-half the lines required to produce the entire picture. Adjacent lines in the picture are contained in alternate fields.

Frame: The information required for one complete picture in an interlaced video system. For the NTSC system, there are two fields per frame.

H (horizontal): In television signals, *H* may refer to any of the following: the horizontal period or rate, horizontal line of video information, or horizontal sync pulse.

Hue: One of the characteristics that distinguishes one color from another. Hue defines color on the basis of its position in the spectrum (red, blue, green, yellow, etc.). Hue is one of the three characteristics of television color. Hue is often referred to as *tint.* In NTSC and PAL video signals, the hue information at any particular point in the picture is conveyed by the corresponding instantaneous phase of the active video subcarrier.

Hum bars: Horizontal black and white bars that extend over the entire TV picture and usually drift slowly through it. Hum bars are caused by an interfering power line frequency or one of its harmonics.

Integral cavity klystron: A klystron device in which the resonant cavities are located inside the vacuum envelope of the tube.

Interlaced: A shortened version of *interlaced scanning* (also called *line interlace*). Interlaced scanning is a system of video scanning whereby the odd- and even-numbered lines of a picture are transmitted consecutively as two separate interleaved fields.

IRE: A unit equal to 1/140 of the peak-to-peak amplitude of a video signal, which is typically 1 V. The 0 IRE point is at blanking level, with the sync tip at –40 IRE and white extending to +100 IRE. IRE stands for *Institute of Radio Engineers*, an organization preceding the IEEE, which defined the unit.

Klystrode: An amplifier device for UHF-TV signals that combines aspects of a tetrode (grid modulation) with a klystron (velocity modulation of an electron beam). The result is a more efficient, less expensive device for many applications. (Klystrode is a trademark of EIMAC, a division of Varian Associates.) The term *Inductive Output Tube* (IOT) is a generic name for this class of device.

Klystron: An amplifier device for UHF and microwave signals based on velocity modulation of an electron beam. The beam is directed through an input cavity, where the input RF signal polarity initializes a *bunching effect* on electrons in the beam. The bunching effect excites subsequent cavities, which increase the bunching through an energy flywheel concept. Finally, the beam passes an output cavity that couples the amplified signal to the load (antenna system). The beam falls onto a collector element that forms the return path for the current and dissipates the heat resulting from electron beam bombardment.

Low-power TV (LPTV): A television service authorized by the FCC to serve specific confined areas. An LPTV station may typically radiate between 100 and 1000 W of power, covering a geographic radius of 10 to 15 mi.

Multistage depressed collector (MSDC) klystron: A specially designed klystron in which decreasing voltage zones cause the electron beam to be reduced in velocity before striking the collector element. The effect is to reduce the amount of heat that must be dissipated by the device, improving operating efficiency.

Pixel: The smallest distinguishable and resolvable area in a video image. A pixel is a single point on the screen. The word pixel is derived from *picture element.*

Raster: A predetermined pattern of scanning the screen of a CRT. *Raster* may also refer to the illuminated area produced by scanning lines on a CRT when no video is present.

Saturation: The intensity of the colors in the active picture, the voltage levels of the colors. Saturation relates to the degree by which the eye perceives a color as departing from a gray or white scale of the same brightness. A 100% saturated color does not contain any white; adding white reduces saturation. In NTSC and PAL video signals, the color saturation at any particular instant in the picture is conveyed by the corresponding instantaneous amplitude of the active video subcarrier.

Scan: One sweep of the target area in a camera tube or of the screen in a picture tube.

Setup: A video term relating to the specified base of an active picture signal. In NTSC, the active picture signal is placed 7.5 IRE units above blanking (0 IRE). Setup is the separation in level between the *video blanking* and *reference black* levels.

Synchronous detection: A demodulation process in which the original signal is recovered by multiplying the modulated signal by the output of a synchronous oscillator locked to the carrier.

Translator: An unattended television or FM broadcast repeater that receives a distant signal and retransmits the picture and/or audio locally on another channel.

Vectorscope: An oscilloscope-type device used to display the color parameters of a video signal. A vectorscope decodes color information into R-Y and B-Y components, which are then used to drive the *X* and *Y* axis of the scope. The total lack of color in a video signal is displayed as a dot in the center of the vectorscope. The angle, distance around the circle, magnitude, and distance away from the center indicate the phase and amplitude of the color signal.

69.4 High-Definition Television

Martin S. Roden

When standards were developed for television, few people dreamed of its evolution into a type of universal communication terminal. While these traditional standards are acceptable for entertainment video, they are not adequate for many emerging applications, such as videotext. We must evolve into a high-resolution standard. High-definition TV (HDTV) is a term applied to a broad class of new systems whose developments have received worldwide attention.

We begin with a brief review of the current television standards. The reader is referred to Section 69.3 for a more detailed treatment of conventional television.

Japan and North America use the National Television Systems Committee (NTSC) standard that specifies 525 scanning lines per picture, a field rate of 59.94 per second (nominally 60 Hz), and 2:1 **interlaced scanning** (although there are about 60 fields per second, there are only 30 new frames per second). The **aspect ratio** (ratio of width to height) is 4:3. The bandwidth of the television signal is 6 MHz, including the sound signal. In Europe and some other countries, the phase-alternation line (PAL) or the sequential color and memory (SECAM) standard is used. This specifies 625 scanning lines per picture and a field rate of 50 per second. The bandwidth of this type of television signal is 8 MHz.

HDTV systems nominally double the number of scan lines in a frame and change the aspect ratio to 16:9. Of course, if we were willing to start from scratch and abandon all existing television systems, we could set the bandwidth of each channel to a number greater than 6 (or 8) MHz, thereby achieving higher resolution. The Japan Broadcasting Corporation (NHK) has done just this in their HDTV system. This system permits 1125 lines per frame with 30 frames per second and 60 fields per second (2:1 interlaced scanning). The aspect ratio

is 16:9. The system is designed for a bandwidth of 10 MHz per channel. With the 1990 launching of the BS-3 satellite, two channels were devoted to this form of HDTV. To fit the channel within a 10-MHz bandwidth (instead of the approximately 50 MHz that would be needed to transmit using traditional techniques), bandwidth compression was required. It should be noted that the Japanese system is primarily analog frequency modulation (FM) (the sound is digital). The approach to decreasing bandwidth is multiple sub-Nyquist encoding (**MUSE**). The sampling below Nyquist lowers the bandwidth requirement, but moving images suffer from less resolution.

Europe began its HDTV project in mid-1986 with a joint initiative involving West Germany (Robert Bosch GmbH), the Netherlands (NV Phillips), France (Thomson SA), and the United Kingdom (Thorn/EMI Plc.). The system, termed **Eureka 95** or D2-MAC, has 1152 lines per frame, 50 fields per second, 2:1 interlaced scanning, and a 16:9 aspect ratio. A more recent European proposed standard is for 1250 scanning lines at 50 fields per second. This is known as the **Eureka EU95.** It is significant to note that the number of lines specified by Eureka EU95 is exactly twice that of the PAL and SECAM standard currently in use. The field rate is the same, so it is possible to devise compatible systems that would permit reception of HDTV by current receivers (of course, with adapters and without enhanced definition). The HDTV signal requires nominally 30 MHz of bandwidth.

In the United States, the FCC has ruled (in March 1990) that any new HDTV system must permit continuation of service to contemporary NTSC receivers. This significant constraint applies to terrestrial broadcasting (as opposed to videodisk, videotape, and cable television). The HDTV signals will be sent on **"taboo channels,"** those that are not used in metropolitan areas to provide adequate separation. Thus, these currently unused channels would be used for simulcast signals. Since the proposed HDTV system for the United States uses digital transmission, transmitter power can be less than that used for conventional television — this reduces interference with adjacent channels. Indeed, in heavily populated urban areas (where many stations are licensed for broadcast), the HDTV signals will have to be severely limited in power.

When a color television signal is converted from analog to digital (A/D), the luminance, hue, and saturation signals must each be digitized using 8 bits of A/D per sample. Digital transmission of conventional television therefore requires a nominal bit rate of about 216 megabits/s, while uncompressed HDTV nominally requires about 1200 megabits/s. If we were to use a digital modulation system that transmits 1 bit per hertz of bandwidth, we see that the HDTV signal requires over 1 GHz of bandwidth, yet only 6 MHz is allocated. Clearly significant data compression is required!

Proposed Systems

In the early 1990s, four digital HDTV approaches were submitted for FCC testing. The four were proposed by General Instrument Corporation, the Advanced Television Research Consortium (composed of NBC, David Sarnoff Research Center, Philips Consumer Electronics, and Thomson Consumer Electronics, Inc.), Zenith Electronics in cooperation with AT&T Bell Labs and AT&T Microelectronics, and the American Television Alliance (General Instrument Corporation and MIT). There were many common aspects to the four proposals, but major differences existed in the data compression approaches. The data compression techniques can be viewed as two-dimensional extensions of techniques used in voice encoding.

Something unprecedented happened in Spring 1993. The various competing parties decided, with some encouragement from an FCC advisory committee, to merge to form a **Grand Alliance**. The Alliance consists of seven members: AT&T, General Instrument Corp., MIT, Philips, Sarnoff, Thomson, and Zenith. This permitted the selection of the "best" features of each of the proposals. The advisory committee was then able to spend Fall 1995 on completion of the proposed HDTV standard. In the following, we describe a generic system. The reader is referred to the references for details.

Figure 69.22 shows a general block diagram of a digital HDTV transmitter. Each frame from the camera is digitized, and the system has the capability of storing one entire frame. Thus the processor works with two inputs—the current frame (*A*) and the previous frame (*B*). The current frame and the previous frame are compared in a **motion detector** that generates coded motion information (*C*). Algorithms used for motion estimation attempt to produce three-dimensional parameters from sequential two-dimensional information. Parameters may include velocity estimates for blocks of the picture.

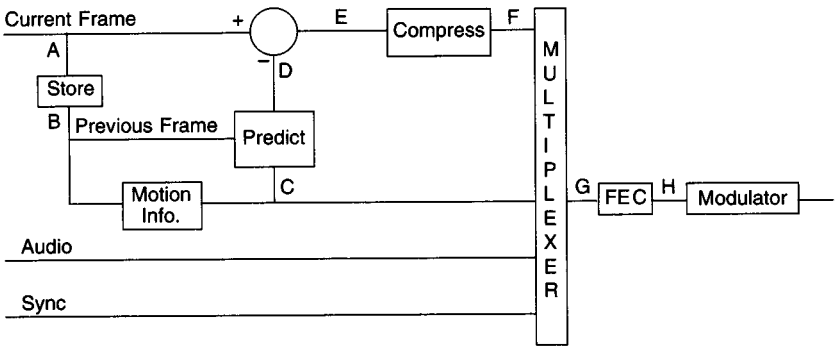

FIGURE 69.22 Block diagram of HDTV transmitter.

The parameters from the motion detector are processed along with the previous frame to produce a *prediction* of the current frame (*D*). Since the motion detector parameters are transmitted, the receiver can perform a similar prediction of the current frame.

The predicted current frame is compared to the actual current frame, and a difference signal (*E*) is generated. This difference signal will generally have a smaller dynamic range than the original signal. For example, if the television image is static (is not changing with time), the difference signal will be zero.

The difference signal is *compressed* to form the transmitted video signal (*F*). This compression is performed both in the time and transform domains. **Entropy coding** of the type used in facsimile can be incorporated to take spatial continuity into account (i.e., a picture usually does not change over the span of a single picture element, so variations of "run length" coding can often compress the data). The compression technique incorporates the **MPEG-2** syntax. The actual compression algorithms (based on the **discrete cosine transform**) are adaptive so a variety of formats can be accommodated (e.g., 1080-line interlaced scanning, 720-line progressive, bi-directional). The main feature is that the data rate is decreased by extracting essential parameters that describe the waveform.

Four data streams are asynchronously multiplexed to form the information to be transmitted (*G*). These four signals consist of the coded differential video, the motion detector parameters, the digital audio signal (using Dolby Labs' AC-3 digital audio), and the synchronizing signals. Other information can be multiplexed, including various control signals that may be needed by cable operators.

Forward error correction is applied to the multiplexed digital signal to produce an encoded signal (*H*) that makes the transmission less susceptible to uncorrected bit errors. This is needed because of the anticipated low transmission power rates. Error control is also important because compression can amplify error effects—a single bit error can affect many picture elements.

The encoded data signal forms the input to the modulator. To further conserve bandwidth, a type of quadrature modulation is employed. The actual form is 8-VSB, a variation of **digital vestigial sideband** that includes **trellis coding**. This possesses many of the advantages of guadrature amplitude modulation (QAM).

The corresponding receiver is shown in Fig. 69.23. The receiver simply forms the inverse of each transmitter operation. The received signal is first demodulated. The resulting data signal is decoded to remove the redundancy and correct errors. A demultiplexer separates the signal into the original four (or more) data signals. The audio and synchronization signals need no further processing.

The demultiplexed video signal is, hopefully, the same as the transmitted signal ("*F*"). We use letters with quotation marks to indicate that the signals are estimates of their transmitted counterpart. This reproduced video signal is decompressed, using the inverse algorithm of that used in the transmitter, to yield an estimate of the original differential picture signal ("*E*"). The predict block in the receiver implements the same algorithm as that of the transmitter. Its inputs are the reconstructed motion signal ("*C*") and the previous reconstructed frame ("*B*"). When the predictor output ("*D*") is added to the reconstructed differential picture signal ("*E*"), the result is a reconstructed version of the current frame.

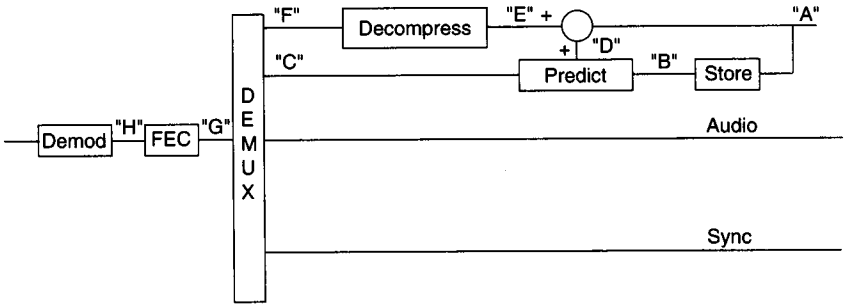

FIGURE 69.23 Block diagram of HDTV receiver.

Defining Terms

Aspect ratio: Ratio of frame width to height.

Digital vestigial sideband: A form of digital modulation where a portion of one of the sidebands is partially suppressed.

Discrete cosine transform: A popular format for video compression. The spatial signal is expanded in a cosine series, where the higher frequencies represent increased video resolution.

Entropy coding: A form of data compression that reduces a transmission to a shorter length by reducing signal redundancy.

Eureka 95 and EU95: European proposed HDTV systems.

Grand Alliance: A consortium formed of seven of the organizations proposing HDTV systems.

Interlaced scanning: A bandwidth reduction technique wherein every other scan line is first transmitted followed by the "in between" lines.

Motion detector: A system that compares two adjacent frames to detect differences.

MPEG-2: Video compression standard devised by the Moving Picture Experts Group.

MUSE: Multiple sub-Nyquist encoding, a technique used in Japanese HDTV system.

Taboo channels: Channels that the FCC does not currently assign in order to avoid interference from adjacent channels.

Trellis coding: A form of digital encoding which provides a constraint (i.e., a structure) to a stream of digital data.

Further Information

As HDTV transitions from a proposed system to a commercially available product, you can expect information to appear in a variety of places from the most esoteric research publications to popular business and entertainment publications. During the development process, the best places to look are the IEEE publications (IEEE, NY) and the broadcasting industry journals. The *IEEE Transactions on Broadcasting* and the *IEEE Transactions on Consumer Electronics* continue to have periodic articles relating to the HDTV standards and implementation of these standards. Another source of information, though not overly technical, is the periodical *Broadcasting and Cable* (Cahners Publishing, NY).

69.5 Digital Audio Broadcasting

Stanley Salek and Almon H. Clegg

Digital audio broadcasting (DAB) is a developing technology that promises to give consumers a new and better aural broadcast system. DAB will offer dramatically better reception quality over existing AM and FM broadcasts by better audio quality and by superior resistance to interference in stationary and mobile/portable reception environments. Additionally, the availability of a digital data stream direct to consumers will open the prospects of providing extra services to augment basic sound delivery.

As of this writing, seven proponents have announced DAB transmission and reception systems. From the data available describing these potential systems, it is clear that there is only partial agreement on which transmission method will provide the best operational balance. This chapter provides a general overview of the common aspects of DAB systems, as well as a description of one of the proposed transmission methods.

The Need for DAB

In the years since the early 1980s, the consumer marketplace has undergone a great shift toward digital electronic technology. The explosion of personal computer use has led to greater demands for information, including multimedia integration. Over the same time period, compact disc (CD) digital audio technology has overtaken long-playing records (and has nearly overtaken analog tape cassettes) as the consumer audio playback media of choice. Similar digital transcription methods and effects also have been incorporated into commonly available audio and video equipment. Additionally, it is virtually certain that the upcoming transition to a high-definition television broadcast system will incorporate full digital methods for video and audio transmission. Because of these market pressures, the radio broadcast industry has determined that the existing analog methods of broadcasting must be updated to keep pace with the advancing audio marketplace.

In addition to providing significantly enhanced audio quality, DAB systems are being developed to overcome the technical deficiencies of existing AM and FM analog broadcast systems. The foremost problem of current broadcast technology, as perceived by the industry, is its susceptibility to interference. AM medium-wave broadcasts, operating in the 530- to 1700-kHz frequency range, are prone to disruption by fluorescent lighting and by power system distribution networks, as well as by numerous other manufactured unintentional radiators, including computer and telephone systems. Additionally, natural effects, such as nighttime skywave propagation interference between stations and lightning, cause irritating service disruption to AM reception. FM broadcast transmissions in the 88- to 108-MHz band are much more resistant to these types of interference. However, multipath propagation and abrupt signal fading, especially found in urban and mountainous areas containing a large number of signal reflectors and shadowers (e.g., buildings and terrain), can seriously degrade FM reception, particularly in automobiles.

DAB System Design Goals

DAB systems are being designed with several technical goals in mind. The first goal is to create a service that delivers compact disc quality stereo sound for broadcast to consumers. The second is to overcome the interference problems of current AM and FM broadcasts, especially under portable and mobile reception conditions.

Third, DAB must be spectrally efficient in that total bandwidth should be no greater than that currently used for FM broadcasts. Fourth, the DAB system should provide space in its data stream to allow for the addition of ancillary services, such as program textual information display or software downloading. Finally, DAB receivers must not be overly cumbersome, complex, or expensive, to foster rapid consumer acceptance.

In addition to these goals, desired features include the reduced RF transmission power requirements (when compared to AM and FM broadcast stations with the same signal coverage), the mechanism to seamlessly fill in coverage areas that are shadowed from the transmitted signal, and the ability to easily integrate DAB receivers into personal, home, and automotive sound systems.

Historical Background

DAB development work began in Europe in 1986, with the initial goal to provide high-quality audio services to consumers directly by satellite. Companion terrestrial systems were developed to evaluate the technology being considered, as well as to provide fill-in service in small areas where the satellite signals were shadowed. A consortium of European technical organizations known as Eureka-147/DAB demonstrated the first working terrestrial DAB system in Geneva in September 1988. Subsequent terrestrial demonstrations of the system followed in Canada in the summer of 1990, and in the United States in April and September of 1991.

For the demonstrations, VHF and UHF transmission frequencies between 200 and 900 MHz were used with satisfactory results. Because most VHF and UHF frequency bands suitable for DAB are already in use (or reserved for high-definition television and other new services), an additional Canadian study in 1991 evaluated frequencies near 1500 MHz (L-band) for use as a potential worldwide DAB allocation. This study concluded that L-band frequencies would support a DAB system such as Eureka-147, while continuing to meet the overall system design goals.

In early 1992, the World Administrative Radio Conference (WARC-92) was held, during which frequency allocations for many different radio systems were debated. As a result of WARC-92, a worldwide L-band standard of 1452 to 1492 MHz was designated for both satellite and terrestrial digital radio broadcasting. However, because of existing government and military uses of L-band, the United States was excluded from the standard. Instead, an S-band allocation of 2310 to 2360 MHz was substituted. Additionally, Asian nations including Japan, China, and CIS opted for an extra S-band allocation in the 2535- to 2655-MHz frequency range.

In mid-1991, because of uncertainty as to the suitability of using S-band frequencies for terrestrial broadcasting, most DAB system development work in the United States shifted from out-band (i.e., UHF, L-band, and S-band) to in-band. In-band terrestrial systems would merge DAB services with existing AM and FM broadcasts, using novel adjacent- and co-channel modulating schemes. Since 1992, two system proponents have demonstrated proprietary methods of extracting a compatible digital RF signal from co-channel analog FM broadcast transmissions. Thus, in-band DAB could permit a logical transition from analog to digital broadcasting for current broadcasters, within the current channel allocation scheme.

In 1991, a digital radio broadcasting standards committee was formed by the Electronic Industries Association (EIA). Present estimates are that the committee may complete its testing and evaluation of the various proposed systems by 1997. As of mid-1996, laboratory testing of several proponent systems had been completed, and field testing of some of those systems, near San Francisco, Calif. was getting underway.

Technical Overview of DAB

Regardless of the actual signal delivery system used, all DAB systems share a common overall topology. Figure 69.24 presents a block diagram of a typical DAB transmission system.

To maintain the highest possible audio quality, program material would be broadcast from digital sources, such as CD players and digital audio recorders, or digital audio feeds from network sources. Analog sources, such as microphones, are converted to a digital audio data stream using an analog-to-digital (A/D) converter, prior to switching or summation with the other digital sources.

The linear digital audio data stream from the studio is then applied to the input of a **source encoder.** The purpose of this device is to reduce the required bandwidth of the audio information, helping to produce a spectrally efficient RF broadcast signal. For example, 16-bit linear digital audio sampled at 48 kHz (the standard

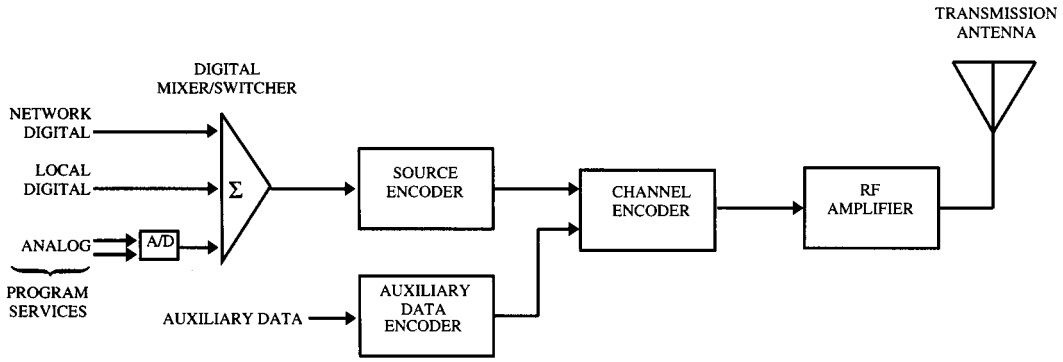

FIGURE 69.24 An example DAB transmission system. (*Source:* Hammett & Edison, Inc., Consulting Engineers.)

professional rate) requires a data stream of 1.536 megabits/s to transmit a stereo program in a serial format. This output represents a bandwidth of approximately 1.5 MHz, much greater than that used by an equivalent analog audio modulating signal [Smyth, 1992]. Source encoders can reduce the data rate by factors of 8:1 or more, yielding a much more efficient modulating signal.

Following the source encoder, the resulting serial digital signal is applied to the input of the **channel encoder,** a device that modulates the transmitted RF wave with the reduced-rate audio information. Auxiliary serial data, such as program information and/or receiver control functions, also can be input to the channel encoder for simultaneous transmission.

The channel encoder uses sophisticated modulating techniques to accomplish the goals of interference cancellation and high spectral efficiency. Methods of interference cancellation include expansion of time and frequency diversity of the transmitted information, as well as the inclusion of error correction codes in the data stream. Time diversity involves transmitting the same information multiple times by using a predetermined time interval. Frequency diversity, such as that produced by spread-spectrum, multiple-carrier, or frequency-hopping systems, provides the means to transmit identical data on several different frequencies within the bandwidth of the system. At the receiver, real-time mathematical processes are used to locate the required data on a known frequency at a known time. If the initial information is found to be unusable because of signal interference, the receiver simply uses the same data found on another frequency and/or at another time, producing seamless demodulation.

Spectral efficiency is a function of the modulation system used. Among the modulation formats that have been proposed for DAB transmission are QPSK, M-ary QAM, and MSK [Springer, 1992]. Using these and other formats, digital transmission systems that use no more spectrum than their analog counterparts have been designed.

The RF output signal of the channel encoder is amplified to the appropriate power level for transmission. Because the carrier-to-noise (C/N) ratio of the modulated waveform is not generally so critical as that required for analog communications systems, relatively low transmission power often can be used. Depending on the sophistication of the data recovery circuits contained in the DAB receiver, the use of C/N ratios as low as 6 dB are possible, without causing a degradation to the received signal.

DAB reception is largely the inverse of the transmission process, with the inclusion of sophisticated error correction circuits. Fig. 69.25 shows a typical DAB receiver.

DAB reception begins in a similar manner as is used in virtually all receivers. A receiving antenna feeds an appropriate stage of RF selectivity and amplification from which a sample of the coded DAB signal is derived. This signal then drives a channel decoder, which reconstructs the audio and auxiliary data streams. To accomplish this task, the channel decoder must demodulate and de-interleave the data contained on the RF carrier and then apply appropriate computational and statistical error correction functions.

The source decoder converts the reduced bit-rate audio stream back to pseudolinear at the original sampling rate. The decoder computationally expands the mathematically reduced data and fills the gaps left from the extraction of irrelevant audio information with averaged code or other masking data. The output of the source

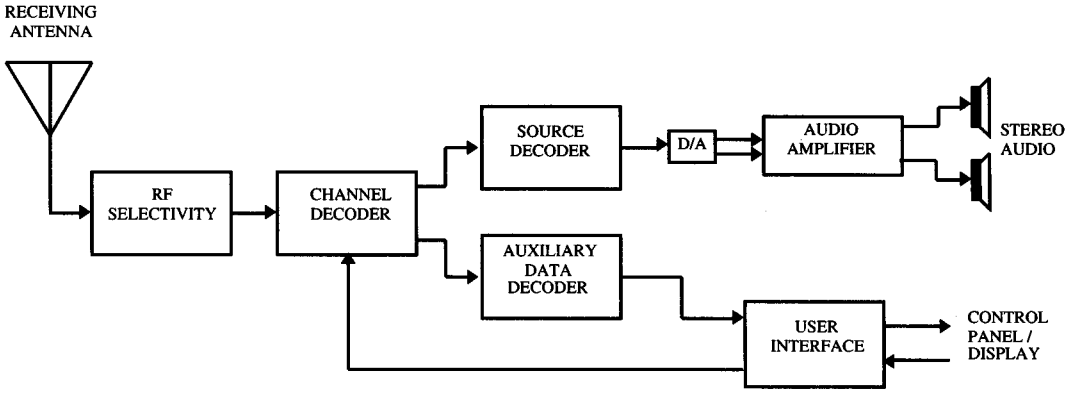

FIGURE 69.25 An example DAB receiver. (*Source:* Hammett & Edison, Inc., Consulting Engineers.)

decoder feeds audio digital-to-analog (D/A) converters, and the resulting analog stereo audio signal is amplified for the listener.

In addition to audio extraction, DAB receivers likely will be capable of decoding auxiliary data. This data can be used in conjunction with the user interface to control receiver functions, or for a completely separate purpose. A typical user interface could contain a data display screen in addition to the usual receiver tuning and audio controls. This data screen could be used to obtain information about the programming, news reports, sports scores, advertising, or any other useful data sent by the station or an originating network. Also, external interfaces could be used to provide a software link to personal computer systems.

Audio Compression and Source Encoding

The development of digital audio encoding started with research into pulse-code modulation (PCM) in the late 1930s and evolved, shortly thereafter, to include work on the principles of digital PCM coding. Linear predictive coding (LPC) and adaptive delta pulse-code modulation (ADPCM) algorithms had evolved in the early 1970s and later were adopted into standards such as C.721 (published by the CCITT) and CD-I (Compact Disc-Interactive). At the same time, algorithms were being invented for use with phoneme-based speech coding. Phonetic coding, a first-generation "model-based" speech-coding algorithm, was mainly implemented for low bit-rate speech and text-to-speech applications. These classes of algorithms for speech further evolved to include both CELP (Code Excited Linear Predictive) and VSELP (Vector Selectable Excited Linear Predictive) algorithms by the mid-1980s. In the late 1980s, these classes of algorithms were also shown to be useful for high-quality audio music coding. These audio algorithms were put to commercial use from the late 1970s to the latter part of the 1980s.

Subband coders evolved from the early work on quadrature mirror filters in the mid-1970s and continued with polyphase filter-based schemes in the mid-1980s. Hybrid algorithms employing both subband and ADPCM coding were developed in the latter part of the 1970s and standardized (e.g., CCITT G.722) in the mid- to late 1980s. Adaptive transform coders for audio evolved in the mid-1980s from speech coding work done in the late 1970s.

By employing psychoacoustic noise-masking properties of the human ear, perceptual encoding evolved from early work of the 1970s and where high-quality speech coders were employed. Music quality bit-rate reduction schemes such as MPEG (Motion Picture Expert Group), PASC (Precision Adaptive Subband Coding), and ATRAC (Adaptive TRansform Acoustic Coding) have been developed. Further refinements to the technology will focus attention on novel approaches such as wavelet-based coding and the use of entropy coding schemes. However, recent progress has been significant, and the various audio coding schemes that have been demonstrated publicly over the time period from 1990 to 1995 have shown steady increases in compression ratios at given audio quality levels.

Audio coding for digital broadcasting will likely use one of the many perceptual encoding schemes previously mentioned or some variation thereof. Fundamentally, they all depend on two basic psychoacoustic phenomena:

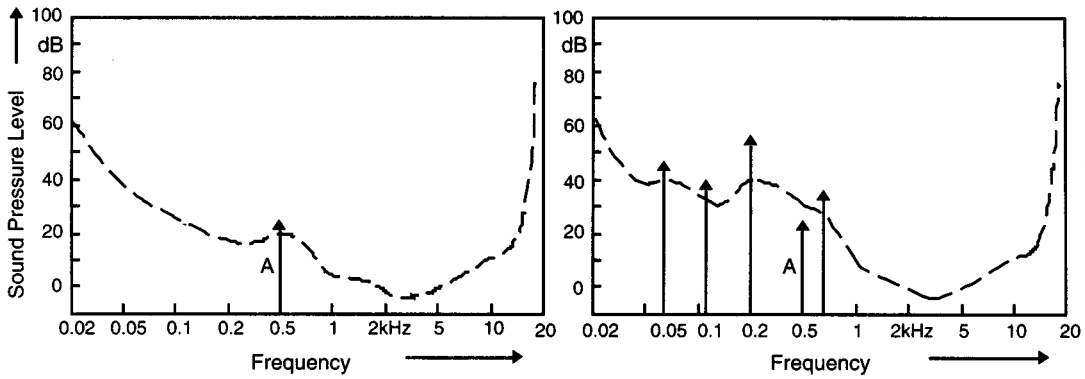

FIGURE 69.26 An example of the masking effect. Based on the hearing threshold of the human ear (dashed line), a 500-Hz sinusoidal acoustic waveform, shown at *A* on the left graph, is easily audible at relatively low levels. However, it can be masked by adding nearby higher-amplitude components, as shown on the right. (*Source:* CCi.)

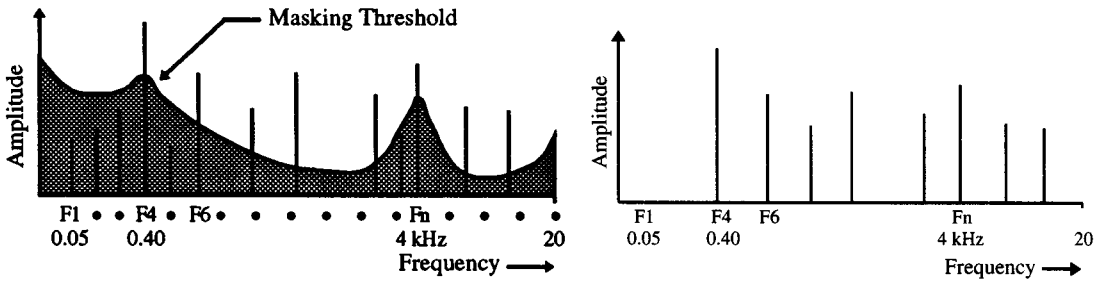

FIGURE 69.27 Source encoders use an empirically derived masking threshold to determine which audio components can be discarded (left). As shown on the right, only the audio components with amplitudes above the masking threshold are retained. (*Source:* CCi.)

(1) the threshold of human hearing, and (2) masking of nearby frequency components. In the early days of hearing research, Harvey Fletcher, a researcher at Bell Laboratories, measured the hearing of many human beings and published the well-known Fletcher-Munson threshold-of-hearing chart. Basically it states that, depending on the frequency, audio sounds below certain levels cannot be heard by the human ear. Further, the masking effect, simply stated, is when two frequencies are very close to each other and one is a higher level than the other, the weaker of the two is masked and will not be heard. These two principles allow for as much as 80% of the data representing a musical signal to be discarded.

Figure 69.26 shows how introduction of frequency components affects the ear's threshold of hearing versus frequency. Figure 69.27 shows how the revised envelope of audibility results in the elimination of components that would not be heard.

The electronic implementation of these algorithms employs a digital filter that breaks the audio spectrum into many subbands, and various coefficient elements are built into the program to decide when it is permissible to remove one or more of the signal components. The details of how the bands are divided and how the coefficients are determined are usually proprietary to the individual system developers. Standardization groups have spent many worker-hours of evaluation attempting to determine the most accurate coding system.

System Example: Eureka-147/DAB

As of this writing, Eureka-147/DAB is the only fully developed DAB system that has demonstrated a capability to meet virtually all the described system goals. Developed by a European consortium, it is an out-band system

in that its design is based on the use of a frequency spectrum outside the AM and FM radio broadcast bands. Out-band operation is required because the system packs up to 16 stereophonic broadcast channels (plus auxiliary data) into one contiguous band of frequencies, which can occupy a total bandwidth of up to 4 MHz. Thus, overall efficiency is maintained, with 16 digital program channels occupying about the same total bandwidth as 16 equivalent analog FM broadcast channels. System developers have promoted Eureka-147/DAB for satellite transmission, as well as for terrestrial applications in locations that have a suitable block of unused spectrum in the L-band frequency range or below.

In recent tests and demonstrations, the ISO/MPEG-2 source encoding/decoding system has been used. Originally developed by IRT (Institut für Rundfunktecknik) in Germany as MUSICAM (Masking pattern-adapted Universal Subband Integrated Coding And Multiplexing), the system works by dividing the original digital audio source into 32 subbands. As with the source encoders described earlier, each of the bands is digitally processed to remove redundant information and sounds that are not perceptible to the human ear. Using this technique, the original audio, sampled at a rate of 768 kilobits/s per channel, is reduced to as little as 96 kilobits/s per channel, representing a compression ratio of 8:1.

The Eureka-147/DAB channel encoder operates by combining the transmitted program channels into a large number of adjacent narrowband RF carriers, which are each modulated using QPSK and grouped in a way that maximizes spectrum efficiency known as orthogonal frequency-division multiplex (OFDM). The information to be transmitted is distributed among the RF carriers and is also time-interleaved to reduce the effects of selective fading. A guard interval is inserted between blocks of transmitted data to improve system resistance to intersymbol interference caused by multipath propagation. Convolutional coding is used in conjunction with a Viterbi maximum-likelihood decoding algorithm at the receiver to make constructive use of echoed signals and to correct random errors [Alard and Lassalle, 1988].

RF power levels of just a few tens of watts per program channel have been used in system demonstrations, providing a relatively wide coverage area, depending on the height of the transmitting antenna above surrounding terrain. This low power level is possible because the system can operate at a C/N ratio of less than 10 dB, as opposed to the more than 30 dB that is required for high-fidelity demodulation of analog FM broadcasts.

Another demonstrated capability of the system is its ability to use "**gap filler**" transmitters to augment signal coverage in shadowed areas. A gap filler is simply a system that directly receives the DAB signal at an unobstructed location, provides RF amplification, and retransmits the signal, on the same channel, into the shadowed area. Because the system can make constructive use of signal reflections (within a time window defined by the guard interval and other factors), the demodulated signal is uninterrupted on a mobile receiver when it travels between an area served by the main signal into the service area of the gap filler.

Defining Terms

Channel encoder: A device that converts source-encoded digital information into an analog RF signal for transmission. The type of modulation used depends on the particular digital audio broadcasting (DAB) system, although most modulation techniques employ methods by which the transmitted signal can be made more resistant to frequency-selective signal fading and multipath distortion effects.

Gap filler: A low-power transmitter that boosts the strength of transmitted DAB RF signals in areas which normally would be shadowed due to terrain obstruction. Gap fillers can operate on the same frequency as DAB transmissions or on alternate channels that can be located by DAB receivers using automatic switching.

Source encoder: A device that substantially reduces the data rate of linearly digitized audio signals by taking advantage of the psychoacoustic properties of human hearing, eliminating redundant and subjectively irrelevant information from the output signal. Transform source encoders work entirely within the frequency domain, while time-domain source encoders work primarily in the time domain. Source decoders reverse the process, using various masking techniques to simulate the properties of the original linear data.

70.1 Error Control Coding

Richard C. Dorf and Zhen Wan

Error correcting codes may be classified into two broad categories: **block codes** and **tree codes.** A block code is a mapping of k input binary symbols into n output binary symbols. Consequently, the block coder is a *memoryless* device. Since $n > k$, the code can be selected to provide redundancy, such as *parity bits*, which are used by the decoder to provide some error detection and error correction. The codes are denoted by (n, k), where the code rate R is defined by $R = k/n$. Practical values of R range from 1/4 to 7/8, and k ranges from 3 to several hundred [Clark and Cain, 1981]. Some properties of block codes are given in Table 70.1.

A tree code is produced by a coder that has *memory.* **Convolutional codes** are a subset of tree codes. The convolutional coder accepts k binary symbols at its input and produces n binary symbols at its output, where the n output symbols are affected by $v + k$ input symbols. Memory is incorporated since $v > 0$. The code rate is defined by $R = k/n$. Typical values for k and n range from 1 to 8, and the values for v range from 2 to 60. The range of R is between 1/4 and 7/8 [Clark and Cain, 1981].

Block Codes

In block code, the n code digits generated in a particular time unit depend only on the k message digits within that time unit. Some of the errors can be detected and corrected if $d \geq s + t + 1$, where s is the number of errors that can be detected, t is the number of errors that can be corrected, and d is the hamming distance. Usually, $s \geq t$, thus, $d \geq 2t + 1$. A general code word can be expressed as $a_1, a_2,...,a_k, c_1, c_2,...,c_r$. k is the number of information bits and r is the number of check bits. Total word length is $n = k + r$.

In Fig. 70.1, the gain h_{ij} $(i = 1, 2,..., r, j = 1, 2,..., k)$ are elements of the parity check matrix **H**. The k data bits are shifted in each time, while $k + r$ bits are simultaneously shifted out by the commutator.

Cyclic Codes

Cyclic codes are block codes such that another code word can be obtained by taking any one code word, shifting the bits to the right, and placing the dropped-off bits on the left. An encoding circuit with $(n - k)$ shift registers is shown in Fig. 70.2.

TABLE 70.1 Properties of Block Codes

	Code[a]			
Property	BCH	Reed–Solomon	Hamming	Maximal Length
Block length	$n = 2^m - 1$, $m = 3, 4, 5, \ldots$	$n = m(2^m - 1)$ bits	$n = 2^m - 1$	$n = 2^m - 1$
Number of parity bits		$r = m2t$ bits	$r = m$	
Minimum distance	$d \geq 2t + 1$	$d = m(2t + 1)$ bits	$d = 3$	$d = 2^m - 1$
Number of information bits	$k \geq n - mt$			$k = m$

[a] m is any positive integer unless otherwise indicated; n is the block length; k is the number of information bits; t is the number of errors that can be corrected; r is the number of parity bits; d is the distance.

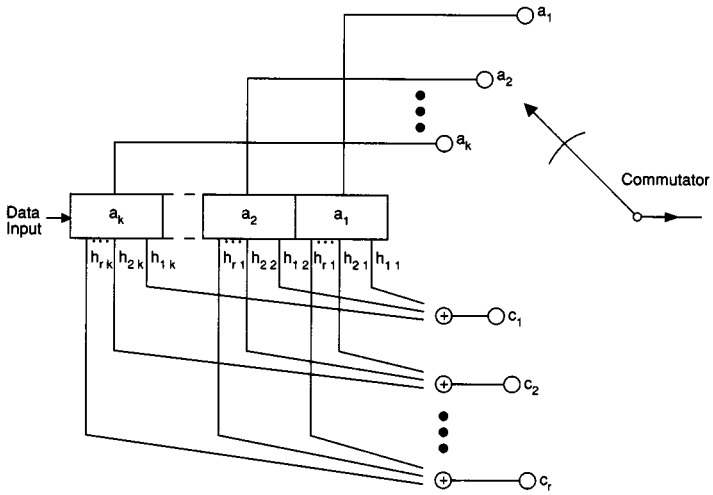

FIGURE 70.1 An encoding circuit of (n, k) block code.

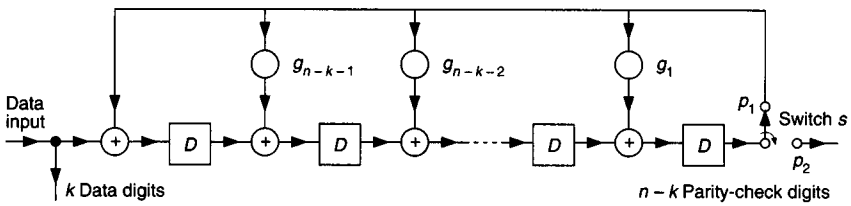

FIGURE 70.2 An encoder for systematic cyclic code. (*Source:* B.P. Lathi, *Modern Digital and Analog Communications,* New York: CBS College Publishing, 1983. With permission.)

In Fig. 70.2, the gain g_ks are the coefficients of the generator polynomial $g(x) = x^{n-k} + g_1x^{n-k-1} + \ldots + g_{n-k-1}x + 1$. The gains g_k are either 0 or 1. The k data digits are shifted in one at a time at the input with the switch s held at position p_1. The symbol D represents a one-digit delay. As the data digits move through the encoder, they are also shifted out onto the output lines, because the first k digits of code word are the data digits themselves. As soon as the last (or kth) data digit clears the last $(n - k)$ register, all the registers contain the parity-check digits. The switch s is now thrown to position p_2, and the $n - k$ parity-check digits are shifted out one at a time onto the line.

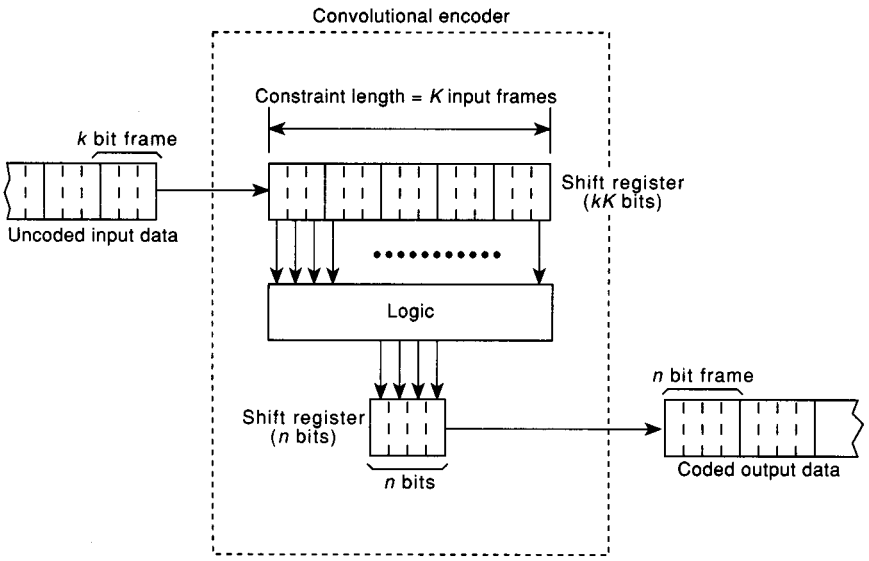

FIGURE 70.3 Convolutional encoding ($k = 3$, $n = 4$, $K = 5$, and $R = 3/4$).

2. Reed–Solomon
3. Hamming
4. Maximal length
5. Reed–Muller
6. Golay codes

Convolutional Codes

In convolutional code, the block of n code digits generated by the encoder in a particular time unit depends not only on the block of k message digits within that time unit but also on the block of data digits within a previous span of $N - 1$ time units ($N > 1$). A convolutional encoder is illustrated in Fig. 70.3.

Here k bits (one input frame) are shifted in each time, and concurrently n bits (the output frame) are shifted out, where $n > k$. Thus, every k-bit input frame produces an n-bit output frame. Redundancy is provided in the output, since $n > k$. Also, there is memory in the coder, since the output frame depends on the previous K input frames where $K > 1$. The *code rate* is $R = k/n$, which is 3/4 in this illustration. The *constraint length*, K, is the number of input frames that are held in the kK bit shift register. Depending on the particular convolutional code that is to be generated, data from the kK stages of the shift register are added (modulo 2) and used to set the bits in the n-stage output register.

Code Performance

The improvement in the performance of a digital communication system that can be achieved by the use of coding is illustrated in Fig. 70.4. It is assumed that a digital signal plus channel noise is present at the receiver input. The performance of a system that uses binary-phase-shift-keyed (BPSK) signaling is shown both for the case when coding is used and for the case when there is no coding. For the BPSK no code case, $P_e = Q(\sqrt{2(E_b/N_o)})$. For the coded case a (23,12) Golay code is used; P_e is the *probability of bit error*—also called the *bit error rate* (BER)—that is measured at the receiver output.

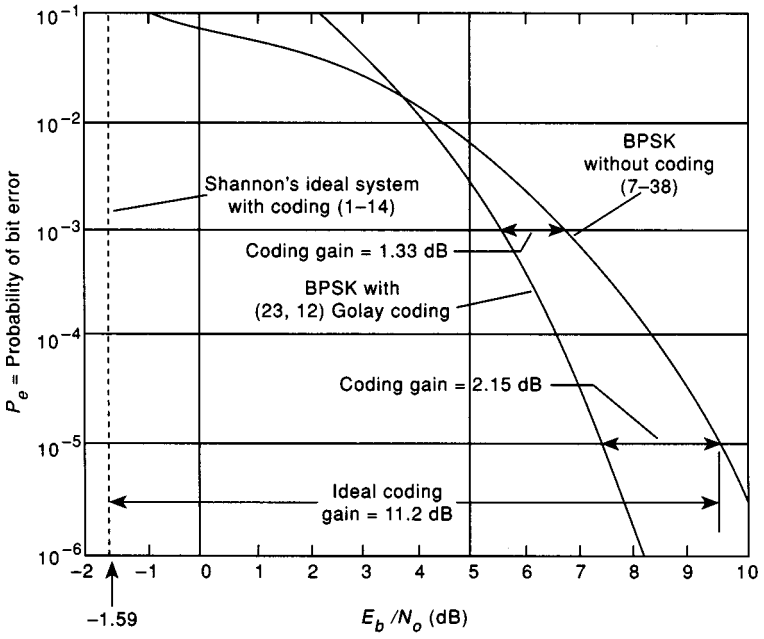

FIGURE 70.4 Performance of digital systems—with and without coding. E_b is the energy-per-bit to noise-density at the receiver input. The function $Q(x)$ is $Q(x) = (1/\sqrt{2\pi x})e^{-x2/2}$.

TABLE 70.2 Coding Gains with BPSK or QPSK

Coding Technique Used	Coding Gain (dB) at 10^{-5} BER	Coding Gain (dB) at 10^{-8} BER	Data Rate Capability
Ideal coding	11.2	13.6	
Concatenated Reed–Solomon and convolution (Viterbi decoding)	6.5–7.5	8.5–9.5	Moderate
Convolutional with sequential decoding (soft decisions)	6.0–7.0	8.0–9.0	Moderate
Block codes (soft decisions)	5.0–6.0	6.5–7.5	Moderate
Concatenated Reed–Solomon and short block	4.5–5.5	6.5–7.5	Very high
Convolutional with Viterbi decoding	4.0–5.5	5.0–6.5	High
Convolutional with sequential decoding (hard decisions)	4.0–5.0	6.0–7.0	High
Block codes (hard decisions)	3.0–4.0	4.5–5.5	High
Block codes with threshold decoding	2.0–4.0	3.5–5.5	High
Convolutional with threshold decoding	1.5–3.0	2.5–4.0	Very high

BPSK: modulation technique—binary phase-shift keying; QPSK: modulation technique—quadrature phase-shift keying; BER: bit error rate.

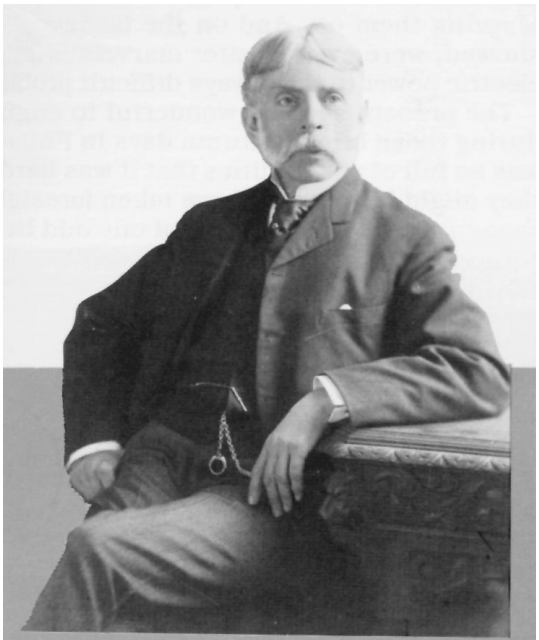
Trellis-Coded Modulation

Trellis-coded modulation (TCM) combines multilevel modulation and coding to achieve coding gain without bandwidth expansion [Ungerboeck, 1982, 1987]. TCM has been adopted for use in the new CCITT V.32 modem that allows an information data rate of 9600 b/s (bits per second) to be transmitted over VF (voice frequency) lines. The TCM has a coding gain of 4 dB [Wei, 1984]. The combined modulation and coding operation of TCM is shown in Fig. 70.5(b). Here, the serial data from the source, $m(t)$, are converted into parallel (m-bit)

George Anson Hamilton (1843–1935)

Telegraphy captivated George Hamilton's interest while he was still a boy — to the extent that he built a small telegraph line himself, from sinking the poles to making the necessary apparatus. By the time he was 17, he was the manager of the telegraph office of the Atlantic & Great Western Railroad at Ravenna, Ohio. Hamilton continued to hold managerial positions with telegraph companies until 1873 when he became assistant to Moses G. Farmer in his work on general electrical apparatus and machinery.

In 1875, Hamilton joined Western Union as assistant electrician and, for the next two years, worked with Gerritt Smith in establishing and maintaining the first quadruplex telegraph circuits in both America and England. He then focused on the development of the Wheatstone high-speed automatic system and was also the chief electrician on the Key West–Havana cable repair expedition. Hamilton left Western Union in 1889, however, to join Western Electric, where he was placed in charge of the production of fine electrical instruments until the time of his retirement. (Courtesy of the IEEE Center for the History of Electrical Engineering.)



George Anson Hamilton (1843-1935)

data, which are partitioned into k-bit and $(m - k)$-bit words where $k \geq m$. The k-bit words (frames) are convolutionally encoded into $(n = k + 1)$-bit words so that the code rate is $R = k/(k + 1)$. The amplitude and phase are then set jointly on the basis of the coded n-bit word and the uncoded $(m - k)$-bit word. Almost 6 dB of coding gain can be realized if coders of constraint length 9 are used.

Defining Terms

Block code: A mapping of k input binary symbols into n output binary symbols.

Convolutional code: A subset of tree codes, accepting k binary symbols at its input and producing n binary symbols at its output.

Cyclic code: Block code such that another code word can be obtained by taking any one code word, shifting the bits to the right, and placing the dropped-off bits on the left.

Tree code: Produced by a coder that has memory.

70.2 Equalization

Richard C. Dorf and Zhen Wan

In bandwidth-efficient digital communication systems the effect of each symbol transmitted over a time dispersive channel extends beyond the time interval used to represent that symbol. The distortion caused by the resulting overlap of received symbols is called **intersymbol interference** (ISI) [Lucky et al., 1968]. ISI arises in all pulse-modulation systems, including frequency-shift keying (FSK), phase-shift keying (PSK), and quadrature amplitude modulation (QAM) [Lucky et al., 1968]. However, its effect can be most easily described for a baseband PAM system.

The purpose of an **equalizer,** placed in the path of the received signal, is to reduce the ISI as much as possible to maximize the probability of correct decisions.

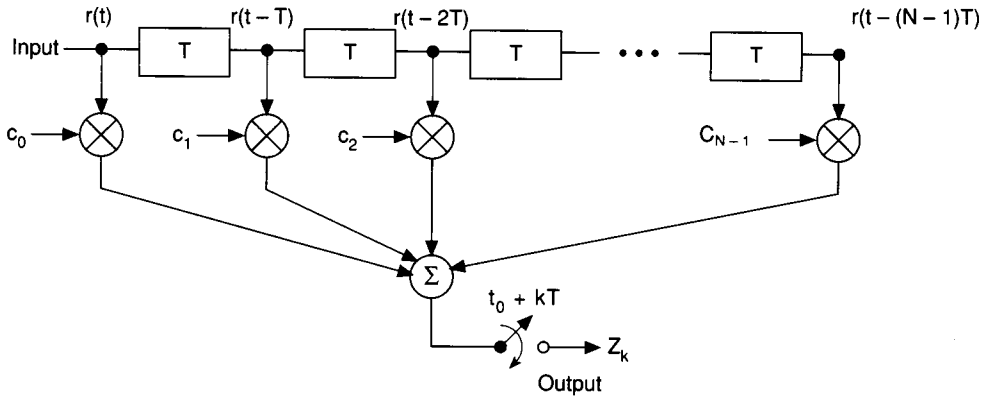

FIGURE 70.6 Linear transversal equalizer. (*Source:* K. Feher, *Advanced Digital Communications*, Englewood Cliffs, N.J.: Prentice-Hall, 1987, p. 648. With permission.)

Linear Transversal Equalizers

Among the many structures used for equalization, the simplest is the transversal (tapped delay line or nonrecursive) equalizer shown in Fig. 70.6. In such an equalizer the current and past values $r(t - nT)$ of the received signal are linearly weighted by equalizer coefficients (tap gains) c_n and summed to produce the output. In the commonly used digital implementation, samples of the received signal at the symbol rate are stored in a digital shift register (or memory), and the equalizer output samples (sums of products) $z(t_0 + kT)$ or z_k are computed digitally, once per symbol, according to

$$z_k = \sum_{n=0}^{N-1} c_n r(t_0 + kT - nt)$$

where N is the number of equalizer coefficients and t_0 denotes sample timing.

The equalizer coefficients, c_n, $n = 0, 1, \ldots, N-1$, may be chosen to force the samples of the combined channel and equalizer impulse response to zero at all but one of the NT-spaced instants in the span of the equalizer. Such an equalizer is called a *zero-forcing* (ZF) equalizer [Lucky, 1965].

If we let the number of coefficients of a ZF equalizer increase without bound, we would obtain an infinite-length equalizer with zero ISI at its output. An infinite-length zero-ISI equalizer is simply an inverse filter, which inverts the folded frequency response of the channel. Clearly, the ZF criterion neglects the effect of noise altogether. A finite-length ZF equalizer is approximately inverse to the folded frequency response of the channel. Also, a finite-length ZF equalizer is guaranteed to minimize the peak distortion or worst-case ISI only if the peak distortion before equalization is less than 100% [Lucky, 1965].

The *least-mean-squared* (LMS) equalizer [Lucky et al.,1968] is more robust. Here the equalizer coefficients are chosen to minimize the mean squared error (MSE)—the sum of squares of all the ISI terms plus the noise power at the output of the equalizer. Therefore, the LMS equalizer maximizes the signal-to-distortion ratio (S/D) at its output within the constraints of the equalizer time span and the delay through the equalizer.

Automatic Synthesis

Before regular data transmission begins, automatic synthesis of the ZF or LMS equalizers for unknown channels may be carried out during a training period. During the training period, a known signal is transmitted and a synchronized version of this signal is generated in the receiver to acquire information about the channel characteristics. The automatic adaptive equalizer is shown in Fig. 70.7. A noisy but unbiased estimate:

$$\frac{\delta e_k^2}{\delta c_n(k)} = 2e_k r(t_0 + kT - nT)$$

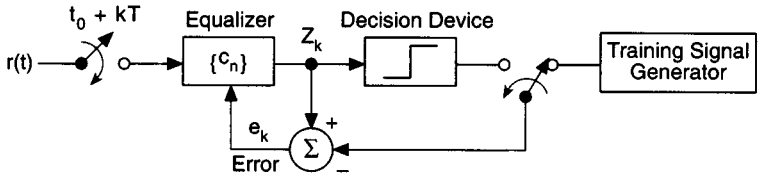

FIGURE 70.7 Automatic adaptive equalizer. (*Source:* K. Feher, *Advanced Digital Communications*, Englewood Cliffs, N.J.: Prentice-Hall, 1987, p. 651. With permission.)

is used. Thus, the tap gains are updated according to

$$c_n(k+1) = c_n(k) - \Delta e_k r(t_0 + kT - nT), \quad n = 0, 1, \ldots, N-1$$

where $c_n(k)$ is the nth tap gain at time k, e_k is the error signal, and Δ is a positive adaptation constant or step size, error signals $e_k = z_k - q_k$ can be computed at the equalizer output and used to adjust the equalizer coefficients to reduce the sum of the squared errors. Note $q_k = \hat{x}_k$.

The most popular equalizer adjustment method involves updates to each tap gain during each symbol interval. The adjustment to each tap gain is in a direction opposite to an estimate of the gradient of the MSE with respect to that tap gain. The idea is to move the set of equalizer coefficients closer to the unique optimum set corresponding to the minimum MSE. This symbol-by-symbol procedure developed by Widrow and Hoff [Feher, 1987] is commonly referred to as the *stochastic gradient* method.

Adaptive Equalization

After the initial training period (if there is one), the coefficients of an adaptive equalizer may be continually adjusted in a *decision-directed* manner. In this mode the error signal $e_k = z_k - q_k$ is derived from the final (not necessarily correct) receiver estimate $\{q_k\}$ of the transmitted sequence $\{x_k\}$ where q_k is the estimate of x_k. In normal operation the receiver decisions are correct with high probability, so that the error estimates are correct often enough to allow the adaptive equalizer to maintain precise equalization. Moreover, a decision-directed adaptive equalizer can track slow variations in the channel characteristics or linear perturbations in the receiver front end, such as slow jitter in the sampler phase.

Nonlinear Equalizers

Decision-Feedback Equalizers

A decision-feedback equalizer (DFE) is a simple nonlinear equalizer [Monsen, 1971], which is particularly useful for channels with severe amplitude distortion and uses decision feedback to cancel the interference from symbols which have already been detected. Fig. 70.8 shows the diagram of the equalizer.

The equalized signal is the sum of the outputs of the forward and feedback parts of the equalizer. The forward part is like the linear transversal equalizer discussed earlier. Decisions made on the equalized signal are fed back via a second transversal filter. The basic idea is that if the values of the symbols already detected are known (past decisions are assumed to be correct), then the ISI contributed by these symbols can be canceled exactly, by subtracting past symbol values with appropriate weighting from the equalizer output.

The forward and feedback coefficients may be adjusted simultaneously to minimize the MSE. The update equation for the forward coefficients is the same as for the linear equalizer. The feedback coefficients are adjusted according to

$$b_m(k+1) = b_m(k) + \Delta e_k \hat{x}_{k-m} \quad m = 1, \ldots, M$$

where $\hat{x}_k$ is the kth symbol decision, $b_m(k)$ is the mth feedback coefficient at time k, and there are M feedback coefficients in all. The optimum LMS settings of b_m, $m = 1, \ldots, M$, are those that reduce the ISI to zero, within the span of the feedback part, in a manner similar to a ZF equalizer.

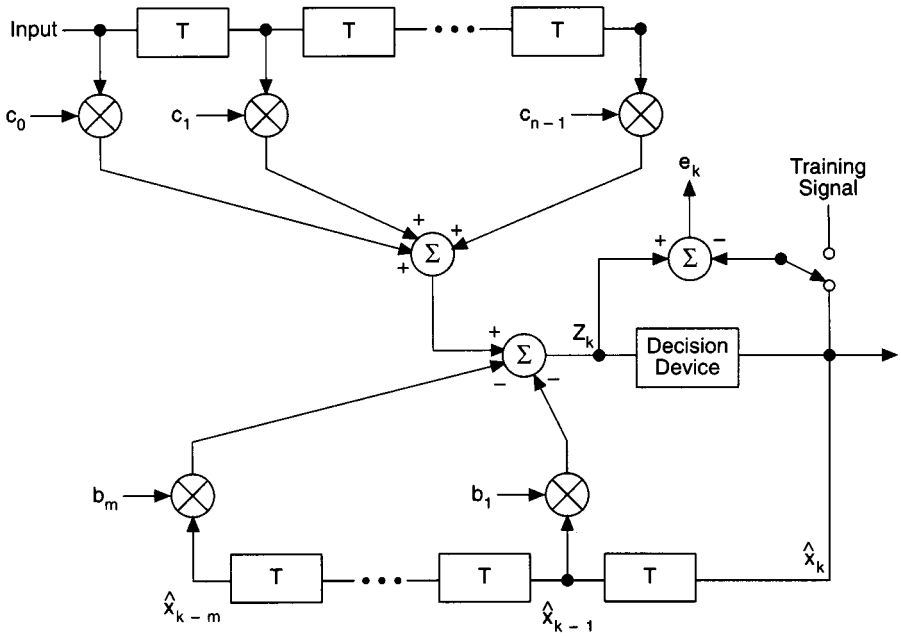

FIGURE 70.8 Decision-feedback equalizer. (*Source:* K. Feher, *Advanced Digital Communications*, Englewood Cliffs, N.J.: Prentice-Hall, 1987, p. 655. With permission.)

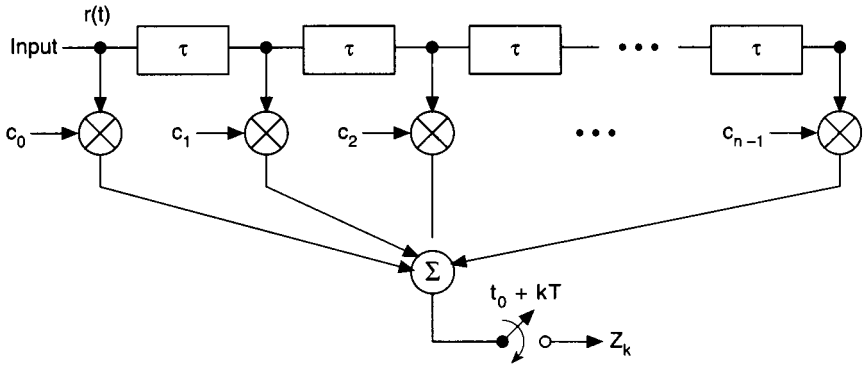

FIGURE 70.9 Fractionally spaced equalizer. (*Source:* K. Feher, *Advanced Digital Communications*, Englewood Cliffs, N.J.: Prentice-Hall, p. 656. With permission.)

Fractionally Spaced Equalizers

The optimum receive filter in a linear modulation system is the cascade of a filter matched to the actual channel, with a transversal *T*-spaced equalizer [Forney, 1972]. The fractionally spaced equalizer (FSE), by virtue of its sampling rate, can synthesize the best combination of the characteristics of an adaptive matched filter and a *T*-spaced equalizer, within the constraints of its length and delay. A *T*-spaced equalizer, with symbol-rate sampling at its input, cannot perform matched filtering. A *fractionally spaced equalizer* can effectively compensate for more severe delay distortion and deal with amplitude distortion with less noise enhancement than a *T*-equalizer.

A fractionally spaced transversal equalizer [Monsen, 1971] is shown in Fig. 70.9. The delay-line taps of such an equalizer are spaced at an interval τ, which is less than, or a fraction of, the symbol interval *T*. The tap spacing τ is typically selected such that the bandwidth occupied by the signal at the equalizer input is $|f| <$

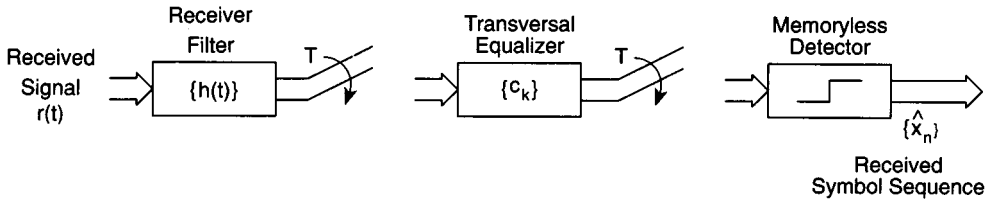

FIGURE 70.10 Conventional linear receiver.

$1/2\tau$: that is, τ-spaced sampling satisfies the sampling theorem. In an analog implementation, there is no other restriction on τ, and the output of the equalizer can be sampled at the symbol rate. In a digital implementation τ must be KT/M, where K and M are integers and $M > K$. (In practice, it is convenient to choose $\tau = T/M$, where M is a small integer, e.g., 2.) The received signal is sampled and shifted into the equalizer delay line at a rate M/T, and one input is produced each symbol interval (for every M input sample). In general, the equalizer output is given by

$$z_k = \sum_{n=0}^{N-1} c_n r\left(t_0 + kT - \frac{nKT}{M}\right)$$

The coefficients of a KT/M equalizer may be updated once per symbol based on the error computed for that symbol according to

$$c_n(k+1) = c_n(k) - \Delta e_k r\left(t_0 + kT - \frac{nKT}{M}\right), \qquad n = 0, 1, \ldots, N-1$$

Linear Receivers

When the channel does not introduce any amplitude distortion, the linear receiver is optimum with respect to the ultimate criterion of minimum probability of symbol error. The *conventional linear receiver* consists of a matched filter, a symbol-rate sampler, an infinite-length T-spaced equalizer, and a memoryless detector. The linear receiver structure is shown in Fig. 70.10.

In the conventional linear receiver, a memoryless threshold detector is sufficient to minimize the probability of error; the equalizer response is designed to satisfy the zero-ISI constraint, and the matched filter is designed to minimize the effect of the noise while maximizing the signal.

Matched Filter

The matched filter is the linear filter that maximizes $(S/N)_{\text{out}} = s_0^2(t)/n_0^2(t)$ of Fig. 70.11 and has a transfer function given by

$$H(f) = K \frac{S^*(f)}{P_n(f)} e^{-j\omega t_0}$$

where $S(f) = F[s(t)]$ is the Fourier transform of the known input signal $s(t)$ of duration T sec. $P_n(f)$ is the PSD of the input noise, t_0 is the sampling time when $(S/N)_{\text{out}}$ is evaluated, and K is an arbitrary real nonzero constant.

A general representation for a matched filter is illustrated in Fig. 70.11. The input signal is denoted by $s(t)$ and the output signal by $s_0(t)$. Similar notation is used for the noise.

Nonlinear Receivers

When amplitude distortion is present in the channel, a memoryless detector operating on the output of this receiver filter no longer minimizes symbol error probability. Recognizing this fact, several authors have investigated optimum or approximately optimum nonlinear receiver structures subject to a variety of criteria [Lucky, 1973].

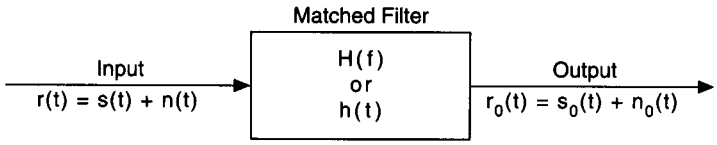

FIGURE 70.11 Matched filter.

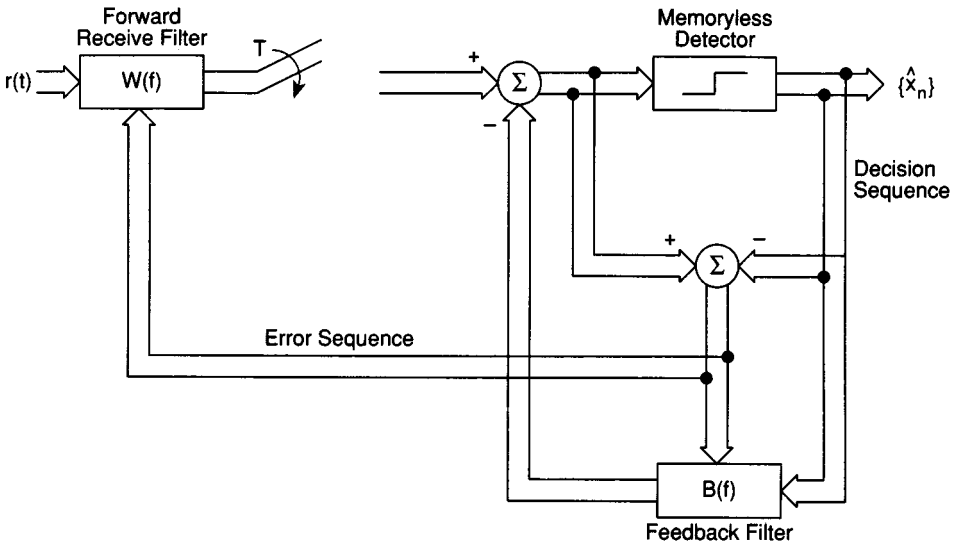

FIGURE 70.12 Conventional decision-feedback receiver. (*Source:* K. Feher, *Advanced Digital Communications*, Englewood Cliffs, N.J.: Prentice-Hall, 1987, p. 675. With permission.)

Decision-Feedback Equalizers

A DFE takes advantage of the symbols that have already been detected (correctly with high probability) to cancel the ISI due to these symbols without noise enhancement. A DFE makes memoryless decisions and cancels all trailing ISI terms. Even when the whitened matched filter (WMF) is used as the receive filter for the DFE, the DFE suffers from a reduced effective signal-to-noise ratio, and error propagation, due to its inability to defer decisions.

An infinite-length DFE receiver takes the general form (shown in Fig. 70.12) of a forward linear receive filter, symbol-rate sampler, canceler, and memoryless detector. The symbol-rate output of the detector is then used by the feedback filter to generate future outputs for cancellation.

Adaptive Filters for MLSE

For unknown and/or slowly time-varying channels, the receive filter must be adaptive in order to obtain the ultimate performance gain from MLSE (maximum-likelihood sequence estimation). Secondly, the complexity of the MLSE becomes prohibitive for practical channels with a large number of ISI terms. Therefore, in a practical receiver, an adaptive receive filter may be used prior to Viterbi detection to limit the time spread of the channel as well as to track slow time variation in the channel characteristics [Falconer and Magee, 1973].

Several adaptive receive filters are available that minimize the MSE at the input to the Viterbi algorithm. These methods differ in the form of constraint [Falconer and Magee, 1973] on the desired impulse response (DIR) which is necessary in this optimization process to exclude the selection of the null DIR corresponding to no transmission through the channel. The general form of such a receiver is shown in Fig. 70.13.

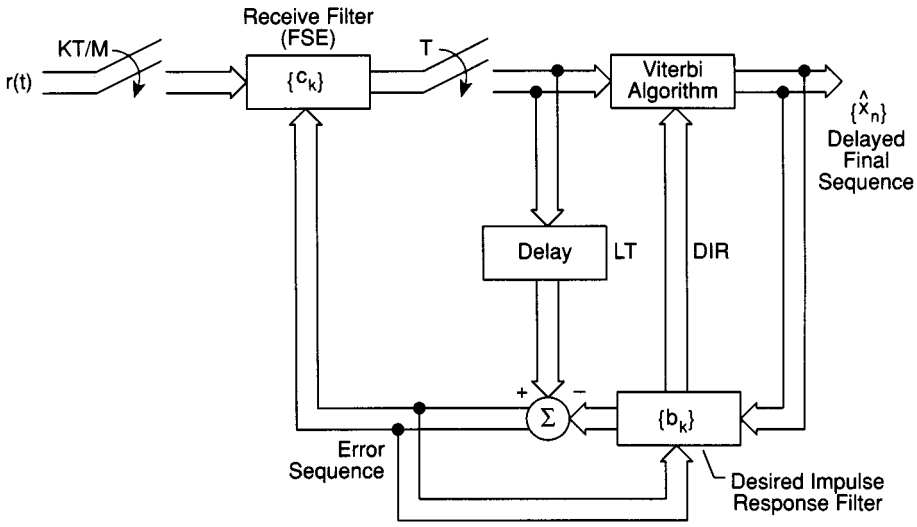

FIGURE 70.13 General form of adaptive MLSE receiver with finite-length DIR. (*Source:* K. Feher, *Advanced Digital Communications*, Englewood Cliffs, N.J.: Prentice-Hall, 1987, p. 684. With permission.)

One such constraint is to restrict the DIR to be causal and to restrict the first coefficient of the DIR to be unity. In this case the delay (LT) in Fig. 70.13 is equal to the delay through the Viterbi algorithm and the first coefficient of $\{b_k\}$ is constrained to be unity.

The least restrictive constraint on the DIR is the unit energy constraint proposed by Falconer and Magee [1973]. This leads to yet another form of the receiver structure as shown in Fig. 70.13. However, the adaptation algorithm for updating the DIR coefficients $\{b_k\}$ is considerably more complicated [Falconer and Magee, 1973]. Note that the fixed predetermined WMF and T-spaced prefilter combination of Falconer and Magee [1973] has been replaced in Fig. 70.13 by a general fractionally spaced adaptive filter.

Defining Terms

Equalizer: A filter used to reduce the effect of intersymbol interference.
Intersymbol interference: The distortion caused by the overlap (in time) of adjacent symbols.

70.3 Spread Spectrum Communications[1]

L.B. Milstein and M.K. Simon

A Brief History

Spread spectrum (SS) has its origin in the military arena where the friendly communicator is (1) susceptible to detection/interception by the enemy and (2) vulnerable to intentionally introduced unfriendly interference (jamming). Communication systems that employ spread spectrum to reduce the communicator's detectability and combat the enemy-introduced interference are respectively referred to as **low probability of intercept (LPI)** and **antijam** (AJ) **communication systems.** With the change in the current world political situation wherein the U.S. Department of Defense (DOD) has reduced its emphasis on the development and acquisition of new communication systems for the original purposes, a host of new commercial applications for SS has evolved, particularly in the area of cellular mobile communications. This shift from military to commercial applications of SS has demonstrated that the basic concepts that make SS techniques to useful in the military can also be put to practical peacetime use. In the next section, we give a simple description of these basic concepts using the original military application as the basis of explanation. The extension of these concepts to the mentioned commercial applications will be treated later on in the chapter.

Why Spread Spectrum?

Spread spectrum is a communication technique wherein the transmitted modulation is *spread* (increased) in bandwidth prior to transmission over the channel and then *despread* (decreased) in bandwidth by the same amount at the receiver. If it were not for the fact that the communication channel introduces some form of narrowband (relative to the spread bandwidth) interference, the receiver performance would be transparent to the spreading and despreading operations (assuming that they are identical inverses of each other). That is, after **despreading** the received signal would be identical to the transmitted signal prior to **spreading.** In the presence of narrowband interference, however, there is a significant advantage to employing the spreading/despreading procedure described. The reason for this is as follows. Since the interference is introduced after the transmitted signal is spread, then, whereas the despreading operation at the receiver shrinks the desired signal back to its original bandwidth, at the same time it spreads the undesired signal (interference) in bandwidth by the same amount, thus reducing its power spectral density. This, in turn, serves to diminish the effect of the interference on the receiver performance, which depends on the amount of interference power in the spread bandwidth. It is indeed this very simple explanation, which is at the heart of all spread spectrum techniques.

Basic Concepts and Terminology

To describe this process analytically and at the same time introduce some terminology that is common in spread spectrum parlance, we proceed as follows. Consider a communicator that desires to send a message using a transmitted power S Watts (W) at an information rate R_b bits/s (bps). By introducing a SS modulation, the bandwidth of the transmitted signal is increased from R_b Hz to W_{ss} Hz where $W_{ss} \gg R_b$ denotes the **spread spectrum bandwidth.** Assume that the channel introduces, in addition to the usual thermal noise (assumed to have a single-sided power spectral density (PSD) equal to N_0 W/Hz), an additive interference (jamming) having power J distributed over some bandwidth W_J. After despreading, the desired signal bandwidth is once again now equal to R_b Hz and the interference PSD is now $N_J = J/W_{ss}$. Note that since the thermal noise is assumed to be white, i.e., it is uniformly distributed over all frequencies, its PSD is unchanged by the despreading operation and, thus, remains equal to N_0. Regardless of the signal and interferer waveforms, the equivalent bit energy-to-total noise ratio is, in terms of the given parameters,

[1]The material in this article was previously published by CRC Press in *The Mobile Communications Handbook,* Jerry P. Gibson, Editor-in-Chief, 1996.

$$\frac{E_b}{N_t} = \frac{E_b}{N_0 + N_J} = \frac{S/R_b}{N_0 + J/W_{ss}} \tag{70.1}$$

For most practical scenarios, the jammer limits performance and, thus, the effects of receiver noise in the channel can be ignored. Thus, assuming $N_J \gg N_0$, we can rewrite Eq. (70.1) as

$$\frac{E_b}{N_t} \cong \frac{E_b}{N_J} = \frac{S/R_b}{J/W_{ss}} = \frac{S}{J}\frac{W_{ss}}{R_b} \tag{70.2}$$

where the ratio J/S is the *jammer-to-signal power ratio* and the ratio W_{ss}/R_b is the **spreading ratio** and is defined as the **processing gain** of the system. Since the ultimate error probability performance of the communication receiver depends on the ratio E_b/N_J, we see that from the communicator's viewpoint his goal should be to minimize J/S (by choice of S) and maximize the processing gain (by choice of W_{ss} for a given desired information rate). The possible strategies for the jammer will be discussed in the section on military applications dealing with AJ communications.

Spread Spectrum Techniques

By far the two most popular spreading techniques are **direct sequence (DS) modulation** and **frequency hopping (FH) modulation.** In the following subsections, we present a brief description of each.

Direct Sequence Modulation

A direct sequence modulation $c(t)$ is formed by linearly modulating the output sequence $\{c_n\}$ of a pseudorandom number generator onto a train of pulses, each having a duration T_c called the **chip time.** In mathematical form,

$$c(t) = \sum_{n=-\infty}^{\infty} c_n p(t - nT_c) \tag{70.3}$$

where $p(t)$ is the basic pulse shape and is assumed to be of rectangular form. This type of modulation is usually used with binary phase-shift-keyed (BPSK) information signals, which have the complex form $d(t)\exp\{j(2\pi f_c t + \theta_c)\}$, where $d(t)$ is a binary-valued data waveform of rate $1/T_b$ bit/s and f_c and θ_c are the frequency and phase of the data-modulated carrier, respectively. As such, a DS/BPSK signal is formed by multiplying the BPSK signal by $c(t)$ (see Fig. 70.14), resulting in the real transmitted signal

$$x(t) = \mathrm{Re}\left\{c(t)d(t)\exp\left[j(2\pi f_c t + \theta_c)\right]\right\} \tag{70.4}$$

Since T_c is chosen so that $T_b \gg T_c$, then relative to the bandwidth of the BPSK information signal, the bandwidth of the DS/BPSK signal[2] is effectively increased by the ratio $T_b/T_c = W_{ss}/2R_b$, which is one-half the spreading factor or processing gain of the system. At the receiver, the sum of the transmitted DS/BPSK signal and the channel interference $I(t)$ (as discussed before, we ignore the presence of the additive thermal noise) are ideally multiplied by the identical DS modulation (this operation is known as despreading), which returns the DS/BPSK signal to its original BPSK form whereas the real interference signal is now the real wideband signal $\mathrm{Re}\{(t)c(t)\}$. In the previous sentence, we used the word ideally, which implies that the PN waveform used for despreading at the receiver is identical to that used for spreading at the transmitter. This simple implication covers up a

[2]For the usual case of a rectangular spreading pulse $p(t)$, the PSD of the DS/BPSK modulation will have $(\sin x/x)^2$ form with first zero crossing at $1/T_c$, which is nominally taken as one-half the spread spectrum bandwidth W_{ss}.

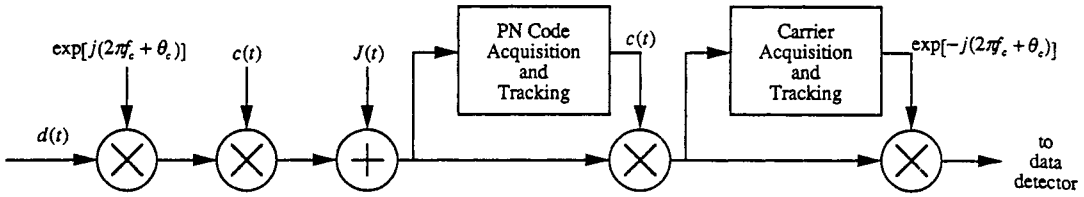

FIGURE 70.14 A DS-BPSK system (complex form).

multitude of tasks that a practical DS receiver must perform. In particular, the receiver must first acquire the PN waveform. That is, the local PN random generator that generates the PN waveform at the receiver used for despreading must be aligned (synchronized) to within one chip of the PN waveform of the received DS/BPSK signal. This is accomplished by employing some sort of **search algorithm** which typically steps the local PN waveform sequentially in time by a fraction of a chip (e.g., half a chip) and at each position searches for a high degree of correlation between the received and local PN reference waveforms. The search terminates when the correlation exceeds a given threshold, which is an indication that the alignment has been achieved. After bringing the two PN waveforms into **coarse alignment**, a **tracking algorithm** is employed to maintain **fine alignment**. The most popular forms of tracking loops are the continuous time **delay-locked loop** and its time-multiplexed version of the **tau-dither loop**. It is the difficulty in synchronizing the receiver PN generator to subnanosecond accuracy that limits PN chip rates to values on the order of hundreds of Mchips/s, which implies the same limitation on the DS spread spectrum bandwidth W_{ss}.

Frequency Hopping Modulation

A **frequency hopping (FH) modulation** $c(t)$ is formed by nonlinearly modulating a train of pulses with a sequence of pseudorandomly generated frequency shifts $\{f_n\}$. In mathematical terms, $c(t)$ has the complex form

$$c(t) = \sum_{n=-\infty}^{\infty} \exp\{j(2\pi f_n + \phi_n)\} p(t - nT_h) \tag{70.5}$$

where $p(t)$ is again the basic pulse shape having a duration T_h, called the **hop time** and $\{\phi_n\}$ is a sequence of random phases associated with the generation of the hops. FH modulation is traditionally used with multiple-frequency-shift-keyed (MFSK) information signals, which have the complex form $\exp\{j[2\pi(f_c + d(t))t]\}$, where $d(t)$ is an M-level digital waveform (M denotes the symbol alphabet size) representing the information frequency modulation at a rate $1/T_s$ symbols/s (sps). As such, an FH/MFSK signal is formed by complex multiplying the MFSK signal by $c(t)$ resulting in the real transmitted signal

$$x(t) = \mathrm{Re}\{c(t) \exp\{j[2\pi(f_c + d(t))t]\}\} \tag{70.6}$$

In reality, $c(t)$ is never generated in the transmitter. Rather, $x(t)$ is obtained by applying the sequence of pseudorandom frequency shifts $\{f_n\}$ directly to the frequency synthesizer that generates the carrier frequency f_c (see Fig. 70.15). In terms of the actual implementation, successive (not necessarily disjoint) k-chip segments of a PN sequence drive a frequency synthesizer, which hops the carrier over 2^k frequencies. In view of the large bandwidths over which the frequency synthesizer must operate, it is difficult to maintain phase coherence from hop to hop, which explains the inclusion of the sequence $\{\phi_n\}$ in the Eq. (70.5) model for $c(t)$. On a short term basis, e.g., within a given hop, the signal bandwidth is identical to that of the MFSK information modulation, which is typically much smaller than W_{ss}. On the other hand, when averaged over many hops, the signal bandwidth is equal to W_{ss}, which can be on the order of several GHz, i.e., an order of magnitude larger than that of implementable DS bandwidths. The exact relation between W_{ss}, T_h, T_s and the number of frequency shifts in the set $\{f_n\}$ will be discussed shortly.

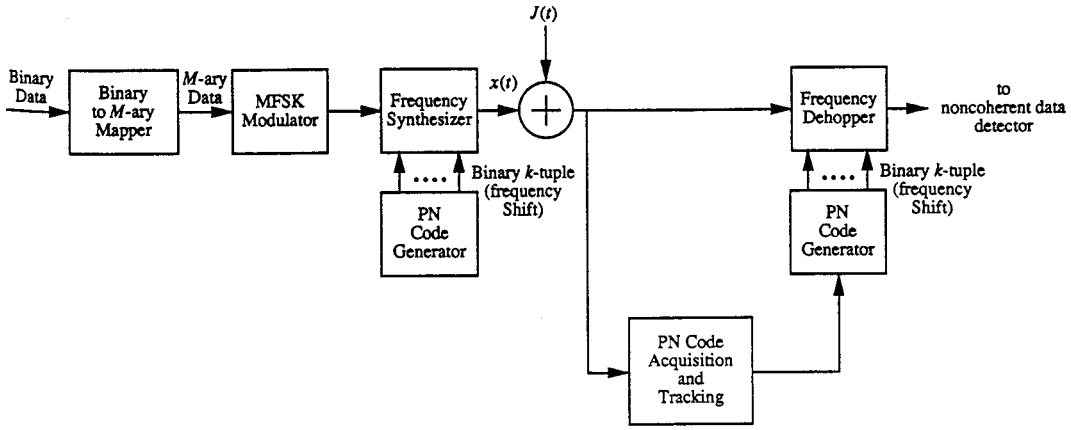

FIGURE 70.15 An FH-MFSK system.

At the receiver, the sum of the transmitted FH/MFSK signal and the channel interference $I(t)$ is ideally complex multiplied by the identical FH modulation (this operation is known as **dehopping**), which returns the FH/MFSK signal to its original MFSK form, whereas the real interference signal is now the wideband (in the average sense) signal $\mathrm{Re}\{I(t)c(t)\}$. Analogous to the DS case, the receiver must acquire and track the FH signal so that the dehopping waveform is as close to the hopping waveform $c(t)$ as possible.

FH systems are traditionally classified in accordance with the relationship between T_h and T_s. **Fast frequency-hopped (FFH)** systems are ones in which there exists one or more hops per data symbol, that is, $T_s = NT_h$ (N an integer) whereas **slow frequency-hopped (SFH)** systems are ones in which there exists more than one symbol per hop, that is, $T_h = NT_s$. It is customary in SS parlance to refer to the FH/MFSK tone of shortest duration as a "chip", despite the same usage for the PN chips associated with the code generator that drives the frequency synthesizer. Keeping this distinction in mind, in an FFH system where, as already stated, there are multiple hops per data symbol, a chip is equal to a hop. For SFH, where there are multiple data symbols per hop, a chip is equal to an MFSK symbol. Combining these two statements, the chip rate R_c in an FH system is given by the larger of $R_h = 1/T_h$ and $R_s = 1/T_s$ and, as such, is the highest system clock rate.

The frequency spacing between the FH/MFSK tones is governed by the chip rate R_c and is, thus, dependent on whether the FH modulation is FFH or SFH. In particular, for SFH where $R_c = R_s$, the spacing between FH/MFSK tones is equal to the spacing between the MFSK tones themselves. For noncoherent detection (the most commonly encountered in FH/MFSK systems), the separation of the MFSK symbols necessary to provide orthogonality[3] is an integer multiple of R_s. Assuming the minimum spacing, i.e., R_s, the entire spread spectrum band is then partitioned into a total of $N_t = W_{ss}/R_s = W_{ss}/R_c$ equally spaced FH tones. One arrangement, which is by far the most common, is to group these N_t tones into $N_b = N_t/M$ contiguous, nonoverlapping bands, each with bandwidth $M\,R_s = M\,R_c$; see Fig. 70.16(a). Assuming symmetric MFSK modulation around the carrier frequency, then the center frequencies of the $N_b = 2^k$ bands represent the set of hop carriers, each of which is assigned to a given k-tuple of the PN code generator. In this fixed arrangement, each of the N_t FH/MFSK tones corresponds to the combination of a unique hop carrier (PN code k-tuple) and a unique MFSK symbol. Another arrangement, which provides more protection against the sophisticated interferer (jammer), is to overlap adjacent M -ary bands by an amount equal to R_c; see Fig. 70.16(b). Assuming again that the center frequency of each band corresponds to a possible hop carrier, then since all but $M - 1$ of the N_t tones are available as center frequencies, the number of hop carriers has been increased from N_t/M to $N_t - (M - 1)$, which for $N_t \gg M$ is approximately an increase in randomness by a factor of M.

[3]An optimum noncoherent MFSK detector consists of a bank of energy detectors each matched to one of the M frequencies in the MFSK set. In terms of this structure, the notion of *orthogonality* implies that for a given transmitted frequency there will be no crosstalk (energy spillover) in any of the other M-1 energy detectors.

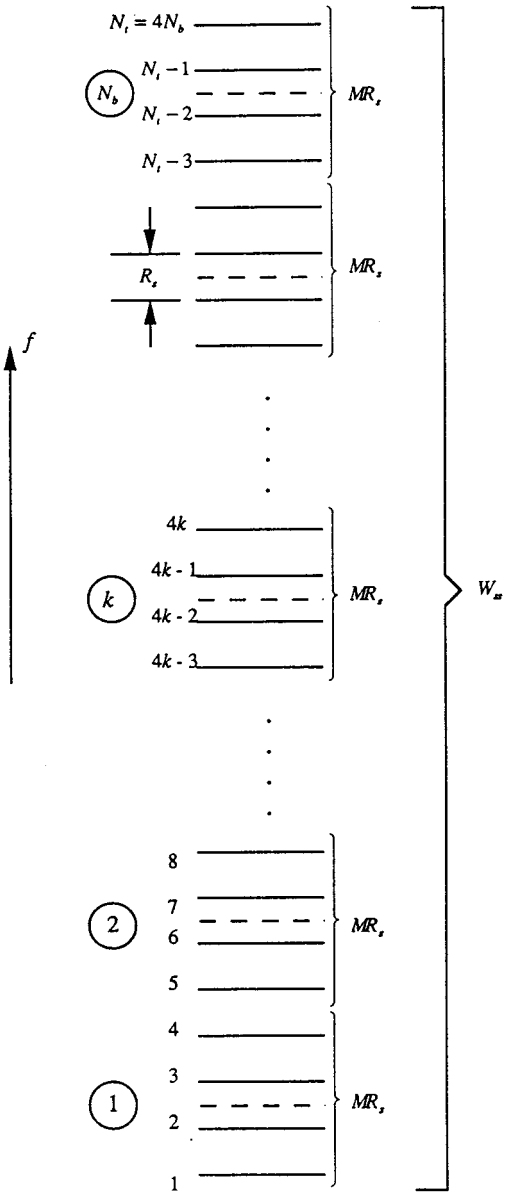

FIGURE 70.16(a) Frequency distribution for FH-4FSK —nonoverlapping bands. Dashed lines indicate lo cation of hop frequencies.

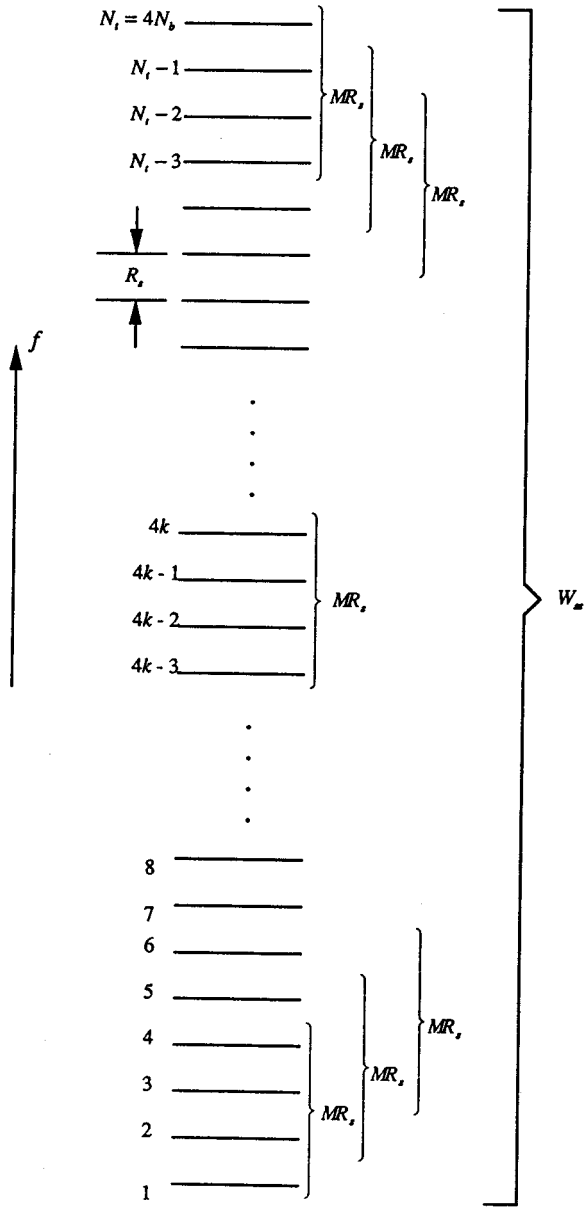

FIGURE 70.16(b) Frequency distribution for FH-4FSK — overlapping bands.

For FFH, where $R_c = R_h$, the spacing between FH/MFSK tones is equal to the hop rate. Thus, the entire spread spectrum band is partitioned into a total of $N_t = W_{ss}/R_h = W_{ss}/R_c$ equally spaced FH tones, each of which is assigned to a unique k-tuple of the PN code generator that drives the frequency synthesizer. Since for FFH there are R_h/R_s hops per symbol, then the metric used to make a noncoherent decision on a particular symbol is obtained by summing up R_h/R_s detected chip (hop) energies, resulting in a so-called *noncoherent combining loss.*

Time Hopping Modulation

Time hopping (TH) is to spread spectrum modulation what pulse position modulation (PPM) is to information modulation. In particular, consider segmenting time into intervals of T_f seconds and further segment each T_f interval into M_T increments of width T_f/M_T. Assuming a pulse of maximum duration equal to T_f/M_T, then a **time hopping spread spectrum** modulation would take the form

$$c(t) = \sum_{n=-\infty}^{\infty} p\left[t - \left(n + \frac{a_n}{M_T}\right)T_f\right] \tag{70.7}$$

where a_n denotes the pseudorandom position (one of M_T uniformly spaced locations) of the pulse within the T_r-second interval.

For DS and FH, we saw that *multiplicative* modulation, that is the transmitted signal is the product of the SS and information signals, was the natural choice. For TH, *delay* modulation is the natural choice. In particular, a TH-SS modulation takes the form

$$x(t) = \mathrm{Re}\left\{c\left(t - d(t)\right)\exp\left[j\left(2\pi f_c + \phi_T\right)\right]\right\} \tag{70.8}$$

where $d(t)$ is a digital information modulation at a rate $1/T_s$. Finally, the dehopping procedure at the receiver consists of removing the sequence of delays introduced by $c(t)$, which restores the information signal back to its original form and spreads the interferer.

Hybrid Modulations

By blending together several of the previous types of SS modulation, one can form **hybrid** modulations that, depending on the system design objectives, can achieve a better performance against the interferer than can any of the SS modulations acting alone. One possibility is to multiply several of the $c(t)$ wideband waveforms [now denoted by $c^{(i)}(t)$ to distinguish them from one another] resulting in a SS modulation of the form

$$c(t) = \prod_i c^{(i)}(t) \tag{70.9}$$

Such a modulation may embrace the advantages of the various $c^{(i)}(t)$, while at the same time mitigating their individual disadvantages.

Applications of Spread Spectrum

Military

Antijam (AJ) Communications. As already noted, one of the key applications of spread spectrum is for antijam communications in a hostile environment. The basic mechanism by which a **direct sequence spread spectrum** receiver attenuates a noise jammer was illustrated in Sec. 70.3. Therefore, in this section, we will concentrate on tone jamming.

Assume the received signal, denoted $r(t)$, is given by

$$r(t) = Ax(t) + I(t) + n_w(t) \tag{70.10}$$

where $x(t)$ is given in Eq. (70.4), A is a constant amplitude,

$$I(t) = \alpha\cos\left(2\pi f_c t + \theta\right) \tag{70.11}$$

and $n_w(t)$ is additive while Gaussian noise (AWGN) having two sided spectral density $N_0/2$. In Eq. (70.11), α is the amplitude of the tone jammer and θ is a random phase uniformly distributed in $[0, 2\pi]$.

If we employ the standard correlation receiver of Fig. 70.17, it is straightforward to show that the final test statistic out of the receiver is given by

$$g(T_b) = AT_b + \alpha\cos\theta\int_0^{T_b} c(t)\mathrm{d}t + N(T_b) \tag{70.12}$$

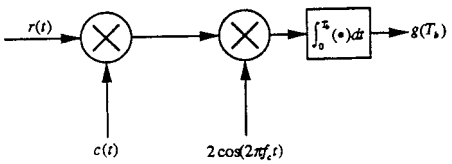

FIGURE 70.17

where $N(T_b)$ is the contribution to the test statistic due to the AWGN. Noting that, for rectangular chips, we can express

$$\int_0^{T_b} c(t)\,dt = T_c \sum_{i=1}^{M} c_i \tag{70.13}$$

where

$$M \triangleq \frac{T_b}{T_c} \tag{70.14}$$

is one-half of the processing gain. it is straightforward to show that, for a given value of θ, the signal-to-noise-plus-interference ratio, denoted by S/N_{total}, is given by

$$\frac{S}{N_{\text{total}}} = \frac{1}{\dfrac{N_0}{2E_b} + \left(\dfrac{J}{MS}\right)\cos^2\theta} \tag{70.15}$$

In Eq. (70.15), the jammer power is

$$J \triangleq \frac{\alpha^2}{2} \tag{70.16}$$

and the signal power is

$$S \triangleq \frac{A^2}{2} \tag{70.17}$$

If we look at the second term in the denominator of Eq. (70.15), we see that the ratio *J/S* is divided by *M*. Realizing that *J/S* is the ratio of the jammer power to the signal power before despreading, and *J/MS* is the ratio of the same quantity after despreading, we see that, as was the case for noise jamming, the benefit of employing direct sequence spread spectrum signalling in the presence of tone jamming is to reduce the effect of the jammer by an amount on the order of the processing gain.

Finally, one can show that an estimate of the average probability of error of a system of this type is given by

$$P_e = \frac{1}{2\pi}\int_0^{2\pi} \phi\left(-\sqrt{\frac{S}{N_{\text{total}}}}\right) d\theta \tag{70.18}$$

where

$$\phi(x) \triangleq \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{x} e^{-y^2/2}\,dy \tag{70.19}$$

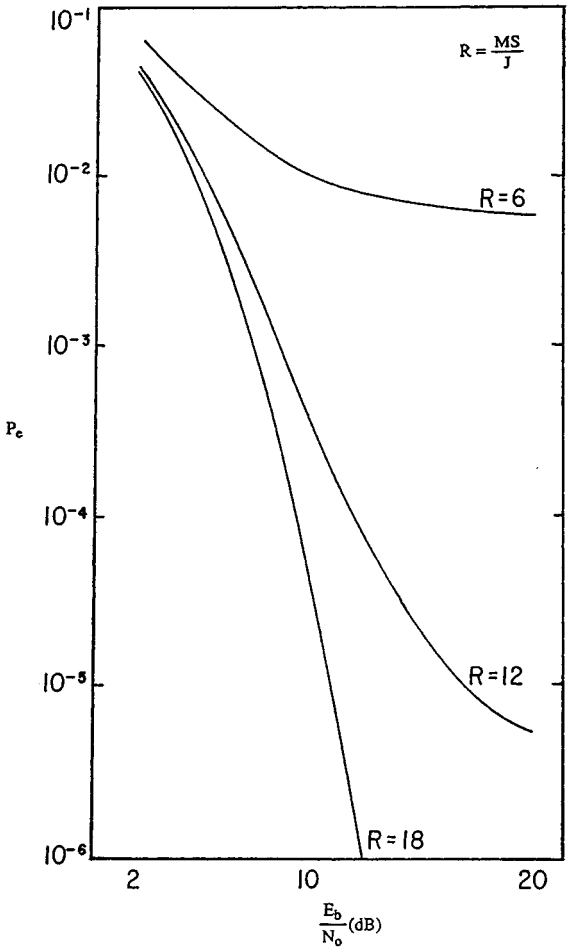

FIGURE 70.18

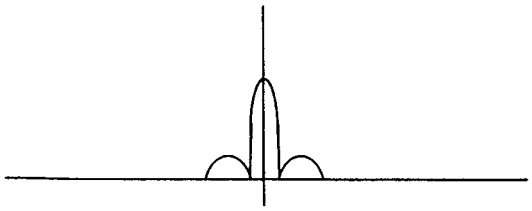
If Eq. (70.18) is evaluated numerically and plotted, the results are as shown in Fig. 70.18. It is clear from this figure that a large initial power advantage of the jammer can be overcome by a sufficiently large value of the processing gain.

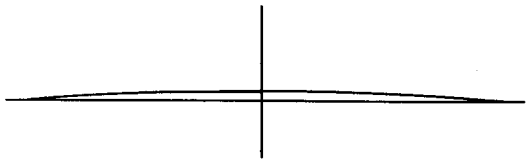
Low-Probability of Intercept (LPI). The opposite side of the AJ problem is that of LPI, that is, the desire to hide your signal from detection by an intelligent adversary so that your transmissions will remain unnoticed and, thus, neither jammed nor exploited in any manner. This idea of designing an LPI system is achieved in a variety of ways, including transmitting at the smallest possible power level, and limiting the transmission time to as short an interval in time as is possible. The choice of signal design is also important, however, and it is here that spread spectrum techniques become relevant.

The basic mechanism is reasonably straightforward; if we start with a conventional narrowband signal, say a BPSK waveform having a spectrum as shown in Fig. 70.19(a), and then spread it so that its new spectrum is as shown in Fig. 70.19(b), the peak amplitude of the spectrum after spreading has been reduced by an amount on the order of the processing gain relative to what it was before spreading. Indeed, a sufficiently large processing gain will result in the spectrum of the signal after spreading falling below the ambient thermal noise level. Thus, there is no easy way for an unintended listener to determine that a transmission is taking place.

That is not to say the spread signal cannot be detected, however, merely that it is more difficult for an adversary to learn of the transmission. Indeed, there are many forms of so-called intercept receivers that are specifically designed to accomplish this very task. By way of example, probably the best known and simplest to implement is a **radiometer,** which is just a device that measures the total power present in the received signal.



(a)



(b)

FIGURE 70.19

In the case of our intercept problem, even though we have lowered the power spectral density of the transmitted signal so that it falls below the noise floor, we have not lowered its power (i.e., we have merely spread its power over a wider frequency range). Thus, if the radiometer integrates over a sufficiently long period of time, it will eventually determine the presence of the transmitted signal buried in the noise. The key point, of course, is that the use of the spreading makes the interceptor's task much more difficult, since he has no knowledge of the spreading code and, thus, cannot despread the signal.

Commercial

Multiple Access Communications. From the perspective of commercial applications, probably the most important use of spread spectrum communications is as a multiple accessing technique. When used in this manner, it becomes an alternative to either frequency division multiple access (FDMA) or time division multiple access (TDMA) and is typically referred to as either code division multiple access (CDMA) or spread spectrum multiple access (SSMA). When using CDMA, each signal in the set is given its own spreading sequence. As opposed to either FDMA, wherein all users occupy disjoint frequency bands but are transmitted simultaneously in time, or TDMA, whereby all users occupy the same bandwidth but transmit in disjoint intervals of time, in CDMA, all signals occupy the same bandwidth and are transmitted simultaneously in time; the different waveforms in CDMA are distinguished from one another at the receiver by the specific spreading codes they employ.

Since most CDMA detectors are correlation receivers, it is important when deploying such a system to have a set of spreading sequences that have relatively low-pairwise cross-correlation between any two sequences in the set. Further, there are two fundamental types of operation in CDMA, synchronous and asynchronous. In the former case, the symbol transition times of all of the users are aligned; this allows for orthogonal sequences to be used as the spreading sequences and, thus, eliminates interference from one user to another. Alternatively, if no effort is made to align the sequences, the system operates asynchronously; in this latter mode, multiple access interference limits the ultimate channel capacity, but the system design exhibits much more flexibility.

CDMA has been of particular interest recently for applications in wireless communications. These applications include cellular communications, personal communications services (PCS), and wireless local area networks. The reason for this popularity is primarily due to the performance that spread spectrum waveforms display when transmitted over a multipath fading channel.

To illustrate this idea, consider DS signalling. As long as the duration of a single chip of the spreading sequence is less than the multipath delay spread, the use of DS waveforms provides the system designer with

one or two options. First, the multipath can be treated as a form of interference, which means the receiver should attempt to attenuate it as much as possible. Indeed, under this condition, all of the multipath returns that arrive at the receiver with a time delay greater than a chip duration from the multipath return to which the receiver is synchronized (usually the first return) will be attenuated because of the processing gain of the system.

Alternately, the multipath returns that are separated by more than a chip duration from the main path represent independent "looks" at the received signal and can be used constructively to enhance the overall performance of the receiver. That is, because all of the multipath returns contain information regarding the data that is being sent, that information can be extracted by an appropriately designed receiver. Such a receiver, typically referred to as a RAKE receiver, attempts to resolve as many individual multipath returns as possible and then to sum them coherently. This results in an *implicit* diversity gain, comparable to the use of *explicit* diversity, such as receiving the signal with multiple antennas.

The condition under which the two options are available can be stated in an alternate manner. If one envisions what is taking place in the frequency domain, it is straightforward to show that the condition of the chip duration being smaller than the multipath delay spread is equivalent to requiring that the spread bandwidth of the transmitted waveform exceed what is called the coherence bandwidth of the channel. This latter quantity is simply the inverse of the multipath delay spread and is a measure of the range of frequencies that fade in a highly correlated manner. Indeed, anytime the coherence bandwidth of the channel is less than the spread bandwidth of the signal, the channel is said to be *frequency selective* with respect to the signal. Thus, we see that to take advantage of DS signalling when used over a multipath fading channel, that signal should be designed such that it makes the channel appear frequency selective.

In addition to the desirable properties that spread spectrum signals display over multipath channels, there are two other reasons why such signals are of interest in cellular-type applications. The first has to do with a concept known as the reuse factor. In conventional cellular systems, either analog or digital, in order to avoid excessive interference from one cell to its neighbor cells, the frequencies used by a given cell are not used by its immediate neighbors (i.e., the system is designed so that there is a certain spatial separation between cells that use the same carrier frequencies). For CDMA, however, such spatial isolation is typically not needed, so that so-called *universal reuse* is possible.

Further, because CDMA systems tend to be interference limited, for those applications involving voice transmission, an additional gain in the capacity of the system can be achieved by the use of *voice activity detection.* That is, in any given two-way telephone conversation, each user is typically talking only about 50% of the time. During the time when a user is quiet, he is not contributing to the instantaneous interference. Thus, if a sufficiently large number of users can be supported by the system, statistically only about one-half of them will be active simultaneously, and the effective capacity can be doubled.

Interference Rejection. In addition to providing multiple accessing capability, spread spectrum techniques are of interest in the commercial sector for basically the same reasons they are in the military community, namely their AJ and LPI characteristics. However, the motivations for such interest differ. For example, whereas the military is interested in ensuring that systems they deploy are robust to interference generated by an intelligent adversary (i.e., exhibit jamming resistance), the interference of concern in commercial applications is unintentional. It is sometimes referred to as co-channel interference (CCI) and arises naturally as the result of many services using the same frequency band at the same time. And while such scenarios almost always allow for some type of spatial isolation between the interfering waveforms, such as the use of narrow-beam antenna patterns, at times the use of the inherent interference suppression property of a spread spectrum signal is also desired. Similarly, whereas the military is very much interested in the LPI property of a spread spectrum waveform, as indicated in Sec. 70.3, there are applications in the commercial segment where the same characteristic can be used to advantage.

To illustrate these two ideas, consider a scenario whereby a given band of frequencies is somewhat sparsely occupied by a set of conventional (i.e., nonspread) signals. To increase the overall spectral efficiency of the band, a set of spread spectrum waveforms can be overlaid on the same frequency band, thus forcing the two sets of users to share common spectrum. Clearly, this scheme is feasible only if the mutual interference that one set of users imposes on the other is within tolerable limits. Because of the interference suppression properties

of spread spectrum waveforms, the despreading process at each spread spectrum receiver will attenuate the components of the final test statistic due to the overlaid narrowband signals. Similarly, because of the LPI characteristics of spread spectrum waveforms, the increase in the overall noise level as seen by any of the conventional signals, due to the overlay, can be kept relatively small.

Defining Terms

Antijam communication system: A communication system designed to resist intentional jamming by the enemy.

Chip time (interval): The duration of a single pulse in a direct sequence modulation; typically much smaller than the formation symbol interval.

Coarse alignment: The process whereby the received signal and the despreading signal are aligned to within a single chip interval.

Dehopping: Despreading using a frequency-hopping modulation.

Delay-locked loop: A particular implementation of a closed-loop technique for maintaining fine alignment.

Despreading: The notion of decreasing the bandwidth of the received (spread) signal back to its information bandwidth.

Direct sequence modulation: A signal formed by linearly modulating the output sequence of a pseudorandom number generator onto a train of pulses.

Direct sequence spread spectrum: A spreading technique achieved by multiplying the information signal by a direct sequence modulation.

Fast frequency-hopping: A spread spectrum technique wherein the hop time is less than or equal to the information symbol interval, i.e., there exist one or more hops per data symbol.

Fine alignment: The state of the system wherein the received signal and the despreading signal are aligned to within a small fraction of a single chip interval.

Frequency-hopping modulation: A signal formed by nonlinearly modulating a train of pulses with a sequence of pseudorandomly generated frequency shifts.

Hop time (interval): The duration of a single pulse in a frequency-hopping modulation.

Hybrid spread spectrum: A spreading technique formed by blending together several spread spectrum techniques, e.g., direct sequence, frequency-hopping, etc.

Low-probability-of-intercept communication system: A communication system designed to operate in a hostile environment wherein the enemy tries to detect the presence and perhaps characteristics of the friendly communicator's transmission.

Processing gain (spreading ratio): The ratio of the spread spectrum bandwidth to the information data rate.

Radiometer: A device used to measure the total energy in the received signal.

Slow frequency-hopping: A spread spectrum technique wherein the hop time is greater than the information symbol interval, i.e., there exists more than one data symbol per hop.

Spread spectrum bandwidth: The bandwidth of the transmitted signal after spreading.

Spreading: The notion of increasing the bandwidth of the transmitted signal by a factor far in excess of its information bandwidth.

Search algorithm: A means for coarse aligning (synchronizing) the despreading signal with the received spread spectrum signal.

Tau-dither loop: A particular implementation of a closed-loop technique for maintaining fine alignment.

Time-hopping spread spectrum: A spreading technique that is analogous to pulse position modulation.

Tracking algorithm: An algorithm (typically closed loop) for maintaining fine alignment.

71.1 Lightwave Technology for Video Transmission

T. E. Darcie

Lightwave technology has revolutionized the transmission of analog and, in particular, video information. Because the light output intensity from a semiconductor laser is linearly proportional to the injected current, and the current generated in a photodetector is linearly proportional to the incident optical intensity, analog information is transmitted as modulation of the optical intensity. The lightwave system is analogous to a **linear** electrical link, where current or voltage translates linearly into optical intensity. High-speed semiconductor lasers and photodetectors enable intensity-modulation bandwidths greater than 10 GHz. Hence, a wide variety of radio frequency (RF) and microwave applications have been developed [Darcie, 1990].

Converting microwaves into intensity-modulated (IM) light allows the use of optical fiber for transmission in place of bulky inflexible coaxial cable or microwave waveguide. Since the fiber attenuation is 0.2–0.4 dB/km, compared with several decibels per meter for waveguide, entirely new applications and architectures are possible. In addition, the signal is confined tightly to the core of single-mode fiber, where it is immune to electromagnetic interference, cross talk, or spectral regulatory control.

To achieve these advantages, several limitations must be overcome. The conversion of current to light intensity must be linear. Several nonlinear mechanisms must be avoided by proper laser design or by the use of various linearization techniques. Also, because the photon energy is much larger than in microwave systems, the signal fidelity is limited by quantum or **shot noise**.

This section describes the basic technology for the transmission of various video formats. We begin by describing the most common video formats and defining transmission requirements for each. Sources of noise, including shot noise, **relative intensity noise** (RIN), and receiver noise are then quantified. Limitations imposed by source nonlinearity, for both **direct modulation** of the laser bias current and **external modulation** using an interferometric $LiNbO_3$ modulator, are compared. Finally, several other impairments caused by **fiber nonlinearity** or **fiber dispersion** are discussed.

Video Formats and Applications

Each video format represents a compromise between transmission bandwidth and robustness or immunity to impairment. With the exception of emerging digital formats, each is also an entrenched standard that often reflects the inefficiencies of outdated technology.

FM Video

Frequency-modulated (FM) video has served for decades as the basis for satellite video transmission [Pratt and Bostian, 1986], where high signal-to-noise ratios (SNRs) are difficult to achieve. Video information with a bandwidth of $B_v = 4.2$ MHz is used to FM modulate an RF carrier. The resulting channel bandwidth B is given by

$$B \sim \Delta f_{pp} + 2f_m \tag{71.1}$$

where Δf_{pp} is the frequency deviation (22.5 MHz) and f_m is the audio subcarrier frequency (6.8 MHz). As a result of this bandwidth expansion to typically 36 MHz, a high SNR can be obtained for the baseband video bandwidth B_v even if the received carrier-to-noise ratio (CNR) over the FM bandwidth B is small. The SNR is given by

$$\text{SNR} = \text{CNR} + 10 \log \left[\frac{3B}{2B_v} \left(\frac{\Delta f_{pp}}{B_v} \right) \right] + \text{W} + \text{PE} \tag{71.2}$$

where W is a weighting factor (13.8 dB) that accounts for the way the eye responds to noise in the video bandwidth, and PE is a pre-emphasis factor (0–5 dB) that is gained by emphasizing the high-frequency video components to improve the performance of the FM modulator. High-quality video (SNR = 55 dB) requires a CNR of only 16 dB. This is achieved easily in a lightwave transmission system.

Applications for lightwave FM video transmission include links to satellite transmission facilities, transport of video between cable television company head-ends (super-trunking), and perhaps delivery of video to subscribers over large fiber distribution networks [Way et al., 1988; Olshansky et al., 1988].

AM-VSB Video

The video format of choice, both for broadcast and cable television distribution, is AM-VSB. Each channel consists of an RF carrier that is amplitude modulated (AM) by video information. Single-sideband vestigial (VSB) filtering is used to minimize the bandwidth of the modulated spectrum. The resultant RF spectrum is dominated by the remaining RF carrier, which is reduced by typically 5.6 dB by the AM, and contains relatively low-level signal information, including audio and color subcarriers. An AM-VSB channel requires a bandwidth of only 6 MHz, but CNRs must be at least 50 dB.

For cable distribution, many channels are frequency-division multiplexed (FDM), separated nominally by 6 MHz (8 MHz in Europe), over the bandwidth supported by the coaxial cable. A typical 60-channel cable system operates between 55.25 and 439.25 MHz. Given the large dynamic range required to transmit both the remaining RF carrier and the low-level sidebands, transmission of this multichannel spectrum is a challenge for lightwave technology.

The need for such systems in cable television distribution systems has motivated the development of suitable high-performance lasers. Before the availability of lightwave AM-VSB systems, cable systems used long (up to 20 km) trunks of coaxial cable with dozens of cascaded electronic amplifiers to overcome cable loss. Accumulations of distortion and noise, as well as inherent reliability problems with long cascades, were serious limitations.

Fiber AM-VSB trunk systems can replace the long coaxial trunks so that head-end quality video can be delivered deep within the distribution network [Chiddix et al., 1990]. Inexpensive coaxial cable extends from the optical receivers at the ends of the fiber trunks to each home. Architectures in which the number of electronic amplifiers between each receiver and any home is approximately three or fewer offer a good compromise between cost and performance. The short spans of coaxial cable support bandwidths approaching 1 GHz, two

or three times the bandwidth of the outdated long coaxial cable trunks. With fewer active components, reliability is improved. The cost of the lightwave components can be small compared to the overall system cost. These compelling technical and economic advantages resulted in the immediate demand for lightwave AM-VSB systems.

Compressed Digital Video

The next generation of video formats will be the product of compressed digital video (CDV) technology [Netravali and Haskel, 1988]. For years digital "NTSC-like" video required a bit rate of approximately 100 Mbps. CDV technology can reduce the required bit rate to less than 5 Mbps. This compression requires complex digital signal processing and large-scale circuit integration, but advances in chip and microprocessor design have made inexpensive implementation of the compression algorithms feasible.

Various levels of compression complexity can be used, depending on the ultimate bit rate and quality required. Each degree of complexity removes different types of redundancy from the video image. The image is broken into blocks of pixels, typically 8×8. By comparing different blocks and transmitting only the differences (DPCM), factors of 2 reduction in bit rate can be obtained. No degradation of quality need result. Much of the information within each block is imperceptible to the viewer. Vector quantization (VQ) or discrete-cosine transform (DCT) techniques can be used to eliminate bits corresponding to these imperceptible details. This intraframe coding can result in a factor of 20 reduction in the bit rate, although the evaluation of image quality becomes subjective. Finally, stationary images or moving objects need not require constant retransmission of every detail. Motion compression techniques have been developed to eliminate these interframe redundancies. Combinations of these techniques have resulted in coders that convert NTSC-like video (100 Mbps uncompressed) into a few megabits per second and HDTV images (1 Gbps uncompressed) into less than 20 Mbps.

CDV can be transmitted using time-division multiplexing (TDM) and digital lightwave systems or by using each channel to modulate an RF carrier and transmitting using analog lightwave systems. There are numerous applications for both alternatives. TDM systems for CDV are no different from any other digital transmission system and will not be discussed further.

Using RF techniques offers an additional level of RF compression, wherein advanced multilevel modulation formats are used to maximize the number of bits per hertz of bandwidth [Feher, 1987]. Quadrature-amplitude modulation (QAM) is one example of multilevel digital-to-RF conversion. For example, 64-QAM uses 8 amplitude and 8 phase levels and requires only 1 Hz for 5 bits of information. As the number of levels, hence the number of bits per hertz, increases, the CNR of the channel must increase to maintain error-free transmission. A 64-QAM channel requires a CNR of approximately 30 dB.

A synopsis of the bandwidth and CNR requirements for FM, AM-VSB, and CDV is shown in Fig. 71.1. AM-VSB requires high CNR but low bandwidth. FM is the opposite. Digital video can occupy a wide area, depending on the degree of digital and RF compression. The combination of CDV and QAM offers the possibility of squeezing a high-quality video channel into 1 MHz of bandwidth, with a required CNR of 30 dB. This drastic improvement over AM-VSB or FM could have tremendous impact on future video transmission systems.

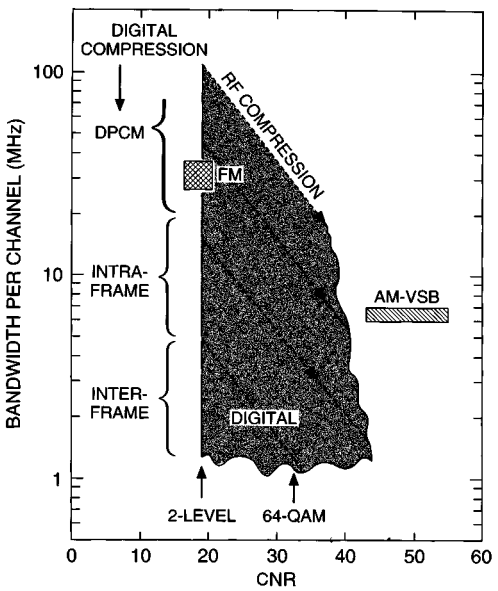

FIGURE 71.1 Bandwidth versus carrier-to-noise ratio (CNR) required for AM-VSB, FM, and digital video. Increasingly complex digital compression techniques reduce the bit rate required for NTSC-like video from 100 Mbps to less than 5 Mbps. Bandwidth efficient RF techniques like QAM minimize the bandwidth required for each bit rate but require greater CNRs.

Intensity Modulation

As mentioned in the introduction, the light output from the laser should be linearly proportional to the injected current. The laser is prebiased to an average output intensity L_0. Many video channels are combined electronically, and the total RF signal is added directly to the laser current. The optical modulation depth (m) is defined as the ratio of the peak modulation L_0 for one channel, divided by L_0. For 60-channel AM-VSB systems, m is typically near 4%.

The laser (optical carrier) is modulated by the sum of the video channels that are combined to form the total RF signal spectrum. The resultant optical spectrum contains sidebands from the IM superimposed on unintentional frequency modulation, or **chirp**, that generally accompanies IM. This complex optical spectrum must by understood if certain subtle impairments are to be avoided.

A photodetector converts the incident optical power into current. Broadband InGaAs photodetectors with responsivities (R_0) of nearly 1.0 A/W and bandwidths greater than 10 GHz are available. The detector generates a dc current corresponding to the average received optical power L_r and the complete RF modulation spectrum that was applied at the transmitter. An ac-coupled electronic preamplifier is used to remove the dc component and boost the signal to usable levels.

Noise Limitations

The definition of CNR deserves clarification. Depending on the video format and RF modulation technique, the RF power spectrum of the modulated RF carrier varies widely. For AM-VSB video the remaining carrier is the dominant feature in the spectrum. It is thereby convenient to define the CNR as the ratio of the power remaining in the carrier to the integrated noise power in a 4-MHz bandwidth centered on the carrier frequency. For FM or digitally modulated carriers, the original carrier is not generally visible in the RF spectrum. It is then necessary to define the CNR as the ratio of the integrated signal power within the channel bandwidth to the integrated noise power.

Shot Noise

Shot noise is a consequence of the statistical nature of the photodetection process. It results in a noise power spectral density, or electrical noise power per unit bandwidth (dBm/Hz) that is proportional to the received photocurrent I_r ($= R_0 L_r$). The total shot noise power in a bandwidth B is given by

$$N_s = 2eI_rB \tag{71.3}$$

where e is the electronic charge.

With small m, the detected signal current is a small fraction of the total received current. The root mean square (rms) signal power for one channel is

$$P_s = \frac{1}{2}(mI_r)^2 \tag{71.4}$$

The total shot noise power then limits the CNR (P_s/N_s) to a level referred to as the quantum limit. Received powers near 1 mW are required if CNRs greater than 50 dB are to be achieved for 40- to 80-channel AM-VSB systems.

Receiver Noise

Receiver noise is generated by the electronic amplifier used to boost the detected photocurrent to usable levels. The easiest receiver to build consists of a *pin* photodiode connected directly to a low-noise 50- to 75-Ω amplifier, as shown in Fig. 71.2(a). The effective input current noise density, (n), for this simple receiver is given by

$$n^2 = \frac{4kTF}{R_L} \tag{71.5}$$

where k is the Boltzmann constant, T is the absolute temperature, F is the **noise figure** of the amplifier, and R_L is the input impedance. For a 50-Ω input impedance and $F = 2$, $n = 20$ pA/$\sqrt{Hz}$.

A variety of more complicated receiver designs can reduce the noise current appreciably [Kasper, 1988]. The example shown in Fig. 71.2(b) uses a high-speed FET. R_L can be increased to maximize the voltage developed by the signal current at the FET input. Input capacitance becomes a limitation by shunting high-frequency components of signal current. High-frequency signals are then reduced with respect to the noise generated in the FET, resulting in poor high-frequency performance. Various impedance matching techniques have been proposed to maximize the CNR for specific frequency ranges.

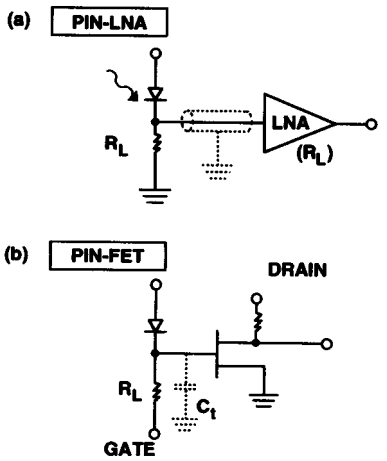

FIGURE 71.2 Receivers for broadband analog lightwave systems. Coupling a *pin* to a low-noise amplifier (a) is simple, but improved performance can be obtained using designs like the *pin* FET (b). C_t is the undesirable input capacitance.

Relative Intensity Noise

Relative intensity noise (RIN) can originate from the laser or from reflections and **Rayleigh backscatter** in the fiber. In the laser, RIN is caused by spontaneous emission in the active layer. Spontaneous emission drives random fluctuations in the number of photons in the laser which appear as a random modulation of the output intensity, with frequency components extending to tens of gigahertz. The noise power spectral density from RIN is I_r^2 RIN, where RIN is expressed in decibels per hertz.

RIN is also caused by component reflections and double-Rayleigh backscatter in the fiber, by a process called multipath interference. Twice-reflected signals arriving at the detector can interfere coherently with the unreflected signal. Depending on the modulated optical spectrum of the laser, this interference results in noise that can be significant [Darcie et al., 1991].

The CNR, including all noise sources discussed, is given by

$$\text{CNR} = \frac{m^2 I_r^2}{2B[n^2 + 2eI_r + I_r^2 \text{RIN}]} \tag{71.6}$$

All sources of intensity noise are combined into RIN. Increasing m improves the CNR but increases the impairment caused by nonlinearity, as discussed in the following subsection. The optimum operating value for m is then a balance between noise and distortion.

Figure 71.3 shows the noise contributions from shot noise, receiver noise, and RIN. For FM or digital systems, the low CNR values required allow operation with small received optical powers. Receiver noise is then generally the limiting factor. Much larger received powers are required if AM-VSB noise requirements are to be met. Although detecting more optical power helps to overcome shot and receiver noise, the ratio of signal to RIN remains constant. RIN can be dominant in high-CNR systems, when the received power is large. AM-VSB systems require special care to minimize all sources of RIN. The dominant noise source is then shot noise, with receiver noise and RIN combining to limit CNRs to within a few decibels of the quantum limit.

Linearity Requirements

Source linearity limits the depth of modulation that can be applied. Linearity, in this case, refers to the linearity of the current-to-light-intensity (I-L) conversion in the laser or voltage-to-light (V-L) transmission for an external modulator. Numerous nonlinear mechanisms must be considered for direct modulation, and no existing external modulator has a linear transfer function.

A Taylor-series expansion of the I-L or V-L characteristic, centered at the bias point, results in linear, quadratic, cubic, and higher-order terms. The linear term describes the efficiency with which the applied signal is converted

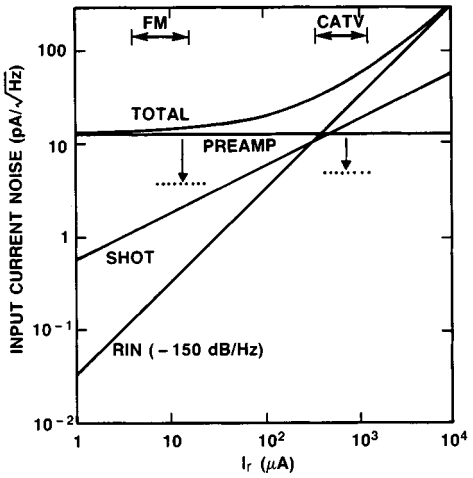

FIGURE 71.3 Current noise densities from receivers, RIN, and shot noise as a function of total received photocurrent. Receiver noise is dominant in FM or some digital systems where the total received power is small. The solid line for receiver noise represents the noise current for a typical 50-Ω low-noise amplifier. More sophisticated receiver designs could reduce the noise to the levels shown approximately by the dotted lines. RIN and shot noise are more important in AM-VSB systems.

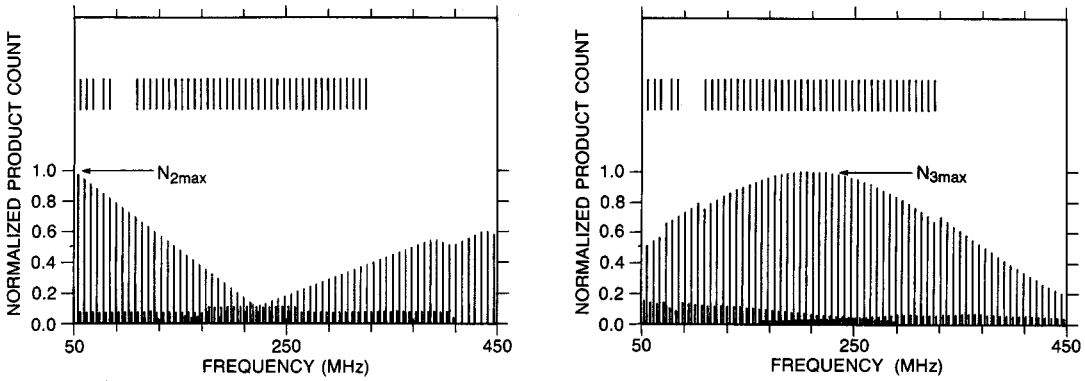

FIGURE 71.4 Second-order (a) and third-order (b) distortion products for 42-channel AM-VSB system. The maximum number of second-order products occurs at the lowest frequency channel, where 30 products contribute to the CSO. The maximum number of third-order products occurs near the center channel, where 530 products contribute to the CTB.

to linear intensity modulation. The quadratic term results in second-order distortion, the cubic produces third-order distortion, and so on.

Requirements on linearity can be derived by considering the number and spectral distribution of the distortion products generated by the nonlinear mixing between carriers in the multichannel signal. Second-order nonlinearity results in sum and difference ($f_i \pm f_j$) mixing products for every combination of the two channels. This results in as many as 50 second-order products within a single channel, in a 60-channel AM-VSB system with the standard U.S. frequency plan. Similarly, for third-order distortion, products result from mixing among all combinations of three channels. However, since the number of combinations of three channels is much larger than for two, up to 1130 third-order products can interfere with one channel. The cable industry defines the **composite second-order (CSO)** distortion as the ratio of the carrier to the largest group of second-order products within each channel. For third-order distortion, the **composite triple beat (CTB)** is the ratio of the carrier to the total accumulation of third-order distortion at the carrier frequency in each channel.

The actual impairment from these distortion products depends on the spectrum of each RF channel and on the exact frequency plan used. A typical 42-channel AM-VSB frequency plan, with carrier frequencies shown as the vertical bars on Fig. 71.4, results in the distributions of second- and third-order products shown in Fig. 71.4(a) and (b), respectively. Since the remaining carrier is the dominant feature in the spectrum of each channel, the distortion products are dominated by the mixing between these carriers. Because high-quality video requires that the CSO is –60 dBc (dB relative to the carrier), each sum or difference product must be less than –73 dBc. Likewise, for the CTB to be less than 60 dB, each product must be less than approximately –90dB.

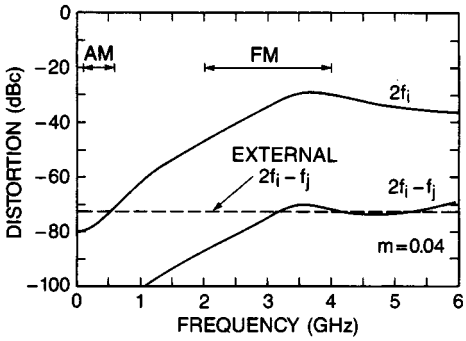

FIGURE 71.5 Resonance distortion for directly modulated laser with resonance frequency of 7 GHz. Both the second-harmonic $2f_i$ and two-tone third-order $2f_i \pm f_j$ distortion peak near half the resonance frequency and are small at low frequency. Also shown is the same third-order distortion for an external modulator biased at the point of zero second-order distortion.

FM or CDV systems have much less restrictive linearity requirements, because of the reduced sensitivity to impairment. Distortion products must be counted, as with the AM-VSB example described previously, but each product is no longer dominated by the remaining carrier. Because the carrier is suppressed entirely by the modulation, each product is distributed over more than the bandwidth of each channel. The impairment resulting from the superposition of many uncorrelated distortion products resembles noise. Quantities analogous to the CSO and CTB can be defined for these systems.

Laser Linearity

Several factors limit the light-versus-current (*L-I*) linearity of directly modulated lasers. Early work on laser dynamics led to a complete understanding of resonance-enhanced distortion (RD). RD arises from the same carrier-photon interaction within the laser that is responsible for the relaxation-oscillation resonance.

The second-harmonic distortion ($2f_i$) and two-tone third-order distortion ($2f_i - f_j$) for a typical 1.3-μm wavelength directly modulated semiconductor laser are shown in Fig. 71.5 [Darcie et al., 1986]. Both distortions are small at low frequencies but rise to maxima at half the relaxation resonance frequency. AM-VSB systems are feasible only within the low-frequency window. FM or uncompressed digital systems require enough bandwidth per channel that multichannel systems must operate in the region of large RD. Fortunately, the CNR requirements allow for the increased distortion. The large second-order RD can be avoided entirely by operating within a one-octave frequency band (e.g., 2–4 GHz), such that all second-order products are out of band.

Within the frequency range between 50 and 500 MHz, nonlinear gain and loss, intervalence-band absorption, and, more importantly, spatial-hole burning (SHB) and carrier leakage can all be significant. Carrier leakage prevents all of the current injected in the laser bond wire from entering the active layer. This leakage must be reduced to immeasurable levels for AM-VSB applications.

SHB results from the nonuniform distribution of optical power along the length of the laser. In DFB lasers, because of the grating feedback, the longitudinal distribution of optical power can be highly nonuniform. This results in distortion [Takemoto et al., 1990] that can add to or cancel other distortion, making it, in some cases, a desirable effect.

Clipping

Even if all nonlinear processes were eliminated, the allowable modulation would be limited by the fact that the minimum output power is zero. Typical operating conditions with, for example, 60 channels, each with an average modulation depth (m) near 4%, result in a peak modulation of 240%. Although improbable, modulations of more than 100% result in clipping.

The effects of clipping were first approximated by Saleh [1989], who calculated the modulation level at which the total power contained in all orders of distortion became appreciable. Even for perfectly linear lasers, the modulation depth is bounded to values beyond which all orders of distortion increase rapidly. Assuming that half the total power in all orders of distortion generated by clipping is distributed evenly over each of N channels, clipping results in a carrier-to-interference ratio (CIR) given by

$$\mathrm{CIR} = \sqrt{2\pi}\,\frac{(1+6\mu^2)}{\mu^3}\,e^{1/2\mu^2} \tag{71.7}$$

where the rms modulation index μ is

$$\mu = m\sqrt{N/2} \tag{71.8}$$

External Modulation

Laser-diode-pumped YAG lasers with low RIN and output powers greater than 200 mW have been developed recently. Combined with linearized external $LiNbO_3$ modulators, these lasers have become high-performance competitors to directly modulated lasers. YAG lasers with external modulation offer a considerable increase in launched power, and the low RIN of the YAG laser translates into a slight CNR improvement. The most challenging technical hurdle is to develop a linear low-loss optical intensity modulator.

Low-loss $LiNbO_3$ Mach–Zehnder modulators are available with insertion losses less than 3 dB, modulation bandwidths greater than a few gigahertz, and switching voltages near 5 V. The output intensity of these modulators is a sinusoidal function of the bias voltage. By prebiasing to 50% transmission, modulation applied to the Mach–Zehnder results in the most linear intensity modulation. This bias point, which corresponds to the point of inflection in the sinusoidal transfer function, produces zero second-order distortion. Unfortunately, the corresponding third-order distortion is approximately 30 dB worse than a typical directly modulated DFB laser, at low frequencies. This comparison is shown on Fig. 71.5. For high-frequency applications where RD is important, external modulators can offer improved linearity. A means of linearizing the third-order nonlinearity is essential for AM-VSB applications.

Various linearization techniques have been explored. The two most popular approaches are feedforward and predistortion. Feedforward requires that a portion of the modulated output signal be detected and compared to the original applied voltage signal to provide an error signal. This error signal is then used to modulate a second laser, which is combined with the first laser such that the total instantaneous intensity of the two lasers is a replica of the applied voltage. In principle, this technique is capable of linearizing any order of distortion and correcting RIN from the laser.

Predistortion requires less circuit complexity than feedforward. A carefully designed nonlinear circuit is placed before the nonlinear modulator, such that the combined transfer function of the predistorter-modulator is linear. Various nonlinear electronic devices or circuits can act as second- or third-order predistorters. Difficulties include matching the frequency dependence of the predistorter with that of the modulator, hence achieving good linearity over a wide frequency range. Numerous circuit designs can provide reductions in third-order distortion by 15 dB.

Miscellaneous Impairments

Laser chirp can cause problems with direct laser modulation. Chirp is modulation of the laser frequency caused by modulation of the refractive index of the laser cavity in response to current modulation. The interaction of chirp and chromatic dispersion in the fiber can cause unacceptable CSO levels for AM-VSB systems as short as a few kilometers. Dispersion converts the FM into IM, which mixes with the signal IM to produce second-order distortion [Phillips et al., 1991]. These systems must operate at wavelengths corresponding to low fiber dispersion, or corrective measures must be taken.

Chirp also causes problems with any optical component that has a transmission that is a function of optical frequency. This can occur if two optical reflections conspire to form a weak interferometer or in an **erbium-doped fiber amplifier** (EDFA) that has a frequency-dependent gain [Kuo and Bergmann, 1991]. Once again, the chirp is converted to IM, which mixes with the signal IM to form second-order distortion.

Although externally modulated systems are immune to chirp-related problems, fiber nonlinearity, in the form of stimulated Brillouin scattering (SBS), places a limit on the launched power. SBS, in which light is scattered from acoustic phonons in the fiber, causes a rapid decrease in CNR for launched powers greater than approximately 10 mW [Mao et al., 1991]. Since the SBS process requires high optical powers within a narrow optical spectral width (20 MHz), it is a problem only in low-chirp externally modulated systems. Chirp in DFB systems broadens the optical spectrum so that SBS is unimportant.

Summary

A wide range of applications for transmission of video signals over optical fiber has been made possible by refinements in lightwave technology. Numerous technology options are available for each application, each with advantages or disadvantages that must be considered in context with specific system requirements. Evolution of these video systems continues to be driven by development of new and improved photonic devices.

Defining Terms

Chirp: Modulation of the optical frequency that occurs when a laser is intensity modulated.

Composite second order (CSO): Ratio of the power in the second-order distortion products to power in the carrier in a cable television channel.

Composite triple beat (CTB): Same as CSO but for third-order distortion.

Direct modulation: Modulation of the optical intensity output from a semiconductor diode laser by direct modulation of the bias current.

Erbium-doped fiber amplifier: Fiber doped with erbium that provides optical gain at wavelengths near 1.55 μm when pumped optically at 0.98 or 1.48 μm.

External modulation: Modulation of the optical intensity using an optical intensity modulator to modulate a constant power (cw) laser.

Fiber dispersion: Characteristic of optical fiber by which the propagation velocity depends on the optical wavelength.

Fiber nonlinearity: Properties of optical fibers by which the propagation velocity, or other characteristic, depends on the optical intensity.

Lightwave technology: Technology based on the use of optical signals and optical fiber for the transmission of information.

Linear: Said of any device for which the output is linearly proportional to the input.

Noise figure: Ratio of the output signal-to-noise ratio (SNR) to the input SNR in an amplifier.

Rayleigh backscatter: Optical power that is scattered in the backwards direction by microscopic inhomogeneities in the composition of optical fibers.

Relative intensity noise: Noise resulting from undesirable fluctuations of the optical power detected in an optical communication system.

Shot noise: Noise generated by the statistical nature of current flowing through a semiconductor *p-n* junction or photodetector.

71.2 Long Distance Fiber Optic Communications

Joseph C. Palais

When the first laser was demonstrated in 1960, numerous applications of this magnificent new tool were anticipated. Some predicted that laser beams would transmit messages through the air at high data rates between distant stations. Although laser beams can indeed travel through the atmosphere, too many problems prevent this scheme from becoming practical. Included in the objections are the need for line-of-sight paths and the unpredictability of transmission through an atmosphere where weather variations randomly change path losses. Guided paths using optical fibers offer the only practical means of optical transmission over long distances.

Long-distance fiber systems tend to have the following operational characteristics: They are more than 10 km long, transmit digital signals (rather than analog), and operate at data rates above a few tens of megabits per second. This section primarily describes systems in this category.

Figure 71.6 illustrates the basic structure of a generalized long-distance fiber optic link. Each of the components will be described in the following paragraphs.

A useful figure of merit for these systems is the product of the system data rate and its length. This figure of merit is the well-known *rate-length product.* The bandwidth of the transmitting and receiving circuits (including the light source and photodetector) limits the achievable system data rate. The bandwidth of the

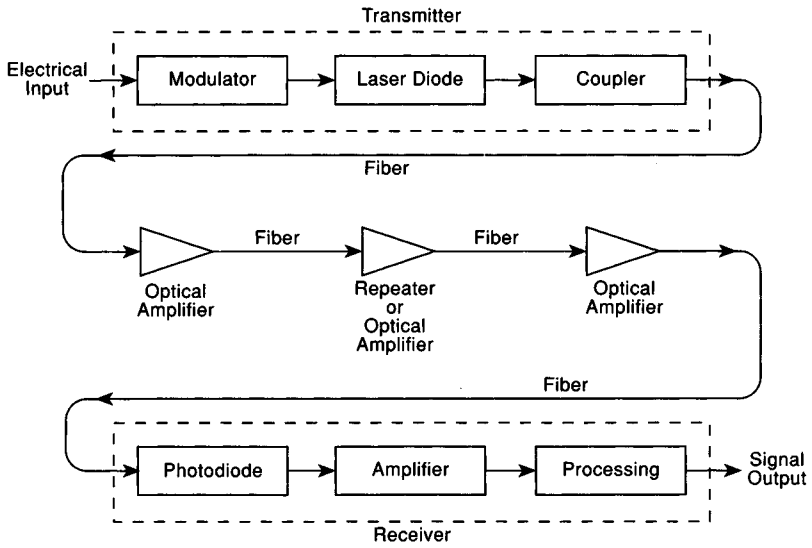

FIGURE 71.6 Long-distance fiber communication system.

fiber decreases with its length, so that the fiber itself limits the rate-length product. The losses in the system, including those in the fiber, also limit the path length. Systems are *bandwidth limited* if the rate-length figure is determined by bandwidth restraints and *loss limited* if determined by attenuation.

The first efficient fiber appeared in 1970, having a loss of 20 dB/km. Just 7 years later the first large-scale application, a link between two telephone exchanges in Chicago, was constructed. By this time the loss had been reduced to around 3 dB/km. The digital technology used could accommodate a rate of 45 Mbps over an unrepeatered length of 10 km and a total length of over 60 km with repeaters. The unrepeatered rate-length product for this initial system was a modest 0.5 Gbps × km. As fiber technology advanced, this figure steadily increased. Unrepeatered rate-length products have improved to 500 Gbps × km (e.g., 8 Gbps over a path of 60 km) and beyond. Allowing repeaters and/or optical amplifiers increases the net rate-length product considerably. Values beyond 70 Tbps × km (70,000 Gbps × km) are achievable with optical amplifiers. This latter figure allows construction of a transmission system operating at 5 Gbps over a 14,000-km path. The longest terrestrial paths are across the Atlantic and Pacific oceans, distances of about 6,000 and 9,000 km, respectively. Fibers are capable of spanning these distances with high-capacity links.

Fiber

All fibers used for long-distance communications are made of silica glass and allow only a single mode of propagation. The silica is doped with other materials to produce the required refractive index variations for the fiber core and cladding. The important fiber characteristics that limit system performance are its loss and its bandwidth. The loss limits the length of the link and the bandwidth limits the data rate.

Figure 71.7 shows the loss characteristics of single-mode silica fibers at the wavelengths of lowest attenuation. As indicated in the figure, there are three possible windows of operation. In the first window (around 820 nm), the loss is typically 3 dB/km. This is too high for long systems. In the second window (near 1300 nm), the loss is about 0.5 dB/km. In addition, the fiber bandwidth is quite high because of low pulse dispersion at this wavelength. The second window is a reasonable operating wavelength for high-capacity, long-distance systems. At 1550 nm (the third window) the loss is lowest, about 0.25 dB/km. This characteristic makes 1550 nm the optimum choice for the very longest links.

Dispersion refers to the spreading of a pulse as it travels along a **single-mode fiber**. It is due to material and waveguide effects. This spreading creates intersymbol interference if allowed to exceed about 70% of the original pulse width, causing receiver errors. The dispersion factor M is usually given in units of picoseconds of pulse spread per nanometer of spectral width of the light source and per kilometer of length of fiber.

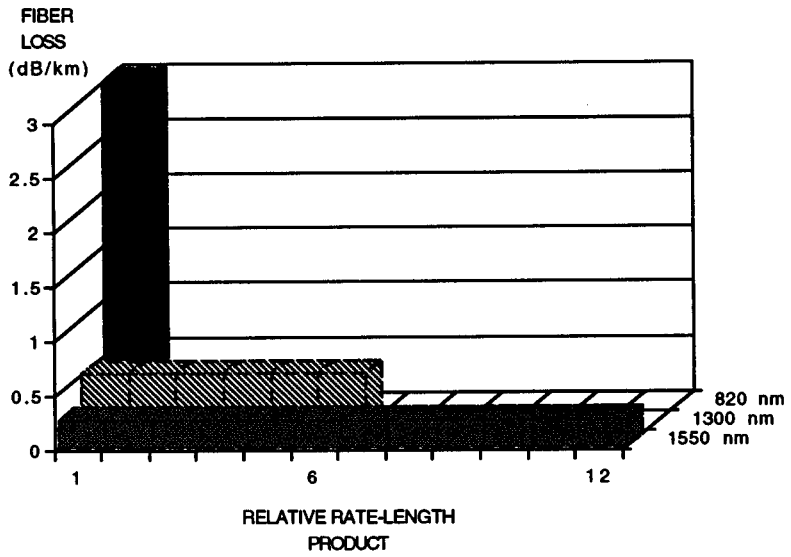

FIGURE 71.7 Fiber loss and relative unrepeatered, unamplified rate-length product.

In the range from 1200 to 1600 nm, the dispersion curve for silica can be approximated by the expression

$$M = \frac{M_0}{4}\left(\lambda - \frac{\lambda_0^4}{\lambda^3}\right) \tag{71.9}$$

where λ is the operating wavelength, λ_0 is the zero dispersion wavelength, and M_0 is the slope at the zero dispersion wavelength. M_0 is approximately 0.095 ps/(nm^2 × km). The pulse spread for a path length L, using a light source whose spectral width is $\Delta\lambda$, is then

$$\Delta\tau = ML\Delta\lambda \tag{71.10}$$

The zero dispersion wavelength, close to 1300 nm for silica fibers, makes this wavelength attractive for high-capacity links. The dispersion at 1550 nm is typically close to 20 ps/(nm × km). This is a moderate amount of dispersion. If a proposed 1550-nm system is bandwidth limited because of this spread, several alternatives are available. One solution is to use dispersion-shifted fiber, which is a special fiber with a refractive index profile designed to shift the zero dispersion wavelength from 1300 nm to 1550 nm. Another solution is to transmit soliton pulses, which use the nonlinearity of the fiber to maintain pulse shape during transmission.

Figure 71.7 includes relative unrepeatered, unamplified values of rate-length products in the three transmission windows. Because of high loss, the first window can be used only for moderate lengths (around 10 km). Because of high dispersion, the data rates are also limited in this region. In the second window, nearly zero dispersion allows high-rate transmission, but the losses limit the distance that can be covered (typically around 50 km). In the third window, the loss is about half the 1300-nm attenuation so that twice as much distance can be covered. Dispersion-shifted fiber allows the same high rates as does 1300-nm operation. Repeaters and amplifiers extend the useful distance of fiber links well beyond the distances listed here.

Modulator

A digital electrical signal modulates the light source. The driver circuit must be fast enough to operate at the system bit rate. As bit rates increase into the multigigabit per second range, this becomes increasingly difficult. Modulation can be done in the optical domain at very high speeds. In this case, the modulator follows the laser diode rather than preceding it. External modulation is usually accomplished using integrated-optic structures.

Light Source

Laser diodes or light-emitting diodes (LEDs) supply the optical carrier waves for most fiber links. LEDs cannot operate at speeds in the gigabit range, but laser diodes can. For this reason, laser diodes are normally required for high-rate, long-distance links. Laser diodes can be modulated at frequencies beyond 40 GHz.

Laser diodes emitting in the second and third fiber transmission windows are semiconductor heterojunctions made of InGaAsP. The exact emission wavelength is primarily determined by the proportions of the constituent atoms. Output powers are commonly on the order of a few milliwatts.

Typical laser diode **spectral widths** are between 1 and 5 nm when operating in more than one longitudinal mode. Single-mode laser diodes can have spectral widths of just a few tenths of a nanometer. As predicted by Eq. (71.10), narrow-spectral-width emitters minimize pulse spreading. Minimizing pulse spreading increases the fiber bandwidth and its data capacity.

Solid-state lasers other than semiconductor laser diodes may be useful in specific applications. Example of such lasers are the Nd:YAG laser and the erbium-doped fiber laser.

Source Coupler

The light emitted from the diode must be coupled as efficiently as possible into the fiber. Because the beam pattern emitted by a laser diode does not perfectly match the pattern of light propagating in the fiber, there is an inevitable mismatch loss. Good coupler designs, sometimes using miniature lenses, reduce this loss to about 3 dB when feeding a single-mode fiber.

Isolator

An optical isolator is a one-way transmission path. It allows power flow from the transmitter toward the receiver but blocks power flow in the opposite direction. It is used to protect the laser diode from back reflections, which tend to increase the laser noise.

Connectors and Splices

Connections between fibers and between the fiber and other components occur at numerous points in a long-distance link. Because there may be many splices in a long system, the loss of each one must be small. Fusion splices with an average loss of no more than 0.05 dB are often specified. Mechanical splices are also suitable. They often involve epoxy for fixing the connection. Connectors are used where remateable connections are required. Good fiber connectors introduce losses of just a few tenths of a decibel.

In addition to having low loss, good connectors and splices also minimize back reflections. This is especially important for connections near the transmitter to reduce laser noise. Fusion splices produce little reflection, but mechanical splices and all connectors must be carefully designed to keep reflected power levels low. Reflections occur because of small gaps at the interface between the mated fibers. Successful techniques for reducing reflections include the physical contact connection, where the fiber end faces are polished into hemispheres (rather than flat surfaces) so that the cores of the two mated fibers are in contact with each other. Even better performance is obtained by angling the end faces a few degrees so that reflected light is filtered out of the single propagating mode.

Optical Amplifier

Many fiber links are loss limited. One cause is the limited power available from the typical laser diode, which (together with the losses in the fiber and the other system components) restricts the length of fiber that can be used. The *fiber optic amplifier* increases the power level of the signal beam without conversion to the electrical domain. For example, gains of 30 dB are attainable at 1550 nm using the erbium-doped fiber amplifier (EDFA). Quite importantly, the EDFA has a bandwidth of over 20 nm so that several WDM or numerous OFDM channels (described later in this section) can be amplified simultaneously.

As indicated in Fig. 71.6, there are a number of possible locations for optical amplifiers in a system. An optical amplifier just following the transmitter increases the optical power traveling down the fiber. Amplifiers

along the fiber path continually keep the power levels above the system noise. An amplifier located at the fiber end acts as a receiver preamplifier, enhancing its sensitivity. Many amplifiers can be placed in a fiber network, extending the total path length to thousands of kilometers.

Repeater

The repeater is a regenerator that detects the optical signal by converting it into electrical form. It then determines the content of the pulse stream and uses this information to generate a new optical signal and launch this improved pulse train into the fiber. The new optical pulse stream is identical to the one originally transmitted. The regenerated pulses are restored to their original shape and power level by the repeater.

Many repeaters may be placed in a fiber network, extending the total path length to thousands of kilometers. The advantage of the optical amplifier over the regenerator is its lower cost and improved efficiency. The greater cost of the regenerator arises from the complexity of conversion between the optical and electrical domains. The regenerator does have the advantage of restoring the signal pulse shape, which increases the system bandwidth. This advantage is negated by a system propagating soliton pulses, which do not degrade with propagation.

Photodetector

This device converts an incoming optical beam into an electrical current. In fiber receivers, the most commonly used photodetectors are semiconductor *pin* photodiodes and avalanche photodiodes (APD). Important detector characteristics are speed of response, spectral response, internal gain, and noise. Because avalanche photodiodes have internal gain, they are preferred for highly sensitive receivers. Both Ge and InGaAs photodiodes respond in the preferred second and third fiber windows. InGaAs performs better at low signal levels because it has smaller values of dark current (that is, it is less noisy).

The current produced by a photodetector in response to incident optical power P is

$$i = G\eta eP/hf \tag{71.11}$$

where G is the detector's gain, η is its quantum efficiency (close to 0.9 for good photodiodes), h is Planck's constant (6.63×10^{-34} J s), e is the magnitude of the charge on an electron (1.6×10^{-19}), and f is the optical frequency. For *pin* photodiodes ($G = 1$), typical responsivities are on the order of 0.5 μA/μW.

Receiver

Because of the low power levels expected at the input to the receiver, an electronic amplifier is normally required following the photodetector. The remainder of the receiver includes such electronic elements as band-limiting filters, equalizers, decision-making circuitry, other amplification stages, switching networks, digital-to-analog converters, and output devices (e.g., telephones, video monitors, and computers).

Other Components

There are a number of other fiber components, not shown in Fig. 71.6, that can be found in some systems. These include passive couplers for tapping off some portion of the beam from the single fiber and wavelength-division multiplexers for coupling different optical carriers onto the transmission fiber.

System Considerations

Long-distance fiber links carry voice, video, and data information. Messages not already in digital form are first converted to it. A single voice channel is normally transmitted at a rate of 64,000 bits per second. Video requires a much higher rate. The rate could be as much as 90 Mbps or so, but video compression techniques can lower this rate significantly. Fiber systems for the telephone network operate at such high rates that many voice channels can be time-division multiplexed (TDM) onto the same fiber for simultaneous transmission. For example, a fiber operating at a rate of 2.3 Gbps could carry more than 30,000 digitized voice channels.

Several optical carriers can simultaneously propagate along the same fiber. Such wavelength-division multiplexed (WDM) links further increase the capacity of the system. Systems using two or three optical carriers are common. Adding more than a few channels (8 or so) puts strong constraints on the multiplexers and light sources. In long systems wideband optical amplifiers are preferred over regenerators for WDM systems because a single amplifier can boost all the individual carriers simultaneously while separate regenerators are needed for each carrier wavelength.

Total cable capacity is also increased by placing numerous fibers inside the cable. This is a cost-effective strategy when installing long fiber cables. The added cost of the extra fibers is small compared to the costs of actually deploying the cable itself. Fiber counts above 100 are practical. Multifiber cables can have enormous total data capacities.

Still further capacity is possible using optical frequency-division multiplexing (OFDM). In this scheme, many optical carriers very closely spaced in wavelength (maybe a few tenths of a nanometer) operate as independent channels. Hundreds of channels can be visualized in each of the two low-loss fiber windows. Systems of this type require **coherent detection** receivers to separate the closely spaced carriers.

Error Rates and Signal-to-Noise Ratio

The signal-to-noise ratio is a measure of signal quality. It determines the error rate in a digital network. At the receiver, it is given by

$$\frac{S}{N} = \frac{(G\rho P)^2 R_L}{G^n 2eR_L B(I_D + \rho P) + 4kTB} \tag{71.12}$$

where P is the received optical power, ρ is the detector's unamplified responsivity, G is the detector gain if an APD is used, n accounts for the excess noise of the APD (usually between 2 and 3), B is the receiver's bandwidth, k is Boltzmann's constant ($k = 1.38 \times 10^{-23}$ J/K), e is the magnitude of the charge on an electron (1.6×10^{-19} coulomb), T is the receiver's temperature in degrees kelvin, I_D is the detector's dark current, and R_L is the resistance of the load resistor that follows the photodetector.

The first term in the denominator of Eq. (71.12) is caused by shot noise and the second term is attributed to thermal noise in the receiver. If the shot noise term dominates (and the APD excess loss and dark current are negligible), the system is shot-noise limited. In this case the probability of error has an upper bound given by:

$$P_e = e^{-n_s} \tag{71.13}$$

where n_s is the average number of photoelectrons generated by the signal during a single bit interval when a binary 1 is received. An error rate of 10^{-9} or better requires about 21 photoelectrons per bit. Shot noise depends on the optical signal level. Because the power level is normally low at the end of a long-distance system, the shot noise is small compared to the thermal noise. Avalanche photodiodes increase the shot noise compared to the thermal noise. With APD receivers, ideal shot-noise limited operation can be approached but (because of the APD excess noise and limited gain) not reached.

If the thermal noise dominates, the error probability is given by

$$P_e = 0.5 - 0.5 \text{ erf } (0.354 \sqrt{S/N}) \tag{71.14}$$

where erf is the error function. An error rate of 10^{-9} requires a signal-to-noise ratio of nearly 22 dB.

System Design

A major part of fiber system design involves the power budget and the bandwidth budget. The next few paragraphs describe these calculations.

In a fiber system, component losses (or gains) are normally given in decibels. The decibel is defined by

$$\text{dB} = 10 \log P_2/P_1 \tag{71.15}$$

where P_2 and P_1 are the output and input powers of the component. The decibel describes relative power levels. Similarly, dBm and dBμ describe absolute power levels. They are given by

$$\text{dBm} = 10 \log P \tag{71.16}$$

where P is in milliwatts and

$$\text{dB}\mu = 10 \log P \tag{71.17}$$

where P is in microwatts.

Power budget calculations are illustrated in Table 71.1 for a system that includes an amplifier. A specific numerical example is found in the last two columns. The receiver sensitivity in dBm is subtracted from the power available from the light source in dBm. This difference is the loss budget (in decibels) for the system. All the system losses and gains are added together (keeping in mind that the losses are negative and the amplifier gains are positive). If the losses are more than the gains (as is usual), the system loss dB_{SL} will be a negative number. The loss margin is the sum of the loss budget and the system loss. It must be positive for the system to meet the receiver sensitivity requirements. The system loss margin must be specified to account for component aging and other possible system degradations. A 6-dB margin was found for the system illustrated in the table. The fiber in the table has a total loss of 24 dB. If its attenuation is 0.25 dB/km, the total length of fiber allowed would be 24/0.25 = 96 km.

TABLE 71.1 Power Budget Calculations

Source power	dBm_s	3	
Receiver sensitivity	dBm_r	–30	
Loss budget: $\text{dBm}_s - dBm_r$	dB_{LB}		33
Component efficiencies			
Connectors	dB_c	–5	
Splices	dB_s	–2	
Source coupling loss	dB_{cl}	–5	
Fiber loss	dB_f	–24	
Isolator insertion loss	dB_i	–1	
Amplifier gain	dB_a	10	
Total system loss			
$\text{dB}_c + \text{dB}_s + \text{dB}_{cl} + \text{dB}_f + \text{dB}_i + \text{dB}_a$	dB_{SL}		–27
Loss margin: $\text{dB}_{LB} + \text{dB}_{SL}$	dB_{LM}		6

In addition to providing sufficient power to the receiver, the system must also satisfy the bandwidth requirements imposed by the rate at which data are transmitted. A convenient method of accounting for the bandwidth is to combine the rise times of the various system components and compare the result with the rise time needed for the given data rate and pulse coding scheme.

The system rise time is given in terms of the data rate by the expression

$$t = 0.7/R_{NRZ} \tag{71.18}$$

for non-return-to-zero (NRZ) pulse codes and

$$t = 0.35/R_{RZ} \tag{71.19}$$

for return-to-zero (RZ) codes.

An example of bandwidth budget calculations appears in Table 71.2. The calculations are based on the accumulated rise times of the various system components.

TABLE 71.2 Bandwidth Budget Calculations[a]

Transmitter	t_t	0.8	
Fiber	t_f	0.36	
Receiver	t_r	1	
System total: $\sqrt{t_t^2 + t_f^2 + t_r^2}$	t_s		1.33
System required	t		1.4

[a]All quantities in the table are rise time values in nanoseconds.

The system in Table 71.2 runs at 500 Mbps with NRZ coding for a 100-km length of fiber. Equation (71.18) yields a required system rise time no more than 1.4 ns. The transmitter is assumed to have a rise time of 0.8 ns. The receiver rise time, taken as 1 ns in the table, is a combination of the photodetector's rise time and that of the receiver's electronics.

The fiber's rise time was calculated for a single-mode fiber operating at a wavelength of 1550 nm. Equation (71.9) shows that $M = 18$ ps/(nm × km) at 1550 nm. The light source was assumed to have a spectral width of 0.2 nm. Then, the pulse dispersion calculated from Eq. (71.10) yields a pulse spread of 0.36 ns. Because the fiber's rise time is close to its pulse spread, this value is placed in the table.

The total system rise time is the square root of the sum of the squares of the transmitter, fiber, and receiver rise times. That is:

$$t_s = \sqrt{t_t^2 + t_f^2 + t_r^2} \tag{71.20}$$

In this example, the system meets the bandwidth requirements by providing a rise time of only 1.33 ns, where as much as 1.4 ns would have been sufficient.

Defining Terms

Coherent detection: The signal beam is mixed with a locally generated laser beam at the receiver. This results in improved receiver sensitivity and in improved receiver discrimination between closely spaced carriers.
Material dispersion: Wavelength dependence of the pulse velocity. It is caused by the refractive index variation with wavelength of glass.
Quantum efficiency: A photodiode's conversion efficiency from incident photons to generated free charges.
Single-mode fiber (SMF): A fiber that can support only a single mode of propagation.
Spectral width: The range of wavelengths emitted by a light source.

71.3 Photonic Networks

Ivan P. Kaminow

Lightwave technology has been developed and widely utilized for local and long-distance transmission in the public telephone network (see Section 71.2 and Miller and Kaminow, 1988) and in modern CATV (cable TV) networks (Section 71.1). Computer communications have been provided utilizing copper transmission lines in private local-area networks (LAN) that cover short distances, $L < 10$ km, and involve low data throughputs $S < 10$ Mb/s. The throughput is defined as

$$S = NB$$

with N the number of simultaneous interconnections and B the communication bit-rate per user. At the higher ranges of the bit-rate-distance product, above BL = (10 Mb/s) (10 km) = 100 Mb/s·km or, equivalently, higher ranges of the bit-rate-delay product

$$M = BD = (BL)(n/c),$$

where D is the propagation delay, c/n is the (group) velocity of bits on the transmission line, and c is the velocity of light, optical fiber may be preferable to copper. For optical fibers, with refractive index $n = 1.5$, the delay is $n/c = 5 \times 10^{-9}$ s/m = 5 μs/km. Thus, with BL = 100 Mb/s·km, M is 500 bits, i.e., there are 500 bits in transit on the transmission line between transmitter and receiver.

As M gets larger, the performance of copper transmission lines—twisted pairs or coax—becomes unsatisfactory because of attenuation and pulse dispersion. The economic break-even value for M, where the added cost of lightwave technology is justified, though not precise, is in the neighborhood of 500 bits. In this section, we will cover aspects of lightwave data networks that utilize the lightwave technology discussed in Section 71.2 and some of the multiple-access methods for LANs discussed in Section 66.3. The latter section touches on commercial LAN standards that utilize optical data links for point-to-point transmission between nodes, often with multimode fiber. Here, we will first discuss some of the recent optical LAN standards and then briefly mention proposed approaches to photonic networks with terabit-per-second throughput and gigabit-per-second user access, and the novel optical components that are needed to realize this high performance. When such networks connect users separated by $L \sim$ 1000s of kilometers, $M \sim$ 10s of megabits may be in transit, requiring new approaches to congestion control for multiple access.

Data Links

A data link consists of a transmitter (T) that converts electrical pulses to optical pulses (E/O) and sends the optical pulses on an optical fiber to a receiver (R) which converts the optical pulses back to electrical pulses (O/E). The transmitter may use a light-emitting diode (LED) or a laser diode (LD) as the optical source. The LED is cheaper but has lower output power into the fiber (~10 μW vs. ~1 mW), lower modulation bandwidths (~100 Mb/s vs. ~1 Gb/s), and wider optical spectrum, leading to chromatic dispersion due to the variation of optical velocity in the fiber with wavelength. Pulse dispersion limits BL when the pulse spreading approaches a bit period. The receiver may employ a PIN (positive-intrinsic-negative) or APD (avalanche photodiode) photodetector. The former is cheaper and easier to bias but has poorer sensitivity by about 5 dB. The sensitivity of a good PIN receiver is about –50 dBm at 100 Mb/s and –35 dBm at 1 Gb/s for a bit-error-rate (BER) of 10^{-9}. Optical devices operating at a wavelength of ~0.87 μm use gallium-aluminum-arsenide materials and are less expensive than those operating at 1.3 or 1.5 μm and using indium-gallium-arsenide-phosphide materials. However, for 1.5 μm, the fiber attenuation and, for 1.3 μm, the chromatic dispersion is much less than for 0.87 μm. The fiber joining transmitter and receiver may be multimode or single mode. Multimode (with a typical core diameter of 62.5 μm) is cheaper, but since each mode travels at a different optical velocity, the modal dispersion further limits BL. The LED data links generally employ multimode fiber, and the combination of chromatic and modal dispersion limits BL to values below ~1 Gb/s·km. For an LD, single-mode fiber (core diameter ~10 μm) data link, BL of ~100 Gb/s·km is possible.

Optical data links are employed to connect electronic components of a LAN when copper is no longer feasible. However, because of its lower cost and the fact that it is often already installed, clever tricks are now being used to extend the utility of copper.

Token Ring: FDDI, FFOL

Figure 71.8 illustrates a ring network. The real topology may be a good deal more irregular than a circle, depending on the accessibility of stations. In its usual application, which uses a token-ring protocol for media access, an electronic repeater that operates at the aggregate network rate is required at each station.

A token—e.g., a "1" or a "0" bit, or a token packet—is propagated in one direction from station to station. When a station has a packet to send to another station, it adds the address of the receiving station in a header

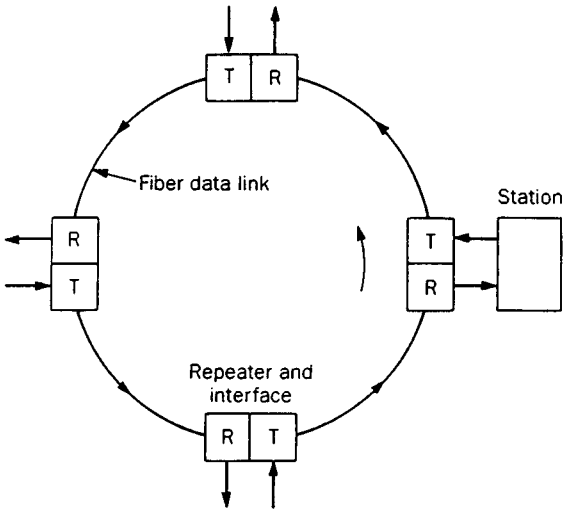

FIGURE 71.8 Undirectional ring network. R and T represent the receiver and transmitter functions, respectively.

and holds the combined packet in a buffer. The sending station reads the tokens as they go by until it receives an empty token, a "0." It then converts the "0" to a "1," a busy token, and appends the packet.

Intermediate stations repeat the bits in the packet and also "listen" for their own addresses. If a station recognizes its address in the packet header, it copies the packet. When the packet returns to the sender, it serves as an acknowledgment, and the sender removes it from the ring, after converting the token back to "0."

Commercial token rings use wire interconnections or optical data links to join stations at rates in the 10-Mb/s range. Actual network use is less than 10 Mb/s because of the time it takes an empty token to pass around the ring. This transit-time delay increases linearly with the number of stations. It includes propagation delay between stations and processing delay at each station, which must examine the header of every packet before repeating the bits to the next station.

A token-ring architecture is not especially attractive for a high-speed optical network (where $S \sim B$ is above 1 Gb/s) because of the cost of high-speed repeater optoelectronics at each station and the packet-processing delay. In addition, at high bit rates, the packet time may be much shorter than the propagation time around the ring, unless a packet contains an impractically large number of bits. Efficient use of the ring with short packets may call for multiple tokens, which can lead to complex protocols. Increasing the number of bits per packet increases the packet time but places added burden on the high-speed buffer at each station.

Reliability—if one station is disabled or if the fiber breaks—is a problem in both fiber and wire rings. To address these reliability problems, a double-ring optical network can provide for bypass of defective stations and loop back around a fiber break. Each station has two inputs and two outputs connected to two rings that operate in opposite directions; this, of course, increases the cost.

The fiber distributed data interface (FDDI) [Ross, 1986, 1989] is a standard proposed by the American National Standard Institute for a 100-Mb/s double-ring, time-division multiplexed (TDM) LAN that uses 1.3-μm multimode fiber and LED (or single-mode fiber and laser diode) data links between stations. This LAN is designed to provide both backbone services that interconnect lower speed LANs and back-end services that interconnect mainframe computers, mass storage systems, and other high-speed peripherals. FDDI provides datagram packet service with up to about 4,500 data bytes per frame. It employs 4B/5B coding so that the clock rate is 125 MHz for maximum S of 100 Mb/s. The FDDI network is designed to operate with low-cost components that were commercially available in 1986. The standard can provide both packet-switched and circuit-switched services. As many as 1000 stations can be connected, with a maximum of 2 km between stations and a maximum perimeter of 200 km.

An FDDI follow on LAN (FFOL) will operate with laser and single-mode fiber data links at bit rates corresponding to the synchronous optical network (SONET) or synchronous digital hierarchy (SDH) standards

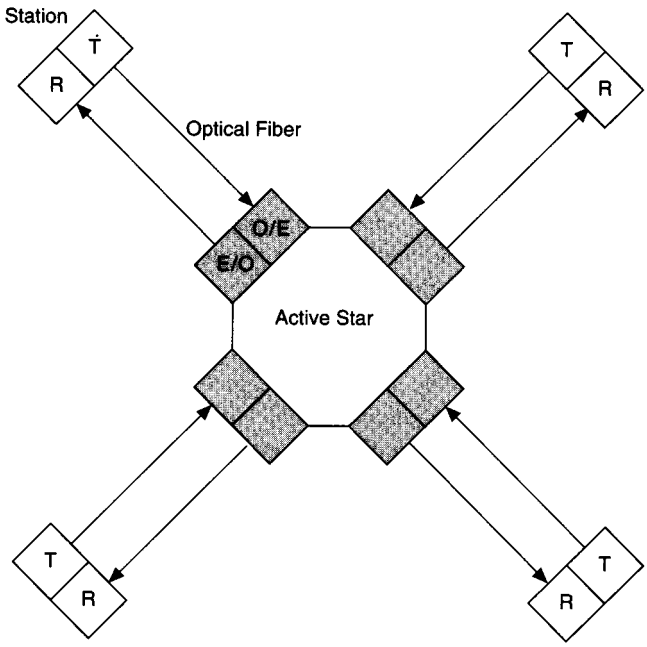

FIGURE 71.9 Active star network. Optical-to-electrical (O/E) and electrical-to-optical (E/O) converters must be provided at the star. R and T represent the receiver and transmitter functions, respectively.

of 622 Mb/s and 2.5 Gb/s, possibly with ATM (asynchronous transfer mode) cells. The geographical size will also be increased.

Active Star Networks: Ethernet, Datakit®

Carrier sense multiple access with collision detection (CSMA/CD) Ethernet networks operating at 10 Mb/s connect users on a copper bus. The length of the bus must be less than 1/2 the distance light propagates in the time required to transmit a packet frame. Thus, for speeds much greater than 10 Mb/s, where optics might be needed, the length of the bus will be limited unless the maximum frame contains an impractically large number of bits. Further, the number of stations that can be supported by an optical bus is limited by the nature of optical taps, as opposed to electrical taps [Kaminow, 1989]. Finally, the collision detection algorithm does not work well on an optical bus because the intensities of optical packets from two different stations may vary considerably along the bus. Thus, an active electronic star, as shown in Fig. 71.9, with optical data links from users is often employed.

The AT&T Datakit [Fraser, 1983] packet switch behaves as a virtual circuit switch (VCS) in that a reliable data path is set up for each session, and packet retransmission because of collisions is not required. Remote stations that may consist of mainframe computers, concentrators that bring together many terminals, or gateways to other networks are connected by 8-Mb/s fiber-optic data links to individual electronic modules at the central node as shown in Fig. 71.10 [Kaminow, 1988]. These modules plug into two electronic buses that are short (about 1 m) compared to a packet propagation length (16 bytes).

In the module, packets are formed and stored with a header that contains the source address. When the packet is complete (it has the full number of bytes, or a fixed waiting period for added bytes has passed), the module transmits its binary address on the contention bus while listening for bits transmitted by others. If the module transmits a 1 and hears a 1, it transmits the next address bit. But if it transmits a 0 and hears a 0, it transmits the next bit; and, if it transmits a 0 and hears a 1, it stops transmission, having lost the contention. This process is equivalent to a logical OR operation and assigns the contention to the highest address. The winner transmits the packet on the contention bus in the next time frame.

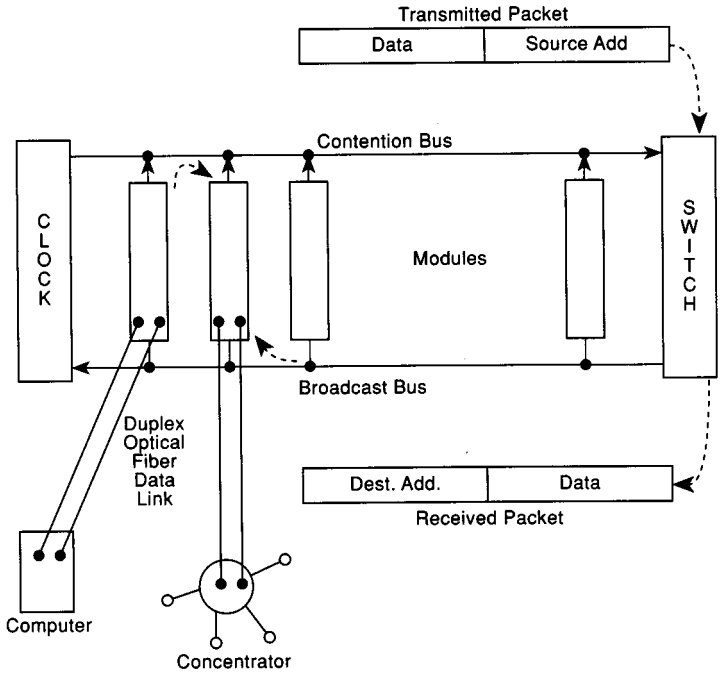

FIGURE 71.10 Datakit® VCS network. Remote stations are connected to the electrical node by 8-Mb/s data links. The length of the bus is much shorter than the propagation length of a packet.

The switch at the end of the bus replaces the source address with the destination address and transmits the packet on the broadcast bus, where the appropriate module records the destination address and sends the packet to the remote station over the fiber link. Because the switch establishes a correspondence between source and destination at the beginning of a session (as in a circuit switch), source modules need not know the bus position of destination modules. The switch has a directory of positions and terminal names.

If we were to go to very high bit rates, the physical bus length might no longer be short compared with a packet, and collisions caused by delays might upset the "perfect scheduling" of packets. Although methods have been proposed [Acampora and Hluchyj, 1984] for overcoming this limitation, the electronic circuit costs and electrical reflections on the bus may limit the effectiveness of a centralized bus at very high data rates.

New Approaches to Optical Networks

The preceding conventional networks with optical data links replacing copper can improve their throughputs thanks to the increased bandwidth of the transmission medium. However, a revolutionary improvement in throughput to terabit-per-second levels with gigabit-per-second access requires entirely new approaches for the physical connectivity, architecture, and access protocols. We can use much of the photonic technology employed in long-haul lightwave systems to provide physical connectivity, but we also need devices with new functionality to realize proposed architectures, and, conversely, with new component functionality we can dream of new architectures.

We can provide connectivity among users in three dimensions: space, time, and optical frequency or wavelength, employing space-division multiplexing (SDM), optical time-division multiplexing (OTDM), and optical frequency-division multiplexing (OFDM) or wavelength-division multiplexing (WDM), respectively. To control the path routing we need optical switches for OTDM and frequency routing technology for OFDM. At present, network architectures and protocols are at the research stage. We mention some of these components and switches in the following paragraphs. More details can be found in the References [Miller and Kaminow, 1988; Special Issue, 1990].

A star topology seems most attractive for gigabit-per-second multiple-access photonic networks [Kaminow, 1989], as shown in Fig. 71.11. Each station has its own transmitter and receiver. For optical TDM, the connectivity can be provided by an $N \times N$ electrooptic switch and suitable controller, and for optical FDM, the connectivity is provided by a passive $N \times N$ star coupler. Electrooptic $N \times N$ switches based on integrated titanium-diffused lithium niobate waveguide elements [Korotky and Alferness, 1988] have been demonstrated with $N = 16$ and operating at $B = 2.5$ Gb/s for each input. The switch connections can be rearranged in a few nanoseconds. It is estimated that such switches could be interconnected to provide $N = 256$. Unlike electronic switches, electrooptic switches are transparent to the bit rate, i.e., they can connect any bit stream independent of B. The problems of suitable multiple-access protocols and controls have not yet been fully addressed.

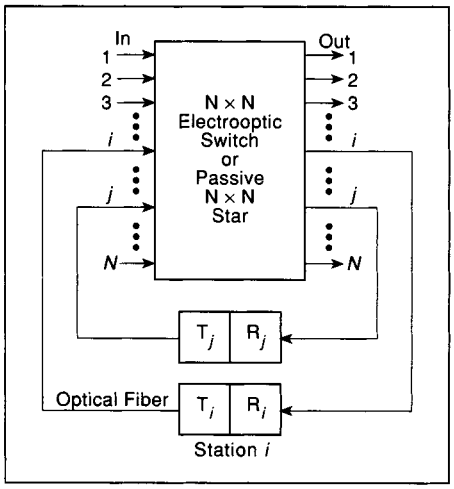

FIGURE 71.11 Electrooptic switch network for optical TDM or passive star network for optical FDM. The $N \times N$ switch or star have N single-mode optical fiber input ports and N optical fiber output ports. As in the active star (Fig. 71.9), two fibers connect a remote station with the star. R_x and T_x represent the receiver and transmitter functions, respectively, for station x.

The passive $N \times N$ star coupler [Kaminow, 1989] in Fig. 71.11 has N single-mode fiber inputs and N outputs. In an ideal passive star, a signal incident on any input is divided equally among all the outputs, i.e., the star broadcasts every input to every output. Unlike the OTDM case, each transmitter uses a different optical frequency and each receiver must tune to the frequency of the channel intended for it, as illustrated in Fig. 71.12. Alternatively, the receiver frequencies may be fixed and the transmitters tunable. Thus, the control can be distributed in the terminals. Calculations indicate that such a network can support throughputs of several terabits per second. Current research [Special Issue, 1990] is aimed at devising multiple-access protocols and demonstrating the novel devices needed for optical frequency routing. These include fast tunable lasers and receivers that can cover many channels (switching speeds of ~10 ns at 2.5 Gb/s with ~50 channels appear feasible), optical frequency translators for frequency reuse, and integrated star couplers and integrated optical frequency routers.

One challenge in photonic network design is to make them "all-optical," as nearly as possible, in order to avoid throughput bottlenecks by electronic components and the expense of O/E and E/O conversions. In principle, clear all-optical channels would offer connectivity independent of data-rate and format for a wide variety of applications. However, many physical technology problems remain and new concepts for multple access and congestion control [Special Issue, 1991] suited to large bit-rate-delay (M) systems must be found.

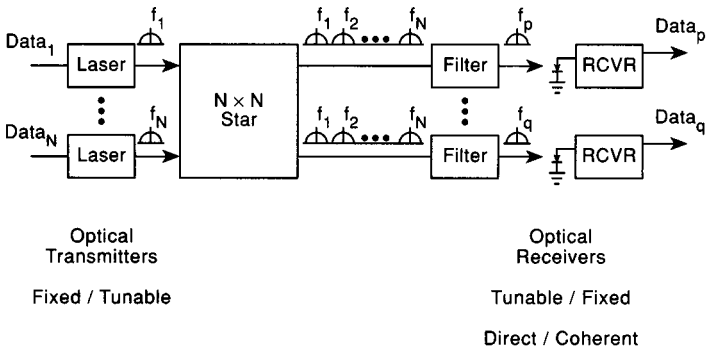

FIGURE 71.12 An optical FDM network with passive star distribution. Optical transmitter frequencies $f_{1 \ldots} f_N$ are modulated with data at the transmitter and selected by a filter at the receiver.

72.1 B-ISDN

Manfred N. Huber

Since the mid-1980s the idea of the **integrated services digital network** (ISDN) has become reality. In ISDN voice services with supplementary features and data services with a bit rate of up to 64 kbit/s are integrated in one network. For voice communication and many text and data applications the 64-kbit/s ISDN will be sufficient. Although it is minor as yet, there exists already a growing demand for **broadband** communication with bit rates from some megabits per second up to approximately 130 Mbit/s [Wiest, 1990] (e.g., high-speed data communication, video communication, high-resolution graphics).

In order to provide the same advantages of ISDN to broadband communication users, network operators, and service providers, the development of an intelligent broadband-ISDN (B-ISDN) is necessary. The future B-ISDN will become the universal network integrating different kinds of services with their individual features and requirements. B-ISDN will support switched, semipermanent and permanent, point-to-point, and point-to-multipoint connections and provide on-demand, reserved, and permanent services. B-ISDN connections support packet mode and circuit mode services of mono- and/or multimedia type of a connection-oriented or connectionless nature in a unidirectional or bidirectional configuration [Händel and Huber, 1991b].

B-ISDN Services and Applications

As already mentioned, there exists some demand for broadband communication which originates from business customers as well as residential customers. In the residential area, on the one hand, people are interested in video distribution services for entertainment purposes, like television and high-definition TV; on the other

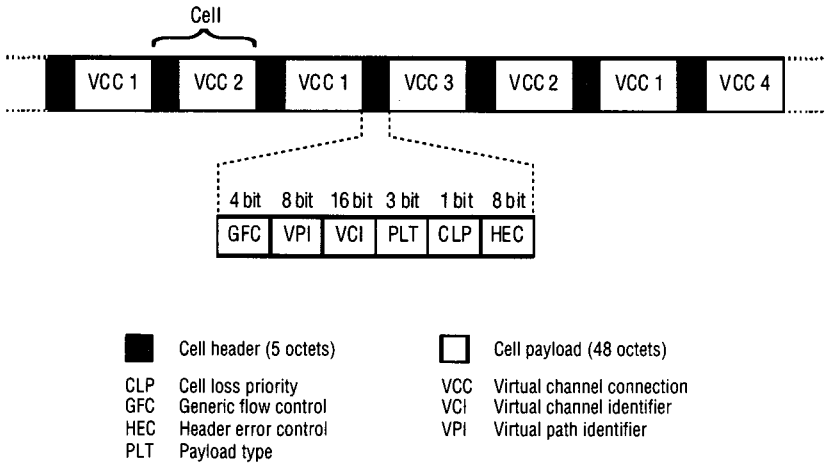

FIGURE 72.1 ATM principle.

hand, they will use video telephony with acceptable quality. Over the long term, video mail services and video retrieval services will become more important.

Voice and text are no longer sufficient for business customers. In the offices and factories of tomorrow, interactive broadband services will be required. Handling complex tasks in the future demands comprehensive support by services for voice, text, data, graphics, video, and documents. In addition to the individual services, the multimedia services and the simultaneous or alternating use of several services with multifunction workstations will gain importance [Armbrüster, 1990].

Interconnection of local-area networks (LANs) or large computers, computer-aided design, and computer-aided manufacturing will become important data applications. The first video services will be video telephony and video conferencing (studio-to-studio and workstation video conferencing). Initially these services may have diminished quality, but for the long term TV quality can be expected.

The bit rates of all services mentioned above are in the range of 2 to 130 Mbit/s (depending on the individual application). Taking into account that in the future more enhanced video coding mechanisms will be available, the required bit rates for video services will become lower without influencing quality significantly.

Asynchronous Transfer Mode

In today's public switched networks the synchronous transfer mode (STM) predominates. Applying STM technology, for the duration of a connection a synchronous channel with constant bit rate is allocated to that connection. STM does not fit very well for the integration of services with bit rates from some kilobits per second to 130 Mbit/s. Therefore, in B-ISDN a new transfer mode called **asynchronous transfer mode** (ATM) is used.

In ATM all kinds of information is transported in **cells**. A cell is a block of fixed length, which consists of a 5-octet cell header and a 48-octet cell payload (see Fig. 72.1). The cell header contains all necessary information for transferring the cell through the network and the cell payload includes the user information. The cell rate of a connection is proportional to the service bit rate. Only if information is available is a cell used by the connection. By having different routing labels, cells of different connections can be transported on the same transmission line (cell multiplexing). If no connection has information ready to transport, idle cells will be inserted. Idle cells do not belong to any connection; they are identified by a standardized cell header.

ATM uses only cells; multiplexing and switching of cells is independent of the applications and of the bit rates of the individual connections. Applying ATM technology, the idea of one universal integrated network becomes a reality. However, the ATM technology also causes some problems. Because of the asynchronous multiplexing buffers are necessary, which results in cell delay, cell delay variation, and cell loss. In order to compensate for these effects additional measures have to be provided.

Figure 72.1 also shows the individual subfields of the cell header. The first field, called generic flow control (GFC), is only available at the user-network interface (UNI). Its main purpose is media access control in shared medium configurations (LAN-like configurations) within the customer premises [Göldner and Huber, 1991]. The proposed GFC procedures are based either on the distributed queue algorithm or the reset timer control mechanism [Händel and Huber, 1991a]. At the network-node interface (NNI) these bits are part of the virtual path identifier (VPI).

The VPI together with the virtual channel identifier (VCI) form the routing label (identifier of the connection). The VPI itself marks only the virtual path (VP). The VP concept allows the flexible configuration of individual subnetworks (e.g., **signaling** network or virtual private network), which can be independent of the underlying transmission network. VP networks are under the control of network management. The bandwidth of a VP will be allocated according to its requirements. Within the VP network the individual connections are established and cleared down dynamically (by signaling).

The payload type field in the cell header differentiates the information in the cell payload of one connection (e.g., user information, operation and maintenance information for ATM). The value of the cell loss priority bit distinguishes cells that can be discarded under some exceptional network conditions without disturbing the quality significantly from those cells that may not be discarded. The last field of the cell header forms the header error control field. The cell header is protected against errors with a mechanism that allows the correction of a single bit error and the detection of multibit errors.

The high transmission speeds for ATM cell transfer require very high-performance switching nodes. Therefore, the switching networks (SNs) have to be implemented in fast hardware. Within the SN the self-routing principle will be applied [Schaffer, 1990]. At the inlet of the SN the cell is extended by an SN-internal header. It is evident that the SN-internal operational speed has to be increased. When passing the individual switching elements, for the processing of the SN-internal header only simple hard-wired logic is necessary. This reduces the control complexity and provides a better failure behavior. When starting several years ago with the implementation of the ATM technology, only the emitter coupled logic (ECL) was available. Nowadays, the complementary metal-oxide semiconductor (CMOS) technology with its low power consumption is used [Fischer et al., 1991].

Transmission of B-ISDN Signals

Transmission systems at the UNI provide bit rates of around 150 and 622 Mbit/s. In addition to these rates, at the NNI around 2.5 Gbit/s and up to 10 Gbit/s will be used in the future [Baur, 1991]. In addition to the high-capacity switching and multiplexing technology, high-speed transmission systems are required. Optical fibers are especially suitable for this purpose; however, for the lower bit rates coaxial cables can be used. Optical transmission uses optical fibers as the transmission medium in low-diameter and low-weight cables to provide large transmission capacities over long distances without the need for repeaters. Optical transmission equipment currently tends to mono-mode fiber and laser diodes with wavelengths of around 1310 nm. For both directions in a transmission system either two separate fibers or one common fiber with wavelength division multiplexing can be used. The second solution may be a good alternative for subscriber lines and short trunk lines [Bauch, 1991].

For ATM cell transmission, two possibilities exist, which are shown in Fig. 72.2: synchronous pulse frame or continuous cell stream (cell-based). The basis for the pulse frame concept is the existing **synchronous digital hierarchy** (SDH). In SDH the cells are transported within the SDH payload; the frame overhead includes operation and maintenance (OAM) of the transmission system. In the cell-based system the OAM for the transmission system is transported within cells. The SDH solution is already defined, whereas for cell-based transmission some problems remain to be solved (e.g., OAM is not yet fully defined).

ATM Adaptation Layer

The **ATM adaptation layer** (AAL) is between the ATM layer and higher layers. Its basic function is the enhanced adaptation of the services provided by ATM to the requirements of the layers above. In order to minimize the number of AAL protocols, the service classification shown in Fig. 72.3 was defined. This classification was made with respect to timing relation, bit rate, and connection mode.

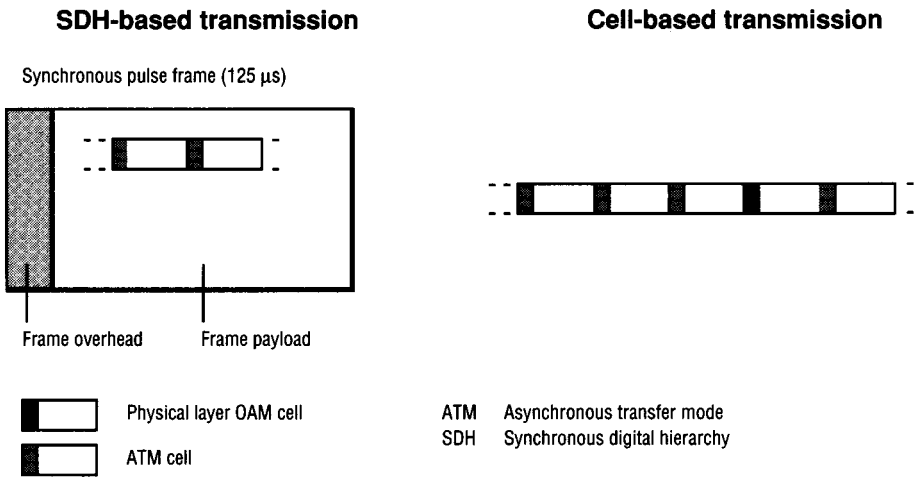

FIGURE 72.2 Transmission principles for B-ISDN.

	Class A	Class B	Class C	Class D
Timing relation between source and destination	Required		Not required	
Bitrate	Constant	Variable		
Connection mode	Connection oriented			Connection-less

FIGURE 72.3 AAL service classification.

The AAL protocols are subdivided into two parts. The lower part performs, at the sending side, the segmentation of long messages into the cell payload and, at the receiving side, reassembly into long messages. The upper part is service dependent and provides the AAL service to the higher layer.

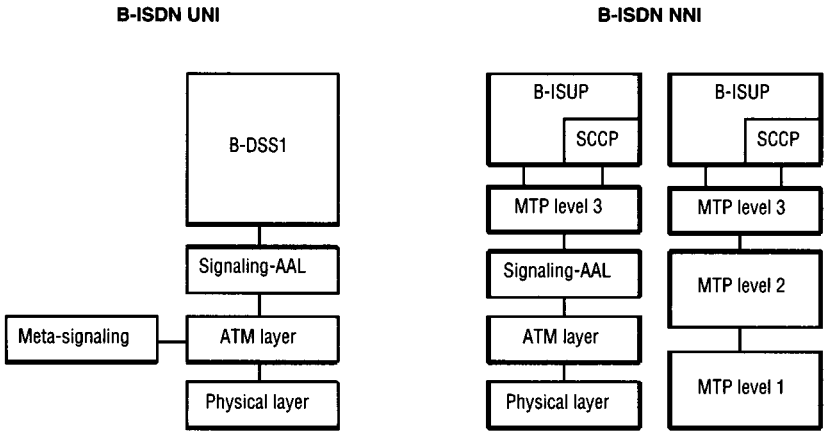
B-ISDN Signaling

For signaling in B-ISDN, existing protocols and infrastructure will be reused as much as possible. Figure 72.4 shows the protocol stacks for UNI and NNI. The upper part concerns signaling applications and the lower part signaling transfer.

For the introduction of simple switched services in B-ISDN, at UNI and NNI, existing signaling application protocols will be reused. The 64-kbit/s ISDN-specific information elements will be removed and new B-ISDN-specific information elements will be added. Right from the beginning these protocols will provide means that allow smooth migration toward future applications, which will include highly sophisticated features like multimedia services [Huber et al., 1992]. This approach guarantees compatibility for future protocol versions.

At the NNI the existing signaling system no. 7 (SS7) can be reused (see right part of the NNI protocol stack in Fig. 72.4). SS7 is a powerful and widespread network that will continue to be applied for rather a long period until ATM penetration has been reached. For the middle term, however, a fully ATM-based network will be available which also carries signaling messages (see left part of the NNI protocol stack in Fig. 72.4). ATM-based signaling at the NNI needs a suitable AAL which provides the services of the existing message transfer part level 2.

At the UNI, right from the beginning, all kinds of traffic (including signaling) is carried within cells. An AAL for signaling at the UNI is also required. This AAL has to provide the services of the existing layer 2 UNI



AAL	ATM adaptation layer
ATM	Asynchronous transfer mode
B-DSS1	Broadband digital subscriber signaling system no. 1
B-ISUP	Broadband-ISDN user part
MTP	Message transfer part
NNI	Network-node interface
SCCP	Signaling connection control part
UNI	User-network interface

FIGURE 72.4 Protocol stacks for B-ISDN signaling.

protocol. The AAL for signaling at UNI and NNI will be common as much as possible. In contrast to the NNI, at the UNI meta-signaling is necessary. Meta-signaling establishes, checks, and removes the signaling channels between customer equipment and the central office in a dynamic way. The signaling channels at the NNI are semipermanent and, therefore, meta-signaling is not required.

Defining Terms

Asynchronous transfer mode: A transfer mode in which the information is organized into cells; it is asynchronous in the sense that the recurrence of cells containing information from an individual user is not necessarily periodic.

ATM adaptation layer: A layer which provides the adaptation of higher layers to ATM.

Broadband: A service or system requiring transmission channels capable of supporting bit rates greater than 2 Mbit/s.

Cell: A block of fixed length which is subdivided into a cell header and an information field. The cell header contains a label which allows the clear allocation of a cell to a connection.

Integrated services digital network: A network which provides end-to-end digital connectivity to support a wide range of services, including voice and nonvoice services, to which users have access by a limited set of standard multipurpose user-network interfaces.

Signaling: Procedures which are used to control (set up and clear down) calls and connections within a telecommunication network.

Synchronous digital hierarchy: A standard for optical transmission which provides transmission facilities with flexible add/drop capabilities to allow simple multiplexing and demultiplexing of signals.

72.2 Computer Communication Networks

J. N. Daigle

A **computer communication network** is a collection of applications hosted on different machines and interconnected by an infrastructure that provides communications among the communicating entities. While the applications are generally understood to be computer programs, the generic model includes the human being as an application. In fact, one or all of the "applications" that are communicating may be human beings.

This section summarizes the major characteristics of computer communication networks. The objective is to provide a concise introduction that will allow the reader to gain an understanding of the key distinguishing characteristics of the major classes of networks that exist today and some of the issues involved in the introduction of emerging technologies.

There are a significant number of well-recognized books in this area. Among these are the excellent texts by Schwartz [1987], Tanenbaum [1988], and Spragins [1991], which have enjoyed wide acceptance by both students and practicing engineers and cover most of the general aspects of computer communication networks. Stallings

[1990a, 1990b, 1990c] covers a broad array of standards in this area. Other books that have been found to be especially useful by practitioners are those by Rose [1990] and Black [1992].

The latest developments are, of course, covered in the current literature, conference proceedings, and the notes of standards meetings. A pedagogically oriented magazine that specializes in computer communications networks is *IEEE Network,* but *IEEE Communications* and *IEEE Computer* often also contain interesting articles in this area. *ACM Communications Review,* in addition to presenting pedagogically oriented articles, often presents very useful summaries of the latest standards activities. Major conferences that specialize in computer communications include the IEEE INFOCOM and ACM SIGCOMM series, which are held annually.

We will begin our discussion with a brief statement of how computer networking came about and a capsule description of the networks that resulted from the early efforts. Networks of this generic class, called **wide-area networks (WANs),** are broadly deployed today, and there are still a large number of unanswered questions with respect to their design. The issues involved in the design of those networks are basic to the design of most networks, whether wide area or otherwise. In the process of introducing these early systems, we will describe and contrast three basic types of communication switching: circuit, message, and packet.

We will next turn to a discussion of computer communication **architecture,** which describes the structure of communication-oriented processing software within a communication processing system. Our discussion is limited to the **International Standards Organization/Open Systems Interconnection** (ISO/OSI) **reference model** (ISORM) because it provides a framework for discussion of some of the modern developments in communications in general and communication networking in particular. This discussion is necessarily simplified in the extreme, thorough coverage requiring on the order of several hundred pages, but we hope our brief description will enable the reader to appreciate some of the issues.

Having introduced the basic architectural structure of communication networks, we will next turn to a discussion of an important variation on this architectural scheme: the **local-area network** (LAN). Discussion of this topic is important because it helps to illustrate what the reference model is and what it is not. In particular, the architecture of LANs illustrates how the ISORM can be adapted for specialized purposes. Specifically, early network architectures anticipate networks in which individual node pairs are interconnected via a single link, and connections through the network are formed by concatenating node-to-node connections.

LAN architectures, on the other hand, anticipate all nodes being interconnected in some fashion over the same communication link (or medium). This, then, introduces the concept of adaption layers in a natural way. It also illustrates that if the services provided by an architectural layer are carefully defined, then the services can be used to implement virtually any service desired by the user, possibly at the price of some inefficiency.

After discussing LANs, we will conclude our article with a discussion of two of the variants in packet switching transmission technology: frame relay and a recent development in basic transmission technology called the **asynchronous transfer mode**, which is a part of the larger **broadband integrated services digital network** effort. These technologies are likely to be important building blocks for the computer communication networks of the future.

General Networking Concepts

Data communication networks have existed since about 1950. The early networks existed primarily for the purpose of connecting users of a large computer to the computer itself, with additional capability to provide communications between computers of the same variety and having the same operating software. The lessons learned during the first twenty or so years of operation of these types of networks have been valuable in preparing the way for modern networks. For the purposes of our current discussion, however, we will think of communication networks as being networks whose purpose is to interconnect a set of applications that are implemented on hosts manufactured by possibly different vendors and managed by a variety of operating systems. Networking capability is provided by software systems that implement standardized interfaces specifically designed for the exchange of information among heterogeneous computers.

During the late 1960s, many forward-looking thinkers began to recognize that significant computing resources (that is, supercomputers) would be expensive and unlikely to be affordable by many of the researchers needing this kind of computer power. In addition, they realized that significant computing resources would not be needed all of the time by those having local access. If the computing resource could be shared by a number of research sites, then the cost of the resource could be shared by its users.

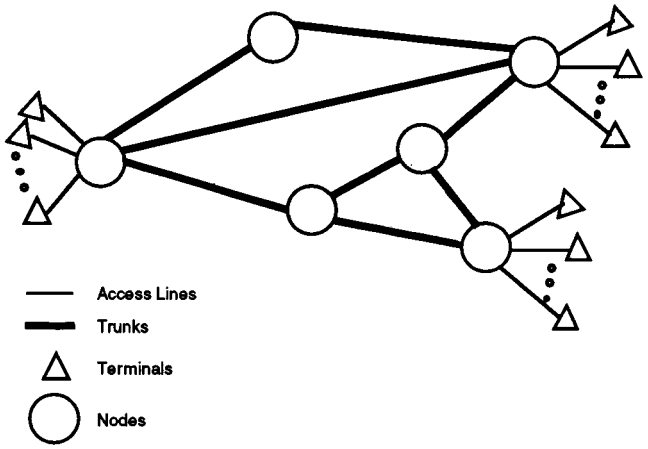

FIGURE 72.5 Generic computer communication network.

Many researchers at this time had computing resources available under the scenario described in the first paragraph above. The idea of interconnecting the computers to extend the reach of these researchers to other computers developed. In addition, the interconnection of the computers would provide for communication among the researchers themselves. In order to investigate the feasibility of providing the interconnectivity anticipated for the future using a new technology called **packet switching,** the Advanced Research Projects Agency (ARPA) of the Department of the Army sponsored a networking effort, which resulted in the computer communication network called the ARPANET.

The end results of the ARPA networking effort, its derivatives, and the early initiatives of many companies such as AT&T, DATAPOINT, DEC, IBM, and NCR have been far-reaching in the extreme. Any finitely delimited discussion of the accomplishments of those efforts would appear to underestimate their impact on our lives. We will concentrate on the most visible product of these efforts, which is a collection of programs that allows applications running in different computers to intercommunicate. Before turning to our discussion of the software, however, we will provide a brief description of a generic computer communication network.

Figure 72.5 shows a diagram of a generic computer communication network. The most visible components of the network are the terminals, the **access lines,** the **trunks,** and the **switching nodes.** Work is accomplished when the users of the network, the terminals, exchange messages over the network.

The terminals represent the set of communication terminating equipment communicating over the network. Equipment in this class includes, but is not limited to, user terminals, general-purpose computers, and database systems. This equipment, either through software or through human interaction, provides the functions required for information exchange between pairs of application programs or between application programs and people. The functions include, but are not limited to, call set-up, session management, and message transmission control. Examples of applications include electronic mail transfer, terminal-to-computer connection for time sharing or other purposes, and terminal-to-database connections.

Access lines provide for data transmission between the terminals and the network switching nodes. These connections may be set up on a permanent basis or they may be switched connections, and there are numerous transmission schemes and protocols available to manage these connections. The essence of these connections, however, from our point of view is a channel that provides data transmission at some number of bits per second (bps), called the channel capacity, *C*. The access line capacities may range from a few hundred bits per second to in excess of millions of bits per second, and they are usually not the same for all terminating equipments of a given network. The actual information-carrying capacity of the link depends upon the protocols employed to effect the transfer; the interested reader is referred to Bertsekas and Gallagher [1987], especially Chapter 2, for a general discussion of the issues involved in transmission of data over communication links.

Trunks, or internodal trunks, are the transmission facilities that provide for transmission of data between pairs of communication switches. These are analogous to access lines, and, from our point of view, they simply provide a communication path at some capacity, specified in bits per second.

There are three basic switching paradigms: circuit, message, and packet switching. **Circuit switching** and packet switching are transmission technologies while message switching is a service technology. In circuit switching, a call connection between two terminating equipments corresponds to the allocation of a prescribed set of physical facilities that provide a transmission path of a certain bandwidth or transmission capacity. These facilities are dedicated to the users for the duration of the call. The primary performance issues, other than those related to quality of transmission, are related to whether or not a transmission path is available at call set-up time and how calls are handled if facilities are not available.

Message switching is similar in concept to the postal system. When a user wants to send a message to one or more recipients, the user forms the message and addresses it. The message switching system reads the address and forwards the complete message to the next switch in the path. The message moves asynchronously through the network on a message switch-to-message switch basis until it reaches its destination. Message switching systems offer services such as mail boxes, multiple destination delivery, automatic verification of message delivery, and bulletin board. Communication links between the message switches may be established using circuit or packet switching networks as is the case with most other networking applications.

Examples of message switching protocols that have been used to build message switching systems are Simple Mail Transfer Protocol (SMTP) and the International Telegraph and Telephone Consultative Committee (CCITT) X.400 series. The former is much more widely deployed, while the latter has significantly broader capabilities, but its deployment is plagued by having two incompatible versions (1984 and 1988) and other problems. Many commercial vendors offer message switching services based on either one of the above protocols or a proprietary protocol.

In the circuit switching case, there is a one-to-one correspondence between the number of trunks between nodes and the number of simultaneous calls that can be carried. That is, a trunk is a facility between two switches that can service exactly one call, and it does not matter how this transmission facility is derived. Major design issues include the specification of the number of trunks between node pairs and the routing strategy used to determine the path through a network in order to achieve a given call blocking probability. When blocked calls are queued, the number of calls that may be queued is also a design question.

A packet-switched communication system exchanges messages among users by transmitting sequences of packets which comprise the messages. That is, the sending terminal equipment partitions a message into a sequence of packets, the packets are transmitted across the network, and the receiving terminal equipment reassembles the packets into messages. The transmission facility interconnecting a given node pair is viewed as a single trunk, and the transmission capacity of this trunk is shared among all users whose packets traverse both nodes. While the trunk capacity is specified in bits per second, the packet handling capacity of a node pair depends both upon the trunk capacity and the nodal processing power.

In many packet-switched networks, the path traversed by a packet through the network is established during a call set-up procedure, and the network is referred to as a virtual circuit packet switching network. Other networks provide datagram service, a service that allows users to transmit individually addressed packets without the need for call set-up. Datagram networks have the advantage of not having to establish connections before communication takes place, but they have the disadvantage that every packet must contain complete addressing information. Virtual circuit networks have the advantage that addressing information is not required in each packet, but have the disadvantage that a call set-up must take place before communication can occur. Datagram is an example of **connectionless service** while virtual circuit is an example of **connection-oriented service.**

Prior to the late 1970s, signaling for circuit establishment was in-band. That is, in order to set up a call through the network, the call set-up information was sent sequentially from switch to switch using the actual circuit that would eventually become the circuit used to connect the end users. In an extreme case, this amounted to trying to find a path through a maze, sometimes having to retrace one's steps before finally emerging at the destination or just simply giving up when no path could be found. This had two negative characteristics: first, the rate of signaling information transfer was limited to the circuit speed, and second, the circuits that could have been used for accomplishing the end objective were being consumed simply to find a path between the end-points. This resulted in tremendous bottlenecks on major holidays, which were solved by virtually disallowing alternate routes through the toll switching network.

An alternate out-of-band signaling system, usually called **common-channel interoffice signaling** (CCIS), was developed primarily to solve this problem. Signaling now takes place over a signaling network that is

partitioned from the network that carries the user traffic. This principle is incorporated into the concept of integrated services digital networks (ISDNs), which is described thoroughly in Helgert [1991]. The basic idea of ISDN is to offer to the user some number of 64-kbps access lines plus a 16-kbps access line through which the user can describe to an ISDN how the user wishes to use each of the 64-kbps circuits at any given time. The channels formed by concatenating the access lines with the network interswitch trunks having the requested characteristics are established using an out-of-band signaling system, the most modern of which is signaling system #7 (SS#7).

In either virtual circuit or datagram networks, packets from a large number of users may simultaneously need transmission services between nodes. Packets arrive at a given node at random times. The switching node determines the next node in the transmission path, and then places the packet in a queue for transmission over a trunk facility to the next node. Packet arrival processes tend to be bursty, that is, the number of packet arrivals over fixed-length intervals of time has a large variance. Because of the burstiness of the arrival process, packets may experience significant delays at the trunks. Queues may also build due to the difference in transmission capacities of the various trunks and access lines. Combining of packets that arrive at random times from different users onto the same line, in this case a trunk, is called statistical multiplexing.

In addition to the delays experienced at the input to trunks, packets may also experience queueing delays within the switching nodes. In particular, the functions required for packet switching are effected by executing various software processes within the nodes, and packets must queue while awaiting execution of the various processes on their behalf.

Both transmission capacities and nodal processing capabilities are available over a wide range of values. If the trunk capacities are relatively low compared to nodal processing capability, then delays at switching nodes may be relatively small. If line capacities are large compared to nodal processing capabilities, however, delays due to nodal processing may be significant. In the general case, all possible sources of delay should be examined to determine where bottlenecks, and consequently delay, occur.

It is often the case that a particular point in the communication network, either a processing node or a trunk, is the primary source of delay. In this case, this point is usually singled out for analysis, and a simple model is invoked to analyze the performance at that point. The results of this analysis, combined with results of other analyses, result in a profile of overall system performance. In this case, the key aspect of the analysis is to choose an appropriate model for the isolated analysis. In this way, a simplified analysis leading to useful results can be performed, and this can lead to an improved network design.

Protocol design and performance issues are frequent topics of discussion at both general conferences in communications and those specialized to networking. The reader is encouraged to consult the proceedings of the conferences mentioned earlier for a better appreciation of the range of issues and the diversity of the proposed solutions to the issues.

Computer Communication Network Architecture

In this section, we will begin with a brief, high-level definition of the ISORM. The reference model has seven layers, none of which can be bypassed conceptually. In general, a layer is defined by the types of services it provides to its users and the quality of those services. For each layer in the ISO/OSI architecture, the user of a layer is the next layer up in the hierarchy, except for the highest layer for which the user is an application. Clearly, when a layered architecture is implemented under this philosophy, then the quality of service obtained by the end user, the application, is a function of the quality of service provided by all of the layers. In order to clarify the communications strategy of the ISO/OSI architecture, we will provide a discussion of the layer 2 services in some detail.

There is significant debate over whether the efforts of the ISO/OSI community are leading to the best standards (or even standards that have any merit whatever!). Limiting our discussion to the ISORM is, by no means, an endorsement of the actual protocols that have been developed in the ISO arena; there are actually more widely deployed and successful standards in other arenas. On the other hand, the ISORM is very useful for discussing network architecture principles, and these principles apply across the board. Thus, we choose to base our discussion on the ISORM.

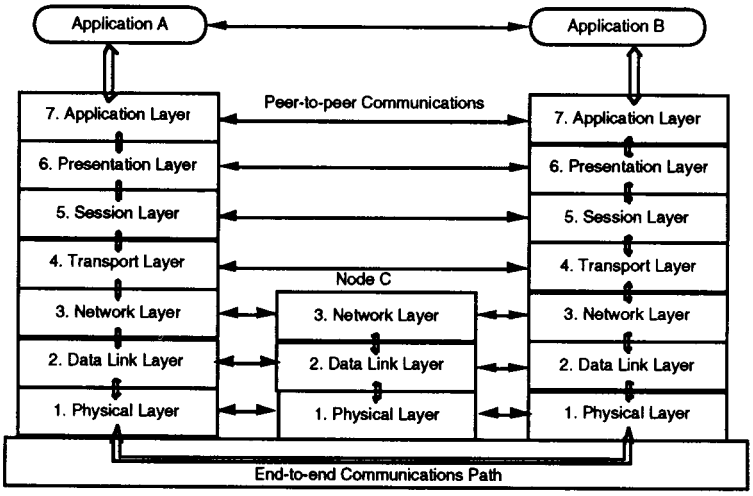

FIGURE 72.6 Layered architecture for ISO/OSI reference model.

Figure 72.6, adopted from Spragins [1991], shows the basic structure of the OSI architecture and how this architecture is envisaged to provide for exchange of information between applications. As shown in the figure, there are seven layers: application, presentation, session, transport, network, data link, and physical. Brief definitions of the layers follow, but the reader should bear in mind that substantial further study will be required to develop an understanding of the practical implications of the definitions:

- *Physical layer:* Provides electrical, functional, and procedural characteristics to activate, maintain, and deactivate physical data links that transparently pass the bit stream for communication between data link **entities.**
- *Data link layer:* Provides functional and procedural means to transfer data between network entities; provides for activation, maintenance, and deactivation of data link connections, character and frame synchronization, grouping of bits into characters and frames, error control, media access control, and flow control.
- *Network layer:* Provides switching and routing functions to establish, maintain, and terminate network layer connections, and transfer data between transport layers.
- *Transport layer:* Provides host-to-host, cost-effective, transparent transfer of data, end-to-end flow control, and end-to-end quality of service as required by applications.
- *Session layer:* Provides mechanisms for organizing and structuring dialogues between application processes.
- *Presentation layer:* Provides for independent data representation and syntax selection by each communicating application and conversion between selected contexts and the internal architecture standard.
- *Application layer:* Provides applications with access to the ISO/OSI communication stack and certain distributed information services.

As we have mentioned previously, a layer is defined by the types of services it provides to its users. In the case of a request or a response, these services are provided via invocation of **service primitives** of the layer in question by the layer that wants the service performed. In the case of an indication or a confirm, these services are provided via invocation of service primitives of the layer in question by the same layer that wants the service performed.

This process is not unlike a user of a programming system calling a subroutine from a scientific subroutine package in order to obtain a service, say, matrix inversion or memory allocation. For example, a request is analogous to a CALL statement in a FORTRAN program, and a response is analogous to the RETURN statement in the subroutine that has been CALLed. The requests for services are generated asynchronously by all of the

users of all of the services and these join (typically prioritized) queues along with other requests and responses while awaiting servicing by the processor or other resource such as a transmission line.

The service primitives fall into four basic types: request, indication, response, and confirm. These types are defined as follows:

- *Request:* A primitive sent by layer $(N + 1)$ to layer N to request a service.
- *Indication:* A primitive sent by layer N to layer $(N + 1)$ to indicate that a service has been requested of layer N by a different layer $(N + 1)$ entity.
- *Response:* A primitive sent by layer $(N + 1)$ to layer N in response to an *indication* primitive.
- *Confirm:* A primitive sent by layer N to layer $(N + 1)$ to indicate that a response to an earlier *request* primitive has been received.

In order to be more specific about how communication takes place, we will now turn to a brief discussion of layer 2, the data link layer. The primitives provided by the ISO data link (DL) layer are as follows [Stallings, 1990a]:

```
DL_CONNECT.request          DL_RESET.request
DL_CONNECT.indication       DL_RESET.indication
DL_CONNECT.response         DL_RESET.response
DL_CONNECT.confirm          DL_RESET.confirm
DL_DATA.request             DL_DISCONNECT.request
DL_DATA.indication          DL_DISCONNECT.indication
DL_DATA.response            DL_UNITDATA.request
DL_DATA.confirm             DL_UNITDATA.indication
```

Each primitive has a set of **formal parameters,** which are analogous to the formal parameters of a procedure in a programming language. For example, the parameters for the DL_CONNECT.request primitive are the Called Address, the Calling Address, and the Quality of Service Parameter Set. The four primitives are used in the establishment of data link connections. The called address and the calling address are analogous to the telephone numbers of two parties of a telephone call, while the quality of service parameter set allows for the negotiation of various agreements such as throughput measured in bits per second.

All four DL_CONNECT primitives are used to establish a data link. An analogy to an ordinary phone call can better illustrate the basic idea of the primitives. The DL_CONNECT.request is equivalent to picking up the phone and dialing. The phone ringing at the called party's end is represented by the DL_CONNECT.indication. DL_CONNECT.response is equivalent to the called party lifting the receiver and answering, and DL_CONNECT.confirm is equivalent to the calling party hearing the response of the called party.

In general, communication takes place between peer layer protocols by the exchange of **protocol data units (PDUs)**, which contain all of the information required for the receiving protocol entity to provide the required service. In order to exchange PDUs, entities at a given layer use the services of the next lower layer. The data link primitives listed above include both connection-mode primitives and connectionless-mode primitives. For connection-mode communications, a connection must be established between two peer entities before they can exchange PDUs.

For example, suppose a network layer entity in Host A wishes to be connected to a network layer entity in Host B, as shown in Fig. 72.6. Then the connection would be accomplished by the concatenation of two data link connections: one between A and C, and one between C and B. In order to establish the connection, the network layer entity in Host A would issue a DL_CONNECT.request to its associated data link entity, providing the required parameters. This data link entity would then transmit this request to a data link entity in C, which would issue a DL_CONNECT.indication to a network entity in C. The network entity in C would then analyze the parameters of the DL_CONNECT.indication and realize that the target destination is B. This network layer entity would then reissue the DL_CONNECT.request to its data link entity, which would transmit the request to a data link entity in B. The data link entity in B would send a DL_CONNECT.indication to a network layer entity in B, and this entity would issue a DL_CONNECT.response back to the data link entity in B. This DL_CONNECT.response would be relayed back to the data link entity in A following the same sequence of events as in the forward path. Eventually, this DL_CONNECT.response would be converted to a

DL_CONNECT.confirm by the data link entity in A and passed to the network entity in A, thus completing the connection.

Once the connection is established, data exchange between the two network layer entities can take place; that is, the entities can exchange PDUs. For example, if a network layer entity in Host A wishes to send a PDU to a network layer entity in Host B, the network layer entity in Host A would issue a DL_DATA.request to the appropriate data link layer entity in Host A. This entity would package the PDU together with appropriate control information into a data link service data unit (DLSDU) and send it to its peer at C. The peer at C would deliver it to the network entity at C, which would forward it to the data link entity in C providing the connection to Host B. This entity would then send the DLSDU to its peer in Host B, and this data link entity would pass the PDU to Host B network entity via a DL_DATA.indication.

Network layer PDUs are called packets and data link layer PDUs are called frames. The data link layer does not know that the information it is transmitting is a packet; to the data link layer entity, the packet is simply user information. From the perspective of a data link entity, it is not necessary to have a network layer. The network layer exists to add value for the user of the network layer to the services provided by the data link layer. In the example above, value was added by the network layer by providing a relaying capability since Hosts A and C were not directly connected. Similarly, the data link layer functions on a hop-by-hop basis, each hop being completely unaware that there are any other hops involved in the communication. We will see later that the data link need not be limited to a single physical connection.

The philosophy of the ISO/OSI architecture is that in addition to the software being layered, implementations are not allowed to bypass entire layers; that is, every layer must appear in the implementation. This approach was developed after the approach defined for the ARPANET project, which is hierarchical, was fully developed. In the hierarchical approach, the layer interfaces are carefully designed, but any number of layers of software can be bypassed by any application (or other higher-layer protocol) that provides the appropriate functionality. These two approaches have been hotly debated for a number of years, but as the years pass, the approaches are actually beginning to look more and more alike for a variety of reasons that will not be discussed here.

The ISO/OSI layered architecture described above would appear to be very rigid, not allowing for any variations in underlying topology or variations in link reliability. However, as we shall see, this is not necessarily the case. As an example, ISO 8348, which developed as a result of the X.25 project, provides only connection-oriented service, and it was originally intended as the only network layer standard for ISO/OSI. However, ISO 8473, or ISO-IP, which is virtually identical to the Department of Defense (DoD) internet protocol (DoD-IP) developed in the ARPANET project, has since been added to the protocol suite to provide connectionless service as well as internet service. An interesting aside is that because of the addressing limitations of DoD-IP, the Internet Administrative Board (IAB) has recently recommended replacement of the DoD-IP protocol by the ISO-IP protocol, thus bringing the process full circle.

The ISO/OSI protocol suite is in a constant state of revision as new experience reveals the need for additional capabilities and flexibility. Some of this additional flexibility and functionality is being provided through the use of so-called **adaption sublayers**, which enhance the capabilities of a given layer so that it can use the services of a lower layer with which it was not specifically designed for compatibility.

Interestingly, the use of adaption sublayers is only a short step away from using adaption layers that would allow applications to directly interface with any ISO layer. This would result in a hierarchical rather than layered architecture; to wit: ISORM becomes DoDRM. Indeed, fundamental changes in the national (and worldwide) communications infrastructure appear to be leading naturally in the hierarchical direction. Of course, the indiscriminate use of such adaptions would lead back to the proliferation of incompatible protocols and interfaces, the frustration that led to the current twenty-year standardization crusade! It is refreshing to note that a return to our former state does not appear to be around the corner; most standardization work is actually headed in the direction of allowing open systems to intercommunicate.

Local-Area Networks and Internets

We will now turn to a discussion of LANs, which have inherent properties that make the use of sublayers particularly attractive. In this section, we will discuss the organization of communications software for LANs. In addition, we will introduce the idea of **internets**, which were brought about to a large extent by the advent

of LANs. We will discuss the types of networks only briefly and refer the reader to the many excellent texts on the subject. Layers 4 and above for local-area communications networks are identical to those of wide-area networks. However, because the hosts communicating over a LAN share a single physical transmission facility, the routing functions provided by the network layer, layer 3, are not necessary. Thus, the functionality of a layer 3 in a LAN can be substantially simplified without loss of utility. On the other hand, a data link layer entity must now manage many simultaneous data link layer connections because all connections entering and leaving a host on a single LAN do so over a single physical link. Thus, in the case of connection-oriented communications, the software must manage several virtual connections over a single physical link.

There were several basic types of transmission schemes in use in early LANs. Three of these received serious consideration for standardization: the **token ring, token bus,** and **carrier-sense multiple access** (CSMA). In a token ring network, the stations are configured on a physical ring around the medium. A token rotates around this physical ring, visiting each host (or station) in turn. A station wishing to transmit data must wait until the token is available to that station. In a token bus LAN, the situation is the same, except that the stations share a common bus and the ring is logical rather than physical. In a CSMA network, the stations are bus connected, and a station may transmit whenever other stations are not currently transmitting. That is, a station wishing to transmit senses the channel, and if there is no activity, the station may transmit. Of course, the actual access protocol is significantly more complicated than this.

In the early 1980s, there was significant debate over which LAN connection arrangement was superior, a single choice being viewed as necessary. This debate centered on such issues as cost, network throughput, network delay, and growth potential. Performance evaluation based on queueing theory played a major role in putting these issues in perspective. For thorough descriptions of LAN protocols and queueing models used to evaluate their performance, the interested reader is referred to Hammond and O'Reilly [1986].

All three of the access methods mentioned above became IEEE standards (IEEE 802) and eventually became ISO standards (ISO 8802 series) because all merited standardization. On the other hand, all existed for the express purpose of exchanging information among peers, and it was recognized at the outset that the upper end of the data link layer could be shared by all three access techniques. On the other hand, the lower-level functions of the layer deal with interfacing to the physical media. Here, drastic differences in the way the protocol had to interface with the media were recognized. Thus, a different **media-access control sublayer** (MAC) was needed for each of the access techniques.

The decision to use a common logical link control (LLC) sublayer for all of the LAN protocols apparently ushered in the idea of adaption sublayers. The reason for splitting the layer is simple: a user of the data link control (DLC) layer need not know what kind of medium provides the communications; all that is necessary is that the user understand the interface to the DLC layer.

On the other hand, the media of the three types of access protocols provide transmission service in different ways, so software is needed to bridge the gap between what the user of the service needs, which is provided by the LLC, and how the LLC uses the media to provide the required service. Thus, the MAC sublayer was born.

This idea has proven to be valuable as new types of technologies have become available. For example, the new fiber-distributed digital interface (FDDI) uses the LLC of all other LAN protocols, but its MAC is completely different from the token ring MAC even though FDDI is a token ring protocol. Reasons for needing a new MAC for LLC are provided in Stallings [1990b].

One of the more interesting consequences of the advent of local-area networking is that many traditional computer communication networks became internets overnight. LAN technology was used to connect stations to a host computer, and these host computers were already on a WAN. It was then a simple matter to provide a relaying, or bridging, service at the host in order to provide wide-area interconnection of stations to LANs to each other. In short, the previously established WANs became networks for interconnection of LANs; that is, they were interconnecting networks rather than stations. Internet performance suddenly became a primary concern in the design of networks.

More recently, FDDI is being thought of as a mechanism to provide LAN interconnection on a site basis, and a new type of network, the **metropolitan-area network** (MAN) has been under study for the interconnection of LANs within a metropolitan area. The primary media configuration for MANs is a dual bus configuration and it is implemented via the distributed queue, dual bus (DQDB) protocol, also known as IEEE 802.6. The net effect of this protocol is to use the dual bus configuration to provide service approaching the

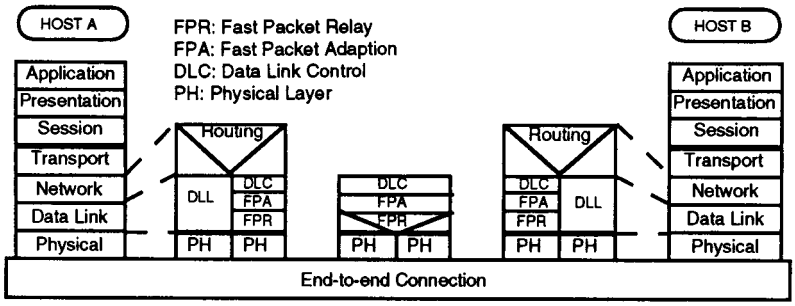

FIGURE 72.7 Fast packet switched layered architecture.

first-come–first-served service discipline to the traffic entering the FDDI network, which is remarkable considering that the LANs being interconnected are geographically dispersed. Interestingly, DQDB concepts have recently been adapted to provide wide-area communications. Specifically, structures have been defined for transmitting DQDB frames over standard DS-1 (1.544 megabits per second [Mb/s]) and DS-3 (6.312 Mb/s) facilities, and these have been used as the basis for a new service offering called switched multimegabit data services (SMDS).

As of this writing, advances in LANs design and new forms of LANs are emerging. One example is wireless LANs, which are LANs in which radio or photonic links serve as cable replacements. Wireless LAN technology is viewed by many as crucial to the evolution of personal communication networks. Another example is the asynchronous transfer mode-based LAN, which is mentioned in the next section following a general discussion of asynchronous transfer mode.

Some Additional Recent Developments

In this subsection, we will describe two recent developments of significant interest in communication networking: **fast packet networks** and transmission using the *asynchronous transfer mode* (ATM), which is a part of the larger *broadband integrated services digital network* (B-ISDN) effort.

As we have mentioned previously, there is really no requirement that the physical media between two adjacent data link layers be composed of a single link. In fact, if a path through the network is initially established between two data link entities, there is no reason that DLC protocols need to be executed at intermediate nodes. Figure 72.7, adapted from Bhargava and Hluchyj [1990] shows how the end-to-end connection might be implemented. A network implemented in the fashion indicated in Fig. 72.7 is called a fast packet network (FPN).

From Fig. 72.7, it is seen that the data link layer is partitioned into three sublayers: the data link control sublayer (which parallels the LLC layer of LANs), the fast packet adaption (FPA) sublayer, and the fast packet relay (FPR) sublayer. The function of the fast packet adaption sublayer is to segment the layer-2 PDU, the frame, into smaller units, called fast packets, for transmission over the FPN. These fast packets contain information that identifies the source and destination node names and the frame to which they belong so that they can be routed through the network and reassembled at the destination.

The fast packets are statistically multiplexed onto a common physical link by the FPR sublayer for transmission. At intermediate nodes, minor error checking, fast packet framing, fast packet switching, and queueing takes place. If errors are found, then the fast packet is dropped. When the fast packets reach their destination, they are reassembled into a frame by the FPA sublayer and passed on to the DLC sublayer where normal DLC functions are performed.

The motivation for FPNs is that since link transmission is becoming more reliable, extensive error checking and flow control are not needed across individual links; an end-to-end check should be sufficient. Meanwhile, the savings in processing due to not processing at the network layer can be applied to frame processing, which allows interconnection of the switches at higher line speeds.

Since bits-per-second costs decrease with increased line speed, service providers can offer savings to their customers through FPNs. Significant issues are fast packet loss probability and retransmission delay. Such factors will determine the retransmission strategy deployed in the network. Of course, the goal is to improve

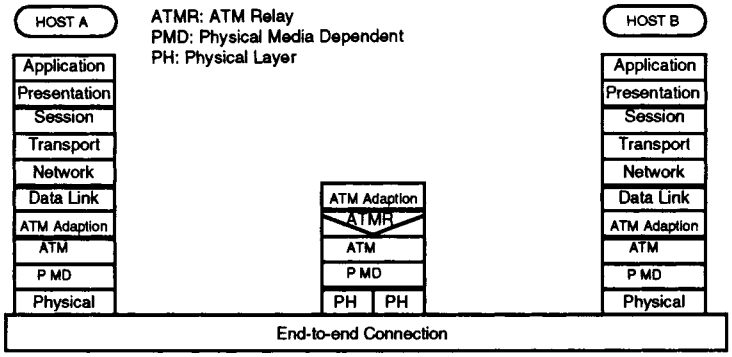

FIGURE 72.8 Asynchronous transfer mode layered architecture.

network efficiency, so a significant issue is whether FPNs are better than ordinary packet networks and, if so, by how much.

Another recent innovation is the ATM, usually associated with B-ISDN. The idea of ATM is to partition a user's data into many small segments, called cells, for transmission over the network. Independent of the data's origin, the cell size is 53 octets, of which 5 octets are for use by the network itself for routing and error control. Users of the ATM are responsible for segmentation and reassembly of their data. Any control information required for this purpose must be included in the 48 octets of user information in each cell. In the usual case, these cells would be transmitted over networks that would provide users with 135 Mb/s and above data transmission capacity (with user overhead included in the capacity).

The segmentation of units of data into cells introduces tremendous flexibility for handling different types of information, such as voice, data, image, and video, over a single transmission facility. As a result, LANs, WANs, and MANs based on the ATM paradigm are being designed, and indeed deployed. A significant portion of the deployment activity is a national testbed program, which involves industrial/academia cooperation, under joint sponsorship of the National Science Foundation (NSF) and the Defense Advanced Research Projects Agency (DARPA). There is also significant private investment in developing this technology; for example, experimental ATM-based LANs are already in place at the Digital Equipment Corporation (DEC) research facility in Palo Alto, California. There is some possibility that LANs of this type, rather than of the FDDI type, will be the dominant means of providing high-speed LAN and LAN-interconnect services.

There are numerous possibilities for connection of hosts to ATM networks, but they all share a common architecture, which consists of three sublayers: the ATM adaption layer (AAL), the ATM layer, and the physical media-dependent (PMD) layer. Connection of hosts to ATM at a given layer is achieved through developing an AAL for the layer in question. For example, one might decide to adapt to ATM at the network layer. In that case, the transport layer would operate as usual, and the AAL would be designed to process data structures from the transport layer to produce data structures for use by the ATM layer and vice versa. Of course, all hosts communicating with each other in this way would use the same AAL.

Figure 72.8 shows an example of how an ISO/OSI host might connect to an ATM network. Below the data link layer is the ATM adaption layer (AAL), which provides for call control across the ATM network and for segmentation and reassembly of frames from the data link layer. The current estimate for the amount of overhead needed per cell for AAL purposes is 4 octets, leaving 44 octets for user information.

At the present time, end-to-end connections at the ATM level are expected to be connection oriented. As cells traverse the network, they are switched on a one-by-one basis, using information contained in the five ATM overhead octets to follow the virtual path established during the ATM call set-up. Typically, cells outbound on a common link are statistically multiplexed, and if buffers are full, cells are dropped. In addition, if one or more errors are found in a cell, then the cell is dropped.

In the case of data transmission, a lost cell will result in an unusable frame unless the data is encoded to guard against cell loss prior to transmission. Coding might be provided by the AAL, for example. The trade-offs involved in coding and retransmission and their impact upon network throughput, delay and complexity are not well understood at the time of this writing. Part of the reason for this is that cell loss probability and

the types of traffic that are likely to use the network are not thoroughly understood. Resolution of these issues accounts for a significant portion of the research activity in computer communication networking at this time. The relevant American National Standards Institute and CCITT documents are frequently updated to include the results.

Defining Terms

Access line: A communication line that connects a user's terminal equipment to a switching node.

Adaption sublayer: Software that is added between two protocol layers to allow the upper layer to take advantage of the services offered by the lower layer in situations where the upper layer is not specifically designed to interface directly to the lower layer.

Architecture: The set of protocols defining a computer communication network.

Asynchronous transfer mode (ATM): A mode of communication in which communication takes place through the exchange of tiny units of information called cells.

Broadband integrated services digital network (B-ISDN): A generic term that generally refers to the future network infrastructure that will provide ubiquitous availability of integrated voice, data, imagery, and video services.

Carrier-sense multiple access: A random-access method of sharing a bus-type communications medium in which a potential user of the medium listens before beginning to transmit.

Circuit switching: A method of communication in which a physical circuit is established between two terminating equipments before communication begins to take place. This is analogous to an ordinary phone call.

Common-channel interoffice signaling: The use of a special network, dedicated to signaling, to establish a path through a communication network, which is dedicated to the transfer of user information.

Computer communication network: Collection of applications hosted on different machines and interconnected by an infrastructure that provides intercommunications.

Connection-oriented service: A mode of packet switching in which a call is established prior to any information exchange taking place. This is analogous to an ordinary phone call, except that no physical resources need to be allocated.

Connectionless service: A mode of packet switching in which packets are exchanged without first establishing a connection. Conceptually, this is very close to message switching, except that if the destination node is not active, then the packet is lost.

Entity: A software process that implements a part of a protocol in a computer communication network.

Fast packet networks: Networks in which packets are transferred by switching at the frame layer rather than the packet layer. Such networks are sometimes called frame relay networks. At this time, it is becoming in vogue to think of frame relay as a service, rather than transmission, technology.

Formal parameters: The parameters passed during the invocation of a service primitive; similar to the arguments passed in a subroutine call in a computer program.

International Standards Organization reference model: A model, established by ISO, that organizes the functions required by a complete communication network into seven layers.

Internet: A network formed by the interconnection of networks.

Local-area network: A computer communication network spanning a limited geographic area, such as a building or college campus.

Media-access control: A sublayer of the link layer protocol whose implementation is specific to the type of physical medium over which communication takes place and which controls access to that medium.

Message switching: A service-oriented class of communication in which messages are exchanged among terminating equipments by traversing a set of switching nodes in a store-and-forward manner. This is analogous to an ordinary postal system. The destination terminal need not be active at the same time as the originator in order that the message exchange take place.

Metropolitan-area network: A computer communication network spanning a limited geographic area, such as a city; sometimes features interconnection of LANs.

Packet switching: A method of communication in which messages are exchanged between terminating equipments via the exchange of a sequence of fragments of the message called packets.

Protocol data unit (PDU): The unit of exchange of protocol information between entities. Typically, a PDU is analogous to a structure in C or a record in Pascal; the protocol is executed by processing a sequence of PDUs.

Service primitive: The name of a procedure that provides a service; similar to the name of a subroutine or procedure in a scientific subroutine library.

Switching node: A computer or computing equipment that provides access to networking services.

Token bus: A method of sharing a bus-type communications medium that uses a token to schedule access to the medium. When a particular station has completed its use of the token, it broadcasts the token on the bus, and the station to which it is addressed takes control of the medium.

Token ring: A method of sharing a ring-type communications medium that uses a token to schedule access to the medium. When a particular station has completed its use of the token, it transmits the token on the ring, and the station that is physically next on the ring takes control.

Trunk: A communication line between two switching nodes.

Wide-area network: A computer communication network spanning a broad geographic area, such as a state or country.

Further Information

There are many conferences and workshops that provide up-to-date coverage in the computer communications area. Among these are the IEEE INFOCOM and ACM SIGCOMM conferences and the IEEE Computer Communications Workshop, which specialize in computer communications and are held annually. In addition, IEEE GLOBCOM (annual), IEEE ICC (annual), IFIPS ICCC (biannual), and the International Telecommunications Congress (biannual) regularly feature a substantial number of paper and panel sessions in networking.

The *ACM Communications Review,* a quarterly, specializes in computer communications and often presents summaries of the latest standards activities. *IEEE Network,* a bimonthly, contains tutorial articles on all aspects

of computer communications and includes a regular column on books related to the discipline. Additionally, *IEEE Communications* and *IEEE Computer,* monthly magazines, frequently have articles on specific aspects of networking.

For those who wish to be involved in the most up-to-date activities, there are many interest groups on the Internet, a worldwide TCP/IP-based network, that specialize in some aspect of networking. *The User's Directory of Computer Networks* (Digital Press, T. L. LaQuey, Ed.) provides an excellent introduction to the activities surrounding internetworking and how to obtain timely information.

72.3 Local-Area Networks

Joseph Bannister and Mario Gerla

The local-area network (LAN) is a communication network that interconnects computers and computer-based devices, such as file servers, printers, and graphics terminals. The LAN is characterized as being contained completely within the premises of a single business entity—which almost always owns and operates the network—and this distinguishes the LAN from public-domain networks such as metropolitan- or wide-area networks. The LAN, then, is normally restricted to a few hundred stations (i.e., devices that attach directly to the LAN) that span a limited geographical area, so that no two connected stations are separated by a distance of more than a few kilometers. Moreover, the LAN can be distinguished from the computer or backplane bus, which interconnects components, boards, or devices that comprise a single computer. The LAN uses serial—rather than parallel—transmission, which also differentiates it from the computer bus. In contrast to today's wide-area networks, information is transmitted over LANs at high speeds and with very low error rates.

The LAN often employs fully broadcast media, or **physical media** that allow each station's transmissions to be received by all other stations. Thus, a broadcast capability is often an integral feature of the LAN. Frequently, the LAN also provides for multicasting, a generalization of broadcasting in which a specified subset of stations receives a transmission.

LANs are based on a variety of technologies that include twisted copper-wire pairs, coaxial cable, optical fibers, wireless infrared and radio for signal transport, as well as several integrated circuit families for transmitters, receivers, and the implementation of low-level protocols.

The **topology** of a LAN refers to the physical layout of the transmission media and the logical arrangement of the stations on those media. Four topologies are commonly used in LANs: the bus, ring, star, and tree topologies, which are illustrated in Fig. 72.9.

The LAN Service Model

Within the scope of the well-known Open Systems Interconnection seven-layer reference model, the LAN occupies the two bottom layers, namely, the physical and data link layers, as shown in Fig. 72.10. The physical layer specifies the most primitive services of the LAN, e.g., media characteristics, signal formats, waveforms, signaling rates, timing, and mechanical aspects of connectors, etc. The data link layer uses the services of the physical layer to provide multiple access for stations sharing the media. Station or network management, which is shown as a vertical "layer" in Fig. 72.10, is responsible for maintaining a necessary level of performance, fault detection and recovery, and configuration and security functions.

The Physical Layer

Since the physical layer provides the most primitive services to LAN users, this layer is most closely associated with the implementation technology of the LAN. At a fundamental level the transmission media can be either electrical or optical waveguides. The physical media can be laid out as one of those topologies illustrated in Fig. 72.9. However, certain media are better suited to some topologies, e.g., the bus is frequently used with electrical but not with optical media, because there is high insertion loss associated with taps in the latter.

Signaling is also a critical element of the physical layer. Baseband modulation, in which digital signals (0s and 1s) are transmitted as electrical or optical pulses, is common in LANs because of its simplicity. Modulation of carriers is less common but especially important when several independent channels are employed. Amplitude,

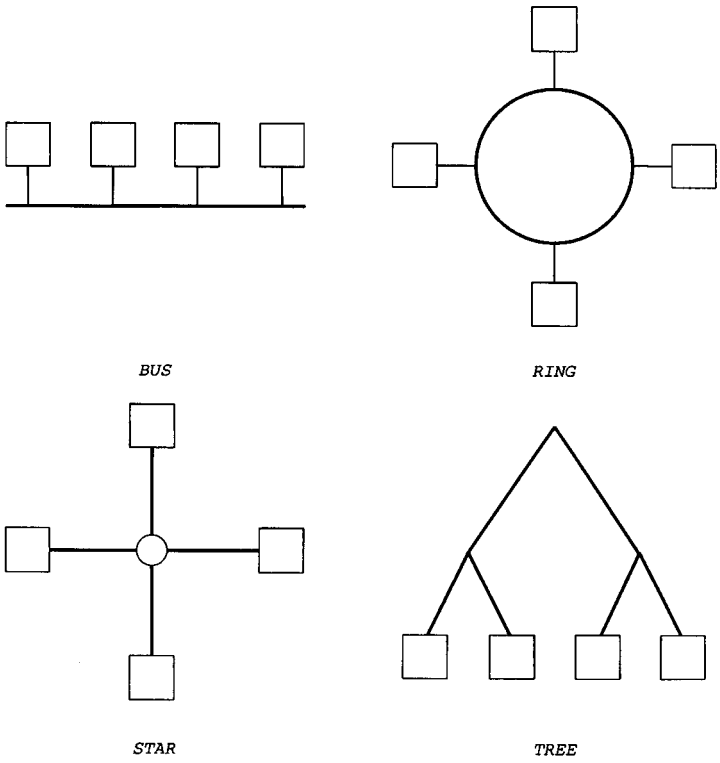

FIGURE 72.9 LAN topologies.

frequency, and phase modulation have been used in community antenna television (CATV) systems to support multichannel LANs. Coherent lightwave systems, although still largely experimental, are expected to increase in importance because they permit multiplexing a large number of channels over a single-mode optical fiber. Also of increasing importance is atmospheric propagation of electromagnetic signals. The growing demand for mobile communication and ubiquitous computing is driving the development of the personal communication network, which is to be based on code-division multiple access.

The signaling rates and formats are also part of the physical layer specification. Electrical media generally use Manchester baseband encoding, which has a 50% duty cycle and operates at rates below 100 Mb/s. Optical media often use the so-called 4B/5B intensity-modulation encoding, which achieves 80% efficiency by representing 27 distinct symbols (of which 16 are data and 11 are control symbols) by five bits in such a manner that four consecutive 0s (i.e., low-light power levels) should never occur. Similarly, 8B/6T encoding is sometimes used with electrical media to encode an octet of data as six ternary digits, achieving an efficiency of 75%.

Connector and cable-plant technology is another critical element of the physical layer. Thorough characterization of the transmission media is required if users are to interoperate with each other. The type of cable—e.g., shielded or unshielded twisted copper-wire pairs, coaxial cable, and single-mode or multimode optical fiber—must be specified. Furthermore, the connectors between stations and the cable plant are defined as part of the physical layer. Stations can attach via passive taps or can actively repeat signals; in the latter case a bypass switch is usually provided as the station's interface to the cable plant.

The Data Link Layer

The data link layer is often divided into two sublayers, i.e., the media-access and logical-link control (MAC and LLC) sublayers, as shown in Fig. 72.10. The LLC sublayer [see *Logical Link Control*] uses the services of the MAC sublayer to provide to its user a connection-oriented service between stations that includes flow and error control or a connectionless service that does little more than multiplex upper-layer connections. The

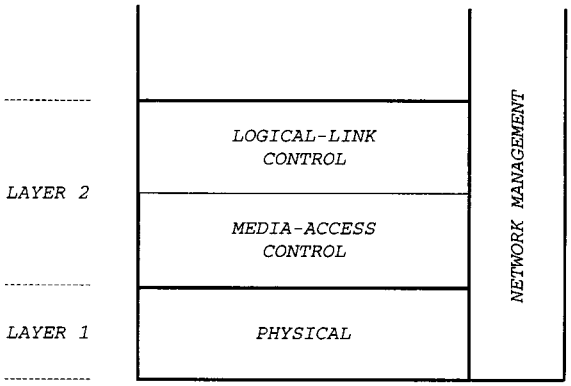

FIGURE 72.10 LANservice model.

connection-oriented LLC protocol gives the service user the illusion of having a dedicated point-to-point link between a pair of communicating stations.

The MAC sublayer specifies the **media access protocol** that stations use to share the media. In fully broadcast media no more than one station may transmit at a time, so the MAC sublayer manages exclusive access to the broadcast media. The ring topology is well suited to a token-passing MAC protocol, which gives transmission rights to the station holding the token. The token is represented by a special packet that is passed sequentially from station to station. When a station recognizes the token, it seizes it and begins transmitting buffered packets, or passes the token to the next station if it has no packet to transmit. To limit the time that a station can hold the token, the MAC protocol can implement one of several disciplines:

- One-shot service, in which the station releases the token when it has transmitted one packet
- Exhaustive service, in which the station releases the token when it has no more packets to transmit
- Gated service, in which the station releases the token when all packets that were buffered at token-acquisition time have been transmitted
- Token-timing service, in which the station releases the token at the expiration of a timer

The IEEE 802.5 token ring standard specifies a token-timing service discipline that requires transmissions to be completed within a fixed time after the token is seized, but implementations sometimes use the simpler one-shot service discipline. The ANSI X3T9.5 fiber distributed data interface (FDDI) standard uses an adaptive token-timing service discipline that is intended to guarantee a minimum amount of (synchronous) bandwidth to each station.

A variation of the token ring protocol is the token bus protocol, which allows the token to be passed in a specified order. In the token bus protocol, which is often used with the bus or tree topologies, a station broadcasts the token, specifying the successor station in an address field of the token packet. Although all stations receive the token, only the addressed successor station can seize it.

A MAC scheme that is widely used with the bus topology is carrier-sense multiple access (CSMA). A contention protocol, CSMA operates by allowing any station to transmit a buffered packet if it senses that the bus is idle. If two stations are ready to transmit their packets at nearly the same time, they will both sense that the bus is idle and their transmissions will collide, i.e., the superimposed bits of the packets will be garbled. The propagation delay—or time it takes for the packet to travel from one station to the other—dictates the window of vulnerability for CSMA; the larger the window, the more collisions are likely. To overcome the problem of collisions, CSMA is often enhanced with collision detection (CSMA/CD) by enabling stations to monitor their transmissions for the garbled bits associated with collisions. When a collision is detected, the station aborts its transmission and reschedules it by backing off for a period of time. The binary exponential backoff algorithm specifies that the random backoff time is drawn uniformly from the interval between 0 and $2^n - 1$ time units, where n is the number of times the packet has collided.

A time-slotted bus maintains on the bus a continuous stream of short, fixed-length frames that are initially empty but can be filled with data as they pass stations with waiting packets. The distributed queue, dual bus (DQDB) local- and metropolitan-area network uses two-directional buses so that a station can reserve on its downstream bus a frame for its upstream-destined packets.

In the star topology stations are homed into a central hub which can manage their access to the media. Active hubs physically control media access, while passive hubs merely broadcast incoming packets to specific output ports. Linear combiner/dividers based on lithium niobate technology allow incoming optical signals to be combined and distributed to output ports according to electronically programmed combining and dividing ratios. A common scheme is to use time-division multiplexing with the star topology. The hub can serve as the central controller, allocating time slots to individual stations, or reservations can be used in the manner of a satellite-based network.

The Management Layer

LAN-specific network management functions are referred to as station management. Station management covers five areas—configuration, performance, fault, accounting, and security management.

Monitoring and controlling the LAN are essential elements of station management. By monitoring the media, stations maintain a record of important measurements, such as the number of a specific type of packet transmitted or received, the number of different kinds of errors, and the source addresses of received packets. Such measurements are made available to an application in the station or to a management center. Thus are applications able to monitor and collect, correlate, and act upon key LAN statistics. Likewise, designated applications are able to effect changes in the LAN by writing to specific variables within stations, which collectively comprise the so-called management information base. For instance, station management informs the MAC sublayer of its unique LAN address by writing the value to a special MAC register.

Some management functions are distributed across the LAN and are implemented at a low level. To recover after the failure of a dual-fiber cable, stations automatically enter into a procedure to reconfigure around the failure and reestablish connectivity. Although such procedures can be viewed as station management, they are sometimes specified as part of the MAC sublayer, because they are so tightly integrated with media access.

Other Features

The basic features of media access are often augmented to provide specialized services and features.

Specialized LAN Services

LAN users have special communication requirements that must be supported by the physical and data link layers. In particular, the MAC sublayer is responsible for providing specialized services. Although all MAC sublayers support asynchronous traffic by providing for the simple, best-effort delivery of packets, some MAC sublayers also support other classes of traffic. To synchronous traffic, which requires a set amount of preallocated bandwidth, the properly designed MAC sublayer guarantees a maximum packet response time. The adaptively timed token-passing protocol of FDDI is capable of supporting synchronous traffic, i.e., at token-capture time the station has a fixed amount of time during which to transmit synchronous packets, and the token is guaranteed to return within a certain amount of time. Isochronous traffic, which requires a fixed amount of traffic to be periodically delivered, is also accommodated by some MAC sublayers. DQDB uses preallocated time slots to provide isochronous service.

Priorities are also important in LANs. Therefore many LANs transmit queued packets in accordance with priorities assigned to the packets. Prioritization can be on a LAN-wide basis or merely within the station. Most LANs offer some method for prioritizing the transmission of packets.

Reliability and Availability

Being a shared resource, the LAN should have a high degree of reliability and availability. The media should not be a single point of failure, and no individual station should be able to prevent—maliciously or otherwise—the delivery of service to other stations. LANs are designed to withstand both transient and permanent failures of the media and stations.

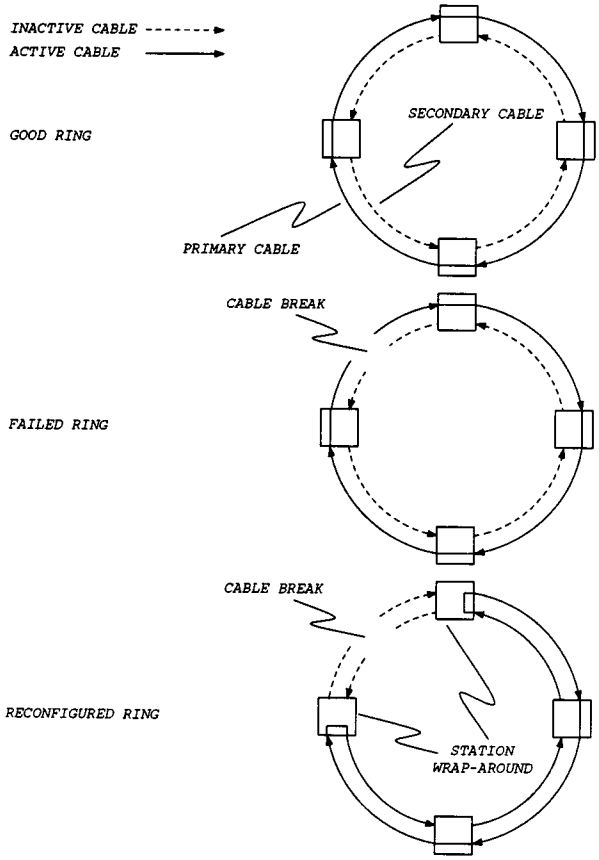

FIGURE 72.11 Reconfiguration of dual counter-rotating rings.

Transmitted information is subject to short bursts of errors and must also be protected. The connection-oriented service at the LLC sublayer is intended to recover from errors—such as garbled, dropped, or out-of-sequence packets—by positively acknowledging packets and retransmitting packets not acknowledged within the timeout window. The MAC sublayer usually provides error-detecting codes that can recognize an error burst of several consecutive bits (a favorite is the 32-bit cyclic redundancy code, which is easily implemented as a linear feedback shift register). Errors can also be recognized at the physical layer when they cause code violations, e.g., the absence of transitions in the Manchester or 4B/5B codes. Some LANs even use error-correcting codes for protecting time-sensitive information.

Other protection mechanisms are used to tolerate cable breaks and station malfunctions. The use of fully broadcast media makes a LAN vulnerable to media failure, since this effectively partitions the stations into noncommunicating groups. To cope with this problem, redundant cables are provided and a mechanism for reconfiguring from the bad to the good cable is built into the LAN protocols. A popular approach for the token ring can be seen in the counter-rotating dual-ring scheme, which is illustrated in Fig. 72.11. If a cable segment or an active station fails, the stations adjacent to the failure can reconfigure the ring by executing "wrap-around" operations. The new configuration uses the spare cable in conjunction with the original cable to form a new ring. Given the complexity of such a reconfiguration procedure, it is usually necessary for station management to coordinate the actions of the stations.

Special mechanisms for adding and removing stations to and from the LAN might also be required. Since the physical addition or removal of a station can disrupt the transmission of data, protocols for reestablishing a lost token could also be necessary.

TABLE 72.1 Characteristics of Standard LANs

	CSMA/CD	Token Ring	Token Bus	FDDI	DQDB
Standard	IEEE 802.3	IEEE 802.5	IEEE 802.4	ANS X3T9.5	IEEE 802.6
Topology	Bus, tree, star	Ring	Tree	Ring	Pseudobus
Media	Coax, UTP, MMF	STP	Coax	MMF, SMF	SMF
Encoding	MC, FSK, AM/PSK 4B/5B, 8B/6T	DMC	FSK, AM/PSK	4B/5B	4B/5B
Data rate	10 Mb/s, 100 Mb/s	4 Mb/s 16 Mb/s	1 Mb/s 5 Mb/s 10 Mb/s	100 Mb/s	34 Mb/s 45 Mb/s 140 Mb/s 155 Mb/s
Features		Priorities	Priorities, ST, multichannel	Priorities, ST, dual ring	Priorities, IT, dual bus

AM/PSK = amplitude modulation/phase-shift keying
ANS = American National Standard
CSMA/CD = carrier-sense multiple-access with collision detection
DMC = differential Manchester coding
DQDB = distributed queue, dual bus
FDDI = fiber distributed data interface
FSK = frequency-shift keying
IEEE = Institute of Electrical and Electronics Engineers
IT = isochronous traffic
MC = Manchester coding
MMF = multimode fiber
SMF = single-mode fiber
ST = synchronous traffic
STP = shielded twisted pair
UTP = unshielded twisted pair
*n*B/*m*B = *n*-bit/*m*-bit
*n*B/*m*T = *n*-bit/*m*-trit

The Importance of LAN Standards

LAN standards play a central role in promoting the goal of universal connectivity among a community of users. The standardization of communication services and protocols allows all conforming implementations to exchange information. Consequently, the importance of LAN standards has grown steadily. Currently, several LAN standards have been established to support the different communication requirements of users.

The first LANs—developed in the early 1970s—were proprietary products meant to interconnect one vendor's computer products. By 1980, however, Project 802 of the Institute of Electrical and Electronics Engineers (IEEE) had recognized the need for publicly disseminated LAN standards and eventually published a specification of the CSMA/CD protocol that any vendor may implement. Furthermore, the definition of the standard was sanctioned by companies that participated in the IEEE Working Group's balloting process, so that the standard was viewed as an open, nonproprietary solution. The IEEE 802.3 Working Group chose a protocol that was based closely on the Ethernet LAN originally developed at Xerox by Robert Metcalfe and David Boggs.

The IEEE Project 802 has broadened its scope to encompass other LAN standards. These include the following:

- 802.3: The CSMA/CD protocols for baseband coaxial cable (10Base5 and 10Base2), unshielded twisted copper-wire pairs (10BaseT), broadband coaxial cable (10Broad36), and optical fiber (10BaseF)
- 802.4: The token bus protocol for multichannel broadband coaxial cable
- 802.5: The token ring protocol for shielded twisted copper-wire pairs
- 802.6: The DQDB protocol for redundant optical fibers

Other standards-making bodies, such as the American National Standards Institute (ANSI) and the International Organization for Standards/International Electrotechnical Committee (ISO/IEC) have developed or cross-adopted LAN standards. ANSI's X3T9.5 committee is responsible for the FDDI LAN standard, a high-speed token ring that uses redundant optical fibers. Some of the important LAN standards and their characteristics are shown in Table 72.1.

The trend is for vendors to market LAN products that conform to specific standards. However, proprietary networks have been successfully marketed and were instrumental in the development of LAN standards. Some of the better known proprietary-LAN product offerings were the Xerox Ethernet, Datapoint Arcnet, Network Systems Hyperchannel, Proteon Pronet, Sytek System 20, and AT&T DATAKIT.

Summary

The LAN is the preferred method for connecting computers within a customer's premises. A number of transmission media, topologies, data rates, and services are available to meet users' needs. The services offered by the LAN are used to implement higher-layer protocols that are required by distributed computing systems. LANs will continue to grow more capable in the data and bit-error rates they achieve, the functionality they provide, and the number and geographical span of the stations they support.

Defining Terms

Media-access protocol: The protocol that permits one of a group of contending stations to access the media exclusively. Media-access protocols are generally based on token passing or carrier sense.

Physical media: The communication channel over which signals are transmitted. Broadcast media, in which all stations receive each transmission, are primarily used in local-area networks. Common media are optical fibers, coaxial cable, twisted copper-wire pairs, and airwaves.

Topology: The paths and switches of a local-area network that provide the physical interconnection among stations. The most common topologies are the bus, ring, tree, and star.

Leading journals that publish research articles on LANs include:

- IEEE Transactions on Communications
- IEEE Transactions on Networking
- Computer Networks and ISDN Systems
- IEEE Network

Four annual conferences that cover the topic of LANs are:

- The IEEE INFOCOM Conference on Computer Communications
- The IEEE Conference on Local Computer Networks
- The ACM SIGCOMM Conference on Communications Architectures and Protocols
- The EFOC/LAN European Fibre Optic Communications and Local Area Networks Conference

72.4 The Intelligent Network

Richard B. Robrock II

The term *intelligent network* refers to the concept of deploying centralized databases in the telecommunications network and querying those databases to provide a wide variety of network services such as 800 Service (toll-free service) and credit card calling. The first use of these centralized databases was in AT&T's network in 1981 where they were used to facilitate the setup of telephone calls charged to a Calling Card. Today such databases are widely deployed throughout North America and support the handling of close to 100 billion telephone calls per year.

The words *intelligent network,* when first used, had a relatively narrow definition, but that definition has broadened considerably with the introduction of the advanced intelligent network, the wireless intelligent network, and soon, the broadband intelligent network. The advanced intelligent network has introduced powerful service creation tools which have empowered network providers to create their own network services. The network providers, in turn, are beginning to broaden the participation in service creation by allowing their customers or third parties to use these tools to create services. The result has been a rapid growth in new network services.

A History of Intelligence in the Network

The first "intelligence" in the telephone network took the form of rows of human telephone operators, sitting side by side, plugging cords into jacks to facilitate the handling of calls. These operators established calls to far-away points, selected the best routes and provided billing information. They were also an information source—providing time or weather or perhaps disseminating the local news. Moreover, they had the opportunity to demonstrate a kind of heroism—gathering volunteers to save a house from fire, helping to catch a prowler, locating a lost child, and on and on. In the early years of telephony, the feats of the telephone operator were indeed legendary.

In the 1920s, however, technology became available that allowed automatic switching of telephone calls through the use of sophisticated electromechanical switching systems. Initially, these switches served as an aid to operators; ultimately, they led to the replacement of operators. The combination of the rotary telephone dial and the electromechanical switch allowed customers to directly dial calls without the assistance of operators. This led to a reduction of human intelligence in the network.

Another dramatic change took place in the telephone network in 1965; it was called software. It came with the marriage of the computer and the telephone switching system in the first stored-program control switch. With the introduction of switching software came a family of Custom Calling services (speed calling, call waiting, call forwarding, and three-way calling) for residential customers, and a robust set of Centrex features (station attendant, call transfer, abbreviated dialing, etc.) for business customers. The first software programs for these stored-program control switches contained approximately 100,000 lines of code; by 1990 some of these switching systems became enormously complex, containing 10 million lines of code and offering hundreds of different services to telephone users.

During the 1980s, a new architectural concept was introduced; it came to be called the intelligent network. It allowed new telecommunications services to be introduced rapidly and in a ubiquitous and uniform fashion. Feature and service availability in the network ceased to be solely dependent upon the hardware and software in stored-program control switches. Rather some new intelligence was centralized in databases which were accessed using packet switching techniques. Most significantly, the intelligent network started to provide some of the capabilities that operators had made available in the early years of telephony. The remaining sections of this chapter describe the intelligent network, its characteristics, and its services. They also provide a description of the advanced intelligent network, which dramatically broadens the participation in the creation of new services.

The Intelligent Network

The intelligent network architecture is illustrated in Fig. 72.12; its primary elements are a switching system, a signaling network, a centralized database, and an operations support system which supports the database. The

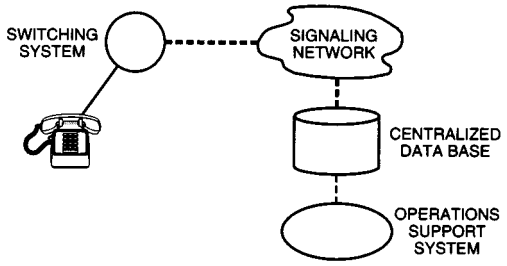

FIGURE 72.12 Intelligent network architecture—telephone calls which require special handling are intercepted in a switching system which launches queries through a signaling network to a centralized database. (*Source:* R. B. Robrock II, "The intelligent network—Changing the face of telecommunications," *Proc. IEEE,* vol. 79, no. 1, pp. 7–20, January 1991. © 1991 IEEE.)

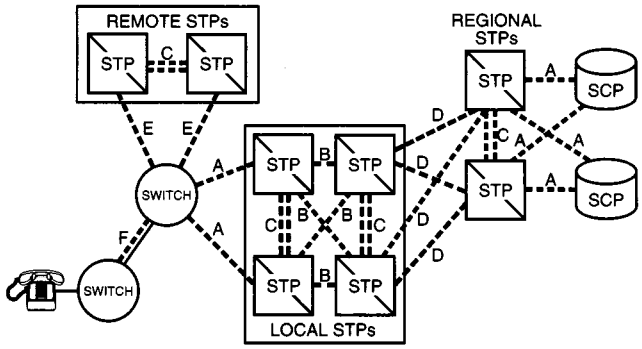

FIGURE 72.13 Link arrangements in a CCS7 signaling network. (*Source:* R. B. Robrock II, "The intelligent network—Changing the face of telecommunications," *Proc. IEEE,* vol. 79, no. 1, pp. 7–20, January 1991. © 1991 IEEE.)

architectural concept is a simple one. When a customer places a telephone call which requires special handling, such as a toll-free call (800 Service) or credit card call, that call is intercepted by the switching system which suspends call processing while it launches a query through a signaling network to a centralized database. The database, in turn, retrieves the necessary information to handle the call and returns that information through the signaling network to the switch so that the call can be completed. The role of the operations support system is to administer the appropriate network and customer information that resides in the database.

It is conceivable that the database in this architecture could reside in the switching system, and the signaling network in this instance would not be required. However, that would magnify the task of administering the customer information, since that information would be contained in thousands of switches instead of dozens of centralized databases. In addition, even more importantly, there are two shortcomings associated with basing many of the potential new services in switches, rather than utilizing centralized databases to provide information for the switches. The first is a deployment problem. As of 1990 there were more than 15,000 switches in the United States, and a single switch can cost millions of dollars. To introduce a new service in local switches and to make it widely available generally requires some not-so-simple changes in those switches or, in some cases, replacement of certain switch types altogether. These switch modifications typically take years to implement and require a tremendous capital investment. As a result, ten years after introduction, Custom Calling services were available to fewer than 1% of the residential customers in the United States.

A second problem with switch-based services has been that a single service sometimes behaves differently in different switch types. For example, the speed calling access patterns are different in various stored-program control switches. The public is not particularly sensitive to this fact, because speed calling is not associated with an individual but rather an individual's station set. People live in a mobile society, however, and they want to have their services available from any station set and have them behave the same from any station set.

The intelligent network architecture has been the key to solving both the deployment problem and service uniformity problem associated with switch-based services. Services deployed using an intelligent network centralized database are immediately ubiquitous and uniform throughout a company's serving area.

Intelligent Network Systems

In 1981, AT&T introduced into the Bell System a set of centralized databases called network control points; they supported two applications—the Billing Validation Application for Calling Card Service (credit card calling) and the INWATS database used to support 800 Service. Queries were launched to these databases through AT&T's common-channel interoffice signaling (CCIS) network.

In 1984, following the divestiture of the Regional Bell Operating Companies from AT&T, the regional companies began planning to deploy their own **common-channel signaling (CCS)** networks and their own centralized databases. They selected the **signaling system 7** protocol for use in their signaling networks, called CCS7 networks, and they named their databases **service control points (SCPs).**

The CCS7 Network

A general architecture for a regional signaling network is shown in Fig. 72.13. The network is made up of **signal transfer points (STPs),** which are very reliable, high-capacity packet switches that route signaling messages between network access nodes such as switches and SCPs. To perform these routing functions, the STPs each possess a large routing database containing translation data.

The CCS7 network in Fig. 72.13 contains both local STPs and regional STPs. The STPs are typically deployed in geographically separated pairs so that in the event of a natural disaster at one site, such as an earthquake, flood, or fire, the total traffic volume can be handled by the second site. Indeed, redundancy is provided at all key points so that no single failure can isolate a node.

As illustrated in Fig. 72.13, the following link types have been designated:

- A-links connect an access node, such as a switching system or SCP, to both members of an STP pair.
- B-links interconnect two STP pairs forming a "quad" of four signaling links where each STP independently connects to each member of the other pair.
- C-links are the high-capacity connections between the geographically separated members of an STP pair.
- D-links connect one STP pair to a second STP pair at another level in the signaling hierarchy or to another carrier.
- E-links connect an access node to a remote STP pair in the signaling network and are rarely used.
- F-links directly interconnect two access nodes without the use of an STP; they are nonredundant.

The CCS7 links normally function at 56 kb/s in North America while links operating at 64 kb/s are common in Europe.

The CCS7 signaling network provides the underlying foundation for the intelligent network, and the regional telephone companies in the United States began wide-scale deployment of these networks in 1986; several large independent telephone companies and interexchange carriers (ICs) soon followed. They used these networks for both trunk signaling between switches as well as for direct signaling from a switch to a database.

The Service Control Point

The "brains" of the intelligent network is the SCP. It is an on-line, fault-tolerant, transaction-processing database which provides call handling information in response to network queries. The SCP deployed for 800 Service is a high-capacity system capable of handling more than 900 queries per second or 3 million per hour. It is a real-time system with a response time of less than one half second, and it is a high-availability system with a downtime of less than 3 minutes per year for a mated SCP pair. The SCP is also designed to accommodate growth, which means that processing power or memory can be added to an in-service system without interrupting service. In addition, it is designed to accommodate graceful retrofit, which means that a new software program can be loaded into an in-service SCP without disrupting service.

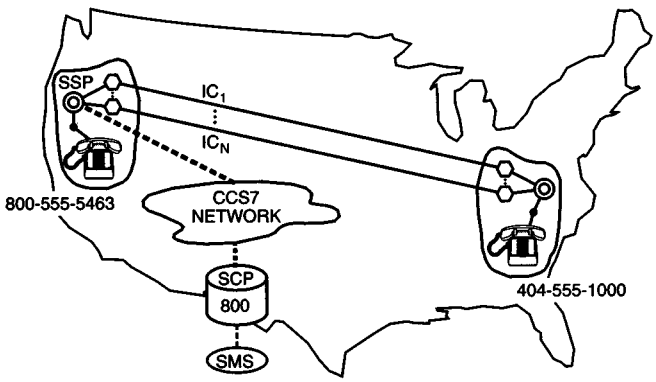

FIGURE 72.14 Data Base 800 Service—800-number calls are routed to an SSP which launches queries through a CCS7 network to an SCP containing the 800 database. In this example, the SCP translates the 800 Service number of 800-555-5463 into the POTS number of 404-555-1000. (*Source:* R. B. Robrock II, "The intelligent network—Changing the face of telecommunications," *Proc. IEEE*, vol. 79, no. 1. pp. 7–20, January 1991. © 1991 IEEE.)

Data Base 800 Service

SCPs have been deployed throughout the United States in support of the Data Base 800 Service mandated by the Federal Communications Commission. This service provides its subscribers with number portability so that a single 800 number can be used with different carriers. The Data Base 800 Service architecture is shown in Fig. 72.14. With this architecture, 800-number calls are routed from an end office to a service switching point (SSP) which launches queries through a CCS7 signaling network to the SCP. The SCP identifies the appropriate carrier, as specified by the 800 Service subscriber, and then, if appropriate, translates the 800 number to a plain old telephone (POTS) number. This information is subsequently returned to the SSP so that the call can be routed through the network by handing the call off to the appropriate carrier. This technology allows subscribers to select the carrier and the POTS number as a function of criteria such as time of day, day of week, percent allocation, and the location of the calling station. Thus the SCP provides two customer-specified routing information functions: a carrier identification function and an address translation function.

The SCP 800 Service database is administered by a single national **service management system (SMS).** The SMS is an interactive operations support system that is used to process and update customer records. It is the interface between the customer and the SCP. It translates a language which is friendly to a customer into a language which is friendly to on-line, real-time databases. Along the way, it validates the customer input.

Alternate Billing Services

Alternate billing services (ABS) have also been implemented using the intelligent network architecture. Alternate billing is an umbrella title which includes Calling Card Service, collect calling, and bill-to-third-number calling. The network configuration supporting ABS is shown in Fig. 72.15.

With this architecture, when a customer places a Calling Card call, the call is routed to an operator services system (OSS) which suspends call processing and launches a query through a CCS7 signaling network. The query is delivered to an SCP which contains the **line information database (LIDB)** application software. The LIDB application can provide routing information, such as identifying the customer-specified carrier which is to handle the call, as well as provide screening functions, such as the Calling Card validation used to authorize a call. The LIDB then returns the appropriate information to the OSS so that the call can be completed. The LIDBs are supported by the **database administration system (DBAS),** which is an operations support system that processes updates for Calling Card Service as well as other services. Multiple DBAS systems typically support each LIDB.

During 1991, each of the Regional Bell Operating Companies and a number of large independent telephone companies interconnected their CCS7 networks, mostly through STP hubs, to create a national signaling network; it was a process called LIDB interconnect. When it was finished, it meant that a person carrying a

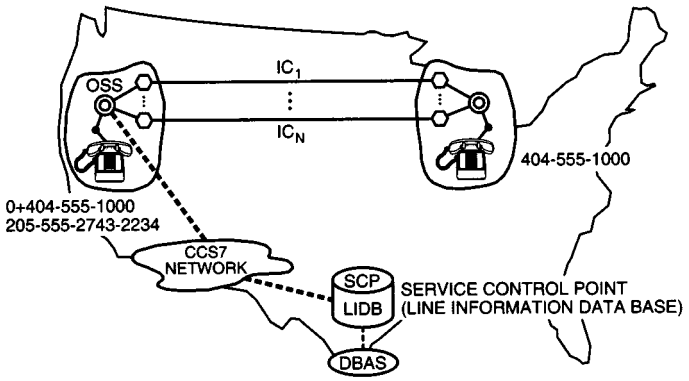

FIGURE 72.15 Alternate billing services—calls are routed to an OSS which launches queries through the CCS7 network to SCPs containing the LIDB application. (*Source:* R. B. Robrock II, "The intelligent network—Changing the face of telecommunications," *Proc. IEEE,* vol. 79, no. 1. pp. 7–20, January 1991. © 1991 IEEE.)

particular company's Calling Card could, from anywhere in the United States, query the LIDB containing the associated Calling Card number.

Although the LIDB was originally developed to support Calling Card Service, it has since found wide application in the telecommunications industry. For example, the LIDB is used to translate the telephone number of a calling party to a name as part of Calling Name Delivery service, or to convert that number to a nine-digit ZIP code as part of Single Number Service. The LIDB databases now contain more than a quarter of a billion customer records which are updated at a rate of more than a million changes per day. Although physically distributed, the LIDBs appear logically as a single database. They represent a national resource.

Other Services

For alternate billing services, the SCP is essentially designed to perform two functions: carrier identification and billing authorization. For 800 Service, the SCP provides carrier identification and address translation. These basic functions of authorization, address translation and carrier identification can be used again and again in many different ways. For example, the intelligent network has been used to support private virtual networks (PVNs). PVNs make use of the public telephone network but, by means of software control, appear to have the characteristics of private networks. A PVN serves a closed-user group, and a caller requires authorization to gain access to the network. This screening function on originating calls uses an authorization function. Second, a PVN may offer an abbreviated dialing plan, for example, four-digit dialing. In this instance, the SCP performs an address translation function, converting a four-digit number to a ten-digit POTS number. There may also be a customer-specified routing information function which involves selecting from a hierarchy of facilities; this can be accomplished through use of the SCP carrier identification function.

The SCP in the intelligent network can support a vast number of services ranging from Calling Name Delivery service to messaging service. With Calling Name Delivery, a switch sends a query to the SCP with the ten-digit calling party number; the response is the calling party name which is then forwarded by the switch to a display unit attached to the called party station set. In support of messaging services, the address translation capability of the SCP can be used to translate a person's telephone number to an electronic-mail address. As a result, the sender of electronic mail need only know a person's telephone number.

The Advanced Intelligent Network

The intelligent network architecture discussed thus far is often referred to in the literature as Intelligent Network/1; this architecture has addressed the deployment problem and the service uniformity problem. The next phase in the evolution of this network has come to be called the advanced intelligent network (AIN), with the AIN standards defined by Bellcore.

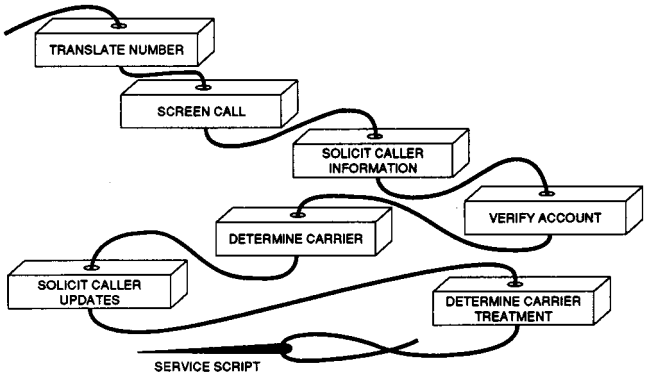

FIGURE 72.16 Creating the service script or scenario for a call by stitching together functional blocks. (*Source:* R. B. Robrock II, "The intelligent network—Changing the face of telecommunications," *Proc. IEEE,* vol. 79, no. 1. pp. 7–20, January 1991. © 1991 IEEE.)

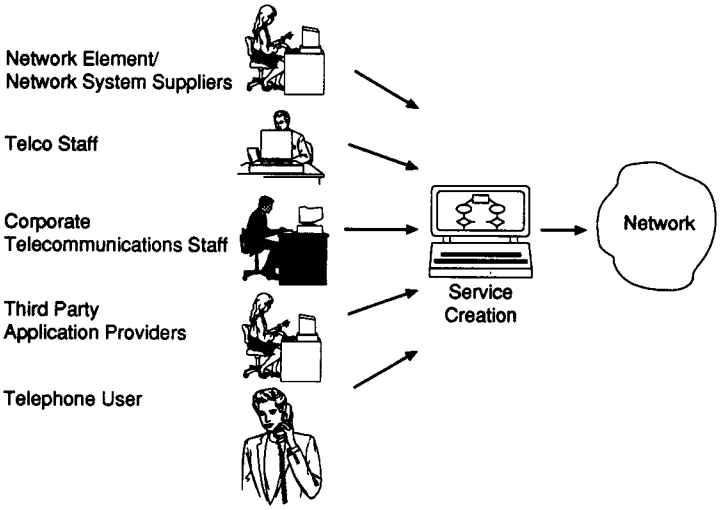

FIGURE 72.17 The advanced intelligent network—a business perspective. (*Source:* R. B. Robrock II, "Putting the Telephone User in the Driver's Seat," International Council for Computer Communication Conference on Intelligent Networks, pp. 144–150, May 1992.)

The concept of AIN is that new services can be developed and introduced into the network without requiring carriers to wait for switch generics to be upgraded. Some AIN applications introduce powerful service-creation capabilities which allow nonprogrammers to invoke basic functions offered in the network and stitch together those functions, as illustrated in Fig. 72.16, to constitute a new service. As a result, AIN promises to dramatically shorten the interval required to develop new services. Perhaps of greater significance, it promises to broaden the participation in service creation. In addition, it offers the opportunity to personalize or customize services. The silicon revolution has driven the cost of memory down to the point where it is economically viable to have enough memory in the network to store the service scripts or call processing scenarios that are unique to individuals.

Many people think of the AIN as a collection of network elements, network systems and operations systems; this view might be called a technologist's view. Perhaps a better representation is shown in Fig. 72.17; it shows a collection of people—people empowered to create services.

Historically, the creation of new services provided by the telephone network has been the sole domain of the network element and network system suppliers. There is perhaps a good analogy with the automobile

industry. A market study in the early 1900s predicted that 200,000 was the maximum number of cars that could ever be sold in a single year in the United States; the reasoning was that 200,000 was the maximum number of chauffeurs that could enter the workforce in a single year. In the telecommunications business, the network element and network system suppliers have been the chauffeurs of the network services business.

The service-creation tools offered by the AIN, however, empower telephone company staff to create new services. Moreover, similar tools may well be used by the telecommunications staff of large corporations, or by third-party application providers or even by some segment of the telephone user population. As a result, we may see an explosion in the number of network services.

The AIN introduces very powerful service-creation tools which are used to produce service-logic scripts (programs). In one arrangement, the service creation is done by assembling service-logic graphs from graphical icons that represent functional components of services. The completed graph is then validated with an expert system and tested off-line by executing every leg of the service-logic graph. At this point the service-logic program can be downloaded into the service control point so that it is ready for execution.

To make use of the new service, it is then necessary to set "triggers" in the appropriate service switching point. These triggers can be set for both originating and terminating calls, and they represent events which, should they occur, indicate the need for the switch to launch a query to the SCP for information the switch needs to process the call. The AIN switch generics, which are presently deployed, support several triggers such as "immediate off hook" or "called address." Future AIN switch generics are expected to support several dozen triggers. The first phase of the AIN, called AIN 0, became reality in late 1991 when friendly user trials began in two of the Regional Bell Operating Companies.

AIN 0 evolved to AIN 0.1 and then AIN 0.2, with each new version of AIN containing additional triggers. Today over 100 AIN services are deployed in North America and the number is growing rapidly.

The European Telecommunications Standards Institute (ETSI) has defined a European AIN standard referred to as Core INAP, and deployment of Core INAP systems in Europe began in 1996.

The architectural concepts of AIN are now beginning to carry over into wireless networks as well as broadband networks. Although the standards in these domains are just being developed, the value added by the wireless intelligent network (WIN) and the broadband intelligent network (BIN) promises to surpass the value seen in the narrowband wireline world.

Back to the Future

The intelligent network, with its centralized databases, has offered a means to rapidly introduce new services in a ubiquitous fashion and with operational uniformity as seen by the end user. The advanced intelligent network has gone on to provide a service-independent architecture, and, with its powerful service-creation capabilities, has empowered nonprogrammers to participate in the development of new services. In many ways, as we go into the future, we are going back to a time when operators were the "human intelligence" in the network. The human intelligence was all but eliminated with the introduction of switching systems, but now the intelligent network is working to put the intelligence of the human operator back into the network.

Defining Terms

Common-channel signaling (CCS): A technique for routing signaling information through a packet-switched network.

Database administration systems (DBAS): An operations support system that administers updates for the line information database.

Line information database (LIDB): An application running on the service control point that contains information on telephone lines and Calling Cards.

Service control point (SCP): An on-line, real-time, fault-tolerant, transaction-processing database which provides call-handling information in response to network queries.

Service management system (SMS): An operations support system which administers customer records for the service control point.

Signal transfer point (STP): A packet switch found in the common-channel signaling network; it is used to route signaling messages between network access nodes such as switches and SCPs.

Signaling system 7 (SS7): A communications protocol used in common-channel signaling networks.

73.1 Signal Detection

H. Vincent Poor

The field of signal detection and estimation is concerned with the processing of information-bearing signals for the purpose of extracting the information they contain. The applications of this methodology are quite broad, ranging from areas of electrical engineering such as automatic control, digital communications, image processing, and remote sensing, into other engineering disciplines and the physical, biological, and social sciences.

There are two basic types of problems of interest in this context. *Signal detection* problems are concerned primarily with situations in which the information to be extracted from a signal is discrete in nature. That is, signal detection procedures are techniques for deciding among a discrete (usually finite) number of possible alternatives. An example of such a problem is the demodulation of a digital communication signal, in which the task of interest is to decide which of several possible transmitted symbols has elicited a given received signal. *Estimation* problems, on the other hand, deal with the determination of some numerical quantity taking values in a continuum. An example of an estimation problem is that of determining the phase or frequency of the carrier underlying a communication signal.

Although signal detection and estimation is an area of considerable current research activity, the fundamental principles are quite well developed. These principles, which are based on the theory of statistical inference, explain and motivate most of the basic signal detection and estimation procedures used in practice. In this section, we will give a brief overview of the basic principles underlying the field of signal detection. Estimation is treated elsewhere this volume, notably in Section 16.2. A more complete introduction to these subjects is found in Poor [1994].

General Considerations

The basic principles of signal detection can be conveniently discussed in the context of decision-making between two possible statistical models for a set of real-valued measurements, $Y_1, Y_2, \ldots, Y_n$. In particular, on observing $Y_1, Y_2, \ldots, Y_n$, we wish to decide whether these measurements are most consistent with the model

$$Y_k = N_k, \qquad k = 1, 2, \ldots, n \tag{73.1}$$

or with the model

$$Y_k = N_k + S_k, \quad k = 1, 2, \ldots, n \tag{73.2}$$

where $N_1, N_2, \ldots, N_n$ is a random sequence representing noise, and where $S_1, S_2, \ldots, S_n$ is a sequence representing a (possibly random) signal.

In deciding between Eqs. (73.1) and (73.2), there are two types of errors possible: a *false alarm,* in which (73.2) is falsely chosen, and a *miss,* in which (73.1) is falsely chosen. The probabilities of these two types of errors can be used as performance indices in the optimization of rules for deciding between (73.1) and (73.2). Obviously, it is desirable to minimize both of these probabilities to the extent possible. However, the minimization of the **false-alarm probability** and the minimization of the **miss probability** are opposing criteria. So, it is necessary to effect a trade-off between them in order to design a signal detection procedure. There are several ways of trading off the probabilities of miss and false alarm: the **Bayesian detector** minimizes an average of the two probabilities taken with respect to prior probabilities of the two conditions (73.1) and (73.2), the *minimax* detector minimizes the maximum of the two error probabilities, and the **Neyman-Pearson detector** minimizes the miss probability under an upper-bound constraint on the false-alarm probability.

If the statistics of noise and signal are known, the Bayesian, minimax, and Neyman-Pearson detectors are all of the same form. Namely, they reduce the measurements to a single number by computing the **likelihood ratio**

$$L(Y_1, Y_2, \ldots, Y_n) \triangleq \frac{p_{S+N}(Y_1, Y_2, \ldots, Y_n)}{p_N(Y_1, Y_2, \ldots, Y_n)} \tag{73.3}$$

where p_{S+N} and p_N denote the probability density functions of the measurements under signal-plus-noise (73.2) and noise-only (73.1) conditions, respectively. The likelihood ratio is then compared to a *decision threshold,* with the signal-present model (73.2) being chosen if the threshold is exceeded, and the signal-absent model (73.1) being chosen otherwise. Choice of the decision threshold determines a trade-off of the two error probabilities, and the optimum procedures for the three criteria mentioned above differ only in this choice.

There are several basic signal detection structures that can be derived from Eqs. (73.1) to (73.3) under the assumption that the noise sequence consists of a set of independent and identically distributed (i.i.d.) Gaussian random variables with zero means. Such a sequence is known as **discrete-time white Gaussian noise.** Thus, until further notice, we will make this assumption about the noise. It should be noted that this assumption is physically justifiable in many applications.

Detection of Known Signals

If the signal sequence $S_1, S_2, \ldots, S_n$ is known to be given by a specific sequence, say $s_1, s_2, \ldots, s_n$ (a situation known as *coherent detection*), then the likelihood ratio (73.3) is given in the white Gaussian noise case by

$$\exp\left\{\left(\sum_{k=1}^{n} s_k Y_k - \frac{1}{2}\sum_{k=1}^{n} s_k^2\right) / \sigma^2\right\} \tag{73.4}$$

where σ^2 is the variance of the noise samples. The only part of (73.4) that depends on the measurements is the term $\Sigma_{k=1}^{n} s_k Y_k$ and the likelihood ratio is a monotonically increasing function of this quantity. Thus, optimum detection of a coherent signal can be accomplished via a correlation detector, which operates by comparing the quantity

$$\sum_{k=1}^{n} s_k Y_k \tag{73.5}$$

to a threshold, announcing signal presence when the threshold is exceeded.

Note that this detector works on the principle that the signal will correlate well with itself, yielding a large value of (73.5) when present, whereas the random noise will tend to average out in the sum (73.5), yielding a relatively small value when the signal is absent. This detector is illustrated in Fig. 73.1.

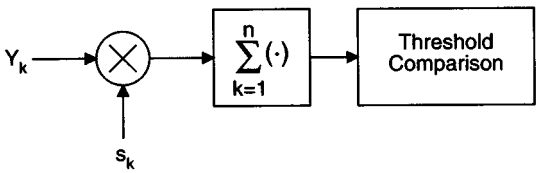

FIGURE 73.1 Correlation detector for a coherent signal in additive white Gaussian noise.

Detection of Parametrized Signals

The correlation detector cannot usually be used directly unless the signal is known exactly. If, alternatively, the signal is known up to a short vector $\boldsymbol{\theta}$ of random parameters (such as frequencies or phases) that are independent of the noise, then an optimum test can be implemented by threshold comparison of the quantity

$$\int_{\Lambda} \exp\left\{\left(\sum_{k=1}^{n} s_k(\boldsymbol{\theta}) Y_k - \frac{1}{2}\sum_{k=1}^{n} \left[s_k(\boldsymbol{\theta})\right]^2\right) / \sigma^2\right\} p(\boldsymbol{\theta}) d\boldsymbol{\theta} \tag{73.6}$$

where we have written $S_k = s_k(\boldsymbol{\theta})$ to indicate the functional dependence of the signal on the parameters, and where Λ and $p(\boldsymbol{\theta})$ denote the range and probability density function, respectively, of the parameters.

The most important example of such a parametrized signal is that in which the signal is a modulated sinusoid with random phase; i.e.,

$$S_k = a_k \cos(\omega_c k + \theta), \qquad k = 1, 2, \ldots, n \tag{73.7}$$

where $a_1, a_2, \ldots, a_n$ is a known amplitude modulation sequence, ω_c is a known (discrete-time) carrier frequency, and the random phase θ is uniformly distributed in the interval $[-\pi,\pi]$. In this case, the likelihood ratio is a monotonically increasing function of the quantity

$$\left[\sum_{k=1}^{n} a_k \cos(\omega_c k) Y_k\right]^2 + \left[\sum_{k=1}^{n} a_k \sin(\omega_c k) Y_k\right]^2 \tag{73.8}$$

Thus, optimum detection can be implemented via comparison of (73.8) with a threshold, a structure known as an **envelope detector.** Note that this detector correlates the measurements with two orthogonal components of the signal, $a_k \cos(\omega_c k)$ and $a_k \sin(\omega_c k)$. These two correlations, known as the in-phase and quadrature components of the measurements, respectively, capture all of the energy in the signal, regardless of the value of θ. Since θ is unknown, however, these two correlations cannot be combined coherently, and thus they are combined noncoherently via (73.8) before the result is compared with a threshold. This detector is illustrated in Fig. 73.2.

Parametrized signals also arise in situations in which it is not appropriate to model the unknown parameters as random variables with a known distribution. In such cases, it is not possible to compute the likelihood ratio (73.6) so an alternative to the likelihood ratio detector must then be used. (An exception is that in which the likelihood ratio detector is invariant to the unknown parameters—a case known as *uniformly most powerful detection.*) Several alternatives to the likelihood ratio detector exist for these cases.

One useful such procedure is to test for the signal's presence by threshold comparison of the *generalized likelihood ratio,* given by

$$\max_{\boldsymbol{\theta} \in \Lambda} L_{\boldsymbol{\theta}}(Y_1, Y_2, \ldots, Y_n) \tag{73.9}$$

where $L_{\boldsymbol{\theta}}$ denotes the likelihood ratio for Eqs. (73.1) and (73.2) for the known-signal problem with the parameter vector fixed at $\boldsymbol{\theta}$. In the case of white Gaussian noise, we have

$$L_{\boldsymbol{\theta}}(Y_1, Y_2, \ldots, Y_n) = \exp\left\{\left(\sum_{k=1}^{n} s_k(\boldsymbol{\theta}) Y_k - \frac{1}{2}\sum_{k=1}^{n}\left[s_k(\boldsymbol{\theta})\right]^2\right) / \sigma^2\right\} \tag{73.10}$$

It should be noted that this formulation is also valid if the statistics of the noise have unknown parameters, e.g., the noise variance in the white Gaussian case.

One common application in which the generalized likelihood ratio detector is useful is that of detecting a signal that is known except for its time of arrival. That is, we are often interested in signals parametrized as

$$s_k(\theta) = a_{k-\theta} \tag{73.11}$$

where $\{a_k\}$ is a known finite-duration signal sequence and where θ ranges over the integers. Assuming white Gaussian noise and an observation interval much longer than the duration of $\{a_k\}$, the generalized likelihood ratio detector in this case announces the presence of the signal if the quantity

$$\max_{\theta} \sum_{k} a_{k-\theta} Y_k \tag{73.12}$$

exceeds a fixed threshold. This type of detector is known as a *matched filter,* since it can be implemented by filtering the measurements with a digital filter whose pulse response is a time-reversed version of the known

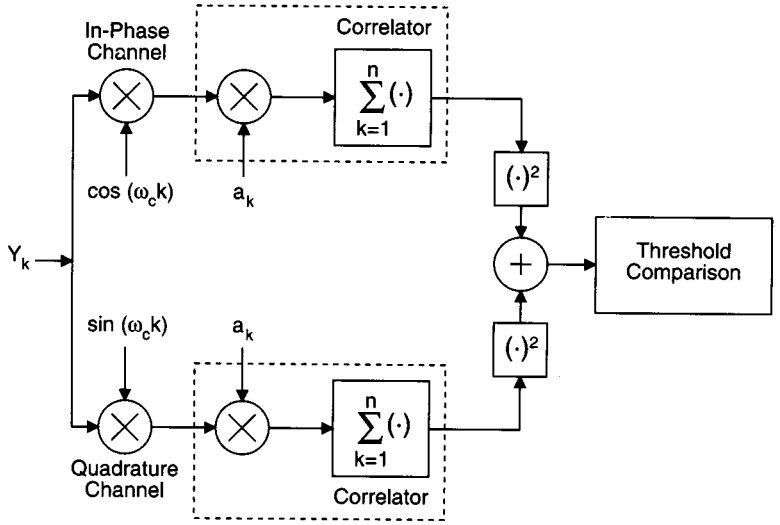

FIGURE 73.2 Envelope detector for a noncoherent signal in additive white Gaussian noise.

signal $\{a_k\}$ (hence it is "matched" to the signal), and announcing the signal's presence if the filter output exceeds the decision threshold at any time.

Detection of Random Signals

In some applications, particularly in remote sensing applications such as sonar and radio astronomy, it is appropriate to consider the signal sequence $S_1, S_2, \ldots, S_n$ itself to be a random sequence, statistically independent of the noise. In such cases, the likelihood ratio formula of (73.6) is still valid with the parameter vector $\boldsymbol{\theta}$ simply taken to be the signal itself. However, for long measurement records (i.e., large n), (73.6) is not a very practical formula except in some specific cases, the most important of which is the case in which the signal is Gaussian.

In particular, if the signal is Gaussian with zero-mean and autocorrelation sequence $r_{k,l} \triangleq E\{S_k S_l\}$, then the likelihood ratio is a monotonically increasing function of the quantity

$$\sum_{k=1}^{n} \sum_{l=1}^{n} q_{k,l} Y_k Y_l \tag{73.13}$$

with $q_{k,l}$ the element in the kth row and lth column of the positive-definite matrix

$$\mathbf{Q} \triangleq \mathbf{I} - (\mathbf{I} + \mathbf{R}/\sigma^2)^{-1} \tag{73.14}$$

where $\mathbf{I}$ denotes the $n \times n$ identity matrix, and R is the covariance matrix of the signal, i.e., it is the $n \times n$ matrix with elements $r_{k,l}$.

Note that (73.13) is a quadratic function of the measurements; thus, a detector based on the comparison of this quantity to a threshold is known as a **quadratic detector.** The simplest form of this detector results from the situation in which the signal samples are, like the noise samples, i.i.d. In this case, the quadratic function (73.13) reduces to a positive constant multiple of the quantity

$$\sum_{k=1}^{n} Y_k^2 \tag{73.15}$$

A detector based on (73.15) simply measures the energy in the measurements and then announces the presence of the signal if this energy is large enough. This type of detector is known as a *radiometer.*

Thus, radiometry is optimum in the case in which both signal and noise are i.i.d. Gaussian sequences with zero means. Since in this case the presence of the signal is manifested only by an increase in energy level, it is intuitively obvious that radiometry is the only way of detecting the signal's presence. More generally, when the signal is correlated, the quadratic function (73.13) exploits both the increased energy level and the correlation structure introduced by the presence of the signal. For example, if the signal is a narrowband Gaussian process, then the quadratic function (73.13) acts as a narrowband radiometer with bandpass characteristic that approximately matches that of the signal. In general, the quadratic detector will make use of whatever spectral properties the signal exhibits.

If the signal is random but not Gaussian, then its optimum detection [described by (73.6)] typically requires more complicated nonlinear processing than the quadratic processing of (73.13) in order to exploit the distributional differences between signal and noise. This type of processing is often not practical for implementation, and thus approximations to the optimum detector are typically used. An interesting family of such detectors uses cubic or quartic functions of the measurements, which exploit the higher-order spectral properties of the signal [Mendel, 1991]. As with deterministic signals, random signals can be parametrized. In this case, however, it is the distribution of the signal that is parametrized. For example, the power spectrum of the signal of interest may be known only up to a set of unknown parameters. Generalized likelihood ratio detectors (73.9) are often used to detect such signals.

Deciding Among Multiple Signals

The preceding results have been developed under the model (73.1)–(73.2) that there is a single signal that is either present or absent. In digital communications applications, it is more common to have the situation in which we wish to decide between the presence of two (or more) possible signals in a given set of measurements. The foregoing results can be adapted straightforwardly to such problems. This can be seen most easily in the case of deciding among known signals. In particular, consider the problem of deciding between two alternatives:

$$Y_k = N_k + s_k^{(0)}, \qquad k = 1, 2, \ldots, n \tag{73.16}$$

and

$$Y_k = N_k + s_k^{(1)}, \qquad k = 1, 2, \ldots, n \tag{73.17}$$

where $s_1^{(0)}, s_2^{(0)}, \ldots, s_n^{(0)}$ and $s_1^{(1)}, s_2^{(1)}, \ldots, s_n^{(1)}$ are two known signals. Such problems arise in data transmission problems, in which the two signals $s^{(0)}$ and $s^{(1)}$ correspond to the waveforms received after transmission of a logical "zero" and "one," respectively. In such problems, we are generally interested in minimizing the *average probability of error,* which is the average of the two error probabilities weighted by the prior probabilities of occurrence of the two signals. This is a Bayesian performance criterion, and the optimum decision rule is a straightforward extension of the correlation detector based on (73.5). In particular, under the assumptions that the two signals are equally likely to occur prior to measurement, and that the noise is white and Gaussian, the optimum decision between (73.16) and (73.17) is to choose the model (73.16) if $\Sigma_{k=1}^{n} s_k^{(0)} Y_k$ is larger than $\Sigma_{k=1}^{n} s_k^{(1)} Y_k$, and to choose the model (73.17) otherwise.

More generally, many problems in digital communications involve deciding among M equally likely signals with $M > 2$. In this case, again assuming white Gaussian noise, the decision rule that minimizes the error probability is to choose the signal $s_1^{(j)}, s_2^{(j)}, \ldots, s_n^{(j)}$, where j is a solution of the maximization problem

$$\sum_{k=1}^{n} s_k^{(j)} Y_k = \max_{0 \le m \le M-1} \sum_{k=1}^{n} s_k^{(m)} Y_k \tag{73.18}$$

There are two basic types of digital communications applications in which the problem (73.18) arises. One is in *M-ary data transmission,* in which a symbol alphabet with M elements is used to transmit data, and a decision among these M symbols must be made in each symbol interval [Proakis, 1983]. The other type of application in which (73.18) arises is that in which data symbols are correlated in some way because of intersymbol interference, coding, or multiuser transmission. In such cases, each of the M possible signals represents a frame of data symbols, and a joint decision must be made about the entire frame since individual symbol decisions cannot be decoupled. Within this latter framework, the problem (73.18) is known as *sequence detection.* The basic distinction between M-ary transmission and sequence detection is one of degree. In typical M-ary transmission, the number of elements in the signaling alphabet is typically a small power of 2 (say 8 or 32), whereas the number of symbols in a frame of data could be on the order of thousands. Thus, solution of (73.18) by exhaustive search is prohibitive for sequence detection, and less complex algorithms must be used. Typical digital communications applications in which sequence detection is necessary admit dynamic programming solutions to (73.18) (see, e.g., Verdú [1993]).

Detection of Signals in More General Noise Processes

In the foregoing paragraphs, we have described three basic detection procedures: correlation detection of signals that are completely known, envelope detection of signals that are known except for a random phase, and quadratic detection for Gaussian random signals. These detectors were all derived under an assumption of white Gaussian noise. This assumption provides an accurate model for the dominant noise arising in many communication channels. For example, the thermal noise generated in signal processing electronics is adequately described as being white and Gaussian. However, there are also many channels in which the statistical behavior of the noise is not well described in this way, particularly when the dominant noise is produced in the physical channel rather than in the receiver electronics.

One type of noise that often arises is noise that is Gaussian but not white. In this case, the detection problem (73.1)–(73.2) can be converted to an equivalent problem with white noise by applying a linear filtering process known as *prewhitening* to the measurements. In particular, on denoting the noise covariance matrix by Σ, we can write

$$\Sigma = \mathbf{C}\mathbf{C}^T \tag{73.19}$$

where $\mathbf{C}$ is an $n \times n$ invertible, lower-triangular matrix and where the superscript T denotes matrix transposition. The representation (73.19) is known as the *Cholesky decomposition.* On multiplying the measurement vector $\mathbf{Y} \triangleq (Y_1, Y_2, \ldots, Y_n)^T$ satisfying (73.1)–(73.2) with noise covariance Σ, by $\mathbf{C}^{-1}$, we produce an equivalent (in terms of information content) measurement vector that satistifies the model (73.1)–(73.2) with white Gaussian noise and with the signal conformally transformed. This model can then be treated using the methods described previously.

In other channels, the noise can be modeled as being i.i.d. but with an amplitude distribution that is not Gaussian. This type of model arises, for example, in channels dominated by impulsive phenomena, such as urban radio channels. In the non-Gaussian case the procedures discussed previously lose their optimality as defined in terms of the error probabilities. These procedures can still be used, and they will work well under many conditions; however, there will be a resulting performance penalty with respect to optimum procedures based on the likelihood ratio. Generally speaking, likelihood-ratio-based procedures for non-Gaussian noise channels involve more complex nonlinear processing of the measurements than is required in the standard detectors, although the retention of the i.i.d. assumption greatly simplifies this problem. A treatment of methods for such channels can be found in Kassam [1988].

When the noise is both non-Gaussian and dependent, the methodology is less well developed, although some techniques are available in these cases. An overview can be found in Poor and Thomas [1993].

Robust and Nonparametric Detection

All of the procedures outlined in the preceding subsection are based on the assumption of a known (possibly up to a set of unknown parameters) statistical model for signals and noise. In many practical situations it is

not possible to specify accurate statistical models for signals or noise, and so it is of interest to design detection procedures that do not rely heavily on such models. Of course, the parametrized models described in the foregoing paragraphs allow for uncertainty in the statistics of the observations. Such models are known as *parametric* models, because the set of possible distributions can be parametrized by a finite set of real parameters.

While parametric models can be used to describe many types of modeling uncertainty, composite models in which the set of possible distributions is much broader than a parametric model would allow are sometimed more realistic in practice. Such models are termed *nonparametric models.* For example, one might be able to assume only some very coarse model for the noise, such as that it is symmetrically distributed. A wide variety of useful and powerful detectors have been developed for signal-detection problems that cannot be parametrized. These are basically of two types: *robust* and *nonparametric.* Robust detectors are those designed to perform well despite small, but potentially damaging, nonparametric deviations from a nominal parametric model, whereas nonparametric detectors are designed to achieve constant false-alarm probability over very wide classes of noise statistics.

Robustness problems are usually treated analytically via minimax formulations that seek best worst-case performance as the design objective. This formulation has proven to be very useful in the design and characterization of robust detectors for a wide variety of detection problems. Solutions typically call for the introduction of light limiting to prevent extremes of gain dictated by an (unrealistic) nominal model. For example, the correlation detector of Fig. 73.1 can be made robust against deviations from the Gaussian noise model by introducing a soft-limiter between the multiplier and the accumulator.

Nonparametric detection is usually based on relatively coarse information about the observations, such as the algebraic signs or the ranks of the observations. One such test is the *sign test,* which bases its decisions on the number of positive observations obtained. This test is nonparametric for the model in which the noise samples are i.i.d. with zero median and is reasonably powerful against alternatives such as the presence of a positive constant signal in such noise. More powerful tests for such problems can be achieved at the expense of complexity by incorporating rank information into the test statistic.

Distributed and Sequential Detection

The detection procedures discussed in the preceding paragraphs are based on the assumption that all measurements can and should be used in the detection of the signal, and moreover that no constraints exist on how measurements can be combined. There are a number of applications, however, in which constraints apply to the information pattern of the measurements.

One type of constrained information pattern that is of interest in a number of applications is a network consisting of a number of distributed or local decision makers, each of which processes a subset of the measurements, and a *fusion center,* which combines the outputs of the distributed decision makers to produce a global detection decision. The communication between the distributed decision makers and the fusion center is constrained, so that each local decision maker must reduce its subset of measurements to a summarizing local decision to be transmitted to the fusion center. Such structures arise in applications such as the testing of large-scale integrated circuits, in which data collection is decentralized, or in detection problems involving very large data sets, in which it is desirable to distribute the computational work of the detection algorithm. Such problems lie in the field of *distributed detection.* Except in some trivial special cases, the constraints imposed by distributing the detection algorithm introduce a further level of difficulty into the design of optimum detection systems. Nevertheless, considerable progress has been made on this problem, a survey of which can be found in Tsitsiklis [1993].

Another type of nonstandard information pattern that arises is that in which the number of measurements is potentially infinite, but in which there is a cost associated with taking each measurement. This type of model arises in applications such as the synchronization of wideband communication signals. In such situations, the error probabilities alone do not completely characterize the performance of a detection system, since consideration must also be given to the cost of sampling. The field of *sequential detection* deals with the optimization of detection systems within such constraints. In sequential detectors, the number of measurements taken becomes a random variable depending on the measurements themselves. A typical performance criterion for optimizing such a system is to seek a detector that minimizes the expected number of measurements for given levels of miss and false-alarm probabilities.

The most commonly used sequential detection procedure is the *sequential probability ratio test,* which operates by recursive comparison of the likelihood ratio (73.3) to two thresholds. In this detector, if the likelihood ratio for a given number of samples exceeds the larger of the two thresholds, then the signal's presence is announced and the test terminates. Alternatively, if the likelihood ratio falls below the smaller of the two thresholds, the signal's absence is announced and the test terminates. However, if neither of the two thresholds is crossed, then another measurement is taken and the test is repeated.

Detection with Continuous-Time Measurements

Note that all of the preceding formulations have involved the assumption of discrete-time (i.e., sampled-data) measurements. From a practical point of view, this is the most natural framework within which to consider these problems, since implementations most often involve digital hardware. However, the procedures discussed in this section all have continuous-time counterparts, which are of both theoretical and practical interest. Mathematically, continuous-time detection problems are more difficult than discrete-time ones, because they involve probabilistic analysis on function spaces. The theory of such problems is quite elegant, and the interested reader is referred to Poor [1994] or Grenander [1981] for more detailed exposition.

Continuous-time models are of primary interest in the front-end stages of radio frequency or optical communication receivers. At radio frequencies, continuous-time versions of the models described in the preceding paragraphs can be used. For example, one may consider the detection of signals in continuous-time Gaussian white noise. At optical wavelengths, one may consider either continuous models (such as Gaussian processes) or point-process models (such as Poisson counting processes), depending on the type of detection used (see, e.g., Snyder and Miller [1991]). In the most fundamental analyses of optical detection problems, it is sometimes desirable to consider the quantum mechanical nature of the measurements [Helstrom, 1976].

Defining Terms

Bayesian detector: A detector that minimizes the average of the false-alarm and miss probabilities, weighted with respect to prior probabilities of signal-absent and signal-present conditions.

Correlation detector: The optimum structure for detecting coherent signals in the presence of additive white Gaussian noise.

Discrete-time white Gaussian noise: Noise samples modeled as independent and identically distributed Gaussian random variables.

Envelope detector: The optimum structure for detecting a modulated sinusoid with random phase in the presence of additive white Gaussian noise.

False-alarm probability: The probability of falsely announcing the presence of a signal.

Likelihood ratio: The optimum processor for reducing a set of signal-detection measurements to a single number for subsequent threshold comparison.

Miss probability: The probability of falsely announcing the absence of a signal.

Neyman-Pearson detector: A detector that minimizes the miss probability within an upper-bound constraint on the false-alarm probability.

Quadratic detector: A detector that makes use of the second-order statistical structure (e.g., the spectral characteristics) of the measurements. The optimum structure for detecting a zero-mean Gaussian signal in the presence of additive Gaussian noise is of this form.

73.2 Noise

Carl G. Looney

Every information signal $s(t)$ is corrupted to some extent by the superimposition of extra-signal fluctuations that assume unpredictable values at each time instant t. Such undesirable signals were called **noise** due to early measurements with sensitive audio amplifiers.

Noise sources are (1) *intrinsic*, (2) *external*, or (3) *process induced*. Intrinsic noise in conductors comes from thermal agitation of molecularly bound ions and electrons, from microboundaries of impurities and grains with varying potential, and from transistor junction areas that become temporarily depleted of electrons/holes. External electromagnetic interference sources include airport radar, x-rays, power and telephone lines, communications transmissions, gasoline engines and electric motors, computers and other electronic devices; and also include lightning, cosmic rays, plasmas (charged particles) in space, and solar/stellar radiation (conductors act as antennas). Reflective objects and other macroboundaries cause multiple paths of signals. Process-induced errors include measurement, quantization, truncation, and signal generation errors. These also corrupt the signal with noise power and loss of resolution.

Statistics of Noise

Statistics allow us to analyze the spectra of noise. We model a noise signal by a **random** (or *stochastic*) **process** $N(t)$, a function whose realized value $N(t) = x_t$ at any time instant t is chosen by the outcome of the random variable $N_t = N(t)$. $N(t)$ has a probability distribution for the values x it can assume. Any particular trajectory $\{(t, x_t)\}$ of outcomes is called a **realization** of the noise process. The *first-order statistic* of $N(t)$ is the *expected value* $\mu_t = E[N(t)]$. The *second-order statistic* is the *autocorrelation function* $R_{NN}(t, t + \tau) = E[N(t)N(t + \tau)]$, where $E[-]$ is the expected value operator. **Autocorrelation** measures the extent to which noise random variables $N_1 = N(t_1)$ and $N_2 = N(t_2)$ at times t_1 and t_2 depend on each other in an average sense.

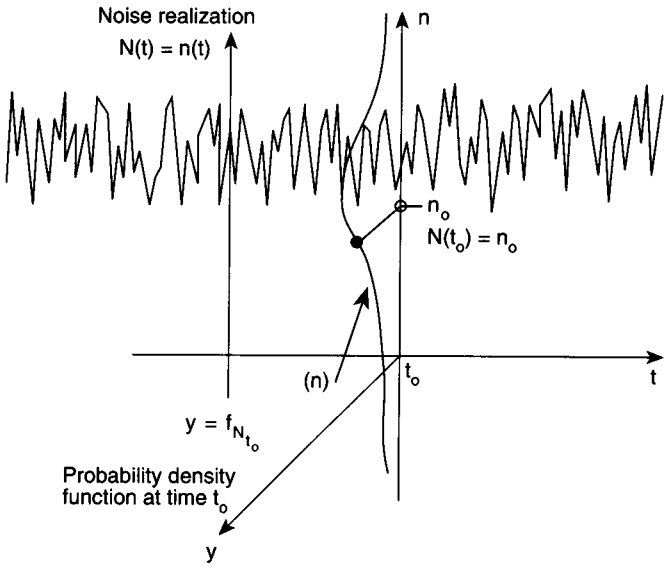

FIGURE 73.3 A noise process.

When the first- and second-order statistics do not change over time, we call the noise a **weakly** (or *wide-sense*) **stationary process**. This means that: (1) $E[N(t)] = \mu_t = \mu$ is constant for all t, and (2) $R_{NN}(t, t+\tau) = E[N(t)N(t+\tau)] = E[N(0)N(\tau)] = R_{NN}(\tau)$ for all t [see Brown, 1983, p. 82; Gardner, 1990, p. 108; or Peebles, 1987, p. 153 for properties of $R_{NN}(\tau)$]. In this case the autocorrelation function depends only on the *offset* τ. We assume hereafter that $\mu = 0$ (we can subtract μ, which does not change the autocorrelation). When $\tau = 0$, $R_{NN}(0) = E[N(t)N(t+0)] = E[(N(t))^2] = \sigma_N^2$, which is the fixed variance of each random variable N_t for all t. Weakly stationary (ws) processes are the most commonly encountered cases and are the ones considered here. *Evolutionary* processes have statistics that change over time and are difficult to analyze.

Figure 73.3 shows a realization of a noise process $N(t)$, where at any particular time t, the probability density function is shown coming out of the page in a third dimension. For a ws noise, the distributions are the same for each t. The most mathematically tractable noises are *Gaussian* ws processes, where at each time t the probability distribution for the random variable $N_t = N(t)$ is Gaussian (also called *normal*). The first- and second-order statistics completely determine Gaussian distributions, and so ws makes their statistics of all orders stationary over time also. It is well known [see Brown, 1983, p. 39] that linear transformations of Gaussian random variables are also Gaussian random variables. The probability density function for a Gaussian random variable N_t is $f_N(x) = \{1/[2\pi\sigma_N{}^2]^{1/2}\exp[-(x-\mu_N)^2/2\sigma_N^2]$, which is the familiar bell-shaped curve centered on $x = \mu_N$. The standard Gaussian probability table [Peebles, 1987, p. 314] is useful, e.g., $\Pr[-\sigma_N < N_t < \sigma_N) = 2\Pr[0 < N_t < \sigma_N) = 0.8413$ from the table.

Noise Power

The noise signal $N(t)$ represents voltage, so the autocorrelation function at offset 0, $R_{NN}(0) = E[N(t)N(t)]$ represents expected power in volts squared, or watts per ohm. When $R = 1\ \Omega$, then $N(t)N(t) = N(t)[N(t)/R] = N(t)I(t)$ volt-amperes = watts (where $I(t)$ is the current in a 1-Ω resistor). The Fourier transform $\mathbf{F}[R_{NN}(\tau)]$ of the autocorrelation function $R_{NN}(\tau)$ is the power spectrum, called the **power spectral density function** (psdf), $S_{NN}(w)$ in W/(rad/s). Then

$$S_{NN}(w) = \int_{-\infty}^{\infty} R_{NN}(\tau)e^{-jws}d\tau = \mathbf{F}[R_{NN}(\tau)]$$
$$R_{NN}(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} S_{NN}(w)e^{jws}dw = \mathbf{F}^{-1}[S_{NN}(w)] \tag{73.20}$$

The psdf at frequency f is defined to be the expected power that the voltage $N(t)$, bandlimited to an incremental band df centered at f, would dissipate in a 1-Ω resistance, divided by df.

Equations (73.20) are known as the *Wiener-Khinchin* relations that establish that $S_{NN}(w)$ and $R_{NN}(\tau)$ are a Fourier transform pair for ws random processes [Brown, 1983; Gardner, 1990, p. 230; Peebles, 1987]. The psdf $S_{NN}(w)$ has units of W/(rad/s), whereas the autocorrelation function $R_{NN}(\tau)$ has units of watts. When $\tau = 0$ in the second integral of Eq. (73.20), the exponential becomes $e^0 = 1$, so that $R_{NN}(0)$ $(= E[N(t)^2] = \sigma_N^2)$ is the integral of the psdf $S_{NN}(w)$ over all radian frequencies, $-\infty < w < \infty$. The rms (root-mean-square) voltage is $N_{\text{rms}} = \sigma_N$ (the *standard deviation*). The power spectrum in W/(rad/s) is a density that is summed up via an integral over the radian frequency band w_1 to w_2 to obtain the total power over that band.

$$P_{NN}(w_1, w_2) = \frac{1}{2\pi}\int_{w1}^{w2} S_{NN}(w)\cdot dw \quad \text{watts}$$
$$P_{NN} = \sigma_N^2 = E[N(t)^2] = \frac{1}{2\pi}\int_{-\infty}^{\infty} S_{NN}(w)\cdot dw \quad \text{watts} \tag{73.21}$$

The variance $\sigma_N^2 = R_{NN}(0)$ is the mean instantaneous power P_{NN} over all frequencies at any time t.

Effect of Linear Transformations on Autocorrelation and Power Spectral Density

Let $h(t)$ be the impulse response function of a time-invariant linear system L and $H(w) = \mathbf{F}[h(t)]$ be its transfer function. Let an input noise signal $N(t)$ have autocorrelation function $R_{NN}(\tau)$ and psdf $S_{NN}(w)$. We denote the output noise signal by $Y(t) = L[N(t)]$. The Fourier transforms $Y(w) \equiv \mathbf{F}[Y(t)]$ and $N(w) \equiv \mathbf{F}[N(t)]$ do not exist, but they are not needed. The output $Y(t)$ of a linear system is ws whenever the input $N(t)$ is ws [see Gardner, 1990, p. 195; or Peebles, 1987, p. 215]. The output psdf $S_{YY}(w)$ and autocorrelation function $R_{YY}(\tau)$ are given by, respectively,

$$S_{YY}(w) = |H(w)|^2 S_{NN}(w),\ R_{YY}(\tau) = \mathrm{F}^{-1}[S_{YY}(w)] \tag{73.22}$$

[see Gardner, 1990, p. 223]. The output noise power is

$$\sigma_Y^2 = P_{YY} = \frac{1}{2\pi}\int_{-\infty}^{\infty} S_{YY}(w)dw = \frac{1}{2\pi}\int_{-\infty}^{\infty} |H(w)|^2 S_{NN}(w)dw \tag{73.23}$$

White, Gaussian, and Pink Noise Models

White noise [see Brown, 1983; Gardner, 1990, p. 234; or Peebles, 1987] is a theoretical model $W(t)$ of noise that is ws with zero mean. It has a constant power level n_o over all frequencies (analogous to white light), so its psdf is $S_{WW}(w) = n_o$ W/(rad/s), $-\infty < w < \infty$. The inverse Fourier transform of this is the impulse function $R_{WW}(\tau) = (n_o)\delta(\tau)$, which is zero for all offsets except $\tau = 0$. Therefore, white noise $W(t)$ is a process that is uncorrelated over time, i.e., $E[W(t_1)W(t_2)] = 0$ for t_1 not equal to t_2. Figure 73.4(a) shows the autocorrelation and psdf for white noise where the offset is $s = \tau$. A *Gaussian white noise* is white noise such that the probability distribution of each random variable $W_t = W(t)$ is Gaussian. When two Gaussian random variables W_1 and W_2 are *uncorrelated*, i.e., $E[W_1W_2] = 0$, they are independent [see Gardner, 1990, p. 37]. We use Gaussian models because of the *central limit theorem* that states that the sum of a number of random variables is approximately Gaussian.

Actual circuits attenuate signals above cut-off frequencies, and also the power must be finite. However, for white noise, $P_{WW} = R_{NN}(0) = \infty$, so we often truncate the white noise spectral density (psdf) at cut-offs $-w_c$ to w_c. The result is known as *pink noise*, $P(t)$, and is usually taken to be Gaussian because linear filtering of any white noise (through the effect of the central limit theorem) tends to make the noise Gaussian [see Gardner,

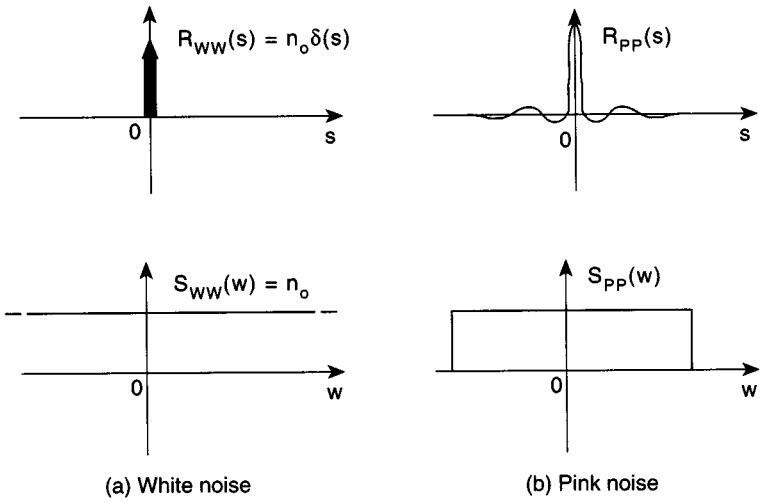

FIGURE 73.4 Power transform pairs for white and pink noise.

Figure 73.5 not available

FIGURE 73.5 Thermal noise in a resistor.

1990, p. 241]. Figure 73.4(b) shows the sinc function $R_{PP}(s) = \mathrm{F}^{-1}[S_{PP}(w)]$ for pink noise. Random variables P_1 and P_2 at times t_1 and t_2 are correlated only for t_1 and t_2 close.

Thermal Noise as Gaussian White Noise

Brown observed in 1828 that pollen and dust particles moved randomly when suspended in liquid. In 1906, Einstein analyzed such motion based on the random walk model. Perrin confirmed in 1908 that the thermal activity of molecules in a liquid caused irregular bombardment of the much larger particles. It was predicted that charges bound to thermally vibrating molecules would generate electromotive force (emf) at the open terminals of a conductor, and that this placed a limit on the sensitivity of galvanometers. Thermal noise (also called *Johnson noise*) was first observed by J. B. Johnson at Bell Laboratories in 1927. Figure 73.5 displays white noise as seen in the laboratory on an oscilloscope.

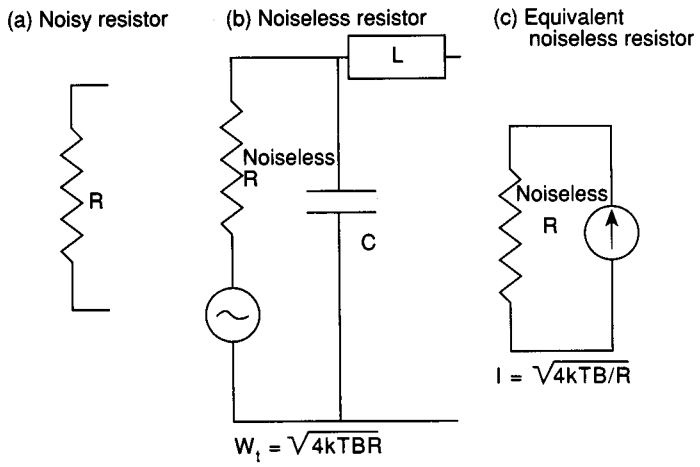

FIGURE 73.6 Thermal noise in a resistor.

The voltage $N(t)$ generated thermally between two points in an open circuit conductor is the sum of an extremely large number of superimposed, independent electronically and ionically induced microvoltages at all frequencies up to f_c = 6,000 GHz at room temperature [see Gardner 1990, p. 235], near infrared. The mean relaxation time of free electrons is $1/f_c = 0.5 \times 10^{-10}/T$ s, so at room temperature of T = 290K, it is 0.17 ps (1 picosecond = 10^{-12} s). The values of $N(t)$ at different times are uncorrelated for time differences (offsets) greater than $\tau_c = 1/f_c$. The expected value of $N(t)$ is zero. The power is fairly constant across a broad spectrum, and we cannot sample signals at picosecond periods, so we model Johnson noise $N(t)$ with Gaussian white noise $W(t)$. Although $\mu = E[W(t)] = 0$, the average power is positive at temperatures above 0K, and is $\sigma_W^2 = R_{WW}(0)$ [see the right side of Eq. (73.21)]. A disadvantage of the white noise model is its infinite power, i.e., $R_{WW}(0) = \sigma_W^2 = \infty$, but it is valid over a limited bandwidth of B Hz, in which case its power is finite.

In 1927, Nyquist [1928] theoretically derived thermal noise power in a resistor to be

$$P_{WW}(B) = 4kTRB \text{ (watts)} \tag{73.24}$$

where R is resistance (ohms), B is the frequency bandwidth of measurement in Hz (all emf fluctuations outside of B are ignored), $P_{WW}(B)$ is the mean power over B (see Eq. 73.21), and Boltzmann's constant is $k = 1.38 \times 10^{-23}$ J/K [see Ott, 1988; Gardner, 1990, p. 288; or Peebles, 1987, p. 227]. Under external emf, the thermally induced collisions are the main source of resistance in conductors (electrons pulled into motion by an external emf at 0K meet no resistance). The rms voltage is $W_{\text{rms}} = \sigma_W = [(4kTRB)]^{1/2}$ V over a bandwidth of B Hz.

Planck's radiation law is $S_{NN}(w) = (2h|f|)/[\exp(h|f|/kT) - 1]$, where $h = 6.63 \times 10^{-34}$ J/s is Planck's constant, and f is the frequency [see Gardner, 1990, p. 234]. For $|f|$ much smaller than $kT/h = 6.04 \times 10^{12}$ Hz $\approx$ 6,000 GHz, the exponential above can be approximated by $\exp(\text{h}|f|/\text{kT}) = 1 + \text{h}|f|/\text{kT}$. The denominator of $S_{NN}(w)$ becomes $h|f|/kT$, so $S_{NN}(w) = (2h|f|)/(h|f|/kT) = 2kT$ W/Hz in a 1-Ω resistor. Over a resistance of R Ω and a bandwidth of B Hz (positive frequencies), this yields the total power $P_{WW}(B) = 2BRS_{NN}(w) = 4kTRB$ W over the two-sided frequency spectrum. This is Nyquist's result.

Thermal noise is the same in a 1000-Ω carbon resistor as it is in a 1000-Ω tantalum thin-film resistor [see Ott, 1988]. While the intrinsic noise may never be less, it may be higher because of other superimposed noise (described in later sections). We model the thermal noise in a resistor by an internal source (generator), as shown in Fig. 73.6. Capacitance cannot be ignored at high f, but pure reactance (C or L) cannot dissipate energy, and so cannot generate thermal noise. The white noise model $W(t)$ for thermal noise $N(t)$ has a constant psdf $S_{WW}(w) = n_o$ W/(rad/s) for $-\infty < w < \infty$. By Eq. 73.21, the white noise mean power over the frequency bandwidth B is

$$P_{WW}(B) = \frac{1}{2\pi}\int_{-2\pi B}^{2\pi B} S_{WW}(w)dw = n_o(4\pi B/2\pi) = 2n_oB \tag{73.25}$$

Solving for the constant n_o, we obtain $n_o = P_{WW}(B)/2B$, which we put into Eq. (73.20) to get the spectral density as a function of temperature and resistance using Nyquist's result above.

$$S_{WW}(w) = n_o = P_{WW}(B)/4\pi B = 4kTR2\pi B/4\pi B = 2kTR \text{ watts/(rad/s)} \qquad (73.26)$$

Some Examples

The parasitic capacitance in the terminals of a resistor may cause a roll-off of about 20 dB/octave in actual resistors [Brown, 1983, p. 139]. At 290K (room temperature), we have $2kT = 2 \times 1.38 \times 10^{-23} \times 290 = 0.8 \times 10^{-20}$ W/Hz due to each ohm [see Ott, 1988]. For $R = 1$ MΩ (10^6 Ω), $S_{WW}(w) = 0.8 \times 10^{-14}$. Over a band of 10^8 Hz, we have $P_{WW}(B) = S_{WW}(w)B = 0.8 \times 10^{-14} \times 10^8 = 0.8 \times 10^{-6}$ W = 0.8 μW by Eqs. (73.24) and (73.26). In practice, parasitic capacitance causes thermal noise to be bandlimited (pink noise). Now consider Fig. 73.6(b) and let the temperature be 300K, $R = 10^6$ Ω, $C = 1$ pf (1 picofarad = 10^{-12} farads), and assume L is 0H. By Eq. (73.26), the thermal noise power is

$$S_{WW}(w) = 2kTR = 2 \times 1.38 \times 10^{-23} \times 300 \times 10^6 = 828 \times 10^{-17} \text{ W/Hz}$$

The power across a bandwidth $B = 10^6$ is $P_{WW}(B) = S_{WW}(w)B = 8280 \times 10^{-12}$ W, so the rms voltage is $W_{\text{rms}} = [P_{WW}(B)]^{1/2} = 91$ μV.

Now let $Y(t)$ be the output voltage across the capacitor. The transfer function can be seen to be $H(w) = \{I(w)(1/jwC)\}/\{I(w)[R + (1/jwC)]\} = (1/jwC)/[R + 1/jwC] = 1/[1 + jwRC]$ (where $I(w)$ is the Fourier transform of the current). The output psdf [see Eq. (73.22)] is

$$S_{YY}(w) = |H(w)|^2 S_{WW}(w) = (1/[1 + w^2R^2C^2])S_{WW}(w)$$

Integrating $S_{YY}(w) = (1/[1 + w^2R^2C^2])S_{WW}(w)$ over all radian frequencies $w = 2\pi f$ [see Eq. (73.21)], we obtain the antiderivative $(828 \times 10^{-17})(1/RC)\text{atan}(RCw)/2\pi$. Upon substituting the limits $w = \pm\infty$, this becomes $828 \times 10^{-17}[\pi/2 + \pi/2]/2\pi RC = 414 \times 10^{-17}(1/2\text{RC}) = 207 \times 10^{-17} \times 10^6 = 2070 \times 10^{-12}$ W/Hz. Then $\sigma_Y^2 = E[Y(t)^2] = P_{YY}(-\infty,\infty) = 2070 \times 10^{-12}$ W, so $Y_{\text{rms}}(\text{t}) = \sigma_Y = [P_{YY}(-\infty,\infty)]^{1/2} = 45.5$ μV. The half-power (cut-off) radian frequency is $w_c = 1/RC = 10^6$ rad/s, or $f_c = w_c/2\pi = 159.2$ kHz. Approximating $S_{YY}(w)$ by the rectangular spectrum $S_{YY}(w) = n_o, -10^6 < w < 10^6$ rad/s (0 elsewhere), we have that $R_{YY}(\tau) = (w_c/\pi)\text{sinc}(w_c\tau)$, which has the first zeros at $|w_c\tau| = \pi$, that is $|\tau| = 1/(2f_c)$ [see Fig. 73.4(b)]. We approximate the autocorrelation by $R_{YY}(\tau) = 0$ for $|s| \geq 1/2f_c$.

Measuring Thermal Noise

In Fig. 73.7, the thermal noise from a noisy resistor R is to be measured, where R_L is the measurement load. The incremental noise power in R over an incremental frequency band of width df is $P_{WW}(df) = 4kTRdf$ W, by Eq. (73.24). $P_{YY}(df)$ is the integral of $S_{YY}(w)$ over df by Eqs. (73.21), where $S_{YY}(w) = |H(w)|^2 S_{WW}(w)$, by Eq. (73.22). In this case, the transfer function $H(w)$ is nonreactive and does not depend upon the radian frequency (we can factor it out of the integral). Thus,

$$P_{YY}(df) = \int_{-df}^{df} |H(f)|^2 \, (2kTR)df = \{R_L/(R + R_L)^2\}(4kTRdf)$$

To maximize the power measured, let $R_L = R$. The *incremental available power* measured is then $P_{YY}(df) = 4kTR^2df/(4R^2) = kTdf$ [see Ott, 1988, p. 201; Gardner, 1990, p. 288; or Peebles, 1987, p. 227]. Thus, we have the result that incremental available power over bandwidth df depends only on the temperature T.

$$P_{YY}(df) = kTdf \qquad (\text{output power over } df) \qquad (73.27)$$

Albert Einstein used statistical mechanics in 1906 to postulate that the mean kinetic energy per degree of freedom of a particle, $(1/2)mE[v^2(t)]$, is equal to $(1/2)kT$, where m is the mass of the particle, $v(t)$ is its

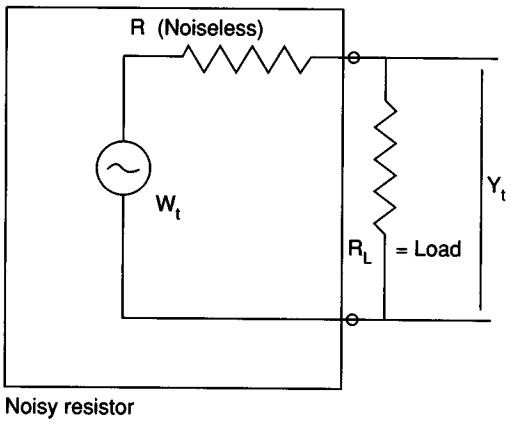

FIGURE 73.7 Measuring thermal noise voltage.

instantaneous velocity in a single dimension, k is Boltzmann's constant, and T is the temperature in kelvin. A shunt capacitor C is charged by the thermal noise in the resistor [see Fig. 73.6(b), where L is taken to be zero]. The average potential energy stored is $(1/2)CE[W(t)^2]$. Equating this to $1/2kT$ and solving, we obtain the mean square power

$$E[W(t)^2] = kT/C \tag{73.28}$$

For example, let $T = 300$K and $C = 50$ pf, and recall that $k = 1.38 \times 10^{-23}$ J/K. Then $E[W(t)^2] = kT/C = 82.8 \times 10^{-12}$, so that the input rms voltage is $\{E[W(t)^2]\}^{1/2} = 9.09$ μV.

Effective Noise and Antenna Noise

Let two series resistors R_1 and R_2 have respective temperatures of T_1 and T_2. The total noise power over an incremental frequency band df is $P_{\text{Total}}(df) = P_{11}(df) + P_{22}(df) = 4kT_1R_1\,df + 4kT_2R_2\,df = 4k(T_1R_1 + T_2R_2)df$. By putting

$$T_E = (T_1R_1 + T_2R_2)/(R_1 + R_2) \tag{73.29}$$

we can write $P_{\text{Total}}(df) = 4kT_E(R_1 + R_2)df$. T_E is called the *effective noise temperature* [see Gardner, 1990, p. 289; or Peebles, 1987, p. 228]. An antenna receives noise from various sources of electromagnetic radiation, such as radio transmissions and harmonics, switching equipment (such as computers, electrical motor controllers), thermal (blackbody) radiation of the atmosphere and other matter, solar radiation, stellar radiation, and galaxial radiation (the ambient noise of the universe). To account for noise at the antenna output, we model the noise with an equivalent thermal noise using an effective noise temperature T_E. The incremental available power (output) over an incremental frequency band df is $P_{YY}(df) = kT_E\,df$, from Eq. (73.27). T_E is often called *antenna temperature*, denoted by T_A. Although it varies with the frequency band, it is usually virtually constant over a small bandwidth.

Noise Factor and Noise Ratio

In reference to Fig. 73.8(a), we define the *noise factor* F = (*noise power output of actual device*)/(*noise power output of ideal device*), where (noise power output of ideal device) = (power output due to thermal noise source). The noise source is taken to be a noisy resistor R at a temperature T, and all output noise measurements must be taken over a resistive load R_L (reactance is ignored). Letting $P_{WW}(B) = 4kTRB$ be the open circuit thermal noise power of the source resistor over a frequency bandwidth B, and noting that the gain of the device is G, the output power due to the resistive noise source becomes $G^2P_{WW}(B) = 4kTRBG^2/R_L$. Now let $Y(t)$ be the output voltage measured at the output across R_L. Then the noise factor is

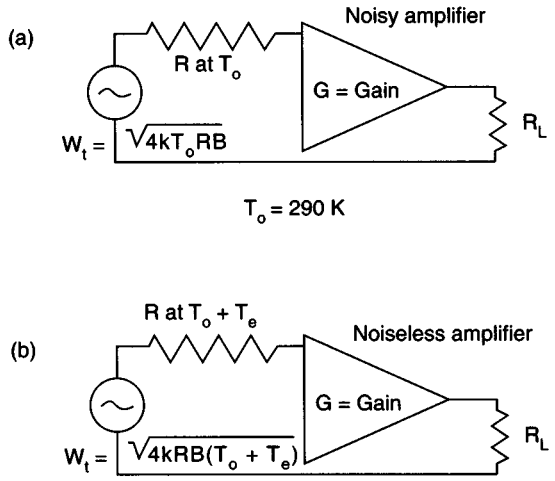

FIGURE 73.8 Equivalent input noise and noise factor.

$$F = (P_{YY}(B)/R_L)/(G^2P_{WW}(B)/R_L) = (P_{YY}(B))/(4kTRBG^2) \tag{73.30}$$

F is seen to be independent of R_L, but not R. To compare two noise factors, the same source must be used. In the ideal noiseless case, $F = 1$, but as the noise level in the device increases, F increases. Because this is a power ratio, we may take the logarithm, called the *noise ratio*, which is

$$N_F = 10\log_{10}(F) = 10\log_{10}(P_{YY}(B)) - 10\log_{10}(4kTRBG^2) \tag{73.31}$$

The noise power output $P_{YY}(B)$ of an actual device is a superposition of the amplified source thermal noise $G^2P_{WW}(B)$ and the device noise, i.e., $P_{YY}(B) = G^2P_{WW}(B)$ + (device noise). The output noise across R_L can be measured by putting a single frequency (in the passband) source generator $S(t)$ as input. First, $S(t)$ is turned off, and the output rms voltage $Y(t)$ is measured and the output power $P_{Y(W)}(B)$ is recorded. This is the sum of the thermal available power and the device noise. Next, $S(t)$ is turned on and adjusted until the output power doubles, i.e., until the output power $P_{Y(W)}(B) + P_{Y(S)}(B) = 2P_{Y(W)}(B)$. This $P_{SS}(B)$ is recorded. Solving for $P_{Y(S)}(B) = P_{Y(W)}(B)$, we substitute this in $F = P_{Y(W)}(B)/(G^2P_{WW}(B))$ to obtain

$$F = P_{Y(S)}(B)/(G^2 \cdot P_{WW}(B)) = (G^2P_{SS}(B))/(G^24kTRB) = P_{SS}(B)/4kTRB \tag{73.32}$$

A better way is to input white noise $W(t)$ in place of $S(t)$ (a noise diode may be used). The disadvantages of noise factors are (1) when the device has low noise relative to thermal noise, the noise factor has value close to 1; (2) a low resistance causes high values; and (3) increasing the source resistance decreases the noise factor while increasing the total noise in the circuit [Ott, 1988, p. 216]. Thus, accuracy is not good. For cascaded devices, the noise factors can be conveniently computed [see Buckingham, 1985, p. 67; or Ott, 1988, p. 228].

Equivalent Input Noise

Shot noise (see below) and other noise can be modeled by equivalent thermal noise that would be generated in an input resistor by increased temperature. Recall that the (maximum) incremental available power (output) in a frequency bandwidth df is $P_{WW}(df) = kTdf$ from Eq. (73.27). Figure 73.8(b) presents the situation. Let the resistor be the noise source at temperature T_o with thermal noise $W(t)$. Then $E[W(t)^2] = 4kT_oRdf$, by Eq. (73.24) (Nyquist's result). Let the open circuit output noise power at R_L be $E[Y(t)^2]$. The incremental available noise power $P_{YY}(df)$ at the output ($R_L = R$) can be considered to be due to the resistor R having a higher temperature and an ideal (noiseless) device, usually an amplifier. We must find a temperature T_e at which a pseudothermal

noise power $E[W_e(t)^2] = 4kT_eRdf$ yields the extra "input" noise power. Let $V(t) = W(t) + W_e(t)$. Then $P_{VV}(df) = 4kT_oRdf + 4kT_eRdf = 4k(T_o + T_e)Rdf$ W, from Eq. (73.24). T_e is called the *equivalent input noise temperature*. It is related to the noise factor F by $T_e = 290(F - 1)$. In cascaded amplifiers with gains $G_1, G_2, \ldots$ and equivalent input noise temperatures $T_{e1}, T_{e2}, \ldots$, the total equivalent input noise temperature is

$$T_{e(\text{Total})} = T_{e1} + T_{e2}/G_1 + T_{e3}/G_1G_2 + \ldots \tag{73.33}$$

[see Gardner, 1990, p. 289].

Other Electrical Noise

Thermal noise and shot noise (which can be modeled by thermal noise with equivalent input noise) are the main noise sources. Other noises are discussed in the following paragraphs.

Shot Noise

In a conductor under an external emf, there is an average flow of electrons, holes, photons, etc. In addition to this induced net flow and thermal noise, there is another effect. The potential differs across the boundaries of metallic grains and particles of impurities, and when the kinetic energy of electrons exceeds this potential, electrons jump across the barrier. This summed random flow is known as *shot noise* [see Gardner, 1990, p. 239; Ott, 1988, p. 208]. The shot effect was analyzed by Schottky in 1918 as $I_{\text{sh}} = (2qI_{\text{dc}}B)^{1/2}$, where $q = 1.6 \times 10^{-19}$ coulombs per electron, I_{dc} = average dc current in amperes, and B = noise bandwidth (Hz).

Partition Noise

Partition noise is caused by a parting of the flow of electrons to different electrodes into streams of randomly varying density. Suppose that electrons from some source S flow to destination electrodes A and B. Let $n(A)$ and $n(B)$ be the average numbers of electrons per second that go to nodes A and B respectively, so that $n(S) = n(A) + n(B)$ is the average total number of electrons emitted per second. It is a success when an electron goes to A, and the probability of success on a single trial is p, where

$$p = n(A)/n(S),\ 1 - p = n(B)/n(S) \tag{73.34}$$

The current to the respective destinations is $I(A) = n(A)q$, $I(B) = n(B)q$, where q is the charge of an electron, so that $I(A)/I(S) = p$ and $I(B)/I(S) = 1 - p$. Using the binomial model, the average numbers of successes are $E[n(A)] = n(S)p$ and $E[n(B)] = n(S)(1 - p)$. The variance is $\text{Var}(n(A)) = n(S)p(1 - p) = \text{Var}(n(B))$ (from the binomial formula for variance). Therefore, substitution yields

$$\text{Var}(I(A)) = q^2[n(S)p(1 - p)] = q^2n(S)\{I(A)I(B)/[I(A) + I(B)]\} \tag{73.35}$$

Partition noise applies to pentodes, where the source is the cathode, A is the anode (success), and B is the grid. For transistors, the source is the emitter, A is the collector, and B represents recombination in the base. In photo devices, a photoelectron is absorbed, and either an electron is emitted (a success) or not. Even a partially silvered mirror can be considered to be a partitioner: the passing of a photon is a success and reflection is a failure. While the binomial model applies to partitions with destinations A and B, multinomial models are analogous for more than two destinations.

Flicker, Contact, and Burst Noise

J.B. Johnson first noticed in 1925 that noise across thermionic gates exceeded the expected shot noise at lower frequencies. It is most noticeable up to about 2 kHz. The psdf of the extra noise, called *flicker noise*, is

$$S(f) = I^2/\alpha f,\ f > 0 \tag{73.36}$$

where I is the dc current flowing through the device and f is the positive frequency. Empirical values of α are about 1 to 1.6 for different sources. These sources vary but include the irregularity of the size of macro regions

of the cathode surface, impurities in the conducting channel, and generation and recombination noise in transistors. In the early days of transistors, this generation-recombination was of great concern because the materials were not of high purity. Flicker noise occurs in thin layers of metallic or semiconducting material, solid state devices, carbon resistors, and vacuum tubes [see Buckingham, 1985, p. 143]. It includes *contact noise* because it is caused by fluctuating conductivity due to imperfect contact between two surfaces, especially in switches and relays. Flicker noise may be high at low frequencies.

Burst noise is also called *popcorn noise:* audio amplifiers sound like popcorn popping in a frying pan background (thermal noise). Its characteristic is $1/f^n$ (usually $n = 2$), so its power density falls off rapidly, where f is frequency. It may be problematic at low frequencies. The cause is manufacturing defects in the junction of transistors (usually a metallic impurity).

Barkhousen and Other Noise

Barkhousen noise is due to the variations in size and orientation of small regions of ferromagnetic material and is especially noticeable in the steeply rising region of the hysteresis loop. There is also secondary emission, photo and collision ionization, etc.

Measurement and Quantization Noise

Measurement Error

The measurement X_t of a signal $X(t)$ at any t results in a measured value $X_t = x$ that contains error, and so is not equal to the true value $X_t = x_T$. The probability is higher that the magnitude of $e = (x - x_T)$ is closer to zero. The bell-shaped Gaussian probability density $f(e) = [1/(2\pi\sigma^2]^{1/2}\exp(-e^2/2\pi\sigma)$ fits the error well. This noise process is stationary over time. The expected value is $\mu_e = 0$, the mean-square error is σ_e^2, and the rms error is σ_e. Its instantaneous power at time t is σ_e^2. To see this, the error signal $e(t) = (x - x_T)$ has instantaneous power per Ω of

$$P_i = e(t)\,i(t) = e(t)[\,e(t)/R] = e^2(t) \tag{73.37}$$

where $R = 1\ \Omega$ and $i(t)$ is the current. The average power is the summed instantaneous power over a period of time T, divided by the time, taken in the limit as $T \to \infty$, i.e.,

$$P_{\text{ave}} = \lim_{T\to\infty}(1/T)\int_0^T e^2(t)dt$$

This average power can be determined by sampling on known signal values and then computing the sample variance (assuming ergodicity: see Gardner [1990, p. 163]). The error and signal are probabilistically independent (unless the error depends on the values of X). The signal-to-noise power ratio is computed by $S/N = P_{\text{signal}}/P_{\text{ave}}$.

Quantization Noise

Quantization noise is due to the digitization of an exact signal value $v_t = v(t)$ captured at sampling time t by an A/D converter. The binary representation is $b_{n-1}b_{n-2}\ldots b_1b_0$ (an n-bit word). The n-bit digitization has 2^n different values possible, from 0 to 2^n–1. Let the voltage range be R. The *resolution* is $dv = R/2^n$. Any voltage v_t is coded into the nearest lower binary value x_b, where the error $e = x_t - x_b$ satisfies $0 \le e \le dv$. Thus, the errors e are distributed over the interval $[0, dv]$ in an equally likely fashion that implies the uniform distribution on $[0, dv]$. The expected value of $e = e_t = e(t)$ at any time is $\mu_e = dv/2$, and the variance is $\mu_e^2 = dv^2/12$ (the variance of a uniform distribution on an interval $[a,b]$ is $\sigma = (b - a)^2/12$). Thus the noise is ws and the power of quantization noise is

$$\begin{aligned}\sigma_e^2 &= \int_0^{dv}(e - dv/2)^2(1/dv)de \\ &= (e - dv/2)^3/3dv\,\Big|_0^{dv} = [(dv)^3 + (dv)^3]/24dv = dv^2/12\end{aligned} \tag{73.38}$$

We can find the signal-to-noise voltage ratio for the total range R via $R/(dv/(12)^{1/2}) = 2^n dv/(dv/(12)^{1/2}) = 2^n(12)^{1/2}$. The power ratio is the square of this, which is $(2^{2n})(12)$. In decibels this becomes $(S/N)_{\text{dB}} = 10\log_{10}(2^{2n}\cdot 12) = 10\log_{10}(12) + 20n\log_{10}(2) = 10.8 + 6.02n$. Thus, quantization S/N power ratio depends directly upon the number of bits n in that the higher S/N power ratio is better, just as we would have expected.

Coping with Noise

External interference is ubiquitous. Intrinsic noise is present up to the incremental available power at temperatures above absolute zero, and other intrinsic noises depend on material purity and connection integrity. Processing error is always introduced in some form.

External Sources

Standard defenses are (1) shielding of lines and circuits, (2) twisted wire pairs or coaxial cables, (3) short lines and leads, (4) digital regeneration at waypoints of digital signals, (5) narrowband signals, (6) correlation of received signals with multipaths, and (7) adaptive notch filtering to eliminate interference at known frequencies; e.g., the second harmonic of 60-Hz ac power lines may interfere with biological microvoltage measurements but could be eliminated via adaptive notch filtering. Ferrite beads can dampen interference [Barnes, 1987]. Digital signal processing, spectral shaping filters [see Brown, 1983], and frequency-shift filters [see Gardner, 1990, p. 400] can be used to lower noise power. Kalman filtering is a powerful estimation method, and frequency-shift filtering is a newer technique for discriminating against both measurement error (e.g., in system identification applications) and extrinsic sources of both noise and interference [Gardner, 1990, p. 400].

Intrinsic Sources

Strategies for minimizing intrinsic noise are (a) small bandwidth B, (b) small resistances R, (c) low temperature T (higher temperatures can be devastating), (d) low voltage and currents (CMOS transistors), (e) modern materials of high purity, (f) wrapped wire resistors (thermal noise is the same, but other noise will be less), (g) fewer and better connections (of gold), (h) smaller circuits of lower power, and (i) shunt capacitors to reduce noise bandwidth. Greater purity of integrated circuit materials nowadays essentially reduces intrinsic noise to thermal noise. Better design and materials are the keys to lower noise.

Processing Sources

Processing errors can be reduced by using higher resolution of analog-to-digital converters, i.e., more bits to represent each value. This lowers the quantization error power. Measurement error can be reduced while using the same instruments by taking multiple measurements and averaging. Other estimation/correlation can yield better values (e.g., the Global Positioning System location determination can be reduced from meters to a few centimeters by multiple measurement estimation).

Defining Terms

Autocorrelation: A function associated with a random signal $X(t)$ that is defined on pairs of time instants t_1 and t_2 and whose value is the expected value of the product of the random variables $X(t_1)$ and $X(t_2)$, i.e., $R_{XX}(t_1,t_2) = E[X(t_1)X(t_2)]$. For weakly stationary random signals, it depends only on the offset $\tau = t_2 - t_1$, so we write $R_{XX}(\tau) = E[X(t)X(t+\tau)]$.

Noise: A signal $N(t)$ whose value at any time t is randomly selected by events beyond our control. At any time instant t, $N(t)$ is a random variable N_t with a probability distribution that determines the relative frequencies at which N_t assumes values. The statistics of the family of random variables $\{N_t\}$ may be constant (stationary) over time (the usual case) or may vary.

Power spectral density: The Fourier transform of the power $X^2(t)$ does not necessarily exist, but it does for $X_T^2(t)/2T$ ($X_T(t) = 0$ for $|t| > T$, $= X(t)$ elsewhere), for any $T > 0$. Letting $T \to \infty$, the expected value of the Fourier transforms $E[\mathrm{F}[X_T^2(t)/2T] = \mathrm{F}[E[X_T^2(t)]/2T$ goes to the limit of the average power in $X(t)$ over $-T$ to T, known as the power spectral density function $S_{xx\,(w)}$. Summed up over all frequencies, it gives the total power in the signal $X(t)$.

Random process: (signal): A signal that is either a noise, an interfering signal $s(t)$, or a sum of these such as $X(t) = s_1(t) + \ldots + s_m(t) + N_1(t) + \ldots + N_n(t)$.

Realization: A trajectory $\{(t, x_t)\colon X(t) = x_t\}$ determined by the actual outcomes $\{x_t\}$ of values from a random signal $X(t)$, where $X(t) = x_t$ at each instant t. A trajectory is also called a *sample function* of $X(t)$.

Weakly stationary (ws) random process (signal): A random signal whose first- and second-order statistics remain stationary (fixed) over time.

73.3 Stochastic Processes

Carl G. Looney

Introduction to Random Variables

A *random variable* (rv) A is specified by its *probability density function* (pdf)

$$f_A(a) = \lim_{\varepsilon\to 0}\ (1/\varepsilon)P[a - (\varepsilon/2) < A \le a + (\varepsilon/2)]$$

In other words, the rectangular area $\varepsilon \cdot f_A(a)$ approximates the probability $P[(A \le a + (\varepsilon/2)] - P[a - (\varepsilon/2) < A]$. The joint pdf of two rv's A and B is specified by

$$f_{AB}(a,b) = \lim_{\varepsilon\to 0}\ (1/\varepsilon^2)P[\,a - \varepsilon < A \le a + (\varepsilon/2) \text{ and } b - \varepsilon < B \le b + (\varepsilon/2)]$$

A similar definition holds for any finite number of rv's.

The *expected value* $E[A]$, or *mean* μ_A, of a rv A is the first moment of the pdf, and the *variance* of A is the second centralized moment, defined respectively by

$$\mu_A = E[A] \equiv \int_{-\infty}^{\infty} a f_A(a)da \tag{73.39a}$$

$$\sigma_A^2 = E[(A-\mu_A)^2] \equiv \int_{-\infty}^{\infty} (a-\mu_A)^2 f_A(a)da \tag{73.39b}$$

The square root of the variance is the *standard deviation*, which is also called the *root mean square* (rms) error. The *covariance* of two rv's A and B is the second-order centralized joint moment

$$\sigma_{AB} = E[(A-\mu_A)(B-\mu_B)] \equiv \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} (a-\mu_A)(b-\mu_B) f_{AB}(a,b)dadb \tag{73.40}$$

The noncentralized second moments are the *mean-square value* and the *correlation*, respectively,

$$E[A^2] = \int_{-\infty}^{\infty} a^2 f_A(a)da = \sigma_A^2 + \mu_A^2, \quad E[AB] = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} abf_{AB}(a,b)dadb = \sigma_{AB} + \mu_A\mu_B$$

A set of rv's A, B, and C is defined to be *independent* whenever their joint pdf factors as

$$f_{ABC}(a,b,c) = f_A(a)f_B(b)f_C(c) \tag{73.41}$$

for all a, b, and c, and similarly for any finite set of rv's. A *weak independence* holds when the second moment of the joint pdf, the correlation, factors as $E[AB] = E[A]E[B]$, so that $\sigma_{AB} = 0$, in which case the rv's are said to be *uncorrelated*. The covariance of A and B is a measure of how often A and B vary together (have the same sign), how often they vary oppositely (different signs), and by how much, on the average over trials of outcomes. To standardize so that units do not influence the measure of dependence, we use the *correlation coefficient*

$$\rho_{AB} \equiv \sigma_{AB}/\sigma_A\sigma_B$$

The accuracy of approximating a rv A as a linear function of another rv B, $A \approx cB + d$, for real coefficients c and d, is found by minimizing the mean-square error $\varepsilon = E\{[A - (cB + d)]^2\}$. Upon squaring and taking the expected values, we can obtain $\varepsilon_{\min} = \sigma_A^2(1 - |\rho_{AB}|^2)$, which shows $|\rho_{AB}|$ to be a measure of the degree of linear relationship between A and B. Because $\varepsilon_{\min} \geq 0$, this shows that $|\rho_{AB}| \leq 1$, which demonstrates the Cauchy-Schwarz inequality

$$|E[AB]| \leq \{E[A^2]E[B^2]\}^{1/2} \tag{73.42}$$

When $|\rho_{AB}| = 1$, then knowledge of one of A or B completely determines the other ($c \neq 0$), and so A and B are completely dependent, while $|\rho_{AB}| = 0$ indicates there is no linear relationship, i.e., that A and B are uncorrelated.

An important result is the *fundamental theorem of expectation*: if $g(\cdot)$ is any real function, then the expected value of the rv $B = g(A)$ is given by

$$E[B] = E[g(A)] = \int_{-\infty}^{\infty} g(a)f_A(a)da \tag{73.43}$$

Stochastic Processes

A **stochastic** (or *random*) **process** is a collection of random variables $\{X_t : t \in T\}$, indexed on an ordered set T that is usually a subset of the real numbers or integers. Examples are the Dow-Jones averages $D(t)$ at each time t, the pressure $R(x)$ in a pipe at distance x, or a noise voltage $N(t)$ at time t. A process is thus a *random function* $X(t)$ of t whose value at each t is drawn randomly from a range of outcomes for the rv $X_t = X(t)$ according to a probability distribution for X_t. A trajectory $\{x_t : t \in T\}$ of outcomes over all $t \in T$, where $X_t = x_t$ is the realized value at each t, is called a **sample function** (or *realization*) of the process. A stochastic process $X(t)$ has mean

TABLE 73.1 Continuous/Discrete Classification of Stochastic Processes

	X Values	
T Values	Continuous	Discrete
Continuous	Continuous stochastic processes	Discrete valued stochastic processes
Discrete	Continuous random sequences	Discrete valued random sequences

value $E[X(t)] = \mu(t)$ at time t, and **autocorrelation function** $R_{XX}(t, t+\tau) = E[X(t)X(t+\tau)]$ at times t and $t+\tau$, the correlation of two rv's at two times offset by τ. When $\mu(t) = 0$ for all t, the autocorrelation function equals the *autocovariance function* $C_{XX}(t, t+\tau) = E[(X(t) - \mu(t))(X(t+\tau) - \mu(t+\tau))]$.

A process $X(t)$ is completely determined by its joint pdf's $f_{X(t(1)) \ldots X(t(n))}(x(t_1), \ldots, x(t_n))$ for all time combinations $t_1, \ldots, t_n$ and all positive integers n (where $t(j) = t_j$). When the rv's $X(t)$ are *iid* (independent, identically distributed), then knowledge of one pdf yields the knowledge of all joint pdf's. This is because we can construct the joint pdf by factorization, per Eq. (73.41).

Classifications of Stochastic Processes

The ordered set T can be continuous or discrete, and the values that $X(t)$ assumes at each t may also be continuous or discrete, as shown in Table 73.1.

In another classification, a stochastic process $X(t)$ is *deterministic* whenever an entire sample function can be determined from an initial segment $\{x;\ t \le t_1\}$ of $X(t)$. Otherwise, it is *nondeterministic* [see Brown, 1983, p. 79; or Gardner, 1990, p. 304].

Stationarity of Processes

A stochastic process is *nth order* (*strongly*) *stationary* whenever all joint pdf's of n and fewer rv's are independent of all translations of times $t_1, \ldots, t_n$ to times $\tau + t_1, \ldots, \tau + t_n$. The case of $n = 2$ is very useful. Another type of process is called **weakly stationary** (ws), or *wide-sense stationary*, and is defined to have first- and second-order moments that are independent of time (see Section 73.2 on noise). These satisfy (1) $\mu(t) = \mu$ (constant) for all t, and (2) $R_{XX}(t, t+\tau) = R_{XX}(t+s, t+s+\tau)$ for all values of s. For $s = -t$, this yields $R_{XX}(t, t+\tau) = R_{XX}(0, 0+\tau)$, which is abbreviated to $R_{XX}(\tau)$. $X(t)$ is *uncorrelated* whenever $C_{XX}(\tau) = 0$ for τ not zero [we say $X(t)$ has *no memory*]. If $X(t)$ is correlated, then $X(t_1)$ depends on values $X(t)$ for $t \ne t_1$ [$X(t)$ has *memory*].

Some properties of autocorrelation functions for ws processes follow. First, $|R_{XX}(\tau)| \le R_{XX}(0)$, $-\infty < \tau < \infty$, as can be seen from Eq. (73.42) with $|R_{XX}(\tau)|^2 = E[X(0)X(\tau)] \le E[X(0)^2]E[X(\tau)^2] = R_{XX}(0)R_{XX}(\tau)$. Next, $R_{XX}(\tau)$ is real and even, i.e., $R_{XX}(-\tau) = R_{XX}(\tau)$, which is evident from substituting $s = t - \tau$ in $E[X(s)X(s+\tau)]$and using time independence. If $X(t)$ has a periodic component, then $R_{XX}(\tau)$ will have that same periodic component, which follows from the definition. Finally, if $X(t)$ has a nonzero mean μ and no periodic components, then the variance goes to zero (the memory fades) and so $\lim_{\tau\to\infty} R_{XX}(\tau) \to 0 + \mu^2 = \mu^2$.

Gaussian and Markov Processes

A process $X(t)$ is defined to be *Gaussian* if for every possible finite set $\{t_1, \ldots, t_n\}$ of times, the rv's $X(t_1), \ldots, X(t_n)$ are *jointly Gaussian*, which means that every linear combination $Z = a_1X(t_1) + \ldots + a_nX(t_n)$ is a Gaussian rv, defined by the Gaussian pdf

$$f_Z(z) = \left[1/(\sigma_Z\sqrt{2\pi})\right] \exp\{-(z - \mu_Z)^2/2\sigma_Z^2\} \tag{73.44}$$

In case the n rv's are *linearly independent*, i.e., $Z = 0$ only if $a_1 = \cdots = a_n = 0$, the joint pdf has the Gaussian form [see Gardner, 1990, pp. 39–40]

$$f_{X(t(1))\ldots X(t(n))}(x_1, \ldots, x_n) = [1/(2\pi)^{n/2}|C|^{1/2}] \cdot \exp\{-(\mathrm{x} - \boldsymbol{\mu})^t C^{-1}(\mathrm{x} - \boldsymbol{\mu})\} \quad (73.45)$$

where $\mathbf{x} = (x_1, \ldots, x_n)$ is a column vector, $\mathbf{x}^t$ is its transpose, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_n)$ is the mean vector, C is the *covariance matrix*

$$C = \begin{pmatrix} \sigma_1^2 & \cdots & \sigma_{1n} \\ \vdots & \vdots & \\ \sigma_{n1} & \cdots & \sigma_n^2 \end{pmatrix} \quad (73.46)$$

and $|C|$ is the determinant of C. If $X(t_1), \ldots, X(t_n)$ are linearly dependent, then the joint pdf takes on a form similar to Eq. (73.45), but contains impulses [see Gardner, 1990, p. 40].

A weakly stationary Gaussian process is strongly stationary to all orders *n:* all Gaussian joint pdf's are completely determined by their first and second moments by Eq. (73.45), and those moments are time independent by weak stationarity, and so all joint pdf's are also. Every second-order strongly stationary stochastic process $X(t)$ is also weakly stationary because the time translation independence of the joint pdf's determines the first and second moments to have the same property. However, non-Gaussian weakly stationary processes need not be strongly second-order stationary.

Rather than with pdf's, a process $X(t)$ may be specified in terms of conditional pdf's

$$f_{X(t(1))\ldots X(t(n))}(x_1, \ldots, x_n) = f_{X(t(n))|X(t(n-1))}(x_n|x_{n-1}) \cdot \ldots \cdot f_{X(t(2))|X(t(1))}(x_2|x_1) f_{X(t(1))}(x_1)$$

by successive applications of Bayes' law, for $t_1 < t_2 < \cdots < t_n$. The conditional pdf's satisfy

$$f_{A|B}(a|b) = f_{AB}(a,b)/f_B(b) \quad (73.47)$$

The conditional factorization property may satisfy

$$f_{X(t(n))|X(t(n-1))\ldots X(t(1))}(x_n|x_{n-1}, \ldots, x_1) = f_{X(t(n))|X(t(n-1))}(x_n|x_{n-1}) \quad (73.48)$$

which indicates that the pdf of the process at any time t_n, given values of the process at any number of previous times $t_{n-1}, \ldots, t_1$, is the same as the pdf at t_n given the value of the process at the most recent time t_{n-1}. Such an $X(t)$ is called a *first-order Markov process*, in which case we say the process remembers only the previous value (the previous value has influence). In general, an *nth-order Markov* process remembers only the n most recent previous values. A first-order Markov process can be fully specified in terms of its first-order conditional pdf's $f_{X(t)|X(s)}(x_t, x_s)$ and its unconditional first-order pdf at some initial time t_0, $f_{X(t(0))}(x_0)$.

Examples of Stochastic Processes

Figure 73.9 shows two sample functions of nonstationary processes. Now consider the discrete time process $X(k) = A$, for all $k \geq 0$, where A is a rv (a *random initial condition*) that assumes a value 1 or –1 with respective probabilities p and $1 - p$ at $k = 0$. This value does not change, once the initial random draw is done at $k = 0$. This stochastic sequence has two sample functions only, the constant sequences $\{-1\}$ and $\{1\}$. The expected value of $X(k)$ at any time k is $E[X(k)] = E[A] = p \cdot 1 + (1 - p) \cdot (-1) = 2p - 1$, which is independent of k. The autocorrelation function is, by definition, $E[X(k)X(k + m)] = E[A \cdot A] = E[A^2] = p \cdot 1^2 + (1 - p) \cdot (-1)^2 = 1$ which is also independent of time k. Thus $X(k)$ is perfectly correlated for all time (the process has *infinite memory*). This process is deterministic.

For another example, put $X(t) = (c) \cdot \cos(wt + \Phi)$, where Φ is the uniform rv on $(-\pi, \pi)$. Then $X(t)$ is a function of the rv Φ (as well as t), so by use of Eq. (73.39a), we obtain

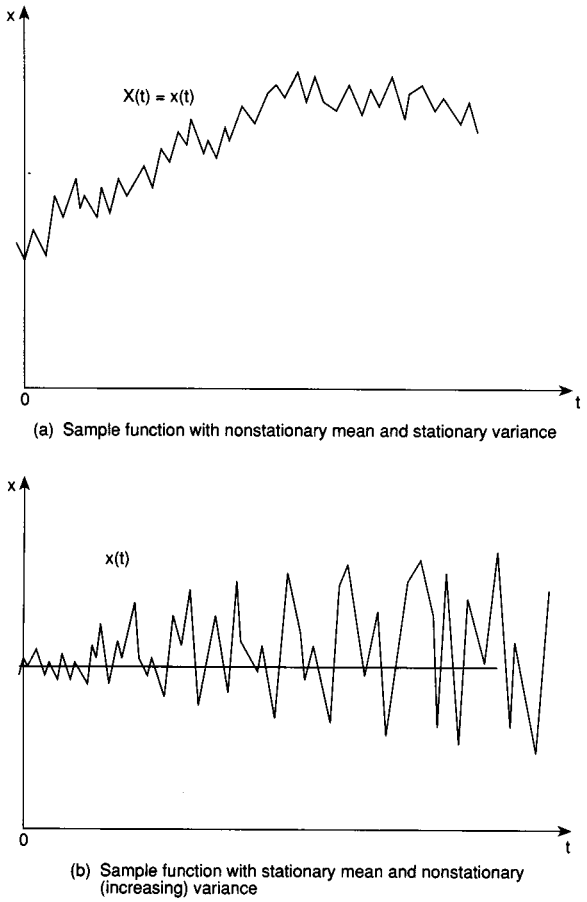

FIGURE 73.9 Examples of nonstationary processes.

$$E[X(t) = c \cdot \int_{-\pi}^{\pi} \cos(wt + \phi) f_{\Phi}(\phi) d\phi = (c/2\pi) \sin(wt + \phi)\Big|_{-\pi}^{\pi} = 0$$

Therefore, the mean does not vary with time t. The autocorrelation is

$$\begin{aligned} R_{XX}(t, t + \tau) &= E[(c) \cdot \cos(wt + \Phi)(c) \cdot \cos(wt + w\tau + \Phi)] \\ &= c^2 E[\cos(wt + \Phi) \cos(wt + w\tau + \Phi)] \\ &= c^2 \int_{-\pi}^{\pi} \cos(wt + \phi) \cos(wt + w\tau + \Phi) f_{\Phi}(\phi) d\phi \\ &= (c^2/2) \int_{-\pi}^{\pi} \{\cos(2wt + 2\phi + w\tau) + \cos(w\tau)\}(1/2\pi) d\phi \\ &= (c^2/4\pi) \cdot \{\sin(\Theta + 2\pi) - \sin(\Theta - 2\pi) + \cos(w\tau) \cdot 2\pi\} \\ &= (c^2/4\pi) \cdot \{\cos(w\tau) \cdot 2\pi\} = (c^2/2) \cos(w\tau) \end{aligned}$$

[using $\cos(x)\cos(y) = \frac{1}{2}\{\cos(x + y) + \cos(x - y)\}$ and letting $\Theta = 2wt + 2\Phi + w\tau$]. Therefore, $X(t)$ is ws. The autocorrelation is periodic in the offset variable τ.

Now consider the example $X(t) = A\cos(2\pi f_0 t)$ for each t, where f_0 is a constant frequency, and the amplitude A is a random initial condition as given above. There are only two sample functions here: (1) x(t) = $\cos(2\pi f_0 t)$ and (2) $x(t) = -\cos(2\pi f_0 t)$. A related example is $X(t) = A\cos(2\pi f_0 t + \Phi)$, where A is given above, the phase Φ is the uniform random variable on $[0,\pi]$, and A and Φ are independent. Again, Φ and A do not depend on time (initial random conditions). Thus, the sample functions for $X(t)$ are $x(t) = \pm\cos(2\pi ft + \phi)$, where $\Phi = \phi$ is the value assumed initially. There are infinitely many sample functions because of the phase. Equation (73.39b) and the independence of A and Φ yield

$$\begin{aligned} E[X(t)] &= E[A\cos(2\pi ft + \Phi)] = E[A]E[g(\Phi)] = \mu_A \int_0^{\pi} \cos(2\pi ft + \phi)(1/\pi)d\phi \\ &= (\mu_A/\pi)\sin(2\pi t + \phi)\Big|_{\phi=0}^{\pi} = (\mu_A/\pi)[\sin(2\pi t + \pi) - \sin(2\pi t)] \\ &= (\mu_A/\pi)[\sin(-2\pi t) - \sin(2\pi t)] = (-2\mu_A/\pi)\sin(2\pi t) \end{aligned}$$

which is dependent upon time. Thus, $X(t)$ is not ws.

Next, let $X(t) = [a + S(t)]\cos[2\pi ft + \Phi]$, where the signal $S(t)$ is a nondeterministic stochastic process. This is an amplitude-modulated sine wave carrier. The carrier $\cos[2\pi ft + \Phi]$ has random initial condition Φ and is deterministic. Because $S(t)$ is nondeterministic, $X(t)$ is also. The expected value $E[X(t)] = E[a + S(t)]E[\cos(2\pi ft + \Phi)]$ can be found as above by independence of $S(t)$ and Φ.

Finally, let $X(t)$ be uncorrelated ($E[X(t)X(t + \tau)] = 0$ for τ not zero) such that each rv $X(t) = X_t$ is Gaussian with zero mean and variance $\sigma^2(t) = t$, for all $t > 0$. Any realized sample function $x(t)$ of $X(t)$ cannot be predicted in any average sense based on past values (uncorrelated Gaussian random variables are independent). The variance grows in an unbounded manner over time, so $X(t)$ is neither stationary nor deterministic. This is called the *Wiener* process.

A useful model of a ws process is that for which $\mu = 0$ and $R_{XX}(\tau) = \sigma_X^2\exp(-\alpha|\tau|)$. If this process is also Gaussian, then it is strongly stationary and all of its joint pdf's are fully specified by $R_{XX}(\tau)$. In this case it is also a first-order Markov process and is called the *Ornstein-Uhlenbeck* process [see Gardner, 1990, p. 102]. Unlike white noise, many real-world ws stochastic processes are correlated ($|R_{XX}(t, t + \tau)| > 0$) for $|\tau| > 0$. The autocorrelation either goes to zero as τ goes to infinity, or else it has periodic or other nondecaying memory. We consider ws processes henceforth [for nonstationary processes, see Gardner, 1990]. We will also assume without loss of generality that $\mu = 0$.

Linear Filtering of Weakly Stationary Processes

Let the ws stochastic process $X(t)$ be the input to a linear time-invariant stable filter with impulse response function $h(t)$. The output of the filter is also a ws stochastic process and is given by the convolution

$$Y(t) = h(t) * X(t) = \int_{-\infty}^{\infty} h(s)X(t-s)ds \tag{73.49}$$

The mean of the output process is obtained by using the linearity of the expectation operator [see Gardner, 1990, p. 32]

$$\begin{aligned} \mu_Y &= E[Y(t)] = E\left[\int_{-\infty}^{\infty} h(s)X(t - s)ds\right] = \int_{-\infty}^{\infty} h(s)E[X(t - s)]ds = \int_{-\infty}^{\infty} h(s)\mu_X ds \\ &= \mu_X \int_{-\infty}^{\infty} h(s)ds = \mu_X \cdot H(0) \end{aligned} \tag{73.50}$$

where $H(f) = \int_{-\infty}^{\infty} h(t)\,e^{-j2\pi ft}dt$ is the filter transfer function and $H(0)$ is the dc gain of the filter.

The autocorrelation of the output process, obtained by using the linearity of $E[\cdot]$, is

$$\begin{aligned} R_{YY}(\tau) &= E[Y(t)Y(t+\tau)] = E\left[\int_{-\infty}^{\infty} h(v)X(t-v)dv \int_{-\infty}^{\infty} h(u)X(t+\tau-u)du\right] \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} E[X(t-v)X(t+\tau-u)]h(v)h(u)dvdu \\ &= \int_{-\infty}^{\infty}\left\{\int_{-\infty}^{\infty} R_{XX}(\tau-u+v)h(u)du\right\}h(v)dv \\ &= \int_{-\infty}^{\infty}\left\{\int_{-\infty}^{\infty} R_{XX}([\tau-(-v)]-u)h(u)du\right\}h(-v)(dv) \\ &= \int_{-\infty}^{\infty}\left\{R_{XX}(\tau+v) * h(\tau+v)\right\}h(-v)dv \\ &= [R_{XX}(\tau) * h(\tau)] * h(-\tau) = R_{XX}(\tau) * [h(\tau) * h(-\tau)] = R_{XX}(\tau) * r_h(\tau) \end{aligned} \tag{73.51}$$

where $r_h(\tau) = \int_{-\infty}^{\infty} h(\tau + u)h(u)du$. However, $r_h(\tau)$ has Fourier transform $H(f)H^*(f) = |H(f)|^2$, because the Fourier transform of the convolution of two functions is the product of their Fourier transforms, and the Fourier transform of $h(-\tau)$ is the complex conjugate $H^*(f)$ of the Fourier transform $H(f)$ of $h(\tau)$. Thus, the Fourier transform of $R_{YY}(\tau)$, denoted by $\mathrm{F}\{R_{YY}(\tau)\}$, is

$$\mathbf{F}\{R_{YY}(\tau)\} = \mathbf{F}\{R_{XX}(\tau) * h(\tau) * h(-\tau)\} = \mathbf{F}\{R_{XX}(\tau)\} \cdot H(f)H^*(f) = \mathbf{F}\{R_{XX}(\tau)\} \cdot |H(f)|^2$$

Upon defining the functions

$$S_{XX}(f) \equiv \mathbf{F}\{R_{XX}(\tau)\},\ S_{YY}(f) \equiv \mathbf{F}\{R_{YY}(\tau)\} \tag{73.52}$$

we can also determine $R_{YY}(\tau)$ via the two steps

$$S_{YY}(f) = S_{XX}(f) \cdot |H(f)|^2 \tag{73.53}$$

$$R_{YY}(\tau) = \mathbf{F}^{-1}\{S_{YY}(f)\} = \int_{-\infty}^{\infty} S_{YY}(f)e^{j2\pi f\tau}df \tag{73.54}$$

Equations (73.52) define the *power spectral density functions* (psdf's) $S_{XX}(f)$ for $X(t)$ and $S_{YY}(f)$ for $Y(t)$. Thus, $R_{XX}(\tau)$ and $S_{XX}(f)$ are Fourier transform pairs, as are $R_{YY}(\tau)$ and $S_{YY}(f)$ (see Eq. 73.20). Further, the psdf $S_{XX}(f)$ of $X(t)$ is a power spectrum (in an average sense). If $X(t)$ is the voltage dropped across a 1-Ω resistor, then $X^2(t)$ is the instantaneous power dissipation in the resistance. Consequently, $R_{XX}(0) = E[X^2(t)]$ is the expected power dissipation over all frequencies, i.e., by Eq. (73.54) with $\tau = 0$, we have

$$R_{XX}(0) = \int_{-\infty} S_{XX}(f)df$$

We want to show that when we pass $X(t)$ through a narrow bandpass filter with a bandwidth δ centered at the frequency $\pm f_0$, the expected power at the output terminals, divided by the bandwidth δ, is $S_{XX}(f_0)$ in the limit as $\delta \to 0$. This shows that $S_{XX}(f)$ is a density function (whose area is the total expected power over all frequencies, just as the area under a pdf is the total probability). This result that $R_{XX}(\tau)$ and $S_{XX}(f)$ are a Fourier transform pair is known as the *Wiener-Khinchin* relation [see Gardner, 1990, p. 230].

To verify this relation, let $H(f)$ be the transfer function of an ideal bandpass filter, where

$$H(f) = 1, |f - f_0| < \delta/2; \qquad H(f) = 0, \text{ otherwise}$$

Let Y(t) be the output of the filter. Then Eqs. (73.54) and (73.53) provide

$$E[Y^2(t)] = R_{YY}(0) = \int_{-\infty}^{\infty} S_{YY}(f)df = \int_{-\infty}^{\infty} S_{XX}(f) \mid H(f) \mid^2 df$$

$$= \int_{f_0-\delta/2}^{f_0+\delta/2} S_{XX}(f)df + \int_{-f_0-\delta/2}^{-f_0+\delta/2} S_{XX}(f)df$$

Dividing by 2δ and taking the limit as $\delta \to 0$ yields $(1/2)S_{XX}(f_0) + (1/2)S_{XX}(-f_0)$, which becomes $S_{XX}(f_0)$ when we use the fact that psdf's are even and real functions (because they are the Fourier transforms of autocorrelation functions, which are even and real).

For example, let $X(t)$ be white noise, with $S_{XX}(f) = N_0$, being put through a first-order linear time-invariant system with respective impulse response and transfer functions

$$h(t) = \exp\{-\alpha t\},\ t \geq 0;\ h(t) = 0,\ t < 0 \qquad H(f) = 1/[\alpha + j2\pi f],\ \text{all } f$$

The temporal correlation of $h(t)$ with itself is $r_h(\tau) = (1/2\alpha)\exp\{-\alpha|\tau|\}$, so the power transfer function is $|H(f)|^2 = 1/[\alpha^2 + (2\pi f)^2]$. The autocorrelation for the input $X(t)$ is

$$R_{XX}(\tau) = \int_{-\infty}^{\infty} N_0 e^{j2\pi f\tau} df = N_0\delta(\tau)$$

which is an impulse. It follows (see Eq. 73.22) that the output $Y(t)$ has respective autocorrelation and psdf

$$R_{YY}(\tau) = [N_0\delta(\tau)] * [(1/2\alpha)\, e^{-\alpha|\tau|}] = (N_0/2\alpha)\, e^{-\alpha|\tau|},\ S_{YY}(f) = N_0/[\alpha^2 + (2\pi f)^2]$$

The output expected power $E[Y^2(t)]$ can be found from either one of

$$E[Y^2(t)] = R_{YY}(0) = N_0/2\alpha \qquad \text{or} \qquad E[Y^2(t)] = \int_{-\infty}^{\infty} S_{YY}(f)df = N_0/2\alpha$$

If the input $X(t)$ to a linear system is Gaussian, then the output will also be Gaussian [see Brown, 1983; or Gardner, 1990]. Thus, the output of a first-order linear time-invariant system driven by Gaussian white noise is the Ornstein–Uhlenbeck process, which is also a first-order Markov process.

For another example, let $X(t) = A\cos(w_o t + \Theta)$, where the random amplitude A has zero mean, the random phase Θ is uniform on $[-\pi, \pi]$, and A and Θ are independent. As before, we obtain $R_{XX}(\tau) = \sigma_A{}^2\cos(w_o\tau)$, from which it follows that $S_{XX}(f) = (\sigma_A{}^2/2)[\delta(f - w_o/2\pi) + \delta(f + w_o/2\pi)]$. These impulses in the psdf, called *spectral lines*, represent positive amounts of power at discrete frequencies.

Cross-Correlation of Processes

The *cross-correlation function* for two random processes $X(t)$ and $Y(t)$ is defined via

$$R_{XY}(t,\ t+\tau) \equiv E[X(t)Y(t+\tau)] \tag{73.55}$$

Let both processes be ws with zero means, so the covariance coincides with the correlation function. We say that two ws processes $X(t)$ and $Y(t)$ are *jointly ws* whenever $R_{XY}(t,t+\tau) = R_{XY}(\tau)$. In case $Y(t)$ is the output of a filter with impulse response $h(t)$,we can find the cross-correlation $R_{XY}(\tau)$ between the input and output via

$$R_{XY}(\tau) = E[X(t)Y(t+\tau)] = E[X(t)\int_{-\infty}^{\infty} h(u)X(t+\tau-u)du]$$
$$= \int_{-\infty}^{\infty} h(u)E[X(t)X(t+\tau-u)]\,du \tag{73.56}$$
$$= \int_{-\infty}^{\infty} h(u)R_{XX}(\tau-u)du = R_{XX}(\tau) * h(\tau)$$

Cross-correlation functions of ws processes satisfy (1) $R_{XY}(-\tau) = R_{YX}(\tau)$, (2) $|R_{XY}(\tau)|^2 \le R_{XX}(0)R_{YY}(0)$, and (3) $|R_{XY}(\tau)| \le (1/2)[R_{XX}(0) + R_{YY}(0)]$. The first follows from the definition, while the second comes from expanding $E[\{Y(t+\tau) - \alpha X(t)\}^2] \ge 0$. The third comes from the fact that the geometric mean cannot exceed the arithmetic mean [see Peebles, 1987, p. 154].

Taking the Fourier transform of the leftmost and rightmost sides of Eqs. (73.56) yields

$$S_{XY}(f) = S_{XX}(f)H(f) \tag{73.57}$$

The Fourier transform of the cross-correlation function is the *cross-spectral density function*

$$S_{XY}(f) = \int_{-\infty}^{\infty} R_{XY}(\tau)e^{-j2\pi f\tau}d\tau \tag{73.58}$$

According to Gardner [1990, p. 228], this is a *spectral correlation density function* that does not represent power in any sense.

Equation (73.57) suggests a method for identifying a linear time-invariant system. If the system is subjected to a ws input $X(t)$ and the power spectral density of $X(t)$ and the cross-spectral density of $X(t)$ and the output $Y(t)$ are measured, then the ratio yields the system transfer function

$$H(f) = S_{XY}(f)/S_{XX}(f) \tag{73.59}$$

In fact, it can be shown that this method gives the best linear time-invariant model of the (possibly time varying and nonlinear) system in the sense that the time-averaged mean-square error between the outputs of the actual system and of the model, when both are subjected to the same input, is minimized [see Gardner, 1990, pp. 282–286].

As an application, suppose that an undersea sonar-based device is to find the range to a target, as shown in Fig. 73.10, by transmitting a sonar signal $X(t)$ and receiving the reflected signal $Y(t)$. If v is the velocity of the sonar signal, and τ_o is the offset that maximizes the cross-correlation $R_{XY}(\tau)$, then the range (distance) d can be determined from $d = v\tau_o/2$ (note that the signal travels twice the range d).

Coherence

When $X(t)$ and $Y(t)$ have no spectral lines at f, the finite spectral correlation $S_{XY}(f)$ is actually a spectral covariance and the two associated variances are $S_{XX}(f)$ and $S_{YY}(f)$. We can normalize $S_{XY}(f)$ to obtain a *spectral correlation coefficient* $\Upsilon_{XY}(f)$ defined by

$$\Upsilon_{XY}(f)^2 = |S_{XY}(f)|^2/S_{XX}(f)S_{YY}(f) \tag{73.60}$$

We call $\Upsilon_{XY}(f)$ the *coherence function*. It is a measure of the power correlation of $X(t)$ and $Y(t)$ at each frequency f. When $Y(t) = X(t)*h(t)$, it has a maximum: by Eqs. (73.53), (73.59), and (73.60), $|\Upsilon_{XY}(f)|^2 = |S_{XX}(f) \cdot H(f)|^2/[S_{XX}(f) \cdot S_{XX}(f) \cdot |H(f)|^2] = 1$. In the general case we have

$$|S_{XY}(f)| \le [S_{XX}(f)S_{YY}(f)]^{1/2} \tag{73.61}$$

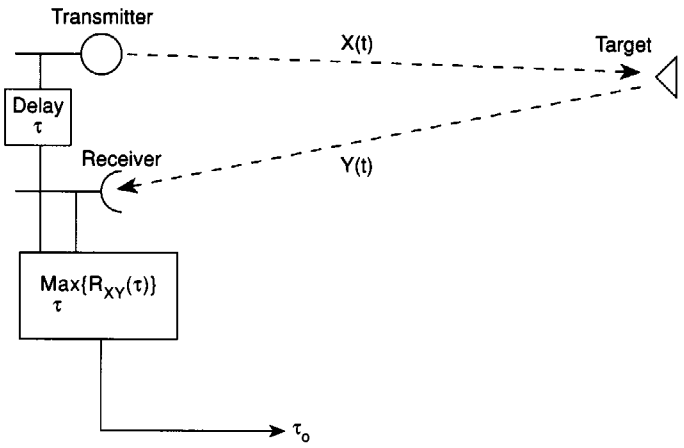

FIGURE 73.10 A sonar range finder.

Upon minimizing the mean-square error $\varepsilon = E[(Y(t) - X(t)*h(t))^2]$ over all possible impulse response functions $h(t)$, the optimal one, $h_o(t)$, has transfer function

$$H_o(f) = S_{XY}(f)/S_{XX}(f) \tag{73.62}$$

Further, the resultant minimum value is given by

$$\varepsilon_{\min} = \int_{-\infty}^{\infty} S_{YY}(f)[1 - |\Upsilon_{XY}(f)|^2]\,df$$

[see Gardner, 1990, pp. 434–436; or Bendat and Piersol, 1986]. At frequencies f where $|\Upsilon_{XY}(f)| \approx 1$, $\varepsilon_{\min} \approx 0$. Thus $1 - |\Upsilon_{XY}(f)|^2$ is the mean-square proportion of $Y(t)$ not accounted for by $X(t)$, while $|\Upsilon_{XY}(f)|^2$ is the proportion due to $X(t)$. When $Y(t) = X(t)*h(t)$, $\varepsilon_{\min} = 0$.

The optimum system $H_o(f)$ of Eq. (73.62) is known as the *Wiener filter* for minimum mean-square error estimation of one process $Y(t)$ using a filtered version of another process $X(t)$ [see Gardner, 1990; or Peebles, 1987, p. 262].

Ergodicity

When the **time average**

$$\lim_{T\to\infty}(1/T)\int_{-T/2}^{T/2} X(t)dt$$

exists and equals the corresponding expected value $E[X(t)]$, then the process $X(t)$ is said to possess an *ergodic property associated with the mean*. There are ergodic properties associated with the mean, autocorrelation (and power spectral density), and all finite-order joint moments, as well as finite-order joint pdf's. If a process has all possible ergodic properties, it is said to be an *ergodic process*.

Let $Y(t) = g[X(t + t_1), \ldots, X(t + t_n)]$, where $g[\cdot]$ is any nonrandom real function, so that $Y(t)$ is a function of a finite number of time samples of a strongly stationary process. For example, let (1) $Y(t) = X(t + t_1)X(t + t_2)$, $E[Y(t)] = R_{XX}(t_1 - t_2)$ and (2) $Y(t) = 1$ if $X(t) < x$, $Y(t) = 0$, otherwise, so that

$$E[Y(t)] = 1\cdot P(X(t) < x) + 0\cdot P(X(t) \geq x) = P(X(t) < x) = \int_{-\infty}^{1} f_{X(t)}(z)dz$$

We want to know under what conditions the mean-square error between the time average

$$\langle Y(t) \rangle_T \equiv (1/T)\int_{-T/2}^{T/2} Y(t)dt$$

and the expected value $E[Y(t)]$ will converge to zero. It can be shown that a necessary and sufficient condition for the mean-square ergodic property

$$\lim_{T\to\infty} E[\{\langle Y(t) \rangle_T - E[Y(t)]\}^2] = 0 \tag{73.63}$$

to hold is that

$$\lim_{T\to\infty} (1/T)\int_0^T C_{YY}(\tau)d\tau = 0 \tag{73.64}$$

For example, if $C_{YY}(\tau) \to 0$ as $\tau \to \infty$, then Eq. (73.64) will hold, and thus Eq. (73.63) will also, where $C_{YY}(\tau)$ is the covariance function of $Y(t)$. As long as the two sets of rv's $\{X(t + t_1), \ldots, X(t + t_n)\}$ and $\{X(t + t_1 + \tau), \ldots, X(t + t_n + \tau)\}$ become independent of each other as $\tau \to \infty$, the above condition holds, so Eq. (73.63) holds [see Gardner, 1990, pp. 163–174].

In practice, if $X(t)$ exhibits ergodicity associated with the autocorrelation, then we can estimate $R_{XX}(\tau)$ using the time average

$$\langle X(t)X(t+\tau) \rangle_T \equiv (1/T)\int_{-T/2}^{T/2} X(t)X(t+\tau)dt \tag{73.65}$$

In this case the mean-square estimation error $E[\{\langle X(t)X(t+\tau)\rangle_T - R_{XX}(\tau)\}^2]$ will converge to zero as T increases to infinity, and the power spectral density $S_{XX}(f)$ can also be estimated via time averaging [see Gardner, 1990, pp. 230–231].

Defining Terms

Autocorrelation function: A function $R_{XX}(t, t + \tau) = E[X(t)X(t + \tau)]$ that measures the degree to which any two rv's $X(t)$ and $X(t + \tau)$, at times t and $t + \tau$, are correlated.

Coherence function: A function of frequency f that provides the degree of correlation of two stochastic processes at each f by the ratio of their cross-spectral density function to the product of their power spectral density functions.

Power spectral density function: The Fourier transform of the autocorrelation function of a stochastic process $X(t)$, denoted by $S_{XX}(f)$. The area under its curve between f_1 and f_2 represents the total power over all t in $X(t)$ in the band of frequencies f_1 to f_2. Its dimension is watts per Hz.

Sample function: A real-valued function $x(t)$ of t where at each time t the value $x(t)$ at the argument t was determined by the outcome of a rv $X_t = x(t)$.

Stochastic process: A collection of rv's $\{X_t; t \in T\}$, where T is an ordered set such as the real numbers or integers [$X(t)$ is also called a random function, on the domain T].

Time average: Any real function $g(t)$ of time has average value g_{ave} on the interval $[a,b]$ such that the rectangular area $g_{ave}(b - a)$ is equal to the area under the curve between a and b, i.e., $g_{ave} = [1/(b - a)] \int_a^b g(t)dt$. The time average of a sample function $x(t)$ is the limit of its average value over $[0, T]$ as T goes to infinity.

Weakly stationary: The property of a stochastic process $X(t)$ whose mean $E[X(t)] = \mu(t)$ is a fixed constant μ over all time t, and whose autocorrelation is also independent of time in that $R_{XX}(t, t + \tau) = R_{XX}(s + t, s + t + \tau)$ for any s. Thus, $R_{XX}(t, t + \tau) = R_{XX}(0, \tau) = R_{XX}(\tau)$.

73.4 The Sampling Theorem

R. J. Marks II

Most signals originating from physical phenomena are analog. Most computational engines, on the other hand, are digital. Transforming from analog to digital is straightforward: we simply sample. Regaining the original signal from these samples and assessing the information lost in the sampling process are the fundamental questions addressed by the **sampling theorem**.

The fundamental result of the sampling theorem is, remarkably, that a bandlimited signal is uniquely specified by its sufficiently close equally spaced samples. Indeed, the sampling theorem illustrates how the original signal can be regained from knowledge of the samples and the sampling rate at which they were taken.

Popularization of the sampling theorem is credited to Shannon [1948] who, in 1948, used it to show the equivalence of the information content of a bandlimited signal and a sequence of discrete numbers. Shannon was aware of the pioneering work of Whittaker [1915] and Whittaker's son [1929] in formulating the sampling theorem. Kotel'nikov's [1933] independent discovery in the then Soviet Union deserves mention. Higgins [1985] credits Borel [1897] with first recognizing that a signal could be recovered from its samples.

Surveys of sampling theory are in the widely cited paper of Jerri [1977] and in two books by the author [1991, 1993]. Marvasti [1987] has written a book devoted to nonuniform sampling.

The Cardinal Series

If a signal has finite energy, the minimum **sampling rate** is equal to two samples per period of the highest frequency component of the signal. Specifically, if the highest frequency component of the signal is B Hz, then the signal, $x(t)$, can be recovered from the samples by

$$x(t) = \frac{1}{\pi} \sum_{n=-\infty}^{\infty} x\left(\frac{n}{2B}\right) \frac{\sin[\pi(2Bt - n)]}{2Bt - n} \tag{73.66}$$

The frequency B is also referred to as the signal's bandwidth and, if B is finite, $x(t)$ is said to be bandlimited. The signal, $x(t)$, is here being sampled at a rate of 2 B samples per second. If sampling were done at a lower

rate, the replications would overlap and the information about $X(\omega)$ [and thus $x(t)$] is irretrievably lost. Undersampling results in *aliased* data. The minimum sampling rate at which **aliasing** does not occur is referred to as the **Nyquist rate** which, in our example, is $2B$. Eq. (73.66) was dubbed the **cardinal series** by the junior Whittaker [1929].

A signal is bandlimited in the low-pass sense if there is a $B > 0$ such that

$$X(\omega) = X(\omega)\Pi\left(\frac{\omega}{4\pi B}\right) \tag{73.67}$$

where the gate function $\Pi(\xi)$ is one for $\xi \le 1/2$ and is otherwise zero, and

$$X(\omega) = \int_{-\infty}^{\infty} x(t)e^{-j\omega t}dt \tag{73.68}$$

is the **Fourier transform** of $x(t)$. That is, the spectrum is identically zero for $|\omega| > 2\pi B$. The B parameter is referred to as the signal's bandwidth. The inverse Fourier transform is

$$x(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)\, e^{j\omega t}d\omega \tag{73.69}$$

The sampling theorem reduces the normally continuum infinity of ordered pairs required to specify a function to a countable—although still infinite—set. Remarkably, these elements are obtained directly by sampling.

How can the cardinal series interpolate uniquely the bandlimited signal from which the samples were taken? Could not the same samples be generated from another bandlimited signal? The answer is no. Bandlimited functions are smooth. Any behavior deviating from smooth would result in high-frequency components which in turn invalidates the required property of being bandlimited. The smoothness of the signal between samples precludes arbitrary variation of the signal there.

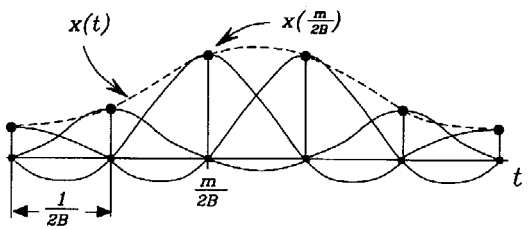

FIGURE 73.11 Illustration of the interpolation that results from the cardinal series. A sinc function, weighted by the sample, is placed at each sample bottom. The sum of the sincs exactly generates the original bandlimited function from which the samples were taken.

Let's examine the cardinal series more closely. Evaluate Eq. (73.74) at $t = m/2B$. Since $\text{sinc}(n)$ is one for $n = 0$ and is otherwise zero, only the sample at $t = m/2B$ contributes to the interpolation at that point. This is illustrated in Fig. 73.11, where the reconstruction of a signal from its samples using the cardinal series is shown. The value of $x(t)$ at a point other than a sample location [e.g., $t = (m + 1/2)/2B$] is determined by all of the sample values.

Proof of the Sampling Theorem

Borel [1897] and Shannon [1948] both discussed the sampling theorem as the Fourier transform dual of the Fourier series. Let $x(t)$ have a bandwidth of B. Consider the periodic signal

$$Y(\omega) = \sum_{n=-\infty}^{\infty} X(\omega - 4\pi nB) \tag{73.70}$$

The function $Y(\omega)$ is a periodic function with period $4\pi B$. From Eq. (73.67) $X(\omega)$ is zero for $\omega > 2\pi B$ and is thus finite in extent. The terms in Eq. (73.70) therefore do not overlap. Periodic functions can be expressed as a Fourier series.

$$Y(\omega) = \sum_{n=-\infty}^{\infty} \alpha_n \exp\left(\frac{-jn\omega}{2B}\right) \tag{73.71}$$

where the Fourier series coefficients are

$$\alpha_n = \frac{1}{4\pi B} \int_{-2\pi B}^{2\pi B} Y(\omega) \exp\left(\frac{jn\omega}{2B}\right) d\omega$$

or

$$\alpha_n = \frac{1}{2B} x\left(\frac{n}{2B}\right) \tag{73.72}$$

where we have used the inverse Fourier transform in Eq. (73.69). Substituting into the Fourier series in Eq. (73.71) gives

$$Y(\omega) = \frac{1}{2B} \sum_{n=-\infty}^{\infty} x\left(\frac{n}{2B}\right) \exp\left(\frac{-jn\omega}{2B}\right) \tag{73.73}$$

Since a period of $Y(\omega)$ is $X(\omega)$, we can get back the original spectrum by

$$X(\omega) = Y(\omega) \prod\left(\frac{\omega}{4\pi B}\right)$$

Substitute Eq. (73.73) and inverse transforming gives, using Eq. (73.69),

$$x(t) = \frac{1}{4\pi B} \int_{-2\pi B}^{2\pi B} \sum_{n=-\infty}^{\infty} x\left(\frac{n}{2B}\right) \exp\left(\frac{-jn\omega}{2B}\right) e^{j\omega t} d\omega$$

or

$$x(t) = \sum_{n=-\infty}^{\infty} x\left(\frac{n}{2B}\right) \text{sinc}\,(2Bt - n) \tag{73.74}$$

where

$$\text{sinc}\,(t) = \frac{\sin \pi t}{\pi t}$$

is the inverse Fourier transform of $\Pi\,(\omega/2\pi)$. Eq. (73.74) is, of course, the cardinal series.

The sampling theorem generally converges uniformly, in the sense that

$$\lim_{N\to\infty} \left| x(t) - x_N(t) \right|^2 = 0$$

where the truncated cardinal series is

$$x_N(t) = \sum_{n=-N}^{N} x\left(\frac{n}{2B}\right) \operatorname{sinc}(2Bt - n) \tag{73.75}$$

Sufficient conditions for uniform convergence are [Marks, 1991]

1. the signal, $x(t)$, has finite energy, E,

$$E = \int_{-\infty}^{\infty} \left| x(t) \right|^2 dt < \infty$$

2. or $X(\omega)$ has finite area,

$$A = \int_{-\infty}^{\infty} \left| X(\omega) \right| d\omega < \infty$$

Care must be taken in the second case, though, when singularities exist at $\omega = \pm 2\pi B$. Here, sampling may be required to be strictly greater than $2B$. Such is the case, for example, for the signal, $x(t) = \sin(2\pi Bt)$. Although the signal is bandlimited, and although its Fourier transform has finite area, all of the samples of $x(t)$ taken at $t = n/2B$ are zero. The cardinal series in Eq. (73.74) will thus interpolate to zero everywhere. If the sampling rate is a bit greater than $2B$, however, the samples are not zero and the cardinal series will uniformly converge to the proper answer.

The Time-Bandwidth Product

The cardinal series requires knowledge of an infinite number of samples. In practice, only a finite number of samples can be used. If most of the energy of a signal exists in the interval $0 \le t \le T$, and we sample at the Nyquist rate of $2B$ samples per second, then a total of $S = \langle 2BT \rangle$ samples are taken. ($\langle\theta\rangle$ denotes the largest number not exceeding θ.) The number S is a measure of the degrees of freedom of the signal and is referred to as its **time-bandwidth product.** A 5-min single-track audio recording requiring fidelity up to 20,000 Hz, for example, requires a minimum of $S = 2 \times 20{,}000 \times 5 \times 60 = 12$ million samples. In practice, audio sampling is performed well above the Nyquist rate.

Sources of Error

Exact interpolation using the cardinal series assumes that (1) the values of the samples are known exactly, (2) the sample locations are known exactly, and (3) an infinite number of terms are used in the series. Deviation from these requirements results in interpolation error due to (1) data noise, (2) jitter, and (3) truncation, respectively. The effect of data error on the restoration can be significant. Some innocently appearing sampling theorem generalizations, when subjected to performance analysis in the presence of data error, are revealed as ill-posed. In other words, a bounded error on the data can result in unbounded error on the restoration [Marks, 1991].

Data Noise

The source of data noise can be the signal from which samples are taken, or from round-off error due to finite sampling precision. If the noise is additive and random, instead of the samples

$$x\left(\frac{n}{2B}\right)$$

we must deal with the samples

$$x\left(\frac{n}{2B}\right)+\xi\left(\frac{n}{2B}\right)$$

where $\xi(t)$ is a stochastic process. If these noisy samples are used in the cardinal series, the interpolation, instead of simple $x(t)$, is

$$x(t)\ +\ \eta(t)$$

where the interpolation noise is

$$\eta(t)=\sum_{n=-\infty}^{\infty}\xi\left(\frac{n}{2B}\right)\mathrm{sinc}\,(2Bt-n)$$

If $\xi(t)$ is a zero mean process, then so is the interpolation noise. Thus, the noisy interpolation is an unbiased version of $x(t)$. More remarkably, if $\xi(t)$ is a zero-mean (wide-sense) stationary process with uncertainty (variance) σ^2, then so is $\eta(t)$. In other words, *the uncertainty at the sample point locations is the same as at all points of interpolation* [Marks, 1991].

Truncation

The truncated cardinal series is in Eq. (73.75). A signal cannot be both bandlimited and of finite duration. Indeed, a bandlimited function cannot be identically zero over any finite interval. Thus, other than the rare case where an infinite number of the signal's zero crossings coincide with the sample locations, truncation will result in an error.

The magnitude of this **truncation error** can be estimated through the use of Parseval's theorem for the cardinal series that states

$$\begin{aligned}E\ &=\ \int_{-\infty}^{\infty}\left|\,x(t)\,\right|^2dt\\ &=\ \frac{1}{2B}\sum_{-\infty}^{\infty}\left|x\left(\frac{n}{2B}\right)\right|^2\end{aligned}$$

The energy of a signal can thus be determined directly from either the signals or the samples. The energy associated with the truncated signal is

$$E_N\ =\ \frac{1}{2B}\sum_{-N}^{N}\left|x\left(\frac{n}{2B}\right)\right|^2$$

If $E - E_N << E$, then the truncation error is small.

Jitter

Jitter occurs when samples are taken near to but not exactly at the desired sample locations. Instead of the samples $x\,(n/2W)$, we have the samples

$$x\left(\frac{n}{2W} - \sigma_n\right)$$

where σ_n is the jitter offset of the nth sample. For jitter, the σ_n's are not known. If they were, an appropriate nonuniform sampling theorem [Marks, 1993; Marvasti, 1987] could be used to interpolate the signal.

Using the jittered samples in the cardinal series results in an interpolation that is not an unbiased estimate of $x(t)$. Indeed, if the probability density function of the jitter is the same at all sample locations, the expected value of the jittered interpolation is the convolution of $x(t)$ with the probability density function of the jitter. This bias can be removed by inverse filtering at a cost of decreasing the signal-to-noise ratio of the interpolation [Marks, 1993].

Generalizations of the Sampling Theorem

There exist numerous generalizations of the sampling theorem [Marks, 1991; Marks, 1993].

1. **Stochastic processes.** A wide-sense stationary stochastic process, $\chi(t)$, is said to be bandlimited if its autocorrelation, $R_\chi(t)$, is a bandlimited function. The cardinal series

$$\hat{\chi}(t) = \sum_{n=-\infty}^{\infty} \chi\left(\frac{n}{2B}\right) \operatorname{sinc}(2Bt - n)$$

converges to $\chi(t)$ in the sense that

$$E\left[\left|\hat{\chi}(t) - \chi(t)\right|^2\right] = 0$$

where E denotes expectation.
2. **Nonuniform sampling.** There exist numerous scenarios wherein interpolation can be performed from samples that are not spaced uniformly. Marvasti [1987] devotes a book to the topic.
3. **Kramer's generalization.** Kramer generalized the sampling theorem to integral transforms other than Fourier, for example, to Legendre and Laguerre transforms.
4. **Papoulis' generalization.** Shannon noted that a bandlimited signal could be restored when sampling was performed at half the Nyquist rate if, at every sample location, a sample of the signal's derivative were also taken. Recurrent nonuniform sampling is where P samples are spaced the same in every P Nyquist intervals. Another sampling scenario is when a signal and its Hilbert transform are both sampled at half their respective Nyquist rates. Restoration of the signal from these and numerous other sampling scenarios are subsumed in an eloquent generalization of the sampling theorem by Papoulis.
5. **Lagrangian interpolation.** Lagrangian interpolation is a topic familiar in numerical analysis. An Nth order polynomial is fit to $N + 1$ arbitrarily spaced sample points. If an infinite number of samples are equally spaced, then Lagrangian interpolation is equivalent to the cardinal series.
6. **Trigonometric polynomials.** All periodic bandlimited signals can be expressed as trigonometric polynomials (i.e., a Fourier series with a finite number of terms). If the series has M terms, then the signal has M degrees of freedom which can be determined from M samples taken within a single period.
7. **Multidimensional sampling theorems.** Multidimensional signals, such as images, require dimensional extensions of the sampling theorem. The sampling of the signal now requires geometrical interpretation. Uniform sampling of an image, for example, can either be done on a rectangular or hexagonal grid. The minimum sampling density for one geometry may differ from that of another. The smallest sampling density that does not result in aliasing can be achieved, in many cases, with a number of different uniform sampling geometries and is referred to as the Nyquist density. Interestingly, sampling can sometimes be performed below the Nyquist density with nonuniform sampling geometries such that the multidimensional signal can be restored. Such is not the case for one dimension.

8. **Continuous sampling.** When a signal is known on one or more disjoint intervals, it is said to have been continuously sampled. Divide the time line into intervals of T. Periodic continuous sampling assumes that the signal is known on each interval over an interval of αT where α is the duty cycle. Continuously sampled signals can be accurately interpolated even in the presence of aliasing. Other continuously sampled cases, each of which can be considered as a limiting case of continuously periodically sampled restoration, include
   (a) **Interpolation.** The tails of a signal are known and we wish to restore the middle.
   (b) **Extrapolation.** We wish to generate the tails of a function with knowledge of the middle.
   (c) **Prediction.** A signal for $t > 0$ is to be estimated from knowledge of the signal for $t < 0$.

Final Remarks

Since its popularization in the late 1940s, the sampling theorem has been studied in depth. More than 1000 papers have been generated on the topic [Marks, 1993]. Its understanding is fundamental in matching the largely continuous world to digital computation engines.

Defining Terms

Aliasing: A phenomenon that occurs when a signal is undersampled. High-frequency information about the signal is lost.

Cardinal series: The formula by which samples of a bandlimited signal are interpolated to form a continuous time signal.

Fourier transform: The mathematical operation that converts a time-domain signal into the frequency domain.

Jitter: A sample is temporally displaced by an unknown, usually small, interval.

Kramer's generalization: A sampling theory based on other than Fourier transforms and frequency.

Lagrangian interpolation: A classic interpolation procedure used in numerical analysis. The sampling theorem is a special case.

Nyquist rate: The minimum sampling rate that does not result in aliasing.

Papoulis' generalization: A sampling theory applicable to many cases wherein signal samples are obtained either nonuniformly and/or indirectly.

Sampling rate: The number of samples per second.

Sampling theorem: Samples of a bandlimited signal, if taken close enough together, exactly specify the continuous time signal from which the samples were taken.

Signal bandwidth: The maximum frequency component of a signal.

Time bandwidth product: The product of a signal's duration and bandwidth approximates the number of samples required to characterize the signal.

Truncation error: The error that occurs when a finite number of samples are used to interpolate a continuous time signal.

The sampling theorem is treated generically in the *IEEE Transactions on Signal Processing*. For applications, topical journals are the best source of current literature.

73.5 Channel Capacity

Sergio Verdú

Information Rates

Tens of millions of users access the Internet daily via standard telephone lines. **Modems** operating at data rates of up to 28,800 bits per second enable the transmission of text, audio, color images, and even low-resolution video. The progression in modern technology for the standard telephone channel shown in Fig. 73.12 exhibits, if not the exponential increases ubiquitous in computer engineering, then a steady slope of abut 825 bits per second per year.

Few technological advances can result in as many time-savings for worldwide daily life as advances in modem information rates. However, modem designers are faced with a fundamental limitation in the maximum transmissible information rate. Every communication channel has a number associated with it called **channel capacity**, which determines the maximum information rate that can flow through the channel regardless of the complexity of the transmitting and receiving devices. Thus, the progression of modem rates shown in Fig. 73.12 is sure to come to a halt. But, at what rate? Answering this question for any communication channel model is one of the major goals of information theory—a discipline founded in 1948 by Claude E. Shannon [Shannon, 1948].

Communication Channels

The communication channel is the set of devices and systems that connects the transmitter to the receiver. The transmitter and receiver consist of an **encoder** and **decoder**, respectively, which translate the information stream produced by the source into a signal suitable for channel transmission and vice versa (Fig. 73.13). For example, in the case of the telephone line, two communication channels (one in each direction) share the same physical channel that connects the two modems. That physical channel usually consists of twisted copper wires at both ends and a variety of switching and signal processing operations that occur at the telephone exchanges. The modems themselves are not included in the communication channel. A microwave radio link is another example of a communication channel that consists of an amplifier and an antenna (at both ends) and a certain portion of the radio spectrum. In this case, the communication channel model does not fully correspond with the physical channel. Why not, for example, view the antenna as part of the transmitter rather than the channel

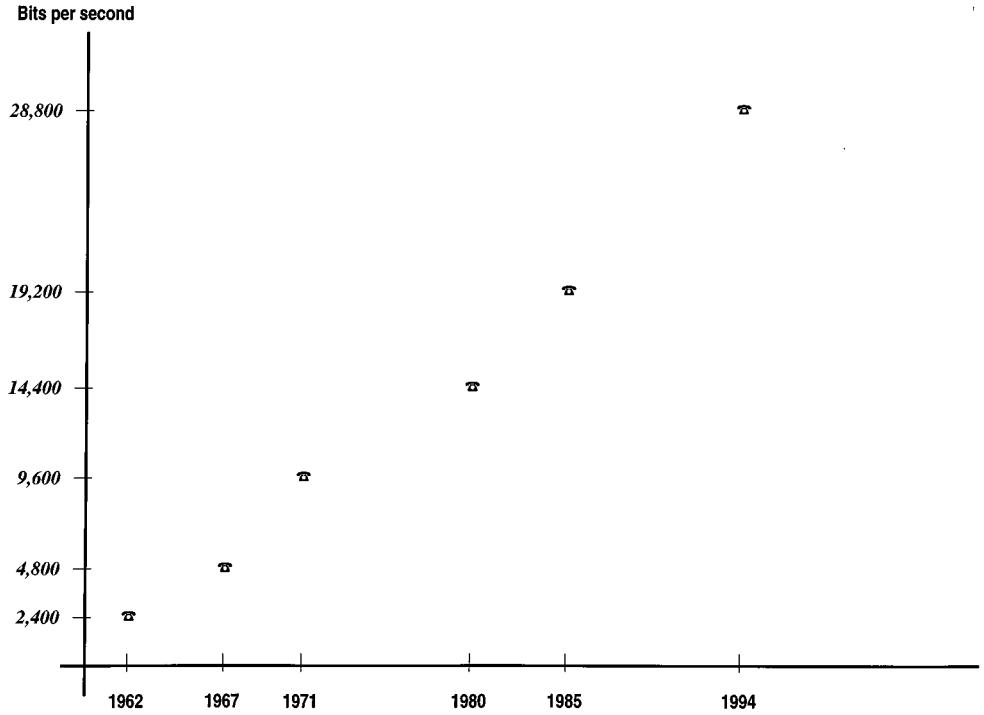

FIGURE 73.12 Information rates of modems for telephone channels.

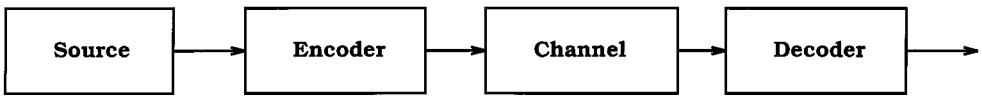

FIGURE 73.13 Elements of a communication system.

(Fig. 73.13)? Because considerations other than the optimization of the efficiency of the link are likely to dictate the choice of antenna size. This illustrates that the boundaries encoder–channel and channel–decoder in Fig. 73.13 are not always uniquely defined. This suggests an alternative definition of a channel as that part of the communication system that the designer is unable or unwilling to change.

A channel is characterized by the probability distributions of the output signals given every possible input signal. Channels are divided into (1) **discrete-time channels** and (2) **continuous-time channels** depending on whether the input/output signals are sequences or functions of a real variable. Some examples are as follows.

Example 1: Binary Symmetric Channel

A discrete-time **memoryless channel** with binary inputs and outputs (Fig. 73.14) where the probabilities that 0 and 1 are received erroneously are equal.

Example 2: Z-Channel

A discrete-time memoryless channel with binary inputs and outputs (Fig. 73.15) where 0 is received error-free.

Example 3: Erasure Channel

A discrete-time memoryless channel with binary inputs and ternary outputs (Fig. 73.16). The symbols 0 and 1 cannot be mistaken for each other but they can be "erased".

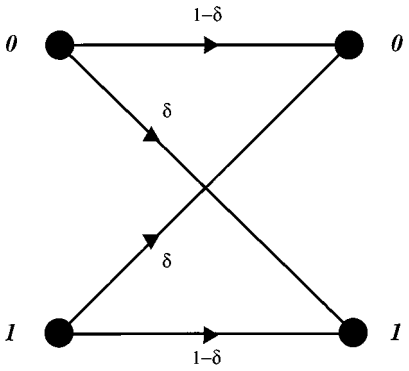

FIGURE 73.14 Binary symmetric channel.

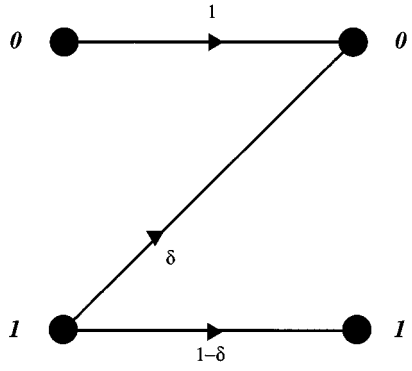

FIGURE 73.15 Z-channel.

Example 4: White Gaussian Discrete-Time Channel

A discrete-time channel whose output sequence is given by

$$y_i = x_i + n_i \tag{73.76}$$

where x_i is the input sequence and n_i is a sequence of independent Gaussian random variables with equal variance.

Example 5: Linear Continuous-Time Gaussian Channel

A continuous-time channel whose output signal is given by (Fig. 73.17)

$$y(t) = h(t) * x(t) + n(t) \tag{73.77}$$

where $x(t)$ is the input signal, $n(t)$ is a stationary Gaussian process, and $h(t)$ is the impulse response of a linear time-invariant system. The telephone channel is typically modeled by Eq. (73.77).

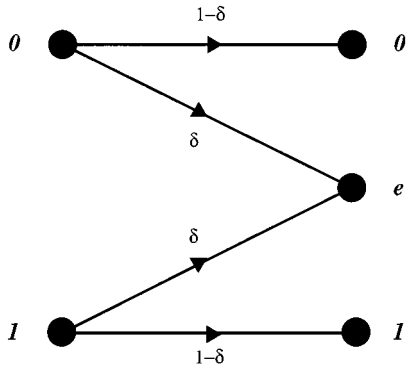

FIGURE 73.16 Erasure channel.

The goal of the encoder (Fig. 73.13) is to convert strings of binary data (messages) into channel-input signals. Source strings of m bits are translated into channel input strings of n symbols (with $m \leq n$) for discrete channels, and into continuous-time signals of duration T for continuous-time channels. The channel code (or more precisely the codebook) is the list of 2^m **codewords** (channel input signals) that may be sent by the encoder. The **rate** of the code is equal to the logarithm of its size divided by the duration of the codewords. Thus, the rate is equal to

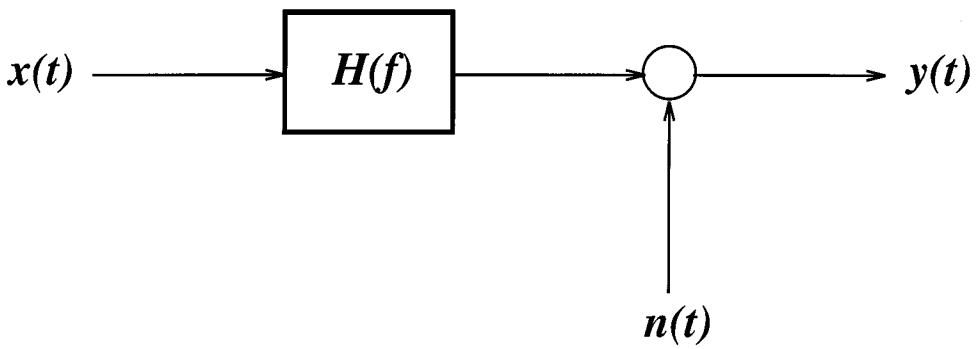

FIGURE 73.17 Linear continuous-time gaussian channel.

$$\frac{m}{n} \quad \text{bits per channel use}$$

for a discrete-time channel, whereas it is equal to

$$\frac{m}{T} \quad \text{bits per second}$$

for a continuous-time channel.

Once a codeword has been chosen by the encoder, the channel probabilistic mechanisms govern the distortion suffered by the transmitted signal. The role of the decoder is to recover the transmitted binary string (message) upon reception of the channel-distorted version of the transmitted codeword. To that end, the decoder knows the codebook used by the encoder. For most channels (including those above) there is a nonzero probability that the best decoder (maximum likelihood decoder) selects the wrong message. Thus, for a given channel the two figures of merit and of interest are the rate and the probability of error. The higher the tolerated probability of error, the higher the allowed rate; however, computing the exact tradeoff is a formidable task unless the code size either is very small or tends to infinity. The latter case was the one considered by Shannon and treated in the following section.

Reliable Information Transmission: Shannon's Theorem

Shannon [1948] considered the situation in which the codeword duration grows without bound. Channel capacity is the maximum rate for which encoders and decoders exist whose probability of error vanishes as the codewords get longer and longer.

Shannon's Theorem [Shannon, 1948] The capacity of a discrete memoryless channel is equal to

$$C = \max_X I(X; Y), \tag{73.78}$$

where $I(X; Y)$ stands for the input-output mutual information, which is a measure of the dependence of the input and the output defined as the divergence between the joint input/output distribution and the product of its marginals, $D(P_{XY}||P_X P_Y)$. For any pair of probability mass functions P and Q defined on the same space, divergence is an asymmetric measure of their similarity:

$$D(P||Q) = \sum_{x \in A} P(x) \log \frac{P(x)}{Q(x)}. \tag{73.79}$$

Divergence is zero if both distributions are equal; otherwise it is strictly positive. The maximization in Eq. (73.78) is over the set of input distributions. Although, in general, there is no closed-form solution for that optimization problem, an efficient algorithm was obtained by Blahut and Arimoto in 1972 [Blahut, 1987]. The distribution that attains the maximum in Eq. (73.78) determines the statistical behavior of optimal codes and, thus, is of interest to the designer of the encoder. For the discrete memoryless channels mentioned above, the capacity is given by the following examples.

Example 1: Binary Symmetric Channel

$$C = 1 - \delta \log \frac{1}{\delta} - (1 - \delta) \log \frac{1}{1 - \delta}$$

attained by an equiprobable distribution and shown in Fig. 73.18.

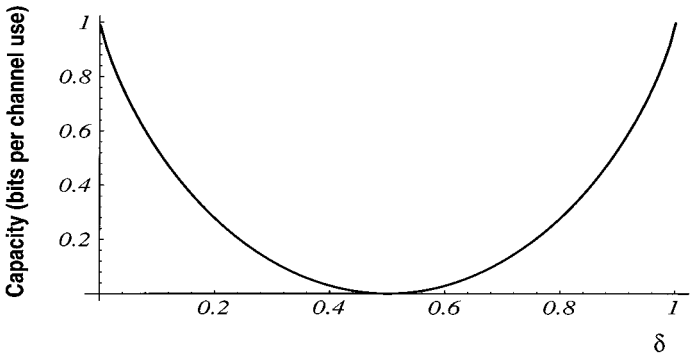

FIGURE 73.18 Capacity of the binary symmetric channel as a function of crossover probability.

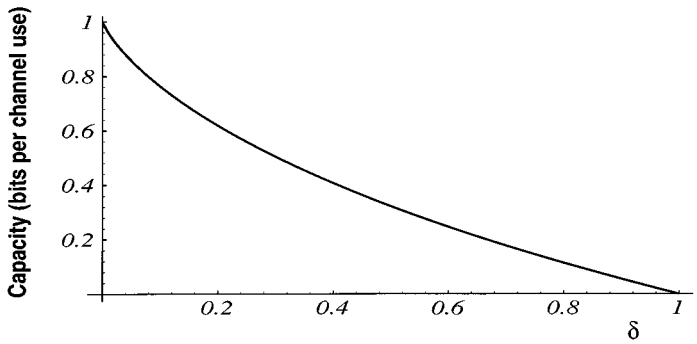

FIGURE 73.19 Capacity of the Z-channel.

Example 2: Z-Channel

$$C = \log\left(1 - \delta^{\frac{1}{1-\delta}} + \delta^{\frac{\delta}{1-\delta}}\right)$$

attained for a distribution whose probability mass at 0 ranges from 1/2 ($\delta = 0$) to $1/e$ ($\delta \to 1$) (Fig. 73.19).

Example 3: Erasure Channel

$$C = 1 - \delta$$

attained for equiprobable inputs.

Oftentimes the designer is satisfied with not exceeding a certain fixed level of bit error rate, ϵ, rather than the more stringent criterion of vanishing probability of selecting the wrong block of data. In such a case, it is possible to transmit information at a rate equal to capacity times

$$\left(1 - \epsilon \log \frac{1}{\epsilon} - (1 - \epsilon) \log \frac{1}{1 - \epsilon}\right)^{-1}$$

which is shown in Fig. 73.20.

If, contrary to what we have assumed thus far, the message source in Fig. 73.13 is not a source of pure bits, the significance of capacity can be extended to show that as long as the source entropy (see Chapter 73.6 on

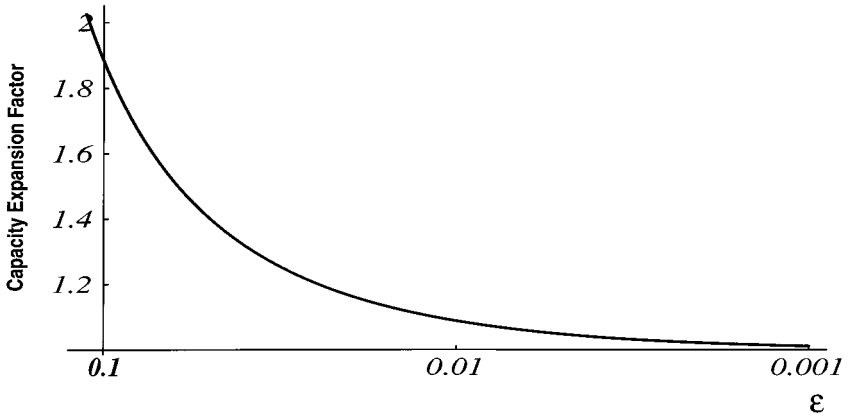

FIGURE 73.20 Capacity expansion factor as a function of bit-error-rate.

Data Compression) is below the channel capacity, an encoder/decoder pair exists that enables arbitrarily reliable communication. Conversely, if the source entropy is above capacity, then no such encoder/decoder pair exists.

Bandwidth and Capacity

The foregoing formulas for discrete channels do not lead to the capacity of continuous-time channels such as Example 5. We have seen that in the case of the telephone channel whose bandwidth is approximately equal to 3 kHz, capacity is lower bounded by 28,800 bits per second. How does bandwidth translate into capacity? The answer depends on the noise level and distribution. For example, if in the channel of Example 5, the noise is absent, capacity is infinite regardless of bandwidth. We can encode any amount of information as the binary expansion of a single scalar, which can be sent over the channel as the amplitude or phase of a single sinusoid; knowing the channel transfer function, the decoder can recover the transmitted scalar error-free. Clearly, such a transmission method is not recommended in practice because it hinges on the non-physical scenario of noiseless transmission.

In the simplest special case of Example 5, the noise is white, the channel has an ideal flat transfer function with bandwidth B (in Hz), and the input power is limited. Then, the channel capacity is equal to

$$C = B\ SNR^{dB} \log_2 10^{0.1} \quad \text{bits per second} \tag{73.80}$$

where $\log_2 10^{0.1} = 0.33$ and SNR^{dB} is equal to the optimum signal-to-noise ratio (in dB) of a linear estimate of a flat input signal given the channel output signal. Such an optimum signal-to-noise ratio is equal to one plus the power alloted to the input divided by the noise power in the channel band, i.e.,

$$SNR^{dB} = 10 \log_{10} \left(1 + \frac{P}{BN_0}\right).$$

It is interesting to notice that as the bandwidth grows, the channel capacity does not grow without bound. It tends to

$$\frac{P}{N_0} \log_2 e \qquad \text{bits per second}$$

where $\log_2 e = 1.44$. This means that the energy per bit necessary for reliable communication is equal to 0.69 times the noise power spectral density level. When the channel bandwidth is finite, the energy necessary to send one bit of information is strictly larger. The energy required to send one bit of information reliably can

be computed for other (non-Gaussian) channels even in cases where expressions for channel capacity are not known [Verdú, 1990].

When the channel transfer function $H(f)$ and/or noise spectral density $N(f)$ are not flat, the constant in Eq. (73.80) no longer applies. The so-called water-filling formula [Shannon, 1949] gives the channel capacity as

$$C = \frac{1}{2}\int \log\left(1 + \frac{\max\{0,\ w - M(f)\}}{M(f)}\right) df$$

where w is chosen so that

$$\int \max\{0,\ w - M(f)\}\, df = P,$$

and

$$M(f) = \frac{N(f)}{|H(f)|^2}.$$

The linear Gaussian-noise channel is a widely used model for space communication (in the power limited region) and for the telephone channel (in the bandwidth limited region). Thanks to the prevalence of digital switching and digital transmission in modern telephone systems, not only signal-to-noise ratios have improved over time but the Gaussian-noise model in Example 5 becomes increasingly questionable because quantization is responsible for a major component of the channel distortion. Therefore, future improvements in modem speeds are expected to arise mainly from finer modeling of the channel.

Due to the effect of time-varying received power (fading), several important channels fall outside the scope of Example 5 such as high-frequency radio links, tropospheric scatter links, and mobile radio channels.

Channel Coding Theorems

In information theory, the results that give a formula for channel capacity in terms of the probabilistic description of the channel are known as channel coding theorems. They typically involve two parts: an achievability part, which shows that codes with vanishing error probability exist for any rate below capacity; and a converse part, which shows that if the code rate exceeds capacity, then the probability of error is necessarily bounded away from zero. Shannon gave the first achievability results in [Shannon, 1948] for discrete memory channels. His method of proof, later formalized as the method of "typical sequences" (e.g., [Cover and Thomas, 1991]), is based on showing that the average probability of error of a code chosen at random vanishes with blocklength. Other known achievability proofs such as Feinstein's [1954], Gallager's [1968], and the method of types [Csiszar and Korner, 1981] are similarly non-constructive. The discipline of coding theory deals with constructive methods to design codes that approach the Shannon limit (see Chapter 71.1). The first converse channel coding theorem was not given by Shannon, but by Fano in 1952. A decade after Shannon's pioneering paper, several authors obtained the first channel coding theorems for channels with memory [Dobrushin, 1963]. The most general formula for channel capacity known to date can be found in [Verdú and Han, 1994]. The capacity of channels with feedback was first considered by Shannon in 1961 [Shannon, 1961], with later developments for Gaussian channels summarized in [Cover and Thomas, 1991]. In his 1961 paper [Shannon, 1961], Shannon founded the discipline of multiuser information theory by posing several challenging channels with more than one transmitter and/or receiver. In contrast to the **multiaccess channel** (one receiver) which has been solved in considerable generality, the capacities of channels involving more than one receiver, such as **broadcast channels** [Cover, 1972] and **interference channels** remain unsolved except in special cases.

Channel capacity has been shown to have a meaning outside the domain of information transmission [Han and Verdú, 1993]: it is the minimum rate of random bits required to generate any input random process so that the output process is simulated with arbitrary accuracy.

Defining Terms

Blocklength: The duration of a codeword, usually in the context of discrete-time channels.

Channel capacity: The maximum rate for which encoders and decoders exist whose probability of error vanishes as the codewords get longer and longer.

Codeword: Channel-input signal chosen by the encoder to represent the message.

Communication channel: Set of devices and systems that connect the transmitter to the receiver, not subject to optimization.

Broadcast channel: A communication channel with one input and several outputs each connected to a different receiver such that possibly different messages are to be conveyed to each receiver.

Discrete memoryless channel: A discrete-time memoryless channel where each channel input and output takes a finite number of values.

Discrete-time channel: A communication channel whose input/output signals are sequences of values. Its capacity is given in terms of bits per "channel use".

Continuous-time channel: A communication channel whose input/output signals are functions of a real variable (time). Its capacity is given in terms of bits per second.

Interference channel: A channel with several inputs/outputs such that autonomous transmitters are connected to each input and such that each receiver is interested in decoding the message sent by one and only one transmitter.

Memoryless channel: A channel where the conditional probability of the output given the current input is independent of all other inputs or outputs.

Multiaccess channel: A channel with several inputs and one output such that autonomous transmitters are connected to each input and such that the receiver is interested in decoding the messages sent by all the transmitters.

Decoder: Mapping from the set of channel-output signals to the set of messages.

Maximum-likelihood decoder: A decoder which selects the message that best explains the received signal, assuming all messages are equally likely.

Encoder: Mapping from the set of messages to the set of input codewords.

Modem: Device that converts binary information streams into electrical signals (and vice-versa) for transmission through the voiceband telephone channel.

Rate: The rate of a code is the number of bits transmitted (logarithm of code size) per second for a continuous-time channel or per channel use for a discrete-time channel.

73.6 Data Compression

Joy A. Thomas and Thomas M. Cover

Data compression is a process of finding the most efficient representation of an information source in order to minimize communication or storage. It often consists of two stages—the first is the choice of a (probabilistic) model for the source and the second is the design of an efficient coding system for the model. In this section, we will concentrate on the second aspect of the compression process, though we will touch on some common sources and models in the last subsection.

Thus, a data compressor (sometimes called a source coder) maps an information source into a sequence of bits, with a corresponding decompressor, that given these bits provides a reconstruction of the source. Data compression systems can be classified into two types: *lossless,* where the reconstruction is exactly equal to the original source, and *lossy,* where the reconstruction is a distorted version of the original source. For lossless data compression, the fundamental lower bound on the rate of the data compression system is given by the entropy rate of the source. For lossy data compression, we have a tradeoff between the rate of the compressor and the distortion we incur, and the fundamental limit is given by the rate distortion function, which is discussed later in this section.

Shannon [1948] was the first to distinguish the probabilistic model that underlies an information source from the semantics of the information. An information source produces one of many possible messages; the goal of communication is to transmit an unambiguous specification of the message so that the receiver can reconstruct the original message. For example, the information to be sent may be the result of a horse race. If the recipient is assumed to know the names and numbers of the horses, then all that must be transmitted is the number of the horse that won. In a different context, the same number might mean something quite different, e.g., the price of a barrel of oil. The significant fact is that the difficulty in communication depends only on the length of the representation. Thus, finding the best (shortest) representation of an information source is critical to efficient communication.

When the possible messages are all equally likely, then it makes sense to represent them by strings of equal length. For example, if there are 32 possible equally likely messages, then each message can be represented by a binary string of 5 bits. However, if the messages are not equally likely, then it is more efficient on the average to allot short strings to the frequently occurring messages and longer strings to the rare messages. Thus, the Morse code allots the shortest string (a dot) to the most frequent letter (E) and allots long strings to the infrequent letters (e.g., dash, dash, dot, dash for Q). The minimum average length of the representation is a fundamental quantity called the entropy of the source, which is defined in the next subsection.

Entropy

An information source will be represented by a random variable X, which takes on one of a finite number of possibilities $i \in \mathcal{X}$ with probability $p_i = \Pr(X = i)$. The entropy of the random variable X is defined as

$$H(X) = -\sum_{i \in \mathcal{X}} p_i \log p_i \tag{73.81}$$

where the log is to base 2 and the entropy is measured in *bits*. We will use logarithms to base 2 throughout this chapter.

Example 73.1 Let X be a random variable that takes on a value 1 with probability θ and takes on the value 0 with probability $1 - \theta$. Then $H(X) = -\theta \log \theta - (1 - \theta) \log (1 - \theta)$. In particular, the entropy of a fair coin toss with $\theta = \frac{1}{2}$ is 1 bit.

This definition of entropy is related to the definition of entropy in thermodynamics. It is the fundamental lower bound on the average length of a code for the random variable.

A **code** for a random variable X is a mapping from $\mathcal{X}$, the range of X, to the set of finite-length binary strings. We will denote the code word corresponding to i by $C(i)$, and the length of the code word by l_i. The average length of the code is then $L(C) = \Sigma_i p_i l_i$.

A code is said to be *instantaneous* or *prefix-free* if no code word is a prefix of any other code word. This condition is sufficient (but not necessary) to allow a sequence of received bits to be parsed unambiguously into a sequence of code words.

Example 73.2 Consider a random variable X taking on the values $\{1, 2, 3\}$ with probabilities (0.5, 0.25, 0.25). An instantaneous code for this random variable might be (0, 10, 11). Thus, a string 01001110 can be uniquely parsed into 0, 10, 0, 11, 10, which decodes to the string $x = (1, 2, 1, 3, 2)$. Note that the average length of the code is 1.5 bits, which is the same as the entropy of the source.

For any instantaneous code, the following property of binary trees called the *Kraft inequality* [Cover and Thomas, 1991].

$$\sum_i 2^{-l_i} \leq 1 \tag{73.82}$$

must hold. Conversely, it can be shown that given a set of lengths that satisfies the Kraft inequality, we can find a set of prefix-free code words of those lengths.

The problem of finding the best source code then reduces to finding the optimal set of lengths that satisfies the Kraft inequality and minimizes the average length of the code. Simple calculus can then be used to show [Cover and Thomas, 1991] that the average length of any instantaneous code is larger than the entropy of the random variable, i.e., the minimum of $\Sigma p_i l_i$ over all l_i satisfying $\Sigma\, 2^{-l_i} \leq 1$ is $-\Sigma p_i \log p_i$. Also, if we take $l_i = \lceil \log 1/p_i \rceil$ (where $\lceil t \rceil$ denotes the smallest integer greater than or equal to t), we can verify that this choice of lengths satisfies the Kraft inequality and that

$$L(C) = \sum_i p_i \left\lceil \log \frac{1}{p_i} \right\rceil < \sum_i p_i \left(\log \frac{1}{p_i} + 1 \right) = H(X) + 1 \tag{73.83}$$

The optimal code can only have a shorter length, and therefore we have the following theorem:

Theorem 73.1 Let L^* be the average length of the optimal instantaneous code for a random variable X. Then

$$H(X) \leq L^* < H(X) + 1 \tag{73.84}$$

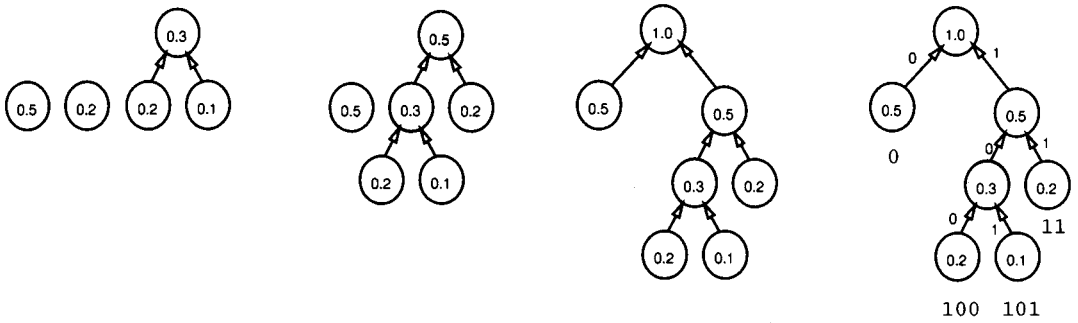

FIGURE 73.21 Example of the Huffman algorithm.

This theorem is one of the fundamental theorems of information theory. It identifies the entropy as the fundamental limit for the average length of the representation of a discrete information source and shows that we can find representations with average length within one bit of the entropy.

The Huffman Algorithm

The choice of code word lengths $l_i = \lceil \log 1/p_i \rceil$ (called the *Shannon code lengths*) is close to optimal, but not necessarily optimal, in terms of average code word length. We will now describe an algorithm (the **Huffman algorithm**) that produces an instantaneous code of minimal average length for a random variable with distribution $p_1, p_2, \ldots, p_m$. The algorithm is a greedy algorithm for building a tree from the bottom up.

Step 1. Arrange the probabilities in decreasing order so that $p_1 \geq p_2 \geq \ldots \geq p_m$.
Step 2. Form a subtree by combining the last two probabilities p_{m-1} and p_m to a single node of weight $p'_{m-1} = p_{m-1} + p_m$.
Step 3. Recursively execute Steps 1 and 2, decreasing the number of nodes each time, until a single node is obtained.
Step 4. Use the tree constructed above to allot code words.

The algorithm for tree construction is illustrated for a source with distribution (0.5, 0.2, 0.2, 0.1) in Fig. 73.21. After constructing the tree, the leaves of the tree (which correspond to the symbols of $\mathcal{X}$) can be assigned code words that correspond to the paths from the root to the leaf. We will not give a proof of the optimality of the Huffman algorithm; the reader is referred to Gallager [1968] or Cover and Thomas [1991] for details.

Entropy Rate

The entropy of a sequence of random variables $X_1, X_2, \ldots, X_n$ with joint distribution $p(x_1, x_2, \ldots, x_n)$ is defined analogously to the entropy of a single random variable as

$$H(X_1, X_2, \ldots, X_n) = -\sum_{x_1}\sum_{x_2}\cdots\sum_{x_n} p(x_1, x_2, \ldots, x_n)\log p(x_1, x_2, \ldots, x_n) \qquad (73.85)$$

For a stationary process $X_1, X_2, \ldots$, we define the *entropy rate* $\mathcal{H}(\mathcal{X})$ of the process as

$$\mathcal{H}(\mathcal{X}) = \lim_{n\to\infty} \frac{H(X_1, X_2, \ldots, X_n)}{n} \qquad (73.86)$$

It can be shown [Cover and Thomas, 1991] that the entropy rate is well defined for all stationary processes. In particular, if $X_1, X_2, \ldots, X_n$ is a sequence of independent and identically distributed (i.i.d.) random variables, then $H(X_1, X_2, \ldots, X_n) = nH(X_1)$, and $\mathcal{H}(\mathcal{X}) = H(X_1)$.

In the previous subsection, we showed the existence of a prefix-free code having an average length within one bit of the entropy. Now instead of trying to represent one occurrence of the random variable, we can form a code to represent a block of n random variables. In this case, the average code length is within one bit of $H(X_1, X_2, \ldots, X_n)$. Thus, the average length of the code per input symbol satisfies

$$\frac{H(X_1, X_2, \ldots, X_n)}{n} \leq \frac{L_n^*}{n} < \frac{H(X_1, X_2, \ldots, X_n)}{n} + \frac{1}{n} \tag{73.87}$$

Since $[H(X_1, X_2, \ldots, X_n)]/n \to \mathcal{H}(\mathcal{X})$, we can get arbitrarily close to the entropy rate by using longer and longer block lengths. Thus, the entropy rate is the fundamental limit for data compression for stationary sources, and we can achieve rates arbitrarily close to this limit by using long blocks.

All the above assumes that we know the probability distribution that underlies the information source. In many practical examples, however, the distribution is unknown or too complex to be used for coding. There are various ways to handle this situation:

- Assume a simple distribution and design an appropriate code for it. Use this code on the real source. If an estimated distribution $\hat{p}$ is used when in fact the true distribution is p, then the average length of the code is lower bounded by $H(X) + \Sigma_x p(x) \log [p(x)/\hat{p}(x)]$. The second term, which is denoted $D(p \| \hat{p})$ is called the *relative entropy* or the *Kullback Leibler distance* between the two distributions.
- Estimate the distribution empirically from the source and adapt the code to the distribution. For example, with *adaptive Huffman coding*, the empirical distribution of the source symbols is used to design the Huffman code used for the source.
- Use a *universal coding algorithm* like the **Lempel–Ziv algorithm** (see the subsection "Lempel–Ziv Coding").

Arithmetic Coding

In the previous subsections, it was shown how we could construct a code for a source that achieves an average length within one bit of the entropy. For small source alphabets, however, we have efficient coding only if we use long blocks of source symbols. For example, if the source is binary, and we code each symbol separately, we must use 1 bit per symbol, irrespective of the entropy of the source. If we use long blocks, we can achieve an expected length per symbol close to the entropy rate of the source.

It is therefore desirable to have an efficient coding procedure that works for long blocks of source symbols. Huffman coding is not ideal for this situation, since it is a bottom-up procedure with a complexity that grows rapidly with the block length. Arithmetic coding is an incremental coding algorithm that works efficiently for long block lengths and achieves an average length within one bit of the entropy for the block.

The essential idea of arithmetic coding is to represent a sequence $x^n = x_1, x_2, \ldots, x_n$ by the cumulative distribution function $F(x^n)$ (the sum of the probability of all sequences less than x^n) expressed to an appropriate accuracy. The cumulative distribution function for x^n is illustrated in Fig. 73.22. We can use any real number in the interval $[F(x^n) - p(x^n), F(x^n)]$ as the code for x^n. Expressing $F(x^n)$ to an accuracy of $\lceil \log 1/p(x^n) \rceil$ will give us a code for the source. The receiver can draw the cumulative distribution function, draw a horizontal line corresponding to the truncated value $\lfloor F(x^n) \rfloor$ that was sent, and read off the corresponding x^n. (This code is not prefix-free but can be easily modified to construct a prefix-free code [Cover and Thomas, 1991]). To implement arithmetic coding, however, we need efficient algorithms to calculate $p(x^n)$ and $F(x^n)$ to the appropriate accuracy based on a probabilistic model for the source. Details can be found in Langdon [1984] and Bell et al. [1990].

Lempel–Ziv Coding

The Lempel–Ziv algorithm [Ziv and Lempel, 1978] is a universal coding procedure that does not require knowledge of the source statistics and yet is asymptotically optimal. The basic idea of the algorithm is to construct a table or dictionary of frequently occurring strings and to represent new strings by pointing to their prefixes in the table. We first parse the string into sequences that have not appeared so far. For example, the

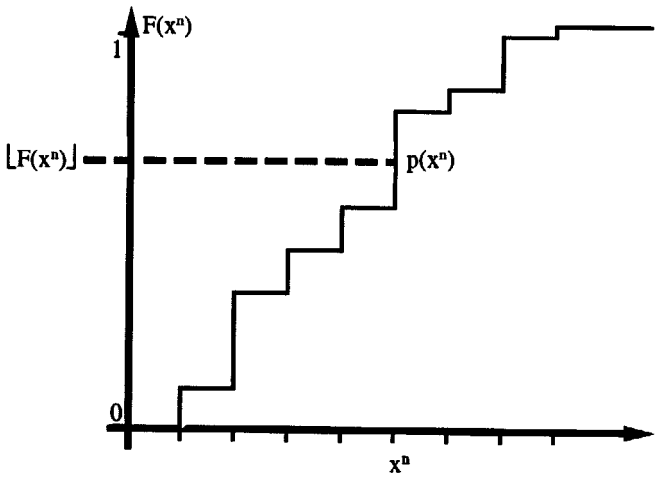

FIGURE 73.22 Cumulative distribution function for sequences x^n.

binary string 11010011011100 is parsed into 1,10,100,11,0,111,00. Then instead of sending the bits of each phrase, we send a pointer to its prefix and the value of the last bit. Thus, if we use three bits for the pointer, we will represent this string by (000,1), (001,0), (010,0), (001,1), (000,0), (100,1), (101,0), etc. For this short example, the algorithm has not compressed the string—it has in fact expanded it.

The very surprising fact is that, as Lempel and Ziv have shown, the algorithm is asymptotically optimal for any stationary ergodic source. This is expressed in the following theorem [Ziv and Lempel, 1978; Cover and Thomas, 1991]:

Theorem 73.2 Let L_n be the length of the Lempel–Ziv code for n symbols drawn from a stationary ergodic process $X_1, X_2, \ldots, X_n$ with entropy rate $\mathcal{H}(\mathcal{X})$. Then

$$\frac{L_n}{n} \to \mathcal{H}(\mathcal{X}) \quad \text{with probability 1} \tag{73.88}$$

Thus, for long enough block lengths, the Lempel–Ziv algorithm (which does not make any assumptions about the distribution of the source) does as well as if we knew the distribution in advance and designed the optimal code for this distribution.

The algorithm described above is only one of a large class of similar adaptive dictionary-based algorithms, which are all rather loosely called Lempel–Ziv. These algorithms are simple and fast and have been implemented in both software and hardware, e.g., in the *compress* command in UNIX and the *PKZIP* command on PCs. On ASCII text files, the Lempel–Ziv algorithm achieves compressions on the order of 50%. It has also been implemented in hardware and has been used to "double" the capacity of data storage media or to "double" the effective transmission rate of a modem. Many variations on the basic algorithm can be found in Bell et al. [1990].

Rate Distortion Theory

An infinite number of bits are required to describe an arbitrary real number, and therefore it is not possible to perfectly represent a continuous random variable with a finite number of bits. How "good" can the representation be? We first define a distortion measure, which is a measure of the distance between the random variable and its representation. We can then consider the trade-off between the number of bits used to represent a random variable and the distortion incurred. This trade-off is represented by the **rate distortion function** $R(D)$, which represents the minimum rate required to represent a random variable with a distortion D.

We will consider a discrete information source that produces random variables $X_1, X_2, \ldots, X_n$ that are drawn i.i.d. according to $p(x)$. (The results are also valid for continuous sources.) The encoder of the rate distortion

system of rate R will encode a block of n outputs X^n as an index $f(X^n) \in \{1, 2, \ldots, \lfloor 2^{nR} \rfloor\}$. (Thus, the index will require R bits/input symbol.) The decoder will calculate a representation $\hat{X}^n(f(X^n))$ of X^n. Normally, the representation alphabet $\hat{X}$ of the representation is the same as the source alphabet $\mathcal{X}$, but that need not be the case.

Definition: A *distortion function* or *distortion measure* is a mapping

$$d : \mathcal{X} \times \hat{\mathcal{X}} \rightarrow R^+ \tag{73.89}$$

from the set of source alphabet–reproduction alphabet pairs into the set of nonnegative real numbers. The distortion $d(x, \hat{x})$ is a measure of the cost of representing the symbol x by the symbol $\hat{x}$.

Examples of common distortion functions are

- *Hamming (probability of error) distortion.* The Hamming distortion is given by

$$d(x, \hat{x}) = \begin{cases} 0 \text{ if } x = \hat{x} \\ 1 \text{ if } x \neq \hat{x} \end{cases} \tag{73.90}$$

  and thus $Ed(X, \hat{X}) = \Pr(X \neq \hat{X})$.
- *Squared error distortion.* The squared error distortion

$$d(x, \hat{x}) = (x - \hat{x})^2 \tag{73.91}$$

  is the most popular distortion measure used for continuous alphabets. Its advantages are its simplicity and its relationship to least squares prediction. However, for information sources such as images and speech, the squared error is not an appropriate measure for distortion as perceived by a human observer.

The distortion between sequences x^n and $\hat{x}^n$ of length n is defined by

$$d(x^n, \hat{x}^n) = \frac{1}{n} \sum_{i=1}^{n} d(x_i, \hat{x}_i) \tag{73.92}$$

For a rate distortion system, the expected distortion D is defined as

$$D = Ed(X^n, \hat{X}^n(f(X^n))) = \sum_{x^n} p(x^n) d(x^n, \hat{X}^n(f(x^n))) \tag{73.93}$$

Definition: The rate distortion pair (R,D) is said to be achievable if there exists a rate distortion code of rate R with expected distortion D. The *rate distortion function* $R(D)$ is the infimum of rates R such that (R,D) is achievable for a given D.

Definition: The *mutual information* $I(X, \hat{X})$ between random variables X and $\hat{X}$, with joint probability mass function $p(x, \hat{x})$ and marginal probability mass functions $p(x)$ and $p(\hat{x})$ is defined as

$$I(X; \hat{X}) = \sum_{x \in \mathcal{X}} \sum_{\hat{x} \in \hat{\mathcal{X}}} p(x, \hat{x}) \log \frac{p(x, \hat{x})}{p(x)p(\hat{x})} \tag{73.94}$$

The mutual information is a measure of the amount of information that one random variable carries about another.

The main result of rate distortion theory is contained in the following theorem, which provides a characterization of the rate distortion function in terms of the mutual information of joint distributions that satisfy the expected distortion constraint:

Theorem 73.3 The rate distortion function for an i.i.d. source X with distribution $p(x)$ and distortion function $d(x, \hat{x})$ is

$$R(D) = \min_{p(\hat{x}|x):\Sigma_{(x,\hat{x})}p(x)p(\hat{x}|x)d(x,\hat{x})\le D} I(X; \hat{X}) \tag{73.95}$$

We can construct rate distortion codes that can achieve distortion D at any rate greater than $R(D)$, and we cannot construct such codes at any rate below $R(D)$.

The proof of this theorem uses ideas of random coding and long block lengths as in the proof of the channel capacity theorem. The basic idea is to generate a code book of 2^{nR} reproduction code words $\hat{X}^n$ at random and show that for long block lengths, for any source sequence, it is very likely that there is at least one code word in this code book that is within distortion D of that source sequence. See Gallager [1968] or Cover and Thomas [1991] for details of the proof.

Example 73.3 (*Binary source*) The rate distortion function for a Bernoulli (p) source (a random variable that takes on values $\{0, 1\}$ with probabilities p, $1 - p$) with Hamming distortion is given by

$$R(D) = \begin{cases} H(p) - H(D), & 0 \le D \le \min\{p, 1-p\} \\ 0, & D > \min\{p, 1-p\} \end{cases} \tag{73.96}$$

where $H(p) = -p \log p - (1 - p)\log (1 - p)$ is the binary entropy function.

Example 73.4 (*Gaussian source*) The rate distortion function for a Gaussian random variable with variance σ^2 and squared error distortion is

$$R(D) = \begin{cases} \frac{1}{2} \log \frac{\sigma^2}{D}, & 0 \le D \le \sigma^2 \\ 0, & D > \sigma^2 \end{cases} \tag{73.97}$$

Thus, with nR bits, we can describe n i.i.d. Gaussian random variables $X_1, X_2, \ldots, X_n \sim \mathcal{N}(0, \sigma^2)$ with a distortion of $\sigma^2 2^{-2R}$ per symbol.

Quantization and Vector Quantization

The rate distortion function represents the lower bound on the rate that is needed to represent a source with a particular distortion. We now consider simple algorithms that represent a continuous random variable with a few bits. Suppose we want to represent a single sample from a continuous source. Let the random variable to be represented be X and let the representation of X be denoted as $\hat{X}(X)$. If we are given R bits to represent X, then the function $\hat{X}$ can take on 2^R values. The problem of optimum **quantization** is to find the optimum set of values for $\hat{X}$ (called the reproduction points or code points) and the regions that are associated with each value $\hat{X}$ in order to minimize the expected distortion.

For example, let X be a Gaussian random variable with mean 0 and variance σ^2, and assume a squared error distortion measure. In this case, we wish to find the function $\hat{X}(X)$ such that $\hat{X}$ takes on at most 2^R values and minimizes $E(X - \hat{X}(X))^2$. If we are given 1 bit to represent X, it is clear that the bit should distinguish whether $X > 0$ or not. To minimize squared error, each reproduced symbol should be at the conditional mean of its region. If we are given 2 bits to represent the sample, the situation is not as simple. Clearly, we want to divide the real line into four regions and use a point within each region to represent the samples within that region.

We can state two simple properties of optimal regions and reconstruction points for the quantization of a single random variable:

- Given a set of reconstruction points, the distortion is minimized by mapping a source random variable X to the representation $\hat{X}(w)$ that is closest to it (in distortion). The set of regions defined by this mapping is called a Voronoi or Dirichlet partition defined by the reconstruction points.
- The reconstruction points should minimize the conditional expected distortion over their respective assignment regions.

These two properties enable us to construct a simple algorithm to find a "good" quantizer: we start with a set of reconstruction points, find the optimal set of reconstruction regions (which are the nearest neighbor regions with respect to the distortion measure), then find the optimal reconstruction points for these regions (the centroids of these regions if the distortion measure is squared error), and then repeat the iteration for this new set of reconstruction points. The expected distortion is decreased at each stage in the algorithm, so the algorithm will converge to a local minimum of the distortion. This algorithm is called the *Lloyd algorithm* [Gersho and Gray, 1992].

It follows from the arguments of rate distortion theory that we will do better if we encode long blocks of source symbols rather than encoding each symbol individually. In this case, we will consider a block of n symbols from the source as a vector-valued random variable, and we will represent these n-dimensional vectors by a set of 2^{nR} code words. This process is called **vector quantization** (VQ). We can apply the Lloyd algorithm to design a set of representation vectors (the code book) and the corresponding nearest neighbor regions. Instead of using the probability distribution for the source to calculate the centroids of the regions, we can use the empirical distribution from a training sequence. Many variations of the basic vector quantization algorithm are described in Gersho and Gray [1992].

Common information sources like speech produce continuous waveforms, not discrete sequences of random variables as in the models we have been considering so far. By sampling the signal at twice the maximum frequency present (the Nyquist rate), however, we convert the continuous time signal into a set of discrete samples from which the original signal can be recovered (the sampling theorem). We can then apply the theory of rate distortion and vector quantization to such waveform sources as well.

Kolmogorov Complexity

In the 1960s, the Russian mathematican Kolmogorov considered the question "What is the intrinsic descriptive complexity of a binary string?" From the preceding discussion, it follows that if the binary string were a sequence of i.i.d. random variables $X_1, X_2, \ldots, X_n$, then on the average it would take $nH(X)$ bits to represent the sequence. But what if the bits were the first million bits of the binary expansion of π? In that case, the string appears random but can be generated by a simple computer program. So if we wanted to send these million bits to another location which has a computer, we could instead send the program and ask the computer to generate these million bits. Thus, the descriptive complexity of π is quite small.

Motivated by such considerations, Kolmogorov defined the complexity of a binary string to be the length of the shortest program for a universal computer that generates that string. (This concept was also proposed independently and at about the same time by Chaitin and Solomonoff.)

Definition: The ***Kolmogorov complexity*** $K_{\mathcal{U}}(x)$ of a string x with respect to a universal computer $\mathcal{U}$ is defined as

$$K_{\mathcal{U}}(x) = \min_{p:\mathcal{U}(p)=x} l(p) \tag{73.98}$$

the minimum length over all programs that print x and halt. Thus $K_{\mathcal{U}}(x)$ is the shortest description length of x over all descriptions interpreted by computer $\mathcal{U}$.

A universal computer can be thought of as a Turing machine that can simulate any other universal computer. At first sight, the definition of Kolmogorov complexity seems to be useless, since it depends on the particular

computer that we are talking about. But using the fact that any universal computer can simulate any other universal computer, any program for one computer can be converted to a program for another computer by adding a constant length "simulation program" as a prefix. Thus, we can show [Cover and Thomas, 1991] that for any two universal computers, $\mathcal{U}$ and $\mathcal{A}$,

$$\left|K_{\mathcal{U}}(x) - K_{\mathcal{A}}(x)\right| < c \tag{73.99}$$

where the constant c, though large, does not depend on the string x under consideration. Thus, Kolmogorov complexity is universal in that it does not depend on the computer (up to a constant additive factor).

Kolmogorov complexity provides a unified way to think about problems of data compression. It is also the basis of principles of inference (Occam's razor: "The simplest explanation is the best") and is closely tied with the theory of computability.

Data Compression in Practice

The previous subsections discussed the fundamental limits to compression for a stochastic source. We will now consider the application of these algorithms to some practical sources, namely, text, speech, images, and video. In real applications, the sources may not be stationary or ergodic, and the distributions underlying the source are often unknown. Also, in addition to the efficiency of the algorithm, important considerations in practical applications include the computational speed and memory requirements of the algorithm, the perceptual quality of the reproductions to a human observer, etc. A considerable amount of research and engineering has gone into the development of these algorithms, and many issues are only now being explored. We will not go into the details but simply list some popular algorithms for the different sources.

Text

English text is normally represented in ASCII, which uses 8 bits/character. There is considerable redundancy in this representation (the entropy rate of English is about 1.3 bits/character). Popular compression algorithms include variants of the Lempel–Ziv algorithm, which compress text files by about 50% (to about 4 bits/character).

Speech

Telephone quality speech is normally sampled at 8 kHz and quantized at 8 bits/sample (a rate of 64 kbits/s) for uncompressed speech. Simple compression algorithms like adaptive differential pulse code modulation (ADPCM) [Jayant and Noll, 1984] use the correlation between adjacent samples to reduce the number of bits used by a factor of two to four or more with almost imperceptible distortion. Much higher compression ratios can be obtained with algorithms like linear predictive coding (LPC), which model speech as an autoregressive process, and send the parameters of the process as opposed to sending the speech itself. With LPC-based methods, it is possible to code speech at less than 4 kbits/s. At very low bit rates, however, the reproduced speech sounds synthetic.

Images

A single high-quality color image of 1024 by 1024 pixels with 24 bits per pixel represents about 3 MB of storage in an uncompressed form, which will take more than 14 minutes to transmit over a 28800-baud modem. It is therefore very important to use compression to save storage and communication capacity for images. Many different algorithms have been proposed for image compression, and standards are still being developed for compression of images. For example, the popular GIF standard uses a patented version of Lempel–Ziv coding, and the JPEG standard being developed by the Joint Photographic Experts Group uses an 8 by 8 discrete cosine transform (DCT) followed by quantization (the quality of which can be chosen by the user) and Huffman coding. Newer compression algorithms using wavelets or fractals offer higher compression than JPEG. The compression ratios achieved by these algorithms are very dependent on the image being coded. The lossless compression methods achieve compression ratios of up to about 3:1, whereas lossy compression methods achieve ratios up to 50:1 with very little perceptible loss of quality.

Video

Video compression methods exploit the correlation in both space and time of the sequence of images to improve compression. There is a very high correlation between successive frames of a video signal, and this can be exploited along with methods similar to those used for coding images to achieve compression ratios up to 200:1 for high-quality lossy compression. Standards for full-motion video and audio compression are being developed by the Moving Pictures Experts Group (MPEG). Applications of video compression techniques include video-conferencing, multimedia CD-ROMs, and high-definition TV.

A fascinating and very readable introduction to different sources of information, their entropy rates, and different compression algorithms can be found in the book by Lucky [1989]. Implementations of popular data compression algorithms including adaptive Huffman coding, arithmetic coding, Lempel–Ziv and the JPEG algorithm can be found in Nelson and Gailly [1995].

Defining Terms

Code: A mapping from a set of messages into binary strings.

Entropy: A measure of the average uncertainty of a random variable. For a random variable with probability distribution $p(x)$, the entropy $H(X)$ is defined as $\Sigma_x - p(x) \log p(x)$.

Huffman coding: A procedure that constructs the code of minimum average length for a random variable.

Kolmogorov complexity: The minimum length description of a binary string that would enable a universal computer to reconstruct the string.

Lempel-Ziv coding: A dictionary-based procedure for coding that does not use the probability distribution of the source and is nonetheless asymptotically optimal.

Quantization: A process by which the output of a continuous source is represented by one of a set of discrete points.

Rate distortion function: The minimum rate at which a source can be described to within a given average distortion.

Vector quantization: Quantization applied to vectors or blocks of outputs of a continuous source.

74.1 Introduction

The impact of satellites on world communications since commercial operations began in the mid-1960s is such that we now take for granted many services that were not available a few decades ago: worldwide TV, reliable communications with ships and aircraft, wide area data networks, communications to remote areas, direct TV broadcast to homes, position determination, and earth observation (weather and mapping). New and proposed satellite services include global personal communications to hand-held portable telephones, and broadband voice, video, and data to and from small user terminals at customer premises around the world.

Satellites function as line-of-sight microwave relays in orbits high above the earth which can see large areas of the earth's surface. Because of this unique feature, satellites are particularly well suited to communications over wide coverage areas such as for broadcasting, mobile communications, and point-to-multipoint communications. Satellite systems can also provide cost-effective access for many locations where the high investment cost of terrestrial facilities might not be warranted.

74.2 Satellite Applications

Figure 74.1 depicts several kinds of satellite links and orbits. The geostationary earth orbit (GEO) is in the equatorial plane at an altitude of 35,786 km with a period of one sidereal day (23h 56m 4.09s). This orbit is sometimes called the Clarke orbit in honor of Arthur C. Clarke who first described its usefulness for communications in 1945. GEO satellites appear to be almost stationary from the ground (subject to small perturbations) and the earth antennas pointing to these satellites may need only limited or no tracking capability.

An orbit for which the highest altitude (apogee) is greater than GEO is sometimes referred to as high earth orbit (HEO). Low earth orbits (LEO) typically range from a few hundred km to about 2000 km. Medium earth orbits (MEO) are at intermediate altitudes. Circular MEO orbits, also called Intermediate Circular Orbits (ICO)

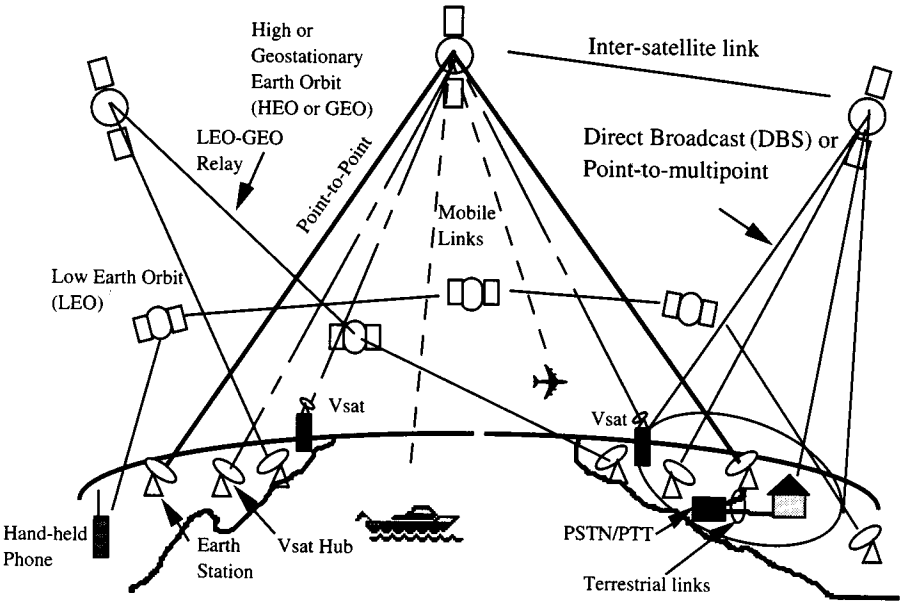

FIGURE 74.1 Several types of satellite links. Illustrated are point-to-point, point-to-multipoint, VSAT, direct broadcast, mobile, personal communications, and intersatellite links.

have been proposed at an altitude of about 10,400 km for global personal communications at frequencies designated for Mobile Satellite Services (MSS) [Johannsen, 1995].

LEO systems for voice communications are called *Big LEOs.* Constellations of so-called *Little LEOs* operating below 1 GHz and having only limited capacity have been proposed for low data rate non-voice services, such as paging and store and forward data for remote location and monitoring, for example, for freight containers and remote vehicles and personnel [Kiesling, 1996].

Initially, satellites were used primarily for point-to-point traffic in the GEO fixed satellite service (FSS), e.g., for telephony across the oceans and for point-to-multipoint TV distribution to cable *head end* stations. Large earth station antennas with high-gain narrow beams and high uplink powers were needed to compensate for limited satellite power. This type of system, exemplified by the early global network of the International Telecommunications Satellite Organization (INTELSAT) used Standard-A earth antennas with 30-m diameters. Since then, many other satellite organizations have been formed around the world to provide international, regional, and domestic services.

As satellites have grown in power and sophistication, the average size of the earth terminals has been reduced. High gain satellite antennas and relatively high power satellite transmitters have led to *very small aperture* earth *terminals* (VSAT) with diameters of less than 2 m, modest powers of less than 10 W [Gagliardi, 1991] and even smaller *ultra-small aperture terminals* (USAT) diameters typically less than 1 m. As depicted in Fig. 74.1, VSAT terminals may be placed atop urban office buildings, permitting private networks of hundreds or thousands of terminals, which bypass terrestrial lines. VSATs are usually incorporated into *star* networks where the small terminals communicate through the satellite with a larger *Hub* terminal. The hub retransmits through the satellite to another small terminal. Such links require two *hops* with attendant time delays. With high gain satellite antennas and relatively narrow-band digital signals, direct single-hop *mesh* interconnections of VSATs may be used.

74.3 Satellite Functions

The traditional function of a satellite is that of a bent pipe quasilinear repeater in space. As shown in Fig. 74.2, *uplink* signals from earth terminals directed at the satellite are received by the satellite's antennas, amplified, translated to a different *downlink* frequency band, channelized into *transponder channels,* further amplified to

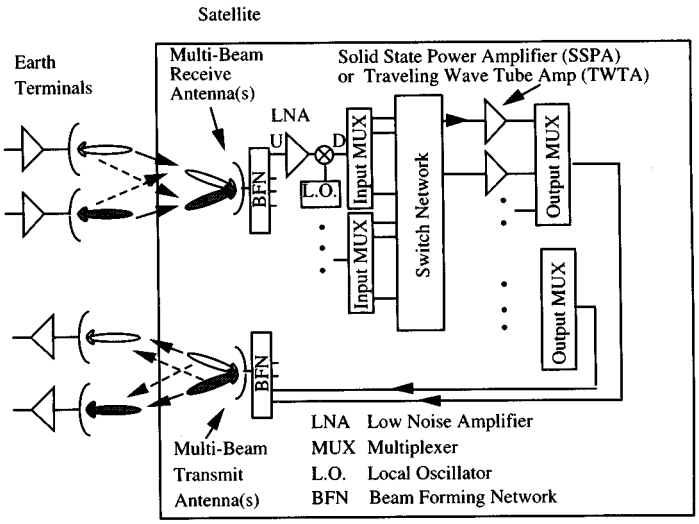

FIGURE 74.2 A satellite repeater receives uplink signals (U), translates them to a downlink frequency band (D), channelizes, amplifies to high power, and retransmits to earth. Multiple beams allow reuse of the available band. Interference (dashed lines) can limit performance. Downconversion may also occur after the input multiplexers. Several intermediate frequencies and downconversions may be used.

relatively high power, and retransmitted toward the earth. Transponder channels are generally rather broad (e.g., bandwidths from 24 MHz to more than 100 MHz) and each may contain many individual or user channels.

The functional diagram in Fig. 74.2 is appropriate to a satellite using frequency-division duplex (FDD), which refers to the fact that the satellites use separate frequency bands for the uplink and downlink and where both links operate simultaneously. This diagram also illustrates a particular *multiple access* technique, known as frequency-division multiple access (FDMA), which has been prevalent in mature satellite systems.

Multiple access, to be discussed later, allows many different user signals to utilize the satellite's resources of power and bandwidth without interfering with each other. Multiple access systems segregate users by frequency division (FDMA) where each user is assigned a specific frequency channel, space-division multiple access (SDMA) by *frequency reuse,* that is by reusing the same frequencies on multiple spatially isolated beams, time-division multiple access (TDMA) where each user signal occupies an entire allocated frequency band but for only part of the time, polarization-division (PD) where frequencies may be reused on spatially overlapping but orthogonally polarized beams, and code-division multiple access (CDMA) where different users occupy the same frequency band but use spread spectrum signals that contain orthogonal signaling codes [Sklar, 1988; Richharia, 1995].

Frequency modulation (FM) has been the most widely used modulation. However, advances in digital voice and video compression have led to the widespread use of digital modulation methods such as quadrature phase shift keying (QPSK) and quadrature amplitude modulation (QAM) [Sklar, 1988].

Newer satellite architectures incorporate digital modulations and on-board demodulation of the uplink signals to baseband bits, subsequent switching and assignment of the baseband signals to an appropriate downlink antenna beam, and re-modulation of the clean baseband signals prior to downlink transmission. These *regenerative repeaters* or *onboard processors* permit flexible routing of the user signals and can improve the overall communications link by separating the uplink noise from that of the downlink. The baseband signals may be those of individual users or they may represent frequency-division multiplexed (FDM) or time-division multiplexed (TDM) signals from many users.

Examples include the NASA Advanced Communications Technology Satellite (ACTS) and the Iridium® system built by Motorola for Iridium LLC. The ACTS is an FDD satellite system operating in the Ka-bands with uplink frequencies from 29.1 to 30.0 GHz and downlink frequencies from 19.2 to 20.1 GHz. It is intended to demonstrate technologies for future broadband voice, video, and data services applicable to the emerging concepts of the Global Information Infrastructure (GII) and National Information Infrastructure (NII) [Gedney, 1996].

Proposed Ka-band satellite systems that would operate at the 20- and 30-GHz bands may incorporate intersatellite links at Ka-band or even at 60 GHz. These systems are intended to provide broadband voice, video, and data services for the GII. Systems have been proposed for operation at GEO and LEO.

The Iridium satellites operate at LEO (altitude = 780 km) with time-division duplex (TDD), using the same 1.6-GHz L-band frequencies for transmission and reception but only receiving or transmitting for somewhat less than half the time each. Iridium uses 66 LEO satellites for personal communications systems (PCS) to enable communications directly to and from small handheld portable telephones at any time and anywhere in the world. Other PCS satellite systems will operate at 1.6 GHz for the uplink and 2.5 GHz for the downlink (e.g., FCC filings for Globalstar and Odyssey).

High-power *direct broadcast satellites* (DBS) or *direct-to-home* (DTH) satellites are operating at Ku-band. In the U.S., satellites operating in the broadcast satellite service (BSS) with downlink frequencies of 12.2 to 12.7 GHz, deliver TV directly to home receivers having parabolic dish antennas as small as 46 cm (18 in.) in diameter. DBS with digital modulation and compressed video is providing more than 150 National Television Systems Committee (NTSC) TV channels from a single orbital location having an allocation of 32 transponder channels, each with 24-MHz bandwidth. DBS is seen as an attractive medium for delivery of high-definition TV (HDTV) to a large number of homes. Other systems using analog FM are operational in Europe and Japan. In the U.S., DTH is also provided by satellites in the FSS frequency bands of 11.7 to 12.2 GHz. These are constrained by regulation to operate at lower downlink power and, therefore, require receiving dishes of about 1-m diameter.

Digital radio broadcast (DRB) from high power GEO satellites has been proposed for direct broadcast of digitally compressed near-CD quality audio to mobile and fixed users in the 2310-2360 MHz bands. [Briskman, 1996].

Mobile satellite services (MSS) operating at L-band around 1.6 GHz have revolutionized communications with ships and aircraft, which would normally be out of reliable communications range of terrestrial radio signals. The International Maritime Satellite Organization (INMARSAT) operates the dominant system of this type.

Links between LEO satellites (or the NASA Shuttle), and GEO satellites are used for data relay, for example, via the NASA tracking and data relay satellite system (TDRSS). Some systems will use intersatellite links (ISL) to improve the interconnectivity of a wide-area network. ISL systems would typically operate at frequencies such as 23 GHz, 60 GHz, or even use optical links.

74.4 Satellite Orbits and Pointing Angles

Reliable communication to and from a satellite requires a knowledge of its position and velocity relative to a location on the earth. Details of the relevant astrodynamic formulas for satellite orbits are given in Griffin and French [1991], Morgan and Gordon [1989], and Chobotov [1991]. Launch vehicles needed to deliver the satellites to their intended orbits are described in Isakowitz [1991].

A satellite, having mass m, in orbit around the earth, having mass M_e, traverses an elliptical path such that the centrifugal force due to its acceleration is balanced by the earth's gravitational attraction, leading to the equation of motion for two bodies:

$$\frac{d^2\mathbf{r}}{dt^2} + \frac{\mu}{r^3}\mathbf{r} = 0 \tag{74.1}$$

where r is the radius vector joining the earth's center and the satellite and $\mu = G(m + M_e) \approx GM_e = 398{,}600.5$ km^3/s^2 is the product of the gravitational constant and the mass of the earth. Because $m \ll M_e$, the center of rotation of the two bodies may be taken as the earth's center, which is at one of the focal points of the orbit ellipse.

Figure 74.3 depicts the orbital elements for a geocentric right-handed coordinate system where the x axis points to the first point of Aries, that is, the fixed position against the stars where the sun's apparent path around the earth crosses the earth's equatorial plane while traveling from the southern toward the northern

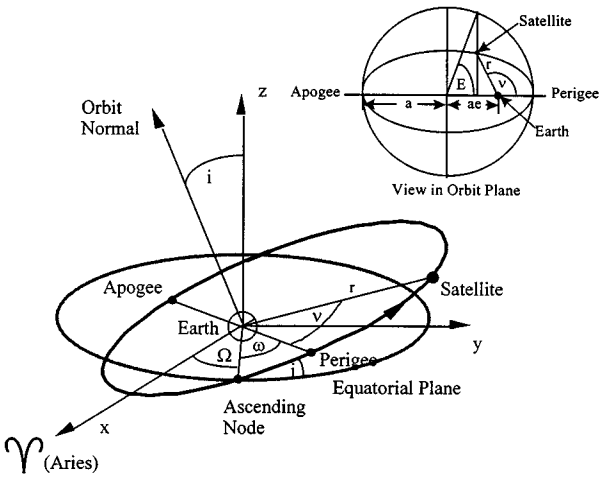

FIGURE 74.3 Orbital elements.

hemisphere at the vernal equinox. The z axis points to the north and the y axis is in the equatorial plane and points to the winter solstice. The elements shown are longitude or right ascension of the ascending node Ω measured in the equatorial plane, the orbit's inclination angle i relative to the equatorial plane; the ellipse semimajor axis length a, the ellipse eccentricity e, the argument (angle) of perigee ω, measured in the orbit plane from the ascending node to the satellite's closest approach to the earth; and the true anomaly (angle) in the orbit plane from the perigee to the satellite ν.

The mean anomaly M is the angle from perigee that would be traversed by a satellite moving at its mean angular velocity n. Given an initial value M_o, usually taken as 0 for a particular epoch (time) at perigee, the mean anomaly at time t is $M = M_o + n(t - t_o)$, where $n = \sqrt{\mu/a^3}$. The eccentric anomaly E may then be found from Kepler's transcendental equation $M = E - e\sin E$ which must be solved numerically by, for example, guessing an initial value for E and using a root finding method. For small eccentricities, the series approximation $E \approx M + e\sin M + (e^2/2)\sin 2M + (e^3/8)(3\sin 3M - \sin M)$ yields good accuracy [Morgan and Gordon, 1989, p. 806]. Other useful quantities include the orbit radius, r, the period, P, of the orbit, [i.e., for $n(t - t_o) = 2\pi$], the velocity, V, and the radial velocity, V_r:

$$r = a(1 = e\cos E) \tag{74.2}$$

$$P = 2\pi\sqrt{a^3/\mu} \tag{74.3}$$

$$V^2 = \mu\left(\frac{2}{r} - \frac{1}{a}\right) \tag{74.4}$$

$$V_r = \frac{e(\mu a)^{1/2}\sin E}{a(1 - e\cos E)} \tag{74.5}$$

Figure 74.4 depicts quantities useful for communications links in the plane formed by the satellite, a point on the earth's surface and the earth's center. Shown to approximate scale for comparison are satellites at altitudes representing LEO, MEO, and GEO orbits.

For a satellite at altitude h, and for the earth's radius at the equator $r_e = 6378.14$ km, the slant range r_s, elevation angle to the satellite from the local horizon el, and the satellite's nadir angle θ, are related by simple

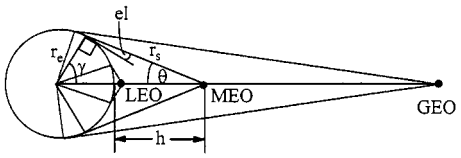

FIGURE 74.4 Geometry for a satellite in the plane defined by the satellite, the center of the earth, and a point on the earth's surface. The elevation angle, *el*, is the angle from the local horizon to the satellite. Shown to approximate scale are satellites at LEO, MEO (or ICO), and GEO.

trigonometry formulas. Note that $\theta + el + \gamma = 90°$, where γ is the earth's central angle and the ground range from the subsatellite point is γr_e. Then,

$$k = \frac{r_e + h}{r_e} = \frac{\cos(el)}{\sin\theta} \tag{74.6}$$

$$\tan(el) = \frac{(\cos\gamma - 1/k)}{\sin\gamma} \tag{74.7}$$

$$r_s = r_e\sqrt{1 + k^2 - 2k\cos\gamma} \tag{74.8}$$

The earth station azimuth angle to the satellite measured clockwise from north in the horizon plane is given in terms of the satellite's declination d, the observer's latitude, ϕ, and the difference of the east longitudes of observer and satellite, $\Delta\lambda$. Then:

$$\tan A = \frac{\sin\Delta\lambda}{(\cos\phi\tan\delta - \sin\phi\cos\Delta\lambda)} \tag{74.9}$$

taking due account of the sign of the denominator to ascertain the quadrant.

The fraction of the earth's surface area covered by the satellite within a circle for a given elevation angle, *el*, and the corresponding earth central angle, γ, is

$$\frac{a_c}{a_e} = \frac{1 - \cos\gamma}{2} \tag{74.10}$$

74.5 Communications Link

Figure 74.5 illustrates the elements of the radio frequency (RF) link between a satellite and earth terminals. The overall link performance is determined by computing the link equation for the uplink and downlink separately and then combining the results along with interference and intermodulation effects.

For a radio link with only thermal noise, the received carrier-to-noise power ratio is

$$\left(\frac{c}{n}\right) = (p_t g_t)\left(\frac{1}{4\pi r_s^2}\right)\left(\frac{g_r}{T}\right)\left(\frac{1}{k}\right)\left(\frac{\lambda^2}{4\pi}\right)\left(\frac{1}{a}\right)(\rho)\left(\frac{1}{b}\right) \tag{74.11a}$$

The same quantities expressed in dB are

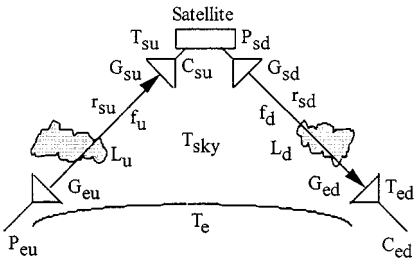

FIGURE 74.5 Quantities for a satellite RF link. P = transmit power (dBW). G = antenna gain (dBi.) C = received carrier power (dBW). T = noise temperature (K). L = dissipative loss (dB). r_s = slant range (m). f = frequency (Hz). u = uplink. d = downlink. e = earth. s = satellite.

$$\left(C/N\right) = EIRP - 10\log\left(4\pi r_s^2\right) + \left(G_r - 10\log T\right) + 228.6 - 10\log\left(4\pi/\lambda^2\right) - A + \Gamma - B \tag{74.11b}$$

where the subscripts in Eq. (74.11a) refer to transmit (t) and receive (r). Lower case terms are the actual quantities in watts, meters, etc. and the capitalized terms in Eq. (74.11b) correspond to the decibel (dB) versions of the parenthesized quantities in Eq. (74.11a). For example, $EIRP = P + G = 10\log p + 10\log g$ decibels relative to 1 W (dBW) and the expression (C/N) should be interpreted as $10\log c - 10\log n$. The uplink and downlink equations have identical form with the appropriate quantities substituted in Eq. (74.11). The relevant quantities are described below.

The ratio of received carrier power to noise power c/n, and its corresponding decibel value $(C/N) = 10\log(c/n)$ dB is the primary measure of link quality. The product of transmit power p_t (W) and the transmit antenna gain g_t, or equivalently, $P_t\,(dBW) + G_t$ [(dBi), that is, gain expressed in decibels relative to an isotropic antenna] is called the equivalent isotropically radiated power ($EIRP$) and its unit is dBW because the antenna gain is dimensionless. The antenna gain is that *in the direction of the link,* i.e., it is not necessarily the antenna's peak gain. The received thermal noise power is $n = kTB$ W where $k = 1.38 \times 10^{-23}$ J/K is Boltzmann's constant and $10\log(k) = -228.6$ dBW/K/Hz. T is the system noise temperature in kelvins (K) and B is the bandwidth in dB Hz. Then, $G - 10\log T$ dB/K is a figure of merit for the receiving system. It is usually written as G/T and read as "gee over tee". The antenna gain and the noise temperature must be defined at the same reference point, e.g., at the receiver's input port or at the antenna terminals.

The spreading factor $4\pi r_s^2$ is independent of frequency and depends *only* on the slant range distance r_s. The gain of an antenna with an effective aperture area of 1 m^2 is $10\log(4\pi/\lambda^2)$, where the wavelength $\lambda = c/f$, f is the frequency in Hz, and $c = 2.9979 \times 10^8$ m/s is the velocity of light. The dB sum of the spreading factor and the gain of a 1-m^2 antenna is the frequency-dependent "path loss". "A" is the signal attenuation due to dissipative losses in the propagation medium. B is the bandwidth in dB Hz, i.e., $B = 10\log(b)$ where b is the bandwidth in Hz.

The polarization mismatch factor between the incident wave and the receive antenna, is given by $\Gamma = 10\log\rho$ where $0 \le \rho \le 1$. This factor may be obtained from the voltage axial ratio of the incident wave r_w, the voltage axial ratio of the receive antenna's polarization response r_a, and the difference in tilt angles of the wave and antenna polarization ellipses $\Delta\tau = \tau_w - \tau_a$, as follows

$$\rho = \frac{1}{2} + \frac{4r_w r_a + \left(r_w^2 - 1\right)\left(r_a^2 - 1\right)\cos\left(2\Delta\tau\right)}{2\left(r_w^2 + 1\right)\left(r_a^2 + 1\right)} \tag{74.12}$$

where the axial ratios are each signed quantities, having a positive sign for right-hand sense and a negative sign for left-hand sense. Therefore, if the wave and antenna are cross-polarized (have opposite senses), the sign of

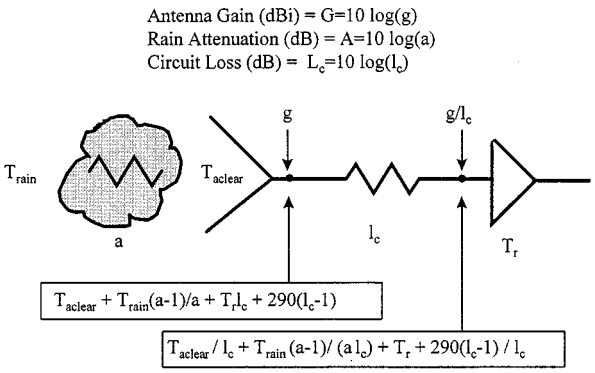

FIGURE 74.6 Tandem connection of antenna, loss elements such as waveguide, and receiver front end. The noise temperature depends on the reference plane but G/T is the same for both points shown.

$4r_w r_a$ is negative. The axial ratio in dB is given as $R = 10\log|r|$. The polarization coupling is maximum when the wave and antenna are copolarized, have identical axial ratios, and their polarization ellipses are aligned ($\Delta\tau = 0$). It is minimum when the axial ratios are identical, the senses are opposite, and the tilt angles differ by 90°.

74.6 System Noise Temperature and *G/T*

The system noise temperature, *T*, incorporates contributions to the noise power radiated into the receiving antenna from the sky, ground, and galaxy, as well as the noise temperature due to circuit and propagation losses, and the noise figure of the receiver. The clear sky antenna temperature for a directive earth antenna depends on the elevation angle since the antenna's sidelobes will receive a small fraction of the thermal noise power radiated by the earth which has a noise temperature $T_{earth} \approx 290$K. At 11 GHz, the clear sky *antenna* noise temperature, T_{aclear}, ranges from 5 to 10 K at zenith ($el = 90°$) to more than 50 K at $el = 5°$ [Pratt and Bostian, 1986].

As shown in Fig. 74.6, the system noise temperature is developed from the standard formula for the equivalent temperature of tandem elements including the antenna in clear sky, propagation (rain) loss of $A = 10\log(a)$ dB, circuit losses between the aperture and receiver of L_c dB, and receiver noise figure of F dB (corresponding to receiver noise temperature T_r K). The system noise temperature referred to the antenna aperture is approximated by the following equation where $T_{rain} \approx 280$ K is a reasonable approximation for the physical temperature of the rain [Pratt and Bostian, 1986, p. 342]:

$$T = T_{aclear} + T_{rain}(a-1)/a + T_r l_c + 290(l_c - 1) \qquad (74.13)$$

The system noise temperature is defined at a specific reference point such as the antenna aperture or the receiver input. However, G/T is independent of the reference point when G correctly accounts for circuit losses. The satellite's noise temperature is generally higher than an earth terminal's under clear sky conditions because the satellite antenna sees a warm earth temperature of ≈150–300 K, depending on the proportion of clouds, oceans, and land in the satellite antenna's beam, whereas a directive earth antenna generally sees cold sky and the sidelobes generally receive only a small fraction of noise power from the warm earth. Furthermore, a satellite receiving system generally has a higher noise temperature due to circuit losses in the beam forming networks, protection circuitry, and extra components for redundancy.

Figure 74.7 illustrates the link loss factors, maximum nadir angle, θ, earth central angle, γ, and earth-space time delay as a function of satellite altitude. The delay for a single *hop* between two earth locations includes the delays for the earth-space path, the space-earth path, and all circuit delays. The path losses are shown for several satellite frequencies in use. The variation in path loss and earth central angle is substantial. For example, L-band LEO personal communications systems to low-cost hand-held telephones with low gain (e.g., $G \approx$

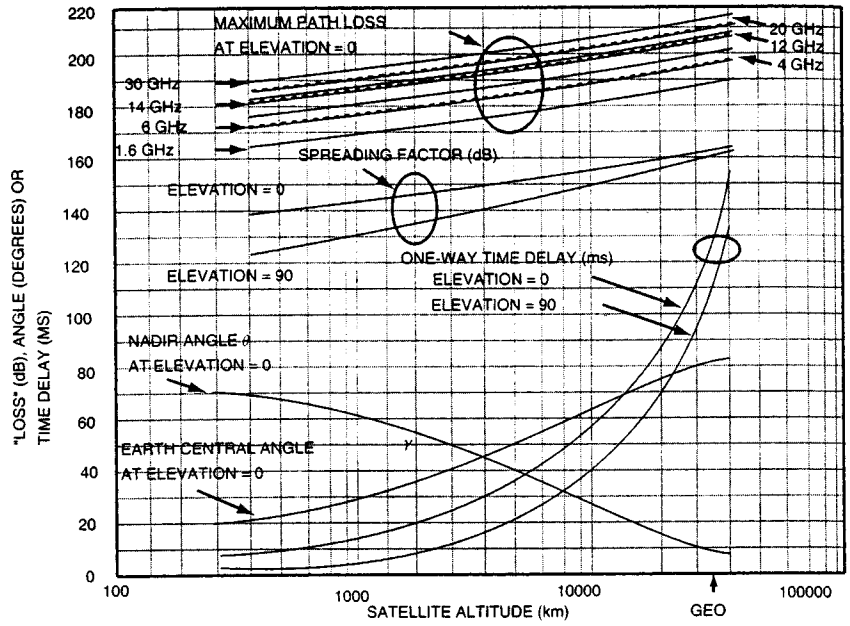

FIGURE 74.7 Satellite link losses, spreading factors, maximum nadir angle, θ–max, earth central angle, γ, and one-way time delay vs. satellite altitude, *h* km.

–2 τo +3 dBi) need less link power than for MEO or GEO. On the other hand, more satellites are needed from LEO constellations to provide full earth coverage since each satellite sees a much smaller fraction of the earth compared with higher orbits.

The design for a constellation of satellites to serve communications needs, such as the number of satellites, their orbital parameters, the satellite *G*/*T* and *EIRP*, etc. are topics related to mission analysis and design and involve trades of many factors such as total communications capacity, link margins, space and earth segment costs, reliability, interconnectivity, availability and cost of launch vehicles, mission lifetime, and system operations [Wertz and Larson, 1991].

74.7 Digital Links

For digital modulation systems, the bit error rate (BER) is related to the dimensionless ratio (dB difference) of energy per bit, E_b dB J and the total noise power density $N_o = 10\log(kT)$ dB J [Sklar, 1988]. For a system with only thermal noise N_o,

$$\left(E_b/N_o\right) = \left(C/N\right) + B - R = \left(C/N_o\right) - R \text{ dB} \tag{74.14}$$

where $R = 10\log$ (bit rate in bit/s), B is the bandwidth (dB Hz), and (C/N_o) is the *carrier-to-thermal noise density ratio,* that is, (C/N) normalized to unit bandwidth. Curves relating the communications performance measure of (BER) vs. (E_b/N_o) for different modulations may be found in [Sklar, 1988]. The link equation may then be expressed in terms of (E_b/N_o) and data rate, R, without explicit reference to the bandwidth:

$$\begin{aligned}\left(E_b/N_o\right) = {} & EIRP + \left(G/T\right) + 228.6 - 20\log\left(4\pi r_s/\lambda\right) \\ & - A + \Gamma - R \quad \text{dB}\end{aligned} \tag{74.15}$$

where the appropriate quantities are substituted depending on whether the uplink or downlink is being considered.

74.8 Interference

A complete transponder link analysis must include the contributions of the uplink, downlink, and also the power sum of all interference signals due, for example, to intermodulation products generated in the output stages of the amplifiers, external interference from other systems, and intra-system interference from reusing the same frequency band on spatially isolated or dual-polarized antenna beams to increase communications capacity. For most applications the total interference power may be taken as the power sum of interfering signals as long as they are not correlated with each other or the desired carrier. The values for the interfering signals due to, for example, frequency reuse cross-polarization, multiple beam interferers, and interference power received from other systems, must be obtained by carefully constructing the link equation for each case, taking into account the antenna gains for each polarization and beam direction of concern.

For an interference power i W, and carrier power, c W the interference ratio, c/i must be combined with the uplink and downlink c/n values to yield the total c/n. Here, the ratios are written in lower case to indicate they are *numerical power ratios.*

$$\left(\frac{c}{n}\right)_{total} = \frac{1}{\left(\frac{c}{n}\right)_u^{-1} + \left(\frac{c}{n}\right)_d^{-1} + \left(\frac{c}{i}\right)_{other}^{-1}} \tag{74.16}$$

Equation (74.16) applies to a "bent pipe" satellite. If on-board signal regeneration is used for digital transmission, the uplink signal is demodulated and a *clean* set of baseband bits is remodulated. This has the effect of separating the accumulation of uplink and downlink noise contributions by causing the uplink noise to be effectively modulated onto the downlink carrier with the desired signal [Gagliardi, 1991]. In that case, only the uplink or the downlink term in the denominator of Eq. (74.16) would be used as appropriate. Remodulation is also useful for intersatellite links. In each case, a savings in power or antenna size may be obtained at the expense of circuit and processing complexity.

The degradation to a digital link from interference follows a form similar to that of Eq. (74.16) in terms of e_b/n_o where the lower case quantities refer to numerical ratios. For a link that is subject to a *given* additive white noise-like interference power expressed as a ratio of desired signal power to interference power, c/i, and assuming digital modulation with m bits per symbol,

$$\frac{e_b}{i_o} = \frac{1}{m}\frac{c}{i} \tag{74.17}$$

The ratio of energy per bit to total thermal noise plus interference power density is

$$\left(\frac{e_b}{n_o + i_o}\right) = \frac{1}{\left(\frac{e_b}{n_o}\right)^{-1} + \left(\frac{e_b}{i_o}\right)^{-1}} \tag{74.18}$$

For a system employing frequency reuse via dual polarizations, the polarization coupling factor Γ between a wave and antenna determines the interference power. The (C/I) due to polarization is the ratio of desired (copolarized) receive power and undesired (cross polarized) receive powers as measured at the same receive port. This *polarization isolation* may be found by application of Eq. (74.12) to co-polarized and cross-polarized cases.

74.9 Some Particular Orbits

A *geosynchronous* orbit has a period that is a multiple of the earth's rotation period, but the orbit is not necessarily circular, and it may be inclined. A *geostationary* earth orbit (GEO) is a special case of a geosynchronous orbit

TABLE 74.1 Comparison of Orbit and Link Parameters for LEO, MEO, and GEO for the Particular Case of Circular Orbits (eccentricity, e, = 0) and for Elevation Angle (el = 10°)

Orbit	LEO	MEO/ICO	GEO
Example system	Iridium®	ICO-P	INTELSAT
Inclination, i (deg.)	86.4	±45	0
Altitude, h (km)	780	10,400	35,786
Semi-major axis radius, a (km)	7159	16,778	42,164
Orbit period (minutes)	100.5	360.5	1436.1
$(r_e + h)/r_e$	1.1222	2.6305	6.6107
Earth central angle, γ (deg.)	18.658	58.015	71.433
Nadir angle, θ (deg.)	61.3	22	8.6
Nadir spread factor			
$10 \log(4\pi h^2$ (dB m^2))	128.8	151.3	162.1
Slant range, r_s (km)	2325	14,450	40,586
One-way time delay (ms)	2.6	51.8	139.1
Maximum spread factor			
$10 \log(4\pi r_s^2$ (dB m^2))	138.3	154.2	163.2
$20 \log(r_s/h$ (dB))	9.5	2.9	1.1
Ground coverage area (km^2)	13.433×106	120.2×106	174.2×106
Fraction of earth area	0.026	0.235	0.34

Note: earth radius, r_e, (km) = 6378.14; earth surface area, a_e, (km^2) = 511.2×10^6; elevation angle, el (degrees) = 10.

where $e = 0$, $i = 0$, $k = (r_e + h)/r_e = 6.61$, and $h = 35{,}786$ km. When $el = 0$ the maximum nadir angle θ = 8.7°, the maximum slant range is 41,680 km, and, from Eq. (74.7), γ = 81.3°. Therefore, a GEO satellite cannot see the earth above 81.3° latitude [Gordon and Morgan, 1993].

Molniya and Tundra orbits have inclination $i = 63.4°$. This highly inclined elliptical orbit (HIEO) causes the satellite's subsatellite ground trace to dwell at apogee at the same place each day. One such orbit whose subsatellite path traces a repetitive loop (LOOPUS) allows several satellites to be phased to offer quasi-stationary satellite service at high latitudes. For full earth coverage from a constellation of LEO satellites, circular polar constellations [Adams and Rider, 1987] and constellations of orbit planes with different inclinations, e.g., Walker Orbits [Walker, 1977] have received attention.

The oblateness of the earth causes the right ascension of the ascending node Ω (Fig. 74.3) to move with time in the equatorial plane in a direction opposite to the satelliteís motion as seen from above the ascending node. This is called regression of the nodes. For inclination $i < 90°$ (prograde orbit) the ascending node rotates westward. For $i > 90°$ (retrograde orbit) the ascending node rotates eastward. For $i = 90°$ the regression is zero. The orbit parameters may be chosen such that the nodal regression is 360°/365.24 = 0.9856° eastward per day. In that case, the orbit plane will maintain a constant angle with the sun. The local solar time for the line of nodes is constant, that is, the satellite crosses a given latitude at the same solar time and same solar lighting conditions each day. This *sun-synchronous* orbit has advantages for certain applications such as weather and surveillance satellites [Roddy, 1996 p. 60].

Table 74.1 compares the geometry, coverage, and some parameters relevant to the communications links for typical LEO, MEO (or ICO), and GEO systems. Reference should be made to Fig. 74.4 for the geometry and to the given equations for geometrical and link parameters.

74.10 Access and Modulation

Satellites act as central relay nodes, which are visible to a large number of users who must efficiently use the limited power and bandwidth resources. For detailed discussions of access issues see Gagliardi [1991], Pritchard et al. [1993], Miya [1985], Roddy [1996], and Feher [1983]. A brief summary of issues specific to satellite systems is now given.

Frequency-division multiple access (FDMA) has been the most prevalent access for satellite systems until recently. Individual users assigned a particular frequency band may communicate at any time. Satellite filters

sub-divide a broad frequency band into a number of *transponder channels*. For example, the 500 MHz uplink FSS band from 5.925 to 6.425 GHz may be divided into 12 transponder channels of 36 MHz bandwidth plus guard bands. This limits the interference among adjacent channels in the corresponding downlink band of 3.7 to 4.2 GHz.

FDMA implies that several individual carriers co-exist in the transmit amplifiers. In order to limit intermodulation products caused by non-linearities, the amplifiers must be operated in a *backed off* condition relative to their saturated output power. For example, to limit third-order intermodulation power for two carriers in a conventional traveling wave tube (TWT) amplifier to Å –20 dB relative to the carrier, its input power must be reduced (*input backoff*) by about 10 dB relative to the power that would drive it to saturation. The output power of the carriers is reduced by about 4 to 5 dB (*output backoff*). Amplifiers with fixed bias levels will consume power even if no carrier is present. Therefore, DC-to-RF efficiency degrades as the operating point is backed off. For amplifiers with many carriers, the intermodulation products have a noise-like spectrum and the noise power ratio is a good measure of multi-carrier performance.

When reusing the available frequency spectrum by multiple spatially isolated beams (SDMA), interference can result if the sidelobes of one beam receives or transmits substantial energy in the direction of the other beams. Two beams that point in the same direction may reuse frequencies provided that they are orthogonally polarized, for example, vertical and horizontal linear polarizations or right- and left-hand circular polarizations. Typical values of sidelobe or polarization isolation among beams reusing the same frequency bands are from 27 to 35 dB.

Time-division multiple access (TDMA) users share a common frequency band and are each assigned a unique time slot for their digital transmissions. At any instant the DC-RF efficiency is high because there is only one carrier in the transmit amplifier, which may be operated near saturation. A drawback is the system complexity required to synchronize widely dispersed users in order to avoid intersymbol interference caused by more than one signal appearing in a given time slot. Also, the total transmission rate in a TDMA satellite channel must be essentially the sum of the users' rates, including overhead bits such as for framing, synchronization and clock recovery, and source coding. Earth terminal hardware costs for TDMA have been higher than for FDMA. Nevertheless, TDMA systems have gained acceptance for some applications as their costs decreased.

Code-division multiple access (CDMA) modulates each carrier with a unique pseudo-random code, usually by means of either a direct sequence or frequency hopping spread spectrum modulation. CDMA users occupy the same frequency band at the same time. The aggregate signal in the satellite amplifier is noise-like and individual signals are extracted at the receiver by correlation processes. CDMA tolerates noise-like interference but does not tolerate large deviations from average loading conditions. One or more very strong carriers could violate the noise-like interference condition and generate strong intermodulation signals. Careful power control of each user's signal is usually required in CDMA systems.

User access is via assignments of a frequency, time slot, or code. Fixed assigned channels allow a user unlimited access. However, this may result in poor utilization efficiency for the satellite resources and may imply higher user costs (analogous to a leased terrestrial line). Other assignment schemes include *demand assigned multiple access* (DAMA) and *random access* (e.g., for the Aloha concept). DAMA systems require the user to first send a channel request over a common control channel. The network controller (at another earth station) seeks an empty channel and instructs the sending unit to tune to it either in frequency or time slot. A link is maintained for the call duration and then released to the system for other users to request. Random access is economical for lightly used burst traffic such as data. It relies on random time of arrival of data packets and protocols are in place for repeat requests in the event of collisions [Gagliardi 1991].

In practice, combinations of multiplexing and access techniques may be used. A broad band may be channelized or *frequency-division multiplexed* (FDM) and FDMA may be used in each sub-band (FDM/FDMA).

74.11 Frequency Allocations

Table 74.2 contains a partial list of frequency allocations for satellite communications. The World Administrative Radio Conference, WARC-92, allocated L-band frequencies for LEO personal communications services and for LEO small satellite data relay. The World Radiocommunication Conference, WRC-95, allocated S-Band frequencies for Mobile Satellite Services (MSS). Most of the other bands have been in force for years.

TABLE 74.2 Partial List of Satellite Frequency Allocations

Band	Uplink	Downlink	Satellite Service
VHF		0.137–0.138	Mobile
VHF	0.3120–0.315	0.387–0.390	Mobile
L-Band		1.492–1.525	Mobile
	1.610–1.6138		Mobile, radio astronomy
	1.613.8–1.6265	1.6138–1.6265	Mobile LEO
	1.6265–1.6605	1.525–1.545	Mobile
		1.575	Global positioning system
		1.227	GPS
S-Band	1.980–2.010	2.170–2.200	MSS (available Jan. 1, 2000)
	1.980–1.990	2.165–2.200	(proposed for U.S. in 2000)
	2.110–2.120	2.290–2.300	Deep-space research
		2.4835–2.500	Mobile
C-Band	5.85–7.075	3.4–4.2	Fixed (FSS)
	7.250–7.300	4.5–4.8	FSS
X-Band	7.9–8.4	7.25–7.75	FSS
Ku-Band	12.75–13.25	10.7–12.2	FSS
	14.0–14.8	12.2–12.7	Direct Broadcast (BSS) (U.S.)
Ka-Band		17.3–17.7	FSS (BSS in U.S.)
			22.55–23.55 Intersatellite
			24.45–24.75 Intersatellite
			25.25–27.5 Intersatellite
	27–31	17–21	FSS
Q	42.5–43.5, 47.2–50.2	37.5–40.5	FSS, MSS
	50.4–51.4		Fixed
		40.5–42.5	Broadcast Satellite
V	54.24–58.2–		Intersatellite
	59–64		Intersatellite

Note: Frequencies in GHz. Allocations are not always global and may differ from region to region in all or subsets of the allocated bands.

74.12 Satellite Subsystems

The major satellite subsystems are described in, for example, Griffin and French [1991]. They are propulsion, power, antenna, communications repeater, structures, thermal, **attitude** determination and control, telemetry, tracking, and command. Thermal control is described in [Gilmore, 1994].

The satellite *antennas* typically are offset-fed paraboloids. Typical sizes are constrained by launch vehicles and have ranged from less than 1 m to more than 5 m for some applications. The INTELSAT VI satellite used a 3.2 m antenna at 4 GHz. Ku-band satellites may use a diameter $D > 2$ m (i.e., $D > 80\ \lambda$). Multiple feeds in the focal region each produce a narrow *component beam* whose beamwidth is $\approx 65\lambda/D$ and whose directions are established by the displacement of the feeds from the focal point. These beams are combined to produce a shaped beam with relatively high gain over a geographical region. Multiple beams are also used to reuse frequencies on the satellite. Figure 74.2 suggests that a satellite may have several beams for frequency reuse. In that case, the carriers occupying the same frequencies must be isolated from each other by either polarization orthogonality or antenna sidelobe suppression. As long as the sidelobes of one beam do not radiate strongly in the direction of another, both may use the same frequency band to increase the satellite's capacity.

The *repeaters* include the following main elements (see Fig. 74.2): a low noise amplifier (LNA) amplifies the received signal and establishes the uplink noise. The *G/T* of the satellite receiver includes the effect of losses in the satellite antenna, the noise figure of the LNA, and the noise temperature of the earth seen from space (from 150 to 290 K depending on the percentage of the beam area over oceans and clouds). In a conventional repeater, the overall frequency band is down-converted by a local oscillator (LO) and mixer from the uplink band to the downlink band. It is channelized by an input multiplexer into a number (e.g., 12) of transponder channels.

These channelized signals each are amplified by a separate high-power amplifier. Typically, a traveling wave tube amplifier (TWTA) is used with powers from a few watts to >200 W for a DBS. Solid-state amplifiers can provide more than 15 W at C- and Ku-Bands.

The *attitude determination and control system* (ADCS) must maintain the proper angular orientation of the satellite in its orbit in order to keep the antennas pointed to the earth and the solar arrays aimed toward the sun (for example). The two prevalent stabilization methods are spin stabilization and body stabilization. In the former, the satellite body spins and the angular momentum maintains gyroscopic stiffness. The latter uses momentum wheels to keep the spacecraft body orientation fixed. Components of this subsystem include the momentum wheels, torquers (which interact with the earth's magnetic field), gyros, sun and earth sensors, and thrusters to maintain orientation.

The *telemetry tracking and command* (TT&C) subsystem receives data from the ground and enables functions on the satellite to be activated by appropriate codes transmitted from the ground. This system operates with low data rates and requires omni-directional antennas to maintain ground contact in the event the satellite loses its orientation.

The *power* subsystem comprises batteries and a solar array. The solar array must provide enough power to drive the communications electronics as well as the housekeeping functions and it must also have enough capacity to charge the batteries that power the satellite during eclipse, that is, when it is shadowed and receives no power from the sun [Richharia, 1995, p. 39]. Typical battery technology uses nickel-hydrogen cells, which can provide a power density of more than 50 W-h/kg. Silicon solar cells can yield more than 170 W/m^2 at a satellite's beginning of life (BOL). Gallium arsenide solar cells (GaAs) yield more than 210 W/m^2. However, they are more expensive than silicon cells.

The space environment including radiation, thermal, and debris issues are described in Wertz and Larson [1991], Griffin and French [1991], and Committee on Space Debris [1995]. The structure must support all the functional components and withstand the rigors of the launch environment. The thermal subsystem must control the radiation of heat to maintain a required operating temperature for critical electronics [Gilmore, 1994].

74.13 Trends

Satellites continue to exploit their unique wide view of the earth for such applications as broadcast, mobile, and personal communications, and will find new niches for end-to-end broadband communications between customer premises by using the Ka-bands at 20 and 30 GHz and, perhaps, even higher frequencies. Historically, satellite construction has resembled a craft industry with extensive custom design, long lead times, long test programs, and high cost. New trends, pioneered by the lean production and design-to-cost concepts for the Iridium and Globalstar programs are leading to systems having lower cost per unit of capacity and higher reliability. Technology advances that are being pursued include development of light-weight small satellites for economical provision of data and communications services at low cost, more sophisticated on-board processing to improve interconnectivity, microwave and optical inter-satellite links, and improved components such as batteries and antennas with dynamically reconfigurable beams such as may be implemented by digital beam forming techniques [Bjornstrom, 1993].

Defining Terms

Attitude: The angular orientation of a satellite in its orbit, characterized by roll (R), pitch (P), and yaw (Y). The roll axis points in the direction of flight, the yaw axis points toward the earth's center, and the pitch axis is perpendicular to the orbit plane such that $R \times P \rightarrow Y$. For a GEO satellite, roll motion causes north-south beam pointing errors, pitch motion causes east-west pointing errors, and yaw causes a rotation about the subsatellite axis.

Backoff: Amplifiers are not linear devices when operated near saturation. To reduce intermodulation products for multiple carriers, the drive signal is reduced or backed off. Input backoff is the decibel difference between the input power required for saturation and that employed. Output backoff refers to the reduction in output power relative to saturation.

Beam and polarization isolation: Frequency reuse allocates the same bands to several independent satellite transponder channels. The only way these signals can be kept separate is to isolate the antenna response for one reuse channel in the direction or polarization of another. The beam isolation is the coupling factor for each interfering path and is always measured at the receiving site, that is, the satellite for the uplink and the earth terminal for the downlink.

Bus: The satellite bus is the ensemble of all the subsystems that support the antennas and payload electronics. It includes subsystems for electrical power, attitude control, thermal control, TT&C, and structures.

Frequency reuse: A way to increase the effective bandwidth of a satellite system when available spectrum is limited. Dual polarizations and multiple beams pointing to different earth regions may utilize the same frequencies as long as, for example, the gain of one beam or polarization in the directions of the other beams or polarization (and vice versa) is low enough. Isolations of 27 to 35 dB are typical for reuse systems.

75.1 Mobile Radio and Cellular Communications

William C. Y. Lee

The Difference between Fixed-to-Fixed Radio Communication and Mobile Communication

In fixed-to-fixed radio communications, the transmitter power, antenna location, antenna height, and antenna gain can be determined after calculating the link budget. Also, depending on the frequency range of the carrier affected on the atmospheric variation, different "margin" values will be put in the budget calculation for different system applications. The fixed-to-fixed radio links are usually 10 miles or longer and high above the ground. The signal variation over the link is due mostly to atmospheric changes. Satellite communications, microwave links, troposcatter, etc. are fixed-to-fixed radio communications. In mobile radio communications, the parameters such as transmitter power, antenna location, antenna height, and antenna gain are determined by covering an area or cell. In mobile radio communications, at least one end is in motion. The sizes of cells in urban and suburban areas are less than 10 miles. In mobile radio communications, the design of cell coverage is based on the average power. No margin is applied in calculating the cell coverage.

Natural Problems in Mobile Radio Communications

In mobile radio communications, there are many problems which never occur in fixed-to-fixed radio communication system:

1. *Excessive pathloss:* Vehicles are referred to as mobile units. The antenna height of the mobile unit is very close to the ground. Therefore, the average signal strength received at the mobile unit has two components,

a direct wave and a ground-reflected wave. These two waves act in canceling their average signal strengths and result in excessive pathloss at the receiver.

2. *Multipath fading:* Due to the human-made environment in which mobile units travel, the instantaneous signal sent from the base station is reflected back and forth from buildings and other ground objects before arriving at the mobile unit and causes signal fading received in the time domain. This signal fading causes an increase in the bit error rate (BER) and in the degradation of voice quality.
3. *Human-made noise:* The antenna height of mobile units is usually low. Therefore, human-made industrial noise, automotive ignition noise, etc. are very easily received by the mobile unit. This noise will raise the noise floor and impact system performance.
4. *Dispersive medium:* Due to the human-made environment and the low antenna height of the mobile unit, the signal after bouncing back and forth from the human-made structures produces multiple reflected waves which arrive at the mobile unit at different times. One impulse sent from the base station propagating through the medium becomes multiple reflected impulses received at different times at the mobile unit. This medium is called a dispersive medium. First the dispersive medium does not affect the analog voice channel, but does affect the data channels. Second, the medium becomes effective depending on the transmission symbol rate of the system. The dispersive medium will impact the reception performance when the transmission rate is over 20 kbps. Third, the dispersive medium becomes more effective in urban areas than in suburban areas.

Description of Mobile Radio Systems

There are two basic systems: trunked systems and **cellular systems**.

Trunked Systems

A trunked system is assigned a channel from a number of available channels to a user. The user is never assigned to a fixed channel.

1. Specialized mobile radio (SMR) is a trunked system. The SMR operator is licensed by the FCC to a group of 10 or 20 channels within 14 MHz of the spectrum between 800 and 900 MHz.
   - Loading requirement: A minimum of 70 mobile units per channel is required. SMR can offer privacy, speedier channel access, and efficient services. It can serve up to 125–150 mobile units per channel.
   - Channel spacing: 25 kHz.
   - Channel allocation: The FCC allocates a spectrum of either 500 kHz or 1 MHz to a SMR operator who will serve 10 or 20 paired transmit-receiver voice channels.
   - Coverage: Coverage is about 25 miles in radius since SMR uses only one high-power transmitting tower covering a large area.
   - Telephone interconnect: The public service telephone network (PSTN) extends mobile telephone service to SMR users.
   - Roaming: Mobile units are equipped with software that allows the radio to roam to any SMR system in the network.
   - Handoff: No tower-to-tower **handoff** capability; the channel frequency does not change as the unit moves from one cell to another.
2. ESMR (enhanced SMR): A system used to enhance the SMR system. It was called MIRS (Mobile Integrated Radio Systems). Now it is called IDEN (Integrated Dispatch and Enhanced Network). Features are:
   - Uses the SMR band.
   - Uses **TDMA** (time division multiple access) digital technology, the same digital TDMA standard adopted by the cellular industry.
   - Applies network of low-power cells.
   - Provides cell-to-cell handoffs through a centralized switching facility.
   - A spectrum average of 7–8 MHz is used in each market. The spectrum is not contiguous.
   - A channel bandwidth of 25 kHz is specified with three time slots per channel.
   - Modulation 16 QAM is applied.
   - No equalizer is used.

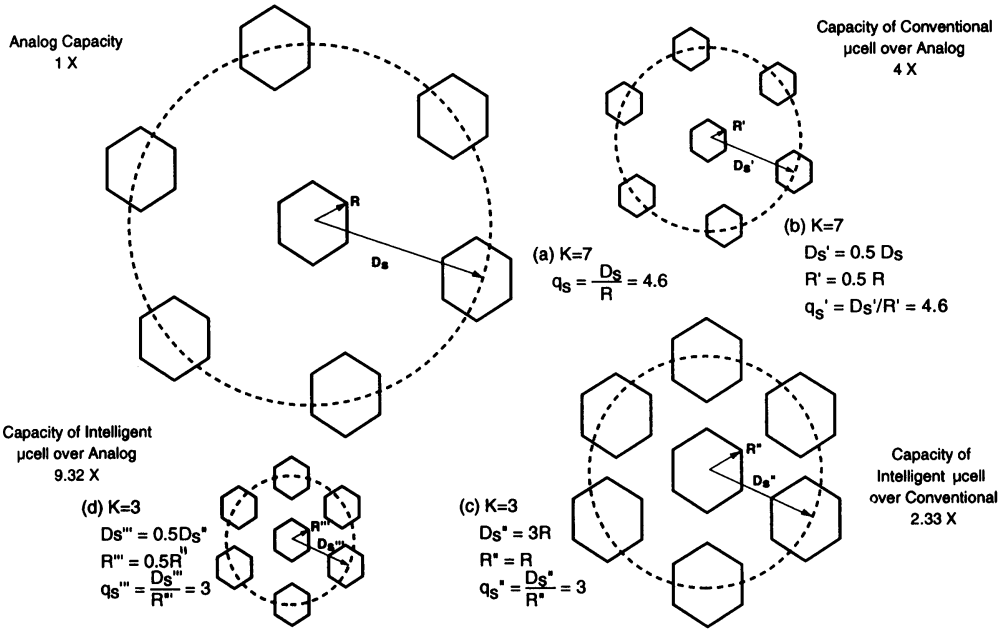

FIGURE 75.1 Four cases of expression of cochannel interference reduction factor.

Cellular Systems

The cellular system [Lee, 1989] is a high-capacity system that uses the frequency reuse concept. The same frequency is used over and over again in different geographical locations. In large cities, the same frequency can be reused over 30 times.

Key Elements: There are several key elements in the cellular system.

- **Cochannel interference reduction factor** q (see Fig. 75.1): Two cells using the same frequency channels are called cochannel cells. The required distance between two cochannel cells in order to receive the accepted voice quality is D_s, and the radius of the cell is R. Then the cochannel interference reduction factor q is

$$q = D_s/R$$

  There are six co-channel cells at the first tier seen from the center cell as shown in Fig. 75.1(a). For an analog cellular system $q_s = 4.6$, and the cell reuse factor K is $K = q_s^2/3 = 7$. The $K = 7$ means that a cluster of seven cells will reuse again and again in a serving area. The capacity increase in a cellular system can be achieved by reducing both the radius of cell R by one half and the separation D_s by one half such that the q_s remains constant and the capacity is increasing by four times. The reason is that a cell shown in Figure 75.1(a) can fit in four small cells shown in Fig. 75.1(b). In Fig. 75.1(c), the size of cells is the same as Fig. 75.1(a), but $q_s = 3$ is achieved by using an intelligent microcell system. The capacity of Fig. 75.1(c) is $7/3 = 2.33$ times over that of Fig. 75.1(a). In Fig. 75.1(d), the radius of the cell is reduced by one half, and K is reduced to 3. The capacity of Fig. 75.1(d) is $4 \times 2.33 = 9.32$ times over that of Fig. 75.1(a).

  The value of q is different in different kinds of cellular systems such as analog, TDMA, and **CDMA** (code division multiple access).

- **Handoff:** Handoff is a feature implemented in cellular systems to handoff a frequency of a cell while the mobile unit changes to another frequency of another cell while the vehicle is entering. The handoff is handled by the system and the user does not notice the handoff occurrences.

TABLE 75.1 Specifications of TDMA and CDMA Systems

TDMA		CDMA	
Bandwidth per channel	30 kHz	Bandwidth per channel	1.23 MHz
Time slots	3	Speech coder	8 kbps(max.)—a variable rate vocoder
Modulation	π/4-DQPSK	Forward radio channels	Pilot (1) sync (1), paging (7), traffic channels (55), total 64 channels
Speech coder	8 kbps—VSELP code (vector sum excited LPC*)		
Channel coding	Rate 1/2 convolutional (13 kbps)	Reverse radio channels	Access (9), traffic channels (55)
Total transmit rate	48 kbps per channel	Power control	Forward, reverse
Equalizer	Up to 40 μs	Diversity	Rake receiver

* LPC = linear predictive code.

- **Cell splitting:** When a cell provides a maximum of 60 radio channels and all are used during busy hours, the cell has to be split into smaller cells in order to provide more radio channels, normally reducing the cell by using a half radius. As a result a cell will be covered by four subcells. Each subcell provides 60 channels. The total area of an original cell will provide 240 radio channels which is four times higher in capacity as compared with the original cell capacity before splitting.

Spectrum Allocation in the United States, Europe, and Japan: In the United States there is 50 MHz of spectrum allocated to cellular radio within 800–900 MHz. Based on duopoly, each city has two licensed operators. Each one operates on a 25-MHz band. There are two bands, Band A and Band B. Each band consists of 416 channels. The channel bandwidth is 30 kHz. Among 416 channels, 21 channels are used for setting up and 395 are used for voice channels.

- *Analog:* The frequency management of both Band A and Band B is shown in Table 75.5.
- *Digital:* There are two potential systems, TDMA and CDMA shown in Table 75.1.

In Europe the spectrum allocation is as shown in Table 75.2 and 75.3.
In Japan the spectrum allocation is as shown in Table 75.4.

TABLE 75.2 Specification of Three European Systems

Analog	England	Scandinavia	West Germany
System	TACS*	NMT*	C450
Transmission frequency (kHz)			
Base station	935–960	463–467.5	461.3–465.74
Mobile station	890–915	453–457.5	451.3–455.74
Spacing between transmission and receiving frequencies (MHz)	45	10	10
Spacing between channels (kHz)	25	25	20
Number of channels	1000 (control channel 21 × 2); interleave used	180	222
Coverage radius (km)	2–20	1.8–40	5–30
Audio signal			
Type of modulation	FM	FM	FM
Frequency deviation (kHz)	±9.5	±5	±4
Control signal			
Type of modulation	FSK	FSK	FSK
Frequency deviation (kHz)	±6.4	±3.5	±2.5
Data transmission rate (kbps)	8	1.2	5.28
Message protection	Principle of majority decision is employed	Receiving steps are predetermined according to the content of the message	Message is sent again when an error is detected

* TACS = total access cellular system; NMT = nordic mobile telephone.

TABLE 75.3 GSM European Standard

GSM Characteristics
• TDMA: 8 slots/radio carrier
• 124 radio carriers (200 kHz/carrier) 935–960 MHz, 890–915 MHz
• GMSK modulation
• Slow frequency hopping (FH) (217 hops/s)
• Block and convolutional channel coding
• Synchronization (up to 233 μs absolute delay)
• Equalization (16 μs dispersion)
• TDMA structure: one frame (8 slots) 4.615 ms; each slot 0.557 ms
• Radio transmission rate: 270.833 kbps
GSM Physical Channels
• RACH: random-access control channel
• BCCH: broadcast common control channel (system parameters, sync.)
• PCH: paging channel
• SDCCH: stand-alone dedicated control channel (for transmit user's data)
• FACCH: fast associate control channel (for handoff)
• SACCH: slow associate control channel (for signaling)
• TCH: traffic channel Full rate: use full rate speech code Half rate

TABLE 75.4 Specification of the Japanese System

Analog	
System	NTT
Transmission frequency (kHz)	
Base station	870–885
Mobile station	925–940
Spacing between transmission and receiving frequencies (MHz)	55
Spacing between channels (kHz)	25
Number of channels	600
Coverage radius (km)	5 (urban area) 10 (suburbs)
Audio signal	
Type of modulation	FM
Frequency deviation (kHz)	±5
Control signal	
Type of modulation	FSK
Frequency deviation (kHz)	±4.5
Data transmission rate (kbps)	0.3
Message protection	Transmitted signal is checked when it is sent back to the sender by the receiver
Digital	
System	PHS* (Japan)
Frequency band	1.9 GHz
Access method	TDMA/TDD (MC)*
Traffic channels/RF carrier	1 (or 8 channels at half rate)
Modulation	π/4-QPSK
Voice codec	32 kbit/s ADPCM
Output power	10 mW
Radio transmission rate	384 kpbs
Carrier spacing	300 kHz

* PHS = personal handy phone system; TDD = time division duplexing; MC = multi-carrier; ADPCM = adaptive differential pulse code modulation.

Mobile Data Systems

The design aspect of developing a mobile data system is different from that of developing a cellular voice system, although the mobile radio environment is the same. The quality of a voice channel has to be determined based on a subjective test. The quality of a data transmission is based on an objective test. In a data transmission, the bit error rate and the word error rate are the parameters to be used to measure the performance at any given carrier-to-interference ratio (C/I). The burst errors caused by the multipath fading and the intersymbol interference caused by the time delay spread are the major concerns in receiving the mobile data. The burst errors can be reduced by interleaving and coding. The intersymbol interference can be reduced by using equalizers or lowering the symbol rate or applying diversity.

The wireless data transmission can be sent via a circuit switched network or a packet switched network. Also, mobile data transmission can be implemented on cellular systems or on a stand-alone system.

ARDIS*	
Transmission rate	4.8 kbps and 19.2 kbps
Transmit power	1 W
Channel	Packet radio
Vendors	IBM/Motorola

RAM*	
Transmission rate	8 kbps
Transmit power	4 W
Channel	Packet radio
Vendor	Ericsson

Cellular Plan II	
Transmission rate	19.2 kbps
Transmit power	0.6–1.2 W
Channel	Packet cellular

Cellular Modems	
Transmission rate	38.4 kbps
Transmission	3 W
Channel	Circuit cellular, carry data over cellular voice channels
Modem vendor	AT&T, PowerTek, Vital

*ARDIS = advanced radio data

*RAM = mobile data service

Personal Communication Service Systems

In June 1990, the FCC started to ask the wireless communication industry to study the development of future personal communication service (PCS) systems. (In late 1994, the FCC started to auction off two of the six spectral bands for over 7 billion dollars. In 1996, Band C was auctioned off for over 4 billion dollars.) PCS systems need to have more capacity than cellular systems. The technologies of increasing the capacity not only apply to GSM, but also apply to CDMA (code division multiple access) and the new microcell system.

CDMA

A San Diego field test held in 1991 showed that a cellular CDMA scheme can provide higher capacity than cellular TDMA (time division multiple access). A cellular CDMA system [Lee, May 1991] does not require a frequency reuse scheme. All the CDMA cells share the same radio channel. Therefore, the capacity of a cellular CDMA system is higher than either cellular **FDMA** (frequency division multiple access) or cellular TDMA systems.

Assume that a spectral bandwidth of 1.2 MHz can be divided into 120 radio channels with a channel bandwidth of 10 kHz. This is an FDMA scheme. A spectral bandwidth of 1.2 MHz can also be divided into 40 radio channels with a radio channel bandwidth of 30 kHz but each radio channel carries three time slots. Therefore, a total of 120 time-slot channels is obtained. This is a TDMA scheme. A spectral bandwidth of 1.2 MHz can also be used as one radio channel but provide 40 code-sequence traffic channels for each sector of a cell. A cell of three sectors will have a total of 120 traffic channels. This is a CDMA scheme. Now we can visualize that as far as channel efficiency is concerned, TDMA, FDMA, and CDMA provide the same number of traffic channels. However, in FDMA or TDMA, frequency reuse has to be applied. Let the **frequency reuse factor** $K = 7$ maintain a required C/I $\geq$ 18 dB; then the total channels will be divided by 7 as:

$$\frac{120}{7} = 17 \text{ channels/cell (in TDMA or FDMA)}$$

In CDMA no frequency reuse is required. Therefore, every cell can have the same 120 channels: number of channels/cell (in CDMA). In cellular, because the frequency reuse factor is applied on FDMA and TDMA schemes but not on CDMA, therefore, cellular CDMA has a greater spectrum efficiency than cellular FDMA or TDMA [Lee, May 1991].

New Microcell System

The conventional microcell system [Lee, Nov. 1991, 1993] reduces the transmit power and makes a cell less than 1 km in radius. The concept of using cell splitting is to increase capacity. Furthermore, the new microcell system needs to find a way to make a conventional microcell to be intelligent. The conventional microcell does not have the intelligence to know where the mobile or portable units are located within the cell. Therefore, the cell site has to cover the signal strength over the whole cell or whole sector. The more unnecessary signal power transmitted, the more interference will be caused in the system and less capacity will be achieved. In this new intelligent microcell system, each cell is an intelligent cell. In a new microcell, there are three or more zones. The cell will know which zone a particular mobile unit is in. Then a small amount of power will be needed to deliver in that zone. The cochannel interference reduction factor (CIRF) now will be measured from two cochannel zones instead of two cochannel cells. Then the two cochannel cells can be located much closer. In this new microcell system, the frequency reuse factor K becomes $K = 3$. As compared to the conventional microcell $K = 7$, the new microcell system has a capacity increase of 2.33 (= 7/3) times. These two techniques can be used in buildings and outside buildings.

Defining Terms

CDMA: A multiple access scheme by using code sequences as traffic channels in a comom radio channel.
Cell splitting: A method of increasing capacity by reducing the size of the cell.
Cochannel interference reduction factor (CIRF): A key factor used to design a cellular system to avoid the cochannel interference.
FDMA: A multiple access scheme by dividing an allocated spectrum into different radio channels.
Frequency reuse factor (*K*): A number based on frequency reuse to determine how many channels per cell.
GSM (Global System Mobile): European digital cellular standard using TDMA.
Handoff: A frequency channel will be changed to a new frequency channel as the vehicle moves from one cell to another cell without the user's intervention.
IDEN (Integrated Dispatch and Enhanced Network): A cellular-like system.
Mobile cellular systems: A high-capacity system operating at 800–900 MHz using a frequency reuse scheme for vehicle and portable telephone communications.
PHS (Personal Handy Phone System): A TDD system deployed in Japan.
SMR (Specialized Mobile Radio): A trunked system for dispatch.
TDMA: A multiple access scheme by dividing a radio channel into many time slots where each slot carries a traffic channel.

75.2 Facsimile

Rodger E. Ziemer

Facsimile combines copying with data transmission to produce an image of a **subject copy** at another location, either nearby or distant. Although the Latin phrase *fac simile* means to "make similar," the compressed phrase facsimile has been taken to mean "exact copy of a transmission" since 1815 [Quinn, 1989]. The image of the subject copy is referred to as a *facsimile copy*, or **record copy**. Often the abbreviated reference "fax" is used in place of the longer term *facsimile*.

Facsimile was invented by Alexander Bain in 1842; Bain's system used a synchronized pendulum arrangement to send a facsimile of dot patterns and record them on electrosensitive paper. Over the years, much technological development has taken place to make facsimile a practical and affordable document transmission process. An equally important role in the wide acceptance of facsimile for image transmission has been the adoption of standards by the Consultative Committee on International Telephone and Telegraph (CCITT). The advent of a nationwide dial telephone network in the 1960s provided impetus for the rebirth of facsimile after television put the damper on early facsimile use. Group 2 fax machines which appeared in the mid-1970s were capable of transmitting a page within a couple of minutes. These machines, based on analog transmission methods, were developed by Graphic Sciences and 3M. The Group 3 fax machines, developed in the mid-1970s by the Japanese, are based on digital transmission technology and are capable of transmitting a page in 20 seconds or less. They can automatically switch to an analog mode to communicate with the older Group 1 and 2 fax machines. Group 4 fax units offer the highest resolution at the fastest rates but rely on digital telephone lines which are just now becoming widely available [Quinn, 1989]. Group 3 facsimile will be featured in the remainder of this article. Group 3 facsimile refers to apparatus which is capable of transmitting an 8.5×11-inch page over telephone-type circuits in one minute or less. Detailed standards for Group 3 equipment may be found in Recommendation T.4 of CCITT, Vol. VII.

Facsimile transmission involves the separate processes of *scanning, encoding, modulation, transmission, demodulation, decoding,* and *recording*. Each of these will be described in greater detail below.

Scanning

Before transmission of the facsimile signal, the subject copy must be **scanned**. This involves the sensing of the diffuse reflectances of light from the elemental areas making up the subject copy. For CCITT Group 3 high-resolution facsimile, these elemental areas are rectangles 1/208 inch wide by 1/196 inch high. The signal corresponding to an elemental area is called a **pixel** which stands for picture element. For pixels that can assume only one of two possible states (i.e., white on black or vice versa), the term used is a **pel**. Various arrangements of illuminating sources, light-sensing transducers, and mechanical scanning methods can be employed. For more than six sweeps per second across the subject copy, electronic scanning utilizing a cathode-ray tube or photosensitive arrays or laser sources with polygon mirrors are utilized. A photosensitive array arrangement for scanning a flood-illuminated subject copy is illustrated in Fig. 75.2. This is the most often encountered scanning mechanism for modern facsimile scanners, and the sensors are typically silicon photosensitive devices. Two photosensor arrays in common use are photodiode arrays and charge-coupled device linear image sensors. For digital facsimile, the array is composed of 1728 sensors in a row 1.02 inches long with the optics designed so that an 8.5 inch subject copy can be scanned.

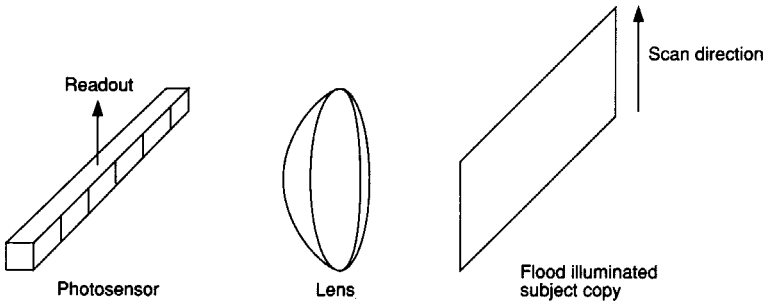

FIGURE 75.2 Arrangement for scanning by means of a linear photosensitive array.

Encoding

The output of the photosensor array for one scan or row of the subject copy consists of 1728 pels (1s or 0s) since Group 3 facsimile recognizes only black or white. Typically, facsimile subject copy is 85% white. The data from scanning the subject copy is reduced through run-length encoding. In the encoding process, it is assumed that a white pel (0) always occurs first. A white run is the number of 0s until the first 1 is encountered (the run length is 0 if the first pel is a 1); after a white run, a black run must follow with length equal to the number of 1s until the first 0 is encountered. All possible run lengths of white and black are then encoded into a binary code using a modified Huffman encoding technique [Jayant and Noll, 1984]. On the average, fewer binary symbols are needed to encode run lengths of the subject copy than if the binary values of the pels themselves were transmitted. For Group 3 facsimile, compression is optionally extended to the vertical dimension through employment of a READ (relative element address designate) code.

Run lengths from 0 to 63 are encoded by *terminating codes*, and run lengths in equal multiples of 64 from 64 to 1728 are encoded by *makeup codes*. Thus any run length up to 1728 can be described by a makeup code plus an appropriate terminating code. Additional makeup codewords are available for equipment that accommodates wider paper while maintaining the same resolution. Tables of modified Huffman run-length terminating and makeup codes are given in [Jayant and Noll, 1984].

Modulation and Transmission

Transmission of the encoded facsimile signal makes use of modem signaling techniques based on CCITT recommendations V.27 (standard) and V.29 (optional addition). The former utilizes 8-phase modulation at 4800 bits per second (bps), and the latter employs 16-QAM (quadrature amplitude modulation) at 9600 bps with adaptive, linear equalization. A facsimile telephone call consists of five phases, labeled A through E. In phase A, the telephone call is placed, with a training sequence sent consisting of signals to establish carrier detection, AGC, timing synchronization, and adjust equalizer tap settings. Phase B consists of the called station responding with a confirmation to receive (CFR) signal. The response is a 300 bps binary coded frequency-shift keyed signal (1 = 1650 ± 6 Hz and 0 = 1850 ± 6 Hz), except for the equalizer training sequence which is at the fast data rate of the digital modem. In phase C the encoded facsimile image is transmitted. Phase D consists of the end-of-transmission signal consisting of six consecutive end-of-lines (EOLs), with receipt required from the receiver. If no more images are to be sent or received, phase E (going on-hook) is effected at both terminals.

Demodulation and Decoding

Demodulation consists of the inverse of the modulation process. Standard techniques are used to demodulate the phase-modulated or QAM signals. Also included in the demodulation process is equalization. The decoding process converts the run-length encoded information to a series of 1s and 0s corresponding to the black and white pels of the image. The demodulated and decoded signal is then used to control the recording of the image.

Recording

Recording of the image at the receiver is effected by applying electricity, heat, light, ink jet, or pressure to a recording medium [Stamps, 1982]. Xerography or ink jet techniques can be used to record on plain paper. Other recording means using electricity, heat, or pressure require specially coated papers. Except for the ink jet, recording processes requiring only a one-step process utilize specially coated papers. Marking transducers are used to apply the image to the recording medium.

Personal Computer Facsimile

Whereas character-oriented text is readily transmitted between personal computers by means of teletex or computer mail, facsimile transmission in conjunction with personal computers extends this capability to images [Hayashi and Motegi, 1989].

Group 4 Facsimile

As mentioned previously, Group 4 facsimile apparatus is used mainly on public data networks of the circuit switched, packet switched, or integrated services digital network varieties (ISDN). Group 4 facsimile machines are subdivided into the following three classes [Yasuda, 1985]:

- Class 1 with the minimum requirement that such equipment can send and receive documents containing facsimile-encoded information
- Class 2, which in addition to the Class 1 capabilities, must be able to receive *teletex* and *mixed-mode documents*
- Class 3, which in addition to Class 1 and Class 2 capabilities, must be able to generate and send *teletex* and *mixed-mode documents.*

An additional feature of the specifications for Group 4 facsimile is that the resolution is equal in the horizontal and vertical directions. Standard resolution for Class 1 is 200 pels per 25.4 mm, and that for Classes 2 and 3 is 200 and 300 pels per 25.4 mm. When operating as a mixed-mode terminal, a receiving density of 240 pels per 25.4 mm is required, which is optional for all three classes. Bit rates range from 2.4 to 48 kbits/s with 64 kbits/s for ISDN. Compression techniques applicable to Group 4 facsimile are overviewed in Arps and Truong [1994].

Defining Terms

Facsimile: The process of making an exact copy of a document through scanning of the subject copy, electronic transmission of the resultant signals modulated by the subject copy, and making a record copy at a remote location.

Mixed-mode documents: Documents containing both character and facsimile information within a page. Such documents can be handled by Group 4 facsimile very efficiently. Group 3 facsimile treats each document as an image to be transmitted pixel by pixel. Mixed-mode documents are subdivided into increasingly smaller parts, such as pages, frames, and blocks. A block is a rectangular area that can contain only one category (character or facsimile information).

Pel: A picture element which has been encoded as black or white, with no gray scale in between.

Pixel: A picture element of a subject or record copy that is represented in shades of gray.

Record copy: The copy of the document made at the receiving end of a facsimile system.

Run-length encoding: The assignment of a codeword to each possible run of 0s (white pel sequence) or run of 1s (black pel sequence) in a scan of the subject copy.

Scanning: The process of scanning the subject copy in a facsimile transmission from left to right and from top to bottom.

Subject copy: The document that is scanned and transmitted in a facsimile system.

Teletex: Representation of character information by code words. Such a representation considerably improves the efficiency of the transmission process, but is not suitable for handwritten characters.

75.3 Wireless Local-Area Networks

Mil Ovan

Wireless local-area networks (LANs) represent a new form of communications among personal computers inside buildings. To better understand its applicability, this paper defines the customer challenges in networking personal computers as well as specific product requirements for a wireless LAN. These insights were gained through market studies of over 1000 corporate and government entities surveyed through different marketing research techniques.

The Wireless In-Building Vision

To date, the evolution of wireless communications has been exemplified by the dramatic growth in **cellular communications**. Cellular has enabled customers to transcend the constraints of fixed telephony in communicating outside of buildings with portable and now personal communications devices.

There has been significant interest and publicity regarding wireless in-building communications lately, both for data and voice. Throughout the 1980s, we have seen the development of a significant range of in-building business communications problems that have been caused by changes in the technological, business, and regulatory environments. Because of these developments, buyers of telecommunications and data communications systems increasingly are having to face significant time, cost, and logistical problems associated with the installation, movement, and management of computing and communications equipment in dynamic office environments.

Over the next 20 years, society will witness a significant "wireless evolution" in both personal and professional communications and change the way we conduct our lives at home, on the road, and at work (see Fig. 75.3). New forms of wireless communications will free us from the "bonds" of wire that today restrict our movements or interaction.

Market Research

Beginning in the middle to late 1980s, a systematic evaluation of the technological and environmental attributes necessary to anticipate and define wireless in-building communications was undertaken. This included a

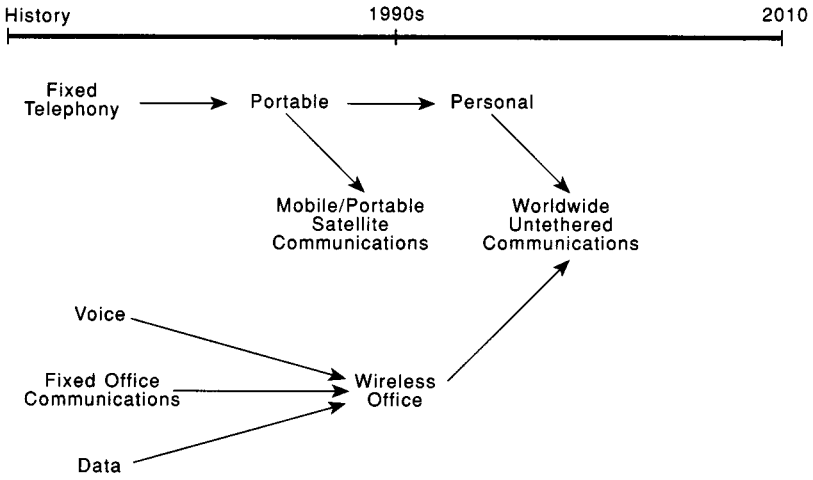

FIGURE 75.3 Evolution of wireless communications. (Courtesy of Motorola, Inc.)

comprehensive marketing needs assessment and research program. The overriding objective was to anticipate and identify customer needs and trends; that is, "What are the specific needs of various customer groups, and what type of product attributes will satisfy their needs?"

To determine answers to these and a whole host of other questions, a multiphased marketing research program was conducted. The overall aim of the program was to anticipate and ascertain the customer need, where this need existed currently, what were the market and customer environmental characteristics, and what product characteristics would be needed to provide an optimal wireless solution.

The remainder of this paper describes a higher-level overview of the results from these market research phases. This includes an overview of market needs, the problems/difficulties with current cabling methods, and a description of market requirements.

LAN Market Factors

Personal Computer Explosion

The move from mainframe and central information processing of the 1960s and 1970s provided an opportunity for minicomputers to enter the market. The minicomputer provided greater computer and applications access by employees. Throughout the 1980s the move to more intelligent desktop devices like personal computers was just that—personal. Organizations, in an effort to empower the worker, provided all types of applications, software, and hardware to the worker. The decremental costs of technology facilitated the distribution of personal computers. More importantly, projections state that business personal computer growth will continue its aggressive pace (see Fig. 75.4).

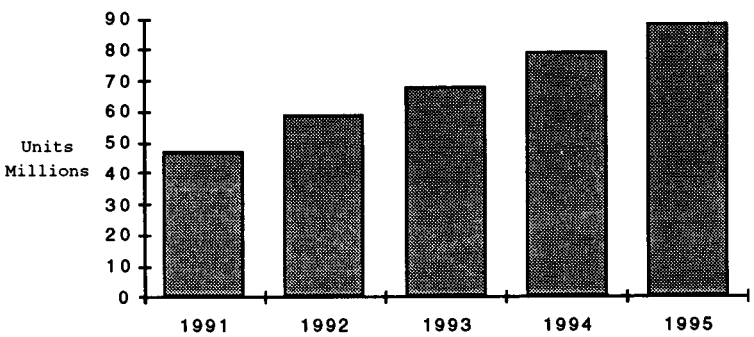

FIGURE 75.4 Worldwide business personal computer-installed base. (*Source:* International Data Corporation.)

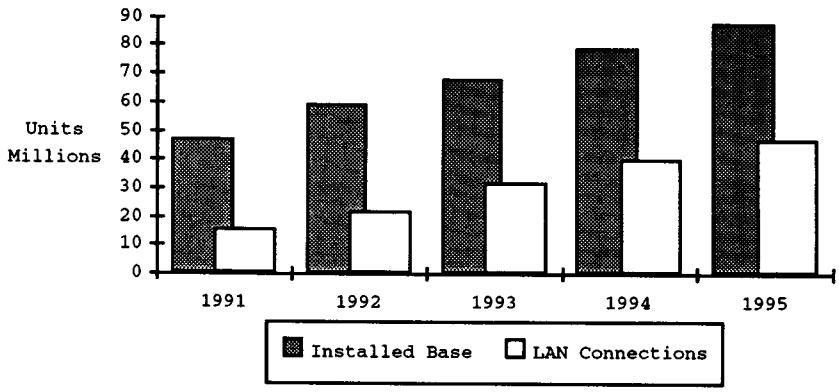

FIGURE 75.5 Worldwide business PCs and those PCs that are LAN connected. (*Source:* International Data Corporation.)

However, the growth of decentralized storage and computing created yet another problem—work groups needed to share information—and much of this information resided in individual hard disks. Furthermore, despite the declining costs of personal computers and associated technology, it was and still is considerably expensive to "fully load" the workforce with all of the applications it needs. The ability to share applications became desirable. It was these two trends which highlighted the need for LANs.

Information and Resource Sharing

The success of LAN computing was predictable. It started with the basic tenet of sharing resources and/or information. The need to amortize and justify the purchase of expensive resources, such as printers and storage, was an obvious factor which supported LAN growth. The need for knowledge workers to exchange data was and is imperative. Furthermore, the ability to share applications supported the growth of network computing.

LAN Growth

The success of LANs throughout the 1980s has been phenomenal. However, the projected growth throughout the 1990s is equally as impressive (see Fig. 75.5). This can be attributed not only to new installations of LANs, but also to the physical and logical segmentation of LANs as traffic and throughput degradations are observed.

Moves/Adds/Changes and Increasing Mobility

The world economies will continue to develop interdependencies and, likewise, global competition. The increasing competitive environment will demand greater worker mobility, changing assignments and reassignments, changing work groups, and mission mobility. The demand to have information how we want it, when we want it, and where we want it will be a strategic and competitive weapon. The need to improve efficiency and the growing need for information will accelerate the adoption of wireless communications.

Today's wired network, for all its great strides, is very restrictive. The cost to deploy and redeploy personnel and workgroups is time consuming and expensive. Cabling in today's environment inhibits the ability to attain efficiency and competitive advantages. The next section will highlight some of the author's market research findings.

Cabling Problems

As each phase of market investigation was conducted, several problems with today's wired networks were uncovered. Whether **copper twisted pair, coax, or optical fiber**, hard wiring for telecommunications and data communications systems within a building environment is expensive and troublesome to install, maintain, and, especially, change. Beneath today's increasingly dense office electronic environment lies a tangled, confusing, unmanageable maze of wiring.

What appeared to be very significant in the focus group research was how quickly the respondents stated the problems they have with wiring. Among the majority of respondents, the most favorable solution was to

free themselves of all wiring. Therefore, their first choice solution would be a wireless system, minimizing the time and effort of implementing a move, add, or change.

Moves/Adds/Changes: Cost and Frequency

A major portion of the cost of LANs is the cost of interconnecting them, which experts acknowledge can sometimes exceed the cost of computer hardware and software. Labor and material costs for wiring are almost always significant and can reach $1000 per node just for copper wire. Coax and optical fiber, not surprisingly, are considerably higher.

The news, however, gets even worse when it comes to maintenance. A study by the Frost and Sullivan[1] group quotes that LAN moves, adds, and changes (MACs) is the third largest cost component for LAN installation and hardware maintenance. They state that MACs account annually for almost $2 billion of a $12.2 billion LAN maintenance market, and that $2 billion does not even include the original cost to install cable.

Estimates of the cost to rewire range from $200 to $1000 per change. In fact, a survey by KPMG Peat Marwick[2] quoted that the average relocation cost for just rewiring a LAN station averages $300 per node. But those are just the direct costs; the time to effect the wired change is a significant problem as well. Moves, for example, often take weeks or longer to coordinate in addition to the time to actually make the physical wiring change.

Most of the research respondents were asked what proportion of their company's staff was involved in some kind of a move involving wiring or rewiring. The majority of the respondents, almost 80%, had some type of relocation or addition of personnel over the last year surveyed. Their responses ranged from as few as 20% per year up to as much as 200% annually. Furthermore, according to the KPMG Peat Marwick study, the average company moves its employees approximately 50% annually. Telecommunications consultant Richard Kuehn states that data terminals are moved as often as 1.5 to 3 times per year. The combined problems of the actual hard relocation costs, however, are just the beginning. Soft, or hidden, costs further exacerbate the cabling dilemma.

Hidden Costs

Significant problems arise when these moves or changes are implemented. There is always the disruption of the workers involved in the move or change, not to mention the loss in productivity. The problems, however, become much more involved when dealing with whole departments and more complex user equipment. In fact, surveyed firms responded that when a relocation takes place, over 60% of the time it involves the movement of an entire department.

The toll of wait time and down time on productivity varies greatly and is difficult to quantify, but certainly is significant and costly. In today's increasingly mobile working environment, it is likely to grow. The situation is exacerbated by relocations and additions which require reconstructions, thereby continuing to add to the effective cost of a move, add, or change.

Costs to rewire rise enormously with the age and complexity of the building. The majority of high-rise office space in large metropolitan areas presents major problems and expense for tenants trying to install, add, or move network wiring. Buildings more than 30 or 40 year old, with designs and construction that did not consider today's electronic office, poorly accommodate communications wiring. If asbestos insulation exists in the building, as it does even in many pre–health-safety regulated buildings, rewiring costs can take on huge proportions.

The coordination of personnel and the moving of one group out to prepare for the new group moving in is a very costly and labor intensive ordeal. In some cases, wiring had to be installed, or different cabling may have been needed to accommodate new or different types of users' equipment.

Cable Is Not Business Friendly

Although office planners, building managers, and network operators are well aware of the problems with wire, the limitations and huge costs of wire have not generated focused attention outside of this community. The general business world seems to accept wire as inevitable. Perhaps that is because there have been no real

[1] *PC Week Magazine*, "Maintenance Costs of LANs Keep Soaring," Frost & Sullivan, Inc.
[2] KPMG Peat Marwick Study, January 1991.

alternatives. Yet, as computing and telecommunications power continues to proliferate and becomes more widely distributed to the "knowledge worker," the problem will increase. Easy, quick, efficient movement of "people assets" within the working environment is also increasingly being recognized as essential to the productivity and competitiveness of a business. Wiring severely inhibits that movement.

The research indicated a need for a flexible, compatible, cost-effective, yet high-performance wireless alternative to extend and complement, if not replace, the capabilities of wire, cable, and fiber for in-building communications networks. More specifically, it is the convenience and flexibility that users need. In fact, the aggregate need for flexibility and convenience was found to be twice that of the perceived benefit for cost savings.

When research respondents were asked how they could improve upon their experiences when implementing a move, add, or change, many solutions were offered. These solutions ranged from having more compatibility among different vendors' equipment, to providing a better way to organize all the different cabling.

Structured Distribution Systems

A number of firms in the research study had deployed a **structured distribution system (SDS)**, a topology which advocates cabling saturation of a desired environment to accommodate all potential personnel movements and reconstructions within that office. SDS requires firms to invest large sums of capital initially on the assumption of not knowing how many telecommunications devices may be employed or where the devices are to be located. Consequently SDS usually plans for worst-case conditions, meaning that some or much of wiring systems capability may never be utilized.

However, many firms which have an SDS deployed also expressed those problems which stress their SDS investment. Some of the most frequently mentioned include:

- High equipment addition/relocations exceeding 40% annually
- Expansion and contraction of their workforce
- Changing technology and business support
- Continued investment and vigilance to maintaining the SDS and its intrinsic advantage
- Continued departmental LAN growth requirements

In short, the latter group of SDS respondents provided some notable requirements. A wireless system must:

- Extend the capabilities of their SDS system
- Facilitate the inherent advantages of the SDS
- Offer enhanced flexibility to nonserviced SDS portions of their building or occupancy

These points indicate that even in SDS environments, there is an opportunity to employ wireless devices. Wiring—the expense, time, and inflexibility of installing, moving, and changing—limits the way companies can productively use networks. To stay productive, these LANs have to move and change with the workforce they support. Therefore, a wireless offering must be a *complementary* solution for buildings with an SDS, in bringing wireless flexibility and extensibility to today's networks.

User Requirements Environment

Office Friendly

Several notable conclusions were derived from the marketing research. **Secondary market research** suggests that over 70% of LAN node installations were estimated to reside in an office environment (as opposed to factories and warehouses). Therefore, as an office-oriented offering, a wireless system would have to be, by definition, office friendly. A traditional office is composed of hard offices with opening and closing doors, furniture and personnel movement, cubicles, conference rooms, and walls of varying thickness and substance. Therefore, a wireless system must continually adapt to different and changing conditions and office layouts.

Optimized Service Area

The second wireless in-building need expressed by the office market is the manageability and reuse of any potential system. Unlike the signal propagation characteristics of many lower-frequency radio products, LAN

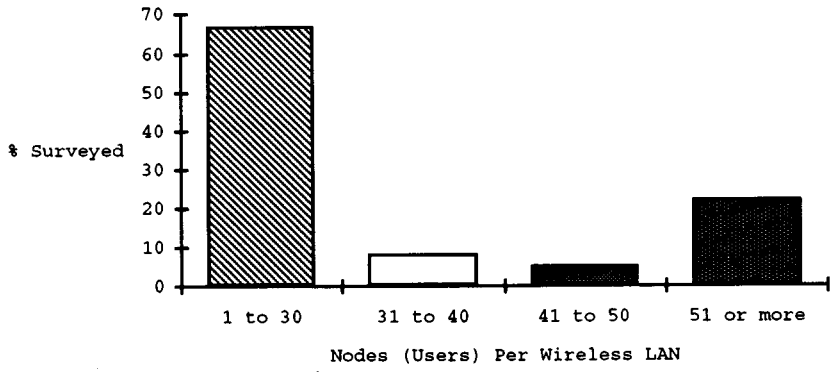

FIGURE 75.6 Survey results: forecast users per wireless LAN. (Courtesy of Motorola, Inc.)

administrators desired the ability to control or, more aptly, contain the coverage of a potential wireless system. The reasons were twofold:

- LAN managers wanted the ability to add different services to a new group of users. In fact these new users may very well be physically adjacent to another system, wireless or wired.
- These same managers wanted the flexibility to connect a new or existing user group to either a **backbone** or to create a stand-alone LAN.

LAN Workgroup Sizes

Respondents were asked as to where a wireless offering might be first installed. The market research indicated that approximately 70% of the installations would contain less than 30 users (see Fig. 75.6). Furthermore, the average LAN appeared to be in the 12- to-15-node range. This is further corroborated by the KPMG Peat Marwick study which found that the average LAN size is about 15 users per LAN.

Furthermore, the system must have the flexibility to manage the service area. That ability, to either incrementally add systems whether on the backbone or in a stand-alone configuration, must accommodate scalability within an organization.

It is interesting to note that these figures are consistent with good LAN administration practices for purposes of maintaining high throughput and fault isolation. As LANs become larger and traffic more intensive, there is a natural inclination to begin segmenting LANs into more logical and defined user areas/groups.

Coverage Area

To satisfy the majority of requirements, we determined that approximately 70% of LANs would be deployed in areas of less than 5000 ft^2 (see Fig. 75.7). This must take into consideration the fairly dense environment, made up of cubicles and apportioned hallway space. The market investigations indicated that a wireless offering must accommodate, at the least, 150 ft^2 per user. This is equivalent to 32 users/system in a 5,000 ft^2 area.

Product Requirements: End User Reaction

Transparency, Compatibility, and Performance

To justify the expense of a wireless system to end users, a wireless offering would have to provide reliable performance, as well as be practical and cost effective. Our market research indicated that the ideal system should be:

- Easy both to install and move, preferably by the user
- Able to coexist with both existing wire and cable, as well as with future optical fiber
- Easy to operate, virtually transparent to the user
- Almost universally applicable, suitable to replace any LAN cable or wire, in any office environment
- Secure, absolutely reliable, and cost effective

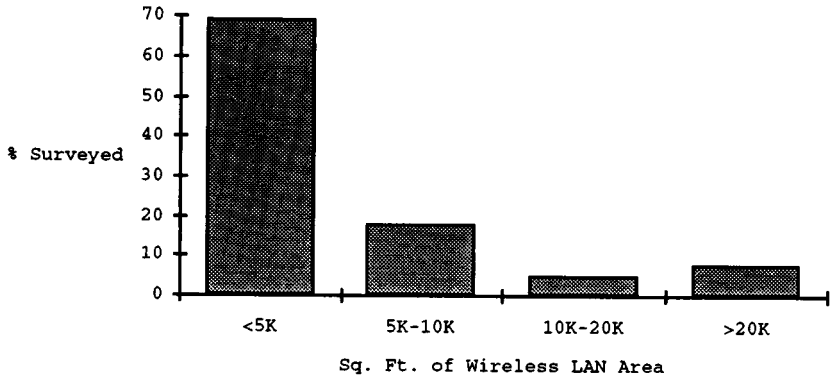

FIGURE 75.7 Survey results: forecast office area of wireless LAN. (Courtesy of Motorola, Inc.)

A wireless system must be totally transparent. If customers are to enjoy the attributes of wireless, the respondents indicated that the wireless implementation must not require the users to change the way they operate or interface with their personal computers. Also, a wireless offering must provide true compatibility. The wireless connection must be compatible with standards-based components such as operating systems and applications, LAN cards and other devices, as well as LAN wire that is already in place.

Security and Reliability

In addition, the market mandated that a wireless product offering be absolutely secure and reliable. Security was a requirement across several dimensions. To provide sufficient data security a wireless system should first prevent the effective capture of data by a receiver outside of the wireless system and, second, prevent capture of the data by unauthorized wireless hardware within the system. A wireless product must be secure from eavesdropping, either accidental or intentional.

Reliability was another important attribute. The users required absolute reliability. That is, users wanted a guaranteed packet delivery from the entry/exit wireline points—and they wanted it at least as error free as their current cabled environment.

Cost Effective

Finally, most businesses will place any capital or expense under rigorous financial analysis. As such, the acceptance of a new technology/application must pass the payback test for that business. Therefore, demonstrable payback and justification is needed to facilitate an organization's evaluation of any potential wireless offering.

Technology Alternatives in Meeting Customer Requirements

Infrared and Spread Spectrum Technologies Lack Performance

Developing the ideal system, obviously, is no trivial problem. Several wireless network products, to be sure, are available, but many suffer from limited performance and operational problems inherent to the technologies on which they are based. As such, they are perhaps interim point solutions, primarily for small networks but are not the long-term answer to the wire communications dilemma described earlier.

Two basic technologies characterize the wireless LANs currently available. Infrared (IR) systems use a part of the electromagnetic spectrum just below visible light as a transmission medium. IR, being light, travels in a straight, or line-of-sight, path. It is blocked by opaque objects and reflects well only off hard, mirror-like surfaces. This factor stands as a serious obstacle to IR systems for applications other than in open working environments.

Radio technologies form the platform for other wireless LAN products. Many of the radio LANs are based on spread spectrum technology. This technology, developed by the U.S. military, uses a combination of several small, narrow bands within a general region of this band as carrier frequencies. However, the commercial products operate with fewer frequencies than are available for military systems; hence interference rejection

and performance are lower. (In radio transmission, the wider the bandwidth or available frequencies on which to encode data, the higher the achievable total data rate.)

Another important issue in this ultrahigh frequency (UHF) environment is that radio frequency (RF) energy at these frequencies tends to propagate through and around obstacles, reaching beyond the confines of the network it is serving. That property makes this RF band suitable for receiving commercial broadcast signals from distant stations through the walls of buildings to receivers inside. It also makes it suitable for mobile cellular telephones, but it cannot be well contained within the confines of the **microcell** described earlier, which limits **spectrum reuse** and overall network capacity requirements absolutely essential in a viable wireless network communications system. Current UHF spread spectrum wireless in-building communications systems, then, suffer from critical bandwidth and spectrum reuse shortcomings that seem likely to prevent them from expanding beyond limited applications.

The 18- to 19-GHz Radio Band: An Ideal Choice for Wireless In-Building Microcellular Networks

A region of the electromagnetic spectrum above the kilohertz and megahertz radio bands, yet below the extremely high frequencies of the infrared band, offers two very compelling advantages. Specifically, the 18- to 19-GHz portion of this band fulfills the key requirements of spectrum reuse and bandwidth availability that eliminates most other frequencies from consideration.

Properties Right for Both Microcell Coverage and Confinement

The first major advantage of the 18-GHz band is its excellent propagation characteristics for a microcellular network. Indeed, the behavior and properties of these higher frequencies that are disadvantages for traditional long-range broadcast applications become critical advantages for wireless microcellular network applications. Propagation characteristics of 18-GHz radio waves make them well suited to diffuse thoroughly through a network microcell using only a minimum of transmitted power, yet still stay confined within it so that the same frequencies can be reused by another system within as little as 120 feet or so, or even on the other side of a dense, continuous barrier such as a cement floor. Typical microcells might encompass, for example, a level or floor, or portions of a floor, in a standard office building.

As one might expect, 18-GHz radio waves exhibit a blend of the characteristics of UHF frequencies below them and IR light above them. For example, 18-GHz waves act like light and unlike radio in that they are blocked and reflected by large structures such as concrete and steel. Reflecting back and forth would allow them to fill an area defined by concrete floors and walls with only very small amounts of transmitted power, yet not pass beyond. They also refract like light, penetrating tiny holes and cracks such as closed doors to diffuse and spread through the space beyond. What little radio signal that might escape the microcell would be rapidly dissipated.

Also, unlike lower frequency radio, 18-GHz radio is of a high enough frequency that not only office equipment but even high-energy factory equipment and processes do not interfere with it. Likewise, with its high-frequency and low-required transmitted power, the 18-GHz signals themselves from such a system would not interfere with other electronic systems or equipment. On the other hand, like radio and unlike light, 18-GHz signals still can pass through less dense materials such as drywall and interior office separators and, combined with their reflectivity, are thus not subject to "line-of-sight" limitations. They can also be modulated to carry information just as traditional radio signals are. Finally, since antenna size and design are largely a function of wavelength, which decreases as frequency increases, the antennas for the 16-mm wavelengths of an 18-GHz radio system would be relatively small and compact.

Plenty of Bandwidth in an Otherwise Crowded Spectrum

The second major advantage of 18-GHz radio is its available bandwidth. Few other areas of the electromagnetic spectrum are as interference-free, clear, and available as this band, certainly not the VHF and UHF bands, which must accommodate television, FM radio, cellular telephone, baby monitors, and more.

The reason for this clear band is largely that these higher frequencies have been difficult to work with. The particular technical properties of 18-GHz frequencies and the expense, size, and complexity of the equipment to use them have prevented them from being an attractive option for many commercial applications. As a result, the military has been the primary developer and user of the 15- to 300-GHz band, and the few commercial

uses that have emerged (weather, aircraft and police radar, point-to-point telecom transmission, etc.) use expensive technology pioneered by military-funded research.

Developing a comprehensive in-building radio system, however, had never been done until Motorola recently developed the Altair™ wireless ethernet network. Such an application required the creation of new, improved performance data handling and signal processing hardware and software, as well as a radio antenna system that could transmit and capture these data speeds on 18-GHz frequencies in an in-building environment.

Summary

The numerous problems with wiring will become even more acute in the office of the 1990s. This environment will be characterized by:

- The proliferation of decentralized computing resources
- Increased number of telephones and personal computers as an outgrowth of a country's economic shift toward service industries

As the penetration of personal computers nears a one-to-one relationship with phones in the office workplace, the limitations of separate voice and data networks will become even more evident. If these problems are not addressed, an organization's flexibility in redeploying "people assets" and ultimately competitiveness will be seriously hindered. The time it takes to move/add/change equipment and reconfigure communications wires will be the limiting factor in rapidly reorganizing workgroups and responding to new assignments. Wireless LANs will become an attractive solution in the office of the 1990s, interconnecting personal computers and offering data communications capabilities without the need for elaborate cabling methodologies. The obvious and inherent flexibility offered by wireless LANs is the obvious primary benefit. However, the ability to retrieve that investment, never retrievable until now, clearly presents a significant economical benefit.

Defining Terms

Backbone: Wiring which runs within and between floors of a building and connects local-area network segments together.

Cellular communications: Traditionally an outside-of-building radio telephone system that allows users to communicate from their car or from their portable telephone.

Copper twisted pair, coax, and optical fiber: Wired media which connects telephone and computer equipment.

Microcell A low-power radio network which transmits its signal over a confined distance.

Secondary marketing research: Market research conducted by other organizations.

Spectrum reuse: Reusing frequencies over and over again in a confined area, resulting in more efficient utilization and higher radio network capacity.

Structured distribution systems (SDS): A topology which advocates cabling saturation of a desired environment to accommodate all potential personnel movements and reconstructions within that office.

Wireless local-area networks: A method of connecting personal computers together without extensive cabling, allowing communications among these devices in an area such as a department or floor of a building.

75.4 Wireless PCS

Giridhar D. Mandyam

Personal Communications Services (**PCS**) promise to introduce a wide range of variety of digital wireless services; including high-speed data, improved voice services, and messaging (e-mail or paging). These services are also often identified with the part of the spectrum in which they are deployed, that is, the PCS band. In North America, this part of the spectrum lies between 1850 and 1990 MHz, and is divided into six blocks of either 5 or 15 MHz each. The Federal Communications Commission (FCC) of the United States has been auctioning these blocks since 1994. The DCS (Digital Cellular System) band, which also spans the range of 1.8 to 2 GHz, has been set aside for these advanced services in several parts of the world.

PCS can be contrasted with services already deployed in the cellular band — that is, the part of the spectrum ranging from 806 to 890 MHz. This band is divided into channels of 30 kHz apiece. In North America, the mature analog technology known as **AMPS** is widely deployed and provides the largest amount of coverage of all public wireless technologies available today. However, digital wireless does in fact exist in the cellular band. A depiction of spectral allocation can be found in Figure 75.8.

In addition, digital PCS technologies can be divided into two categories: **2nd generation** and **3rd generation** wireless systems. 3rd generation wireless systems, which have yet to be deployed, promise an improvement on 2nd generation (already deployed) systems in voice quality and data services. In particular, high rate packet data is a critical requirement of 3rd generation systems.

Cellular Band Systems

The first system to appear in the cellular band in the United States was AMPS. This system provided user traffic channels of 30 kHz, as part of a frequency division multiple access (**FDMA**) scheme. In addition, this system used the concept of frequency division duplexing (**FDD**) to provide different channels for an individual user to send and receive traffic. This system used analog frequency-modulation technology, and was primarily designed to provide voice service only, although some systems do exist that provide data services through AMPS. The first public service began operation in the Chicago area in 1983.

A problem with AMPS is the occupation of an entire 30-kHz channel by a single user. This affected the overall capacity of AMPS systems. Another problem is the lack of privacy in AMPS, which has led to a serious problem of phone cloning. In addition, the performance of analog FM in the mobile channel suffers from the threshold effect, where signal quality degrades rapidly once received signal levels fall below a threshold value.

Digital technologies take advantage of coding and modulation to increase signal quality when received signal levels are low. Moreover, digital technologies employ encryption, which addresses to a certain extent the problem of cloning phones. As a result, digital wireless systems were developed for use in the cellular band to address some of the problems with AMPS. A summary of the AMPS radio interface is given in Table 75.6.

A digital technology, which emerged in the United States in the late 1980s, was time division multiple access (**TDMA**). TDMA systems took advantage of time multiplexing different users into the same 30-kHz channel, which was used by AMPS. The **IS-54** public wireless standard introduces the concept of three-slot TDMA, in which three users were time multiplexed into a single 30-kHz channel. This has the effect of tripling the effective capacity of an AMPS network; therefore, sometimes TDMA is referred to as D-AMPS, for digital AMPS. The first commercial TDMA system to be launched in the United States was in 1991. The **IS-136** standard, which

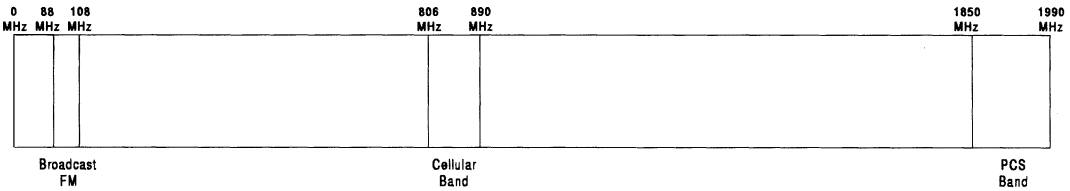

FIGURE 75.8 Frequency allocation.

TABLE 75.6 AMPS System Parameters

System Parameter	AMPS
Multiple access	FDMA
Channel bandwidth	30 kHz
Number of users per channel	1
Reverse (uplink) frequency range	824–849 MHz
Forward (downlink) frequency range	869–894 MHz
Voice modulation	FM
Voice peak frequency deviation	12 kHz
Control channel modulation	Binary FSK
Control channel peak frequency deviation	8 kHz
Control channel data rate	10 Kbps (Manchester encoded)
Control channel error correcting code	BCH

TABLE 75.7 IS-54/IS-136 System Parameters

System Parameter	IS-54/IS-136
Multiple access	TDMA
Channel bandwidth	30 kHz
Number of users per channel	3
Reverse (uplink) frequency range	824–849 MHz
Forward (downlink) frequency range	869–894 MHz
Modulation	π/4-DQPSK
Forward and reverse data rate	48.6 Kbps
Error correcting code	Rate ½ convolutional code, K = 7

was released in the mid-1990s, introduced enhancements to **IS-54,** including PCS functionality. The radio interface for IS-54 and **IS-136** is summarized in Table 75.7.

GSM is the European-originated digital **TDMA** standard. It also appears in the sub-1-GHz part of the spectrum, with the uplink band in the 890 to 915 MHz range and the downlink band in the 935 to 960 MHz range. However, GSM differs from IS-136 in several respects, including modulation (GSM uses GMSK), data rate (270.83 Kbps), and channel spacing (200 kHz). GSM systems exist in many parts of the world outside of Europe, including North America.

Another digital technology, introduced for cellular systems in the early 1990s, was code division multiple access (**CDMA**). This technology is based on the principles of spread spectrum, in which narrow-band user traffic is transformed into wideband signals resembling white noise over the resultant signal bandwidth. This is accomplished by modulating user traffic with a higher-rate spreading sequence, normally generated by maximum-length shift registers. This technology was used in military communications for its inherent security and resistance to jamming. The **IS-95** public wireless standard introduced CDMA, with each user occupying a 1.25-MHz bandwidth. The first commercial CDMA systems were launched in the United States in 1996. The radio interface for IS-95 is summarized in Table 75.8.

TABLE 75.8 IS-95 System Parameters

System Parameter	IS-95
Multiple access	CDMA
Channel bandwidth	1.25 MHz
Reverse (uplink) frequency range	824–849 MHz
Forward (downlink) frequency range	869–894 MHz
Modulation	BPSK — Quadrature Spread
Forward and reverse data rate	9.6 Kbps
Error correcting code	Rate ½ convolutional code, K = 9

It is of interest to note that in **IS-95,** the number of users per data channel is not specified in Table 75.8. This is due to the fact that such a quantity is not easy to derive for all conditions, due to a number of factors. The downlink for IS-95 provides two forms of user channelization, based on spreading sequence time offsets and Walsh codes. However, spreading sequence offsets alone provide uplink channelization. Moreover, both the uplink and downlink are interference-limited, due to multiple users occupying the same frequency band simultaneously.

PCS Services

Both the **IS-136** and IS-95 digital wireless standards have evolved to provide enhanced services for **PCS**. These enhancements include enhanced voice services, data services and short message services (SMS), and paging and e-mail.

Enhanced Voice Services

IS-136 employed an 8 Kbps speech coder, **VSELP**, as its initial codec for voice services. It takes as input 64 Kbps voice in pulse-coded modulation (PCM) format, and outputs 8 Kbps. Processing is performed on 20-ms intervals, or frames. The 13 Kbps **EFR** codec provides an evolution to PCS services, and has been introduced for **TDMA** systems, including IS-136 and **GSM.** This codec provides improvements in voice quality, and provides additional error correction under noisy conditions.

IS-95 also initially employed an 8 Kbps speech coder developed by Qualcomm Inc., **QCELP8.** In order to evolve to higher voice quality, the **QCELP13** 13 Kbps coder was introduced primarily for PCS applications. Both of these codecs employ variable-rate coding, choosing from four different compression rates for each 20-ms frame. This is done to enhance capacity, allowing individual users to occupy more of the channel when their voice activity was high. However, the evolution to 13 Kbps resulted in weakened error-corrective coding. As a result, another variable-rate 8 Kbps codec, **EVRC**, was introduced. This codec provides comparable voice quality to QCELP13 at a lower rate. EVRC uses only three of the original four coding rates used by QCELP8 for each frame.

Data Services

Both IS-95 and IS-136 systems presently support a "packet-over-circuit" approach to data services. This employs transmitting packet data originating from an application (usually running over TCP/IP) through a dedicated wireless traffic channel. Although such data transfer is straightforward, it is wasteful in that a user may be transmitting or receiving blank traffic frames while waiting for a packet burst from the application.

IS-136 also employs the **CDPD** method for packet data transfer over an existing **AMPS** channel. This method is efficient in that the user must "share" the channel with other users, so as to take advantage of the bursty nature of packet data.

IS-95 has also incorporated channel aggregation in recent revisions. As mentioned before, IS-95 supports two voice codec rates of 8 Kbps and 13 Kbps. As proposed in the recent IS-95-B wireless standard, a single user can send or receive multiple traffic channels, each of which either support 8 Kbps or 13 Kbps (but not both rates mixed). The maximum number of such channels is eight in either the uplink or downlink, and only one channel is variable rate.

SMS

Presently, both IS-95 and IS-136 support SMS. SMS is used to provide a host of teleservices, including over-the-air programming and alphanumeric messaging (typically less than 250 characters). SMS can also support low-rate data applications employing a transparent transport layer, such as UDP.

Paging and E-mail

Both IS-95 and IS-136 support user paging and wireless e-mail services. This is normally accomplished through generic data burst messaging on common control channels.

3rd Generation Enhancements

3rd Generation versions of IS-95 and IS-136 are currently being developed and standardized, with the projected deployment being in the PCS band. The requirements of these systems has in general been provided by the

International Telecommunications Union (ITU) as part of its IMT-2000 (International Mobile Telecommunications 2000) project. Enhancements provided to both systems encompass data rates of up to 2 Mbps, suitable performance under a variety of mobile channel conditions (indoor and outdoor), support of simultaneous user services, compatibility with existing **2nd generation** systems, and several other considerations. It is of interest to note that **GSM** and **IS-136** are both evolving to a common standard known as **EDGE**.

Both versions encompass a significant modification of their 2nd generation counterparts, including modulation, error correction coding, and user bandwidths. However, both versions take advantage of existing 2nd generation voice codecs.

In addition, another **CDMA** standard known as Wideband CDMA (**W-CDMA**) is under development in Europe and Japan. Although this standard is a CDMA standard, it is not backwards-compatible with **IS-95,** and is not designed in such a way that W-CDMA equipment can be used interchangeably with **3rd generation** IS-95 equipment.

The development of 3rd generation systems is ongoing, with equipment deployment forecast for the first part of the new millennium. Much work remains to be done before these standards can solidify sufficiently for equipment development and deployment to be completed.

Defining Terms

AMPS: Advanced Mobile Phone Services. A public, multiple-access wireless system that uses analog frequency-modulation technology. This service primarily appears in the cellular band (806–890 MHz).

CDMA: Code Division Multiple Access. A method of multiple access in which individual users are assigned unique code sequences while using a common frequency.

CDPD: Cellular Digital Packet Data. A packet data service over the 30 kHz analog channel. Can easily be overlaid over existing AMPS networks.

EDGE: Enhanced Data Rates for Global TDMA Evolution. 3rd Generation standard for both GSM and IS-136.

EFR: Enhanced Full Rate coding. 13-Kbps linear predictive coder used in IS-136 TDMA systems.

EVRC: Enhanced Variable Rate Coder. 8-Kbps variable-rate linear predictive coder used in IS-95 CDMA systems.

FDD: Frequency Division Duplexing. The practice of providing multiple frequency bands for an individual user. For example an individual user can receive traffic in one band and send traffic in a different band.

FDMA: Frequency Division Multiple Access. A method of multiple access in which individual users are assigned different frequencies.

1st Generation: Term referring to earliest deployed public wireless systems. AMPS is included in this category.

GSM: Global System for Mobile. A TDMA-based digital public wireless system first deployed in Europe.

IS-95: North American CDMA standard, developed by the Telecommunications Industry Association.

IS-54: North American TDMA standard, developed by the Telecommunications Industry Association. Replaced by IS-136.

IS-136: North American TDMA standard, developed by the Telecommunications Industry Association. Supplanted IS-54.

PCS: Personal Communications Services. Refers either to advanced digital wireless services, or to the frequency band where such services are normally deployed (1850–1990 MHz).

QCELP8: Qualcomm Code Excited Linear Predictive coding. 8 Kbps variable-rate linear predictive coder used in IS-95 CDMA systems.

QCELP13: Qualcomm Code Excited Linear Predictive coding. 13 Kbps variable-rate linear predictive coder used in IS-95 CDMA systems.

2nd Generation: Term referring to the first deployed digital public wireless systems. This category includes CDMA and TDMA technologies.

TDMA: Time Division Multiple Access. A method of multiple access where individual users are assigned time slots while using a common frequency.

3rd Generation: Term referring to digital public wireless systems that offer significant enhancements over 2nd generation systems. These enhancements include high-speed Internet access, realtime video communications, high-fidelity voice, multiple simultaneous services per user, broadcast capability, enhanced capacity, and many other desirable features.

VSELP: Vector Sum Excited Linear Predictive coding. 8 Kbps linear predictive coder used in IS-54/IS-136 TDMA systems.

W-CDMA: Wideband CDMA. 3rd Generation wireless standard currently being developed in Europe and Japan.

76.1 Introduction

A *phase-locked loop* (PLL) is a system that uses feedback to maintain an output signal in a specific phase relationship with a reference signal. PLLs are used in many areas of electronics to control the frequency and/or phase of a signal. These applications include frequency synthesizers, analog and digital modulators and demodulators, and clock recovery circuits. Figure 76.1 shows the block diagram of a basic PLL system. The *phase detector* consists of a device that produces an output voltage proportional to the phase difference of the two input signals. The *VCO* (voltage-controlled oscillator) is a circuit that produces an ac output signal whose frequency is proportional to the input control voltage. The *divide by N* is a device that produces an output signal whose frequency is an integer (denoted by *N*) division of the input signal frequency. The **loop filter** is a circuit that is used to control the PLL dynamics and therefore the performance of the system. The $F(s)$ term is used to denote the Laplace transfer function of this filter.

Servo theory can now be used to derive the equations for the output signal phase relative to the reference input signal phase. Because the VCO control voltage sets the frequency of the oscillation (rather than the phase), this will produce a pure integration when writing this expression. Several of the components of the PLL have a fixed gain associated with them. These are the **VCO** control voltage to output frequency conversion gain (K_v), the **phase detector** input signal phase difference to output voltage conversion gain (K_ϕ), and the feedback division ratio (N). These gains can be combined into a single factor called the loop gain (K). This loop gain is calculated using Eq. (76.1) and is then used in the following equations to calculate the loop transfer function.

$$K = \frac{K_\phi \times K_v}{N} \tag{76.1}$$

The closed-loop transfer function $[H(s)]$ can now be written and is shown in Eq. (76.2). This function is typically used to examine the frequency or time-domain response of a PLL and defines the relationship of the phase of the VCO output signal (θ_o) to the phase of the reference input (θ_i). It also describes the relationship of a change in the output frequency to a change in the input frequency. This function is low-pass in nature.

$$H(s) = \frac{\theta_o(s)}{\theta_i(s)} = \frac{KF(s)}{s + KF(s)} \tag{76.2}$$

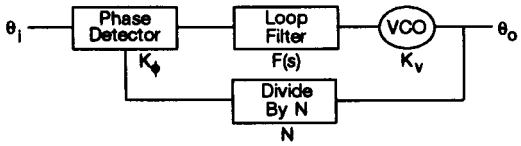

FIGURE 76.1 PLL block diagram.

The loop error function, shown in Eq. (76.3), describes the difference between the VCO phase and the reference phase and is typically used to examine the performance of PLLs that are modulated. This function is high-pass in nature.

$$\frac{\theta_i(s) - \theta_o(s)}{\theta_i(s)} = \frac{\theta_e(s)}{\theta_i(s)} = \frac{s}{s + KF(s)} \tag{76.3}$$

The open-loop transfer function $[G(s)]$ is shown in Eq. (76.4). This function describes the operation of the loop before the feedback path is completed. It is useful during the design of the system in determining the gain and phase margin of the PLL. These are indications of the stability of a PLL when the feedback loop is connected.

$$G(s) = \frac{KF(s)}{s} \tag{76.4}$$

These functions describe the performance of the basic PLL and can now be used to derive synthesis equations. The synthesis equations will be used to calculate circuit components that will give a desired performance characteristic. These characteristics usually involve the low-pass corner frequency and shape of the closed-loop response characteristic [Eq. (76.2)] and determine such things as the loop lock-up time, the ability to track the input signal, and the output signal noise characteristics.

76.2 Loop Filter

The loop filter is used to shape the overall response of the PLL to meet the design goals of the system. There are two implementations of the loop filter that are used in the vast majority of PLLs: the passive lag circuit shown in Fig. 76.2 and the active circuit shown in Fig. 76.3. These two circuits both produce a PLL with a second-order response characteristic.

The transfer functions of these loop filter circuits may now be derived and are shown in Eqs. (76.5) for the passive circuit (Fig. 76.2) and (76.6) for the active circuit (Fig. 76.3).

$$F_p(s) = \frac{sC_1R_2 + 1}{s(R_1 + R_2)C_1 + 1} \tag{76.5}$$

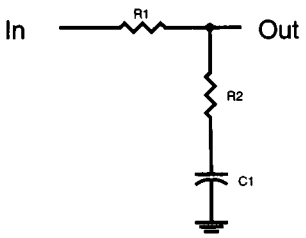

FIGURE 76.2 Passive loop filter.

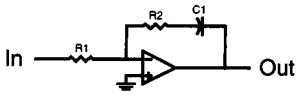

FIGURE 76.3 Active loop filter.

$$F_a(s) = \frac{sR_2C_1 + 1}{sR_1C_1} \tag{76.6}$$

These loop filter equations may now be substituted into Eq. (76.2) to form the closed-loop transfer functions of the PLL. These are shown as Eqs. (76.7) for the case of the passive filter and (76.8) for the active.

$$H_p(s) = \frac{s\dfrac{KR_2}{R_1 + R_2} + \dfrac{K}{(R_1 + R_2)C_1}}{s^2 + s\left[\dfrac{1}{(R_1 + R_2)C_1} + \dfrac{KR_2}{R_1 + R_2}\right] + \dfrac{K}{(R_1 + R_2)C_1}} \tag{76.7}$$

$$H_a(s) = \frac{s\dfrac{KR_2}{R_1} + \dfrac{K}{R_1C_1}}{s^2 + s\dfrac{KR_2}{R_1} + \dfrac{K}{R_1C_1}} \tag{76.8}$$

These closed-loop equations can also be written in the forms shown below to place the function in terms of the **damping factor** (ζ) and the loop natural frequency (ω_n). It will be shown later that these are very useful parameters in specifying PLL performance. Equation (76.9) is the form used for the PLL with a passive loop filter, and Eq. (76.10) is used for the active loop filter case.

$$H_p(s) = \frac{s[2\zeta\omega_n - (\omega_n^2/K)] + \omega_n^2}{s^2 + s2\zeta\omega_n + \omega_n^2} \tag{76.9}$$

$$H_a(s) = \frac{s2\zeta\omega_n + \omega_n^2}{s^2 + s2\zeta\omega_n + \omega_n^2} \tag{76.10}$$

Solving Eqs. (76.7) and (76.9) for R_1 and R_2 in terms of the loop parameters ζ and ω_n, we now obtain the synthesis equations for a PLL with a passive loop filter. These are shown as Eqs. (76.11) and (76.12).

$$R_2 = \frac{2\zeta}{\omega_n C} - \frac{1}{KC} \tag{76.11}$$

$$R_1 = \frac{K}{\omega_n^2 C} - R_2 \tag{76.12}$$

To maintain resistor values that are positive the passive loop filter PLL must meet the constraint shown in Eq. (76.13).

$$\zeta > \frac{\omega_n}{2K} \tag{76.13}$$

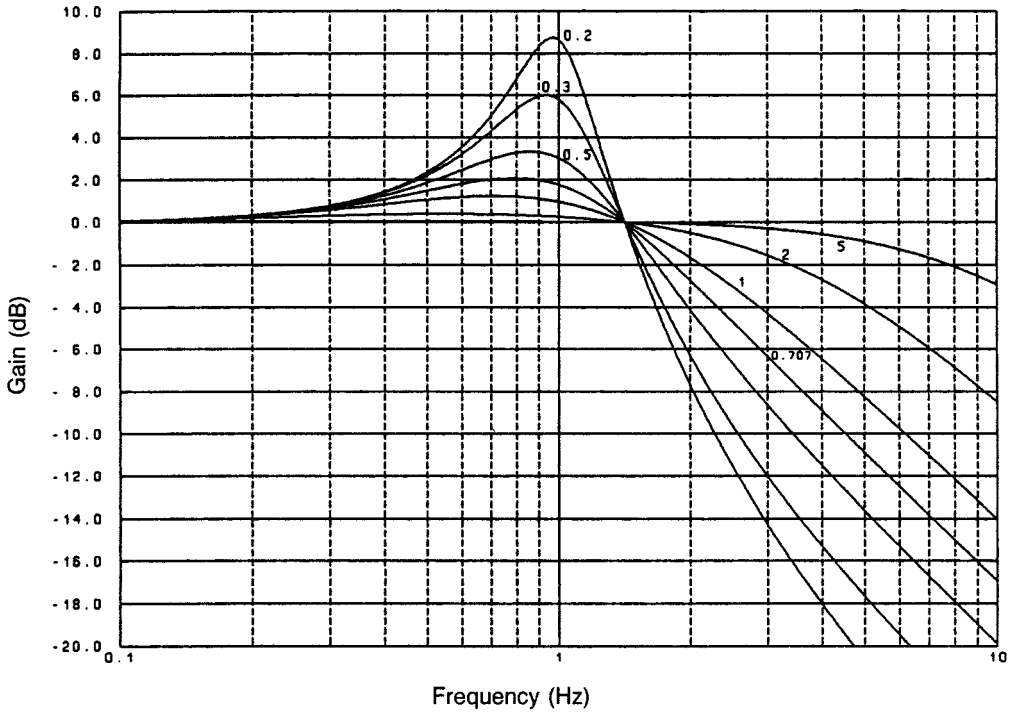

FIGURE 76.4 Closed-loop second-order type-2 PLL error response for various damping factors.

For the active loop filter case Eqs. (76.8) and (76.10) are solved and yield the synthesis equations shown in Eqs. (76.14) and (76.15). It can be seen that no constraints on the loop damping factor exist in this case.

$$R_1 = \frac{K}{\omega_n^2 C} \tag{76.14}$$

$$R_2 = \frac{2\zeta}{\omega_n C} \tag{76.15}$$

A typical design procedure for these loop filters would be, first, to select the loop damping factor and natural frequency based on the system requirements. Next, all the loop gain parameters are determined. A convenient capacitor value may then be selected. The remaining resistors can now be computed from the synthesis equations presented above.

Figure 76.4 shows the closed-loop frequency response of a PLL with an active loop filter [Eq. (76.10)] for various values of damping factor. The loop natural frequency has been normalized to 1 Hz for all cases.

Substituting Eq. (76.6) into (76.3) will give the loop error response in terms of damping factor. This function is shown plotted in Fig. 76.5. These plots may be used to select the PLL performance parameters that will give a desired frequency response shape.

The time response of a PLL with an active loop filter to a step in input phase was also computed and is shown plotted in Fig. 76.6.

76.3 Noise

An important design aspect of a PLL is the noise content of the output. The dominant resultant noise will appear as phase noise (jitter) on the output signal from the VCO. Due to the dynamics of the PLL some of these noise sources will be filtered by the loop transfer function [Eq. (76.2)] that is a low-pass characteristic.

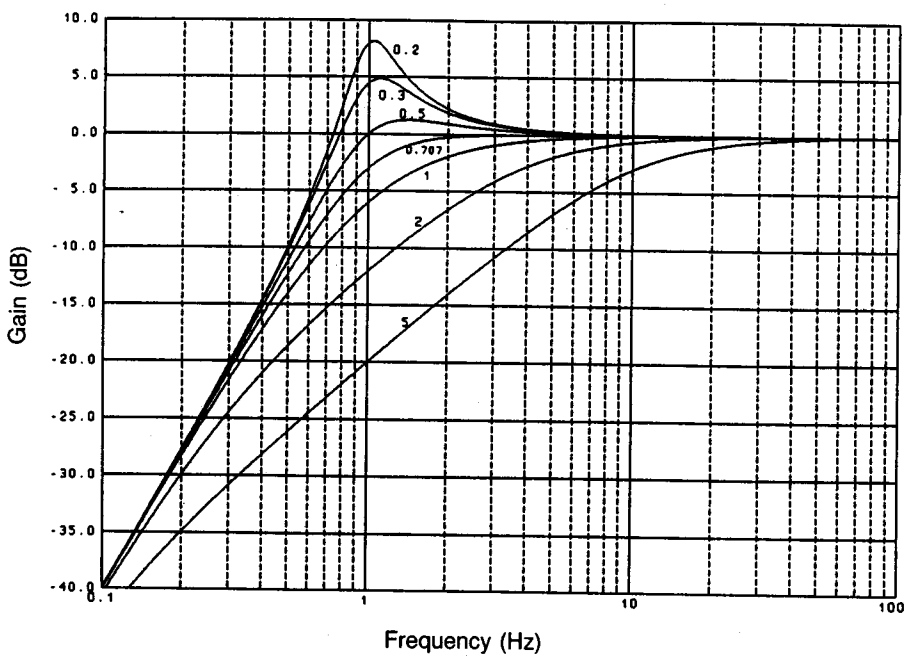

FIGURE 76.5 Closed-loop second-order type-2 PLL step response for various damping factors.

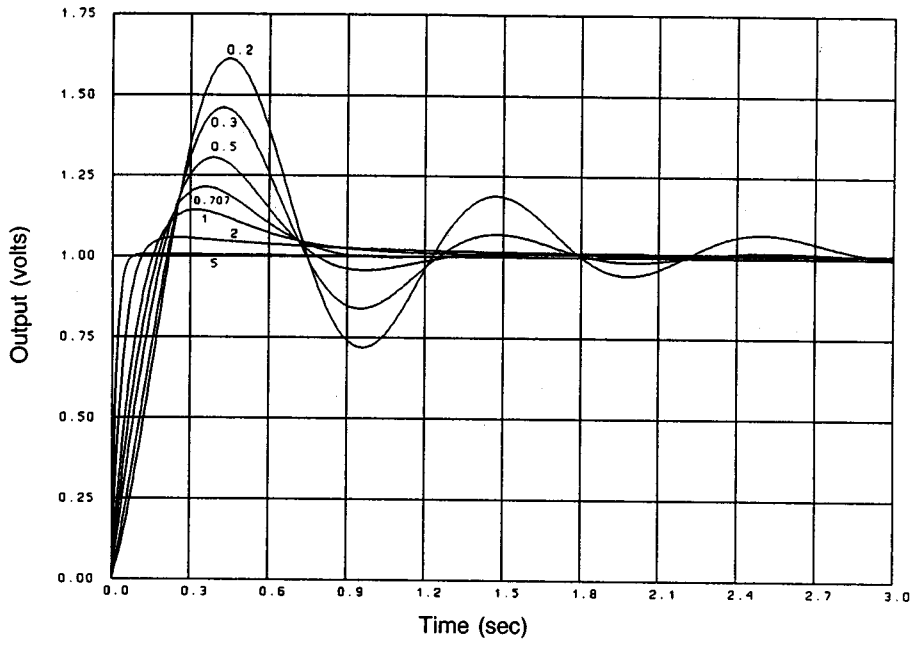

FIGURE 76.6 Closed-loop PLL response for various damping factors.

Others will be processed by the loop error function [Eq. (76.3)] that is a high-pass characteristic. Table 76.1 shows the major sources of noise in a PLL and the effect of the loop dynamics on this noise. All these factors must be combined to evaluate the complete noise performance of a PLL. Often it will be found that one particular noise source will be dominant and the PLL performance can then be adjusted to minimize the output noise.

TABLE 76.1 PLL Noise Sources

Noise Source	Filter Function
Reference oscillator phase noise	Low pass
Phase detector noise	Low pass
Active loop filter input noise	Low pass
Digital divider noise	Low pass
Active loop filter output noise	High pass
VCO free-running phase noise	High pass

A PLL is frequently used to enhance the noise performance of an oscillator by taking advantage of these noise-filtering properties. For example, a crystal oscillator typically has very good low-frequency noise characteristics, and a free-running LC oscillator can be designed with very good high-frequency noise performance but will exhibit poor low-frequency noise characteristics. By phase-locking an LC oscillator to a crystal oscillator and setting the loop response corner frequency to the noise crossover point between the two oscillators, the desirable characteristics of both oscillators are realized.

When designing frequency synthesizers using PLLs, care must be taken to prevent noise from the PLL components from introducing excessive noise. The divider ratio (N) used in the feedback of the loop has the effect of multiplying any noise that appears at the input or output of the phase detector by this factor. Frequently, a large value of N is required to achieve the desired output frequencies. This can cause excessive output noise. All these effects must be taken into account to achieve a PLL design with optimum noise performance.

76.4 PLL Design Procedures

The specific steps used to design a PLL depend on the intended application. Typically the architecture of the loop will be determined by the output frequency agility required (frequency synthesizer) and the reference sources available. Other requirements such as size and cost play important factors, as well as available standard components. Once the topology has been determined, then the desired loop transfer function must be synthesized. This may be dictated by noise requirements as discussed above or other factors such as loop lock-up time or input signal tracking ability. The design Eqs. (76.11) through (76.15) may then be used to determine the component values required in the loop filter.

Frequently several of these factors must be balanced or traded off to obtain an acceptable design. A design that requires high performance in several of these areas usually can be realized at the expense of design complexity or increased component cost.

76.5 Components

The development of large-scale integrated circuits over the past several years has made the design and implementation of PLLs and frequency synthesizers much cheaper and easier. Several major manufacturers (Motorola, Signetics, National, Plessey, etc.) currently supply a wide range of components for PLL implementation. The most complex of these are the synthesizer circuits that provide a programmable reference divider, programmable divide by N, and a phase detector. Several configurations of these circuits are available to suit most applications. Integrated circuits are also available to implement most of the individual blocks shown in Fig. 76.1.

A wide variety of phase detector circuits are available, and the optimum type will depend on the circuit requirements. An analog multiplier (or mixer) may be used and is most common in applications where the comparison frequency must be very high. This type of phase detector produces an output that is the multiplication of the two input signals. If the inputs are sine waves, the output will consist of a double-frequency component as well as a dc component that is proportional to the cosine of the input phase difference. The double-frequency component can be removed with a **low-pass filter**, leaving only the dc component. The analog multiplier has a somewhat limited phase range of ±90 degrees. The remainder of the phase detector types discussed here are digital in nature and operate using digital edges or transitions of the signals to be compared.

The sample-and-hold phase detector is widely used where optimum noise performance is required. This circuit operates by using one of the phase detector inputs to sample the voltage on the other input. This latter input is usually converted to a triangle wave to give a linear phase detector characteristic. Once the input is sampled, its voltage is held using a capacitor. The good noise performance is achieved since most of the time the phase detector output is simply a stored charge on this capacitor. The phase range of the sample-and-hold phase detector depends on the type of waveform shaping used and can range from ±90 to ±180 degrees.

One of the simplest types of phase detectors to implement uses an exclusive OR gate to digitally multiply the two signals together. The output must then be low-pass filtered to extract only the dc component. The main drawback to this circuit is the large component that exists in the output at twice the input frequency. This requires a large amount of low-pass filtering and may restrict the PLL design. The phase range of this type of circuit is ±90 degrees.

One of the main drawbacks of all the above types of phase detectors is that they only provide an output that is proportional to phase and not to a frequency difference in the input signals. For many applications the PLL input signals are initially not on the same frequency. Several techniques have been used in the past to resolve this such as sweeping the VCO or using separate circuitry to first acquire the input frequency. The sequential (sometimes called phase/frequency) phase detector has become the most commonly used solution due to its wide availability in integrated form. This type of phase detector produces pulses with the width of the pulses indicating the phase difference of the inputs. It also has the characteristic of providing the correct output to steer the VCO to the correct frequency. The noise characteristic of this type of phase detector is also quite good since either no or very narrow pulses are produced when the inputs are in phase with each other. The phase range of this type of circuit is ±360 degrees.

Digital dividers are widely available and may either have programmable or fixed division ratios depending on the application. For optimum noise performance a synchronous type of divider should be used. When a programmable divider is required to operate at a high frequency (>50 MHz), a dual modulus circuit is normally used. This circuit uses a technique called *pulse swallowing* to extend the range of normal programmable divider integrated circuits by using a dual modulus prescaler (usually ECL). The dual modulus prescaler is a high-frequency divider that can be programmed to divide by only two sequential values. A second programmable divider section is then used to control the prescaler. Further details of this type of divider are available from component manufacturers' data sheets as well as in the references.

The voltage-controlled oscillator is typically the most critical circuit in determining the overall noise performance of a PLL. For this reason it is often implemented using discrete components, especially at the higher frequencies. Some digital integrated circuits exist for lower-frequency VCOs, and microwave integrated circuit VCOs are now available for use to several gigahertz. The major design parameters for a VCO include the operating frequency, tuning range, tuning linearity, and phase noise performance. Further information on the design of VCOs is contained in the references.

Loop filters used in PLLs may be either active or passive depending on the specific application. Active filters are normally used in more critical applications when superior control of loop parameters and reference frequency suppression is required. The loop filter is typically followed by a low-pass filter to remove any residual reference frequency component from the phase detector. This low-pass filter will affect the calculated loop response and will typically appear to reduce the loop damping factor as its corner frequency is brought closer to the loop natural frequency. To avoid this degradation the corner frequency of this filter should be approximately one order of magnitude greater than the loop natural frequency. In some cases a notch filter may be used to reduce the reference frequency when it is close to the reference frequency.

76.6 Applications

Phase-locked loops are used in many applications including frequency synthesis, modulation, demodulation, and clock recovery. A frequency synthesizer is a PLL that uses a programmable divider in the feedback. By selecting various values of division ratio, several output frequencies may be obtained that are integer multiples of the reference frequency (Fref). Frequency synthesizers are widely used in radio communications equipment to obtain a stable frequency source that may be tuned to a desired radio channel. Since the output frequency is an integer multiple of the reference frequency, this will determine the channel spacing obtained. The main

design parameters for a synthesizer are typically determined by the required channel change time and output noise.

Transmitting equipment for radio communications frequently uses PLLs to obtain frequency modulation (FM) or phase modulation (PM). A PLL is first designed to generate a radio frequency signal. The modulation signal (i.e., voice) is then applied to the loop. For FM the modulating signal is added to the output of the loop filter. The PLL will maintain the center frequency of the VCO, while the modulation will vary the VCO frequency about this center. The frequency response of the FM input will exhibit a high-pass response and is described by the error function shown in Eq. (76.3). Phase modulation is obtained by adding the modulation signal to the input of the loop filter. The modulation will then vary the phase of the VCO output signal. The frequency response of the PM input will be a low-pass characteristic described by the closed-loop transfer function shown in Eq. (76.2).

A communications receiver must extract the modulation from a radio frequency carrier. A PLL may be used by phase locking a VCO to the received input signal. The loop filter output will then contain the extracted FM signal, and the loop filter input will contain the PM signal. In this case the frequency response of the FM output will be a low-pass function described by the closed-loop transfer function and the PM output response will be a high-pass function described by the error function.

In digital communications (modems) it is frequently necessary to extract a coherent clock signal from an input data stream. A PLL is often used for this task by locking a VCO to the input data. Depending on the type of data encoding that is used, the data may first need to be processed before connecting the PLL. The VCO output is then used as the clock to extract the data bits from the input signal.

Defining Terms

Capture range: The range of input frequencies over which the PLL can acquire phase lock.

Damping factor: A measure of the ability of the PLL to track an input signal step. Usually used to indicate the amount of overshoot present in the output to a step perturbation in the input.

Free-run frequency: The frequency at which the VCO will oscillate when no input signal is presented to the PLL. Sometimes referred to as the rest frequency.

Lock range: The range of input frequencies over which the PLL will remain in phase lock once acquisition has occurred.

Loop filter: The filter function that follows the phase detector and determines the system dynamic performance.

Loop gain: The combination of all dc gains in the PLL.

Low-pass filter: A filter that usually follows the loop filter and is used to remove the reference frequency components generated by the phase detector.

Natural frequency: The characteristic frequency of the PLL dynamic performance. The frequency of the closed-loop transfer function dominant pole.

Phase detector gain: The ratio of the dc output voltage of the phase detector to the input phase difference. This is usually expressed in units of volts/radian.

VCO gain: The ratio of the VCO output frequency to the dc control input level. This is usually expressed in units of radians/second/volt.

77.1 Introduction to Telemetry

Telemetry, or measurement at a distance, takes many and varied forms. It may use the principles of radio, electricity, optics, mechanics, or hydraulics to convey measurements made at one place to indicators, actuators, recorders, or computers at another. By far the most popular telemetry systems are electrical and use radio or wire links to convey information. In this respect, all of the considerations in the foregoing chapters on communications apply, as well as considerations of antennas, power supplies and convertors, heat removal, and radio frequency interference. Additional considerations that are unique to telemetry are treated here.

The deeper an instrumented vehicle probes into the remote reaches of outer space, the more technologically spectacular seem the achievements of telemetry. There is still something exciting and uncanny about performing measurements of a physical quantity at a distant location and precisely reproducing them at a more convenient place for reading or recording them.

Yet the vast distances spanned by telemetry signals are less challenging technically than the stubborn problems of almost sheer inaccessibility in some industrial applications to the quantities being measured. Signals from a missile-launched space probe soaring toward the sun are often easier to obtain than measurements from inside a stolid, earthbound motor only a foot or two away. To find the temperature of the spinning rotor, housed in a steel casing and surrounded by a strong alternating magnetic field, may require more ingenuity to transcend the operating environment than taking measurements from the most distant instrument payload speeding through the unaccommodating environment of space.

The technology that has produced missile and space telemetry is also spawning new forms of industrial radio telemetry, capitalizing on the development of new transducers, powerful miniature radio transmitters, improved self-contained power sources, and better techniques of environmental protection.

Simply enough, to telemeter is to measure at a distance. First, at the remote point, is needed a transducer, a device that converts the physical quantity being measured into a signal, usually an electrical one, so that it

can be more conveniently transmitted. Then a connecting link between the location where the measurement is being made and the point where one can read or record the signal being sent is required. This link can be either an electrical circuit—there have been wired telemetry systems since long before the turn of the century—or pneumatic or hydraulic lines, a beam of light, or now, more practically, a radio carrier.

A radio telemetry system comprises (1) transducers that convert measurements into electrical systems, (2) a subcarrier oscillator modulated by the transducers, (3) a radio transmitter modulated by the subcarrier, (4) a transmitting antenna, (5) a receiving antenna, (6) a radio receiver, and (7) a subcarrier discriminator. The radio link can transmit an analog of the continuous variable being measured, or, with pulse-code methods, it sends the measurement data digitally as a finite number of symbols representing a finite number of possible values of the measurement signal at the time it is sampled. The range of a radio link is limited by the power radiated toward the receiver from the transmitter and by the sensitivity of the receiver. The wider the bandwidth, the more the effect from noise, and therefore the more transmitted power required for a detectable signal.

Optical, mechanical, and hydraulic telemeters represent a smaller segment of the telemetry field than do electrical and radio telemeters; they will be given only brief treatment here.

Optical telemeters use light transmitted through space or through optical fibers, the light being modulated by the measurement signal. The modulation may be produced either electrically or mechanically. Electrically, light-emitting diodes, lasers, or electroluminescent material are used to convert the electricity to light. The light may then be modulated with the measurement information by modulating the electricity that produces the light or it may be polarized and rotated by Kerr or Pockels cells, absorbed by electrically activated chromofors, or converted to another wavelength by electrically controlled nonlinear elements, all of which are activated by the modulating signal.

Hydraulic telemeters are generally used in conjunction with hydraulic sensors and hydraulic displays, such as pressure gauges. They are immune to all electrical and optical interference and hence find application in unfavorable electrical and optical environments. A typical hydraulic telemeter is used to measure load lifted and boom angle on a crane. Here a hydraulic piston is activated by the tension of a lifting rope pushed sidewise by the piston roller. An increase in tension produced by the load tends to straighten the deflected rope and press the piston into its cylinder. The change in pressure is communicated through fluid in a tube to a remote indicator. The hydraulic telemeter measures the boom angle by simply placing a fluid reservoir on the boom, which when it is raised provides increased pressure through its tube to a second remote indicator. In this way, with remote indicators, the operator monitors the crane to prevent overloading and/or overturning.

Electrical telemeters proliferate through (1) space, (2) battlefields, and (3) industrial sites, varying in size, configuration, and information-carrying capacity with their various applications. Space research and missile development used the first significant multichannel telemeters. Telemeters developed at the Naval Research Laboratories and built by the Raytheon Company were first used to explore outside the earth's atmosphere in German V-2 rockets launched at the White Sands Proving Ground. These telemeters used 1000-MHz pulse position modulated signals at ranges greater than 100 miles. Conrad H. Hoeppner designed the equipment and managed the installations and operation. From 1945 onward, telemetry developed rapidly and found its way to the various missile ranges also being developed.

To permit tests to be made interchangeably at all ranges, it was necessary to standardize types of telemeters at the ranges. To this end the Department of Defense Research and Development Board formed the Guided Missiles Committee, which in turn formed the Working Group on Telemetry. This later became the Inter-Range Instrumentation Group (IRIG), which has published telemetry standards that are widely accepted.

Meanwhile, industrial telemetry has developed along different lines, producing miniaturized complete capsules for applications to process control, detection of defects, and machine design. Medical science is currently using telemetry in experimental, clinical, and diagnostic applications. Some of the particular body characteristics telemetered include heartbeat, brain waves, blood pressure, temperature, voice patterns, heart sounds, respiration sounds, and muscle tensions. Similar studies are being pursued in the biological and psychological fields, where more experimental latitude permits embedding of transmitters within living animals.

The basic telemetry system consists of three building blocks. These are (1) input transducer, (2) the transmitter, and (3) the receiving station. Transducers convert the measured physical quantity into a usable form for transmission. The conversion of the desired information into a form capable of being transmitted to the receiver is a function of the type of transducer employed. Transducers convert the physical quantities to be

measured into electrical, light, pneumatic, or hydraulic energy. The type of energy conversion is determined by the type of transmission desired. In a radio telemetry system, the transmitter and receiver have much in common with communications equipment. The transducers, however, are unique to telemetry and will be described in some detail here.

One of the most common types of transducers generates electrical signals as a function of the changing physical quantity, and one of the most common varieties of this type is the resistance wire strain gauge. In this transducer, the ability of the wire to change its dimension as it is stressed causes a corresponding change in its electrical resistance. A decrease in wire diameter generally results in greater resistance to the flow of electricity. Similarly, temperature-sensitive materials that have electrical characteristics changing with temperature make temperature detection possible.

In most transducers, the electrical output is varied as a function of changes in the physical parameter. These electrical changes can be transmitted by wire direct to a control center, data display area, or to a data analysis section for evaluation. The difficulties with the use of wire in many applications have given rise to wireless telemetry. In order to transmit the transducer information through the air, it is necessary to apply this information to a high-frequency electrical carrier, as is commonly done in radio. Application of the transducer information to a high-frequency carrier is commonly called modulation. High-frequency or rapidly changing electricity has the capability of being propagated through space, whereas low-frequency or battery, nonchanging voltage does not possess this ability.

The technique used for applying or modulating the high-frequency carrier by the transducer output involves any one of three different methods. It is possible to modulate a carrier by a change in amplitude, a change in frequency, or a change in the carrier phase. The last technique is similar to the modulation used in transmitting color by television. In color TV the brightness signal is transmitted as amplitude modulation (AM), the sound as frequency modulation (FM), and the color as phase modulation (PM), or pulse coding. Pulse coding is used to modulate the radio frequency carrier in either AM, FM, or PM.

A common and extremely useful technique for increasing the information-carrying capability of a single transmitting telemetry line is called multiplexing. When it is desirable to monitor different physical parameters, such as temperature and pressure, it may be wasteful to have duplicating telemetry transmission lines. Multiplexing techniques can usually be considered to be of two types: frequency division multiplexing and time division multiplexing. In the frequency division multiplexing system, different subcarrier frequencies are modulated by their respective changing physical parameter; these subcarrier frequencies are then used to modulate the carrier frequency, enabling the transmission of all desired channels of information, simultaneously by one carrier. At the receiver, these subcarrier frequencies must be individually removed. This is accomplished by filters that allow any one of the respective subcarrier frequencies to pass. Each subcarrier frequency is then converted back to a voltage by the discriminator. The discriminator voltages can be used to actuate recorders and/or similar devices. Time division telemetry systems may use pulse modulation or pulse code modulation. In these systems the information signal is applied, in time sequence, to modulate the radio carrier. The characteristics of a pulse signal can be affected by modulating its amplitude, frequency, or phase.

Telemetry began as a wire communication technique between two remotely located stations. As science extends its domains into the realm of space, telemetry will be the essential communicating link among satellites, spaceships, robots, and other scientific devices yet to be designed.

The range of a radio link is limited by the strength of the signal radiated by the transmitter toward the receiver and by the sensitivity of that receiver. A 10-microwatt (μW) output will transmit data easily 100 feet with a bandwidth of 100 kHz. The wider the bandwidth, the more the effect from noise, and therefore the more transmitting power required for an acceptable signal.

At the receiving station, there are usually no space restrictions in accommodating large antennas, sensitive radio tuners and recorders, and an ample power supply, but the transmitting station often must be small, possibly doughnut-size, but sometimes no bigger than a pea, and must be self-sufficient, carrying its own power or perhaps receiving it by radio.

On the surface, industrial radio telemetry seems to be simply a matter of hardware. It almost is, except that the functional requirements are a lot different from those in missile and space telemetry. Distances are much shorter, a matter of a few feet to a few hundred yards; signal power can be radiated directly from the transmitter circuitry or from an antenna as simple as an inch or two of wire. Most tests are repeatable—no missile blowing

up on the pad here, taking with it valuable instruments and invaluable records of the events leading up to that failure.

Quantities can be measured one or two at a time, rather than requiring an enormous amount of information to be transmitted at once. This results in relatively inefficient use of the radio link but enables simpler circuitry at both the transmitting and receiving ends.

Surprisingly, environment plays the most critical role in industrial telemetry. It makes by far the largest difference between telemetry operations from missiles and spacecraft and those used in industrial remote measurement. While missile telemetry equipment is expected to withstand accelerations of 10 to 20 *g*, the rotating applications of telemetry in industry, such as the embedding of a transducer in a spinning shaft, require immunity to 10,000 or 20,000 *g* centrifugal accelerations.

The environmental extremes under which industrial telemeters must work are considered normal operating conditions by their users. Unlike missile telemetry equipment, which is shielded and insulated against extremes of temperature, shock, and vibrations and which is carefully calibrated for weeks before it is used only once in an actual shot, industrial telemeters must operate repeatedly without adjustment and calibration. Used outdoors, they are often subjected to a temperature range of –40 to +140°F. They must operate when immersed in hot or cold fluids, and thus it is almost mandatory that they be completely encapsulated to be impervious not only to humidity and water but to many other chemical fluids and fumes. Many lubricating oils operate at temperatures of 300 or 350°F.

We know that missile telemetry components must be small and light, yet an order of magnitude reduction in size and weight has been necessary to make telemetry suitable for high-speed rotating shafts or for biological implants. They must be so reliable that no maintenance is required, for there are no service centers set up to handle this kind of equipment, and it must work without failure to continue to gain industrial acceptance.

Information theory has been used extensively to develop space telemetry for the most efficient data transmission over a maximum distance with a minimum of transmitted power. Inefficiencies, being of no real consequence in industrial telemetry, make for less elaborate, less costly equipment. Radio channels are used in a relatively inefficient manner, and the distances between transmitter and receiver are usually so short that there are few problems of weak signals. In many cases, measurement and testing via telemetry links takes place in completely shielded buildings or in metal housings.

Although telemetry is usually defined as measurement at a distance, it has also gradually begun to embody the concept of control from a distance. In telemetry—the transmission of the value of a quantity from a remote point—it may serve merely to communicate the reading on an instrument at a distance. The output of the instrument can also be fed into a control mechanism, however, such as a relay or an alarm, so that the telemetered signal can activate, stop, or otherwise regulate a process. Measurement may be taken at one location, indication provided at a second location, and the remote control function initiated at one of those two locations or at a third point.

For example, a motor might be pumping oil from one location while oil pressure is being measured at another. When the pressure reading is telemetered to a control station, a decision can be made there to reduce pump motor speed when the pressure is too high, or a valve can be opened at still another location to direct the oil to flow in another path. The decision-making controller may be an experienced pipeline dispatcher or an automatic device.

77.2 Measuring and Transmitting

Telemetry, then, really begins with measurement. A physical quantity is converted to a signal for transmission to another point. The transducer that converts this physical quantity into an electrical signal may be a piezoelectric crystal, a variable resistance, or perhaps an accelerometer. Telemetered information need be no less accurate than that obtained directly under laboratory conditions. For instance, in telemetering strain measurements, it is possible to achieve accuracies of a few microinches per inch or greater. The only limitation is usually the degree of stability in the bond of the strain gauge to the specimen, and not the strain gauge itself.

If great accuracy in temperature measurement is desired, it can be attained by choosing a transducer that provides a large variation of output signal over a small range of process property variation. The resolution which this provides may be translated into true accuracy by careful transducer calibration. Accuracy is reduced,

of course, if a wider range of temperature needs to be detected. Typical single-channel analog telemetry links maintain a measurement accuracy of 1–5%. This is not a limitation of the total system, however, since 1% of a 100° temperature change would only be 1°, so several telemetry channels can easily share the total temperature range to be measured, say a 100°F range divided into four 25°F ranges, to produce an accuracy of one-fourth of a degree.

Special temperature probes have been produced for the range of 70 to 400°F and higher to maximize the stability and accuracy of temperature telemetry. These probes, when used with the proper choice of transmitters and receivers, can provide temperature measurements to closer than 0.05°F.

One of the limitations to accuracy and to repeatability in telemetry is the output level of the transducer. The low electrical levels produced by thermocouples and strain gauges (millivolts) are much more difficult to telemeter than a higher-voltage level of, say, 5 V. At low signal levels, extraneous electrical noises produce great degradation. This noise may be thermally generated, caused by atmospheric effects, or generated by nearby electrical equipment. When low-level transducers are used, stable amplifiers are required to raise the signal voltage to useful modulation levels.

There may be great variations in the strength of the radio signal received because of variations in distance between transmitter and receiver or because of the interposition of metallic objects. In industrial radio telemetry transmission, these effects can be prevented from disturbing the data by resorting to FM of both the subcarrier and the carrier so that the telemetered signal is unchanged by undesirable amplitude variations. This method is called FM/FM telemetry.

If FM is used in the subcarrier of the transmitter, the transducer signal modulates the frequency of the subcarrier oscillator. This can be done by a simple resonant circuit that produces a given frequency in the audio range, say 1,000 Hz, which is varied above or below by the signal from the transducer as it responds to the variable it is measuring. If the signal were fed to a loudspeaker, a rising or falling tone would be heard. The subcarrier oscillator then modulates a radio frequency carrier, varying its frequency (FM) or its amplitude (AM) in accordance with the subcarrier signal. The radio frequency in FM industrial radio telemetry links is usually in the 88- to 108-MHz band. At the receiving end of the link, the radio receiver demodulates the signal, removing the carrier and feeding the subcarrier to a special discriminator circuit that removes the modulation and precisely reproduces the original measurement signal for calibrated indication or recording.

Multiple measurements can also be transmitted over the carrier by sampling the output of several transducers in rapid sequence, a technique called time-division multiplexing. This technique has been employed to handle as many as a million samples per second. It provides for simple data displays and easier separation of channels for recording or analysis, and it is free of cross talk. If possible, it is advantageous to use no multiplexing at all for concurrent data taking, but to use separate radio carriers for each measurement being transmitted.

Many and varied kinds of modulation have been used in telemetry systems. All have general usefulness, with cost and application being the drivers. Synchronized modulation is generally used with other systems, being synchronized to them to give additional information such as range. Typically, a command control uplink to an aircraft is used to synchronize a telemetry downlink with the delay being proportional to distance or the length of the link. Signal-to-noise advantages are also achieved. Another example is one in which telemetry is tacked on to a radar transponder to add additional pulses to indicate altitude, heading identification, or other conditions of the vehicle carrying the transponder. This is usually accomplished with pulse position modulation.

In many instances, a reconnaissance vehicle will carry a television camera. Its signals may be recorded on board but are often telemetered for real-time observations. Data may be placed on the same carrier using a few lines of the TV picture or an additional subcarrier. The much greater bandwidth of the TV signal seriously compromises the combination of range, transmitter power, and antenna directivity, and typically signal-to-noise ratio is reduced as much as 30 dB.

77.3 Applications of Telemetry

High-voltage transmission lines are an excellent example of how inaccessible an object of measurement may be. These lines vibrate in the wind, and the stresses and strains require measurement under the dynamic conditions that contribute to fatigue failure. Strain tests to determine fatigue will show quickly whether the endurance limit of the line has been exceeded, and only if it is exceeded need we be concerned about fatigue

failure. Therefore, it is necessary to measure the number and magnitude of the strain reversals in order to predict the time of failure. Telemetry techniques permit dynamic testing under actual service conditions rather than by simulated laboratory conditions or static tests.

While the transducer that produces an electrical signal proportional to strain may have an output of 0.01 V, the live transmission line to which it is attached may be at a potential of several hundred thousand volts. The problem is to detect this hundredth of a volt in the presence of a very large signal. In the language of the telemetry engineer, this is rejection of a common mode voltage on the order of 10^8 to 1. Then why not deenergize the line? It's a simple matter of economics—an idle line transmits no power, and the wind forces that cause the line to vibrate are neither predictable nor constant. So, weeks or months may be spent in gathering measurements for a particular set of spans. However, a radio telemetry link makes it possible to transmit the strain signal even while power is being carried.

A self-contained FM radio transmitter is attached to the transmission line at a point adjacent to a strain gauge. All remain at the same electrical potential as the line, much like a bird sitting safely on the wire, transmitting the strain gauge output to a radio receiver and recorder located at some convenient point on the ground, where vibration analysis can be made. As a result, armor rods may be placed around the line at the vulnerable points, or vibration absorbers of the correct resonant frequency can be installed at the proper points on the line.

More down to earth, but equally inaccessible to measurement, is strain on the chain belt of an earth mover. Too light a chain will quickly fail from fatigue caused by the alternating stresses imposed by the full and empty buckets it transports. Measurements made under actual operating conditions of the earth hoist mean attaching strain gauges to a chain traveling at 500 ft per minute, subjecting them to violent shock and vibration. On this kind of moving equipment, slip rings and wire-link remote measurements will not work. Here again, radio telemetry is now providing the dynamic measurements needed to test the earth-moving equipment at work. A transducer and a small, rugged transmitter are attached to points along the chain—strain varies from link to link, depending on the proximity to the bucket—until the most vulnerable part of the chain is found. It is preferable to use several transducers and multiple-channel telemetry equipment for such measurements to simplify correlation between load and the resulting strain at various links.

Telemetry can also determine water levels and flow rates of rivers to provide vital data for flood control or for efficient hydroelectric power generation. Data on the potential watershed into rivers can be obtained by analyzing the water content of snow that would eventually melt and feed them. One requirement is to measure the depth and water content of snow in the mountains, then transmit these data from remote points to a central receiving station. The snow-measuring transducer may consist of a radioactive source atop a tall pole and a radiation intensity meter on the ground beneath the snow. The gamma-ray intensity reaching the meter is a function of the height and water content of the intervening snow. Both the meter and the transmitting equipment can be powered by a storage battery and controlled by a clock timer that sets the time of transmission to a few seconds per day.

In the design of machinery, one of the most difficult factors to cope with is alternating fatigue-producing stresses that occur at some parts of the machine. It has long been the custom to measure stress in equipment with bonded strain gauges to predict the failure limits before actual failure occurs. This had only been possible on those portions of the equipment that could be connected by wires. With radio telemetry, it is not possible on all members. Costly fatigue failures are now avoidable through installation of miniature telemetry components that are reliable, rugged, and accurate in heretofore inaccessible locations and environments. Industrial uses are virtually limitless; systems can be built to specifications and encapsulated to withstand the most adverse conditions. Low-cost measurement and telemetry systems have been applied to read internal vibrations and strain in rotating equipment, chains, vehicles, and projectiles—eliminating slip rings and wires. Measurement can be made under operating conditions of vibration, acceleration, strain, temperature, pressure, magnetic fields, electrical current, and voltage, under such adverse conditions as in a field of high electrical potential, in fluids, in steam, or in high-velocity gases.

Power Sources

Power sources for the transmitter in industrial telemetry applications are seldom a problem. Batteries can be used for temporary applications and at temperatures below 200°F. Small and light, rechargeable and expendable

batteries are available solidly encapsulated in epoxy resin to withstand almost as rugged environments as the telemeter itself.

In a moving or rotating application, stationary magnets can be placed so that they generate electricity in a moving coil and are used to provide automatic power generation. If this method is not feasible, a stationary coil can be placed in the vicinity of the transmitter and fed electrical energy at a high frequency, so that its field can easily couple into a moving coil in almost any environment. The stationary coil ring may be large, even encompassing a whole room; usually only one turn of wire is necessary. The stationary coil may also be made extremely small, 1/4 to 1/2 in. in diameter, and coupled to the end of a rotating shaft. These power supplies and coil configurations are standard available units.

Power Plants

In power plants, coal is fed in turn to a number of hoppers by conveyor belt. A tripper on the conveyor belt diverts the coal into a particular hopper until it is full. Either an operator or a mechanical sensing device determines when the hopper is full, and a signal is transmitted to the conveyor to move onto the next hopper. Before telemetering equipment was in use, costly accidents could occur if the operator should be away momentarily or if the sensor failed to function. As much as six tons of coal a minute could overflow onto the power station floor.

To prevent this, pressure switches are installed in the tripper chute to activate a radio transmitter if coal backs up into the tripper. The transmitter sends its signal to a receiver located at the conveyor belt and sounds an alarm. This type of control is difficult if not impossible to achieve by wired power connections because the tripper is moving and because the corrosive coal dust atmosphere attacks the wires. For this reason, a radio transmitter equipped with long-life batteries is mounted on the tripper. The receiver at the control end is powered by ac. Subcarrier tone (frequency) coding is used to eliminate the effects of interference and noise, giving positive protection at all times.

77.4 Limitations of Telemetry

The preceding paragraphs describe a number of the requirements placed upon telemetry systems by the transducers and quantities being measured. Unfortunately, the development of telemetry has not been such as to satisfy all requirements, and in many cases the telemetry system seriously limits the measurement. A compromise is therefore required between telemetry capabilities and the requirements of measurement. The shortcomings and limitations of the telemetry system place restrictions upon measurements above and beyond those encountered in the laboratory when the telemeter is not used. In the first place, an electrical output from the measuring device is required in order that the measurement may be placed on a radio link. Consequently, transducers that produce an electrical output on one form or another are necessary. Also, the telemetry system may not be perfectly stable down to zero frequency (dc), and transducers and methods of measurement must be chosen to minimize the effects of drift. Overmodulating the subcarrier, or the time-division multiplexer, may also affect adjacent channels, as well as produce erroneous data in its own channel. If various measuring devices are switched, the switching transients must be minimized, or the accuracy of the telemetry system may be impaired. When mechanical commutators or time multiplexers are used, the measurement of the time occurrence of the event, such as the impact of cosmic particles or the receipt of a guidance pulse, is made more difficult and the time ambiguity of the multiplexed system is a serious limitation.

The measurement of a large number of parameters requires extensive and bulky equipment, unless the parameters can be combined in groups of similar inputs to minimize the signal conditioning required. This fact generally dictates a relatively standard transducer rather than an optimum one for each particular measurement.

The bandwidth of the measurement, or the frequency with which the measured quantity changes, is also seriously limited by the telemeter. In the FM/FM telemeter, the permissible bandwidth varies from a relatively low value on the lower-frequency subcarriers to a reasonably high value on the high-frequency subcarriers. The bandwidth of the measurement must not exceed the subcarrier bandwidth limitations, or sidebands will be generated in adjacent channels, thereby reducing the accuracy of other measurements (if multiplexed), or interference with adjacent RF signals will be caused.

In a time-multiplexed system, the problem of "folded data" is present whenever the rate of data change is faster than one-half the sampling rate. When this occurs, it is not known whether the measured quantity has reversed itself several times between samples or if there has been no reversal at all. It is considered desirable to limit the bandwidth of the data so that this ambiguity is not present; however, with refined techniques of analysis, this is not a rigid requirement. The form in which the data is displayed or recorded is also a limitation on measurement. In general, time-history plots of the measured quantity are desired. In this case, the speed at which the recording medium moves is often a severe limitation. If sampling is not regular, demultiplexing difficulties are magnified.

77.5 Transmitters and Batteries

The transmitter is made up of two components: the subcarrier oscillator and the radio frequency oscillator. The subcarrier can be bridge controlled (BCO) or voltage controlled (VCO). The subcarrier center frequency is 4,000 Hz, which can be modulated ±400 Hz by the strain or voltage being measured. Using BCOs, a strain as large as 2,500 microinches per inch (μin./in.) and as small as 2 μin./in. can be measured and transmitted. The temperature measurement range of the VCO is from –200 to 4,000°F. With a copper-constantan thermocouple, a temperature change as small as 2°F can be sensed and transmitted.

The single-resistance strain gauge transmitter does not have a subcarrier oscillator and can be used from –40 to 212°F. It has only a radio frequency oscillator, which is modulated by the sensor signal. For this reason, it is not suitable for static strain measurements and must be used for dynamic strain measurements only. It has a frequency response to 25,000 Hz or greater. A static strain signal transmitted by this device will drift. It is provided with self-contained rechargeable nickel-cadmium batteries. Pins protruding through the epoxy case are used for all electrical connections. Only one screw adjustment is provided, and this is used to set the radio frequency.

Rechargeable nickel-cadmium batteries are used with the BCO and the VCO. The BCO batteries have useful lives of 4 and 9 hr. A VCO battery has 40 hr useful life. The single-resistance strain gauge transmitter has a built-in nickel-cadmium battery with a life of 4 hr.

77.6 Receivers and Discriminators

A typical industrial receiver has a tuning range of 88 to 108 MHz. When the transmitter is used in its greatest sensitivity mode, the output of the discriminator is approximately 1 V for a 25-μin./in. strain with a single active gauge in the bridge. At the most insensitive mode 1 V is obtained for an approximately 500-μin./in. strain. The discriminator can withstand a 500% overload, which means that a 5-V signal will be obtained from a strain of 125-μin./in. at the maximum sensitivity and from 2,500-μin./in. at the minimum sensitivity.

77.7 Antennas and Total System Operation

A nickel-cadmium battery supplies the power to the transmitter. For the BCO, the resistance change of the strain gauge changes the frequency of the subcarrier. In the case of the VCO, the millivolt output of the thermocouple changes the frequency of the subcarrier. This change modulates the radio frequency transmitted by the antenna. The receiving antenna picks up the signal and conducts it by wire link to the radio receiver, which is tuned to the transmitting frequency. The radio receiver demodulates the FM carrier to reproduce the subcarrier signal. The subcarrier signal is then fed to the discriminator, which demodulates this signal to obtain a dc voltage, which is then amplified by the dc amplifier and recorded on the oscillograph. The oscillograph record, properly calibrated, is then a display of the strain in microinches per inch for the BCOs, or the temperature in degrees for the VCO. At the same time the dc signal can be read on a VTVM and can be used as a check on the oscillograph.

The transmitter subcarrier oscillators are factory set to operate at a center frequency of about 4,000 Hz. They have a frequency range of ±400 Hz about the 4,000-Hz center frequency. The center frequency is set with a

counter at the time of testing. The change of ±400 Hz is the information frequency change brought about by the change in strain or temperature measured by the sensor. It is this information frequency change that the discriminators isolate as a dc voltage change, which is proportional to the measured strain and is recorded on the oscillograph.

77.8 Calibration

Batteries are calibrated under simulated service conditions for voltage drop versus time. Bridge-controlled transmitters are calibrated for strain subcarrier frequency change using a cantilever beam instrumented with resistance strain gauges. The beam is calibrated for load versus strain using a strain indicator. It is then used to calibrate the bridge-controlled transmitters statically, by measuring the subcarrier frequency change as a function of strain. A dynamic calibration can also be made by using a second cantilever beam driven by a vibration generator. Two resistance strain gauges are mounted back-to-back on the second beam and calibrated. One of the gauges is monitored through the telemetry system and the other by wire link to the oscillograph, and the two signals are then compared. The single-resistance strain gauge transmitter is similarly calibrated, but in this case, the beam is fixed in a fatigue machine operating at 30 Hz. Calibrations are performed at various strain levels. Again, two calibrated gauges are monitored and compared, one using the telemetry systems and the other using wire link.

The effect of temperature on a transmitter and battery is measured at temperatures from 65 to 135°F by placing both in an air-circulating oven, with the receiving equipment and the calibration beams to room temperature outside the oven.

The voltage-controlled transmitter is calibrated for temperature subcarrier frequency change from 78 to 640°F. Two calibrated thermocouples, welded next to one another on a piece of stainless steel, are heated simultaneously. After determining by wire link instrumentation that both thermocouples are indicating the same temperature, the millivolt output of one is fed into the transmitter, and the output of the other is fed by wire into a precision potentiometer. The subcarrier frequency change is determined as a function of temperature, and the radio signal is recorded on the calibrated oscillograph, with a galvanometer determining its deflection as a function of temperature. The data obtained by wire link and radio are then compared to establish the calibration. The effect of thermocouple lengths can also be investigated in the same test setup. The receivers and discriminators are calibrated before these tests.

Cold junction compensation may be investigated from –40 to 258°F by cooling the transmitter and battery, with leads shorted and with a 20-mV input, in a cold chamber below room temperature and by heating in an air-circulating oven to above room temperature. The 20-mV input is imposed with a dc power supply kept outside the temperature chamber.

The discriminators are calibrated with the transmitters. The subcarrier frequency, which is the input to the discriminator, is monitored with a digital counter as the calibration beam is loaded. The voltage output corresponding to the frequency change can be monitored with a vacuum tube voltmeter. The strain, subcarrier frequency change, and the voltage output of the discriminator are then correlated. A digital frequency counter is used to set the transmitter center frequency.

77.9 Telemetry Frequency Allocations

Frequency bands for telemetry have been allocated as follows:

88–108 MHz	Low power, noninterference
216–260 MHz	General telemetry
400–475 MHz	Command destruct
1435–1540 MHz	General telemetry
1710–1850 MHz	Video telemetry
2.2–2.3 GHz	General telemetry

The low-power, 88 to 108 MHz, band is shared with FM broadcast stations. Telemetry is allowed to be used, but it must not interfere with broadcast reception. Transmitter power and antennas are limited to provide a signal strength no greater than 50 μV/m at 50 ft from the antenna and/or transmitter. In use, the telemetry transmitters are generally tuned to operate at frequencies between local FM broadcast stations.

The remaining frequency bands are used mainly with aircraft, unmanned vehicles, space vehicles, and for military applications. Equipment for these applications is rigidly constrained for stability, low spurious emissions, low cross talk, good linearity, etc.

77.10 Telemetry Antennas

When transmitter and receiver are stationery, antenna considerations for telemetry are no different than for communications. The usual case, however, is that the transmitter is moving, both rotating and translating and often obscuring the transmission with reflective material. This poses problems in both receiving the signal and tracking the moving transmitter with a directive receiving antenna. In many cases it is necessary to have two or more receiving antennas to receive from a single transmitter.

Transmitting antennas may be either conformal or protruding. The protruding antennas are usually cheaper and simpler. The radiation pattern must include downward directivity if an aircraft or space vehicle will fly directly overhead. A vertical whip antenna does not provide this coverage. A simple choice to provide smooth coverage from the nadir to the horizon is circular polarization at the nadir and elliptic polarization in between. A circular polarized receiving antenna is used to receive the signals over the complete pattern. It must be polarized in the same circular direction as the transmitting antenna. A spiral or helix antenna is usually used on the ground. Two complete radio frequency systems are generally used to receive signals of any polarization. One system uses a circular polarized right-hand antenna and the other uses a circular polarized left-hand antenna. In this manner, as the vehicle tilts or spins, signals are received continuously unless the transmitting antenna is occluded. To receive occluded signals, diversity reception is required. Each receiving station is located such that one fills in the occluded pattern of the other.

In short distance telemetry the same problems are encountered but from a different cause. If the transmitter is occluded at one position by the shaft of a rotating machine, it would be expected that reflections from nearby objects or walls would fill the gap. In practice it is the usual occurrence that a gap is generated once per revolution. This is caused by multiple signal cancellation. There are two methods of overcoming this signal drop-out: (1) with diverse polarization and (2) by locating the receiving antenna close to the transmitting antenna and effectively surrounding the shaft with it.

While information theory has been used extensively to develop space telemetry for the most efficient data transmission over a maximum distance with a minimum of transmitted power, the very inefficiencies permitted in industrial telemetry make for less elaborate, less costly equipment.

Radio channels are used in a relatively inefficient manner, and the distances between transmitter and receiver are usually so short that there are few problems of weak signals. In many cases, measurement and testing via telemetry links take place in completely shielded buildings or in metal housings.

Although telemetry is usually defined as measurement at a distance, it has also gradually begun to embody the concept of control from a distance. In a telemeter—the transmission of the value of a quantity from a remote point—it may only be necessary to observe the reading of an instrument to determine the temperature, pressure, or vibration of a distant or inaccessible object. One can also feed the output of the instrument into a control mechanism, however, such as a relay or an alarm device, so that the telemetered signal may activate or stop a controllable process. Measurement may be performed at one location, indication provided at a second location, and the remote control function initiated at one of the first two locations or even at a third point.

Take, for example, an oil pipeline in which a motor is pumping oil from one location and oil pressure is being measured at a second location. The pressure reading is telemetered to a station where a decision can be made to reduce the speed of the pump motor when the pressure is too high, or a valve may be opened at still another location to cause the oil flow in another path. The decision-making element may be human, an experienced pipeline dispatcher, or an automatic controller. Human or automatic device—either one telemeters a command to the control points.

77.11 Measuring and Transmitting

Telemetry, then, really begins with measurement. A physical quantity is converted to a signal for transmission to another point. The transducer that converts the physical quantity into an electric signal typically may be a piezoelectric crystal, a variable resistance, or perhaps an accelerometer.

Telemetering the measurement signal of the best transducers in no way degrades the measurement below accuracies attainable under laboratory conditions. For instance, in strain measurement it is possible to achieve accuracies of a few microinches per inch or greater, but the limitation is usually the degree of stability in the bond of the strain gauge to the specimen.

If one wants accuracy in temperature measurement, it can be attained by choosing a transducer that provides a large variation in output signal over a small range of temperature. The resolution that this provides may be translated to true accuracy by careful transducer calibration. Typical analog telemetry links maintain a measurement accuracy on a single channel to 1%. This is not a limitation of the total system, since 1% of a 100-degree temperature change would only be 1 degree, so several telemetry channels can easily share the total temperature range to be measured, say, a 100 range divided into four 25 ranges to produce an accuracy of 1/4 degree.

One of the limitations to accuracy and repeatability in telemetry is the output level of the transducer. The low electrical levels produced by thermocouples and strain gauges (0.010 V) are more difficult to telemeter than high-voltage levels of 5 V. At low signal levels, extraneous electrical noises produce greater degradation. These may be thermally generated or caused by atmospheric effects or generated by nearby electrical equipment. When low-level transducers are used, stable amplifiers are required to raise their signal voltage to useful modulation levels.

77.12 Modulating and Multiplexing

The transducer signal modulates the frequency of the subcarrier oscillator. This is simply a resonant circuit that produces a given frequency in the audio range, say 100 Hz, and is varied plus or minus this center frequency by the signal from the transducer as it responds to the variable that it is measuring. When the signal is fed to a loudspeaker, one actually hears a rising or falling tone. The subcarrier oscillator modulates a radio frequency carrier, varying its frequency in accordance with the subcarrier voltage signal. The radio frequency in FM industrial radio telemetry links is usually in the 88- to 108-MHz band, permitting the use of high-grade radio tuners already mass produced for the high-fidelity market. The radio receiver demodulates the signal, removing the carrier and feeding it to a special discriminator circuit that removes the double modulation and reproduces an analog of the original measurement signal for calibrated indication or recording.

There can be great variations in the strength of the radio signal received because of variations in distance between transmitter and receiver or because of the interposition of metallic objects. In industrial radio telemetry transmission, these effects are prevented from disturbing the data by resorting to FM of both the subcarrier and the carrier so that the telemetered signal is unchanged by undesirable amplitude variations. This method is called FM/FM telemetry. There are other methods of carrier modulation, such as pulse amplitude modulation, phase modulation, and pulse duration modulation. Each has its proper place in missile and space telemetry, where great distances must be spanned with a maximum of data over crowded and often noisy communication channels. Pulse code modulation of an FM link, however, may be expected to become more widespread in industrial telemetry.

Particularly in missile telemetry, it is important that multiple measurements be transmitted over a single carrier to save power and minimize electronic equipment and antennas. Such simultaneous transmission of signals over a common path, called multiplexing, is sometimes used in industrial telemetry. When concurrent data about several simultaneous events are transmitted by several subcarriers, each subcarrier oscillator has a distinctive reference frequency and swings from this center frequency toward arbitrary maximum and minimum frequencies in response to signals from a corresponding transducer. Thus a number of separate audio frequency bands are sent over the radio frequency carrier. This is called frequency division multiplexing. The frequency division multiplex requires careful adjustment of subcarrier frequencies and the corresponding filters at the receiver and strong suppression of harmonics to avoid cross talk or interaction between channels.

Multiple measurements may also be transmitted over the carrier by sampling the output of each transducer in rapid sequence, a technique called time-division multiplexing. The technique has been used to handle as many as a million samples per second. It provides for very simple data displays, easier separation of channels for recording or analysis, and is free of cross talk. If possible, though, it is advantageous to use no multiplexing at all for concurrent data talking but to use separate radio carriers for each measurement being transmitted. The multiplex telemeter requires careful adjustment of subcarrier frequencies and precisely tuned filters to separate them at the receiver. This adds to the cost of the equipment and requires considerable experience of an operator.

The telemetry data received may be recorded in a number of ways, but such records must preserve the accuracy of the entire system. For example, if one is monitoring a 1% system and can distinguish 1/64th in. on a paper graph, the minimum graph size for full scale should be approximately 2 in. Similarly, numeric data should be printed to enough decimal places to preserve the accuracy of the system.

A single channel of industrial FM/FM telemetry equipment may cost between $1000 and $2000, depending on the flexibility required and the measurements being made. It buys everything needed for a given remote measurement—transducer, radio link, power supply, and simple indicator.

77.13 Passive Telemeters

Passively powered telemeters offer some interesting advantages. When a number of telemeters are used, they can be powered in sequence or only when measurements are required, thus preventing radio frequency congestion. In medical applications of telemetry, passive devices eliminate the danger involved in swallowing or implanting batteries.

Most passive telemeters are essentially an inductance and a capacitance coupled as a resonant circuit. Either of these components may be pressure sensitive or temperature sensitive. A nearby magnetic coil coupled to this circuit can, by means of a varying frequency, determine the resonant point of the telemeter, which can then be a function of the temperature or pressure being measured.

77.14 The Receiving Station

The industrial telemetry receiving station differs vastly in purpose and principle from the transmitting station. Its usual environment is no more difficult to cope with, in terms of ambient temperature, shock, and vibrations, than an automobile radio. It receives signals over relatively short distances in which the subcarrier frequencies are so widely spaced that harmonics and drift are no problem.

In the FM broadcast band, available professional-grade high-fidelity tuners have 1 or 2 μV sensitivity for 30 dB of quieting of extraneous noises and automatic frequency control circuits, which compensate for both transmitter and receiver drift. They feed telemetry phase-lock discriminators, which lock the receiver into the frequency and phase of the incoming signal.

The transmitters usually radiate from the resonant elements themselves, avoiding elaborate antennas that might be required for longer distance transmission; the receivers use simple dipole or commercial TV antennas. Thus, industrial radio telemetry has become a carefully engineered blend of the borrowed and the new.

78.1 Introduction

It should be clear from the preceding chapters that communication systems exist to perform a wide variety of tasks. The demands placed on today's communication systems necessitate higher data rates, greater flexibility, and increased reliability. Communication systems are therefore becoming increasingly complex, and the resulting systems cannot usually be analyzed using traditional (pencil and paper) analysis techniques. In addition, communication systems often operate in complicated environments that are not analytically tractable. Examples include channels that exhibit severe bandlimiting, multipath, fading, interference, non-Gaussian noise, and perhaps even burst noise. The combination of a complex system and a complex environment makes the design and analysis of these communication systems a formidable task. Some level of computer assistance must usually be invoked in both the design and analysis process. The appropriate level of computer assistance can range from simply using numerical techniques to solve a differential equation defining an element or subsystem to developing a **computer simulation** of the end-to-end communication system.

There is another important reason for the current popularity of computer-aided analysis and simulation techniques. It is now practical to make extensive use of these techniques. The computing power of many personal computers and workstations available today exceeds the capabilities of many large mainframe computers of only a decade ago. The low cost of these computing resources make them widely available. As a result, significant computing resources are available to the communications engineer within the office or even the home environment.

FIGURE 78.1 Basic communication link.

Personal computers and workstations tend to be resources dedicated to a specific individual or project. Since the communications engineer working at his or her desk has control over the computing resource, lengthy simulations can be performed without interfering with the work of others. Over the past few years a number of software packages have been developed that allow complex communication systems to be simulated with relative ease [Shanmugan, 1988]. The best of these packages contains a wide variety of subsystem models as well as integrated graphics packages that allow waveforms, spectra, histograms, and performance characteristics to be displayed without leaving the simulation environment. For those motivated to generate their own simulation code, the widespread availability of high-quality C, Pascal, and FORTRAN compilers makes it possible for large application-specific simulation programs to be developed for personal computers and workstations. When computing tools are both available and convenient to use, they will be employed in the day-to-day efforts of system analysts and designers.

The purpose of this chapter is to provide a brief introduction to the subject of **computer-aided design and analysis** of communication systems. Since computer-aided design and analysis almost always involves some level of simulation, we focus our discussion on the important subject of the simulation of communication systems.

Computer simulations can, of course, never replace a skilled engineer, although they can be a tremendous help in both the design and analysis process. The most powerful simulation program cannot solve all the problems that arise, and the process of making trade-off decisions will always be based on experience. In addition, evaluating and interpreting the results of a complex simulation require considerable skill and insight. While these remarks seem obvious, as computer-aided techniques become more powerful, one is tempted to replace experience and insight with computing power.

78.2 The Role of Simulation

The main purposes of simulation are to help us understand the operation of a complex communication system, to determine acceptable or optimum parameters for implementation of a system, and to determine the performance of a communication system. There are basically two types of systems in which communication engineers have interest: **communication links** and communication networks.

A communication link is usually a single source, a single user, and the components and channel between source and user. A typical link architecture is shown in Fig. 78.1. The important performance parameter in a digital communication link is typically the reliability of the communication link as measured by the symbol or bit error rate (BER). In an analog communication link the performance parameter of interest is typically the signal-to-noise ratio (SNR) at the receiver input or the mean-square error of the receiver output. The simulation is usually performed to determine the effect of system parameters, such as filter bandwidths or code rate, or to determine the effect of environmental parameters, such as noise levels, noise statistics, or power spectral densities.

A communication network is a collection of communication links with many signal sources and many users. Computer simulation programs for networks often deal with problems of routing, flow and congestion control, and the network delay. While this chapter deals with the communication link, the reader is reminded that network simulation is also an important area of study. The simulation methodologies used for communication networks are different from those used on links because, in a communication link simulation, each waveform present in the system is sampled using a constant sampling frequency. In contrast, network simulations are event-driven, with the important events being such quantities as the time of arrival of a message.

Simulations can be developed to investigate either transient phenomena or steady-state properties of a system. The study of the acquisition time of a phase-lock loop receiver is an example of a transient phenomenon. Simulations that are performed to study transient behavior often focus on a single subsystem such as a receiver synchronization system. Simulations that are developed to study steady-state behavior often model the entire system. An example is a simulation to determine the BER of a system.

78.3 Motivation for the Use of Simulation

As mentioned previously, simulation is a reasonable approach to many design and analysis problems because complex problems demand that computer-based techniques be used to support traditional analytical approaches. There are many other motivations for making use of simulation.

A carefully developed simulation is much like having a breadboard implementation of the communication system available for study. Experiments can be performed using the simulation much like experiments can be performed using hardware. System parameters can be easily changed, and the impact of these changes can be evaluated. By continuing this process, parameteric studies can easily be conducted and acceptable, or perhaps even optimum, parameter values can be determined. By changing parameters, or even the system topology, one can play "what if" games much more quickly and economically using a simulation than with a system realized in hardware.

It is often overlooked that simulation can be used to support analysis. Many people incorrectly view simulation as a tool to be used only when a system becomes too complex to be analyzed using traditional analysis techniques. Used properly, simulation goes hand in hand with traditional techniques in that simulation can often be used to guide analysis. A properly developed simulation provides insight into system operation. As an example, if a system has many parameters, these can be varied in a way that allows the most important parameters, in terms of system performance, to be identified. The least important parameters can then often be discarded, with the result being a simpler system that is more tractable analytically. Analysis also aids simulation. The development of an accurate and efficient simulation is often dependent upon a careful analysis of various portions of the system.

78.4 Limitations of Simulation

Simulation, useful as it is, does have limitations. It must be remembered that a system simulation is an approximation to the actual system under study. The nature of the approximations must be understood if one is to have confidence in the simulation results. The accuracy of the simulation is limited by the accuracy to which the various components and subsystems within the system are modeled. It is often necessary to collect extensive experimental data on system components to ensure that simulation models accurately reflect the behavior of the components. Even if this step is done with care, one can only trust the simulation model over the range of values consistent with the previously collected experimental data. A main source of error in a simulation results because models are used at operating points beyond which the models are valid.

In addition to modeling difficulties, it should be realized that the digital simulation of a system can seldom be made perfectly consistent with the actual system under study. The simulation is affected by phenomena not present in the actual system. Examples are the aliasing errors resulting from the sampling operation and the finite word length (quantization) effects present in the simulation. Practical communication systems use a number of filters, and modeling the analog filters present in the actual system by the digital filters required by the simulation involves a number of approximations. The assumptions and approximations used in modeling an analog filter using impulse-invariant digital filter synthesis techniques are quite different from the assumptions and approximations used in bilinear z-transform techniques. Determining the appropriate modeling technique requires careful thought.

Another limitation of simulation lies in the excessive computer run time that is often necessary for estimating performance parameters. An example is the estimation of the system BER for systems having very low nominal bit error rates. We will expand on this topic later in this chapter.

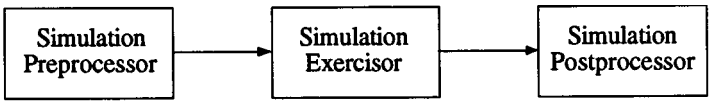

FIGURE 78.2 Typical structure of a simulation program.

78.5 Simulation Structure

As illustrated in Fig. 78.1, a communication system is a collection of subsystems such that the overall system provides a reliable path for information flow from source to user. In a computer simulation of the system, the individual subsystems must first be accurately modeled by signal processing operations. The overall simulation program is a collection of these signal processing operations and must accurately model the overall communication system. The important subject of subsystem modeling will be treated in a following section.

The first step in the development of a simulation program is to define the topology of the system, which specifies the manner in which the individual subsystems are connected. The subsystem models must then be defined by specifying the signal processing operation to be performed by each of the various subsystems. A simulation structure may be either fixed topology or free topology. In a fixed topology simulation, the basic structure shown in Fig. 78.1 is modeled. Various subsystems can be bypassed if desired by setting switches, but the basic topology cannot be modified. In a free topology structure, subsystems can be interconnected in any way desired and new additional subsystems can be added at will.

A simulation program for a communication system is a collection of at least three operations, shown in Fig. 78.2, although in a well-integrated simulation these operations tend to merge together. The first operation, sometimes referred to as the *preprocessor,* defines the parameters of each subsystem and the intrinsic parameters that control the operation of the simulation. The second operation is the *simulation exercisor,* which is the simulation program actually executed on the computer. The third operation performed in a simulation program is that of *postprocessing.* This is a collection of routines that format the simulation output in a way which provides insight into system operations and allows the performance of the communication system under study to be evaluated. A postprocessor usually consists of a number of graphics-based routines, allowing the user to view waveforms and other displays generated by the simulation. The postprocessor also consists of a number of routines that allow estimation of the bit error rate, signal-to-noise ratios, histograms, and power spectral densities.

When faced with the problem of developing a simulation of a communication system, the first fundamental choice is whether to develop a custom simulation using a general-purpose high-level language or to use one of the many special-purpose communication system simulation languages available. If the decision is made to develop a dedicated simulation using a general-purpose language, a number of resources are needed beyond a quality compiler and a mathematics library. Also needed are libraries for filtering routines, software models for each of the subsystems contained in the overall system, channel models, and the waveform display and data analysis routines needed for the analysis of the simulation results (postprocessing). While at least some of the required software will have to be developed at the time the simulation is being written, many of the required routines can probably be obtained from digital signal processing (DSP) programs and other available sources. As more simulation projects are completed, the database of available routines becomes larger.

The other alternative is to use a **dedicated simulation language**, which makes it possible for one who does not have the necessary skills to create a custom simulation using a high-level language to develop a communication system simulation. Many simulation languages are available for both personal computers and workstations [Shanmugan, 1988]. While the use of these resources can speed simulation development, the user must ensure that the assumptions used in developing the models are well understood and applicable to the problem of interest. In choosing a dedicated language from among those that are available, one should select a language that has an extensive model library, an integrated postprocessor with a wide variety of data analysis routines, on-line help and documentation capabilities, and extensive error-checking routines.

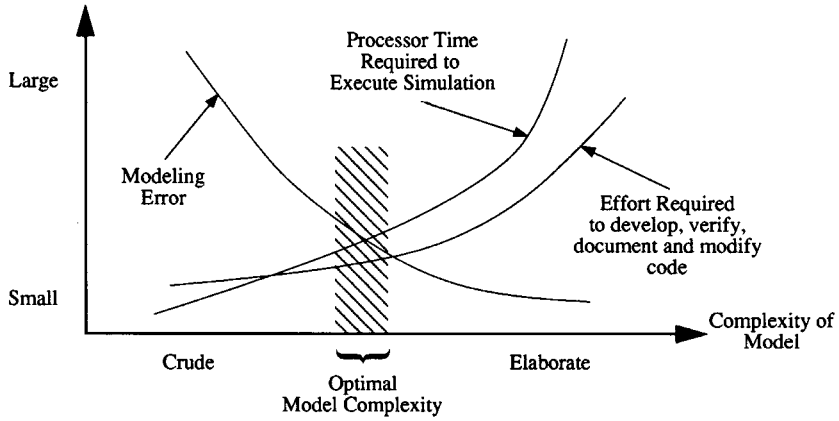

FIGURE 78.3 Design constraints and trade-offs.

78.6 The Interdisciplinary Nature of Simulation

The subject of computer-aided design and analysis of communication systems is very much interdisciplinary in nature. The major disciplines that bear on the subject are communication theory, DSP, numerical analysis, and stochastic process theory. The roles played by these subjects is clear. The simulation user must have knowledge of the behavior of communication theory if the simulation results are to be understood. The analysis techniques of communication theory allow simulation results to be verified. Since each subsystem in the overall communication system is a signal processing operation, the tools of DSP provide the algorithms to realize filters and other subsystems. Numerical analysis techniques are used extensively in the development of signal processing algorithms. Since communication systems involve random data signals, as well as noise and other disturbances, the concepts of stochastic process theory are important in developing models of these quantities and also for determining performance estimates.

78.7 Model Design

Practicing engineers frequently use models to investigate the behavior of complex systems. Traditionally, models have been physical devices or a set of mathematical expressions. The widespread use of powerful digital computers now allows one to generate computer programs that model physical systems. Although the detailed development and use of computer models differs significantly from their physical and mathematical counterparts, the computer models share many of the same design constraints and trade-offs. For any model to be useful one must guarantee that the response of the model to stimuli will closely match the response of the target system, the model must be designed and fabricated in much less time and at significantly less expense than the target system, and the model must be reasonably easy to validate and modify. In addition to these constraints, designers of computer models must assure that the amount of processor time required to execute the model is not excessive. The optimal model is the one that appropriately balances these conflicting requirements. Figure 78.3 describes the typical design trade-off faced when developing computer models. A somewhat surprising observation is that the optimal model is often not the one that most closely approximates the target system. A highly detailed model will typically require a tremendous amount of time to develop, will be difficult to validate and modify, and may require prohibitive processor time to execute. Selecting a model that achieves a good balance between these constraints is as much an art as a science. Being aware of the trade-offs which exist, and must be addressed, is the first step toward mastering the art of modeling.

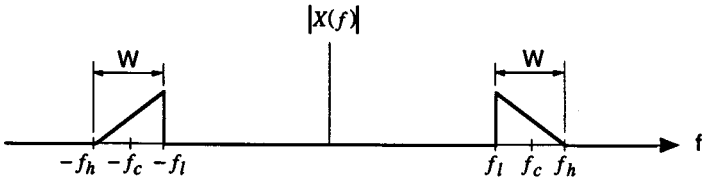

FIGURE 78.4 Amplitude spectrum of a bandpass signal.

78.8 Low-Pass Models

In most cases of practical interest the physical layer of the communication system will use continuous time (CT) signals, while the simulation will operate in discrete time (DT). For the simulation to be useful, one must develop DT signals and systems that closely match their CT counterparts. This topic is discussed at length in introductory DSP texts. A prominent result in this field is the Nyquist sampling theorem, which states that if a CT signal has no energy above frequency f_h Hz, one can create a DT signal that contains *exactly* the same information by sampling the CT signal at any rate in excess of 2 f_h samples per second. Since the execution time of the simulation is proportional to the number of samples it must process, one naturally uses the lowest sampling rate possible. While the Nyquist theorem should not be violated for arbitrary signals, when the CT signal is bandpass one can use low-pass equivalent (LPE) waveforms that contain all the information of the CT signal but can be sampled slower than 2 f_h.

Assume the energy in a bandpass signal is centered about a carrier frequency of f_c Hz and ranges from f_l to f_h Hz, resulting in a bandwidth of $f_h - f_l = W$ Hz, as in Fig. 78.4. It is not unusual for W to be many orders of magnitude less than f_c. The bandpass waveform $x(t)$ can be expressed as a function of two low-pass signals. Two essentially equivalent LPE expansions are known as the envelope/phase representation [Davenport and Root, 1958],

$$x(t) = A(t)\cos[2\pi f_c t + \theta(t)] \tag{78.1}$$

and the quadrature representation,

$$x(t) = x_c(t)\cos(2\pi f_c t) - x_s(t)\sin(2\pi f_c t) \tag{78.2}$$

All four real signals $A(t)$, $\theta(t)$, $x_c(t)$, and $x_s(t)$ are low pass and have zero energy above $W/2$ Hz. A computer simulation that replaces $x(t)$ with a pair of LPE signals will require far less processor time since the LPE waveforms can be sampled at W as opposed to 2 f_h samples per second. It is cumbersome to work with two signals rather than one signal. A more mathematically elegant LPE expansion is

$$x(t) = \mathrm{Re}\{v(t)e^{j2\pi fct}\} \tag{78.3}$$

where $v(t)$ is a low-pass, *complex-time domain signal* that has no energy above $W/2$ Hz. Signal $v(t)$ is known as the complex envelope of $x(t)$ [Haykin, 1983]. It contains all the information of $x(t)$ and can be sampled at W samples per second without aliasing. This notation is disturbing to engineers accustomed to viewing all time domain signals as real. However, a complete theory exists for complex time domain signals, and with surprisingly little effort one can define convolution, Fourier transforms, analog-to-digital and digital-to-analog conversions, and many other signal processing algorithms for complex signals. If f_c and W are known, the LPE mapping is one-to-one so that $x(t)$ can be completely recovered from $v(t)$. While it is conceptually simpler to sample the CT signals at a rate in excess of $2f_h$ and avoid the mathematical difficulties of the LPE representation, the tremendous difference between f_c and W makes the LPE far more efficient for computer simulation. This type

of trade-off frequently occurs in computer simulation. A careful mathematical analysis of the modeling problem conducted *before* any computer code is generated can yield substantial performance improvements over a conceptually simpler, but numerically inefficient approach.

The fundamental reason the LPE representation outlined above is popular in simulation is that one can easily generate **LPE models** of linear time-invariant bandpass filters. The LPE of the output of a bandpass filter is merely the convolution of the LPE of the input signal and the LPE of the impulse response of the filter. It is far more difficult to determine a LPE model for nonlinear and time-varying systems. There are numerous approaches that trade off flexibility and simplicity. If the system is nonlinear and time invariant, a Volterra series can be used. While this series will exactly represent the nonlinear device, it is often analytically intractable and numerically inefficient. For nonlinear devices with a limited amount of memory the AM/AM, AM/PM [Shimbo, 1971] LPE model is useful. This model accurately describes the response of many microwave amplifiers including traveling-wave tubes, solid-state limiting amplifiers, and, under certain conditions, devices which exhibit hysteresis. The Chebyshev transform [Blachman, 1964] is useful for memoryless nonlinearities such as hard and soft limiters. If the nonlinear device is so complex that none of the conventional LPE models can be used, one may need to convert the LPE signal back to its bandpass representation, route the bandpass signal through a model of the nonlinear device, and then reconvert the output to a LPE signal for further processing. If this must be done, one has the choice of increasing the sampling rate for the entire simulation or using different sampling rates for various sections of the simulation. The second of these approaches is known as a *multirate simulation* [Cochiere and Rabiner, 1983]. The interpolation and decimation operations required to convert between sampling rates can consume significant amounts of processor time. One must carefully examine this trade-off to determine if a multirate simulation will substantially reduce the execution time over a single, high sampling rate simulation. Efficient and flexible modeling of nonlinear devices is in general a difficult task and continues to be an area of active research.

78.9 Pseudorandom Signal and Noise Generators

The preceding discussion was motivated by the desire to efficiently model filters and nonlinear amplifiers. Since these devices often consume the majority of the processor time, they are given high priority. However, there are a number of other subsystems that do not resemble filters. One example is the data source that generates the message or waveform which must be transmitted. While signal sources may be analog or digital in nature, we will focus exclusively on binary digital sources. The two basic categories of signals produced by these devices are known as *deterministic* and *random*. When performing worst-case analysis, one will typically produce known, repetitive signal patterns designed to stress a particular subsystem within the overall communication system. For example, a signal with few transitions may stress the symbol synchronization loops, while a signal with many regularly spaced transitions may generate unusually wide bandwidth signals. The generation of this type of signal is straightforward and highly application dependent. To test the nominal system performance one typically uses a random data sequence. While generation of a truly random signal is arguably impossible [Knuth, 1981], one can easily generate pseudorandom (PN) sequences. PN sequence generators have been extensively studied since they are used in Monte Carlo integration and simulation [Rubinstein, 1981] programs and in a variety of wideband and secure communication systems. The two basic structures for generating PN sequences are binary shift registers (BSRs) and linear congruential algorithms (LCAs).

Digital data sources typically use BSRs, while noise generators often use LCAs. A logic diagram for a simple BSR is shown in Fig. 78.5. This BSR consists of a clock, six *D-type* flip-flops (F/F), and an exclusive OR gate denoted by a modulo-two adder. If all the F/F are initialized to 1, the output of the device is the waveform shown in Fig. 78.6. Notice that the waveform is periodic with period $63 = 2^6 - 1$, but within one cycle the output has many of the properties of a random sequence. This demonstrates all the properties of the BSR, LCA, and more advanced PN sequence generators. All PN generators have memory and must therefore be initialized by the user before the first sample is generated. The initialization data is typically called the seed. One must choose this seed carefully to ensure the output will have the desired properties (in this example, one must avoid setting all F/F to zero). All PN sequence generators will produce periodic sequences. This may or may not be

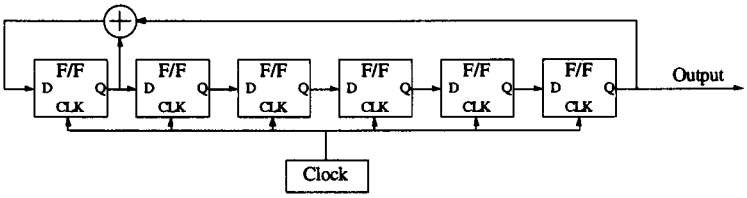

FIGURE 78.5 Six-stage binary shift register PN generator.

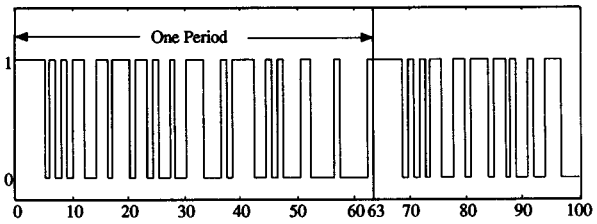

FIGURE 78.6 Output of a six-stage maximal length BSR.

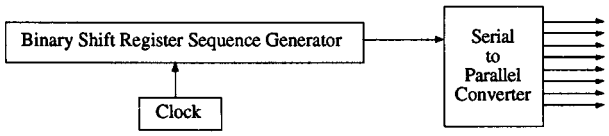

FIGURE 78.7 *M*-ary PN sequence generator.

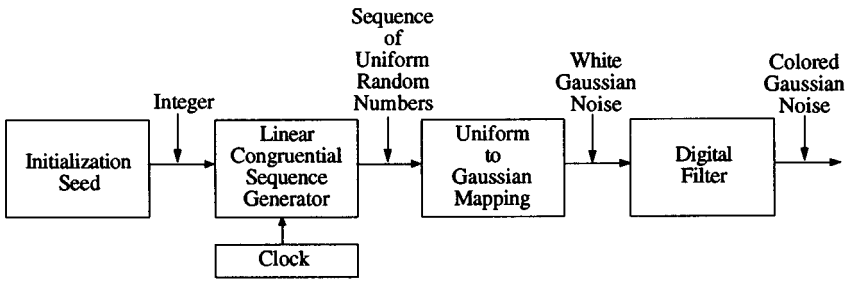

FIGURE 78.8 Generation of Gaussian noise.

a problem. If it is a concern, one should ensure that one period of the PN sequence generator is longer than the total execution time of the simulation. This is usually not a significant problem, since one can easily construct BSRs that have periods greater than 10^{27} clock cycles. The final concern is how closely the behavior of the PN sequence generator matches a truly random sequence. Standard statistical analysis algorithms have been applied to many of these generators to validate their performance.

Many digital communication systems use m bit *(M-ary) sources where* $m > 1$. Figure 78.7 depicts a simple algorithm for generating a M-ary random sequence from a binary sequence. The clock must now cycle through m cycles for every generated symbol, and the period of the generator has been reduced by a factor of m. This may force the use of a longer-period BSR. Another common application of PN sequence generators is to produce

samples of a continuous stochastic process, such as Gaussian noise. A structure for producing these samples is shown in Fig. 78.8. In this case the BSR has been replaced by an LCA [Knuth, 1981]. The LCA is very similar to BSR in that it requires a seed value, is clocked once for each symbol generated, and will generate a periodic sequence. One can generate a white noise process with an arbitrary first-order probability density function (pdf) by passing the output of the LCA through an appropriately designed nonlinear, memoryless mapping. Simple and well-documented algorithms exist for the uniform to Gaussian mapping. If one wishes to generate a nonwhite process, the output can be passed through the appropriate filter. Generation of a wide-sense stationary Gaussian stochastic process with a specified power spectral density is a well-understood and -documented problem. It is also straightforward to generate a white sequence with an arbitrary first-order pdf or to generate a specified power spectral density if one does not attempt to control the pdf. However, the problem of generating a noise source with an arbitrary pdf *and* an arbitrary power spectral density is a significant challenge [Sondhi, 1983].

78.10 Transmitter, Channel, and Receiver Modeling

Most elements of transmitters, channels, and receivers are implemented using standard DSP techniques. Effects that are difficult to characterize using mathematical analysis can often be included in the simulation with little additional effort. Common examples include gain and phase imbalance in quadrature circuits, nonlinear amplifiers, oscillator instabilities, and antenna platform motion. One can typically use LPE waveforms and devices to avoid translating the modulator output to the carrier frequency. Signal levels in physical systems often vary by many orders of magnitude, with the output of the transmitters being extremely high energy signals and the input to receivers at very low energies. To reduce execution time and avoid working with extremely large and small signal level simulations, one often omits the effects of linear amplifiers and attenuators and uses normalized signals. Since the performance of most systems is a function of the signal-to-noise ratio, and not of absolute signal level, normalization will have no effect on the measured performance. One must be careful to document the normalizing constants so that the original signal levels can be reconstructed if needed. Even some rather complex functions, such as error detecting and correcting codes, can be handled in this manner. If one knows the uncoded error rate for a system, the coded error rate can often be closely approximated by applying a mathematical mapping. As will be pointed out below, the amount of processor time required to produce a meaningful error rate estimate is often inversely proportional to the error rate. While an uncoded error rate may be easy to measure, the coded error rate is usually so small that it would be impractical to execute a simulation to measure this quantity directly. The performance of a coded communication system is most often determined by first executing a simulation to establish the channel **symbol error rate**. An analytical mapping can then be used to determine the decoded BER from the channel symbol error rate.

Once the signal has passed though the channel, the original message is recovered by a receiver. This can typically be realized by a sequence of digital filters, feedback loops, and appropriately selected nonlinear devices. A receiver encounters a number of clearly identifiable problems that one may wish to address independently. For example, receivers must initially synchronize themselves to the incoming signal. This may involve detecting that an input signal is present, acquiring an estimate of the carrier amplitude, frequency, phase, symbol synchronization, frame synchronization, and, in the case of spread spectrum systems, code synchronization. Once acquisition is complete, the receiver enters a steady-state mode of operation, where concerns such as symbol error rate, mean time to loss of lock, and reaction to fading and interference are of primary importance. To characterize the system, the user may wish to decouple the analysis of these parameters to investigate relationships that may exist.

For example, one may run a number of acquisition scenarios and gather statistics concerning the probability of acquisition within a specified time interval or the mean time to acquisition. To isolate the problems faced in synchronization from the inherent limitation of the channel, one may wish to use perfect synchronization information to determine the minimum possible BER. Then the symbol or carrier synchronization can be held at fixed errors to determine sensitivity to these parameters and to investigate worst-case performance. Noise processes can be used to vary these parameters to investigate more typical performance. The designer may also

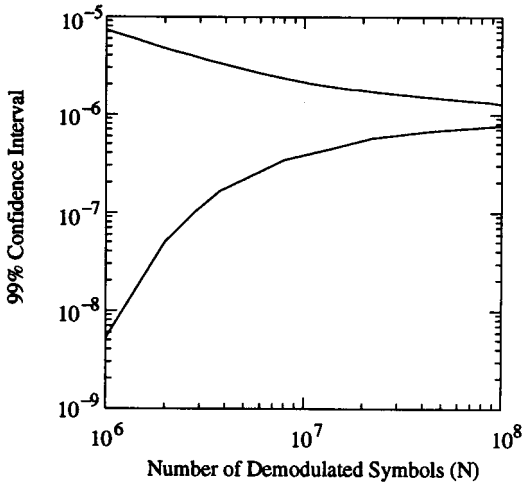

FIGURE 78.9 Typical confidence interval (BER) point estimate = 10^{-6}.

wish to investigate the performance of the synchronization system to various data patterns or the robustness of the synchronization system in the face of interference. The ability to measure the system response to one parameter while a wide range of other parameters are held fixed and the ability to quickly generate a wide variety of environments are some of the more significant advantages that simulation enjoys over more conventional hardware and analytical models.

78.11 Symbol Error Rate Estimation

One of the most fundamental parameters to measure in a digital communication system is the steady-state BER. The simplest method for estimating the BER is to perform a **Monte Carlo (MC) simulation**. The simulation conducts the same test one would perform on the physical system. All data sources and noise sources produce typical waveforms. The output of the demodulator is compared to the output of the message source, and the BER is estimated by dividing the number of observed errors by the number of bits transmitted. This is a simple technique that will work with any system that has ergodic [Papoulis, 1965] noise processes. The downside of this approach is that one must often pass a very large number of samples through the system to produce a reliable estimate of the BER. The question of how many samples must be collected can be answered using confidence intervals. The confidence interval gives a measure of how close the true BER will be to the estimate produced by the MC simulation. A typical confidence interval curve is shown in Fig. 78.9. The ratio of the size of the confidence interval to the size of the estimate is a function of the number of errors observed. Convenient rules of thumb for this work are that after one error is observed the point estimate is accurate to within 3 orders of magnitude, after 10 errors the estimate is accurate to within a factor of 2, and after 100 errors the point estimate will be accurate to a factor of 1.3. This requirement for tens or hundreds of errors to occur frequently limits the usefulness of MC simulations for systems that have low error rates and has motivated research into more efficient methods of estimating BER.

Perhaps the fastest method of BER estimation is the semi-analytic (SA) or quasi-analytic technique [Jeruchim, 1984]. This technique is useful for systems that resemble Fig. 78.10. In this case the mean of the decision metric is a function of the transmitted data pattern and is independent of the noise. All other parameters of the pdf of the decision metric are a function of the noise and are independent of the data. This means that one can analytically determine the conditional pdf of the decision metric given the transmitted data pattern. By using total probability one can then determine the unconditional error rate. The problem with conventional mathematical analysis is that when the channel has a significant amount of memory or the nonlinearity is rather

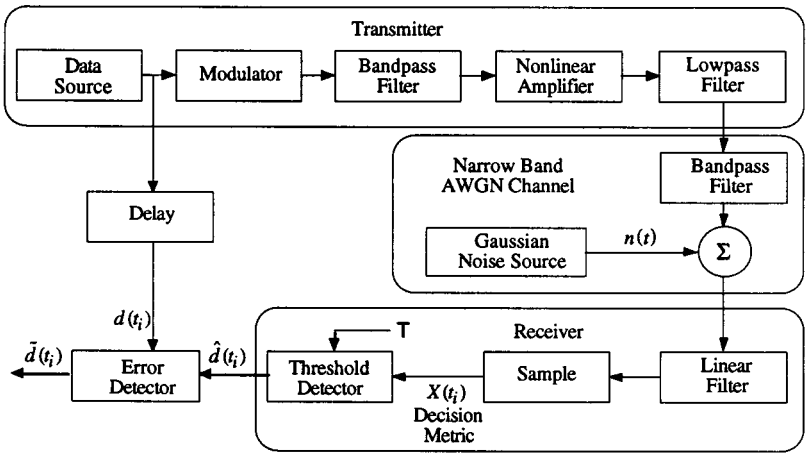

FIGURE 78.10 Typical digital communication system.

complex, one must compute a large number of conditional density functions. Simulation can easily solve this problem for most practical systems. A noise-free simulation is executed, and the value of the decision metric is recorded in a data file. Once the simulation is complete, this information can be used to reconstruct the conditional and ultimately the unconditional error rate. This method generates highly accurate estimates of the BER and makes very efficient use of computer resources, but can only be used in the special cases where one can analytically determine the conditional pdf.

The MC and SA techniques fall at the two extremes of BER estimation. MC simulations require no *a priori* information concerning the system performance or architecture but may require tremendous amounts of computer time to execute. SA techniques require an almost trivial amount of computer time for many cases but require the analyst to have a considerable amount of information concerning the system. There is a continuing search for algorithms that fall in between these extremes. These variance reduction algorithms all share the property of making a limited number of assumptions concerning system performance and architecture, then using this information to reduce the variance of the MC estimate. Popular techniques are summarized in [Jeruchim, 1984] and include importance sampling, large deviation theory, extremal statistics, and tail extrapolation. To successfully use one of these techniques one must first understand the basic concept behind the technique. Then one should carefully determine what assumptions were made concerning the system architecture to determine if the system under study satisfies the requirements. This can be a difficult task since it is not always clear what assumptions are required for a specified technique to be applicable. Finally, one should always determine the accuracy of the measurement through some technique similar to confidence interval estimation.

78.12 Validation of Simulation Results

One often constructs a simulation to determine the value of a single parameter, such as the system BER. However the estimate of this parameter has little or no value unless one can ensure that the simulation model closely resembles the physical system. A number of methods can be used to validate a simulation. Individually, none of them will guarantee that the simulation results are accurate, but taken as a group, they form a convincing argument that the results are realistic. Seven methods of validation are mathematical analysis, comparison with hardware, bounding techniques, degenerate case studies, reasonable relationship tests, subsystem tests, and redundant simulation efforts.

If one has access to mathematical analysis or hardware that predicts or approximates the performance of the system, one should obviously compare the simulation and mathematical results. Unfortunately, in most cases these results will not be available. Even though exact mathematical analysis of the system is not possible, it may be possible to develop bounds on the system performance. If these bounds are tight, they may accurately

characterize the system performance, but even loose bounds will be useful since they help verify the simulation results. Most systems have parameters that can be varied. While it may be mathematically difficult to determine the performance of the system for arbitrary values, it is often possible to mathematically determine the results when parameters assume extreme or degenerate values.

Other methods of validation are decidedly less mathematical. One may wish to vary parameters and ascertain whether the performance parameter changes in a reasonable manner. For example, small changes in SNR rarely cause dramatic changes in system performance. When constructing a simulation, each subsystem, such as filters, nonlinear amplifiers, and noise and data sources, should be thoroughly tested before being included in a larger simulation. Be aware, however, that correct operation of all the various subsystems that make up a communication system does not imply that the overall system performs correctly. If one is writing his or her own code, one must verify that there are no software bugs or fundamental design errors. Even if one purchases a commercial software package, there is no guarantee that the designer of the software models made the same assumptions the user will make when using the model. In most cases it will be far easier to test a module before it is inserted into a simulation than it will be to isolate a problem in a complex piece of code. The final check one may wish to perform is a redundant simulation. There are many methods of simulating a system. One may wish to have two teams investigate a problem or have a single team implement a simulation using two different techniques to verify that the results are reasonable.

78.13 A Simple Example Illustrating Simulation Products

To illustrate the output that is typically generated by a communication system simulation, a simple example is considered. The system is that considered in Fig. 78.10. An OQPSK (offset quadrature phase-shift keyed) modulation format is assumed so that one of four waveforms is transmitted during each symbol period. The data source may be viewed as a single binary source, in which the source symbols are taken two at a time when mapped onto a transmitted waveform, or as two parallel data sources, with one source providing the direct channel modulation and the second source providing the quadrature channel modulation. The signal constellation at the modulator output appears as shown in Fig. 78.11(a), with the corresponding eye diagram appearing as shown in Fig. 78.11(b). The eye diagram is formed by overlaying successive time intervals of a time domain waveform onto a single graph, much as would be done with a common oscilloscope. Since the simulation sampling frequency used in generating Fig. 78.11(b) was 10 samples per data symbol, it is easily seen that the eye diagram was generated by retracing every 2 data symbols or 20 simulation samples. Since Fig. 78.11(a) and (b) correspond to the modulator output, which has not yet been filtered, the transitions between binary states occur in one simulation step. After filtering, the eye diagram appears as shown in Fig. 78.11(c). A seventh-order Butterworth bilinear z-transform digital filter was assumed with a 3-dB bandwidth equal to the bit rate. It should be noted that the bit transitions shown in Fig. 78.11(c) do not occur at the same times as the bit transitions shown in Fig. 78.11(b). The difference is due to the group delay of the filter. Note in Fig. 78.10 that the transmitter also involves a nonlinear amplifier. We will see the effects of this component later in this section.

Another interesting point in the system is within the receiver. Since the communication system is being modeled as a baseband system due to the use of the complex-envelope representation of the bandpass waveforms generated in the simulation, the data detector is represented as an integrate-and-dump detector. The detector is then modeled as a sliding-average integrator, in which the width of the integration window is one bit time. The integration is therefore over a single bit period when the sliding window is synchronized with a bit period. The direct-channel and quadrature-channel waveforms at the output of the sliding-average integrator are shown in Fig. 78.12(a). The corresponding eye diagrams are shown in Fig. 78.12(b). In order to minimize the error probability of the system, the bit decision must be based on the integrator output at the time for which the eye opening is greatest. Thus the eye diagram provides important information concerning the sensitivity of the system to timing errors.

The signal constellation at the sliding integrator output is shown in Fig. 78.12(c) and should be carefully compared to the signal constellation shown in Fig. 78.11(a) for the modulator output. Three effects are apparent. First, the signal points exhibit some scatter, which, in this case, is due to intersymbol interference resulting

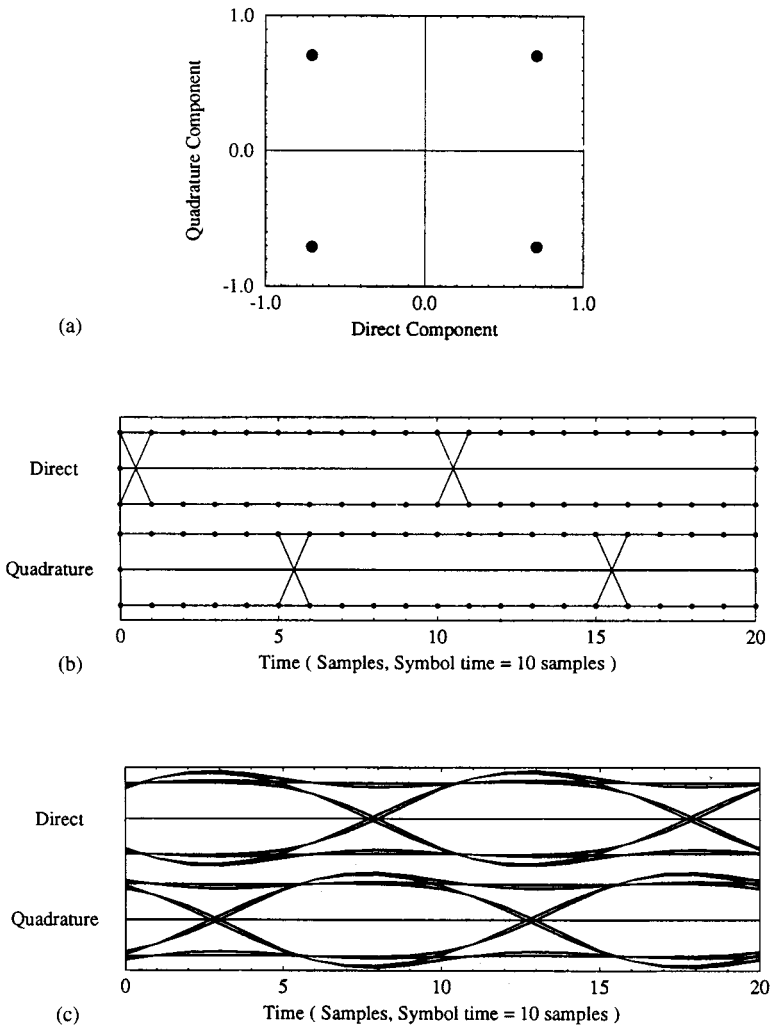

FIGURE 78.11 Transmitter signal constellation and eye diagrams: (a) OQPSK signal constellation; (b) eye diagram of modulator output; (c) eye diagram of filtered modulator output.

from the transmitter filter and additive noise. It is also clear that the signal is both compressed and rotated. These effects are due to the nonlinear amplifier that was mentioned previously. For this example simulation the nonlinear amplifier is operating near the saturation point, and the compression of the signal constellation is due to the AM/AM characteristic of the nonlinearity and the rotation is due to the AM/PM characteristic of the nonlinearity.

The performance of the overall communication system is illustrated in Fig. 78.12(d). The error probability curve is perhaps the most important simulation product. Note that both uncoded and coded results are shown. The coded results were calculated analytically from the uncoded results assuming a (63, 55) Reed–Solomon code. It should be mentioned that **semi-analytic simulation** was used in this example since, as can be seen in Fig. 78.10, the noise is injected into the system on the receiver side of the nonlinearity so that linear analysis may be used to determine the effects of the noise on the system performance.

This simple example serves to illustrate only a few of the possible simulation products. There are many other possibilities including histograms, correlation functions, estimates of statistical moments, estimates of the power spectral density, and estimates of the signal-to-noise ratio at various points in the system.

A word is in order regarding spectral estimation techniques. Two basic techniques can be used for spectral estimation: Fourier techniques and model-based techniques. In most simulation problems one is blessed with a tremendous amount of data concerning sampled waveforms but does not have a simple model describing how these waveforms are produced. For this reason model-based spectral estimation is typically not used. The most common form of spectral estimation used in simulation is the Welch periodogram. While this approach is straightforward, the effects of windowing the data sequence must be carefully considered, and tens or even hundreds of data windows must be averaged to achieve an accurate estimate of the power spectral density.

78.14 Conclusions

We have seen that the analysis and design of today's complex communication systems often requires the use of computer-aided techniques. These techniques allow the solution of problems that are otherwise not tractable and provide considerable insight into the operating characteristics of the communication system.

Defining Terms

Communication link: A point-to-point communication system that typically involves a single information source and a single user. This is in contrast to a communications network, which usually involves many sources and many users.

Computer-aided design and analysis: The process of using computer assistance in the design and analysis of complex systems. In our context, the design and analysis of communication systems, computer-aided design and analysis often involves the extensive use of simulation techniques. Computer-aided techniques often allow one to address design and analysis problems that are not tractable analytically.

Computer simulation: A set of computer programs which allows one to imitate the important aspects of the behavior of the specific system under study. Simulation can aid the design process by, for example, allowing one to determine appropriate system design parameters or aid the analysis process by, for example, allowing one to estimate the end-to-end performance of the system under study.

Dedicated simulation language: A computer language, either text based or graphics based, specifically developed to facilitate the simulation of the various systems under study, such as communication systems.

Low-pass equivalent (LPE) model: A method of representing bandpass signals and systems by low-pass signals and systems. This technique is extremely useful when developing discrete time models of bandpass continuous-time systems. It can substantially reduce the sampling rate required to prevent aliasing and does not result in any loss of information. This in turn reduces the execution time required for the simulation. This modeling technique is closely related to the quadrature representation of bandpass signals.

Monte Carlo simulation: A technique for simulating systems that contain signal sources producing stochastic or random signals. The signal sources are modeled by pseudorandom generators. Performance measures, such as the symbol error rate, are then estimated by time averages. This is a general-purpose technique that can be applied to an extremely wide range of systems. It can, however, require large amounts of computer time to generate accurate estimates.

Pseudorandom generator: An algorithm or device that generates deterministic waveforms which in many ways resemble stochastic or random waveforms. The power spectral density, autocorrelation, and other time averages of pseudorandom signals can closely match the time and ensemble averages of stochastic processes. These generators are useful in computer simulation where one may be unable to generate a truly random process, and they have the added benefit of providing reproducible signals.

Semi-analytic simulation: A numerical analysis technique that can be used to efficiently determine the symbol error rate of digital communication systems. It can be applied whenever one can analytically determine the probability of demodulation error given a particular transmitted data pattern. Although this technique can only be applied to a restricted class of systems, in these cases it is far more efficient, in terms of computer execution time, than Monte Carlo simulations.

Simulation validation: The process of certifying that simulation results are reasonable and can be used with confidence in the design or analysis process.

Symbol error rate: A fundamental performance measure for digital communication systems. The symbol error rate is estimated as the number of errors divided by the total number of demodulated symbols. When the communication system is ergodic, this is equivalent to the probability of making a demodulation error on any symbol.

Further Information

Until recently the subject of computer-aided analysis and simulation of communication systems was a very difficult research area. There were no textbooks devoted to the subject, and the fundamental papers were scattered over a large number of technical journals. While a number of excellent books treated the subject of simulation of systems in which random signals and noise are present [Rubinstein, 1981; Bratley et al., 1987], none of these books specifically focused on communication systems.

Starting in 1984, the *IEEE Journal on Selected Areas in Communications (JSAC)* initiated the publication of a sequence of issues devoted specifically to the subject of computer-aided design and analysis of communication systems. A brief study of the contents of these issues tells much about the rapid development of the discipline. The first issue, published in January 1984 [Balaban et al., 1984], emphasizes communication links, although there are a number of papers devoted to networks. The portion devoted to links contained a large collection of papers devoted to simulation packages.

The second issue of the series was published in 1988 and is roughly evenly split between links and networks [Balaban et al., 1988]. In this issue the emphasis is much more on techniques than on simulation packages. The third part of the series is a two-volume issue devoted exclusively to networks [Mouftah et al., 1990, 1991].

As of this writing, the book by Jeruchim et al. is the only comprehensive treatment of the simulation of communication links [Jeruchim, 1984]. It treats the component and channel modeling problem and the problems associated with using simulation techniques for estimating the performance of communication systems in considerable detail. This textbook, together with the previously cited JSAC issues, gives a good overview of the area.

LCD projection televisions, such as this "Television of the Future" could replace the CRT-based television if certain performance criteria are obtained. One criteria being addressed is the need for a very bright, optically efficient point source for projecting an image through a small LCD. If new lighting technologies are developed, such as an illumination source that can provide a brighter image with better colors than current CRT technology, then the consumer television market will certainly change. ELECTRONIC DESIGNERS have placed increasing significance on digital devices since the late 1960s. This is due primarily to the greater reliability and improved accuracy gained when using electronic devices in a two-level mode (binary mode) as compared to using electronic devices in a continuous mode (analog mode). As silicon integrated circuits (ICs) became denser and more consistently reproducible over the past few decades, so did digital electronic devices. Today digital circuits and digital systems produced from digital devices can be found in every walk of life ranging from children's toys, kitchen appliances, laboratory instruments, personal and workstation computers to space shuttle and satellite applications.

The intent of this section is to present topics related to the utilization and application of digital devices. Chapter 79 establishes the foundation for digital logic elements beginning with IC, logic gates, logical families, bistable devices, and optical devices. Discussed in the next chapter are memory devices, which include integrated circuits (RAM, ROM), disk systems, magnetic tape, and optical disks. Chapter 81 on logical devices discusses switching algebra, logic circuits, registers, programmable arrays (PAL, FPGA), and arithmetic logic units.

The next chapter explains the microprocessor, perhaps the best-known digital device. The topics covered include practical microprocessors and microprocessor applications. Chapter 83 on displays consists of the light-emitting diode, the liquid-crystal display, the cathode ray tube, and the plasma display. The gathering of digital

information, referred to as data acquisition, is discussed next. No digital system is released to production without extensive testing. Chapter 85 presents methods of testing and design for testing.

The variety of topics presented in this section should provide readers with a contemporary overview of digital devices and their applications. To obtain additional information, the reader may refer to the References and Further Information in each chapter.

Nomenclature

Symbol	Quantity	Unit	Symbol	Quantity	Unit
A	area	m^2	λ	radiation wavelength	nm
a	average absorption coefficient		m	magnification factor	
			μ_n	electron mobility	
B	luminance off the projection screen		n	aperture	
			ν	photon frequency	Hz

79.1 IC Logic Family Operation and Characteristics

Gregory L. Moss

Digital logic circuits can be classified as belonging to one of two categories, either combinational (also called combinatorial) or sequential logic circuits. The output logic level of a combinatorial circuit depends only on the current logic levels present at the circuit's inputs. Sequential logic circuits, on the other hand, have a memory characteristic so the sequential circuit's output is dependent not only on the current input conditions but also on the current output state of the circuit. The primary building block in combinational circuits is the logic gate. The three simplest logic gate functions are the inverter (or NOT), AND, and OR. Other common basic logic functions are derived from these three. Table 79.1 gives **truth table** definitions of the various types of logic gates. The memory elements used to construct sequential logic circuits are called latches and flip-flops.

The integrated circuit switching logic used in modern digital systems will generally be from one of three families: transistor-transistor logic (TTL), complementary metal-oxide semiconductor logic (CMOS), or emitter-coupled logic (ECL). Each of the logic families has its advantages and disadvantages. The three major families are also divided into various subfamilies derived from performance improvements in integrated circuit (IC) design technology. Bipolar transistors provide the switching action in both TTL and ECL families, while enhancement-mode MOS transistors are the basis for the CMOS family. Recent improvements in switching circuit performance are also attained using BiCMOS technology, the merging of bipolar and CMOS technologies on a single chip. A particular logic family is usually selected by digital designers based on such criteria as

1. Switching speed
2. Power dissipation
3. PC board area requirements (levels of integration)
4. Output drive capability (**fan-out**)
5. Noise immunity characteristics
6. Product breadth
7. Sourcing of components

TABLE 79.2 Logic Families and Subfamilies

Family and Subfamily	Description
TTL	Transistor-transistor logic
74xx	Standard TTL
74Lxx	Low-power TTL
74Hxx	High-speed TTL
74Sxx	Schottky TTL
74LSxx	Low-power Schottky TTL
74ASxx	Advanced Schottky TTL
74ALSxx	Advanced low-power Schottky TTL
74Fxx	Fast TTL
CMOS	Complementary metal-oxide semiconductor
4xxx	Standard CMOS
74Cxx	Standard CMOS using TTL numbering system
74HCxx	High-speed CMOS
74HCTxx	High-speed CMOS—TTL compatible
74FCTxx	Fast CMOS—TTL compatible
74ACxx	Advanced CMOS
74ACTxx	Advanced CMOS—TTL compatible
74AHCxx	Advanced high-speed CMOS
74AHCTxx	Advanced high-speed CMOS-TTL compatible
ECL (or CML)	Emitter-coupled (current-mode) logic
10xxx	Standard ECL
10Hxxx	High-speed ECL

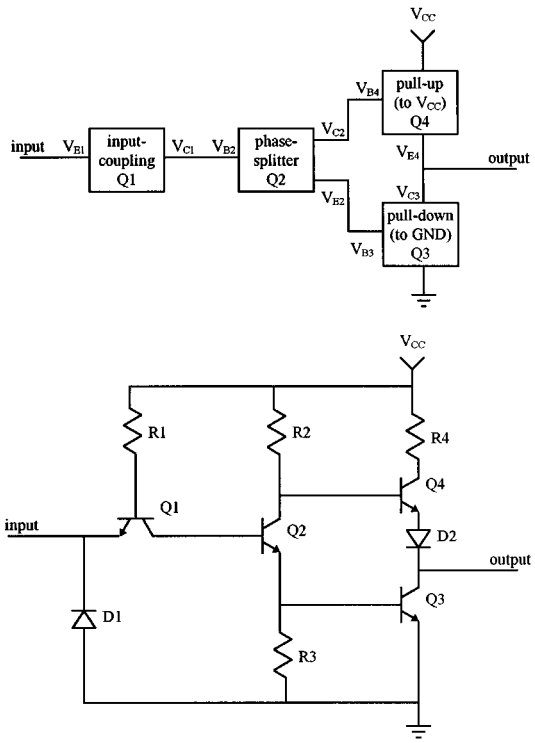
IC Logic Families and Subfamilies

The integrated circuit logic families actually consist of several subfamilies of ICs that differ in various performance characteristics. The TTL logic family has been the most widely used family type for applications that employ small-scale integration (SSI) or medium-scale integration (MSI) integrated circuits. Lower power consumption and higher levels of integration are the principal advantages of the CMOS family. The ECL family is generally used in applications that require high-speed switching logic. Today, the most common device numbering system used in the TTL and CMOS families has a prefix of 54 (generally used in military applications and having an operating temperature range of –55 to 125°C) and 74 (generally used in industrial/commercial applications and having an operating temperature range of 0 to 70°C). Table 79.2 identifies various logic families and subfamilies.

TTL Logic Family

The TTL family has been the most widely used logic family for many years in applications that use SSI and MSI. It is relatively fast and offers a great variety of standard chips.

The active switching element used in all TTL family circuits is the *npn* bipolar junction transistor (BJT). The transistor is turned on when the base is approximately 0.7 V more positive than the emitter and there is a sufficient amount of base current flowing. The turned on transistor (in non-Schottky subfamilies) is said to



input	V_{C1}	Q2	V_{C2}	V_{E2}	Q3	V_{C3}	Q4	V_{E4}	output
hi	hi	on	low	hi	on	low	off	open	low
low	low	off	hi	low	off	open	on	hi	hi

FIGURE 79.1 TTL inverter circuit block diagram and operation.

be in saturation and, ideally, acts like a closed switch between the collector and emitter terminals. The transistor is turned off when the base is not biased with a high enough voltage (with respect to the emitter). Under this condition, the transistor acts like an open switch between the collector and emitter terminals.

Figure 79.1 illustrates the transistor circuit blocks used in a standard TTL inverter. Four transistors are used to achieve the inverter function. The input to the gate connects to the emitter of transistor Q1, the input coupling transistor. A clamping diode on the input prevents negative input voltage spikes from damaging Q1. The collector voltage (and current) of Q1 controls Q2, the phase splitter transistor. Q2, in turn, controls the Q3 and Q4 transistors forming the output circuit, which is called a totem-pole arrangement. Q4 serves as a pull-up transistor to pull the output high when it is turned on. Q3 does just the opposite to the output and serves as a pull-down transistor. Q3 pulls the output low when it is turned on. Only one of the two transistors in the totem pole may be turned on at a time, which is the function of the phase splitter transistor Q2.

When a high **logic level** is applied to the inverter's input, Q1's base-emitter junction will be reverse biased and the base-collector junction will be forward biased. This circuit condition will allow Q1 collector current to flow into the base of Q2, saturating Q2 and thereby providing base current into Q3, turning it on also. The collector voltage of Q2 is too low to turn on Q4 so that it appears as an open in the top part of the totem pole. A diode between the two totem-pole transistors provides an extra voltage drop in series with the base-emitter junction of Q4 to ensure that Q4 will be turned off when Q2 is turned on. The saturated Q3 transistor brings the output near ground potential, producing a low output result for a high input into the inverter.

When a low logic level is applied to the inverter's input, Q1's base-emitter junction will be forward biased and the base-collector junction will be reverse biased. This circuit condition will turn on Q1 so that the collector terminal is shorted to the emitter and, therefore, to ground (low level). This low voltage is also on the base of Q2 and turns Q2 off. With Q2 off, there will be insufficient base current into Q3, turning it off also. Q2 leakage current is shunted to ground with a resistor to prevent the partial turning on of Q3. The collector voltage of

Q2 is pulled to a high potential with another resistor and, as a result, turns on Q4 so that it appears as a short in the top part of the totem pole. The saturated Q4 transistor provides a low resistance path from V_{CC} to the output, producing a high output result for a low input into the inverter.

A TTL NAND gate is very similar to the inverter circuit, with the exception that the input coupling transistor Q1 is constructed with multiple emitter-base junctions and each input to the NAND is connected to a separate emitter terminal. Any of the transistor's multiple emitters can be used to turn on Q1. The TTL NAND gate thus functions in the same manner as the inverter in that if any of the NAND gate inputs are low, the same circuit action will take place as with a low input to the inverter. Therefore, any time a low input is applied to the NAND gate it will produce a high ouput. Only if all of the NAND gate inputs are simultaneously high will it then produce the same circuit action as the inverter with its single input high, and the resultant output will be low. Input coupling transistors with up to eight emitter-base junctions, and therefore, eight input NAND gates, are constructed.

Storage time (the time it takes for the transistor to come out of saturation) is a major factor of propagation delay for saturated BJT transistors. A long storage time limits the switching speed of a standard TTL circuit. The propagation delay can be decreased and, therefore, the switching speed can be increased, by placing a Schottky diode between the base and collector of each transistor that might saturate. The resulting Schottky-clamped transistors do not go into saturation (effectively eliminating storage time) since the diode shunts current from the base into the collector before the transistor can achieve saturation. Today, digital circuit designs implemented with TTL logic almost exclusively use one of the Schottky subfamilies to take advantage of the significant improvement in switching speed.

CMOS Logic Family

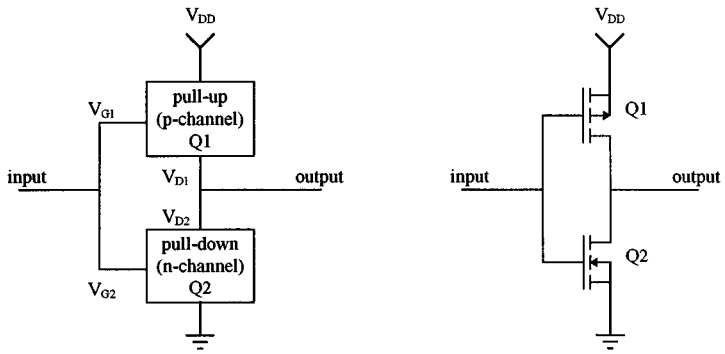
The active switching element used in all CMOS family circuits is the metal-oxide semiconductor field-effect transistor (MOSFET). CMOS stands for complementary MOS transistors and refers to the use of both types of MOSFET transistors, *n*-channel and *p*-channel, in the design of this type of switching circuit. While the physical construction and the internal physics of a MOSFET are quite different from that of the BJT, the circuit switching action of the two transistor types is quite similar. The MOSFET switch is essentially turned off and has a very high channel resistance by applying the same potential to the gate terminal as the source. An *n*-channel MOSFET is turned on and has a very low channel resistance when a high voltage with respect to the source is applied to the gate. A *p*-channel MOSFET operates in the same fashion but with opposite polarities; the gate must be more negative than the source to turn on the transistor.

A block diagram and schematic for a CMOS inverter circuit is shown in Fig. 79.2. Note that it is a simpler and much more compact circuit design than that for the TTL inverter. That fact is a major reason why MOSFET integrated circuits have a much higher circuit density than BJT integrated circuits and is one advantage that MOSFET ICs have over BJT ICs. As a result, CMOS is used in all levels of integration, from SSI through VLSI (very large scale integration).

When a high logic level is applied to the inverter's input, the *p*-channel MOSFET Q1 will be turned off and the *n*-channel MOSFET Q2 will be turned on. This will cause the output to be shorted to ground through the low resistance path of Q2's channel. The turned off Q1 has a very high channel resistance and acts nearly like an open.

When a low logic level is applied to the inverter's input, the *p*-channel MOSFET Q1 will be turned on and the *n*-channel MOSFET Q2 will be turned off. This will cause the output to be shorted to V_{DD} through the low resistance path of Q1's channel. The turned off Q2 has a very high channel resistance and acts nearly like an open.

CMOS NAND gates are constructed by paralleling *p*-channel MOSFETs, one for each input, and putting in series an *n*-channel MOSFET for each input, as shown in the block diagram and schematic of Fig. 79.3. The NAND gate will produce a low output only when both Q3 and Q4 are turned on, creating a low resistance path from the output to ground through the two series channels. This can be accomplished by having a high on both input A and input B. This input condition will also turn off Q1 and Q2 . If either input A or input B or both is low, the respective parallel MOSFET will be turned on, providing a low resistance path for the output to V_{DD}. This will also turn off at least one of the series MOSFETs, resulting in a high resistance path for the output to ground.



input	Q1	V_{D1}	Q2	V_{D2}	output

hi	low	off	on	on	off	hi
hi	hi	off	off	on	on	low

FIGURE 79.3 CMOS two-input NAND circuit block diagram and operation.

ECL Logic Family

ECL is a higher-speed logic family. While it does not offer as large a variety of IC chips as are available in the TTL family, it is quite popular for logic applications requiring high-speed switching.

The active switching element used in the ECL family circuits is also the *npn* BJT. Unlike the TTL family, however, which switches the transistors into saturation when turning them on, ECL switching is designed to prevent driving the transistors into saturation. Whenever bipolar transistors are driven into saturation, their switching speed will be limited by the charge carrier storage delay, a transistor operational characteristic. Thus, the switching speed of ECL circuits will be significantly higher than for TTL circuits. ECL operation is based

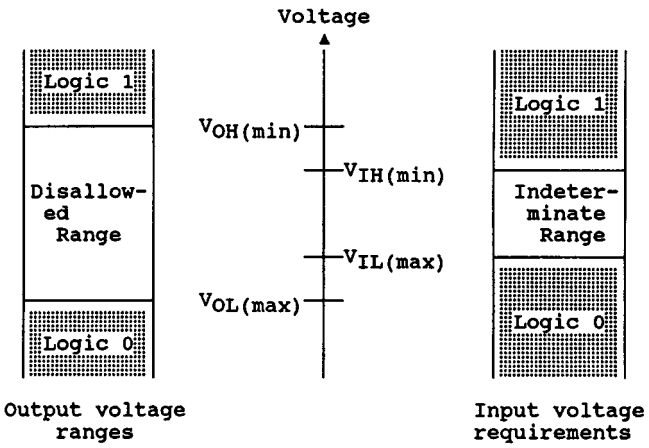

FIGURE 79.4 Switching device logic levels.

74ACxx	3.8	0.4	3.15	1.35
74ACTxx	3.8	0.4	2.0	0.8
74AHCxx	4.5	0.1	3.85	1.65
74AHCTxx	3.65	0.1	2.0	0.8
10xxx	–0.96	–1.65	–1.105	–1.475
10Hxxx	–0.98	–1.63	–1.13	–1.48

on switching a fixed amount of bias current that is less than the saturation amount between two different transistors. The basic circuit found in the ECL family is the differential amplifier. One side of the differential amplifier is controlled by a bias circuit and the other is controlled by the logic inputs to the gate. This logic family is also referred to as current-mode logic (CML) because of its current switching operation.

Logic Family Circuit Parameters

Digital circuits and systems operate with only two states, logic 1 and 0, usually represented by two different voltage levels, a *high* and a *low*. The two logic levels actually consist of a range of values with the numerical quantities dependent upon the specific family that is used. Minimum high logic levels and maximum low logic levels are established by specifications for each family. Minimum device output levels for a logic high are called $V_{OH(min)}$ and minimum input levels are called $V_{IH(min)}$. The abbreviations for maximum output and input low logic levels are $V_{OL(max)}$ and $V_{IL(max)}$, respectively. Figure 79.4 shows the relationships between these parameters. Logic voltage level parameters are illustrated for selected prominent logic subfamilies in Table 79.3. As seen in this illustration, there are many operational incompatibilities between major logic family types.

Noise margin is a quantitative measure of a device's **noise immunity.** High-level noise margin (V_{NH}) and low-level noise margin (V_{NL}) are defined in Eqs. (79.1) and (79.2).

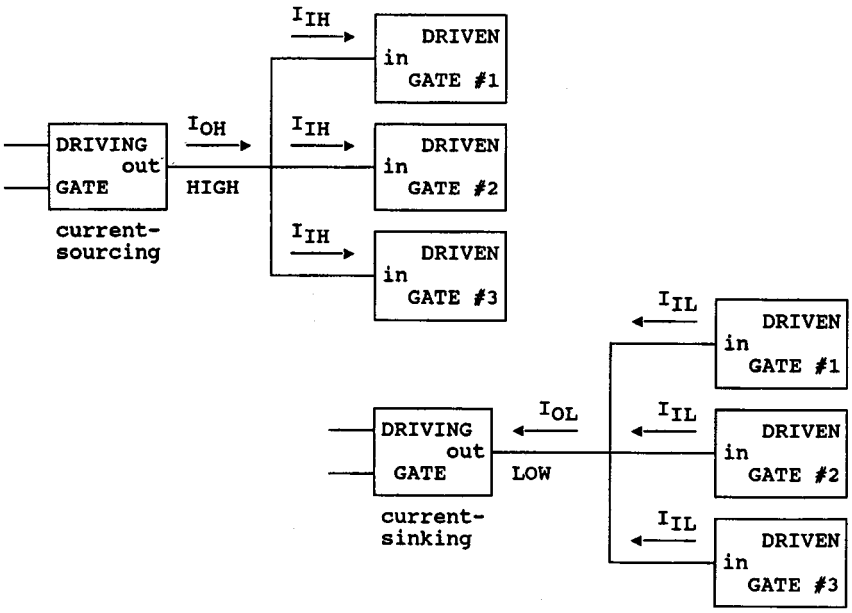

FIGURE 79.5 Current loading of driving gates.

TABLE 79.4 Worst Case Current Parameters for Selected Logic Subfamilies

Subfamily	$I_{OH(max)}$	$I_{OL(max)}$	$I_{IH(max)}$	$I_{IL(max)}$
74xx	–400 μA	16 mA	40 μA	–1.6 μA
74LSxx	–400 μA	8 mA	20 μA	–400 μA
74ASxx	–2 mA	20 mA	200 μA	–2 mA
74ALSxx	–400 μA	8 mA	20 μA	–100 μA
74Fxx	–1 mA	20 mA	20 μA	–0.6 mA
74HCxx	–4 mA	4 mA	1 μA	–1 μA
74HCTxx	–4 mA	4 mA	1 μA	–1 μA
74ACxx	–24 mA	24 mA	1 μA	–1 μA
74ACTxx	–24 mA	24 mA	1 μA	–1 μA
74AHCxx	–8 mA	8 mA	1 μA	–1 μA
74AHCTxx	–8 mA	8 mA	1 μA	–1 μA
10xxx	50 mA	–50 mA	–265 μA	500 nA
10Hxxx	50 mA	–50 mA	–265 μA	500 nA

$$V_{NH} = V_{OH(min)} - V_{IH(min)} \tag{79.1}$$

$$V_{NL} = V_{IL(max)} - V_{OL(max)} \tag{79.2}$$

Using the logic voltage values given in Table 79.3 for the selected subfamilies reveals that highest noise immunity is obtained with logic devices in the CMOS family, while lowest noise immunity is endemic to the ECL family.

Switching circuit outputs are loaded by the inputs of the devices that they are driving, as illustrated in Fig. 79.5. Worst case input loading current levels and output driving current capabilities are listed in Table 79.4 for various logic subfamilies. The fan-out of a driving device is the ratio between its output current capabilities at each logic level and the corresponding gate input current loading value. Switching circuits based on bipolar transistors have fan-out limited primarily by the current-sinking and current-sourcing capabilities of the driving device.

TABLE 79.5 Speed-Power Comparison for Selected Logic Subfamilies

Subfamily	Propagation Delay Time, ns (ave.)	Static Power Dissipation, mW (per gate)	Speed-Power Product, pJ
74xx	10	10	100
74LSxx	9.5	2	19
74ASxx	1.5	2	13
74ALSxx	4	1.2	5
74Fxx	3	6	18
74HCxx	8	0.003	24×10^{-3}

74AHCTxx	5	0.003	14×10^{-3}
10xxx	2	25	50
10Hxxx	1	25	25

CMOS switching circuits are limited by the charging and discharging times associated with the output resistance of the driving gate and the input capacitance of the load gates. Thus, CMOS fan-out depends on the frequency of switching. With fewer (capacitive) loading inputs to drive, the maximum switching frequency of CMOS devices will increase.

The switching speed of logic devices is dependent on the device's **propagation delay time.** The propagation delay of a logic device limits the frequency at which it can be operated. There are two propagation delay times specified for logic gates: t_{PHL}, delay time for the output to change from high to low, and t_{PLH}, delay time for the output to change from low to high. Average typical propagation delay times for a single gate are listed for several logic subfamilies in Table 79.5. The ECL family has the fastest switching speed.

The amount of power required by an IC is normally specified in terms of the amount of current I_{CC} (TTL family), I_{DD} (CMOS family), or I_{EE} (ECL family) drawn from the power supply. For complex IC devices, the required supply current is given under specified test conditions. For TTL chips containing simple gates, the average power dissipation $P_{D(ave)}$ is normally calculated from two measurements, I_{CCH} (when all gate outputs are high) and I_{CCL} (when all gate outputs are low). Table 79.5 compares the static power dissipation of several logic subfamilies. The ECL family has the highest power dissipation, while the lowest is attained with the CMOS family. It should be noted that power dissipation for the CMOS family is directly proportional to the gate input signal frequency. For example, one would typically find that the power dissipation for a CMOS logic circuit would increase by a factor of 100 if the input signal frequency is increased from 1 kHz to 100 kHz.

The **speed-power product** is a relative figure of merit that is calculated by the formula given in Eq. (79.3). This performance measurement is normally expressed in picojoules (pJ).

$$\text{Speed-power product} = (t_{PHL} + t_{PLH})/2 \times P_{D(ave)} \tag{79.3}$$

A low value of speed-power product is desirable to implement high-speed (and, therefore, low propagation delay time) switching devices that consume low amounts of power. Because of the nature of transistor switching circuits, it is difficult to attain high-speed switching with low power dissipation. The continued development of new IC logic families and subfamilies is largely due to the trade-offs between these two device switching parameters. The speed-power product for various subfamilies is also compared in Table 79.5.

Interfacing Between Logic Families

The interconnection of logic chips requires that input and output specifications be satisfied. Figure 79.6 illustrates voltage and current requirements. The driving chip's $V_{OH(min)}$ must be greater than the driven circuit's $V_{IH(min)}$, and the driver's $V_{OL(max)}$ must be less than $V_{IL(max)}$ for the loading circuit. Voltage level shifters must be

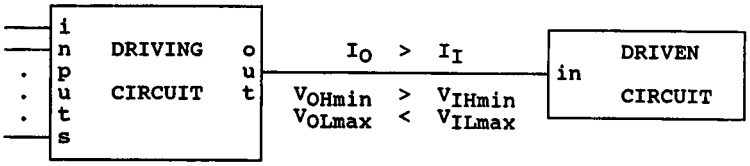

FIGURE 79.6 Circuit interfacing requirements.

used to interface the circuits together if these voltage requirements are not met. Of course, a driving circuit's output must not exceed the maximum and minimum allowable input voltages for the driven circuit. Also, the current sinking and sourcing ability of the driver circuit's output must be greater than the total current requirements for the loading circuit. Buffer gates or stages must be used if current requirements are not satisfied. All chips within a single logic family are designed to be compatible with other chips in the same family. Mixing chips from multiple subfamilies together within a single digital circuit can have adverse effects on the overall circuit's switching speed and noise immunity.

Defining Terms

Fan-out: The specification used to identify the limit to the number of loading inputs that can be reliably driven by a driving device's output.

Logic level: The high or low value of a voltage variable that is assigned to be a 1 or a 0 state.

Noise immunity: A logic device's ability to tolerate input voltage fluctuation caused by noise without changing its output state.

Propagation delay time: The time delay from when the input logic level to a device is changed until the resultant output change is produced by that device.

Speed-power product: An overall performance measurement that is used to compare the various logic families and subfamilies.

Truth table: A listing of the relationship of a circuit's output that is produced for various combinations of logic levels at the inputs.

79.2 Logic Gates (IC)[1]

Peter Graham

This section introduces and analyzes the electronic circuit realizations of the basic gates of the three technologies: transistor-transistor logic (TTL), emitter-coupled logic (ECL), and complementary metal-oxide semiconductor (CMOS) logic. These circuits are commercially available on small-scale integration chips and are also the building blocks for more elaborate logic systems. The three technologies are compared with regard to speed, power consumption, and noise immunity, and parameters are defined which facilitate these comparisons. Also included are recommendations which are useful in choosing and using these technologies.

Gate Specification Parameters

Theoretically almost any logic device or system could be constructed by wiring together the appropriate configuration of the basic gates of the selected technology. In practice, however, the gates are interconnected during the fabrication process to produce a desired system on a single chip. The circuit complexity of a given chip is described by one of the following four rather broad classifications:

- **Small-Scale Integration (SSI).** The inputs and outputs of every gate are available for external connection at the chip pins (with the exception that exclusive OR and AND-OR gates are considered SSI).
- **Medium-Scale Integration (MSI).** Several gates are interconnected to perform somewhat more elaborate logic functions such as flip-flops, counters, multiplexers, etc.

[1]Based on P. Graham, "Gates," in *Handbook of Modern Electronics and Electrical Engineering,* C. Belove, Ed., New York: Wiley-Interscience, 1986, pp. 864–876. With permission.

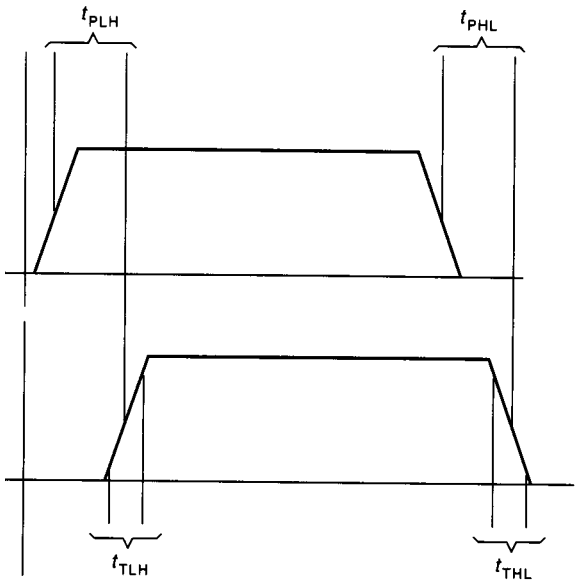

FIGURE 79.7 Definitions of switching times.

- **Large-Scale Integration (LSI).** Several of the more elaborate circuits associated with MSI are interconnected within the integrated circuit to form a logic system on a single chip. Chips such as calculators, digital clocks, and small microprocessors are examples of LSI.
- **Very-Large-Scale Integration (VLSI).** This designation is usually reserved for chips having a very high density, 1000 or more gates per chip. These include the large single-chip memories, gate arrays, and microcomputers.

Specifications of logic speed require definitions of switching times. These definitions can be found in the introductory pages of most data manuals. Four of them pertain directly to gate circuits. These are (see also Fig. 79.7):

- **LOW-to-HIGH Propagation Delay Time (t_{PLH}).** The time between specified reference points on the input and output voltage waveforms when the output is changing from low to high.
- **HIGH-to-LOW Propagation Delay Tune (t_{PHL}).** The time between specified reference points on the input and output voltage waveforms when the output is changing from high to low.
- **Propagation Delay Time (t_{PD}).** *The average of the two propagation delay times:* $t_{PD} = (t_{PD} + t_{PHL})/2$.
- **LOW-to-HIGH Transition Time (t_{TLH}).** *The rise time between specified reference points on the LOW-to-HIGH shift of the output waveform.*
- **HIGH-to-LOW Transition Time (t_{THL}).** *The fall time between specified reference points on the HIGH-to-LOW shift of the output waveform. The reference points usually are 10 and 90% of the voltage level difference in each case.*

Power consumption, driving capability, and effective loading of gates are defined in terms of currents.

- **Supply Current, Outputs High (I_{xxH}).** The current delivered to the chip by the power supply when all outputs are open and at the logical 1 level. The xx subscript depends on the technology.
- **Supply Current, Outputs Low (I_{xxL}).** The current delivered to the chip by the supply when all outputs are open and at the logical 0 level.
- **Supply Current, Worst Case (I_{xx}).** When the output level is unspecified, the input conditions are assumed to correspond to maximum supply current.

- **Input HIGH Current (I_{IH}).** The current flowing into an input when the specified HIGH voltage is applied.
- **Input LOW Current (I_{IL}).** The current flowing into an input when the specified LOW voltage is applied.
- **Output HIGH Current (I_{OH}).** The current flowing into the output when it is in the HIGH state. I_{OHmax} is the largest I_{OH} for which $V_{OH} \geq V_{OHmin}$ is guaranteed.
- **Output LOW Current (I_{OL}).** The current flowing into the output when it is in the LOW state. I_{OLmax} is the largest I_{OL} for which $V_{OL} \geq V_{OLmax}$ is guaranteed.

The most important voltage definitions are concerned with establishing ranges on the logical 1 (HIGH) and logical 0 (LOW) voltage levels.

- **Minimum High-Level Input Voltage (V_{IHmin}).** The least positive value of input voltage guaranteed to result in the output voltage level specified for a logical 1 input.
- **Maximum Low-Level Input Voltage (V_{ILmax}).** The most positive value of input voltage guaranteed to result in the output voltage level specified for a logical 0 input.
- **Minimum High-Level Output Voltage (V_{OHmin}).** The guaranteed least positive output voltage when the input is properly driven to produce a logical 1 at the output.
- **Maximum Low-Level Output Voltage (V_{OLmax}).** The guaranteed most positive output voltage when the input is properly driven to produce a logical 0 at the output.
- **Noise Margins.** $NM_H = V_{OHmin} - V_{IHmin}$ is how much larger the guaranteed least positive output logical 1 level is than the least positive input level that will be interpreted as a logical 1. It represents how large a negative-going glitch on an input 1 can be before it affects the output of the driven device. Similarly, $NM_L = V_{ILmax} - V_{OLmax}$ is the amplitude of the largest positive- going glitch on an input 0 that will not affect the output of the driven device.

Finally, three important definitions are associated with specifying the load that can be driven by a gate. Since in most cases the load on a gate output will be the sum of inputs of other gates, the first definition characterizes the relative current requirements of gate inputs.

- **Load Factor (LF).** Each logic family has a reference gate, each of whose inputs is defined to be a unit load in both the HIGH and the LOW conditions. The respective ratios of the input currents I_{IH} and I_{IL} of a given input to the corresponding I_{IH} and I_{IL} of the reference gate define the HIGH and LOW load factors of that input.
- **Drive Factor (DF).** A device output has drive factors for both the HIGH and the LOW output conditions. These factors are defined as the respective ratios of I_{OHmax} and I_{OLmax} of the gate to I_{OHmax} and I_{OLmax} of the reference gate.
- **Fan-Out.** For a given gate the fan-out is defined as the maximum number of inputs of the same type of gate that can be properly driven by that gate output. When gates of different load and drive factors are interconnected, fan-out must be adjusted accordingly.

Bipolar Transistor Gates

A logic circuit using bipolar junction transistors (BJTs) can be classified either as saturated or as nonsaturated logic. A saturated logic circuit contains at least one BJT that is saturated in one of the stable modes of the circuit. In nonsaturated logic circuits none of the transistors is allowed to saturate. Since bringing a BJT out of saturation requires a few additional nanoseconds (called the storage time), nonsaturated logic is faster. The fastest circuits available at this time are emitter-coupled logic (ECL), with transistor-transistor logic (TTL) having Schottky diodes connected to prevent the transistors from saturating (Schottky TTL) being a fairly close second. Both of these families are nonsaturated logic. All TTL families other than Schottky are saturated logic.

Transistor-Transistor Logic

TTL evolved from resistor-transistor logic (RTL) through the intermediate step of diode-transistor logic (DTL). All three families are catalogued in data books published in 1968, but of the three only TTL is still available.

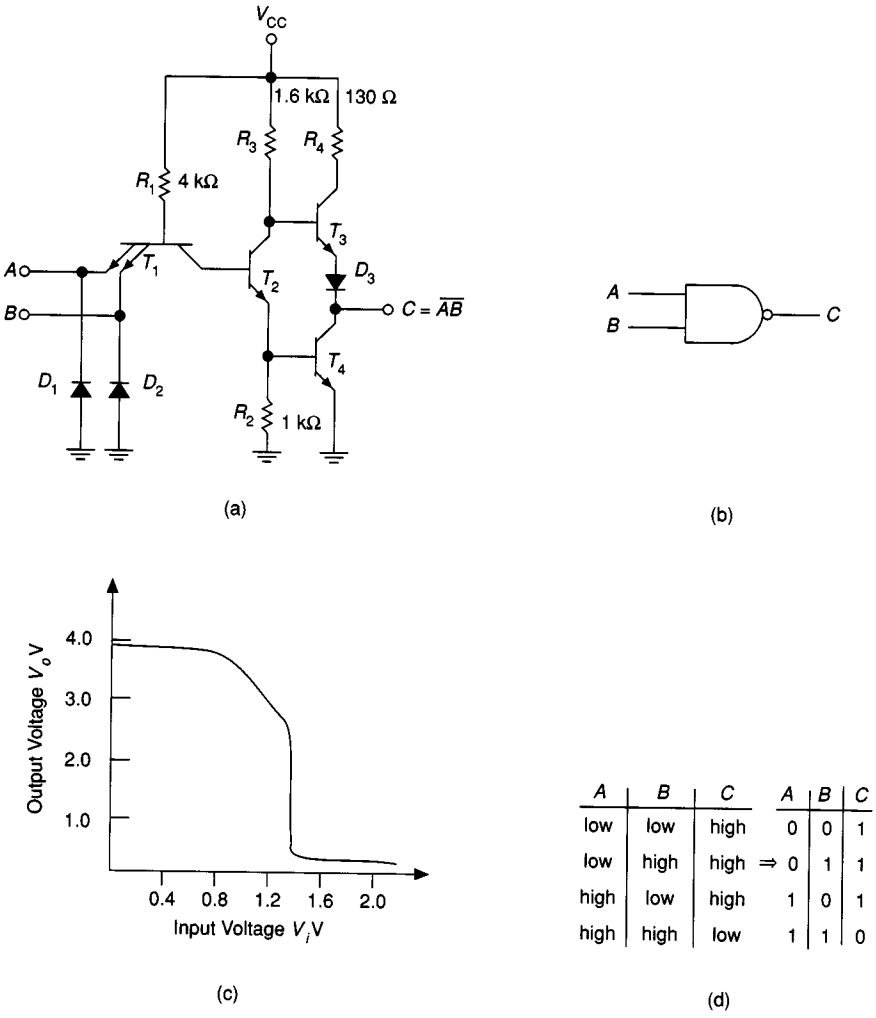

FIGURE 79.8 Two-input transistor-transistor logic (TTL) NAND gate type 7400: (a) circuit, (b) symbol, (c) voltage transfer characteristic (V_i to both inputs), (d) truth table.

The basic circuit of the standard TTL family is typified by the two-input NAND gate shown in Fig. 79.8(a). To estimate the operating levels of voltage and current in this circuit, assume that any transistor in saturation has $V_{CE} = 0.2$ and $V_{BE} = 0.75$ V. Let drops across conducting diodes also be 0.75 V and transistor current gains (when nonsaturated) be about 50. As a starting point, let the voltage levels at both inputs A and B be high enough that T_1 operates in the reversed mode. In this case the emitter currents of T_1 are negligible, and the current into the base of T_1 goes out the collector to become the base current of T_2. This current is readily calculated by observing that the base of T_1 is at $3 \times 0.75 = 2.25$ V so there is a 2.75-V drop across the 4-kΩ resistor. Thus $I_{B1} = I_{B2} = 0.7$ mA, and it follows that T_2 is saturated. With T_2 saturated, the base of T_3 is at $V_C + V_{BE4} = 0.95$ V. If T_4 is also saturated, the emitter of T_3 will be at $V_{D3} + V_{CE4} = 0.95$ V, and T_3 will be cut off. The voltage across the 1.6-kΩ resistor is $5 - 0.95 = 4.05$ V, so the collector current of T_2 is about 2.5 mA. This means the emitter current of T_2 is 3.2 mA. Of this, 0.75 mA goes through the 1-kΩ resistor, leaving 2.45 mA as the base current of T_4. Since the current gain of T_4 is about 50, it will be well into saturation for any collector current less than 100 mA, and the output at C is a logic 0. The corresponding minimum voltage levels required at the inputs are estimated from $V_{BE4} + V_{ECI}$, or about 1.7 V.

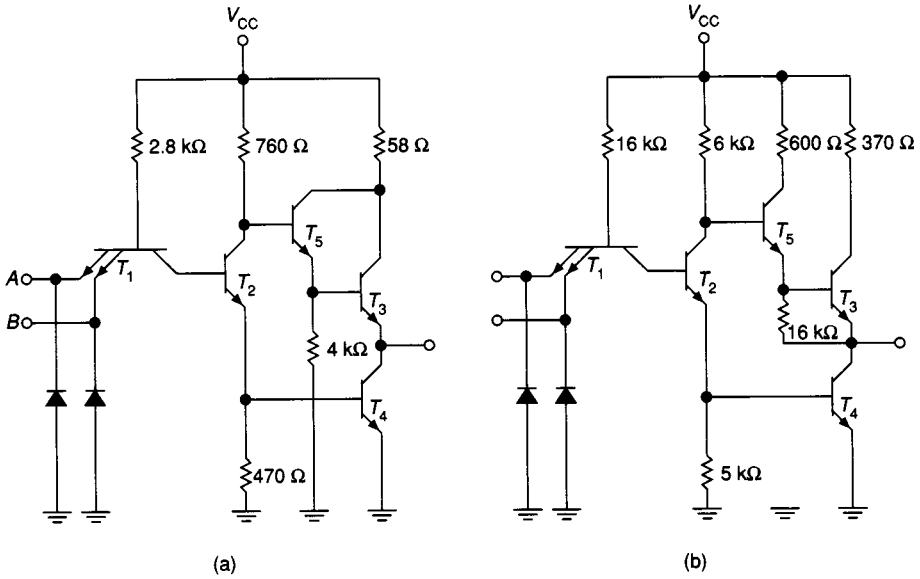

FIGURE 79.9 Modified transistor-transistor logic (TTL) two-input NAND states: (a) type 74Hxx, (b) type 74L00.

Now let either or both of the inputs be dropped to 0.2 V. T_1 is then biased to saturation in the normal mode, so the collector current of T_1 extracts the charge from the base region of T_2. With T_2 cut off, the base of T_4 is at 0 V and T_4 is cut off. T_3 will be biased by the current through the 1.6-kΩ resistor (R_3) to a degree regulated by the current demand at the output C. The drop across R_3 is quite small for light loads, so the output level at C will be $V_{CC} - V_{BE3} - V_{D3}$, which will be about 3.5 V corresponding to the logical 1.

The operation is summarized in the truth table in Fig. 79.8(d), identifying the circuit as a two-input NAND gate. The derivation of the input-output voltage transfer characteristic [Fig. 79.8(c)], where V_i is applied to inputs A and B simultaneously, can be found in most digital circuit textbooks. The sloping portion of the characteristic between $V_i = 0.55$ and 1.2 V corresponds to T_2 passing through the active region in going from cutoff to saturation.

Diodes D_1 and D_2 are present to damp out "ringing" that can occur, for example, when fast voltage level shifts are propagated down an appreciable length (20 cm or more) of microstripline formed by printed circuit board interconnections. Negative overshoots are clamped to the 0.7 V across the diode.

The series combination of the 130-Ω resistor, T_3, D_3, and T_4 in the circuit of Fig. 79.8(a), forming what is called the totem-pole output circuit, provides a low impedance drive in both the source (output $C = 1$) and sink (output $C = 0$) modes and contributes significantly to the relatively high speed of TTL. The available source and sink currents, which are well above the normal requirements for steady state, come into play during the charging and discharging of capacitive loads. Ideally T_3 should have a very large current gain and the 130-Ω resistor should be reduced to 0. The latter, however, would cause a short-circuit load current which would overheat T_3, since T_3 would be unable to saturate. All TTL families other than the standard shown in Fig. 79.8(a) use some form of Darlington connection for T_3, providing increased current gain and eliminating the need for diode D_3. The drop across D_3 is replaced by the base emitter voltage of the added transistor T_5. This connection appears in Fig. 79.9(a), an example of the 74Hxx series of TTL gates that increases speed at the expense of increased power consumption, and in Fig. 79.9(b), a gate from the 74Lxx series that sacrifices speed to lower power dissipation.

A number of TTL logic function implementations are available with open collector outputs. For example, the 7403 two-input NAND gate shown in Fig. 79.10 is the open collector version of Fig. 79.8(a). The open collector output has some useful applications. The current in an external load connected between the open collector and V_{CC} can be switched on and off in response to the input combinations. This load, for example,

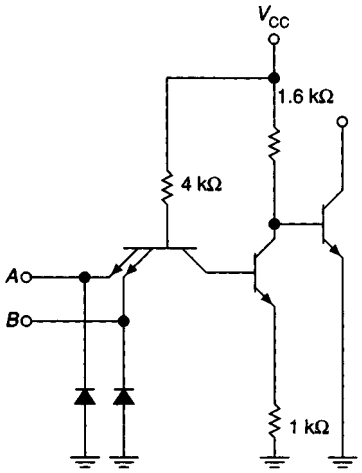

FIGURE 79.10 Open collector two-input NAND gate.

might be a relay, an indicator light, or an LED display. Also, two or more open collector gates can share a common load, resulting in the anding together of the individual gate functions. This is called a "wired-AND connection." In any application, there must be some form of load or the device will not function. There is a lower limit to the resistance of this load which is determined by the current rating of the open collector transistor. For wired-AND applications the resistance range depends on how many outputs are being wired and on the load being driven by the wired outputs. Formulas are given in the data books. Since the open collector configuration does not have the speed enhancement associated with an active pull-up, the low to high propagation delay (t_{PLH}) is about double that of the totem-pole output. It should be observed that totem-pole outputs should not be wired, since excessive currents in the active pull-up circuit could result.

Nonsaturated TTL. Two TTL families, the Schottky (74Sxx) and the low-power Schottky (74LSxx), can be classified as nonsaturating logic. The transistors in these circuits are kept out of saturation by the connection of Schottky diodes, with the anode to the base and the cathode to the collector.

Schottky diodes are formed from junctions of metal and an *n*-type semiconductor, the metal fulfilling the role of the *p*-region. Since there are thus no minority carriers in the region of the forward-biased junction, the storage time required to bring a *pn* junction out of saturation is eliminated. The forward-biased drop across a Schottky diode is around 0.3 V. This clamps the collector at 0.3 V less than the base, thus maintaining V_{CE} above the 0.3-V saturation threshold. Circuits for the two-input NAND gates 74LS00 and 74S00 are given in Fig. 79.11(a) and (b). The special transistor symbol is a short-form notation indicating the presence of the Schottky diode, as illustrated in Fig. 79.11(c).

Note that both of these circuits have an active pull-down transistor T_6 replacing the pull-down resistance connected to the emitter of T_2 in Fig. 79.9. The addition of T_6 decreases the turn-on and turn-off times of T_4. In addition, the transfer characteristic for these devices is improved by the squaring off of the sloping region between $V_i = 0.55$ and 1.2 V [see Fig. 79.8(c)]. This happens because T_2 cannot become active until T_6 turns on, which requires at least 1.2 V at the input.

The diode AND circuit of the 74LS00 in place of the multi-emitter transistor will permit maximum input levels substantially higher than the 5.5-V limit set for all other TTL families. Input leakage currents for 74LSxx are specified at $V_i = 10$ V, and input voltage levels up to 15 V are allowed. The 74LSxx has the additional feature of the Schottky diode D_1 in series with the 100-Ω output resistor. This allows the output to be pulled up to 10 V without causing a reverse breakdown of T_5. The relative characteristics of the several versions of the TTL two-input NAND gate are compared in Table 79.6. The 74F00 represents one of the new technologies that have introduced improved Schottky TTL in recent years.

TTL Design Considerations. Before undertaking construction of a logic system, the wise designer consults the information and recommendations provided in the data books of most manufacturers. Some of the more significant tips are provided here for easy reference.

1. **Power supply, decoupling, and grounding.** The power supply voltage should be 5 V with less than 5% ripple factor and better than 5% regulation. When packages on the same printed circuit board are

74L00	0.44	1.16	31	31	0.4	0.5	0.24/0.1125	5/2.25	20

[a]See text for explanation of abbreviations.

supplied by a bus there should be a 0.05-μF decoupling capacitor between the bus and the ground for every five to ten packages. If a ground bus is used, it should be as wide as possible, and should surround all the packages on the board. Whenever possible, use a ground plane. If a long ground bus is used, both ends must be tied to the common system ground point.

2. **Unused gates and inputs.** If a gate on a package is not used, its inputs should be tied either high or low, whichever results in the least supply current. For example, the 7400 draws three times the current with the output low as with the output high, so the inputs of an unused 7400 gate should be grounded. An unused input of a gate, however, must be connected so as not to affect the function of the active inputs. For a 7400 NAND gate, such an input must either be tied high or paralleled with a used input. It must be recognized that paralleled inputs count as two when determining the fan-out. Inputs that are tied high can be connected either to V_{CC} through a 1-kΩ or more resistance (for protection from supply voltage surges) or to the output of an unused gate whose input will establish a permanent output high. Several inputs can share a common protective resistance. Unused inputs of low-power Schottky TTL can be tied directly to V_{CC}, since 74LSxx inputs tolerate up to 15 V without breakdown. If inputs of low-power Schottky are connected in parallel and driven as a single input, the switching speed is decreased, in contrast to the situation with other TTL families.
3. **Interconnection.** Use of line lengths of up to 10 in. (5 in. for 74S) requires no particular precautions, except that in some critical situations lines cannot run side by side for an appreciable distance without causing cross talk due to capacitive coupling between them. For transmission line connections, a gate should drive only one line, and a line should be terminated in only one gate input. If overshoots are a problem, a 25- to 50-Ω resistor should be used in series with the driving gate input and the receiving gate input should be pulled up to 5 V through a 1-kΩ resistor. Driving and receiving gates should have their own decoupling capacitors between the V_{CC} and ground pins. Parallel lines should have a grounded line separating them to avoid cross talk.
4. **Mixing TTL subfamilies.** Even synchronous sequential systems often have asynchronous features such as reset, preset, load, and so on. Mixing high-speed 74S TTL with lower speed TTL (74LS for example) in some applications can cause timing problems resulting in anomalous behavior. Such mixing is to be avoided, with rare exceptions which must be carefully analyzed.

Emitter-Coupled Logic

ECL is a nonsaturated logic family where saturation is avoided by operating the transistors in the common collector configuration. This feature, in combination with a smaller difference between the HIGH and LOW voltage levels (less than 1 V) than other logic families, makes ECL the fastest logic available at this time. The circuit diagram of a widely used version of the basic two-input ECL gate is given in Fig. 79.12. The power supply terminals V_{CC1}, V_{CC2}, V_{EE}, and V_{TT} are available for flexibility in biasing. In normal operation, V_{CC1} and V_{CC2} are connected to a common ground, V_{EE} is biased to –5.2 V, and V_{TT} is biased to –2 V. With these values the nominal voltage for the logical 0 and 1 are, respectively, –1.75 and –0.9 V. Operation with the V_{CC} terminals grounded maximizes the immunity from noise interference.

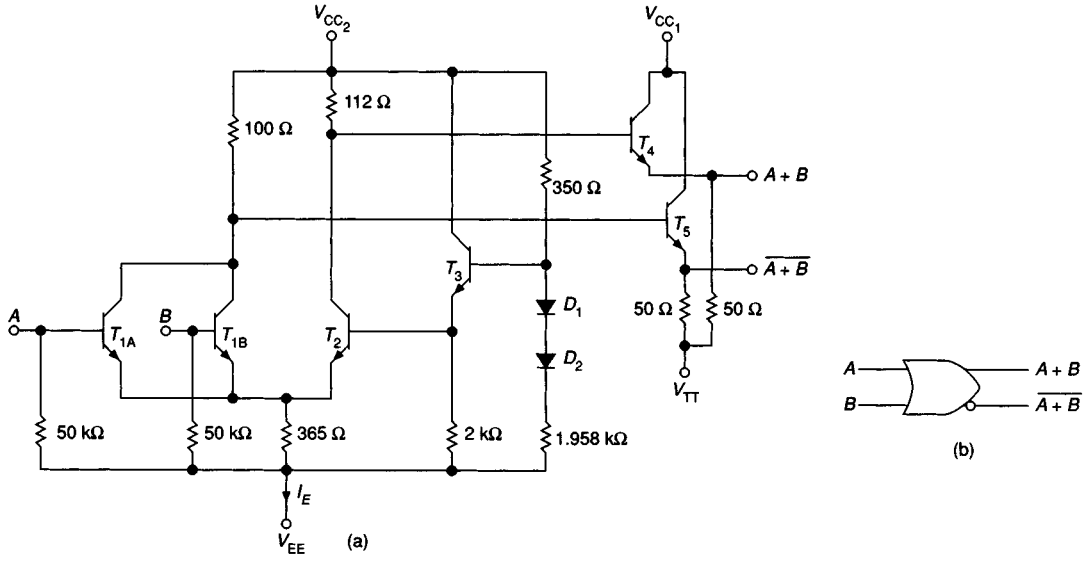

FIGURE 79.12 Emitter-coupled logic basic gate (ECL 10102): (a) circuit, (b) symbol.

A brief description of the operation of the circuit will verify that none of the transistors saturates. For the following discussion, V_{CC1} and V_{CC2} are grounded, V_{EE} is –5.2 V, and V_{TT} is –2 V. Diode drops and base-emitter voltages of active transistors are 0.8 V.

First, observe that the resistor-diode (D_1 and D_2) voltage divider establishes a reference voltage of –0.55 V at the base of T_3, which translates to –1.35 V at the base of T_2. When either or both of the inputs A and B are at the logical 1 level of –0.9 V, the emitters of T_{1A}, T_{1B}, and T_2 will be 0.8 V lower, at –1.7 V. This establishes the base-emitter voltage of T_2 at –1.35 – (–1.7) = 0.35 V, so T_2 is cut off. With T_2 off, T_4 is biased into the active region, and its emitter will be at about –0.9 V, corresponding to a logical 1 at the $(A + B)$ output. Most of the current through the 365-Ω emitter resistor, which is [–1.7 – (–5.2)]/0.365 = 9.6 mA, flows through the 100-Ω collector resistor, dropping the base voltage of T_5 to –0.96 V. Thus the voltage level at the output terminal designated $(A + B)$ is –1.76 V, corresponding to a logical 0.

When both A and B inputs are at the LOW level of –1.75 V, T_2 will be active, with its emitter voltage at –1.35 – 0.8 = –2.15 V. The current through the 365-Ω resistor becomes [–2.15 – (–5.2)]/0.365 = 8.2 mA. This current flows through the 112-Ω resistor pulling the base of T_4 down to –0.94 V, so that the $(A + B)$ output will be at the LOW level of –1.75 V. With T_{1A} and T_{1B} cut off, the base of T_5 is close to 0.0 V, and the $(A + B)$ output will therefore be at the nominal HIGH level of –0.9 V.

Observe that the output transistors T_4 and T_5 are always active and function as emitter followers, providing the low-output impedances required for driving capacitive loads. As T_{1A} and/or T_{1B} turn on, and T_2 turns off as a consequence, the transition is accomplished with very little current change in the 365-Ω emitter resistor. It follows that the supply current from V_{EE} does not undergo the sudden increases and decreases prevalent in TTL, thus eliminating the need for decoupling capacitors. This is a major reason why ECL can be operated successfully with the low noise margins which are inherent in logic having a relatively small voltage difference between the HIGH and LOW voltage levels (see Table 79.7). The small level shifts between LOW and HIGH also permit low propagation times without excessively fast rise and fall times. This reduces the effects of residual capacitive coupling between gates, thereby lessening the required noise margin. For this reason the faster ECL (100xxx) should not be used where the speed of the 10xxx series is sufficient. A comparison of three ECL series is given in Table 79.7. The propagation times t_{PLH} and t_{PHL} and transition times t_{TLH} and t_{THL} are defined in Fig. 79.7. Transitions are between the 20 and 80% levels.

[b] 20 to 80% levels.
[c] Maximum value (all other typical).
[d] Quint 2-input NOR/OR gate.
[e] Dual 5/4-input NOR/OR gate.

The 50-Ω pull-down resistors shown in Fig. 79.12 are connected externally. The outputs of several gates can therefore share a common pull-down resistor to form a wired-OR connection. The open emitter outputs also provide flexibility for driving transmission lines, the use of which in most cases is mandatory for interconnecting this high-speed logic. A twisted pair interconnection can be driven using the complementary outputs $(A + B)$ and $(A + B)$ as a differential output. Such a line should be terminated in an ECL line receiver (10114).

Since ECL is used in high-speed applications, special techniques must be applied in the layout and interconnection of chips on circuit boards. Users should consult design handbooks published by the suppliers before undertaking the construction of an ECL logic system.

While ECL is not compatible with any other logic family, interfacing buffers, called translators, are available. In particular, the 10124 converts TTL output levels to ECL complementary levels, and the 10125 converts either single-ended or differential ECL outputs to TTL levels. Among other applications of these translators, they allow the use of ECL for the highest speed requirements of a system while the rest of the system uses the more rugged TTL. Another translator is the 10177, which converts the ECL output levels to *n*-channel metal-oxide semiconductor (NMOS) levels. This is designed for interfacing ECL with *n*-channel memory systems.

Complementary Metal-Oxide Semiconductor (CMOS) Logic

Metal-oxide semiconductor (MOS) technology is prevalent in LSI systems due to the high circuit densities possible with these devices. *p*-Channel MOS was used in the first LSI systems, and it still is the cheapest to produce because of the higher yields achieved due to the longer experience with PMOS technology. PMOS, however, is largely being replaced by NMOS (*n*-channel MOS), which has the advantages of being faster (since electrons have greater mobility than holes) and having TTL compatibility. In addition, NMOS has a higher function/chip area density than PMOS, the highest density in fact of any of the current technologies. Use of NMOS and PMOS, however, is limited to LSI and VLSI fabrications. The only MOS logic available as SSI and MSI is CMOS (complementary MOS).

CMOS is faster than NMOS and PMOS, and it uses less power per function than any other logic. While it is suitable for LSI, it is more expensive and requires somewhat more chip area than NMOS or PMOS. In many respects it is unsurpassed for SSI and MSI applications. Standard CMOS (the 4000 series) is as fast as low-power TTL (74Lxx) and has the largest noise margin of any logic type.

A unique advantage of CMOS is that for all input combinations the steady-state current from V_{DD} to V_{SS} is almost zero because at least one of the series FETs is open. Since CMOS circuits of any complexity are interconnections of the basic gates, the quiescent currents for these circuits are extremely small, an obvious advantage which becomes a necessity for the practicality of digital watches, for example, and one which alleviates

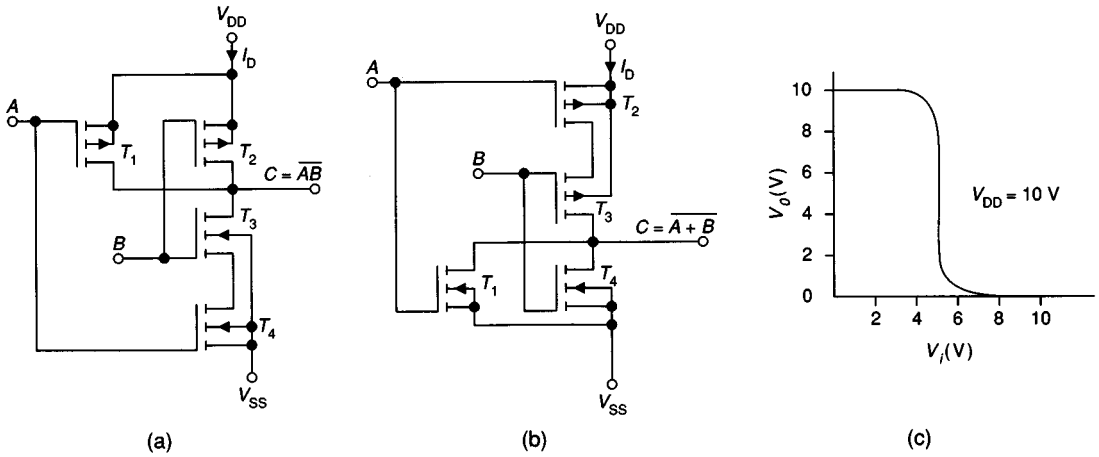

FIGURE 79.13 (a) Complementary metal-oxide semiconductor (CMOS) NAND gate, (b) NOR gate, and (C) inverter transfer characteristic.

heat dissipation problems in high-density chips. Also a noteworthy feature of CMOS digital circuits is the absence of components other than FETs. This attribute, which is shared by PMOS and NMOS, accounts for the much higher function/chip area density than is possible with TTL or ECL. During the time the output of a CMOS gate is switching there will be current flow from V_{DD} to V_{SS}, partly due to the charging of junction capacitances and partly because the path between V_{DD} and V_{SS} closes momentarily as the FETs turn on and off. This causes the dc supply current to increase in proportion to the switching frequency in a CMOS circuit. Manufacturers specify that the supply voltage for standard CMOS can range over $3\ V \le V_{DD} - V_{SS} \le 18\ V$, but switching speeds are slower at the lower voltages, mainly due to the increased resistances of the "on" transistors. The output switches between low and high when the input is midway between V_{DD} and V_{SS}, and the output logical 1 level will be V_{DD} and the logical 0 level V_{SS} [Fig. 79.13(c)]. If CMOS is operated with $V_{DD} = 5$ V and $V_{SS} = 0$ V, the V_{DD} and V_{SS} levels will be almost compatible with TTL except that the TTL totem-pole output high of 3.4 V is marginal as a logical 1 for CMOS. To alleviate this, when CMOS is driven with TTL a 3.3-kΩ pull-up resistor between the TTL output and the common V_{CC}, V_{DD} supply terminal should be used. This raises V_{OH} of the TTL output to 5 V.

All CMOS inputs are diode protected to prevent static charge from accumulating on the FET gates and causing punch-through of the oxide insulating layer. A typical configuration is illustrated in Fig. 79.14. Diodes D_1 and D_2 clamp the transistor gates between V_{DD} and V_{SS}. Care must be taken to avoid input voltages that would cause excessive diode currents. For this reason manufacturers specify an input voltage constraint from $V_{SS} - 0.5$ V to $V_{DD} + 0.5$ V. The resistance R_s helps protect the diodes from excessive currents but is introduced at the expense of switching speed, which is deteriorated by the time constant of this resistance and the junction capacitances.

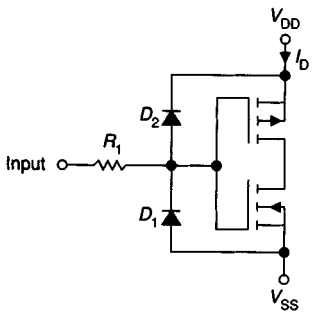

FIGURE 79.14 Diode protection of input transistor gates. $200\ \Omega < R_s < 1.5\ k\Omega$.

Advanced versions of CMOS have been developed which are faster than standard CMOS. The first of these to appear were designated 74HCxx and 74HCTxx. The supply voltage range for this series is limited to $2\ V \le V_{DD} - V_{SS} \le 6\ V$. The pin numbering of a given chip is the same as its correspondingly numbered TTL device. Furthermore, gates with the HCT code have skewed transfer characteristics which match those of its TTL cousin, so that these chips can be directly interchanged with low-power Schottky TTL.

TABLE 79.8 Comparison of Standard, High-Speed, and Advanced High-Speed CMOS

			Standard CMOS NORGates		High-Speed CMOS Inverter		Advanced CMOS Inverter

minimum)								

More recently, a much faster CMOS has appeared and carries the designations 74ACxx and 74ACTxx. These operate in the same supply voltage range and bear the same relationship with TTL as the HCMOS. The driving capabilities (characterized by I_{OH} and I_{OL}) of this series are much greater, such that they can be fanned out to 10 low-power Schottky inputs.

The three types of CMOS are compared in Table 79.8. The relative speeds of these technologies are best illustrated by including in the table the maximum clock frequencies for *D* flip-flops. In each case, the frequency given is the maximum for which the device is guaranteed to work. It is worth noting that a typical maximum clocking of 160 MHz is claimed for the 74ACT374 *D* flip-flop.

CMOS Design Considerations

Design and handling recommendations for CMOS, which are included in several of the data books, should be consulted by the designer using this technology. A few selected recommendations are included here to illustrate the importance of such information.

1. All unused CMOS inputs should be tied either to V_{DD} or V_{SS}, whichever is appropriate for proper operation of the gate. This rule applies even to inputs of unused gates, not only to protect the inputs from possible static charge buildup, but to avoid unnecessary supply current drain. Floating gate inputs will cause all the FETs to be conducting, wasting power and heating the chip unnecessarily.
2. CMOS inputs should never be driven when the supply voltage V_{DD} is off, since damage to the input-protecting diodes could result. Inputs wired to edge connectors should be shunted by resistors to V_{DD} or V_{SS} to guard against this possibility.
3. Slowly changing inputs should be conditioned using Schmitt trigger buffers to avoid oscillations that can arise when a gate input voltage is in the transition region.
4. Wired-AND configurations cannot be used with CMOS gates, since wiring an output HIGH to an output LOW would place two series FETs in the "on" condition directly across the chip supply.
5. Capacitive loads greater than 5000 pF across CMOS gate outputs act as short circuits and can overheat the output FETs at higher frequencies.
6. Designs should be used that avoid the possibility of having low impedances (such as generator outputs) connected to CMOS inputs prior to power-up of the CMOS chip. The resulting current surge when V_{DD} is turned on can damage the input diodes.

While this list of recommendations is incomplete, it should alert the CMOS designer to the value of the information supplied by the manufacturers.

Choosing a Logic Family

A logic designer planning a system using SSI and MSI chips will find that an extensive variety of circuits is available in all three technologies: TTL, ECL, and CMOS. The choice of which technology will dominate the system is governed by what are often conflicting needs, namely, speed, power consumption, noise immunity, cost, availability, and the ease of interfacing. Sometimes the decision is easy. If the need for a low static power drain is paramount, CMOS is the only choice. It used to be the case that speed would dictate the selection; ECL was high speed, TTL was moderate, and CMOS low. With the advent of advanced TTL and, especially, advanced CMOS the choice is no longer clear-cut. All three will work at 100 MHz or more. ECL might be used since it generates the least noise because the transitions are small, yet for that same reason it is more susceptible to externally generated noise. Perhaps TTL might be the best compromise between noise generation and susceptibility. Advanced CMOS is the noisiest because of its rapid rise and fall times, but the designer might opt to cope with the noise problems to take advantage of the low standby power requirements.

A good rule is to use devices which are no faster than the application requires and which consume the least power consistent with the needed driving capability. The information published in the manufacturers' data books and designer handbooks is very helpful when choice is in doubt.

Defining Term

Logic gate: Basic building block for logic systems that controls the flow of pulses.

Further Information

An excellent presentation of the practical design of logic systems using SSI and MSI devices is developed in the referenced book *An Engineering Approach to Digital Design* by William I. Fletcher. The author pays particular attention to the importance of device speed and timing.

The Art of Electronics by Horowitz and Hill is particularly helpful for its practical approach to interfacing digital with analog.

Everything one needs to know about digital devices and their interconnection can be found somewhere in the data manuals, design handbooks, and application notes published by the device manufacturers. Unfortunately, no single publication has it all, so the serious user should acquire as large a collection of these sources as possible.

79.3 Bistable Devices

Richard S. Sandige

This section deals with bistable devices which are also commonly referred to as **bistables, latches,** or **flip-flops.** Bistable devices are **memory elements.** Each bistable provides storage for only 1-bit, i.e., it can store a 1 or a 0. Figure 79.15 shows a graphic classification of bistable devices.

Manufacturers supply integrated circuit (IC) packages containing several bistable devices. One data book for the transistor-transistor logic (TTL) circuit technology lists 4-, 8-, 9-, and 10-bit latches in one IC package. The same data book lists 2-, 4-, 6-, 8-, 9-, and 10-bit flip-flops in one IC package. While a 1-bit bistable can only store 1 bit of information, 8-bit bistables are capable of storing 8 bits of information. Bistable devices implemented with logic gates are **volatile devices.** When power is first applied the first stored value of the bistable is random (it can store a 1 or a 0), and when power is removed the bistable loses its storage capability. Certain memories (also called stores) are nonvolatile and therefore retain their data when power is removed. These devices will not be discussed in this section.

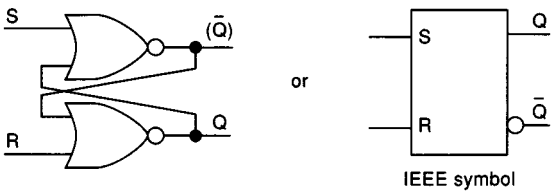

FIGURE 79.16 Basic *S-R* NOR latch implementation. (*Source:* Modified from R. S. Sandige, *Modern Digital Design,* New York: McGraw-Hill, 1990, p. 448. With permission.)

Basic Latches

A latch can be either basic or gated. Figure 79.16 is an example of a basic *S-R* NOR latch implementation using two cross-coupled NOR gates. The logic symbol recommended for the *S-R* NOR latch by the Institute of Electrical and Electronics Engineers (IEEE) is shown to the right of the logic circuit implementation.

The input signal named *S* stands for set while the input signal named *R* stands for reset. Manufacturers often select *Q* as the output signal name for bistable devices in their data books. The *Q*s on the outputs are added for clarity and are not part of the IEEE symbol. The *S-R* NOR latch shown in Fig. 79.16 is a basic latch circuit since the *S* and *R* inputs are not gated with a control signal. The **reduced characteristic table** in Table 79.9 shows the operation of the *S-R* NOR latch circuit.

For $S\,R = 00$, $Q = Q_0$, illustrating that the output for the next state *Q* is the same as the present state output Q_0. For $S\,R = 01$, $Q = 0$, specifying

S	*R*	*Q*	Operation
0	0	Q_0	no change
0	1	0	reset
1	0	1	set
1	1	0	not normally allowed

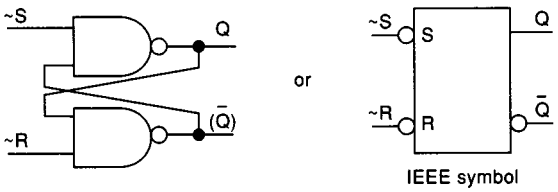

FIGURE 79.17 Basic *S-R* NAND latch implementation. (*Source:* Modified from R. S. Sandige. *Modern Digital Design,* New York: McGraw-Hill, 1990, p. 449. With permission.)

TABLE 79.10 Reduced Characteristic Table for the *S-R* NAND Latch

~*S*	~*R*	*Q*	Operation
0	0	1	not normally allowed
0	1	1	set
1	0	0	reset
1	1	Q_0	no change

that the output for the next state is reset. For $S\,R = 10$, $Q = 1$, indicating that the output for the next state is set. In most cases the input conditions $S\,R = 11$ are not allowed for two reasons. If $S\,R = 11$, then the alternate output for the bistable, shown in parentheses as $\overline{Q}$ in Fig. 79.16, is not logically correct as it is for all other input combinations. The second reason is more subtle since the next state of the bistable can be set or reset due to a **critical race** condition when the inputs are changed from 11 to 00. Such unpredictability is not desirable and therefore the $S\,R = 11$ condition is generally not allowed. Latches and flip-flops that contain a Q and a $\overline{Q}$ output (complementary outputs) provide double-rail outputs.

The *S-R* NAND latch implementation shown in Fig. 79.17 uses two cross-coupled NAND gates. The tildes shown in the logic circuit diagram preceding *S* and *R* represent inline symbols for the logical complements of *S* and *R*, respectively, as recommended by the IEEE. Data books usually refer to the *S-R* NAND latch as the $\overline{S}$-$\overline{R}$ latch. The logic symbol recommended for the *S-R* NAND latch by IEEE is shown to the right of the logic circuit diagram.

The ~*S* and ~*R* on the inputs and *Q*s on the outputs of the IEEE symbol are added for clarity and are not part of the IEEE symbol. The reduced characteristic table illustrated in Table 79.10 shows the operation of the *S-R* NAND latch circuit in Fig. 79.17.

In most cases the input conditions $\sim S\sim R = 00$ ($S\,R = 11$) are not allowed for the same reasons provided above for the *S-R* NOR latch. For $\sim S\sim R = 01$ ($S\,R = 10$), $Q = 1$, indicating that the output for the next state is set. For $\sim S\sim R = 10$ ($S\,R = 01$), $Q = 0$, specifying that the output for the next state is reset. For $\sim S\sim R = 11$ ($S\,R = 00$), $Q = Q_0$, illustrating that the output for the next state Q is the same as the present state output Q_0.

Gated Latches

All other gate level latches and flip-flops are functionally equivalent to either the configuration of the cross-coupled NOR latch circuit or the cross-coupled NAND latch circuit. A gated *S-R* NOR latch circuit and a gated *S-R* NAND latch are illustrated in Fig. 79.18 along with the recommended IEEE symbol. The reduced characteristic table for both of these circuits is provided in Table 79.11.

In each circuit both the *S* and *R* inputs are gated with a control signal *C*. Notice in the reduced characteristic table that the *S* and *R* inputs are only enabled, and thus have an effect on the output, when $C = 1$ (**transparent mode**).

Whatever value the output has when *C* goes to 0 is latched, captured, or stored (memory mode). Like the basic latches, the input conditions for $S\,R = 11$ are not generally allowed for the gated *S-R* latches when *C* goes to 1. The gated *D* latch circuit is perhaps the most used latch circuit since the added Inverter shown in the circuit diagram in Fig. 79.19 ensures that the input conditions for $S\,R = 11$ cannot occur when *C* goes to 1. The reduced characteristic table for the gated *D* latch circuit is shown in Table 79.12.

Flip-Flops

We will use the term *flip-flop* to distinguish between the bistable device called a latch and the bistable device that allows feed-back without oscillation. Early types of flip-flops were of the master-slave (pulse-triggered) variety that had no data-lockout circuitry and caused a storage error if improperly used due to 1s and 0s catching. To prevent 1s and 0s catching, data-lockout (also called variable-skew) circuitry was added to a few

master-slave flip-flop types. Due to the better design features and popularity of **edge-triggered** flip-flops, master-slave flip-flops are not recommended for newer designs and in some cases have been made obsolete by manufacturers, making them difficult to obtain even for repair parts. For this reason only edge-triggered flip-flops will be discussed.

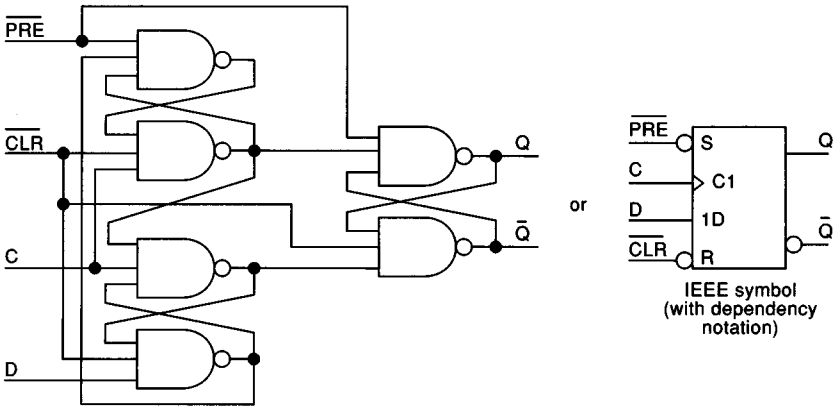

FIGURE 79.20 Positive edge-triggered *D* flip-flop circuit. (*Source:* Modified from R. S. Sandige, *Modern Digital Design,* New York: McGraw-Hill, 1990, p. 490. With permission.)

1	1	1	X	X	Q_0	no change

Edge-Triggered Flip-Flops

Two types of edge-triggered flip-flops are predominantly used in modern designs. These are the *D* type and *J-K* type. The *D* type is perhaps the most used because its circuitry generally takes up less real estate on an IC chip and because most engineers consider it an easier device with which to design. An example of a positive edge-triggered *D* flip-flop circuit is shown in Fig. 79.20. The reduced characteristic table illustrating the operation of this flip-flop is shown in Table 79.13.

The main difference between a latch and an edge-triggered flip-flop is the question of transparency. The gated *D* latch is transparent (the *Q* output follows the *D* input when the control input $C = 1$) and it latches, captures, or stores the value at the *D* input at the time the control input *C* goes to 0. The *positive edge-triggered D* flip-flop is never transparent from its data input *D* to its output *Q*. When the control input *C* is 0 the output *Q* does not follow the *D* input and remains unchanged; however, the value at the *D* input is latched, captured, or stored at the time the *control input C makes a 0 to 1 transition.* The characteristic that makes edge-triggered flip-flops desirable for feedback applications is that, due to their nontransparent property, their outputs can be fed back as inputs to the device without causing oscillation. This is true for all types of edge-triggered flip-flops. A negative edge-triggered *J-K* flip-flop circuit is shown in the circuit diagram in Fig. 79.21 with its corresponding IEEE symbol. Notice that the *J-K* flip-flop requires eight logic gates compared to only six logic gates for the *D* flip-flop in Fig. 79.20. The reduced characteristic table for this negative edge-triggered flip-flop is shown in Table 79.14.

Notice in the reduced characteristic table (Table 79.14 for the *J-K* flip-flop) when the *J* and *K* inputs are both 1 and the control input *C* makes a 1 to 0 transition, the flip-flop **toggles,** i.e., the next state output *Q*

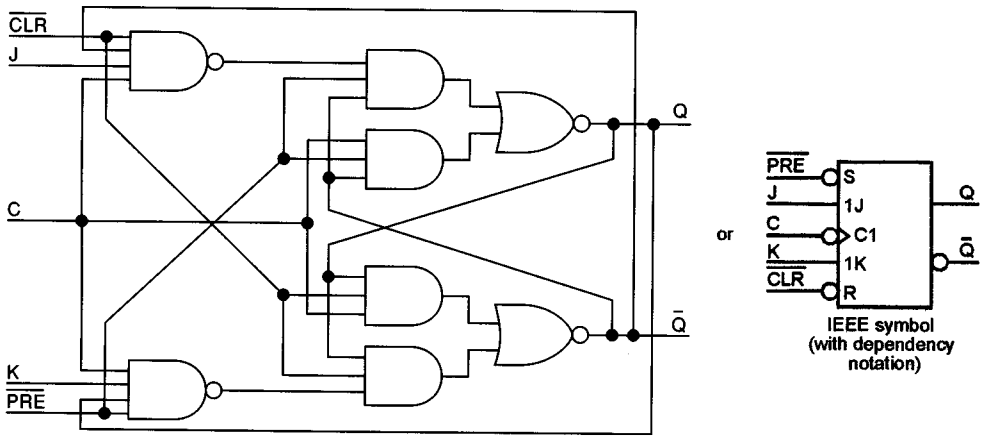

FIGURE 79.21 Negative edge-triggered *J-K* flip-flop circuit. (*Source:* Modified from R. S. Sandige. *Modern Digital Design,* New York: McGraw-Hill, 1990, p. 493. With permission.)

changes to the complement of the present state output Q_0. By simply connecting *J* and *K* together and renaming it *T* for toggle, one can obtain a negative edge-triggered *T* flip-flop.

Special Notes on Using Latches and Flip-Flops

Since bistable devices are asynchronous **fundamental mode** sequential logic circuits, only one input is allowed to change at a time. This means that for proper operation for a basic latch, only one of the data inputs *S* or *R* for a *S-R* NOR latch (~*S* or ~*R* for a *S-R* NAND latch) may be changed at one time. For a gated latch this means for proper operation the data inputs *S* and *R* or data input *D* must meet a **minimum setup** (t_{su}) **and hold time** (t_h) **requirement,** i.e., the data input(s) must be stable for a minimum time period, prior to the control input *C* changing the latch from the transparent mode to the memory mode. For proper operation of an edge-triggered flip-flop this means that the data input *D* or data inputs *J* and *K* must meet a minimum setup time and hold time requirement relative to the control input *C* changing from 0 to 1 (positive edge-triggered) or from 1 to 0 (negative edge-triggered). In manufacturers' data books, the control input *C* is often named the enable input for latches and the clock (*CLK*) input for flip-flops.

Defining Terms

Bistable, latch, and flip-flop: Names used in place of the term **bistable device.**
Critical race: A change in two input variables that results in an unpredictable output value for a bistable device.
Edge-triggered: Term used to describe the edge of a positive or negative pulse applied to the control input of a nontransparent bistable device to latch, capture, or store the value indicated by the data input(s).
Fundamental mode: Operating mode of a circuit that allows only one input to change at a time.
Memory element: A bistable device or element that provides data storage for a logic 1 or a logic 0.
Reduced characteristic table: A tabular representation used to illustrate the operation of various bistable devices.
Setup and hold time requirement: Setup time (hold time) is the time required for the data input(s) to be held stable prior to (or after) the control input *C* changes to latch, capture, or store the value indicated by the data input(s).
Toggle: Change of state from logic 0 to logic 1 or from logic 1 to logic 0 in a bistable device.
Transparent mode: Mode of a bistable device where an output responds to data input signal changes.
Volatile device: A memory or storage device that loses its storage capability when power is removed.

79.4 Optical Devices

H. S. Hinton

Since the first demonstration of optical logic devices in the late 1970s, there have been many different experimental devices reported. Figure 79.22 categorizes optical logic devices into four main classes. The first division is between all-optical and optoelectronic devices. All-optical devices are devices that do not use electrical currents to create the nonlinearity required by digital devices. These devices can be either single-pass devices (light passes through the nonlinear material once) or they can use a resonant cavity to further enhance the optical nonlinearity (multiple passes through the same nonlinear material). Optoelectronic devices, on the other hand, use electrical currents and electronic devices to process a signal that has gone through an optical-to-electrical conversion process. The output of these devices is either provided by electrically driving an optical source such as a laser or LED (detect/emit) or by modulating some external light source (detect/modulate). Below each of these categories are listed some of the devices that have been experimentally demonstrated.

All-Optical Devices

To create an all-optical logic device requires a medium that will allow one beam of light to affect another. This phenomenon can arise from the cubic response to the applied field. These third-order processes can lead to purely dielectric phenomena, such as irradiance-dependent refractive indices. By exploiting purely dielectric third-order nonlinearities, such as the optical Kerr effect, changes can be induced in the optical constants of the medium which can be read out directly at the same wavelength as that inducing them. This then opens up

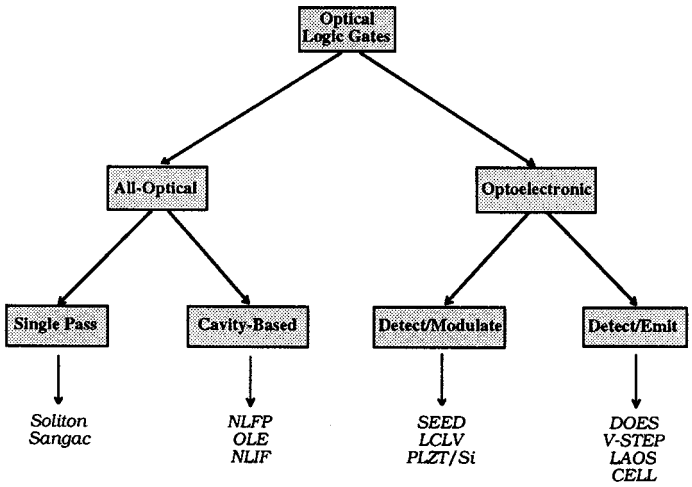

FIGURE 79.22 Classification of optical logic devices.

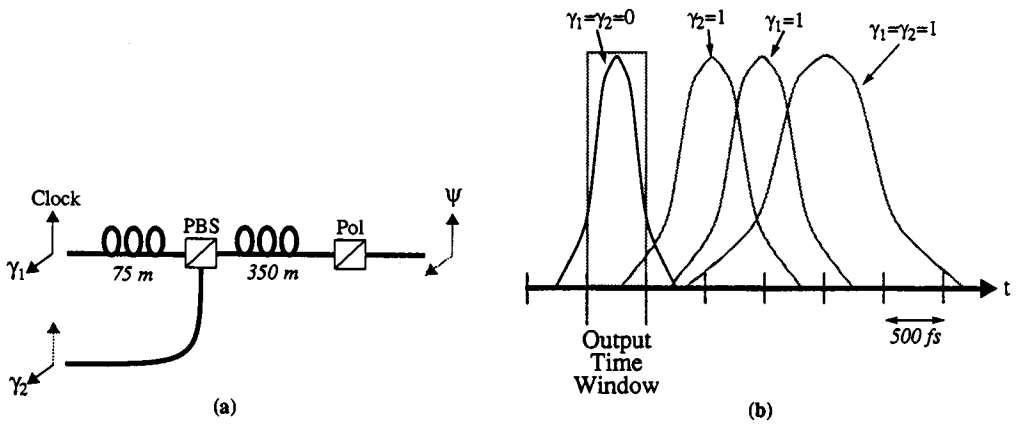

FIGURE 79.23 Soliton NOR gate: (a) physical implementation, (b) timing diagram.

the possibilities for digital optical circuitry based on cascadable all-optical logic gates. Although there have been many different all-optical gates demonstrated, this section will only briefly review the **soliton** gate (single-pass) and one example of the **nonlinear Fabry-Perot** structures (cavity-based).

Single-Pass Devices

An example of an all-optical single-pass optical logic gate is the soliton NOR gate. It is an all-fiber logic gate based on time shifts resulting from soliton dragging. A NOR gate consists of two birefringent fibers connected through a polarizing beamsplitter with the output filtered by a polarizer as shown in Fig. 79.23. The clock pulse, which provides both gain and logic level restoration, propagates along one principal axis in both fibers. For the NOR gate the fiber length is trimmed so that in the absence of any signal the entering clock pulse will arrive within the output time window corresponding to a "1." When either or both of the input signals are incident, they interact with the clock pulse through soliton dragging and shift the clock pulse out of the allowed output time window creating a "0" output. In soliton dragging two temporally coincident, orthogonally polarized pulses interact in the fiber through cross-phase modulation and shift each other's velocities. This velocity shift converts into a time shift after propagating some distance in the fiber. To implement the device, the two input signal pulses γ_1 and γ_2 are polarized orthogonal to the clock. The signals are timed so that γ_1 and the clock

pulse coincide at the input to the first fiber and γ_2 and the clock pulse coincide (in the absence of γ_1) at the input to the second fiber. At the output the two input signals are blocked by the polarizer, allowing only the temporally modified clock pulse to pass. In a prototyped demonstration this all-optical NOR gate required 5.8 pJ of signal energy and provided an effective gain of 6.

Cavity-Based Devices

Cavity-based optical logic devices are composed of two highly reflective mirrors that are separated by a distance d [Fig. 79.24(a)]. The volume between the mirrors, referred to as the cavity of the etalon, is filled with a nonlinear material possessing an index of refraction that varies with intensity according to $n_c = n_0 + n_2 \gamma_c$ where n_0 is the linear index of refraction, n_2 is the nonlinear index of refraction, and γ_c is the intensity of light within the cavity. In the ideal case, the characteristic response of the reflectivity of a Fabry-Perot cavity, R_{fp}, is shown in Fig. 79.24(b). At low intensities, the cavity resonance peak is not coincident with the wavelength of the incident light; thus the reflectivity is high, which allows little of the incident light to be transmitted [solid curves in Fig. 79.24(b)]. As the intensity of the incident light γ increases, so does the intercavity light intensity which shifts the resonance peak [dotted curve in Fig. 79.24(b)]. This shift in the resonant peak increases the transmission which in turn reduces the reflectivity. This reduction in ψ will continue with increasing γ until a minimum value is reached. It should be noted that in practice all systems of interest have both intensity-dependent absorption and n_2.

To implement a two-input NOR gate using the characteristic curve shown in Fig. 79.24(c) requires a third input which is referred to as the *bias beam*, γ_b. This energy source biases the etalon at a point on its operating curve such that any other input will exceed the nonlinear portion of the curve moving the etalon from the high reflection state. This is illustrated in Fig. 79.24(c) where the γ_b combines with the inputs γ_1 and γ_2 to exceed the threshold of the nonlinear characteristic curve.

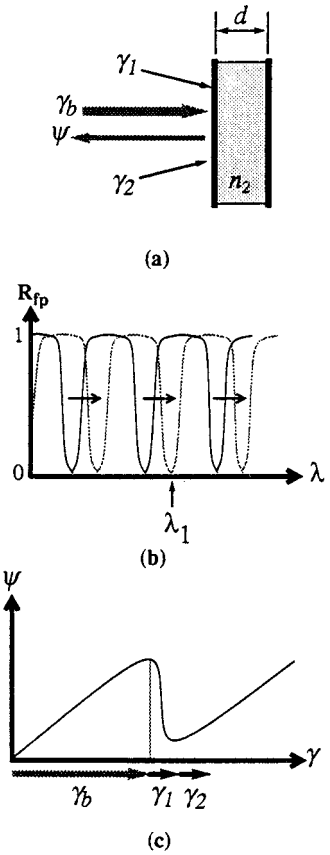

FIGURE 79.24 (a) Nonlinear Fabry-Perot etalon, (b) reflection peaks of NLFP, and (c) NLFP in reflection (NOR).

The first etalon-based optical logic device was in the form of a nonlinear interference filter (NLIF). A simple interference filter has a general form similar to a Fabry-Perot etalon, being constructed by depositing a series of thin layers of transparent material of various refractive indices on a transparent substrate. The first several layers deposited form a stack of alternating high and low refractive indices, all of optical thickness equal to one quarter of the operating wavelength. The next layer is a low integer (1–20) number of half wavelengths thick and finally a further stack is deposited to form the filter. The two outer stacks have the property of high reflectivity at one wavelength, thus playing the role of mirrors forming a cavity. A high finesse cavity is usually formed when both mirrors are identical, i.e., of equal reflectivity. However, unlike a Fabry-Perot etalon with a nonabsorptive material in the cavity, matched (equal) stack reflectivities do not give the optimum cavity design to minimize switch power because of the absorption in the spacer (which may be necessary to induce nonlinearity). A balanced design which takes into account the effective decrease in back mirror reflectivity due to the double pass through the absorbing cavity is preferable and also results in greater contrast between bistable states. The balanced design is easily achieved by varying one or all of the available parameters: number of periods, thickness and refractive index of each layer within either stack.

Optoelectronic Devices

Optoelectronic devices take advantage of both the digital processing capabilities of electronics and communications capabilities of the optical domain. This section will review both the SEED-based optical logic gates and the *pnpn* structures that have demonstrated optical logic.

Detect/Modulate Devices

In the most general terms the self-electro-optic effect device **(SEED) technology** corresponds to any device based on **multiple quantum well** (MQW) modulators. The basic physical mechanism used by this technology is the quantum confined Stark effect. This mechanism creates a shift in the bandedge of a semiconductor with an applied voltage. This is illustrated in Fig. 79.25(a). This shift in the bandedge is then used to vary the absorption of incident light on the MQW material. When this MQW material is placed in the intrinsic region of a *pin* diode and electrically connected to a resistor as shown in Fig. 79.25(b) the characteristic curve shown in Fig. 79.25(c) results. When the incident intensity, γ_i, is low there is no current flowing through the *pin* diode or resistor; thus the majority of the voltage is across the *pin* diode. If the device is operating at the wavelength λ_0, the device will be in a low absorptive state. As the incident intensity increases so does the current flowing in the *pin* diode; this in turn reduces the voltage across the diode which increases the absorption and current flow. This state of increasing absorption creates the nonlinearity in the output signal, ψ, shown in Fig. 79.25(c). Optical logic gates can be formed by optically biasing the R-SEED close to the nonlinearity, γ_b, and then applying lower level data signals γ_1 and γ_2 to the device.

The S-SEED, which behaves like an optical inverting *S-R* latch, is composed of two electrically connected MQW *pin* diodes as illustrated in Fig. 79.26(a). In this figure, the device inputs include the signal, γ_i (Set), and

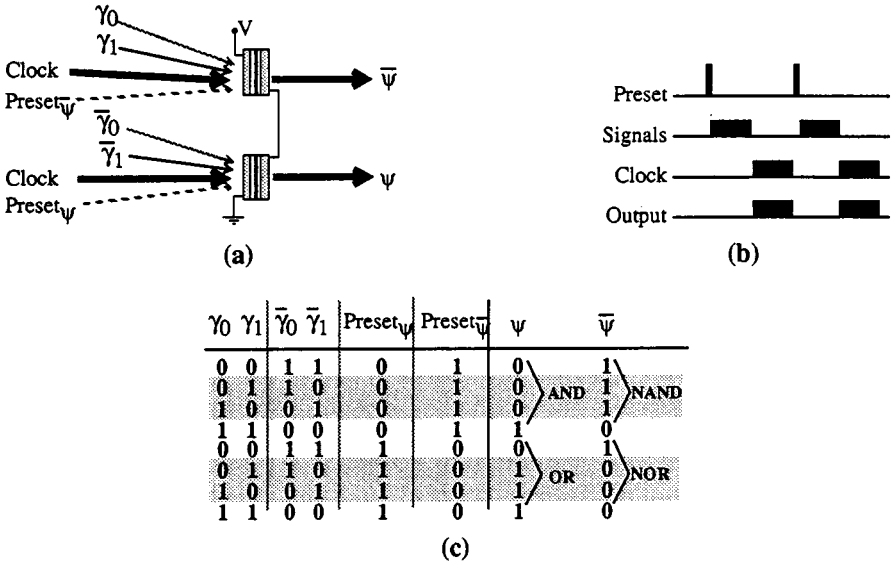

FIGURE 79.27 Logic using S-SEED devices.

its complement, $\bar{\gamma}_i$ (Reset), and a clock signal. To operate the S-SEED the γ_i and $\bar{\gamma}_i$ inputs are also separated in time from the clock inputs as shown in Fig. 79.25(b). The γ_i and $\bar{\gamma}_i$ inputs, which represent the incoming data and its complement, are used to set the state of the device. When $\bar{\gamma}_i > \gamma_i$, the S-SEED will enter a state where the upper MQW *pin* diode will be reflective, forcing the lower diode to be absorptive. When $\gamma_i > \bar{\gamma}_i$ the opposite condition will occur. Low switching intensities are able to change the device's state when the clock signals are not present. After the device has been put into its proper state, the clock beams are applied to both inputs. The ratio of the power between the two clock beams should be approximately one, which will prevent the device from changing states. These higher energy clock pulses, on reflection, will transmit the state of the device to the next stage of the system. Since the inputs γ_i and $\bar{\gamma}_i$ are low-intensity pulses and the clock signals are high-intensity pulses, a large differential gain may be achieved. This type of gain is referred to as time-sequential gain.

The operation of an S-SEED is determined by the power transfer characteristic shown in Fig. 79.26(c). The optical power reflected by the ψ_i window, when the clock signal is applied, is plotted against the ratio of the total optical signal power impinging on the γ_i and $\bar{\gamma}_i$ windows (when the clock signal is not applied). Assuming the clock power incident on both signal windows, γ_i and $\bar{\gamma}_i$, the output power is proportional to the reflectivity, R_i. The ratio of the input signal powers is defined as the input contrast ratio $C_{in} = P_\gamma/P_{\bar{\gamma}i}$. As C_{in} is increased from zero, the reflectivity of the ψ_i window switches from a low value, R_1, to a high value, R_2, at a C_{in} value approximately equal to the ratio of the absorbances of the two optical windows: $T = (1 - R_1)/(1 - R_2)$. Simultaneously, the reflectivity of the other window (ψ_i) switches from R_2 to R_1. The return transition point (ideally) occurs when $C_{in} = (1 - R_2)/(1 - R_1) = 1/T$. The ratio of the two reflectivities, R_2/R_1, is the output contrast, C_{out}. Typical measured values of the preceding parameters include $C_{out} = 3.2$, $T = 1.4$, $R_2 = 50\%$ and $R_1 = 15\%$. The switching energy for these devices has been measured at ~7 fJ/μm^2.

The S-SEED is also capable of performing optical logic functions such as NOR, OR, NAND, and AND. The inputs will also be differential, thus still avoiding any critical biasing of the device. A method of achieving logic gate operation is shown in Fig. 79.27. The logic level of the inputs will be defined as the ratio of the optical power on the two optical windows. When the power of the signal incident on the γ_i input is greater than the power of the signal on the $\bar{\gamma}_i$ input, a logic "1" will be present on the input. On the other hand, when the power of the signal incident on the γ_i input is less than the power of the signal on the $\bar{\gamma}_i$ input, a logic "0" will be incident on the input.

For the noninverting gates, OR and AND, we can represent the output logic level by the power of the signal coming from the ψ output relative to the power of the signal coming from the $\bar{\psi}$ output. As before, when the power of the signal leaving the ψ output is greater than the power of the signal leaving the $\bar{\psi}$ output, a logic

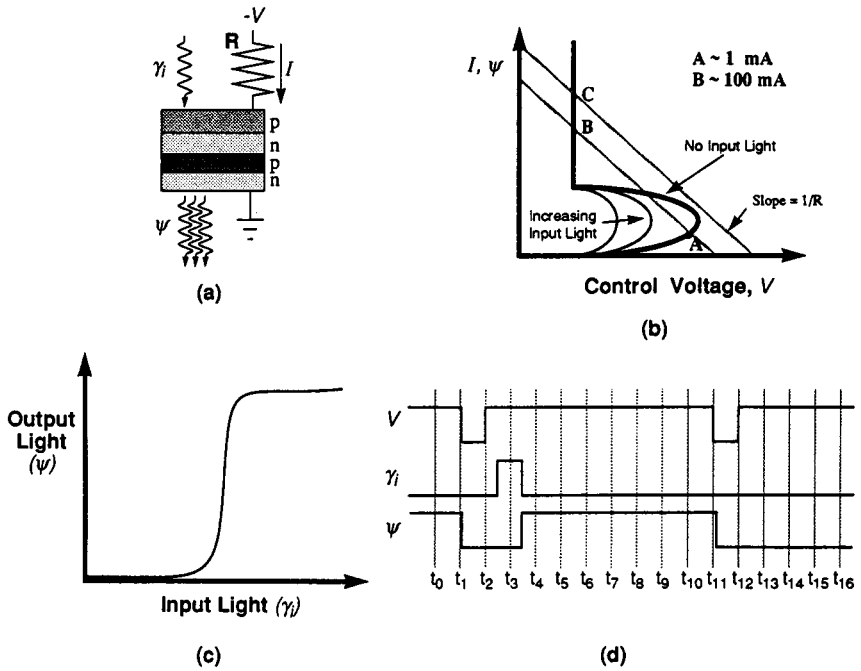

FIGURE 79.28 *pnpn* devices: (a) basic structure, (b) voltage/output characteristics, (c) input/output characteristics, and (d) timing diagram of device operation.

"1" will be represented on the output. To achieve AND operation, the device is initially set to its "off" or logic "0" state (i.e., ψ low and $\overline{\psi}$ high) with preset pulse, $Preset_{\psi}$ incident on only one *pin* diode as shown in Fig. 79.27. If both input signals have logic levels of "1" (i.e., set = 1, reset = 0), then the S-SEED AND gate is set to its "on" state. For any other input combination, there is no change of state, resulting in AND operation. After the signal beams determine the state of the device, the clock beams are then set high to read out the state of the AND gate. For NAND operation, the logic level is represented by the power of the $\overline{\psi}$ output signal relative to the power of the ψ output signal. That is, when the power of the signal leaving the $\overline{\psi}$ output is greater than the power of the signal leaving the ψ output, a logic "1" is present on the output. The operation of the OR and NOR gates is identical to the AND and NAND gates, except that preset pulse $Preset_{\psi}$ is used instead of the preset pulse $Preset_{\overline{\psi}}$. Thus, a single array of devices can perform any or all of the four logic functions and memory functions with the proper optical interconnections and preset pulse routing.

Detect/Emit Devices

Detect/emit devices are optoelectronic structures that detect the incoming signal, process the information, and then transfer the information off the device through the use of active light emitters such as LEDs or lasers. An example of a detect/emit device is the "thyristor-like" *pnpn* device as illustrated in Fig. 79.28(a). It is a digital active optical logic device with "high" and "low" light-emitting optical output states corresponding to electrical states of high impedance (low optical output) or low impedance (high optical output). The device can be driven from one state to the other either electrically or optically. The optical output can be either a lasing output or light-emitting diode output. There are several devices that are based on this general structure. The double heterostructure optoelectronic switch (DOES) is actually an *npnp* structure that is designed as an integrated bipolar inversion channel heterojunction field-effect transistor (BICFET) phototransistor controlling and driving either an LED or microlaser output. The second device is a *pnpn* structure referred to as a vertical-to-surface transmission electrophotonic device (VSTEP).

The operation of these *pnpn* structures can be illustrated through the use of load lines. For the simplest device, the load consists of a resistor and a power supply. In Fig. 79.28(b), we see that for small amounts of light, the device will be at point *A*. Point *A* is in a region of high electrical impedance with little or no optical output. As the input light intensity increases, there is no longer an intersection point near *A* and the device

will switch to point *B* [Fig. 79.28(c)]. At this point the electrical impedance is low and light is emitted. When the input light is removed, the operating point returns via the origin to point *A* by momentarily setting the electrical supply to zero [Fig. 79.28(d)]. These devices can be used as either optical OR or AND gates using a bias beam and several other optical inputs.

The device can also be electrically switched. Assuming no input intensity, the initial operating point is at point *A*. By increasing the power supply voltage, the device will switch to point *C*. Point *C* like point *B* is in the region of light emission and low impedance. To turn off the device, the power supply must then be reduced to zero, after which it may be increased up to some voltage where switching occurs.

A differential *pnpn* device made by simply connecting two *pnpn* devices in parallel and connecting that combination in series with a resistive load is illustrated in Fig. 79.29. The operation of the device can be described as follows. When the device is biased below threshold, that is, with the device unilluminated, both optical switches are "off." When the device is illuminated, the one with the highest power is switched "on." The increase in current leads to a voltage drop across the resistor which in turn leads to a lowering of the voltage across both optical switches. Therefore, the one with the lower input cannot be switched "on." Unless both inputs were illuminated with precisely the same power and both devices had identical characteristics (both of these are impossible), only one of the two optical switches will emit light.

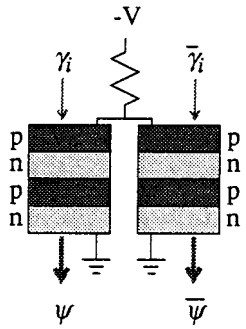

FIGURE 79.29 Differential *pnpn* device.

The required input optical switching energy density can be quite low if the device without light is biased critically just below threshold. Since incoherent light from an LED cannot be effectively collected from small devices or focused onto small devices, a lasing *pnpn* is needed. Microlaser-based structures are also required to reduce the total power dissipation to acceptable levels. Surface-emitting microlasers provide an ideal laser because of their small size, single-mode operation, and low thresholds. The surface-emitting microlasers consist of two AlAs/AlGaAs dielectric mirrors with a thin active layer in between. This active layer typically consists of one or a few MQWs. The material can be etched vertically into small posts, typically 1–5 μm in diameter. Thresholds are typically on the order of milliwatts.

The switching speed of these devices is limited by the time it takes the photogenerated carriers to diffuse into the light-emitting region. Optical turn-off times are also limited by the RC time constant. For devices made so far, the RC time constants are in the range of 1–10 ns, and optical switch-on times were ~10 ns. Performance of the devices is expected to improve as the areas are reduced; switching times comparable to the best electronic devices (~10 ps) are possible, although the optical turn-on times of at least the surface-emitting LED devices will continue to be slower since this time is determined by diffusion effects and not device capacitance and resistance. Lasing devices should offer improved optical turn-on times.

Another approach to active devices is to combine lasers/modulators with electronics and photodiodes as has been proposed for optical interconnections of electronic circuits. Since the logic function is implemented with electronic circuitry, any relatively complex functionality can be achieved. Several examples of logic gates have been made using GaAs circuitry and light-emitting diodes. Again surface-emitting microlasers provide an ideal emitter for this purpose, because of their small size and low threshold current. However, the integration of these lasers with the required electrical components has yet to be demonstrated.

Limitations

In the normal operating regions of most devices, a fixed amount of energy, the switching energy, is required to make them change states. This switching energy can be used to establish a relationship between both the switching speed and the power required to change the state of the device. Since the power required to switch the device is equal to the switching energy divided by the switching time, a shorter switching time will require more power. As an example, for a photonic device with an area of 100 μm^2 and a switching energy of 1 $fJ/\mu m^2$ to change states in 1 ps requires 100 mW of power instead of the 100 μW that would be required if the device were to switch at 1 ns. Thus, for high power signals the device will change states rapidly, while low power signals yield a slow switching response.

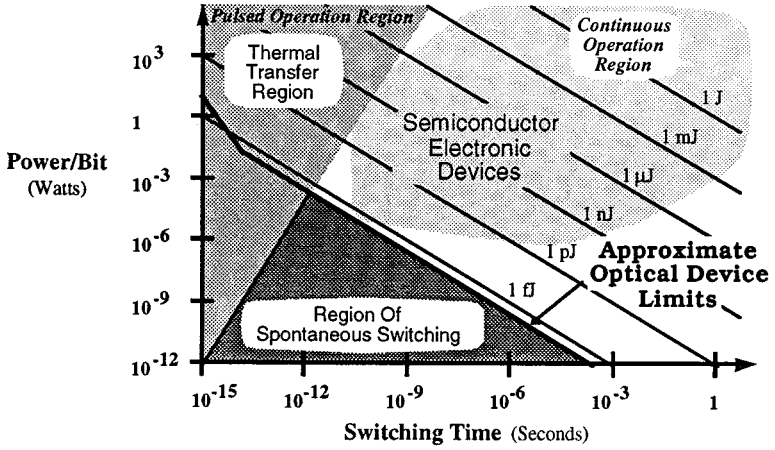

FIGURE 79.30 Fundamental limitations of optical logic devices.

Some approximate limits on the possible switching times of a given device, whether optical or electrical, are illustrated in Fig. 79.30. In this figure the time required to switch the state of a device is on the abscissa while the power/bit required to switch the state of a device is on the ordinate. The region of spontaneous switching is the result of the background thermal energy that is present in a device. If the switching energy for the device is too low, the background thermal energy will cause the device to change states spontaneously. To prevent these random transitions in the state of a device, the switching energy required by the device must be much larger than the background thermal energy. To be able to differentiate statistically between two states, this figure assumes that each bit should be composed of at least 1000 photons. Thus, the total energy of 1000 photons sets the approximate boundary for this region of spontaneous switching. For a wavelength of 850 nm, this implies a minimum switching energy on the order of 0.2 fJ. For the thermal transfer region, it is assumed that for continuous operation, the thermal energy present in the device cannot be removed any faster than 100 W/cm^2 (1 μW/μm^2). There has been some work done to indicate that this value could be as large as 1000 W/cm^2. This region also assumes that there will be no more than an increase of 20°C in the temperature of the device. Devices can be operated in this region using a pulsed rather than continuous mode of operation. Thus, high energy pulses can be used if sufficient time is allowed between pulses to allow the absorbed energy to be removed from the devices. The cloud in Fig. 79.30 represents the performance capabilities of current electronic devices. This figure illustrates that optical devices will not be able to switch states orders of magnitude faster than electronic devices when the system is in a continuous rather than a pulsed mode of operation. There are, however, other considerations in the use of photonic switching devices than how fast a single device can change states. Assume that several physically small devices need to be interconnected so that the state information of one device can be used to control the state of another device. To communicate this information, there needs to be some type of interconnection with a large bandwidth that will allow short pulses to travel between the separated devices. Fortunately, the optical domain can support the bandwidth necessary to allow bit rates in excess of 100 Gb/s, which will allow high-speed communication between these individual switching devices. In the electrical domain, the communications bandwidth between two or more devices is limited by the resistance, capacitance, and inductance of the path between the different devices. Therefore, even though photonic devices cannot switch orders of magnitude faster than their electronic counterparts, the communications capability or transmission bandwidth present in the optical domain should allow higher data rate systems than are possible in the electrical domain.

Defining Terms

Light-amplifying optical switch (LAOS): Vertically integrated heterojunction phototransistor and light-emitting diode which has latching thyristor-type current-voltage characteristics.

Liquid-crystal light valve (LCLV): Optical controlled spatial light modulator based on liquid crystals.

Multiple quantum well (MQW): Collection of alternating thin layers of semiconductors (e.g., GaAs and AlGaAs) that results in strong peaks in the absorption spectrum which can be shifted with an applied voltage.

Nonlinear Fabry-Perot (NLFP): Fabry-Perot etalon or interferometer that has an optically nonlinear medium in its cavity.

Optical logic etalon (OLE): Pulsed nonlinear Fabry-Perot etalon that requires two wavelengths (λ_1 = signal, λ_2 = clock).

PLZT/Si: Technology based on conventional silicon electronics using silicon detectors for the device inputs and PLZT modulators for the outputs.

Sagnac logic gate: An all-optical gate based on a Sagnac interferometer. A Sagnac interferometer is composed of two coils of optical fiber arranged so that light from a single source travels clockwise in one and counterclockwise in the other.

SEED technology: Any device based on multiple quantum well (MQW) modulators.

Soliton: Any isolated wave that propagates without dispersion of energy.

Surface-emitting laser logic (CELL): Device that integrates a phototransistor with a low threshold vertical-cavity surface-emitting laser.

80.1 Integrated Circuits (RAM, ROM)

W. David Pricer

The major forms of semiconductor memory in descending order of present economic importance are

1. Dynamic Random-Access Memories (DRAMs)
2. Static Random-Access Memories (SRAMs)
3. Nonvolatile Programmable Memories (PROMs, EEPROMs, EAROMs, EPROMs)
4. Read-Only Memories (ROMs)

DRAMs and SRAMs differ little in their applications. DRAMs are distinguished from SRAMs in that no bistable electronic circuit internal to the storage cell maintains the information. Instead DRAM information is stored "dynamically" as charge on a capacitor. All modern designs feature one field-effect transistor (FET) to access the information for both reading and writing and a thin film capacitor for information storage. SRAMs maintain their bistability, so long as power is applied, by a cross-coupled pair of inverters within each storage cell. Almost always two additional transistors serve to access the internal nodes for reading and writing. Most modern cell designs are CMOS, with two P-channel and four N-channel FETs.

Programmable memories operate much like read-only memories with the important attribute that they can be programmed at least once, and some can be reprogrammed a million times or more. Storage is almost always by means of a floating-gate FET. Information in such storage cells is not indefinitely nonvolatile. The discharge time constant is on the order of ten years. ROMs are generally programmed by a custom information mask within the fabrication sequence. As the name implies, information thence can only be read. The information thus stored is truly nonvolatile, even when power is removed. This is the most dense form of semiconductor storage (and the least flexible). Other forms of semiconductor memories, such as associative memories and charge-coupled devices, are used rarely.

Dynamic RAMs (DRAMs)

The universally used storage cell circuit of one transistor and one capacitor has remained unchanged for over 20 years. The physical implementation, however, has undergone much diversity and many refinements. The innovation in physical implementation is driven primarily by the need to maintain a nearly constant value of capacitance while the surface area of the cell has decreased. A nearly fixed value of capacitance is needed to meet two important design goals. The cell has no internal amplification. Once the information is accessed, the stored voltage is vastly attenuated by the much larger bit line capacitance (see Fig. 80.1). The resulting signal must be kept larger than the resolution limits of the sensing amplifier. DRAMs in particular are also sensitive to a problem called soft errors. These are typically initiated by atomic events such as the incidence of a single alpha particle. An alpha particle can cause a spurious signal of 50,000 electrons or more. All modern DRAM designs resolve this problem by constructing the capacitor in space out of the plane of the transistors (see Fig. 80.2 for examples). Placing the capacitor in space unusable for transistor fabrication has allowed great strides in DRAM density, generally at the expense of fabrication complexity. DRAM chip capacity has increased by about a factor of four every three years.

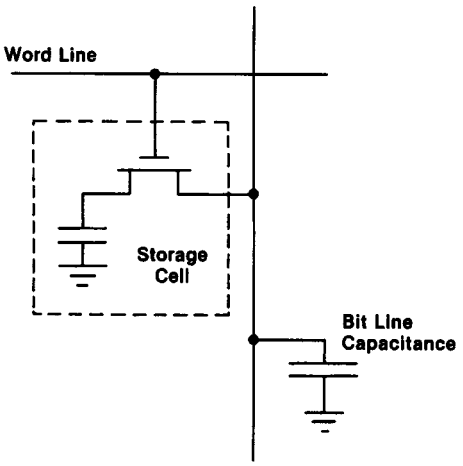

FIGURE 80.1 Cell and bit line capacitance.

DRAMs are somewhat slower than SRAMs. This relationship derives directly from the smaller signal available from DRAMs and from certain constraints put on the support circuitry by the DRAM array. DRAMs also

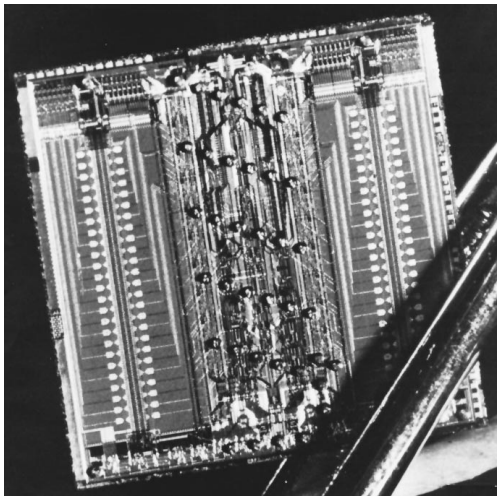
The Revolution of Electronics Technology

The last three decades have witnessed a revolution in electrical and, especially, electronics technology. This revolution was paced by changes in solid-state electronics that greatly expanded capabilities while at the same time radically reduced costs. The entire field of electrical engineering has grown far beyond the boundaries that characterized it just a generation ago. Electrical engineers have become the creators and masters of the most pervasive technology of our time, with profound effects on society and on their profession.

The effects of the electronics revolution are complex. For the profession, the most obvious impact has been explosive growth. The increase in the number of students studying in the field continues to be dramatic and shows no signs of slowing. The electrical engineering community represents the largest single technical group in the world, and the members of the IEEE make up the world's largest engineering society. (Courtesy of the IEEE Center for the History of Electrical Engineering.)



This 64-kB random access memory chip, developed by IBM in 1978, was one of the densest of its time. It could store as many as 64,000 bits of information—roughly equivalent to 1,000 eight-letter words. (Photo courtesy of the IEEE Center for the History of Electrical Engineering.)

require periodic intervals to "refresh" lost charge from the capacitor. This charge is lost primarily across the semiconductor junctions and must be replenished every few milliseconds. The manufacturer usually supplies these "housekeeping" functions with on-chip circuitry.

Signal detection and amplification remain a critical focus of good DRAM design. Figure 80.3 illustrates an arrangement called a "folded bit line." This design cancels many of the noise sources originating in the array and decreases circuit sensitivity to manufacturing process variations. It also achieves a high ratio of storage cells per sense amplifier. Note the presence of the dummy cells, which create a reference signal midway between a "one" and a "zero" for the convenience of the sense amplifier. The stored reference voltage in this case is created by shorting two driven bit lines after one of the storage cells has been written.

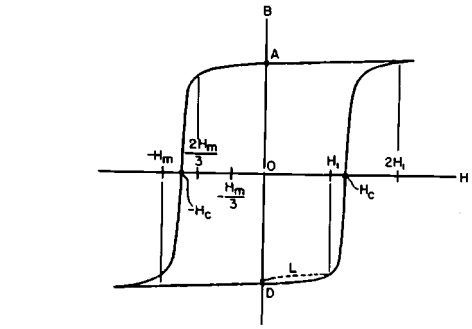
Large DRAM integrated circuit chips frequently provide other features that users may find useful. Faster access is provided between certain adjacent addresses, usually along a common word line. Some designs feature on-chip buffer memories, low standby power modes, or error correction circuitry. A few DRAM chips are designed to mesh with the constraints of particular applications such as image support for CRT displays. Some on-chip features are effectively hidden from the user. These may include redundant memory addresses which the maker activates by laser to improve manufacturing yield.

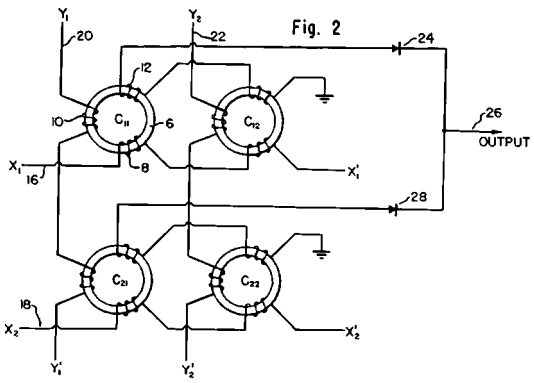
The largest single market for DRAMs is with microprocessors in personal computers. Rapid microprocessor performance improvements have led DRAM manufacturers to offer improvements especially designed for the "PC" environment. Extended Data Out mode (EDO) keeps the data accessed from a DRAM valid over a longer period of the DRAM cycle. EDO mode is intended to ease the synchronization problem between a DRAM and the increasingly higher speed microprocessor. Synchronous DRAM (SDRAM) allows the rapid sequential

Multicoordinate Digital Information Storage Device

Jay W. Forrester
Patented February 28, 1956
#2,736,880

Up to this time, digital data storage was generally done by encoding binary data on rotating magnetic drums or other means where data had to be stored and retrieved sequentially. This patent describes a system whereby data could be stored and retrieved randomly by a simple addressing scheme. It used tiny doughnut-shaped ferromagnetic cores with windings to magnetically polarize the material in one direction or the other. This was about one hundred times faster than rotating drums and took up perhaps 2% of the volume. A 4-Kbyte core memory module would take up about 60 cubic inches and could access data in less than one millisecond. Random access memory (RAM) was born. Core memory (as it has become known) was non-volatile; that is, the information would not be lost when power was cut. Modern non-volatile "flash" memory is yet again thousands of times faster and achieves data density of over 100,000 times greater than the breakthrough magnetic core memory described by Forrester. (Copyright © 1995, DewRay Products, Inc. Used with permission.)





transfer of large blocks of data between the microprocessor and the DRAM without extensive signal "handshaking". While SDRAMs do nothing to improve the access time to first data, they greatly improve the "bandwidth" between microprocessor and DRAM.

Static RAMs (SRAMs)

The primary advantages of SRAMs as compared to DRAMs are high speed and ease of use. In addition, SRAMs fabricated in CMOS technology exhibit extremely low standby power. This later feature is effectively used in much portable equipment like pocket calculators. Bipolar SRAMs are generally faster but less dense than FET versions. Figure 80.4 illustrates two cells. SRAM performance is dominated by the speed of the support circuits, leading some manufacturers to design bipolar support circuits to FET arrays.

Bipolar designs frequently incorporate circuit consolidation unavailable in FET technology, such as the multiemitter cell shown in Fig. 80.4(a). Here one of the two lower emitters is normally forward biased, turning one inverter on and the other off for bistability. The upper emitters can be used either to extract a differential signal

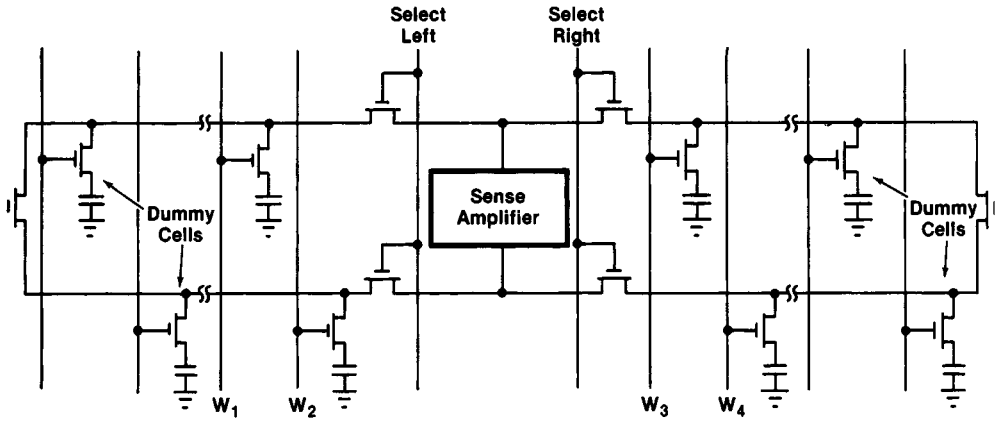


FIGURE 80.3 Folded bit line array.

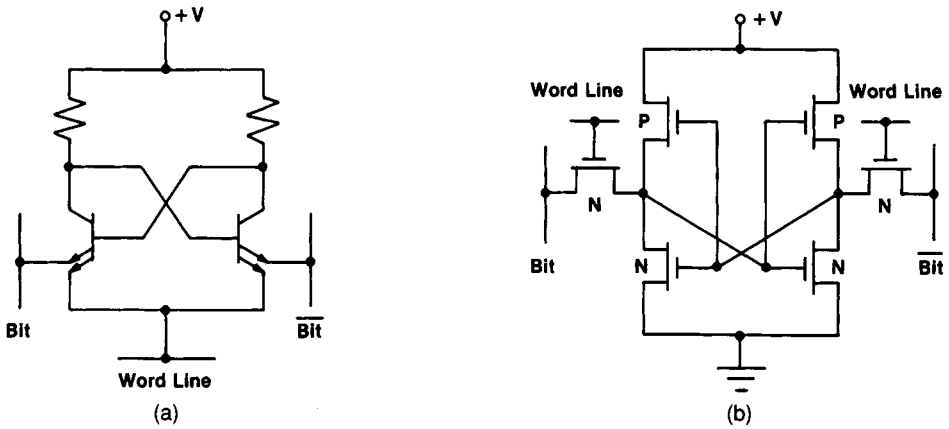

FIGURE 80.4 (a) Bipolar SRAM cell. (b) CMOS SRAM cell.

or to discharge one collector towards ground in order to write the cell. The word line is pulsed positive to both read and write the cell.

A few RAMs use **polysilicon** load resistors of very high resistance value in place of the two P-channel transistors shown in Fig. 80.4(b). Most are full CMOS designs like the one shown. Sometimes the P-channel transistors are constructed by thin film techniques and are physically placed over the N-channel transistors to improve density. When both P- and N-channel transistors are fabricated in the same plane of the single-crystal semiconductor, the standby current can be extremely low. Typically this can be microamps for megabit chips. The low standby current is possible because each cell sources and sinks only that current needed to overcome the actual node leakage within the cell.

Selecting the proper transconductance for each transistor is an important focus of the designer. The accessing transistors should be large enough to extract a large read signal but insufficiently large to disturb the stored information. During the write operation, these same transistors must be capable of overriding the current drive of at least one of the internal CMOS inverters.

The superior performance of SRAMs derives from their larger signal and the absence of a need to refresh the stored information as in a DRAM. As a result, SRAMs need fewer sense amplifiers. Likewise these amplifiers are not constrained to match the cell pitch of the array. SRAM design engineers have exploited this freedom to realize higher-performance sense amplifiers.

Practical SRAM designs routinely achieve access times of a few nanoseconds to a few tens of nanoseconds. Cycle time typically equals access time, and in at least one pipelined design, cycle time is actually less than access time.

SRAM integrated circuit chips have fewer special on-chip features than DRAM chips, primarily because no special performance enhancements are needed. By contrast, many other integrated circuit chips feature on-chip SRAMs. For example, many **ASICs (application-specific integrated circuits)** feature on-chip RAMs because of their low power and ease of use.

All modern microprocessors include one or more on-chip "cache" SRAM memories which provide a high speed link between processor and memory.

Nonvolatile Programmable Memories

A few nonvolatile memories are programmable just once. These have arrays of diodes or transistors with fuses or **antifuses** in series with each semiconductor cross point. Aluminum, titanium, tungsten, platinum silicide, and polysilicon have all been successfully used as fuse technology (see Fig. 80.5).

Most nonvolatile cells rely on trapped charge stored on a floating gate in an FET. These can be rewritten many times. The trapped charge is subject to very long term leakage, on the order of ten years. The number of times the cell may be rewritten is limited by programming stress-induced degradation of the dielectric. Charge reaches the floating gate either by **tunneling** or by **avalanche injection** from a region near the drain. Both phenomena are induced by over-voltage conditions and hence the degradation after repeated erase/write cycles. Commercially available chips typically promise 100 to 100,000 write cycles. Erasure of charge from the floating gate may be by tunneling or by exposure to ultraviolet light. Asperities on the polysilicon gate and silicon-rich oxide have both been shown to enhance charging and discharging of the gate. The nomenclature used is not entirely consistent throughout the industry. However, EPROM is generally used to describe cells which are electronically written but UV erased. EEPROM is used to describe cells which are electronically both written and erased.

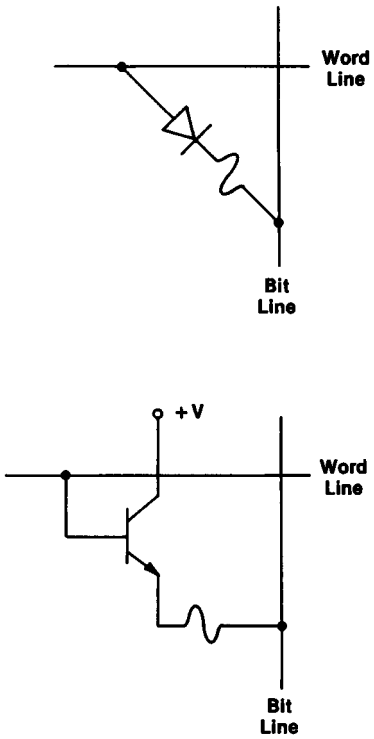

FIGURE 80.5 PROM cells.

Cells are of either a two- or a one-transistor design. Where two transistors are used, the second transistor is a conventional **enhancement mode** transistor (see Fig. 80.6). The second transistor works to minimize the disturb of unselected cells. It also removes some constraints on the writing limits of the programmable transistor, which in one state may be **depletion mode**. The two transistors in series then assume the threshold of the second (enhancement) transistor, or a very high threshold as determined by the programmable transistor. Some designs are so cleverly integrated that the features of the two transistors are merged.

Flash EEPROMs describe a family of single-transistor cell EPPROMs. Cell sizes are about half that of two-transistor EEPROMs, an important economic consideration. Care must be taken that these cells are not programmed into the depletion mode. An array of depletion mode cells would confound the read operation by providing multiple signal paths. Programming to enhancement only thresholds can be accomplished by a sequence of partial program and then monitor subcycles, until the threshold is brought to compliance with specification limits. Flash EEPROMs require bulk erasure of large portions of the array.

NVRAM is a term used to describe a SRAM or DRAM with nonvolatile circuit elements. The cell is built to operate as a RAM with normal power applied. On command or with power failure imminent, the EEPROM elements can be activated to capture the last state of the RAM cell. The nonvolatile information is restored to a SRAM cell by normal internal cell regeneration when power is restored.

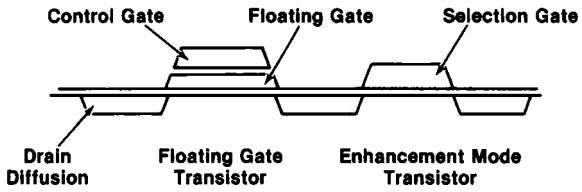

FIGURE 80.6 Cross section of two-transistor EEPROM cells.

Read-Only Memories (ROMs)

ROMs are the only form of semiconductor storage which is permanently nonvolatile. Information is retained without power applied, and there is not even very gradual information loss as in EEPROMs. It is also the most dense form of semiconductor storage. ROMs are, however, less used than RAMs or EEPROMs. ROMs must be personalized by a mask in the fabrication process. This method is cumbersome and expensive unless many identical parts are to be made. Furthermore it seems much "permanent" information is not really permanent and must be occasionally updated.

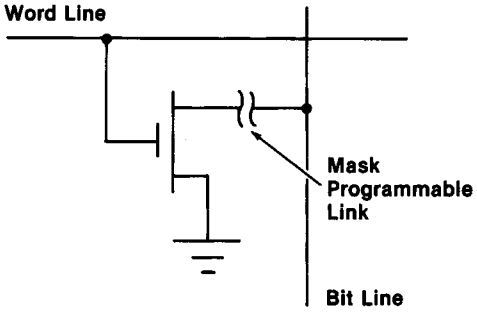

FIGURE 80.7 ROM cell.

ROM cells can be formed as diodes or transistors at every intersection of the word and bit lines of a ROM array (see Fig. 80.7). One of the masks in the chip fabrication process programs which of these devices will be active. Clever layout and circuit techniques may be used to obtain further density. Two such techniques are illustrated in Figs. 80.8 and 80.9. The X array shares bit and virtual ground lines. The AND array places many ROM cells in series. Each of these series AND ROM cells is either

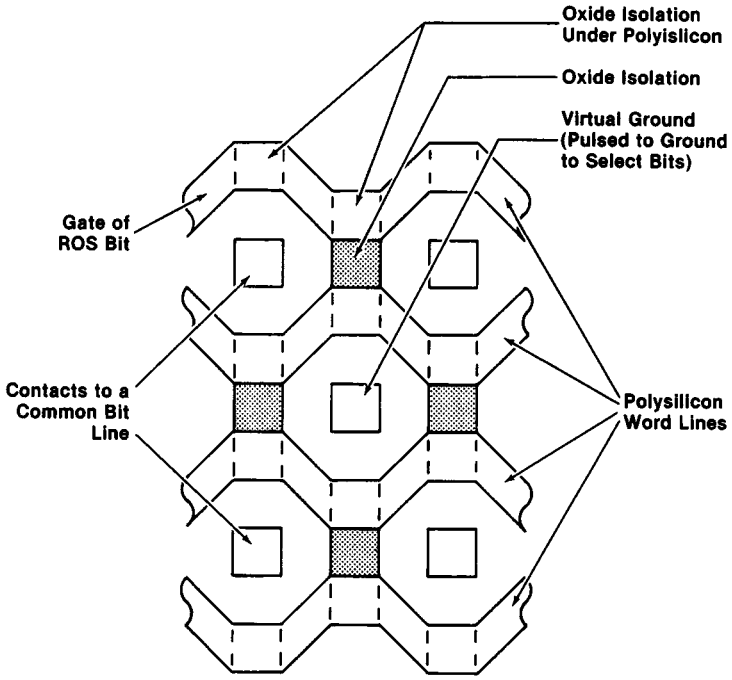

FIGURE 80.8 Layout of ROS X array.

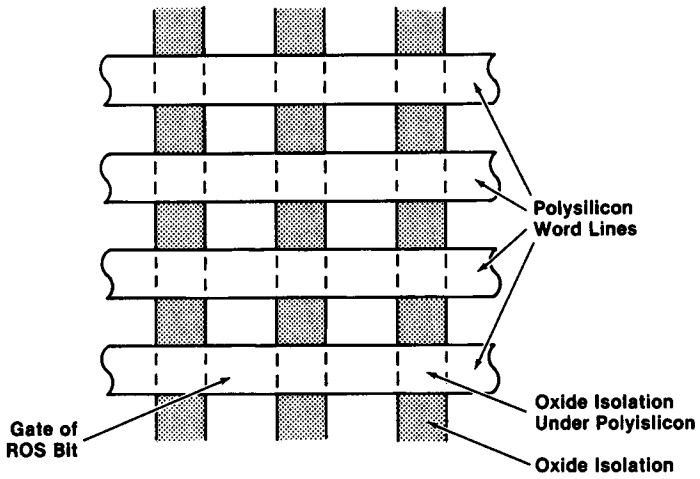

FIGURE 80.9 Layout of ROS AND array.

an enhancement or a depletion channel of an FET. Sensing is accomplished by pulsing the gates of all series cells positive except the gate which is to be interrogated. Current will flow through all series channels only if the interrogated channel is depletion mode.

ROM applications include look-up tables, machine-level instruction code for computers, and small arrays used to perform logic (see PLA in Section 81.4 of this handbook).

Defining Terms

Antifuse: A fuse-like device which when activated becomes low impedance.

Application-specific integrated circuits (ASICs): Integrated circuits specifically designed for one particular application.

Avalanche injection: The physics whereby electrons highly energized in avalanche current at a semiconductor junction can penetrate into a dielectric.

Depletion mode: An FET which is on when zero volts bias is applied from gate to source.

Enhancement mode: An FET which is off when zero volts bias is applied from gate to source.

Polysilicon: Silicon in polycrystalline form.

Tunneling: A physical phenomenon whereby an electron can move instantly through a thin dielectric.

80.2 Basic Disk System Architectures

Randy H. Katz

Architects of high-performance computers have long been forced to acknowledge the existence of a large gap between the speed of the CPU and the speed of its attached I/O devices. A number of techniques have been developed in an attempt to narrow this gap, and we shall review them in this chapter.

A key measure of magnetic disk technology is the growth in the maximum number of bits that can be stored per square inch, i.e., the bits per inch in a disk **track** times the number of tracks per inch of media. Called MAD, for **maximal areal density**, the "First Law in Disk Density" predicts [Frank, 1987]:

$$MAD = 10^{(\text{Year-}1971)/10} \tag{80.1}$$

This is plotted against several real disk products in Fig. 80.10. Magnetic disk technology has doubled capacity and halved price every three years, in line with the growth rate of semiconductor memory. Between 1967 and 1979 the growth in disk capacity of the average IBM data processing system more than kept up with its growth in main memory, maintaining a ratio of 1000:1 between disk capacity and physical memory size [Stevens, 1981].

In contrast to primary memory technologies, the performance of conventional magnetic disks has improved only modestly. These *mechanical* devices, the elements of which are described in more detail in the next section, are dominated by seek and rotation delays: from 1971 to 1981, the raw seek time for a high-end IBM disk improved by only a factor of two while the rotation time did not change [Harker et al., 1981]. Greater recording density translates into a higher transfer rate once the information is located, and extra positioning actuators for the read/write **heads** can reduce the average seek time, but the raw seek time only improved at a rate of 7% per year. This is to be compared to a doubling in processor power every year, a doubling in memory density every two years, and a doubling in disk density every three years. The gap between processor performance and disk speeds continues to widen, and there is no reason to expect a radical improvement in raw disk performance in the near future.

To maintain balance, computer systems have been using even larger main memories or solid-state disks to buffer some of the I/O activity. This may be an acceptable solution for applications whose I/O activity has locality of reference and for which volatility is not an issue, but applications dominated by a high rate of random requests for small pieces of data (e.g., transaction processing) or by a small number of sequential requests for massive amounts of data (e.g., supercomputer applications) face a serious performance limitation.

The rest of the chapter is organized as follows. In the next section, we will briefly review the fundamentals of disk system architecture. The third section describes the characteristics of the applications that demand high I/O system performance. Conventional ways to improve disk performance are discussed in the last section.

Basic Magnetic Disk System Architecture

We will review here the basic terminology of magnetic disk devices and controllers and then examine the disk subsystems of three manufacturers (IBM, Cray, and DEC). Throughout this section we are concerned with technologies that support random access, rather than sequential access (e.g., magnetic tape). A more detailed discussion, focusing on the structure of small dimension disk drives, can be found in Vasudeva [1988]. The basic concepts are illustrated in Fig. 80.11. A spindle consists of a collection of platters. Platters are metal disks

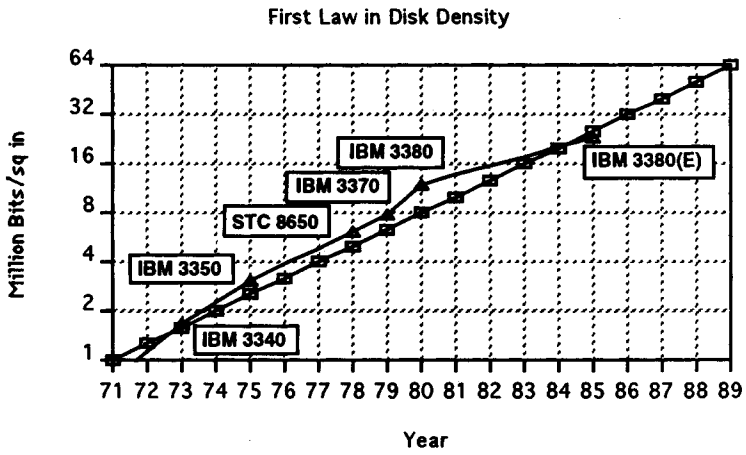

FIGURE 80.10 Maximal areal density law. Squares represent predicted density; triangles are the MAD reported for the indicated products.

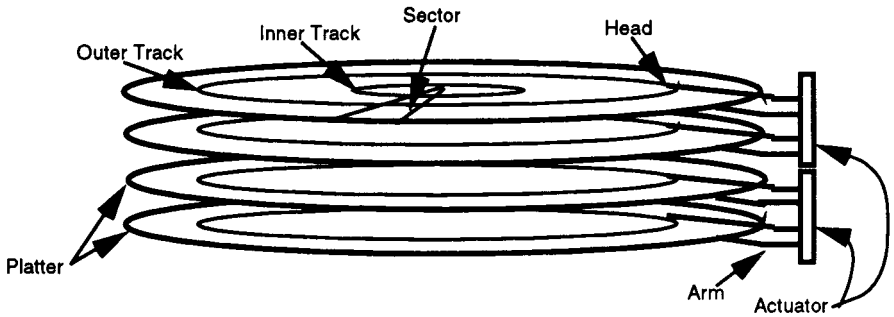

FIGURE 80.11 Disk terminology. Heads reside on arms which are positioned by actuators. Tracks are concentric rings on platters. A sector is the basic unit of read/write. A cylinder is a stack of tracks at one actuator position. An HDA is everything in the figure plus the air-tight casing. In some devices it is possible to transfer from multiple surfaces simultaneously. The collection of heads that participate in a single logical transfer that is spread over multiple surfaces is called a head group.

covered with a magnetic material for recording information. Each platter contains a number of circular recording *tracks*. A sector is a unit of a track that is physically read or written at the same time. In traditional magnetic disks, the constant angular rotation of the platters dictates that sectors on inner tracks are recorded more densely than sectors on the outer tracks. Thus, the platter can spin at a constant rate and the same amount of data can be recorded on the inner and outer tracks.[1] Some modern disks use zone recording techniques to more densely record data on the outer tracks, but this requires more sophisticated read/write electronics.

The read/write *head* is an electromagnet that produces switchable magnetic fields to read and record bit streams on a platter's track. It is associated with a disk **arm**, attached to an actuator. The head "flies" close to, but never touches, the rotating platter (except perhaps when powered down). This is the classical definition of a **Winchester disk.** The actuator is a mechanical assembly that positions the head electronics over the appropriate track. It is possible to have multiple read/write mechanisms per surface, e.g., multiple heads per arm—at one extreme, one could have a head-per-track position, that is, the disk equivalent of a magnetic drum—or

[1]Some optical disks use a technique called constant linear velocity (CLV), where the platter rotates at different speeds depending on the relative position of the track. This allows more data to be stored on the outer tracks than the inner tracks, but because it takes more delay to vary the speed of rotation, the technique is better suited to sequential rather than random access.

multiple arms per surface through multiple actuators. Due to costs and technical limitations, it is usually uneconomical to build a device with a large number of actuators and heads.

A **cylinder** is a stack of tracks at one actuator position. A **head disk assembly** (HDA) is the collection of platters, heads, arms, and actuators, plus the air-tight casing. A *disk drive* is an HDA plus all associated electronics. A *disk* might be a platter, an actuator, or a drive depending the context.

We can illustrate these concepts by describing two first-generation supercomputer disks, the Cray DD-19 and the CDC 819 [Bucher and Hayes, 1980]. These were state-of-the-art disks around 1980. Each disk has 40 recording surfaces (20 platters), 411 cylinders, and 18 (DD-19) or 20 (CDC 819) 512-byte sectors per track. Both disks possess a limited "parallel read-out" capability. A given data word is actually byte interleaved over four surfaces. Rather than a single set of read/write electronics for the actuator, these disks have four sets, so it is possible to read or write with four heads at a time. Four heads on adjacent arms are called a *head group*. A disk track is thus composed of the stacked recording tracks of four adjacent surfaces, and there are 10 tracks per cylinder, spread over 40 surfaces. The advances over the last decade can be illustrated by the Cray DD-49, which is a typical high-end supercomputer disk of today. It consists of 16 recording surfaces (9 platters), 886 cylinders, 42 4096-byte sectors per track, with 32 read/write heads organized into eight head groups, four groups on each of two independent actuators. Each actuator can sweep the entire range of tracks, and by "scheduling" the arms to position the actuator closest to the target track of the pending request, the average seek time can be reduced. The DD-49 has a capacity of 1.2 Gbytes of storage and can transfer at a sustained rate of 9.6 Mbytes/s.

A variety of standard and proprietary interfaces are defined for transferring the data recorded on the disk to or from the host. We concentrate on industry standards here. On the disk surface, information is represented as alternating polarities of magnetic fields. These signals need to be sensed, amplified, and decoded into synchronized pulses by the read electronics. For example, the pulse-level protocol ST506/412 standard describes the way pulses can be extracted from the alternating flux fields. The bit-level ESDI, SMD, and IPI-2 standards describe the bit encoding of signals. At the packet level, these bits must be aligned into bytes, error correcting codes need to be applied, and the extracted data must be delivered to the host. These "intelligent" standards include SCSI (small computer standard interface) and IPI-3.

The ST506 is a low-cost but primitive interface, most appropriate for interfacing floppy disks to personal computers and low-end workstations. For example, the controller must perform data separation on its own; this is not done for it by the disk device. As a result, its transfer rate is limited to 0.625 Mbytes/s. The SMD interface is higher performance and is used extensively in connecting disks to mainframe disk controllers. ESDI is similar, but geared more towards smaller disk systems. One of its innovations over the ST506 is its ability to specify a seek to a particular track number rather than requiring track positioning via step-by-step pulses. Its performance is in the range of 1.25–1.875 Mbytes/s. SCSI has so far been used primarily with workstations and minicomputers, but offers the highest degree of integration and intelligence. Implementations with performance at the level of 1.5–4 Mbytes/s are common. The newer IPI-3 standard has the advantages of SCSI, but provides even higher performance at a higher cost. It is beginning to make inroads into mainframe systems. However, because of the very widespread use of SCSI, many believe that SCSI-2, an extension of SCSI to wider signal paths, will become the de facto standard for high-performance small disks.

The connection pathway between the host and the disk device varies widely depending on the desired level of performance. A low-end workstation or personal computer would use a SCSI interface to directly connect the device to the host. A higher end file server or minicomputer would typically use a separate disk controller to manage several devices at the same time. These devices attach to the controller through SMD interfaces. It is the controller's responsibility to implement error checking and corrections and direct memory transfer to the host.

Mainframes tend to have more devices and more complex interconnection schemes to access them. In IBM terminology [Buzen and Shum, 1986], the *channel path*, i.e., the set of cables and associated electronics that transfer data and control information between an I/O device and main memory, consists of a *channel*, a *storage director*, and a *head of string* (see Fig. 80.12). The collection of disks that share the same pathway to the head of string is called a *string*.

In earlier IBM systems, a channel path and channel are essentially the same thing. The channel processor is the hardware that executes channel programs, which are fetched from the host's memory. A *subchannel* is the

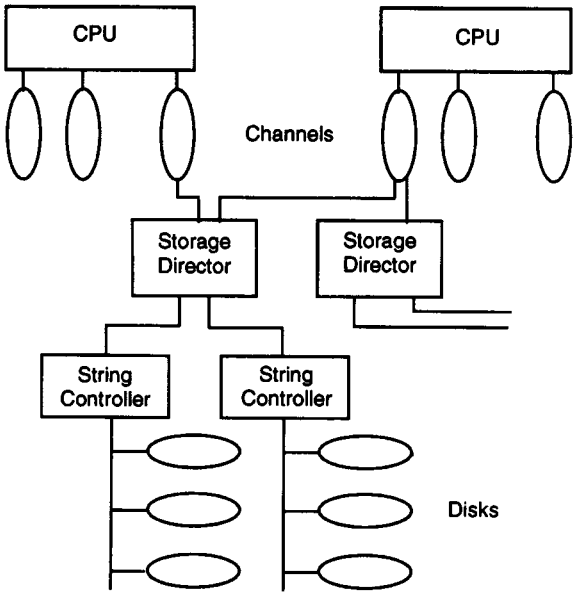

FIGURE 80.12 Host-to-device pathways. For large IBM mainframes, the connection between host and device must pass through a channel, storage director, and string controller. Note that multiple storage directors can be attached to a channel, multiple string controllers per storage director, and multiple devices per string controller. This multipathing approach makes it possible to share devices among hosts and to provide alternative pathways to better utilize the drives and controllers. While logically correct, the figure does not reflect the true physical components of high-end IBM systems (308X, 3090). The concept of channel has disappeared from these systems and has been replaced by a channel path.

execution environment of a channel program, similar to a process on a conventional CPU. Formerly, a subchannel was statically assigned for execution to a particular channel, but a major innovation in high-end IBM systems (308X and 3090) allows subchannels to be dynamically switched among channel paths. This is like allocating a process to a new processor within a multiprocessor system every time it is rescheduled for execution.

I/O program control statements, e.g., *transfer in channel*, are interpreted by the channel, while the storage director (also known as the *device controller* or *control unit*) handles seek and data-transfer requests. Besides these control functions, it may also perform certain datapath functions, such as error detection/correction and mapping between serial and parallel data. In response to requests from the storage director, the device will position the access mechanism, select the appropriate head, and perform the read or write. If the storage director is simply a control unit, then the datapath functions will be handled by the head of string (also known as a *string controller*).

To minimize the **latency** caused by copying into and out of buffers, the IBM I/O system uses little buffering between the device and memory.[1] In a high-performance environment, devices spend a good deal of time waiting for the pathway's resources to become free. These resources are used for time periods related to disk transfer speeds, measured in milliseconds. One possible method for improving utilization is to support disconnect/reconnect. A subchannel can connect to a device, issue a seek, disconnect to free the channel path for other requests, and reconnect later to perform the transfer when the seek is completed. Unfortunately, not all reconnects can be serviced immediately, because the control units are busy servicing other devices. These *RPS misses* (to be described in more detail in the next section) are a major source of delay in heavily utilized IBM storage subsystems [Buzen and Shum, 1987]. Performance can be further improved by providing multiple paths between memory and devices. To this purpose, IBM's high-end systems support *dynamic path reconnect*, a

[1]Only the most recent generation of storage directors (e.g., IBM 3880, 3990) incorporate disk caches, but care must be taken to avoid cache management-related delays [Buzen, 1982].

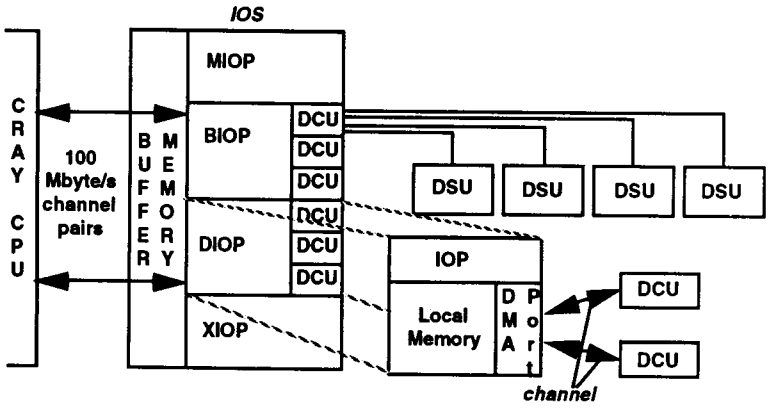

FIGURE 80.13 Elements of the Cray I/O system for the Y-MP. An IOS contains up to four IOPs. The MIOP connects to the operator workstation and performs mainly maintenance functions. The XIOP supports block multiplexing and is most appropriate for controlling relatively slow speed devices, such as tapes. The BIOP and DIOP are designed for controlling high-speed devices like disks. Up to four disk storage units (DSUs) can be attached through the disk control unit (DCU) to the IOP. Three DCUs can be connected to each of the BIOP and DIOP, leading to a total of 24 disks per IOS. The Y-MP can be configured with two IOSs, for a system total of 48 devices.

mechanism that allows a subchannel to change its channel path each time it cycles through a disconnect/reconnect with a given device. Rather than wait for its currently allocated path to become free, it can be assigned to another available path.

Turning to supercomputer I/O systems, we will now examine the I/O architecture of the Cray machines. Because the Cray I/O system (IOS) varies from model to model, the following discussion concentrates on the IOS found on the Cray X-MP and Y-MP [Cray, 1988]. In general, the IOS consists of two to four I/O processors (IOPs), each with its own local memory and sharing a common buffer memory with the other IOPs. The IOP is designed to be a simple, fast machine for controlling data transfers between devices and the central memory of the Cray main processors. Since it executes the control statements of an I/O program, it is not unlike the IBM channel processor in terms of its functionality, except that IO programs reside in its local memory rather than in the host's. An IOP's local memory is connected through a high-speed communications interface, called a *channel* in Cray terminology, to a disk control unit (DCU). A given port into the local memory can be time multiplexed among multiple channels. Data is transferred back and forth between devices and the main processors through the IOP's local memory, which is interfaced to central memory through a 100-Mbyte/s channel pair (one pathway for each direction of transfer).

The DCU provides the interface between the IOP and the disk drives and is similar in functionality to IBM's storage director. It oversees the data transfers between devices and the IOP's local memory, provides speed matching buffer storage, and transmits control signals and status information between the IOP and the devices. Disk storage units (DSUs) are attached to the DCU through point-to-point connections. The DSU contains the disk device and is responsible for dealing with its own defect management, by using a technique called sector slipping. Figure 80.13 summarizes the elements of the Cray I/O system.

Digital Equipment Corporation's high-end I/O strategy is described in terms of the digital storage architecture (DSA) and is embodied in system configurations such as the VAXCluster shared disk system (see Fig. 80.14). The architecture provides a rigorous definition of how storage subsystems and host computers interact. It achieves this by defining a client/server message-based model for I/O interaction based on device-independent interfaces [Massiglia, 1986; Kronenberg et al., 1986]. A *mass storage subsystem* is viewed at the architectural level as consisting of logical block machines capable of storing and retrieving fixed blocks of data, i.e., the I/O system supports the transfer of logical blocks between CPUs and devices given a logical block number. From the viewpoint of physical components, a subsystem consists of *controllers* which connect computers to *drives.*

The software architecture is divided into four levels: the *Operating System Client* (also called the Class Driver), the *Class Server* (Controller), the *Device Client* (Data Controller), and the *Device Server* (Device). The Disk Class Driver, resident on a host CPU, accepts requests for disk I/O service from applications, packages these

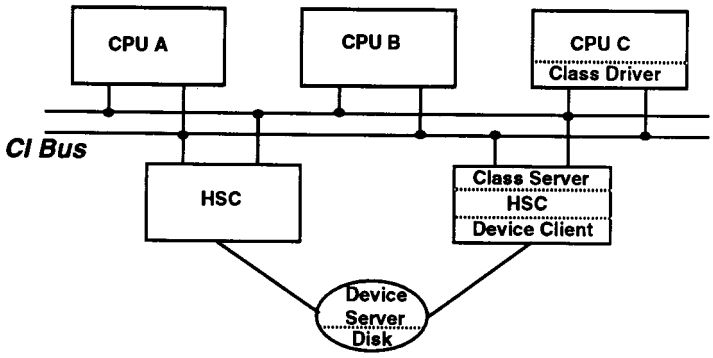

FIGURE 80.14 VAXCluster architecture. CPUs are connected to HSCs (hierarchical storage controllers) through a dual CI (computer interconnect) bus. Thirty-one hosts and 31 HSCs can be connected to a CI. Up to 32 disks can be connected to an HSC-70.

requests into messages, and transmits them via a communications interface (such as the *Computer Interconnect* port driver) to the Disk Class Server resident within a controller in the I/O subsystem. The command set supported by the Class Server includes such relatively device-independent operations as read logical block, write logical block, bring on-line, and request status. The Disk Class Server[1] interprets the transmitted commands, handles the scheduling of command execution, tracks their progress, and reports status back to the Class Driver. Note the absence of seek or select head commands. This interface can be used equally well for solid-state disks as for conventional magnetic disks. Device-specific commands are issued at a lower level of the architecture, i.e., between the Device Client (disk controller) and Device Server (disk device). The former provides the path for moving commands and data between hosts and drives, and it is usually realized physically by a piece of hardware that corresponds to the device controller. The latter coincides with the physical drives used for storing and retrieving data.

It is interesting to contrast these proprietary approaches with an industry standard approach like SCSI, admittedly targeted for the low to mid range of performance. SCSI defines the logical and physical interface between a host bus adapter (HBA) and a disk controller, usually embedded within the assembly of the disk device. The HBA accepts I/O requests from the host, initiates I/O actions by communicating with the controllers, and performs direct memory access transfers between its own buffers and the memory of the host. Requesters of service are called initiators, while providers of service are called targets. Up to eight nodes can reside on a single SCSI string, sharing a common pathway to the HBA. The embedded controller performs device handling and error recovery. Physically, the interface is implemented with a single daisy-chained cable, and the 8-bit datapath is used to communicate control and status information, as well as data. SCSI defines a layered communications protocol, including a message layer for protocol and status, and a command/status layer for target operation execution. The HBA roughly corresponds to the function of the IBM channel processor or Cray IOP, while the embedded controller is similar to the IBM storage director/string controller or the Cray DCU. Despite the differences in terminology, the systems we have surveyed exhibut significant commonality of function and similar approaches for partitioning these functions among hardware components.

Characterization of I/O Workloads

Before characterizing the I/O behavior of different workloads, it is necessary to first understand the elements of disk performance. Disk performance is a function of the service time, which consists of three main components: *seek time*, *rotational latency*, and *data transfer time*.[2] **Seek time** is the time needed to position the heads

[1]Other kinds of class servers are also supported, such as for tape drives.

[2]In a heavily utilized system, delays waiting for a device can match actual disk service times, which in reality is composed of device queuing, controller overhead, seek, rotational latency, reconnect misses, error retries, and data transfer.

to the appropriate track position containing the desired data. It is a function of a substantial initial start-up cost to accelerate the disk head (on the order of 6 ms) as well as the number of tracks that must be traversed. Typical average seek times, i.e., the time to traverse between two randomly selected tracks (approximately 28% of the data band), are in the range of 10 to 20 ms. The track-to-track seek time is usually below 10 ms and as low as 2 ms.

The second component of service time is **rotational latency**. It takes some time for the desired sector to rotate under the head position before it can be read or written. Today's devices spin at a rate of approximately 3600 rpm, or 60 revolutions per second (we expect to see rotation speeds increase to 5400 rpm in the near future). For today's disks, a full revolution is 16 ms, and the average latency is 8 ms. Note that the worst-case latencies are comparable to average seeks.

The last component is the **transfer time,** i.e., the time to physically transfer the bytes from disk to the host. While the transfer time is a strong function of the number of bytes to be transferred, seek and rotational latencies times are independent of the transfer blocksize. If data is to be read or written in large chunks, it makes sense to choose a large blocksize, since the "fixed cost" of seek and latency is better amortized across a large data transfer.

A low-performance I/O system might dedicate the pathway between the host and the disk for the entire duration of the seek, rotate, and transfer times. Assuming small blocksizes, transfer time is a small component of the overall service time, and these pathways can be better utilized if they are shared among multiple devices. Thus, higher performance systems support independent seeks, in which a device can be directed to detach itself from the pathway while seeking to the desired track (recall the discussion of dynamic path reconnect in the previous section). The advantage is that multiple seeks can be overlapped, reducing overall I/O latency and better utilizing the available I/O **bandwidth**.

However, to make it possible for devices to reattach to the pathway, the I/O system must support a mechanism called **rotational position sensing,** i.e., the device interrupts the I/O controller when the desired sector is under the heads. If the pathway is currently in use, the device must pay a full rotational delay before it can again attempt to transfer. These rotational positional reconnect miss delays (RPS delays) represent a major source of degradation in many existing I/O systems [Buzen and Shum, 1987]. This arises from the lack of device buffering and the real-time service requirements of magnetic disks. At the time that these architectures were established, buffer memories were expensive and the demands for high I/O performance were less pressing with slower speed CPUs. An alternative, made more attractive by today's relative costs of electronic and mechanical components, is to associate a **track buffer** with the device that can be filled immediately. This can then be used as the source of the transfer when the pathway becomes available [Houtekamer, 1985].

I/O intensive applications vary widely in the demand they place on the I/O system. They run the gamut from processing small numbers of bulk I/Os that must be handled with minimum delay (supercomputer I/O) to large numbers of simple tasks that touch small amounts of data (transaction processing). An important design challenge is to develop an I/O system that can handle the performance needs of these diverse workloads.

A given workload's demand for I/O service can be specified in terms of three metrics: *throughput*, *latency*, and *bandwidth*. **Throughput** refers to the number of requests for service made per unit time. Latency measures how long it takes to service an individual request. Bandwidth gauges the amount of data flowing between service requesters (i.e., applications) and service providers (i.e., devices).

As observed by Bucher and Hayes [1980], supercomputer I/O can be characterized almost entirely by sequential I/O. Typically, computation parameters are moved in bulk from disk to in-memory data structures, and results are periodically written back to disk. These workloads demand large bandwidth and minimum latency, but are characterized by low throughput. Contrast this with transaction processing, which is characterized by enormous numbers of random accesses, relatively small units of work, and a demand for moderate latency with very high throughput.

Figure 80.15 shows another way of thinking about the varying demands of I/O intensive applications. It shows the percentage of time different applications spend in the three components of I/O service time. Transaction processing systems spend the majority of their service time in seek and rotational latency; thus technological advances which reduce the transfer time will not affect their performance very much. On the other hand, scientific applications spend a more equal amount of time in seek and data transfer, and their performance is sensitive to any improvement in disk technology.

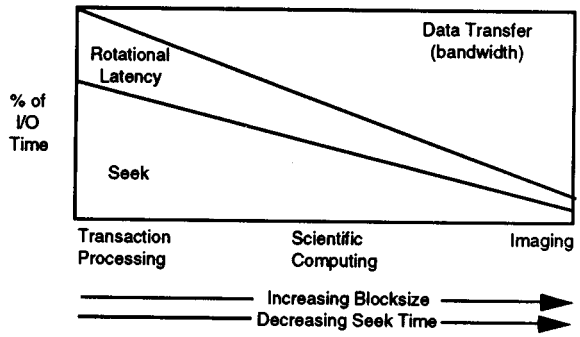

FIGURE 80.15 I/O system parameters as a function of application. Transaction processing applications are seek and rotational latency limited, since only small blocks are usually transferred from disk. Image-processing applications, on the other hand, transfer huge blocks and thus spend most of their I/O time in data transfer. Scientific computing applications tend to fall in between. (*Source:* I. Y. Bucher and A. H. Hayes, "I/O performance measurement on Cray-1 and CDC 7600 computers," *Proc. Cray Users Group Conference*, October 1980. With permission.)

Extensions to Conventional Disk Architectures

In this subsection, we will focus on techniques for improving the performance of conventional disk systems, i.e., methods which allow us to reduce the seek time, rotational latency, or transfer time of conventional disks. By reducing disk service times, we also decrease device queuing delays. These techniques include fixed-head disks, parallel transfer disks, increased disk density, solid-state disks, disk caches, and disk scheduling.

Fixed-Head Disk

The concept of a fixed-head disk is to place a read/write head at every track position. The need for positioning the heads is eliminated, thus eliminating the seek time altogether. The approach does not assist in reducing rotational latencies, nor does it lessen the transfer time. Fixed-head disks were often used in the early days of computing systems as a back-end store for virtual memory. However, since modern disks have hundreds of tracks per surface, placing a head at every position is no longer viewed as an economical solution.

Parallel Transfer Disks

Some high-performance disk drives make it possible to read or write from multiple disk surfaces at the same time. For example, the Cray DD-19 and DD-49 disks described in the second section have a parallel transfer capability. The advantage is that much higher transfer rates can be achieved, but no assistance is provided for seek or rotational latency. Thus transfer units are correspondingly larger in these systems.

A number of economic and technological issues limit the usefulness of parallel transfer disks. From the economic perspective, providing more than one set of read/write electronics *per actuator* is expensive. Further, current disks use sophisticated control systems to lock onto an individual track, and it is difficult to do this simultaneously across tracks within the same cylinder. Hence, the Cray strategy is limiting head groups to only four surfaces. There appears to be a fundamental trade-off between track density and the number of platters: as the track density increases, it becomes ever more difficult to lock onto tracks across many platters, and the number of surfaces that can participate in a parallel transfer is reduced. For example, current Cray track densities are around 980 tracks/inch, and require a rather sophisticated closed-loop track-following servo system to position the heads accurately with finely controlled voice coil actuators. A lower cost ($/megabyte) high-performance disk system can be constructed from several standard drives than from a single parallel transfer device, in part because of the relatively small sales volume of parallel transfer devices compared to standard drives.

Increasing Disk Density

As described in the first section, the improvements in disk recording density are likely to continue. Higher bit densities are achieved through a combination of the use of thinner films on the disk platters (e.g., densities improve from 16,000 bpi to 21,000 bpi when thick iron oxide is replaced with thin film materials), smaller gaps between the poles of the read/write head's electromagnet, and heads which fly closer to the disk surface.

While vertical recording techniques have long been touted as the technology of the future, advances in head technology make it possible to continue using conventional horizontal methods, but still keep disks on the MAD curve. These *magneto-resistive heads* employ noninductive methods for reading, which work well with dense horizontal recording fields. However, a more conventional head is needed for writing, but this dual-head organization permits separate optimizations for read and write.

Also, the choice of coding technique can have a significant effect on density. Standard modified frequency modulation techniques require approximately one flux change per bit, while more advanced run-length limited codes can increase density by an additional factor of 50%. Densities as high as 31,429 bpi can be attained with these techniques. As the recording densities increase, the transfer times decrease, as more bits transit beneath the heads per unit time. Of course, this approach provides no improvement in seek and latency times. Most of the increase in density comes from increases in the number of tracks per inch, which does not improve (and may actually reduce) performance.

Although increased densities are inevitable, the problem is primarily economic. Increasing the tracks per inch may make seeks slower as it becomes more time consuming for the heads to correctly "lock" onto the appropriate track. The sensing electronics get more complex and thus more expensive. Once again, it can be argued that higher capacity can be achieved at lower cost by using several smaller disks rather than one expensive high-density disk.

Solid-State Disks

Solid-state disks (SSD), constructed from relatively slow memory chips, can be viewed either as a kind of large and slow main memory or as a small and high-speed disk. When viewed as large main memory, the SSD is often called expanded storage (ES). The expanded storage found in the IBM 3090 class machines [Buzen and Shum, 1986] supports operations for paging data blocks from and to main memory. Usually, the expanded storage looks to the system more like memory than an I/O device: it is directly attached to main memory through a high-speed bus rather than an I/O controller. The maximum transfer bandwidth on the IBM 3090 between expanded store and memory is two orders of magnitude faster than conventional devices: approximately 216 Mbytes/s—one word each 18.5 ns!

Further, unlike conventional devices, a transfer between memory and expanded storage is performed synchronously with the CPU. This is viewed as acceptable, because the transfer requires so little time and does not involve the usual operating system overheads of I/O set-up and interrupts. Note that to transfer data from ES to disk requires the data to be first staged into main memory.

The Cray X-MP and Y-MP also support SSDs, which can come in configurations of up to 4096 Mbytes, approximately four times the capacity of the DD-49. The SSD has the potential for enormous bandwidth. It can be attached to the Cray IO system or directly to the CPU through up to two 1000-Mbyte/s channels. Access can be arranged in one of three ways [Reinhardt, 1988]. The first alternative is to treat the SSD as a logical disk, with users responsible for staging heavily accessed files to it. Unfortunately, this leads to the inevitable contention for SSD space. Further, the operating system's disk device drivers are not tuned for the special capabilities of SSDs, and some performance is lost. The second alternative is to use the SSD as an extended memory, in much the same manner as IBM's extended storage. Special system calls for accessing the SSD bypass the usual disk-handling code, and a 4096-byte sector can be accessed in 25 μs. The last alternative is to use the SSD as a logical device cache, i.e., as a second-level cache for multitrack chunks of files that resides between the system's in-main memory file cache and the physical disk devices. Cray engineers have observed workload speedups for their UNIX-like operating system of a factor of four over conventional disk when the cache is enabled. These results indicate that SSDs are most appropriate for containing "hot spot" data [Gawlick, 1987]. Conventional wisdom has it that 20% of the data receives 80% of the accesses, and this has been widely observed in transaction processing systems [Gawlick, 1987].

If SSDs are to be used to replace magnetic disks, then they must be made nonvolatile, and herein lies their greatest weakness. This can be achieved through battery back-up, but the technique is controversial. First, it is difficult to verify that the batteries will be fully charged when needed, i.e., when conventional power fails. Second, it is difficult to determine how long is long enough when powering the SSD with batteries. This should probably be long enough to off-load the disk's contents to magnetic media. Fortunately, low-power DRAM and wafer scale integration technology are making feasible longer battery hold times.

Another weakness is their cost. At the present time, there is more than a 10 to 20 times difference in price between the cost of a megabyte of magnetic disk memory and a megabyte of DRAM. While wafer scale integration may bring this price down in the future, for the near term SSDs will be limited to a staging or caching function.

Disk Caches

Disk caches place buffer memories between the host and the device. If disk data is likely to be re-referenced, caches can be effective in eliminating the seek and rotational latencies. Unfortunately, this effectiveness depends critically on the access behavior of the applications. Truly random access with little re-referencing cannot make effective use of disk caches. However, applications that exhibit a large degree of sequential access can use a cache to good purpose, because data can be staged into the cache before it is actually requested.

Disk caches can become even more useful if they are made nonvolatile using the battery back-up techniques described in the previous subsection (and with the same potential problems). A nonvolatile cache will allow "fast writes": the application need not wait for the write I/O to actually complete before it is notified that it has completed. For some applications environments, disk caches have the beneficial effect of reducing the number of reads and thus the number of I/O requests seen by the disks. This has the interesting side effect of increasing the percentage of writes found in the I/O mix, and some observers believe that writes may dominate I/O performance in future systems.

As already mentioned, a disk cache can also lead to better utilization of the host-to-device pathways. A device can transfer data into a cache even if the pathway is in use by another device on the same string. Thus caches are effective in avoiding rotational position sensing misses.

Disk Scheduling

The mechanical delays as seen by a set of simultaneous I/O requests can be reduced through effective disk scheduling. For example, seek times can be reduced if a *shortest-seek-time-first* scheduling algorithm is used [Smith, 1981]. That is, among the queue of pending I/O requests, the one next selected for service is the one that requires the shortest seek time from the current location of the read/write heads. The literature on disk scheduling algorithms is vast, and the effectiveness of a particular scheduling approach depends critically on the workload. It has been observed that scheduling algorithms work best when there are long queues of pending requests; unfortunately, this situation seems to occur rarely in existing systems [Smith, 1981].

Disk Arrays

An alternative to the approaches just described is to exploit parallelism by grouping together a number of physical disks and making these appear to applications as a single logical disk. This has the advantage that the bandwidth of several disks can be harnessed to service a single logical I/O request or can support multiple independent I/Os in parallel. Further, arrays can be constructed using existing, widely available disk technology, rather than the more specialized and more expensive approaches described in the previous subsection. For example, Cray offers a device called the DS-40, which appears as a single logical disk device but which is actually implemented internally as four drives. A logical track is constructed from sectors across the four disks. The DS-40 can transfer at a peak rate of 20 Mbyte/s, with a sustained transfer rate of 9.6 Mbyte/s, and thus is strictly faster than the DD-49.

Defining Terms

Arm: A mechanical assembly that positions the head to the correct track for reading or writing.

Bandwidth: The amount of data per unit time flowing between host computers and storage devices.

Cylinder: A stack of tracks at one acuator position.

Disk drive: An HDA plus all associated electronics.

Head: An electromagnet that produces switchable magnetic fields to read and record bit streams on a platter's track.

Head disk assembly (HDA): The collection of platters, heads, arms, and actuators, plus the air-tight casing, that makes up the storage device. Basically, this is everything but the electronics for controlling the drive and interfacing it to a computer system.

Latency: How long it takes to service an individual request.

Maximal areal density (MAD): The maximum number of bits that can be stored per square inch. Computed by multiplying the bits per inch in a disk track times the number of tracks per inch of media.

Platters: Metal disks covered with a magnetic material for recording information.

Rotational latency: The time it takes for the desired sector to rotate under the head position before it can be read or written.

Rotational position sensing: A storage device interrupts the I/O controller when the desired sector is under the heads.

Sector: A unit of a storage that is physically read or written at the same time.

Seek time: The time needed to position the heads to the appropriate track position containing the desired data.

Spindle: The collection of disk platters.

Track buffer: A memory buffer embedded in the disk drive. It can hold the contents of the current disk track.

Tracks: The circular recording regions on a platter.

Transfer time: The time taken to physically transfer the bytes from disk to the host.

Throughput: The number of requests for disk service per unit time.

Winchester disk: A magnetic disk in which the read/write heads fly above the recording surface on an air bearing. This is in contrast to contact recording, such as a floppy disk, in which the head and the magnetic media are actually touching.

80.3 Magnetic Tape[1]

Peter A. Lee

Computers depend on memory to execute programs and to store program code and data. They also need access to stored program code and data in a **nonvolatile memory** (i.e., a form in which the information is not lost when the power is removed from the computer system). Different types of memory have been developed for different tasks. This memory can be categorized according to its price per bit, **access time**, and other parameters. Table 80.1 shows a typical hierarchy for memory which places the smallest and fastest memory at the top in level 0 and in general the largest, slowest, and cheapest at the bottom in level 4 [Ciminiera and Valenzano, 1987]. Auxiliary (secondary or mass) memory of level 4 forms the large storage capacity for program and code that are not currently required by the CPU. This is usually nonvolatile and is at a low cost per bit. Computer **magnetic tape** falls within this category and is the subject of this section.

A Brief Historical Review

Probably the first recorded storage device, developed by Schickard in 1623, used mechanical positions of cogs and gears to work a semi-automatic calculator. Then came Pascal's calculating machine based on 10 digits per wheel. In 1812 punched cards were used in weaving looms to store patterns for woven material. Since that time there have been many mechanical and, latterly, electromechanical devices developed for memory and storage.

In 1948 at Manchester University in England the cathode ray tube (Williams) and the magnetic drum were developed. These consisted of 1024 bits and 1280 bits and a magnetic drum capacity of 120K bits. Cambridge University developed the mercury delay line in 1949, which represented the first fully operational delay line memory, consisting of 576 bits per tube with a total capacity of 18K bits and a circulation time of 1.1 ms.

The first commercial computer with a magnetic tape system was introduced in 1951. The UNIVAC I had a magnetic tape system of 1.44M bits on 150 feet of tape and was capable of storing 128 characters per inch. The tape could be read at a rate of 100 ips. Optical memories are now available as very fast storage devices and will replace magnetic storage in the next few years. At present these devices are expensive although it is envisaged that optical disks with large silicon caches will be the storage arrangement of the future where computer systems utilizing CAD software and image processing can take advantage of the large storage capacities with fast access times. In the future, semiconductor memories are likely to continue their advancing trend.

Introduction

Today's microprocessors are capable of addressing up to 16 Mbytes of main memory. To take advantage of this large capacity, it is usual to have several programs residing in memory at the same time. With intelligent memory

management units (MMUs), the programs can be swopped in and out of the main memory to the auxiliary memory when required. For the system to keep pace with this program swopping, it must have a fast auxiliary memory to write to. In the past, most auxiliary systems like magnetic tape and disks have had slow access times, and this has meant that expensive systems have evolved to cater for this requirement. Now that auxiliary memory has improved, and access times are fast and the memory cheap, computer systems have been developed that provide memory swopping with large nonvolatile storage systems. Although the basic technology has not changed over the last 20 years, new materials and different approaches have meant that a new form of auxiliary memory has been brought to the market at a very cheap cost.

Magnetic Tape

Magnetic tape currently provides the cheapest form of storage for large quantities of computer data in a nonvolatile form. The tape is arranged on a reel and has several different packaging styles. It is made from a polyester transportation layer with a deposited layer of oxide having a property similar to a ferrite material with a large hysteresis. Magnetic tape is packaged either in a cartridge, on a reel, or in a cassette. The magnetic cartridge is manufactured in several tape lengths and cartridge sizes capable of storing up to 2 G (giga) bytes of data. These can be purchased in many popular preformatted styles.

The magnetic tape reel is usually 1⁄2 inch or 1 inch wide and has lengths of 600, 1200, and 2400 feet. Most reels can store data at rates from 800 bits per inch (bpi) up to 6250 bpi. The reel-to-reel magnetic tape reader is generally bulkier and more expensive than the cartridge readers due to the complicated pneumatic drive mechanisms, but it provides a large data storage capacity with high access speeds [Wiehler, 1974]. An example of a typical magnetic tape drive with the reel-to-reel arrangement is shown in Fig. 80.16.

A cheap storage medium is the magnetic cassette. Based on the audio cassette, this uses the normal audio cassette recorder for reading and writing data via the standard Kansas City interface through a serial computer I/O line. A logic data "1" is recorded by a high frequency and a logic data "0" by a lower frequency. High-density cassettes can store up to 60 Mbytes of data on each tape and are popular with the computer games market as a cheap storage medium for program distribution.

Both reel-to-reel and cartridge tapes are generally organised by using nine separate tracks across the tape as shown in Fig. 80.17(a).

Each track has its own read and write head operated independently from other tracks [see Fig. 80.17(b)]. Tracks 1 to 8 are used for data and track nine for the parity bit. Data is written on the tape in rows of magnetized islands, using for example EBCDIC (Extended Binary Coded Decimal Interchange Code).

Each read/write head is shaped from a **ferromagnetic material** with an air gap 1 μm wide as seen in Fig. 80.18. The writing head is concerned with converting an electrical pulse into a magnetic state and can be magnetized in one of two directions. This is done by passing a current through the magnetic coil which sets up a leakage field across the 1-μm gap. When the current is reversed the field across the gap is changed, reversing the polarity of the magnetic field on the tape. The head magnetizes the passing magnetic tape recording the state of the magnetic field in the air gap. A logic 1 is recorded as a change in polarity on the tape, and a logic 0 is recorded as no change in polarity, as seen in Fig. 80.19. Reading the magnetic tape states from the tape and converting them to electrical signals is done by the read head. The bit sequences in Fig. 80.19 show the change in magnetic

states on the tape. When the tape is passed over the read head, it induces a voltage into the magnetic coil which is converted to digital levels to retrieve the original data.

Tape Format

Information is stored on magnetic tape in the form of a coherent sequence of rows forming a block. This usually corresponds to a page of computer memory and is the minimum amount of data written to or read from

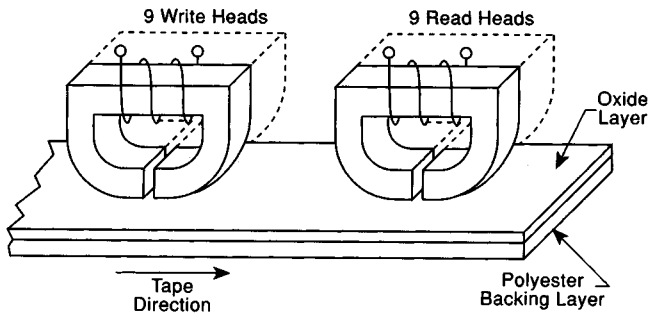

FIGURE 80.18 Read/write head layout. (*Source:* P. A. Lee, "Memory subsystems," in *Digital Systems Reference Book,* B. Holdsworth and G. R. Martin, Eds., Oxford: Butterworth-Heinemann, 1991, p. 2.6/12. With permission.)

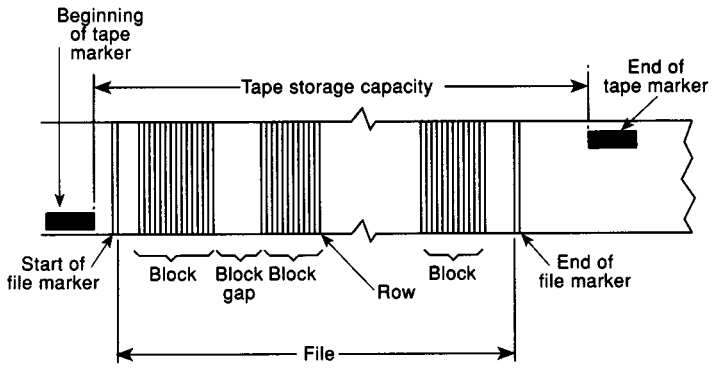

FIGURE 80.20 Magnetic tape format. (*Source:* P. A. Lee, "Memory subsystems," in *Digital Systems Reference Book,* B. Holdsworth and G. R. Martin, Eds., Oxford: Butterworth-Heinemann, 1991, p. 2.6/12. With permission.)

magnetic tape with each program statement. Each block of data is separated by a block gap which is approximately 15 mm long and has no data stored in it. This is shown in Fig. 80.20.

Block gaps are used to allow the tape to accelerate to its operational speed and for the tape to decelerate when stopping at the end of a block. Block gaps use up to 50% of the tape space available for recording, although this may be reduced by making the block sizes larger but has the disadvantage of requiring larger memory buffers to accommodate the data.

A number of blocks make up a file identified by a tape file marker which is written to the tape by the tape controller. The entire length of tape is enclosed between the beginning and end of tape markers. These normally consist of a photosensitive material that triggers sensors on the read/write heads. When a new tape is loaded, it normally advances to the beginning of a tape marker and then it is ready for access by the CPU. The end of tape marker is used to prevent the tape from running off the end of the tape spool and indicates the limit of the storage length.

Recording Modes

Several recording modes are used with the express objective of storing data at the highest density and with the greatest reliability of noncorruption of retrieved data. Two popular but contrasting modes are the *non-return-to-zero* (NRZ) and *phase encoding* (PE) modes. These are incompatible although some magnetic tape drives have detectors to sense the mode and operate in a bimodal way. The NRZ technique is shown in Fig. 80.19, where only the 1 bit is displayed by a reversal of magnetization on the tape. The magnetic polarity remains unchanged for logic 0. An external clock track is also required for this mode because a pulse is not always generated for each row of data on the tape.

The PE technique allows both the 0 and 1 states to be displayed by changes of magnetization. A 1 bit is given by a north-to-north pole on the tape, and a 0 bit is given by a south-to-south pole on the tape. PE provides approximately double the recording density and processor speed of NRZ. PE tapes carry an identification mark called a *burst*, which consists of successive magnetization changes at the beginning of track 4. This allows the tape drive to recognize the tape mode and configure itself accordingly.

Defining Terms

Access time: The cycle time for the computer store to present information to the CPU. Access times vary from less than 40 ns for level 0 register storage up to tens of seconds for magnetic tape storage.

Auxiliary (secondary, mass, or backing) storage: Computer stores which have a capacity to store enormous amounts of information in a *nonvolatile* form. This type of memory has an access time usually greater than main memory and consists of magnetic tape drives, magnetic disk stores, and optical disk stores.

Ferromagnetic material: Materials that exhibit high magnetic properties. These include metals such as cobalt, iron, and some alloys.

Magnetic tape: A polyester film sheet coated with a *ferromagnetic* powder, which is used extensively in auxiliary memory. It is produced on a reel, in a cassette, or in a cartridge transportation medium.

Nonvolatile memory: The class of computer memory that retains its stored information when the power supply is cut off. It includes magnetic tape, magnetic disks, flash memory, and most types of ROM.

80.4 Magneto-Optical Disk Data Storage

M. Mansuripur

Since the early 1940s, magnetic recording has been the mainstay of electronic information storage worldwide. Audio tapes provided the first major application for the storage of information on magnetic media. Magnetic tape has been used extensively in consumer products such as audio tapes and video cassette recorders (VCRs); it has also found application in backup/archival storage of computer files, satellite images, medical records, etc. Large volumetric capacity and low cost are the hallmarks of tape data storage, although sequential access to the recorded information is perhaps the main drawback of this technology. Magnetic hard disk drives have been used as mass storage devices in the computer industry ever since their inception in 1957. With an areal density that has doubled roughly every other year, hard disks have been and remain the medium of choice for secondary storage in computers.[1] Another magnetic data storage device, the floppy disk, has been successful in areas where compactness, removability, and fairly rapid access to the recorded information have been of prime concern. In addition to providing backup and safe storage, inexpensive floppies with their moderate capacities (2 Mbyte on a 3.5-in. diameter platter is typical nowadays) and reasonable transfer rates have provided the crucial function of file/data transfer between isolated machines. All in all, it has been a great half-century of progress and market dominance for magnetic recording devices, which are only now beginning to face a potentially serious challenge from the technology of optical recording.

Like magnetic recording, a major application area for optical data storage systems is the secondary storage of information for computers and computerized systems. Like the high-end magnetic media, optical disks can provide recording densities in the range of 10^7 bits/cm^2 and beyond. The added advantage of optical recording is that, like floppies, these disks can be removed from the drive and stored on the shelf. Thus the functions of the hard disk (i.e., high capacity, high data transfer rate, rapid access) may be combined with those of the floppy (i.e., backup storage, removable media) in a single optical disk drive. Applications of optical recording are not confined to computer data storage. The enormously successful audio **compact disk (CD)**, which was introduced in 1983 and has since become the de facto standard of the music industry, is but one example of the tremendous potentials of the optical technology.

A strength of optical recording is that, unlike its magnetic counterpart, it can support read-only, write-once, and erasable/rewritable modes of data storage. Consider, for example, the technology of optical audio/video disks. Here the information is recorded on a master disk which is then used as a stamper to transfer the embossed patterns to a plastic substrate for rapid, accurate, and inexpensive reproduction. The same process is employed in the mass production of read-only files (CD-ROM, O-ROM) which are now being used to distribute software, catalogues, and other large databases. Or consider the write-once read-many (WORM) technology, where one can permanently store massive amounts of information on a given medium and have rapid, random access to them afterwards. The optical drive can be designed to handle read-only, WORM, and erasable media all in one unit, thus combining their useful features without sacrificing performance and ease of use or occupying too

[1] At the time of this writing, achievable densities on hard disks are in the range of 10^7 bits/cm^2. Random access to arbitrary blocks of data in these devices can take on the order of 10 ms, and individual read/write heads can transfer data at the rate of several megabits per second.

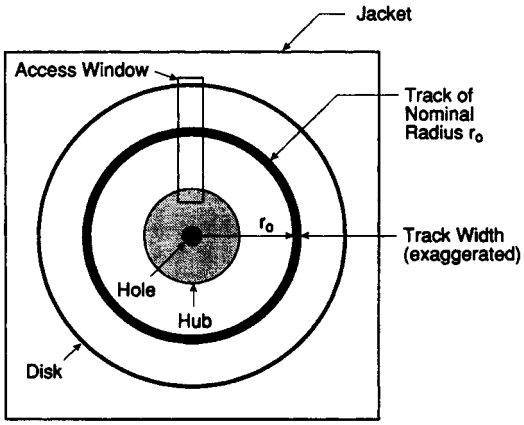

FIGURE 80.21 Physical appearance and general features of an optical disk. The read/write head gains access to the disk through a window in the jacket; the jacket itself is for protection purposes only. The hub is the mechanical interface with the drive for mounting and centering the disk on the spindle. The track shown at radius r_0 is of the concentric-ring type.

much space. What is more, the media can contain regions with prerecorded information as well as regions for read/write/erase operations, both on the same platter. These possibilities open new vistas and offer opportunities for applications that have heretofore been unthinkable; the interactive video disk is perhaps a good example of such applications.

In this article we will lay out the conceptual basis for optical data storage systems; the emphasis will be on disk technology in general and magneto-optical disk in particular. The first section is devoted to a discussion of some elementary aspects of disk data storage including the concept of track and definition of the access time. The second section describes the basic elements of the optical path and its functions; included are the properties of the semiconductor laser diode, characteristics of the beamshaping optics, and certain features of the focusing objective lens. Because of the limited depth of focus of the objective and the eccentricity of tracks, optical disk systems must have a closed-loop feedback mechanism for maintaining the focused spot on the right track. These mechanisms are described in the third and fourth sections for automatic focusing and automatic track following, respectively. The physical process of thermomagnetic recording in magneto-optic (MO) media is described next, followed by a discussion of the MO readout process in the sixth section. The final section describes the properties of the MO media.

Preliminaries and Basic Definitions

A disk, whether magnetic or optical, consists of a number of **tracks** along which the information is recorded. These tracks may be concentric rings of a certain width, W_t, as shown in Fig. 80.21. Neighboring tracks may be separated from each other by a guard band whose width we shall denote by W_g. In the least sophisticated recording scheme imaginable, marks of length Δ_0 are recorded along these tracks. Now, if each mark can be in either one of two states, present or absent, it may be associated with a binary digit, 0 or 1. When the entire disk surface of radius R is covered with such marks, its capacity C_0 will be

$$C_0 = \frac{\pi R^2}{(W_t + W_g)\Delta_0} \quad \text{bits per surface} \tag{80.2}$$

Consider the parameter values typical of current optical disk technology: $R = 67$ mm corresponding to 5.25-in. diameter platters, $\Delta_0 = 0.5$ μm which is roughly determined by the wavelength of the read/write laser diodes, and $W_t + W_g = 1$ μm for the track pitch. The disk capacity will then be around 28×10^9 bits, or 3.5 gigabytes. This is a reasonable estimate and one that is fairly close to reality, despite the many simplifying assumptions made in its derivation. In the following paragraphs we examine some of these assumptions in more detail.

The disk was assumed to be fully covered with information-carrying marks. This is generally not the case in practice. Consider a disk rotating at $\mathcal{N}$ revolutions per second (rps). For reasons to be clarified later, this rotational speed should remain constant during the disk operation. Let the electronic circuitry have a fixed clock duration T_c. Then only pulses of length T_c (or an integer multiple thereof) may be used for writing. Now, a mark written along a track of radius r, with a pulse-width equal to T_c, will have length ℓ, where

$$\ell = 2\pi \mathcal{N}\, rT_c \tag{80.3}$$

Thus for a given rotational speed $\mathcal{N}$ and a fixed clock cycle T_c, the minimum mark length ℓ is a linear function of track radius r, and ℓ decreases toward zero as r approaches zero. One must, therefore, pick a minimum usable track radius, $r_{\min}$, where the spatial extent of the recorded marks is always greater than the minimum allowed mark length, Δ_0. Equation (80.3) yields

$$r_{\min} = \frac{\Delta_0}{2\pi \mathcal{N}\ T_c} \tag{80.4}$$

One may also define a maximum usable track radius r_{max}, although for present purposes $r_{max} = R$ is a perfectly good choice. The region of the disk used for data storage is thus confined to the area between $r_{\min}$ and $r_{\max}$. The total number N of tracks in this region is given by

$$N = \frac{r_{\max} - r_{\min}}{W_t + W_g} \tag{80.5}$$

The number of marks on any given track in this scheme is independent of the track radius; in fact, the number is the same for all tracks, since the period of revolution of the disk and the clock cycle uniquely determine the total number of marks on any individual track. Multiplying the number of usable tracks N with the capacity per track, we obtain for the usable disk capacity

$$C = \frac{N}{\mathcal{N}\ T_c} \tag{80.6}$$

Replacing for N from Eq. (80.5) and for $\mathcal{N}\ T_c$ from Eq. (80.4), we find,

$$C = \frac{2\pi r_{\min}(r_{\max} - r_{\min})}{(W_t + W_g)\Delta_0} \tag{80.7}$$

If the capacity C in Eq. (80.7) is considered a function of $r_{\min}$ with the remaining parameters held constant, it is not difficult to show that maximum capacity is achieved when

$$r_{\min} = \tfrac{1}{2}\ r_{\max} \tag{80.8}$$

With this optimum $r_{\min}$, the value of C in Eq. (80.7) is only half that of C_0 in Eq. (80.2). In other words, the estimate of 3.5 gigabyte per side for 5.25-in. disks seems to have been optimistic by a factor of two.

One scheme often proposed to enhance the capacity entails the use of multiple zones, where either the rotation speed $\mathcal{N}$ or the clock period T_c is allowed to vary from one zone to the next. In general, zoning schemes can reduce the minimum usable track radius below that given by Eq. (80.8). More importantly, however, they allow tracks with larger radii to store more data than tracks with smaller radii. The capacity of the zoned disk is somewhere between C of Eq. (80.7) and C_0 of Eq. (80.2), the exact value depending on the number of zones implemented.

A fraction of the disk surface area is usually reserved for **preformat** information and cannot be used for data storage. Also, prior to recording, additional bits are generally added to the data for **error correction coding** and other housekeeping chores. These constitute a certain amount of overhead on the user data and must be allowed for in determining the capacity. A good rule of thumb is that overhead consumes approximately 20% of the raw capacity of an optical disk, although the exact number may vary among the systems in use. Substrate defects and film contaminants during the deposition process can create bad **sectors** on the disk. These are typically identified during the certification process and are marked for elimination from the sector directory. Needless to say, bad sectors must be discounted when evaluating the capacity.

Modulation codes may be used to enhance the capacity beyond what has been described so far. Modulation coding does not modify the minimum mark length of Δ_0, but frees the longer marks from the constraint of being integer multiples of Δ_0. The use of this type of code results in more efficient data storage and an effective number of bits per Δ_0 that is greater than unity. For example, the popular (2, 7) modulation code has an effective bit density of 1.5 bits per Δ_0. This or any other modulation code can increase the disk capacity beyond the estimate of Eq. (80.7).

The Concept of Track

The information on magnetic and optical disks is recorded along tracks. Typically, a track is a narrow annulus at some distance r from the disk center. The width of the annulus is denoted by W_t, while the width of the guard band, if any, between adjacent tracks is denoted by W_g. The track pitch is the center-to-center distance between neighboring tracks and is therefore equal to $W_t + W_g$. A major difference between the magnetic floppy disk, the magnetic hard disk, and the optical disk is that their respective track pitches are presently of the order of 100, 10, and 1 μm. Tracks may be fictitious entities, in the sense that no independent existence outside the pattern of recorded marks may be ascribed to them. This is the case, for example, with the audio compact disk format where prerecorded marks simply define their own tracks and help guide the laser beam during readout. In the other extreme are tracks that are physically engraved on the disk surface before any data is ever recorded. Examples of this type of track are provided by pregrooved WORM and magneto-optical disks. Figure 80.22 shows micrographs from several recorded optical disk surfaces. The tracks along which the data are written are clearly visible in these pictures.

It is generally desired to keep the read/write head stationary while the disk spins and a given track is being read from or written onto. Thus, in an ideal situation, not only should the track be perfectly circular, but also the disk must be precisely centered on the spindle axis. In practical systems, however, tracks are neither precisely circular, nor are they concentric with the spindle axis. These eccentricity problems are solved in low-performance floppy drives by making tracks wide enough to provide tolerance for misregistrations and misalignments. Thus the head moves blindly to a radius where the track center is nominally expected to be and stays put until the reading or writing is over. By making the head narrower than the track pitch, the track center is allowed to wobble around its nominal position without significantly degrading the performance during the read/write operation. This kind of wobble, however, is unacceptable in optical disk systems, which have a very narrow track, about the same size as the focused beam spot. In a typical situation arising in practice, the eccentricity of a given track may be as much as ±50 μm while the track pitch is only about 1 μm, thus requiring active track-following procedures.

One method of defining tracks on an optical disk is by means of pregrooves that are either etched, stamped, or molded onto the substrate. In **grooved media of optical storage**, the space between neighboring grooves is the so-called land [see Fig. 80.23(a)]. Data may be written in the grooves with the land acting as a guard band. Alternatively, the land regions may be used for recording while the grooves separate adjacent tracks. The groove depth is optimized for generating an optical signal sensitive to the radial position of the read/write laser beam. For the push-pull method of track-error detection the groove depth is in the neighborhood of $\lambda/8$, where λ is the wavelength of the laser beam.

In digital data storage applications, each track is divided into small segments or sectors, intended for the storage of a single block of data (typically either 512 or 1024 bytes). The physical length of a sector is thus a few millimeters. Each sector is preceded by header information such as the identity of the sector, identity of the corresponding track, synchronization marks, etc. The header information may be preformatted onto the

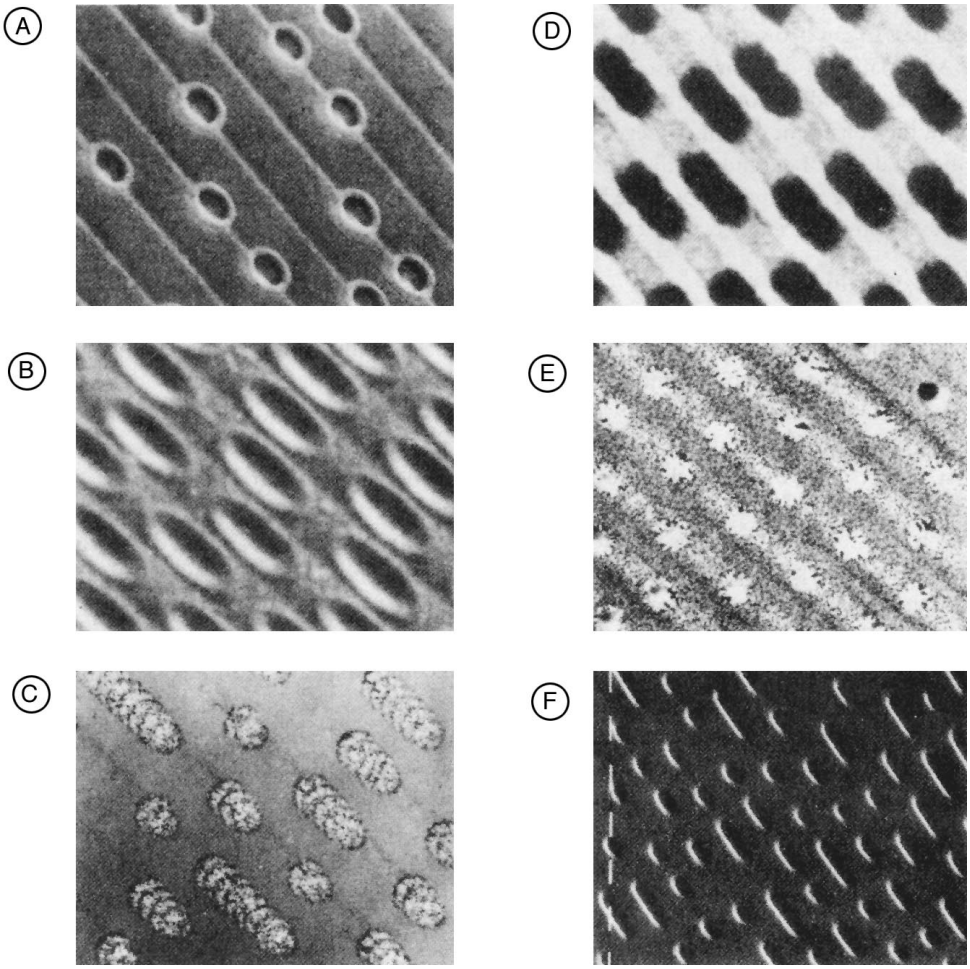

FIGURE 80.22 Micrographs of several types of optical storage media. The tracks are straight and narrow (track pitch = 1.6 μm), with an orientation angle of ≃ –45°. substrate, or it may be written on the storage layer prior to shipping the disk. Pregrooved tracks may be "carved" on the optical disk either as concentric rings or as a single continuous spiral. There are certain advantages to each format. A spiral track can contain a succession of sectors without interruption, whereas concentric rings may each end up with some empty space that is smaller than the required length for a sector. Also, large files may be written onto (and read from) spiral tracks without jumping to the next track, which occurs when concentric tracks are used. On the other hand, multiple-path operations such as write-and-verify or erase-and-write, which require two paths each for a given sector, or still-frame video are more conveniently handled on concentric-ring tracks.

Another track format used in practice is based on the sampled-servo concept. Here the tracks are identified by occasional marks placed permanently on the substrate at regular intervals, as shown in Fig. 80.23. Details of track following by the sampled-servo scheme will follow shortly; suffice it to say at this point that servo marks help the system identify the position of the focused spot relative to the track center. Once the position is determined it is fairly simple to steer the beam and adjust its position.

Disk Rotation Speed

When a disk rotates at a constant angular velocity ω, a track of radius r moves with the constant linear velocity $V = r\omega$. Ideally, one would like to have the same linear velocity for all the tracks, but this is impractical except in a limited number of situations. For instance, when the desired mode of access to the various tracks is sequential, such as in audio and video disk applications, it is possible to place the head in the beginning at the inner radius and move outward from the center thereafter while continuously decreasing the angular velocity. By keeping the product of r and ω constant, one can thus achieve constant linear velocity for all the tracks.[1] Sequential access mode, however, is the exception rather than the norm in data storage systems. In most applications, the tracks are accessed randomly with such rapidity that it becomes impossible to adjust the rotation speed for constant linear velocity. Under these circumstances, the angular velocity is best kept constant during the normal operation of the disk. Typical rotation speeds are 1200 and 1800 rpm for slower drives and 3600 rpm for the high data rate systems. Higher rotation rates (5000 rpm and beyond) are certainly feasible and will likely appear in future storage devices.

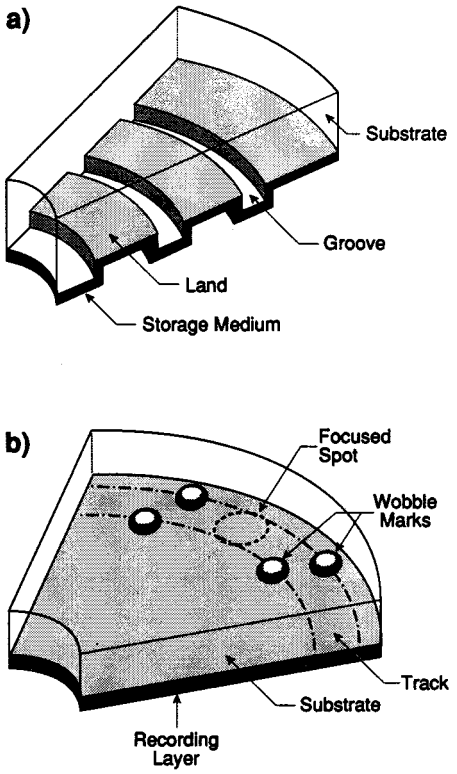

FIGURE 80.23 (a) Lands and grooves in an optical disk. The substrate is transparent, and the laser beam must pass through it before reaching the storage medium. (b) Sampled-servo marks in an optical disk. These marks which are offset from the track-center provide information regarding the position of focused spot.

Access Time

The direct-access storage device or DASD, used in computer systems for the mass storage of digital information, is a disk drive capable of storing large quantities of data and accessing blocks of this data rapidly and in arbitrary order. In read/write operations it is often necessary to move the head to new locations in search of sectors containing specific data items. Such relocations are usually time-consuming and can become the factor that limits performance in certain applications. The access time τ_a is defined as the average time spent in going from one randomly selected spot on the disk to another. τ_a can be considered the sum of a seek time, τ_s, which is the average time needed to acquire the target track, and a latency, τ_l, which is the average time spent on the target track waiting for the desired sector. Thus,

$$\tau_a = \tau_s + \tau_l \tag{80.9}$$

The latency is half the revolution period of the disk, since a randomly selected sector is, on the average, halfway along the track from the point where the head initially lands. Thus for a disk rotating at 1200 rpm $\tau_l = 25$ ms, while at 3600 rpm $\tau_l \simeq 8.3$ ms. The seek time, on the other hand, is independent of the rotation speed, but is determined by the traveling distance of the head during an average seek, as well as by the mechanism of head actuation. It can be shown that the average length of travel in a random seek is one third of the full stroke. (In our notation the full stroke is $r_{max} - r_{min}$.) In magnetic disk drives where the head/actuator assembly is relatively light-weight (a typical Winchester head weighs about 5 grams) the acceleration and deceleration periods are short, and seek times are typically around 10 ms in small drives (i.e., 5.25 and 3.5 in.). In optical disk systems,

[1]In compact disk players the linear velocity is kept constant at 1.2 m/s. The starting position of the head is at the inner radius $r_{min} = 25$ mm, where the disk spins at 460 rpm. The spiral track ends at the outer radius $r_{max} = 58$ mm, where the disk's angular velocity is 200 rpm.

on the other hand, the head, being an assembly of discrete elements, is fairly large and heavy (typical weight ≃100 grams), resulting in values of τ_s that are several times greater than those obtained in magnetic recording systems. The seek times reported for commercially available optical drives presently range from 20 ms in high-performance 3.5-in. drives to about 80 ms in larger drives. We emphasize, however, that the optical disk technology is still in its infancy; with the passage of time, the integration and miniaturization of the elements within the optical head will surely produce lightweight devices capable of achieving seek times of the order of a few milliseconds.

The Optical Path

The **optical path** begins at the light source which, in practically all laser disk systems in use today, is a semiconductor GaAs diode laser. Several unique features have made the laser diode indispensable in optical recording technology, not only for the readout of stored information but also for writing and erasure. The small size of this laser has made possible the construction of compact head assemblies, its coherence properties have enabled diffraction-limited focusing to extremely small spots, and its direct modulation capability has eliminated the need for external modulators. The laser beam is modulated by controlling the injection current; one applies pulses of variable duration to turn the laser on and off during the recording process. The pulse duration can be as short as a few nanoseconds, with rise and fall times typically less than 1 ns. Although readout can be accomplished at constant power level, i.e., in CW mode, it is customary for noise reduction purposes to modulate the laser at a high frequency (e.g., several hundred megahertz during readout).

Collimation and Beam Shaping

Since the cross-sectional area of the active region in a laser diode is only about one micrometer, diffraction effects cause the emerging beam to diverge rapidly. This phenomenon is depicted schematically in Fig. 80.24(a). In practical applications of the laser diode, the expansion of the emerging beam is arrested by a collimating lens, such as that shown in Fig. 80.24(b). If the beam happens to have aberrations (astigmatism is particularly severe in diode lasers), then the collimating lens must be designed to correct this defect as well.

In optical recording it is most desirable to have a beam with circular cross section. The need for shaping the beam arises from the special geometry of the laser cavity with its rectangular cross section. Since the emerging beam has different dimensions in the directions parallel and perpendicular to the junction, its cross section at the collimator becomes elliptical, with the initially narrow dimension expanding more rapidly to become the major axis of the ellipse. The collimating lens thus produces a beam with elliptical cross section. Circularization may be achieved by bending various rays of the beam at a prism, as shown in Fig. 80.24(c). The bending changes the beam's diameter in the plane of incidence but leaves the diameter in the perpendicular direction intact.

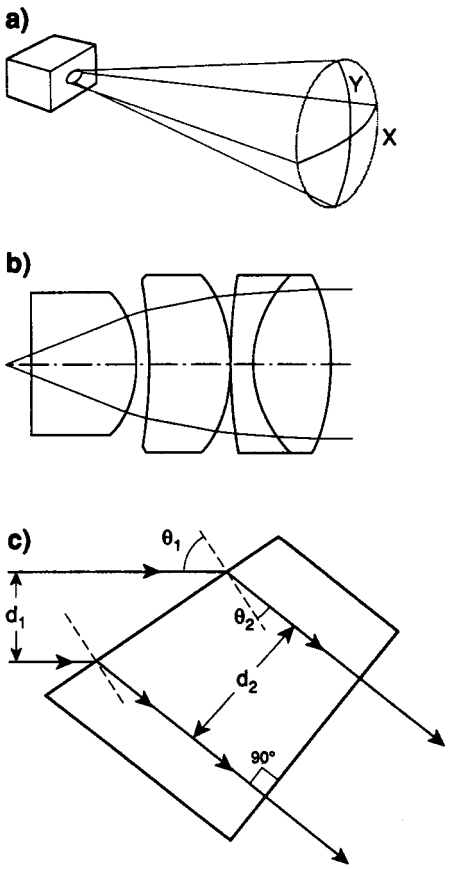

FIGURE 80.24 (a) Away from the facet, the output beam of a diode laser diverges rapidly. In general, the beam diameter along X is different from that along Y, which makes the cross section of the beam elliptical. Also, the radii of curvature R_x and R_y are not the same, thus creating a certain amount of astigmatism in the beam. (b) Multi-element collimator lens for laser diode applications. Aside from collimating, this lens also corrects astigmatic aberrations of the beam. (c) Beam shaping by deflection at a prism surface. θ_1 and θ_2 are related by the Snell's law, and the ratio d_2/d_1 is the same as $\cos\theta_2/\cos\theta_1$. Passage through the prism circularizes the elliptical cross section of the beam.

Focusing by the Objective Lens

The collimated and circularized beam of the diode laser is focused on the surface of the disk using an **objective lens**. The objective is designed to be aberration-free, so that its focused spot size is limited only by the effects of diffraction. Figure 80.25(a) shows the design of a typical objective made from spherical optics. According to the classical theory of diffraction, the diameter of the beam, d, at the objective's focal plane is given by

$$d \simeq \frac{\lambda}{NA} \qquad (80.10)$$

where λ is the wavelength of light, and NA is the numerical aperture of the objective.[1]

In optical recording it is desired to achieve the smallest possible spot, since the size of the spot is directly related to the size of marks recorded on the medium. Also, in readout, the spot size determines the resolution of the system. According to Eq. (80.10) there are two ways to achieve a small spot: first by reducing the wavelength and, second, by increasing the numerical aperture of the objective. The wavelengths currently available from GaAs lasers are in the range of 670–840 nm. It is possible to use a nonlinear optical device to double the frequency of these diode lasers, thus achieving blue light. Good efficiencies have been demonstrated by frequency doubling. Also recent developments in II–VI materials have improved the prospects for obtaining green and blue light directly from semiconductor lasers. Consequently, there is hope that in the near future optical storage systems will operate in the wavelength range of 400–500 nm. As for the numerical aperture, current practice is to use a lens with NA $\simeq$0.5–0.6. Although this value might increase slightly in the coming years, much higher numerical apertures are unlikely, since they put strict constraints on the other characteristics of the system and limit the tolerances. For instance, the working distance at high numerical aperture is relatively short, making access to the recording layer through the substrate more difficult. The smaller depth of focus of a high numerical aperture lens will make attaining/maintaining proper focus more of a problem, while the limited field of view might restrict automatic track-following procedures. A small field of view also places constraints on the possibility of read/write/erase operations involving multiple beams.

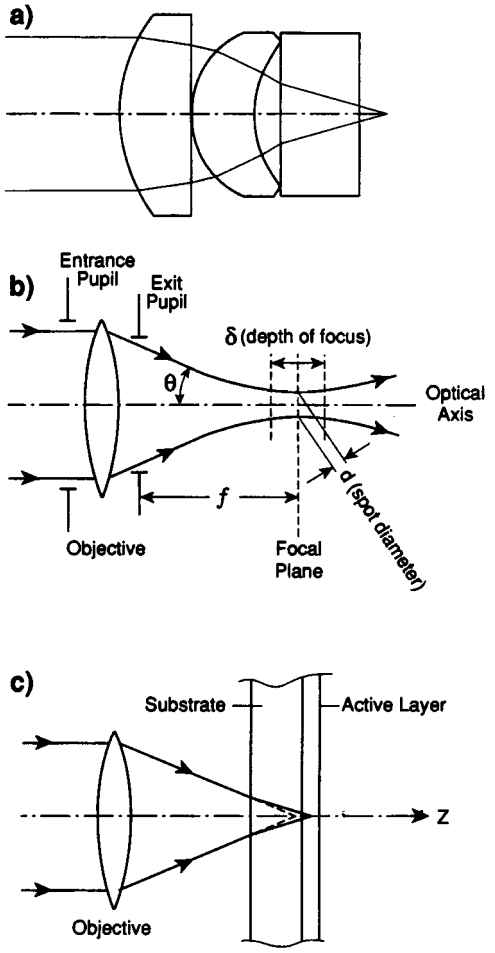

FIGURE 80.25 (a) Multi-element lens design for a high numerical aperture video disk objective. (*Source:* D. Kuntz, "Specifying laser diode optics," *Laser Focus*, March 1984. With permission.) (b) Various parameters of the objective lens. The numerical aperture is $NA = \sin\theta$. The spot diameter d and the depth of focus δ are given by Eqs. (80.10) and (80.11), respectively. (c) Focusing through the substrate can cause spherical aberration at the active layer. The problem can be corrected if the substrate is taken into account while designing the objective.

The depth of focus of a lens, δ, is the distance away from the focal plane over which tight focus can be maintained [see Fig. 80.25(b)]. According to the classical diffraction theory

[1]Numerical aperture is defined as $NA = n \sin\theta$, where n is the refractive index of the image space, and θ is the half-angle subtended by the exit pupil at the focal point. In optical recording systems the image space is air whose index is very nearly unity; thus for all practical purposes $NA = \sin\theta$.

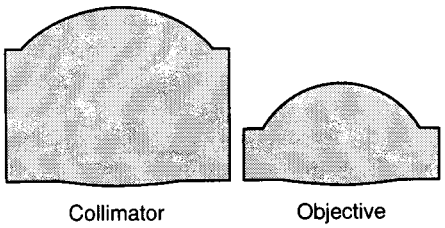

FIGURE 80.26 Molded glass aspheric lens pair for optical disk applications. These singlets can replace the multi-element spherical lenses shown in Figs. 80.24(b) and 80.25(a).

$$\delta \simeq \frac{\lambda}{NA^2} \tag{80.11}$$

Thus for a wavelength of $\lambda = 700$ nm and $NA = 0.6$, the depth of focus is about ± 1 μm. As the disk spins under the optical head at the rate of several thousand rpm, the objective lens must stay within a distance of $f \pm \delta$ from the active layer if proper focus is to be maintained. Given the conditions under which drives usually operate, it is impossible to make rigid enough mechanical systems to yield the required positioning tolerances. On the other hand, it is fairly simple to mount the objective lens in an actuator capable of adjusting its position with the aid of closed-loop feedback control. We shall discuss the technique of **automatic focusing** in the next section. For now, let us emphasize that by going to shorter wavelengths and/or larger numerical apertures (as is required for attaining higher data densities) one will have to face a much stricter regime as far as automatic focusing is concerned. Increasing the numerical aperture is particularly worrisome, since δ drops with the square of *NA*.

A source of spherical aberrations in optical disk systems is the substrate through which the light must travel to reach the active layer of the disk. Figure 80.25(c) shows the bending of the rays at the disk surface that causes the aberration. This problem can be solved by taking into account the effects of the substrate in the design of the objective, so that the lens is corrected for all aberrations including those arising at the substrate. Recent developments in molding of aspheric glass lenses have gone a long way in simplifying the lens design problem. Figure 80.26 shows a pair of molded glass aspherics designed for optical disk system applications; both the collimator and the objective are single-element lenses and are corrected for aberrations.

Automatic Focusing

We mentioned in the preceding section that since the objective has a large numerical aperture ($NA \geq 0.5$), its depth of focus δ is rather shallow ($\delta \simeq \pm 1$ μm at $\lambda = 780$ nm). During all read/write/erase operations, therefore, the disk must remain within a fraction of a micrometer from the focal plane of the objective. In practice, however, the disks are not flat and they are not always mounted rigidly parallel to the focal plane, so that movements away from focus occur a few times during each revolution. The peak-to-peak movement in and out of focus may be as much as 100 μm. Without automatic focusing of the objective along the optical axis, this runout (or disk flutter) will be detrimental to the operation of the system. In practice, the objective is mounted on a small motor (usually a voice coil) and allowed to move back and forth in order to keep its distance within an acceptable range from the disk. The spindle turns at a few thousand rpm, which is a hundred or so revolutions per second. If the disk moves in and out of focus a few times during each revolution, then the voice coil must be fast enough to follow these movements in real time; in other words, its frequency response must extend to several kilohertz.

The signal that controls the voice coil is obtained from the light reflected from the disk. There are several techniques for deriving the focus error signal, one of which is depicted in Fig. 80.27(a). In this so-called obscuration method a secondary lens is placed in the path of the reflected light, one-half of its aperture is covered, and a split detector is placed at its focal plane. When the disk is in focus, the returning beam is collimated and the secondary lens will focus the beam at the center of the split detector, giving a difference

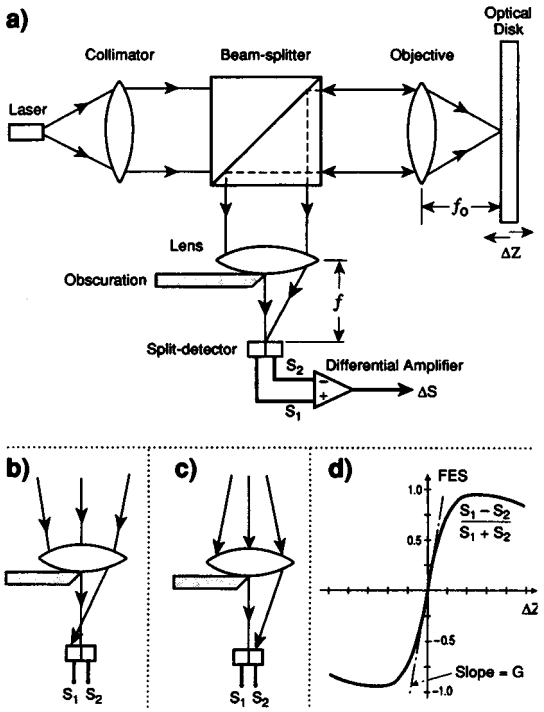

FIGURE 80.27 Focus error detection by the obscuration method. In (a) the disk is in focus, and the two halves of the split detector receive equal amounts of light. When the disk is too far from the objective (b) or too close to it (c), the balance of detector signals shifts to one side or the other. A plot of the focus error signal (FES) versus defocus is shown in (d), and its slope near the origin is identified as the FES gain, *G*.

signal ΔS equal to zero. If the disk now moves away from the objective, the returning beam will become converging, as in Fig. 80.27(b), sending all the light to detector #1. In this case ΔS will be positive and the voice coil will push the lens towards the disk. On the other hand, when the disk moves close to the objective, the returning beam becomes diverging and detector #2 receives the light [see Fig. 80.27(c)]. This results in a negative ΔS that forces the voice coil to pull back in order to return ΔS to zero. A given focus error detection scheme is generally characterized by the shape of its focus error signalΔS versus the amount of defocus Δz; one such curve is shown in Fig. 80.27(d). The slope of the focus error signal (FES) curve near the origin is of particular importance, since it determines the overall performance and stability of the servo loop.

Automatic Tracking

Consider a track at a certain radial location, say r_0, and imagine viewing this track through the access window shown in Fig. 80.21. It is through this window that the head gains access to arbitrarily selected tracks. To a viewer looking through the window, a perfectly circular track centered on the spindle axis will look stationary, irrespective of the rotation rate. However, any eccentricity will cause an apparent radial motion of the track. The peak-to-peak distance traveled by a track (as seen through the window) depends on a number of factors including centering accuracy of the hub, deformability of the substrate, mechanical vibrations, manufacturing tolerances, etc. For a typical 3.5-in. disk, for example, this peak-to-peak motion can be as much as 100 μm during one revolution. Assuming a revolution rate of 3600 rpm, the apparent velocity of the track in the radial direction will be several millimeters per second. Now, if the focused spot remains stationary while trying to read from or write to this track, it is clear that the beam will miss the track for a good fraction of every revolution cycle.

Practical solutions to the above problem are provided by **automatic tracking** techniques. Here the objective is placed in a fine actuator, typically a voice coil, which is capable of moving the necessary radial distances and

maintaining a lock on the desired track. The signal that controls the movement of this actuator is derived from the reflected light itself, which carries information about the position of the focused spot. There exist several mechanisms for extracting the track error signal (TES); all these methods require some sort of structure on the disk surface in order to identify the track. In the case of read-only disks (CD, CD-ROM, and video disk), the embossed pattern of data provides ample information for tracking purposes. In the case of write-once and erasable disks, tracking guides are "carved" on the substrate in the manufacturing process. As mentioned earlier, the two major formats for these tracking guides are pregrooves (for continuous tracking) and sampled-servo marks (for discrete tracking). A combination of the two schemes, known as continuous/composite format, is often used in practice. This scheme is depicted in Fig. 80.28 which shows a small section containing five tracks, each consisting of the tail end of a groove, synchronization marks, a mirror area used for adjusting focus/track offsets, a pair of wobble marks for sampled tracking, and header information for sector identification.

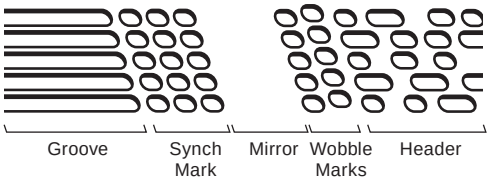

FIGURE 80.28 Servo fields in continuous/composite format contain a mirror area and offset marks for tracking

Tracking on Grooved Regions

As shown in Fig. 80.23(a), grooves are continuous depressions that are either embossed or etched or molded onto the substrate prior to deposition of the storage medium. If the data is recorded on the grooves, then the lands are not used except for providing a guard band between neighboring grooves. Conversely, the land regions may be used to record the information, in which case grooves provide the guard band. Typical track widths are about one wavelength. The guard bands are somewhat narrower than the tracks, their exact shape and dimensions depending on the beam size, required track-servo accuracy, and the acceptable levels of cross-talk between adjacent tracks. The groove depth is usually around one-eighth of one wavelength ($\lambda/8$), since this depth can be shown to give the largest TES in the push-pull method. Cross sections of the grooves may be rectangular, trapezoidal, triangular, etc.

When the focused spot is centered on track, it is diffracted symmetrically from the two edges of the track, resulting in a balanced far field pattern. As soon as the spot moves away from the center, the symmetry breaks down and the light distribution in the far field tends to shift to one side or the other. A split photodetector placed in the path of the reflected light can therefore sense the relative position of the spot and provide the appropriate feedback signal. This strategy is depicted schematically in Fig. 80.29; also shown in the figure are intensity plots at the detector plane for light reflected from various regions of the disk. Note how the intensity shifts to one side or the other depending on the direction of motion of the spot.

Sampled Tracking

Since dynamic track runout is usually a slow and gradual process, there is actually no need for continuous tracking as done on grooved media. A pair of embedded marks, offset from the track center as in Fig. 80.23(b), can provide the necessary information for correcting the relative position of the focused spot. The reflected intensity will indicate the positions of the two servo marks as two successive short pulses. If the beam happens to be on track, the two pulses will have equal magnitudes and there will be no need for correction. If, on the other hand, the beam is off-track, one of the pulses will be stronger than the other. Depending on which pulse is the stronger, the system will recognize the direction in which it has to move and will correct the error accordingly. The servo marks must appear frequently enough along the track to ensure proper track following. In a typical application, the track might be divided into groups of 18 bytes, 2 bytes dedicated as servo offset areas and 16 bytes filled with other format information or left blank for user data.

Thermomagnetic Recording Process

Recording and erasure of information on a magneto-optical disk are both achieved by the **thermomagnetic process**. The essence of thermomagnetic recording is shown in Fig. 80.30. At the ambient temperature the film

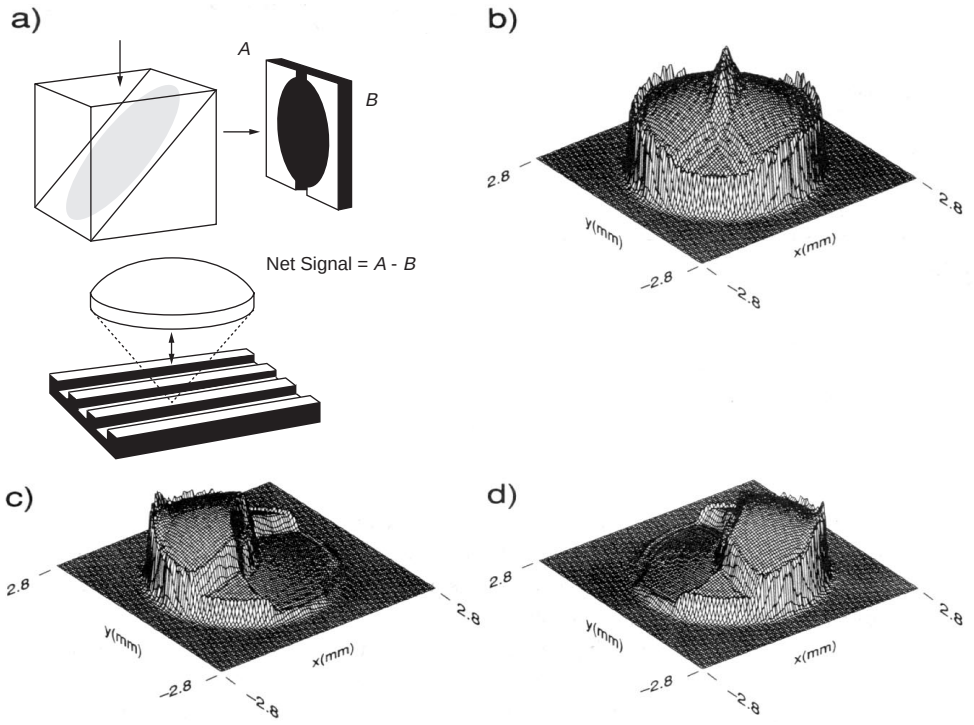

FIGURE 80.29 (a) Push-pull sensor for tracking on grooves. (b) Calculated distribution of light intensity at the detector plane when the disk is in focus and the beam is centered on track. (c) Calculated intensity distribution at the detector plane with disk in focus but the beam centered on the groove edge. (d) Same as (c) except for the spot being focused on the opposite edge of the groove.

has a high magnetic coercivity[1] and therefore does not respond to the externally applied field. When a focused beam raises the local temperature of the film, the hot spot becomes magnetically soft (i.e., its coercivity drops). As the temperature rises, coercivity drops continuously until such time as the field of the electromagnet finally overcomes the material's resistance to reversal and switches its magnetization. Turning the laser off brings the temperatures back to normal, but the reverse-magnetized domain remains frozen in the film. In a typical situation in practice, the film thickness may be around 300 Å, laser power at the disk $\simeq$10 mW, diameter of the focused spot $\simeq$1 μm, laser pulse duration $\simeq$50 ns, linear velocity of the track $\simeq$10 m/s, and the magnetic field strength $\simeq$200 gauss. The temperature may reach a peak of 500 K at the center of the spot, which is sufficient for magnetization reversal, but is not nearly high enough to melt or crystalize or in any other way modify the material's structure.

The materials of magneto-optical recording have strong perpendicular magnetic anisotropy. This type of anisotropy favors the "up" and "down" directions of magnetization over all other orientations. The disk is initialized in one of these two directions, say up, and the recording takes place when small regions are selectively reverse-magnetized by the thermomagnetic process. The resulting magnetization distribution then represents the pattern of recorded information. For instance, binary sequences may be represented by a mapping of zeros to up-magnetized regions and ones to down-magnetized regions (non-return to zero or NRZ). Alternatively, the NRZI scheme might be used, whereby transitions (up-to-down and down-to-up) are used to represent the ones in the bit-sequence.

[1]Coercivity of a magnetic medium is a measure of its resistance to magnetization reversal. For example, consider a thin film with perpendicular magnetic moment saturated in the $+Z$ direction. A magnetic field applied along $-Z$ will succeed in reversing the direction of magnetization only if the field is stronger than the coercivity of the film.

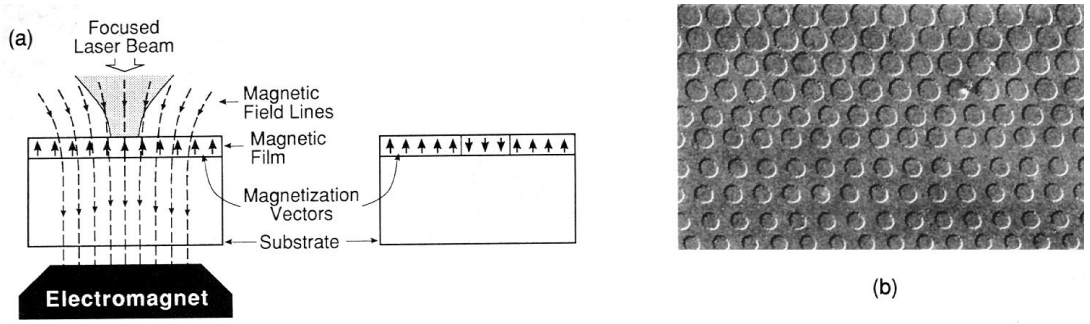

FIGURE 80.30 Thermomagnetic recording process. (a) The field of the electromagnet helps reverse the direction of magnetization in the area heated by the focused laser beam. (b) Lorentz micrograph of domains written thermomagnetically. The various tracks shown here were written at different laser powers, with power level decreasing from top to bottom. (*Source:* F. Greidanus et al., Paper 26B-5, presented at the International Symposium on Optical Memory, Kobe, Japan, September 1989. With permission.)

Recording by Laser Power Modulation (LPM)

In this traditional approach to thermomagnetic recording, the electromagnet produces a constant field, while the information signal is used to modulate the power of the laser beam. As the disk rotates under the focused spot, the on/off laser pulses create a sequence of up/down domains along the track. The Lorentz electron micrograph in Fig. 80.30(b) shows a number of domains recorded by LPM. The domains are highly stable and may be read over and over again without significant degradation. If, however, the user decides to discard a recorded block and to use the space for new data, the LPM scheme does not allow direct overwrite; the system must erase the old data during one disk revolution cycle and record the new data in a subsequent revolution cycle.

During erasure, the direction of the external field is reversed, so that up-magnetized domains in Fig. 80.30(a) now become the favored ones. Whereas writing is achieved with a modulated laser beam, in erasure the laser stays on for a relatively long period of time, erasing an entire sector. Selective erasure of individual domains is not practical, nor is it desired, since mass data storage systems generally deal with data at the level of blocks, which are recorded onto and read from individual sectors. Note that at least one revolution period elapses between the erasure of an old block and its replacement by a new block. The electromagnet therefore need not be capable of rapid switchings. (When the disk rotates at 3600 rpm, for example, there is a period of 16 ms or so between successive switchings.) This kind of slow reversal allows the magnet to be large enough to cover all the tracks simultaneously, thereby eliminating the need for a moving magnet and an actuator. It also affords a relatively large gap between the disk and the magnet, which enables the use of double-sided disks and relaxes the mechanical tolerances of the system without overburdening the magnet's driver.

The obvious disadvantage of LPM is its lack of direct overwrite capability. A more subtle concern is that it is perhaps unsuitable for the PWM (pulse width modulation) scheme of representing binary waveforms. Due to fluctuations in the laser power, spatial variations of material properties, lack of perfect focusing and track following, etc., the length of a recorded domain along the track may fluctuate in small but unpredictable ways. If the information is to be encoded in the distance between adjacent domain walls (i.e., PWM), then the LPM scheme of thermomagnetic writing may suffer from excessive domain-wall jitter. Laser power modulation works well, however, when the information is encoded in the position of domain centers (i.e., pulse position modulation or PPM). In general, PWM is superior to PPM in terms of the recording density, and, therefore, recording techniques that allow PWM are preferred.

Recording by Magnetic Field Modulation

Another method of thermomagnetic recording is based on magnetic field modulation (MFM) and is depicted schematically in Fig. 80.31(a). Here the laser power may be kept constant while the information signal is used to modulate the magnetic field. Photomicrographs of typical domain patterns recorded in the MFM scheme are shown in Fig. 80.31(b). Crescent-shaped domains are the hallmark of the field modulation technique. If one assumes (using a much simplified model) that the magnetization aligns itself with the applied field within

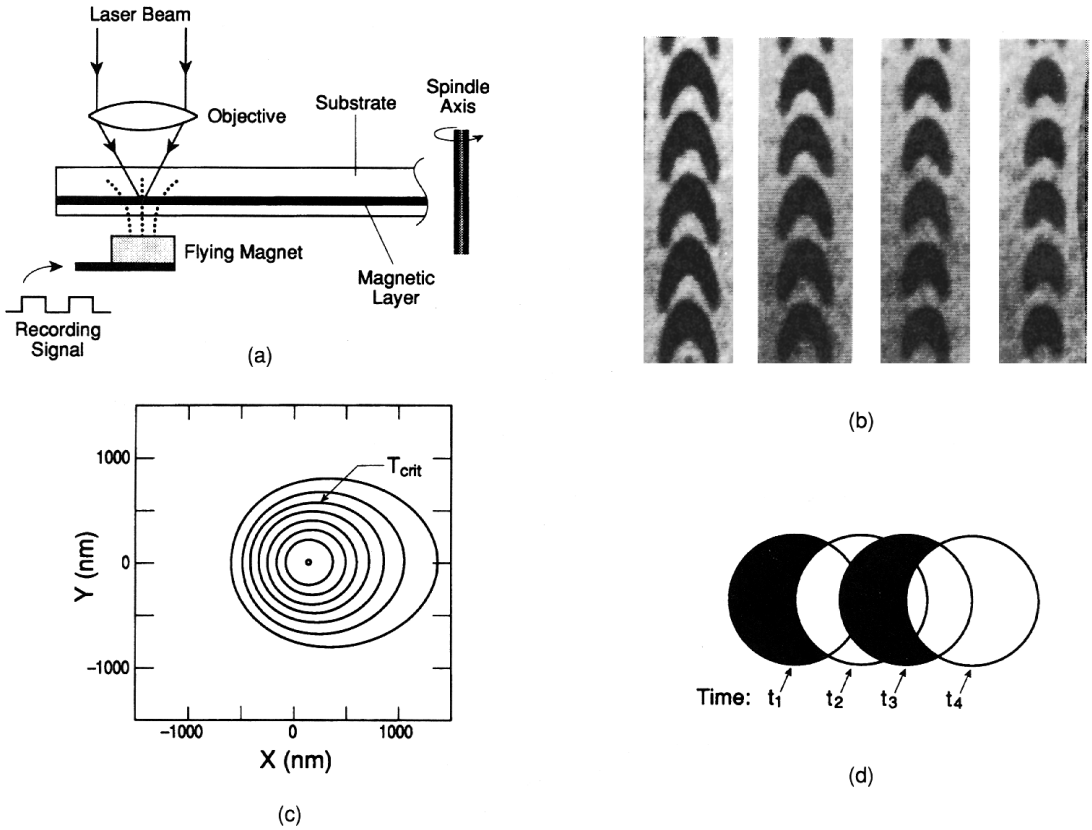

FIGURE 80.31 (a) Thermomagnetic recording by magnetic field modulation. The power of the beam is kept constant, while the magnetic field direction is switched by the data signal. (b) Polarized-light microphotograph of recorded domains. (c) Computed isotherms produced by a CW laser beam, focused on the magnetic layer of a disk. The disk moves with constant velocity under the beam. The region inside the isotherm marked as T_{crit} is above the critical temperature for writing, that is, its magnetization aligns with the direction of the applied field. (d) Magnetization within the heated region (above T_{crit}) follows the direction of the applied field, whose switchings occur at times t_i. The resulting domains are crescent-shaped.

a region whose temperature has passed a certain critical value, T_{crit}, then one can explain the crescent shape of these domains in the following way: With the laser operating in the CW mode and the disk moving at constant velocity, temperature distribution in the magnetic medium assumes a steady-state profile, such as that shown in Fig. 80.31(c). Of course, relative to the laser beam, the temperature profile is stationary, but in the frame of reference of the disk the profile moves along the track with the linear track velocity. The isotherm corresponding to T_{crit} is identified as such in the figure; within this isotherm the magnetization aligns itself with the applied field. Figure 80.31(d) shows a succession of critical isotherms along the track, each obtained at the particular instant of time when the magnetic field switches direction. From this picture it is easy to infer how the crescent-shaped domains form and also understand the relation between the waveform that controls the magnet and the resulting domain pattern.

The advantages of magnetic field modulation recording are that (1) direct overwriting is possible and (2) domain-wall positions along the track, being rather insensitive to defocus and laser power fluctuations, are fairly accurately controlled by the timing of the magnetic field switchings. On the negative side, the magnet must now be small and fly close to the disk surface, if it is to produce rapidly switched fields with a magnitude of a hundred gauss or so. Systems that utilize magnetic field modulation often fly a small electromagnet on the opposite side of the disk from the optical stylus. Since mechanical tolerances are tight, this might compromise the removability of the disk. Moreover, the requirement of close proximity between the magnet and the storage medium dictates the use of single-sided disks in practice.

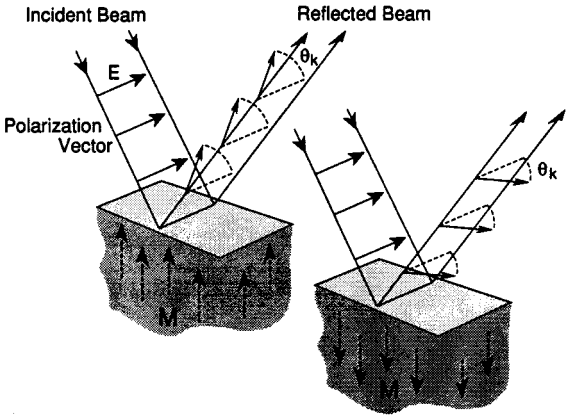

FIGURE 80.32 Schematic diagram describing the polar magneto-optical Kerr effect. Upon reflection from the surface of a perpendicularly magnetized medium, the polarization vector undergoes a rotation. The sense of rotation depends on the direction of magnetization, **M**, and switches sign when **M** is reversed.

Magneto-Optical Readout

The information recorded on a perpendicularly magnetized medium may be read with the aid of the polar **magneto-optical Kerr effect**. When linearly polarized light is normally incident on a perpendicular magnetic medium, its plane of polarization undergoes a slight rotation upon reflection. This rotation of the plane of polarization, whose sense depends on the direction of magnetization in the medium, is known as the polar Kerr effect. The schematic representation of this phenomenon in Fig. 80.32 shows that if the polarization vector suffers a counterclockwise rotation upon reflection from an up-magnetized region, then the same vector will rotate clockwise when the magnetization is down. A magneto-optical medium is characterized in terms of its reflectivity R and its Kerr rotation angle θ_k. R is a real number (between 0 and 1) that indicates the fraction of the incident power reflected back from the medium at normal incidence. θ_k is generally quoted as a positive number, but is understood to be positive or negative depending on the direction of magnetization; in MO readout, it is the sign of θ_k that carries the information about the state of magnetization, i.e., the recorded bit pattern.

The laser used for readout is usually the same as that used for recording, but its output power level is substantially reduced in order to avoid erasing (or otherwise obliterating) the previously recorded information. For instance, if the power of the write/erase beam is 20 mW, then for the read operation the beam is attenuated to about 3 or 4 mW. The same objective lens that focuses the write beam is now used to focus the read beam, creating a diffraction-limited spot for resolving the recorded marks. Whereas in writing the laser was pulsed to selectively reverse-magnetize small regions along the track, in readout it operates with constant power, i.e., in CW mode. Both up- and down-magnetized regions are read as the track passes under the focused spot. The reflected beam, which is now polarization-modulated, goes back through the objective and becomes collimated once again; its information content is subsequently decoded by polarization-sensitive optics, and the scanned pattern of magnetization is reproduced as an electronic signal.

Differential Detection

Figure 80.33 shows the differential detection system that is the basis of magneto-optical readout in practically all erasable optical storage systems in use today. The beam splitter (BS) diverts half of the reflected beam away from the laser and into the detection module.[1] The polarizing beam splitter (PBS) splits the beam into two parts, each carrying the projection of the incident polarization along one axis of the PBS, as shown in Fig. 80.33(b). The component of polarization along one of the axes goes straight through, while the component

[15]The use of an ordinary beam splitter is an inefficient way of separating the incoming and outgoing beams, since half the light is lost in each pass through the splitter. One can do much better by using a so-called "leaky" polarizing beam splitter.

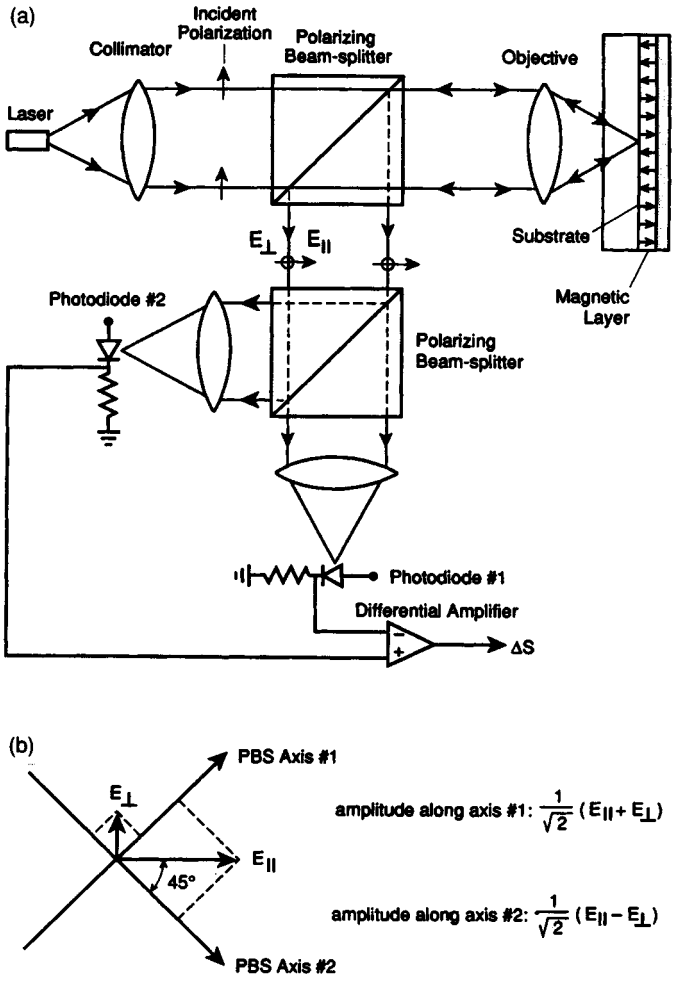

FIGURE 80.33 Differential detection scheme utilizes a polarizing beam splitter and two photodetectors in order to convert the rotation of polarization to an electronic signal. $E_{||}$ and $E_\perp$ are the reflected components of polarization; they are, respectively, parallel and perpendicular to the direction of incident polarization. The diagram in (b) shows the orientation of the PBS axes relative to the polarization vectors.

along the other axis splits off and branches to the side. The PBS is oriented such that in the absence of the Kerr effect its two branches will receive equal amounts of light. In other words, if the polarization, upon reflection from the disk, did not undergo any rotations whatsoever, then the beam entering the PBS would be polarized at 45° to the PBS axes, in which case it would split equally between the two branches. Under this condition, the two detectors generate identical signals and the differential signal ΔS will be zero. Now, if the beam returns from the disk with its polarization rotated clockwise (rotation angle = θ_k), then detector #1 will receive more light than detector #2, and the differential signal will be positive. Similarly, a counterclockwise rotation will generate a negative ΔS. Thus, as the disk rotates under the focused spot, the electronic signal ΔS reproduces the pattern of magnetization along the scanned track.

Materials of Magneto-Optical Data Storage

Amorphous rare earth transition metal alloys are presently the media of choice for erasable optical data storage applications. The general formula for the composition of the alloy may be written $(Tb_yGd_{1-y})_x(Fe_zCo_{1-z})_{1-x}$ where terbium and gadolinium are the rare earth (RE) elements, while iron and cobalt are the transition metals

(TM). In practice, the transition metals constitute roughly 80 atomic percent of the alloy (i.e., $x \simeq 0.2$). In the transition metal subnetwork, the fraction of cobalt is usually small, typically around 10%, and iron is the dominant element ($z \simeq 0.9$). Similarly, in the rare earth subnetwork Tb is the main element ($y \simeq 0.9$) while the gadolinium content is small or it may even be absent in some cases. Since the rare earth elements are highly reactive to oxygen, RE-TM films tend to have poor corrosion resistance and, therefore, require protective coatings. In multilayer disk structures, the dielectric layers that enable optimization of the medium for the best optical/thermal behavior also perform the crucial function of protecting the MO layer from the environment.

The amorphous nature of the material allows its composition to be continuously varied until a number of desirable properties are achieved. In other words, the fractions x, y, z of the various elements are not constrained by the rules of stoichiometry. Disks with very large areas can be coated uniformly with thin films of these media, and, in contrast to polycrystalline films whose grains and grain boundaries scatter the beam and cause noise, amorphous films are continuous, smooth, and substantially free from noise. The films are deposited either by sputtering from an alloy target or by co-sputtering from multiple elemental targets. In the latter case, the substrate moves under the various targets and the fraction of a given element in the alloy is determined by the time spent under each target as well as the power applied to that target. During film deposition the substrate is kept at a low temperature (usually by chilled water) in order to reduce the mobility of deposited atoms and thus inhibit crystal growth. The type of the sputtering gas (argon, krypton, xenon, etc.) and its pressure during sputtering, the bias voltage applied to the substrate, deposition rate, nature of the substarte and its pretreatment, and temperature of the substrate all can have dramatic effects on the composition and short-range order of the deposited film. A comprehensive discussion of the factors that influence film properties will take us beyond the intended scope here; the interested reader may consult the vast literature of this field for further information.

Defining Terms

Automatic focusing: The process in which the distance of the disk from the objective's focal plane is continuously monitored and fed back to the system in order to keep the disk in focus at all times.

Automatic tracking: The process in which the distance of the focused spot from the track center is continuously monitored and the information fed back to the system in order to maintain the read/write beam on track at all times.

Compact disk (CD): A plastic substrate embossed with a pattern of pits that encode audio signals in digital format. The disk is coated with a metallic layer (to enhance its reflectivity) and read in a drive (CD player) that employs a focused laser beam and monitors fluctuations of the reflected intensity in order to detect the pits.

Error correction coding (ECC): Systematic addition of redundant bits to a block of binary data, as insurance against possible read/write errors. A given error-correcting code can recover the original data from a contaminated block, provided that the number of erroneous bits is less than the maximum number allowed by that particular code.

Grooved media of optical storage: A disk embossed with grooves of either the concentric-ring type or the spiral type. If grooves are used as tracks, then the lands (i.e., regions between adjacent grooves) are the guard bands. Alternatively, lands may be used as tracks, in which case the grooves act as guard bands. In a typical grooved optical disk in use today the track width is 1.1 μm, the width of the guard band is 0.5 μm, and the groove depth is 70 nm.

Magneto-optical Kerr effect: The rotation of the plane of polarization of a linearly polarized beam of light upon reflection from the surface of a perpendicularly magnetized medium.

Objective lens: A well-corrected lens of high numerical aperture, similar to a microscope objective, used to focus the beam of light onto the surface of the storage medium. The objective also collects and recollimates the light reflected from the medium.

Optical path: Optical elements in the path of the laser beam in an optical drive. The path begins at the laser itself and contains a collimating lens, beam shaping optics, beam splitters, polarization-sensitive elements, photodetectors, and an objective lens.

Preformat: Information such as sector address, synchronization marks, servo marks, etc., embossed permanently on the optical disk substrate.

Sector: A small section of track with the capacity to store one block of user data (typical blocks are either 512 or 1024 bytes). The surface of the disk is covered with tracks, and tracks are divided into contiguous sectors.

Thermomagnetic process: The process of recording and erasure in magneto-optical media, involving local heating of the medium by a focused laser beam, followed by the formation or annihilation of a reverse-magnetized domain. The successful completion of the process usually requires an external magnetic field to assist the reversal of the magnetization.

Track: A narrow annulus or ring-like region on a disk surface, scanned by the read/write head during one revolution of the spindle; the data bits of magnetic and optical disks are stored sequentially along these tracks. The disk is covered either with concentric rings of densely packed circular tracks or with one continuous, fine-pitched spiral track.

Further Information

Proceedings of the *Optical Data Storage Conference* are published annually by SPIE, the International Society for Optical Engineering. These proceedings document the latest developments in the field of optical recording each year. Two other conferences in this field are the *International Symposium on Optical Memory* (ISOM), whose proceedings are published as a special issue of the *Japanese* J*ournal of Applied Physics*, and the *Magneto-Optical Recording International Symposium* (MORIS), whose proceedings appear in a special issue of the *Journal of the Magnetics Society of Japan.*

devices the techniques were tailored to gate networks of the type described above. The term *gate* was already in use in the forties to denote the logical elements discussed earlier.

There are very many good references on Boolean algebra and we may quote only a selected few of them. Suffice it to mention the texts by Hill and Peterson [1974], Kohavi [1978], and Hohn [1966]. These books give a sufficiently rigorous formulation of the subject, tailored to the analysis and the design of combinational networks. In addition, like most of the earlier books, Hohn's and Kohavi's texts also contain a discussion of the Boolean techniques used in connection with relay circuits. (Some of the more recent works completely omit this topic, which has been but totally overshadowed by the impressive development of electronic networks.) The reader interested in studying the relation of switching algebra to Boolean algebras in general is referred to Preparata and Yeh [1973] for an elementary introduction.

Defining Terms

Boolean algebra: The algebra of logical values enabling the logical designer to obtain expressions for digital circuits.

Boolean expressions: Expressions of logical variables constructed using the connectives *and, or,* and *not.*

Boolean functions: Common designations of binary functions of binary variables.

Combinational logic: Interconnections of memory-free digital elements.

Switching theory: The theory of digital circuits viewed as interconnections of elements whose output can switch between the logical values of 0 and 1.

81.2 Logic Circuits

Richard S. Sandige

Section 81.2 deals with two-state (high or low, 1 or 0, or true or false) logic circuits. Two-state logic circuits can be broken down into two major types of circuits: **combinational logic circuits** and **sequential logic circuits.** By definition, the external output signals of combinational logic circuits are totally dependent on the external input signals applied to the circuit. In contrast, the output signals of sequential logic circuits are dependent on all or part of the present state output signals of the circuit that are fed back as input signals to the circuit as well as any external input signals if they should exist. Sequential logic circuits can be subdivided into **synchronous** or **clock-mode** circuits and asynchronous circuits. Asynchronous circuits can be further divided into fundamental-mode circuits and pulse-mode circuits. Fig. 81.15 is the graphic classification of logic circuits.

Combinational Logic Circuits

The block diagram in Fig. 81.16 illustrates the model for combinational logic circuits. The logic elements inside the block entitled *combinational logic circuit* can be any configuration of two-state logic elements such that the output signals are totally dependent on the input signals to the circuit as indicated by the functional relationships in the figure.

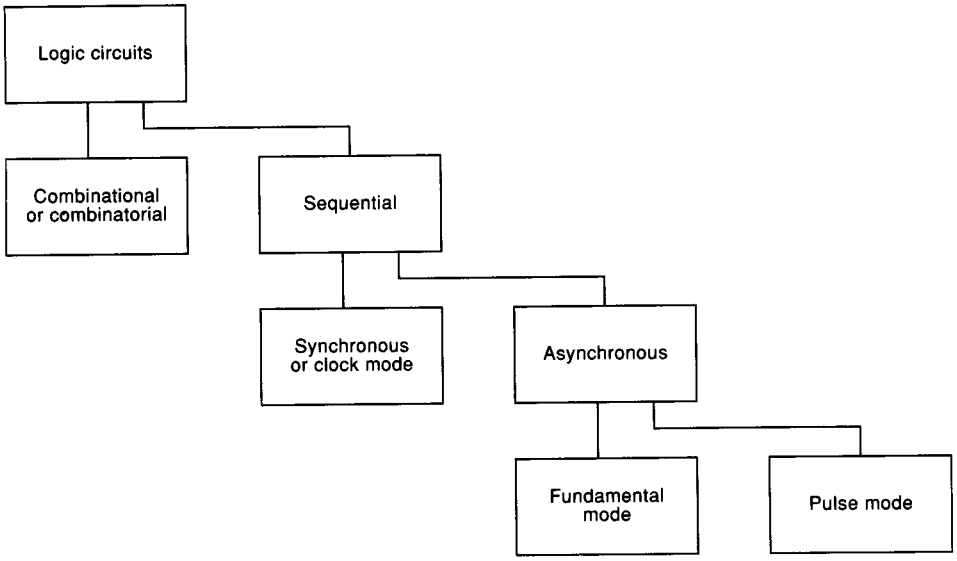

FIGURE 81.15 Graphic classification of logic circuits.

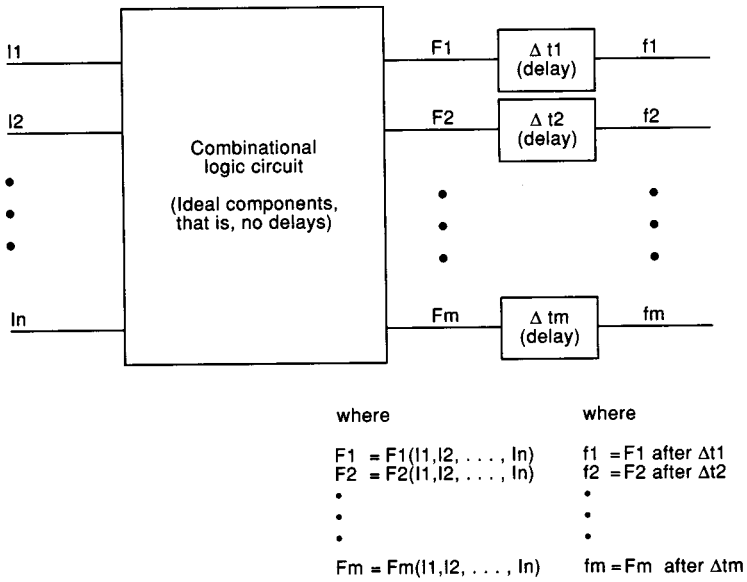

FIGURE 81.16 Block diagram model for combinational logic circuits.

The logic elements can be anything from relays with their slow on and off switching action to modern off-the-shelf integrated circuit (IC) transistor switches with their extremely fast switching action. Modern ICs exist in various technologies and circuit configurations such as transistor-transistor logic (TTL), complementary metal-oxide semiconductor (CMOS), emitter-coupled logic (ECL), and integrated injection logic (I^2L), just to name a few.

The delays in the outputs of the model in Fig. 81.16 represent lumped delays, that is, worst-case delays through the longest delay path from the inputs to each respective output of the combinational logic circuit.

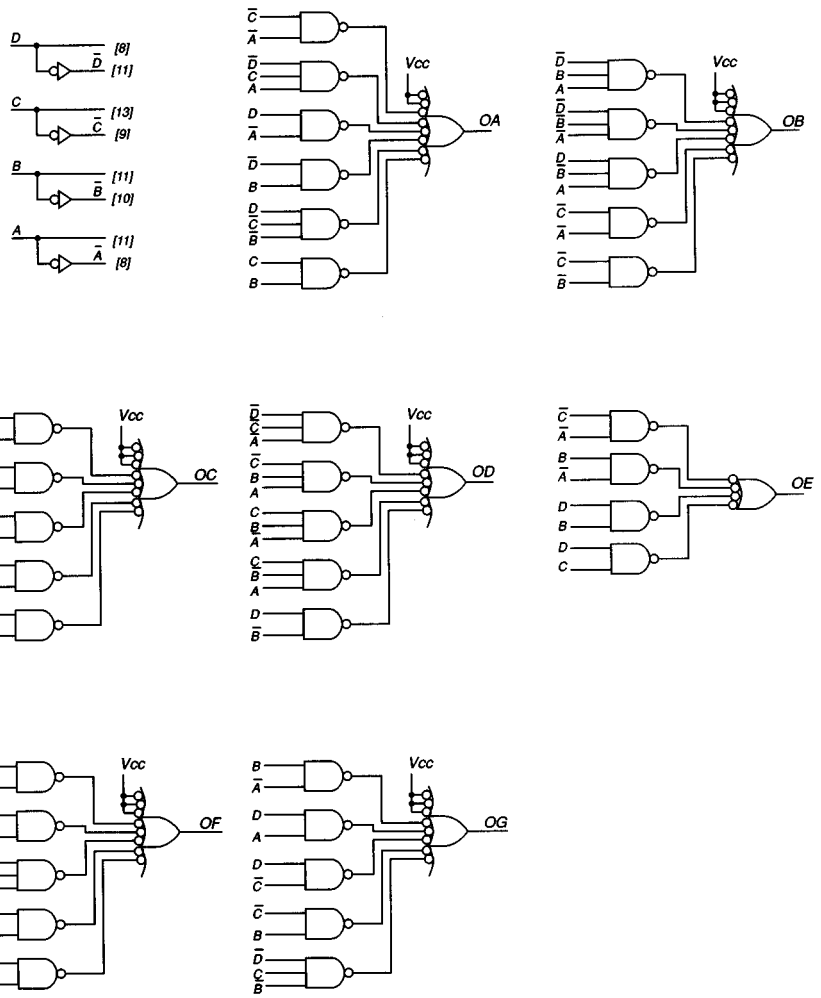

FIGURE 81.17 Gate-level logic circuit for binary to seven-segment hexadecimal character generator.

The lumped delays provide an approximate measure of circuit speed or settling time (the time it takes an output signal to become stable after the input signals have become stable).

Figure 81.17 illustrates the gate-level method (random logic method) of implementing a binary to seven-segment hexadecimal character generator suitable for driving a seven-segment common cathode LED display like the one in Fig. 81.18.

The propagation delays of logic circuits are seldom shown on logic circuit diagrams; however, these delays are inherent in each logic element and must be considered in systems designs. This gate-level combinational logic circuit converts the binary input code 0000 though 1111 represented on the signal inputs D(MSB) C B A(LSB) to the binary code on the signal outputs OA through OG. These outputs generate the hexadecimal characters 0 through F when applied to a seven-segment common cathode LED display. Each of the signal lines D, $\overline{D}$, through A, $\overline{A}$ must be capable of driving the number of gate inputs shown in the brackets (**fan-out requirement**) to both the high-level and low-level required voltages. The output equations for the circuit in Fig. 81.17 are the minimum **sum of products** (SOP) equations for the 1's of the functions OA though OG, respectively, represented by the truth table in Table 81.4.

A more efficient way (in terms of package count) to implement the same combinational logic function would be to use a **medium-scale integration** (MSI) 4- to 16-1ine decoder with gates as illustrated in Fig. 81.19. The tildes are used as in-line symbols for the logical complements of D0 through D15 as recommended by IEEE.

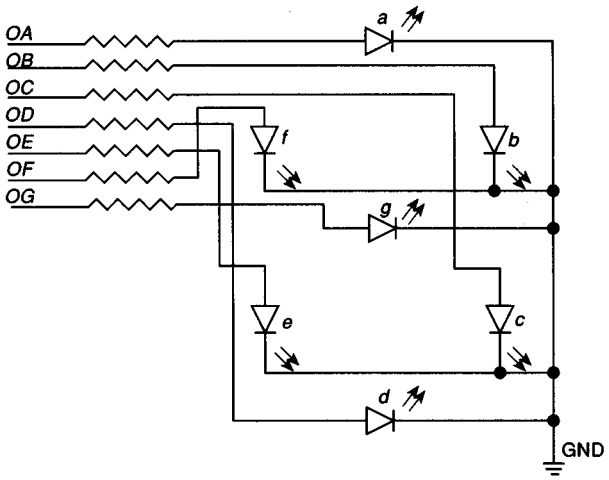

FIGURE 81.18 Seven-segment common cathode LED display.

TABLE 81.4 Truth Table for Binary to Seven-Segment Hexadecimal Character Generator

Binary Inputs				Seven-Segment Outputs							
D	*C*	*B*	*A*	*OA*	*OB*	*OC*	*OD*	*OE*	*OF*	*OG*	Displayed Characters
0	0	0	0	1	1	1	1	1	1	0	0
0	0	0	1	0	1	1	0	0	0	0	1
0	0	1	0	1	1	0	1	1	0	1	2
0	0	1	1	1	1	1	1	0	0	1	3
0	1	0	0	0	1	1	0	0	1	1	4
0	1	0	1	1	0	1	1	0	1	1	5
0	1	1	0	1	0	1	1	1	1	1	6
0	1	1	1	1	1	1	0	0	0	0	7
1	0	0	0	1	1	1	1	1	1	1	8
1	0	0	1	1	1	1	1	0	1	1	9
1	0	1	0	1	1	1	0	1	1	1	A
1	0	1	1	0	0	1	1	1	1	1	b
1	1	0	0	1	0	0	1	1	1	0	C
1	1	0	1	0	1	1	1	1	0	1	d
1	1	1	0	1	0	0	1	1	1	1	E
1	1	1	1	1	0	0	0	1	1	1	F

The decoder circuit in Fig. 81.19 requires only 8 IC packages compared to the gate-level circuit in Fig. 81.17 which requires 18 IC packages. Functionally, both circuits perform the same. The output equations for the circuit in Fig. 81.19 are the canonical or standard SOP equations for the 0's of the functions *OA* though *OG*, respectively, represented by the truth table (Table 81.4). The gates shown in Fig. 81.19 with more than four inputs are eight-input NAND gates with each unused input tied to V_{CC} via a pull-up resistor (not shown on the logic diagram).

An even more efficient way to implement the same combinational logic function would be to utilize part of a simple programmable read only memory (PROM) circuit such as the 27S19 fuse programmable PROM in Fig. 81.20. An equivalent architectural gate structure for a portion of the PROM is shown in Fig. 81.21. The X's in Fig. 81.21 represent fuses that are left intact after programming the device. The code for programming the PROM or generating the truth table of the function can be read either from the truth table (Table 81.4) or directly from each line of the circuit diagram in Fig. 81.21 (expressed in hexadecimal: 7E, 30, 6D, 79, 33, 5B, 5F, 70, 7F, 7B, 77, 1F, 4E, 3D, 4F, and 47) beginning with the first line, which represents binary input 0000,

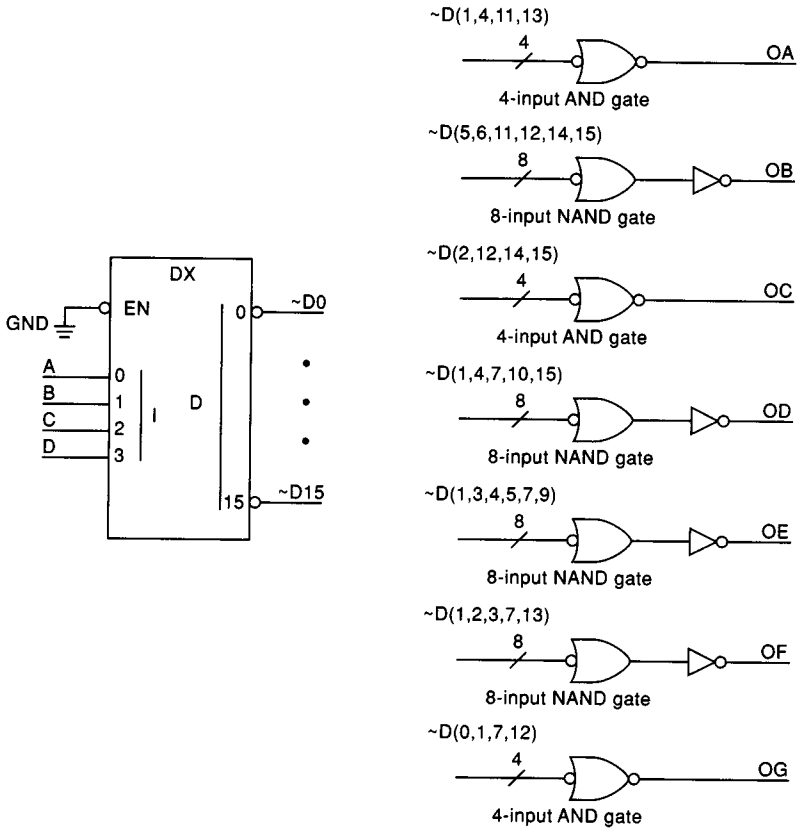

FIGURE 81.19 Decoder logic circuit for binary to seven-segment hexadecimal character generator.

down to the last line, which represents binary input 1111. The PROM solution for the combinational logic circuit is optimum since it represents a maximum efficiency by requiring only a single IC package.

Programmable logic devices (PLDs), such as PROM, programmable array logic (PAL), and programmable logic array (PLA) devices, are fast becoming the preferred devices when implementing combinational as well as sequential logic circuits. This is true because these devices (a) use less real estate on a pc board, (b) shorten design time, (c) allow design changes to be made more easily, and (d) improve reliability because of fewer connections.

Figure 81.22 shows a PAL16L8 implementation for the binary to seven-segment hexadecimal character generator that also requires just a single IC package. The fuse map for this design was obtained using the software program PLDesigner-XL. Karnaugh maps are handy tools that allow a designer to easily obtain minimum SOP equations for either the 1's or 0's of Boolean functions of up to four or five variables; however, there are a host of commercially available software programs that provide not only Boolean reduction but also equation simulation and fuse map generation for PLDs and field programmable gate arrays (FPGAs). PLDesigner-XL (trademark of Minc, Incorporated) is an example of a premier commercial software package available for logic synthesis for PLDs and FPGAs, for both combinational logic and sequential logic circuits.

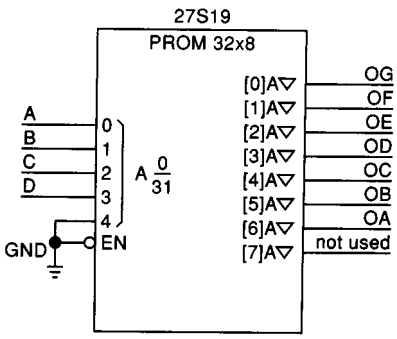

FIGURE 81.20 PROM implementation for binary to seven-segment hexadecimal character generator.

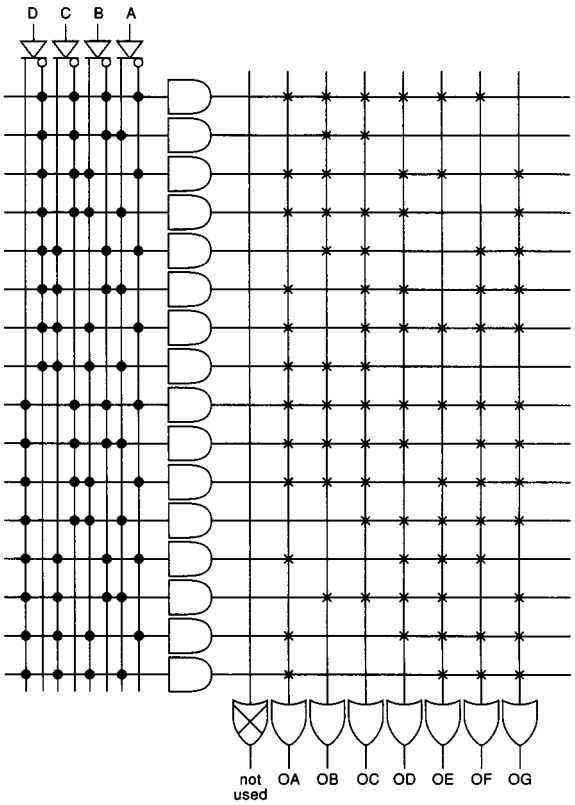

FIGURE 81.21 PROM logic circuit.

Sequential Logic Circuits

A sequential logic circuit is a circuit that has feedback such that the output signals of the circuit are functions of all or part of the present state output signals of the circuit in addition to any external input signals to the circuit. The vast majority of sequential logic circuits designed for industrial applications are synchronous or clock-mode circuits.

Synchronous Sequential Logic Circuits

Synchronous sequential logic circuits change states only at the rising or falling edge of the synchronous clock signal. To allow proper circuit operation, any external input signals to the synchronous sequential logic circuit must generate excitation inputs that occur with the proper setup time (t_{su}) and hold time (t_h) requirements relative to the designated clock edge for the memory elements being used. Synchronous or clock-mode sequential logic circuits depend on the present state of memory devices called bistables or flip-flops (asynchronous sequential logic circuits) that are driven by a system clock as illustrated by the synchronous sequential logic circuit in Fig. 81.23.

With the availability of edge-triggered *D* flip-flops and edge-triggered *J-K* flip-flops in IC packages, a designer can choose which flip-flop type to use as the memory devices in the memory section of a synchronous sequential logic circuit. Many designers prefer to design with edge-triggered *D* flip-flops rather than edge-triggered *J-K* flip-flops because *D* flip-flops are (a) more cost efficient, (b) easier to design with, and (c) more convenient since many of the available PAL devices incorporate edge-triggered *D* flip-flops in the output section of their architectures. PAL devices that contain flip-flops in their output section are referred to as registered PALs (or, in general, registered PLDs). The synchronous sequential logic circuit shown in Fig. 81.24 using edge-triggered *D* flip-flops functionally performs the same as the circuit in Fig. 81.23.

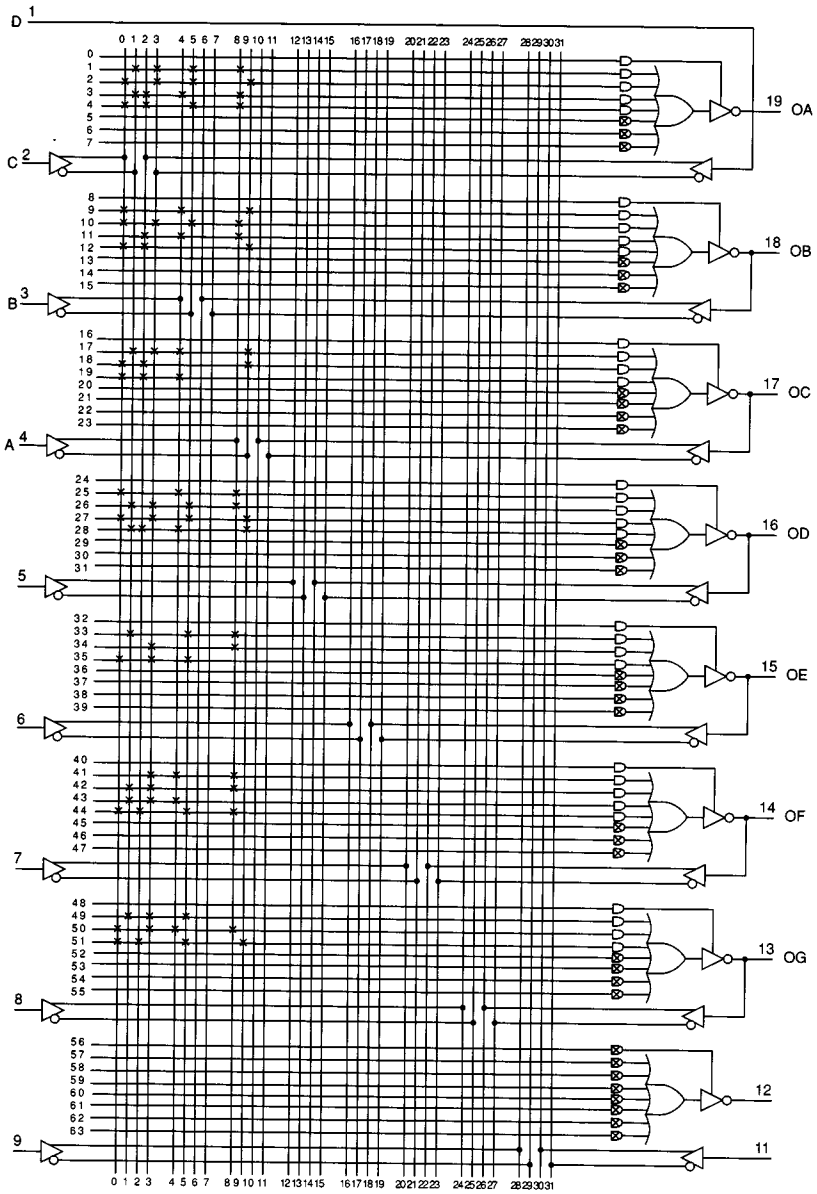

FIGURE 81.22 PAL16L8 implementation for the binary to seven-segment hexadecimal character generator. *(Source: PAL Device Data Book,* Advanced Micro Devices, Sunnyvale, Calif., 1988, p. 5–46.)

Notice that in general more combinational logic gates will be required for *D* flip-flop implementations compared to *J-K* flip-flop implementations of the same synchronous sequential function. Using a registered PAL such as a PAL16RP4A would only require one IC package to implement the circuit in Fig. 81.24. The PAL16RP4A has four edge-triggered *D* flip-flops in its output section, of which only two are required for this design.

Generally speaking, synchronous sequential logic circuits can be designed much more easily (considering design time as the criteria) than fundamental-mode asynchronous sequential logic circuits. With a system clock and edge-triggered flip-flops, a designer does not have to worry about **hazards** or **glitches** (momentary error conditions that occur at the outputs of combinational logic circuits), since outputs are allowed to become stable before the next clock edge occurs. Thus, sequential logic circuit designs allow the use of combinational hazardous circuits as well as the use of arbitrary state assignments, provided the resulting combinational logic gate count or package count is acceptable.

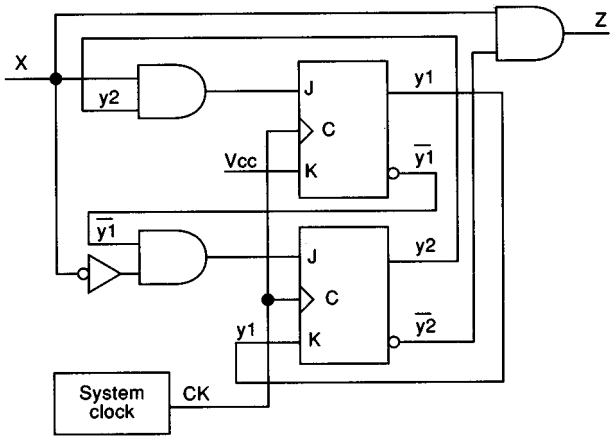

FIGURE 81.23 Synchronous sequential logic circuit using positive edge-triggered *J-K* flip-flops.

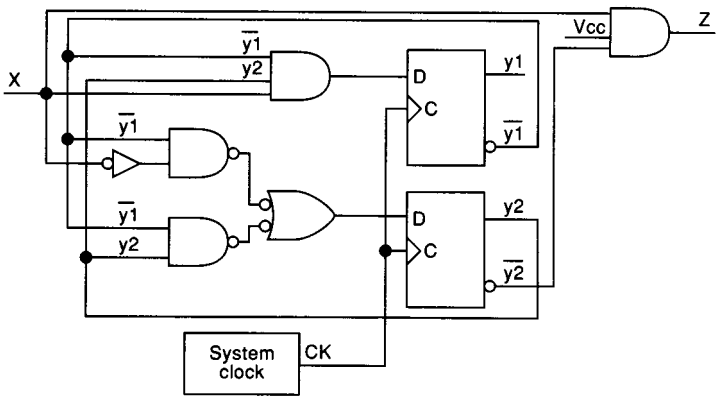

FIGURE 81.24 Synchronous sequential logic circuit using positive edge-triggered *D* flip-flops.

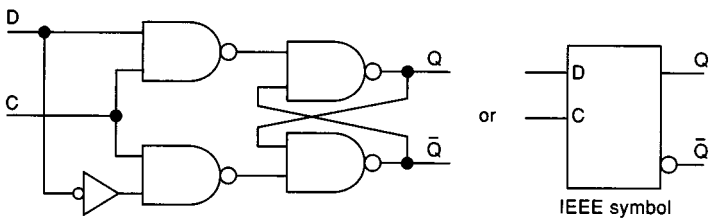

FIGURE 81.25 Fundamental-mode asynchronous sequential logic circuit.

Asynchronous Sequential Logic Circuits

Asynchronous sequential logic circuits may change states any time a single input signal occurs (either a level change for a fundamental mode circuit or a pulse for a pulse mode circuit). No other input signal change (either level change or pulse) is allowed until the circuit reaches a stable internal state. Latches and edge-triggered flip-flops are asynchronous sequential logic circuits and must be designed with care by utilizing hazard-free combinational logic circuits and race-free or critical **race-free state assignments.** Both hazards and race conditions interfere with the proper operation of asynchronous logic circuits. The gated *D* latch circuit

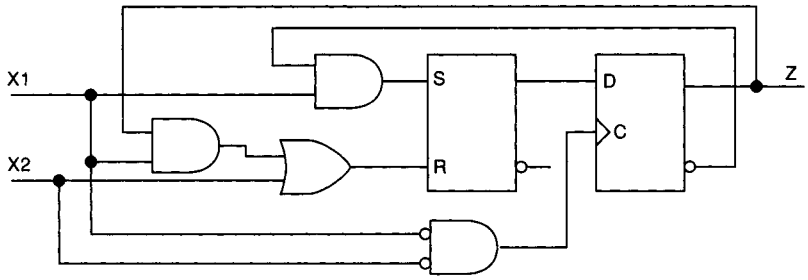

FIGURE 81.26 Double-rank pulse-mode asynchronous sequential logic circuit.

illustrated in Fig. 81.25 is an example of a fundamental-mode asynchronous sequential logic circuit that is used extensively in microprocessor systems for the temporary storage of data.

Quad, octal, 9-bit, and 10-bit transparent latches are readily available as off-the-shelf IC devices for these types of applications. For proper asynchronous circuit operation, the signal applied to the data input *D* of the fundamental-mode circuit in Fig. 81.25 must meet a minimum setup time and hold time requirement relative to the control input *C*, changing the latch to the memory mode when *C* goes to 0. This is a basic requirement for asynchronous circuits with level inputs, i.e., only one input signal is allowed to change at one time. Another restriction requires letting the circuit reach a stable state before allowing the next input signal to change.

An example of a reliable pulse-mode asynchronous sequential logic circuit is shown in Fig. 81.26. While the inputs to asynchronous fundamental-mode circuits are logic levels, the inputs to asynchronous pulse-mode circuits are pulses. Pulse-mode circuits have the restriction that the maximum pulse width of any input pulse must be sufficiently narrow such that an input pulse is no longer present when the new present state output signal becomes available. The purpose of the double-rank circuit in Fig. 81.26 is to ensure that the maximum pulse width requirement is easily met, since the output is not fed back until the input pulse is removed, i.e., goes low or goes to logic 0. The input signals to pulse-mode circuits must also meet the following restrictions: (a) only one input pulse may be applied at one time, (b) the circuit must be allowed to reach a new stable state before applying the next input pulse, and (c) the minimum pulse width of an input pulse is determined by the time it takes to change the slowest flip-flop used in the circuit to a new stable state.

Defining Terms

Asynchronous circuit: A sequential logic circuit without a system clock.

Combinational logic circuit: A circuit with external output signal(s) that are totally dependent on the external input signals applied to the circuit.

Fan-out requirement: The maximum number of loads a device output can drive and still provide dependable 1 and 0 logic levels.

Hazard or glitch: A momentary output error that occurs in a logic circuit because of input signal propagation along different delay paths in the circuit.

Hexadecimal: The name of the number system with a base or radix of 16 with the usual symbols of 0 … 9,A,B,C,D,E,F.

Medium-scale integration: A single packaged IC device with 12 to 99 gate-equivalent circuits.

Race-free state assignment: A state assignment made for asynchronous sequential logic circuits such that no more than a one-bit change occurs between each stable state transition, thus preventing possible critical races.

Sequential logic circuit: A circuit with output signals that are dependent on all or part of the present state output signals fed back as input signals as well as any external input signals if they should exist.

Sum of products (SOP): A standard form for writing a Boolean equation that contains product terms (input variables or signal names either complemented or uncomplemented ANDed together) that are logically summed (ORed together).

Synchronous or clock-mode circuit: A sequential logic circuit that is synchronized with a system clock.

81.3 Registers and Their Applications

B.R. Bannister and D.G. Whitehead

The basic building block of any **register** is the flip-flop, but, just as there are several types of flip-flop, there are many different register arrangements, and an idea of the vast range and their interrelationships is given in Fig. 81.27.

The simplest type of flip-flop is the set-reset flip-flop which can be constructed simply by cross-connecting two NAND/NOR gates. This forms an *asynchronous* flip-flop in which the set or reset signal determines both *what* the flip-flop is to do and *when* it is to operate. In fact, if a state change is required, the flip-flop begins to change state as soon as the input change is detected. This flip-flop is therefore useful as a *latch* which is used to detect when some event has occurred, and is often referred to as a *flag* since it indicates to other circuitry that the event has occurred and remains set until the controlling circuitry responds by resetting it.

Flags are widely used in digital systems to indicate a change of state and all microprocessors have a set of flags which, among other things, are used in deciding whether a program branch should or should not be made. Thus the 8086 family of microprocessors [Intel, 1989], for example, has a group of nine flags—three control flags used to control particular modes of operation of the processor and six status flags indicating whether certain conditions have resulted from the most recent arithmetic or logical instruction: zero, carry, auxiliary carry, overflow, sign and parity. For convenience, although they all act independently, these flags are grouped together into what is known as the *flag register* or *program status word register.*

Gated Registers

The more conventional meaning of register applies to a collection of identical flip-flops which are activated as a set rather than individually. They are, in general, available as four-bit or eight-bit and are used in multiples of eight bits in most cases. It is the number of flip-flops in each register that determines the width of the data

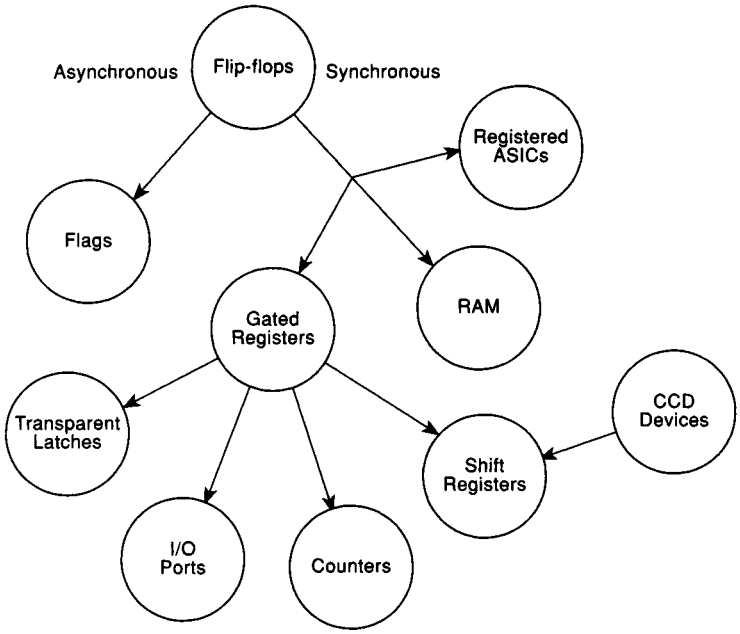

FIGURE 81.27 The register family.

bus in a microprocessor or other bus-based system and that is used to describe the microprocessor. The Z80, for instance, is said to be an eight-bit processor, indicating that the working registers are eight bits wide. The bit values in the register may represent a numerical value in standard fixed point binary, floating point, or some other coded form. Alternatively, they may indicate some logical pattern such as the settings of switches used in an industrial controller.

In order to control *when* the flip-flops set or reset we must make use of *synchronous* flip-flops, leaving the *D* or *J-K* inputs to determine *what* the flip-flop is to do logically, that is to set or reset. In all bus-organized systems it is necessary to control when the data held in the register is fed on to the output bus. This is usually achieved by means of three-state (3S) gates at the register outputs which are disabled, that is, set to their high-impedance state, until the data is required.

A multi-register, bus-structured digital system will have the *n*th bit of each register connected to bit *n* of the data bus at both the input and output of the register. In order to transfer data from one register to another, or, more strictly, to transfer a copy of the contents of one register to another register, the output gates of the source register must be enabled so that the data is fed on to the bus. This data becomes available at the inputs of all registers and is latched in under the control of the appropriate input signals. It is important in the design of the sequencing circuitry that only one set of register output gates can be enabled at any time, although the data can be latched into as many registers as required.

The signal controlling the input to the register is applied to all flip-flops simultaneously and its action depends on the type of flip-flop used. Edge-triggered flip-flops set or reset according to the value on the data inputs at the time the control signal changes. These registers are sometimes known as *staticizers*. After the few nanoseconds required for the flip-flops to settle to their new values, the register content is available at the output gating. The correct operation of the circuitry depends upon certain timing criteria being satisfied and minimum values are quoted by the manufacturers. Each is the smallest time above which the device is guaranteed to operate correctly, but in practice the device probably functions satisfactorily with smaller time intervals on at least some of the parameters. The main timing constraints occur at the inputs to the flip-flops and are illustrated in Fig. 81.28. The interval preceding the active transition of the control input is the setup time, t_{su}, during which the data signal must be held steady; t_h is the hold time and is the interval during which the data signal must be retained following the active transition of the control input; t_w is a minimum pulse width indication which applies to the control inputs such as the clock, reset, and clear. The clock pulse width is usually quoted both for the high state and for the low and is related to the maximum clocking frequency of the flip-flops used in the register.

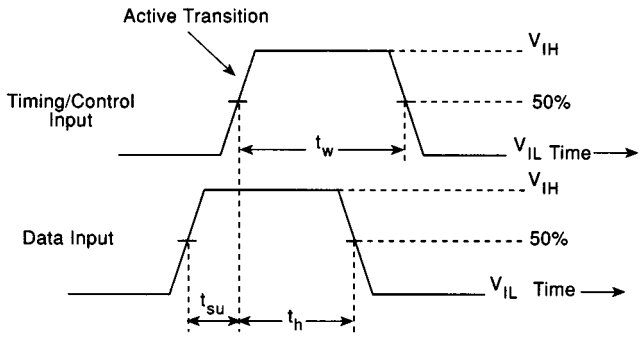

FIGURE 81.28 Control timing parameters.

An alternative flip-flop is the transparent latch, an interesting development of the simple latch. When enabled by a control signal, C, by setting C high or "1", the latch becomes a transparent section of the data path and the data value at the input simply reappears at the output. When the control signal disables the latch, that is C is low or "0", however, the last value applied to the latch is "frozen" and held until the control signal is taken high again. The 74LS373, Fig. 81.29(a), consists of eight transparent latches with a common control input labeled ENABLE. The 74LS374, Fig. 81.29(b), is a typical eight-bit register using positive edge-triggering for all flip-flops. It includes 3S output gates designed specifically for driving highly capacitive loads, such as are found in bus-organized systems, and which respond to an output control signal operating quite independently of the flip-flops. Typical minimum timing figures for the 74LS373 and 74LS374 are shown in Fig. 81.29(c) and the waveforms occurring for the two different types of register are illustrated in Fig. 81.29(d).

An extended form of transparent operation is provided in addressable latches such as the eight-bit 74LS259. As well as being able to store successive bits arriving at a single input, *D*, in the eight addressable latches, using a three-bit address, any latch can be selected for output so that the device can also act as a 1-of-8 decoder or demultiplexer. Four modes of operation are possible under the control of the *enable* and *clear* inputs. In the addressable latch mode the single-addressed latch acts transparently, with all other latches retaining their previous states. When in the memory mode all latches retain their previous states and are unaffected by address or data inputs. In the decode mode the output of the addressed latch follows the level at the *D* input, and in the clear mode all outputs are set low.

Shift Registers

There are essentially two modes of operation for a register, either *serial* or *parallel*, and those we have considered so far have operated in parallel mode. **Parallel operation** affects the entire group of bits held in the register during a single clock pulse. In **serial operation** data bits are inputted (or outputted) sequentially to (or from) the register, one bit for every clock pulse.

A register which has the facility to move the stored bits one place at a time left or right under the control of the clock pulse is called a *shift register* (Fig. 81.30).

Shift registers are normally implemented by means of *D, S-R* or *J-K* flip-flops. As an example, the 74LS165A is shown (Fig. 81.31), consisting of eight *S-R*-type flip-flops with clock, clock inhibit, and shift/load control inputs. The different functions are tabulated in Fig. 81.32.

Data presented to the eight separate inputs is loaded into the register in parallel when the shift/load input is taken low. Shifting occurs when the shift/load input is high and the clock pulse is applied, the action taking place on the low-to-high transition of the clock pulse. Registers are available which switch on the other clock edge. For example, the 74LS295A, which is a four-bit shift register with serial and parallel operating modes, carries out all data transfers and shifting operations on the high-to-low clock transition. This device also provides 3S operation. Selection of the mode of operation is carried out by suitable combinations of the MODE SELECT inputs.

Large-capacity shift registers make use of charge-coupled devices (CCD). These are MOS devices in which data bits are stored *dynamically* as charge between gate and substrate on what is effectively a distributed multi-gate

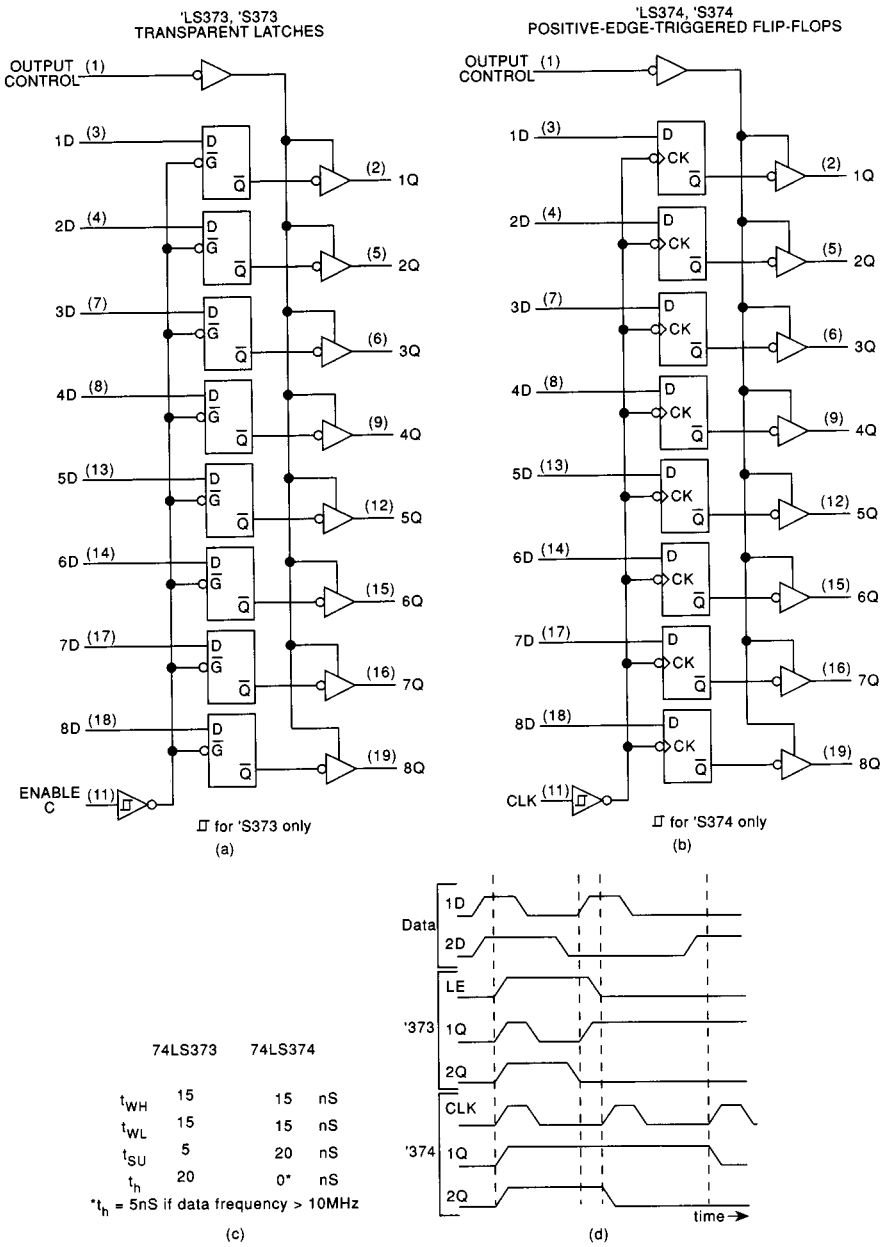

FIGURE 81.29 (a) 74LS373 and (b) 74LS374. (c) Typical minimum timing values and (d) I/O waveforms for the ′LS373/374.

MOS transistor. Consider the diagram (Fig. 81.33) depicting a section through part of an *n*-type substrate which has a series of very closely spaced gate electrodes separating the drain and source of a "stretched" MOS transistor. Using gate "G" and the first storage gate a charge packet of electrons can be introduced into the structure. The overlapping clock pulses allow this charge packet to be moved along the array. At the drain the presence of a charge under the final storage gate is detected by a change in current. Steady-state operation of this type of register is not possible since thermally generated carriers (leakage current) will ultimately cause stationary charge, held beneath a storage gate, to leak away. The result is a minimum operating *shift* frequency of around 20 kHz. The maximum length of the CCD shift register is limited by the charge transfer efficiency; each time the charge packet is transferred between storage gates a fraction is lost. The transfer efficiency also

FIGURE 81.32 Operating modes for 74LS295A.

reduces as the frequency increases, limiting the maximum shift frequency to typically 10 MHz for a 256-bit register. The CCD register is structurally a very simple device and large storage arrays are possible. Devices are available operating from two-, three- and four-phase clocks.

Transfer of data between registers is an important operation in all digital systems and sometimes the data may be modified during the transfer. For example, in an addition routine the contents of one register will be added to the contents of another, the resulting sum then being returned to one of the two registers. Parallel or serial addition could be used, but the example shown in Fig. 81.34 is that of a serial adder. The registers could each be made up of two 74LS295A devices as previously described. The data to be added is transferred to the two shifting registers, *A, B,* using parallel loading of data into the registers, carried out prior to the application of the shift clock pulses shown.

On the falling edge of each clock pulse the data is right-shifted one place. The resultant sum of the two bits plus any carry bit is, on the same clock edge, entered back into register *A*. The *D*-type flip-flop is used to delay the carry bit until the next add time: Data entered at *D* does not appear at *Q* until the falling edge of the clock pulse has occurred, and at such time it is, therefore, too late to modify the previous addition. At the end of the

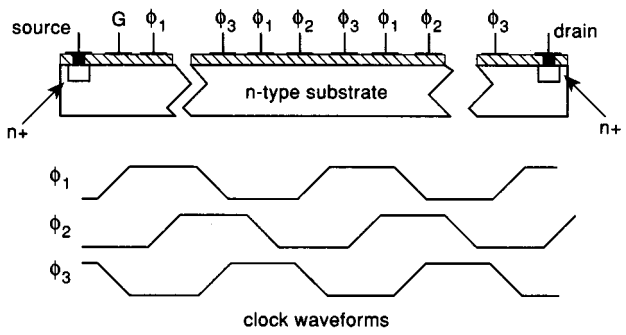

FIGURE 81.33 The CCD register.

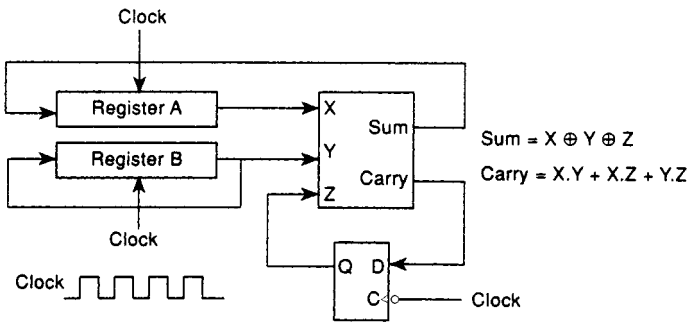

FIGURE 81.34 The serial adder using shifting registers.

addition process, when all the data bits have been shifted through the registers, register *A* contains the sum, and register *B* is unchanged.

A single shift register can be arranged to provide its own input by means of feedback circuits, and its action then becomes **autonomous**, since the only external signal required is the clock signal. There are only a finite number of states of the feedback shift register (FSR), and the output sequence from the register will, therefore, repeat with a cycle length not greater than 2^n bits, where n is the number of flip-flops in the register. This property can be used to create a counter known as a Johnson counter in which the shift register has the *J* and *K* inputs of the first stage fed directly from the Q' *and* Q outputs, respectively, of the last stage. This simple form of feedback leads to the name *twisted-ring counter,* and the result is the generation of a *creeping* or *stepping* code with $2n$ different states. This form of counter is convenient only when the count is small, as the number of flip-flops quickly becomes excessive, but is ideal for a simple decade counter. Unlike standard binary decade counters, the Johnson decade counter requires five flip-flops but no additional feedback circuitry. Gating needed to detect specific settings of the counter is also very simple [Bannister and Whitehead, 1987].

Another set of sequences is obtained if the feedback arrangements are restricted to the use of exclusive-OR, that is modulo-2 functions, and, by correct choice of function, the **linear feedback shift register (LFSR)** so formed generates a *maximal length sequence,* or *m-sequence.* A maximal length sequence has a length of $2^n - 1$ bits (the all-zeros state is not included, since the mod-2 feedback would not allow any escape from that state, so the sequence has a 0 missing) with useful properties of repeatable randomness and is, therefore, described as a *pseudorandom binary sequence* (PRBS). The number of maximal length sequences for a register of length *n*, and the feedback arrangements to achieve them, are not at all obvious, but have been worked out for a large number of cases [Messina, 1972]. A 4-bit LFSR will produce only one maximal length *sequence,* but a 10-bit register can produce 30 distinct *m*-sequences, and a 30-bit register produces no less than 8,910,000 distinct sequences!

Shift registers can be used in parallel to form a *first-in, first-out* (*FIFO*) memory. These are typically 128 × 8-bit register memories with independent input and output buses. At the input port, data is controlled by a

shift-in clock operating in conjunction with an input ready signal which indicates whether the memory is able to accept further words or is now full. The data entered is automatically shifted in parallel to the adjacent memory location if it is empty and as this continues the data words stack up at the output end of the memory. At the output port, data transfers are controlled by a shift-out clock and its associated output ready signal. The output ready signal indicates either that a data word is ready to be shifted out or that the memory is now empty. FIFOs can easily be cascaded to any desired depth and operated in parallel to give any required word length. This type of memory is widely used in controlling transfers of data between digital subsystems which operate at different clock rates and is often known as an *elastic buffer.*

Register Transfer Language

The transfer of data between registers is described using a simple notation termed the register transfer language or RTL. For data transferred from register A to register B we write: $B \leftarrow A$. The symbol $\leftarrow$ is called the *transfer operator.* Note that this statement does not indicate how many bits are to be transferred. To define the size of the register we declare the size thus: $A[8]$, $B[16]$, here defining an 8-bit register and a 16-bit register. If the action to be taken is the transfer of the most significant bit (7th bit) of register A to the least significant bit (bit 0) of register B, then we write: $B[0] \leftarrow A[7]$. Usually data is transferred by the control signal or a clock pulse. If such a signal is designated "C," then we would describe the action by C: $B \leftarrow A$.

Returning to the serial adder circuit shown earlier, we could describe the register transfers thus:

$$A[8],B[8],D[1]$$

$$C\text{: } A[7] \leftarrow A[0] \oplus B[0] \oplus D[0],\ B[7] \leftarrow B[0],\ D[0] \leftarrow \text{Carry}$$

Here in the declaration statement we refer to the D-type flip-flop as a single-bit register. Simultaneous processes are separated by a comma; sequential processes would be separated by a semicolon. The symbol "$\oplus$" is the exclusive-or (XOR) operator. Other logical operations include NOT, AND, OR. The AND operation is also called the *masking* operation because it can be used to remove (or select) specific sections of data from a register. Thus the operation $A[8] \leftarrow A[8]$ &3CH will result in the most significant two bits and the least significant two bits of the eight-bit register A being set to zero. Note that 3CH refers to the hexadecimal number 3C, i.e., 00111100 in binary. Some other terms commonly used are as follows:

$D \leftarrow A'$	transfer the complement of A to D
$A \leftarrow A + 1$	increment A
$A[8{:}15] \leftarrow B[8{:}15]$	transfer bits 8 through 15 from B to A

In order to differentiate between arithmetic and logical operations it is usual to represent OR and AND by $\vee$ and $\wedge$. Table 81.5 lists some typical RTL examples that include arithmetic, bit-by-bit logic, shift, rotate, scale and conditional operations. It is assumed that the three registers are set initially to $A = 10110$, $B = 11000$ and $C = 00001$.

Input/Output Ports

The working registers provided in microprocessors may be thought of as high-speed extensions to the memories used for storing programs and data. The random access memories (RAM) themselves are also arrays of registers, though the form of circuit used differs considerably from the more conventional register. The need to transfer data in and out of the system has led manufacturers to produce special registers which are further extensions to the internal memory and are known as **input and output ports.** One of the simplest of input/output ports is the Intel 8212 (Fig. 81.35). This has two modes of operation selected by the mode input, *MD.* With *MD* at 0 the device acts as an input port and a peripheral unit can enter data on the *DI* lines by sending a high strobe

TABLE 81.5 Typical RTL Examples

Type of Operation	Meaning	Register Bits after Operation
General		
$A_3 \leftarrow A_2$	Bit 2 of A to bit 3 of A	A = 11110
$A_3 \leftarrow B_4$	Bit 4 of B to bit 3 of A	A = 11110
$A_{1-3} \leftarrow B_{1-3}$	Bits 1 through 3 of B to bits 1 through 3 of A	A = 11000
$A_{1,4} \leftarrow B_{1,4}$	Bits 1 and 4 of B to bits 1 and 4 of A	A = 10100
$A_{1-3} \leftarrow B_z$	Groups of bit Z of B to bits 1 through 3 of A	A = 11000
Arithmetic		
$B \leftarrow 0$	Clear B	B = 00000
$A \leftarrow B_2 + C$	Sum of B and C to A	A = 11001
$A \leftarrow B - C$	Difference $B - C$ to A	A = 10111
$C \leftarrow C + 1$	Increment C by 1	C = 00010
Logic		
$A \leftarrow B \wedge C$	Bit-by-bit AND result of B and C to A	A = 00000
$A \leftarrow B \vee C_4$	OR operation result of B with bit 4 of C to A	A = 11000
$C \leftarrow \overline{C}$	Complement C	C = 11110
$B \leftarrow \overline{B} + 1$	2's complement of B	B = 01000
$B \leftarrow A \oplus C$	XOR operation result of A and C to B	B = 10111
Serial		
$B \leftarrow$ sr B	Shift right B one bit	B = 01100
$B \leftarrow$ sl B	Shift right B one bit	B = 00110
$B \leftarrow$ sr2 B	Shift right B two bits	B = 00110
$B \leftarrow$ rr B	Rotate right B one bit	B = 01100
$B \leftarrow$ rl2 B	Rotate left two bits	B = 00011
$B \leftarrow$ scr B	Scale B one bit (shift right with sign bit unchanged)	B = 11100
$B \leftarrow$ scl B	Scale B one bit (shift left with sign bit unchanged)	B = 10000
$B, C \leftarrow$ sr2 B, C	Shift right concatenated B and C two bits	B, C = 0011000000
Conditional		
IF (B_4 = 1)	If bit 4 of B is a 1, then C is cleared	C = 00000
$C \leftarrow 0$		
IF ($B \geq C$)	If B is greater than or equal to C, then B is cleared and C is set to 1	B = 00000
$B \leftarrow 0$, $C_1 \leftarrow 1$		C = 00011

Initial values: A = 10110, $B = \underbrace{11000}_{z}$ and C = 00001.

signal, STB. When the central processor is ready for the data it selects the port by setting the correct address bits on the *device select* inputs. This enables the 3S output buffers and data is routed to the processor data bus via the *DO* lines. This device also includes a service request flip-flop to generate an interrupt signal to the processor when the data is ready. In the alternative mode of use, with the mode input at 1, the device select logic routes data from the processor, now connected to the *DI* inputs, so the 8212 acts as an output port. The data is immediately available to the peripheral unit on the *DO* lines, as the 3S output buffers are permanently enabled. A more sophisticated range of input and output facilities is provided by most microprocessor manufacturers in the form of programmable input/output ports or peripheral interfaces. These are special registers with appropriate buffers and additional built-in control and status registers to facilitate proper system operation.

The majority of input/output devices use 3S bidirectional buffers which switch to the high-impedance state when not enabled. Some input/output ports, however, such as the 8051 family of microcontrollers and derivatives, are provided with *quasi-bidirectional* ports. In this construction, each port pin has an internal pull-up transistor, as shown in Fig. 81.36. For the port pin to be operative as an input the port latch must contain a 1, so that the output FET driver is turned off. (All port latches in the 8051 are set by the reset function.) Under this condition, the pin voltage is pulled high but can be taken low by an external signal when required. These inputs can, therefore, be driven in a normal way by TTL and MOS circuits and can also cope with open-collector or open-drain circuits using the pull-up transistors as load resistors.

Yet more flexible capabilities are provided in the Rockwell 6522 versatile interface adapter (VIA), which, in addition to two 8-bit bidirectional input/output ports, contains two 16-bit programmable timer/counters and

a serial data port using a serial-parallel, parallel-serial shift register. (See internal register summary in Fig. 81.37) Each line of the input/output ports, *A* and *B*, can be individually programmed as an input or an output by means of *data direction registers,* DDR*A* and DDR*B,* respectively, which "mirror" the ports. That is, a bit in the data direction register set at 1 causes the corresponding bit of the port to act as an output, with a value determined by the output latch setting. If the bit in the data direction register is set at 0, this causes the corresponding bit of the port to act as an input, and incoming data may be latched into an internal register under the control of a special peripheral control line, *CA*1 or *CB*1. Data may be written into register bits which are programmed as inputs but the output signal is unaffected. The input latching may be enabled or disabled. When reading a peripheral port with the latching disabled, the value read is the current value on the input pin; with the latching enabled, the value read is the value which existed at the input pin when the active transition occurred at the control input.

The interval timer/counters can operate in a variety of modes and are retriggerable so that an interrupt signal is generated either once, when the interval expires, or continually, when subsequent intervals expire. If an external output is required, it can be either a one-shot output or a squarewave, with the output changing level each time the interval count is completed. The main timer/counter consists of two 8-bit latches operating in

conjunction with a 16-bit counter. The latches store the data which is to be loaded into the counter and are loaded sequentially, since 16 bits are required for the counter but the data bus is only 8 bits wide. When loading the counter with a specific value, the low-order byte is actually routed to the low-order 8-bit latch. Then, when the high-order byte is supplied, it is simultaneously written into both the high-order 8-bit latch and the high-order counter byte, and the low-order byte is also transferred from the latch to the counter. Countdown then begins on the next clock pulse. This method ensures that the correct 16-bit value is loaded, but it also means that the current count value can be modified, during counting if required, by writing to the counter, or the *subsequent* counts can be modified by writing to the latches.

The shift register performs serial data transfers in and out of a given pin under the control of an internal modulo-8 counter. When all the necessary control registers and interrupt handling registers are included with the data direction registers, together with the ports and counters of direct interest to the user, the device requires a total of 16 registers. These are individually addressed using four register select pins, *RS*0–*RS*3.

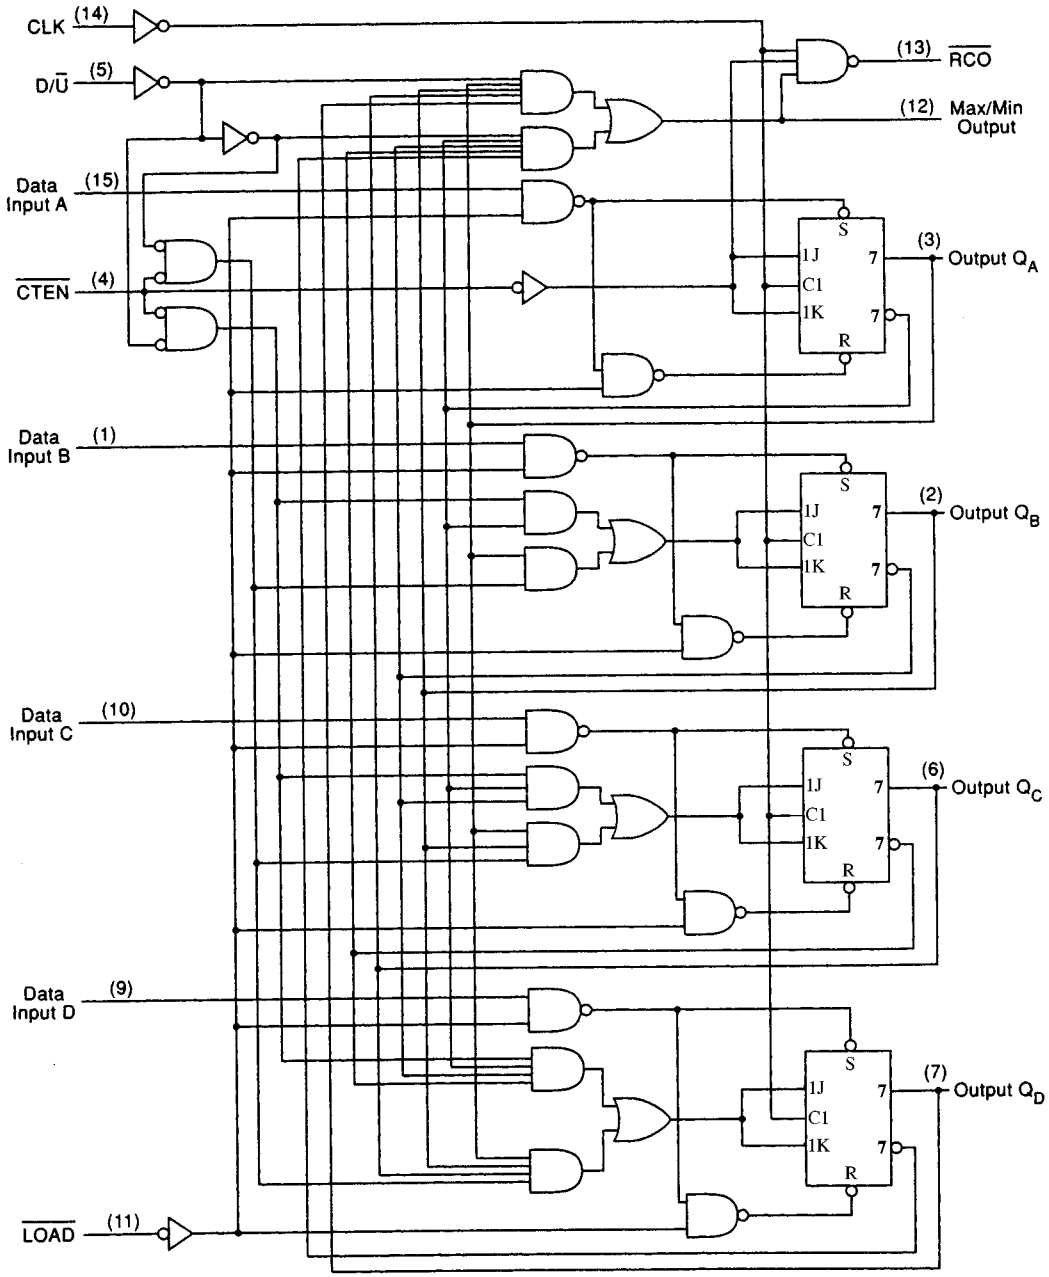

FIGURE 81.38 The 74LS191 programmable counter.

Counters

A register can be loaded with any combination by applying the correct bit pattern to the input data lines and activating the control line. As with the feedback shift registers, it is then only a small step to arrange that the register itself provides the input data by use of feedback connections and, if other circuitry is included to increment the value each time, we have a synchronous counter. The 74L5191 (Fig. 81.38) is a programmable counter which retains the facility for parallel loading of external data.

Each output may be preset to either level by entering the data at the inputs while the LOAD signal is low. The outputs change to the new values independently of the count pulses, and counting continues when pulses

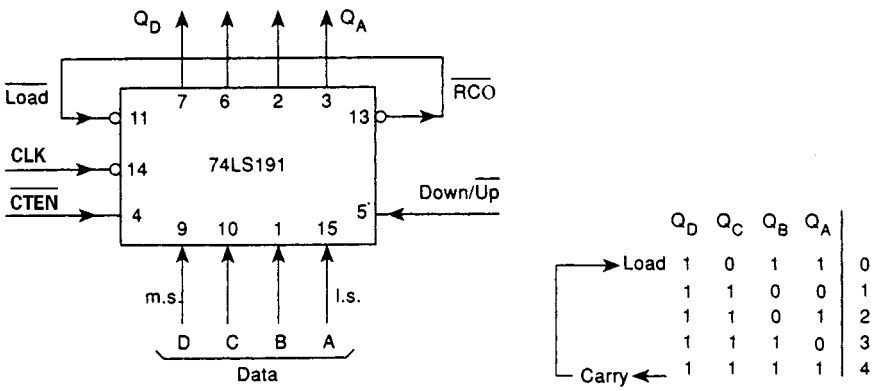

FIGURE 81.39 Programmable counter giving modulo-5.

are applied to the clock input. The master-slave flip-flops are triggered by a low-to-high transition of the clock. The "terminal count" and "ripple clock" outputs facilitate cascading of several counters. The ripple clock carry/borrow output signal, RCO, is a pulse equal in length to the clock pulse when the counter overflows or underflows, that is, when it is incremented from 1111 or decremented from 0000. By using this signal to reload the value at the data inputs we create a counter of modulus less than 16. Figure 81.39, for example, shows the arrangement to give a modulo-5 count, by reloading 1011 each time the ripple clock pulse occurs.

Registered ASICs

Developments in application-specific integrated circuits (ASICs) and field-programmable gate arrays (FPGAs) over recent years have provided digital system designers with a wide range of flexible devices which can be programmed for the specific job in hand. The vast majority of digital subsystems involve sequential logic to a greater or lesser extent, and the array manufactures have provided most devices with registers at either input or output and, sometimes, at both. The Altera EP512 is a good example, and its input structure is shown in Fig. 81.40. The device has eight programmable inputs in which each may be configured as any one of the following:

Synchronous *D*-type flip-flop (register)
Asynchronous *D*-type flip-flop (register)
Synchronous latch
Asynchronous latch
Flowthrough latch (transparent latch)

The *internal latch enable* (ILE) input carries the clock when synchronous mode is selected, whereas asynchronous mode control signals are generated internally. The EP512 contains 12 macrocells and the input/output architecture provides each macrocell with over 50 possible configurations. Each I/O unit can be individually configured for combinatorial or registered output, with the output polarity also programmable. Four different types of flip-flops (*D, T, J-K, S-R*) can be implemented in each I/O unit, for either synchronous or asynchronous operation.

Standard Graphic Symbols

The use of standardized graphical symbols is becoming widespread and the family of registers have their own coherent set of symbols. Two representative examples are given in Fig. 81.41. As shown, the eight-bit shift register is designated SGR8. The direction of shift is given by the arrow. The "1*D*" is part of a notation called *dependency notation.* Clock input C1 controls the inputs labeled 1D, of which only one of four is shown. The reset "*R*" and the clock are common to all units and are shown as inputs to the common block. The external reset line carries a polarity symbol which indicates that a low signal must be applied to reset the 4-bit register. For further details see the References at the end of this section.

Defining Terms

Autonomous operation: Operation of a sequential circuit in which no external signals, other than clock signals, are applied. The necessary logic inputs are derived internally using feedback circuits.

Input/output port: A form of register designed specifically for data input-output purposes in a bus-oriented system.

Linear feedback shift register (LFSR): An autonomous feedback shift register in which the feedback function involves only exclusive-OR operations.

Parallel operation: Data bits on separate lines (often in multiples of eight) are transferred simultaneously under control of signals common to all lines.

Register: A circuit formed from several identical gated flip-flops or latches and capable of storing several bits of data.

Serial operation: Data bits on a single line are transferred sequentially under the control of a single signal.

Further Information

The monthly journal *IEEE Transactions on Computers* regularly has articles involving the design and application of registers and associated systems. Further information can be obtained from IEEE Service Center, 445 Hoes Lane, P.O. Box 1331, Piscataway, NJ 08855-1331.

The *IEE Proceedings-E, Computers and Digital Techniques,* published bi-monthly by the Institution of Electrical Engineers (Michael Faraday House, Six Hills Way, Stevenage, Herts. SG1 2AY UK), is also a useful source of information on the application of register devices.

81.4 Programmable Arrays

Martin Bolton

Programmable arrays or **programmable logic devices** (PLDs) are general-purpose combinational or sequential digital components whose ultimate function is determined by the designer. They leave the manufacturer in an unprogrammed state. The configurations of internal switches are fixed after the particular logic function for the PLD has been prepared and checked using a computer-aided design package appropriate for the PLD family used. PLDs belong to the family of application-specific integrated circuits (ASICs).

PLDs are manufactured today in most digital integrated circuit technologies—principally CMOS and bipolar silicon, and gallium arsenide. The programmable switches themselves can be fuses, antifuses, floating-gate MOSFETs, and RAM cells. The floating-gate devices can usually be erased and reprogrammed, while the RAM-based devices can be reconfigured dynamically. Most PLDs have to be programmed with the aid of a programmer, a unit which is able to deliver the appropriate sequences of programming pulses which configure the PLD's arrays of switches in the pattern specified by the user. Some PLDs can be programmed by sending a data stream to the device in its application environment. This is *in-system programming.*

There are today two major classes of PLDs—those based on the **programmable logic array** (PLA) and **field-programmable gate arrays** (FPGAs). PLA technology is the oldest and is now restricted to the less complex circuits. FPGAs, on the other hand, are a more recent technology and are able to implement complex systems equivalent to networks of several thousand logic gates. The first part of this section will explain the principles of PLA-based PLDs; the second will introduce the concepts of FPGAs. A final section will briefly cover the requirements of computer-aided design for programmable logic.

PLA-Structured Devices

It is possible to represent any Boolean function in the form of a *sum of products.* For example, the expressions for the outputs of a full adder can be represented as:

$$\text{SUM} = A\overline{BC} + ABC + \overline{A}\,\overline{BC} + \overline{AB}C \tag{81.14}$$

$$\text{CARRY} = AC + AB + BC \tag{81.15}$$

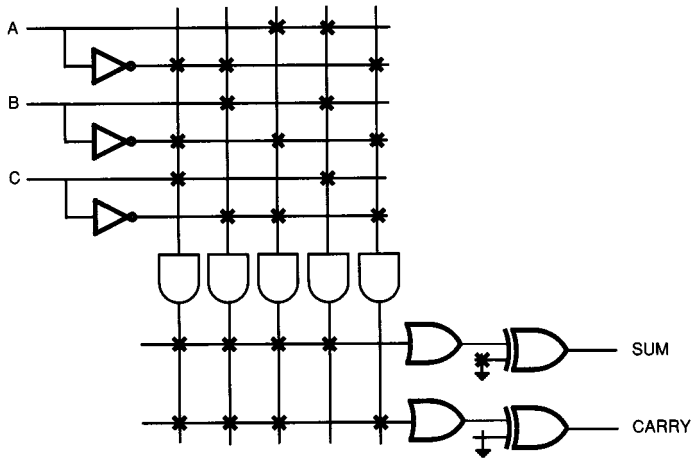

FIGURE 81.42 A full adder implemented in a PLA with programmable output inversion.

where A, B, and C are the inputs. The first equation has four *product terms,* or *products;* the second has three.

A PLA enables functions expressed in this form to be directly implemented. Each product term is generated by a gate which can be programmed to form the AND of any subset of the inputs and their complements, while subsets of products can be summed in a set of programmable OR gates. The programmable gates are constructed in the form of arrays, with the input lines being orthogonal to the product lines, which are themselves orthogonal to the output lines, as shown in Fig. 81.42.

This PLA has three inputs, five product terms, and two outputs. Each input is fed into the first array, the *AND array,* in true and complement form. This enables any product to be formed. The products are all fed into the *OR array.* A cross at an intersection indicates a connection. Notice that some products are used to contribute to both outputs. The ability to share product terms in this way is an important feature of the PLA. The product terms which make up the inputs to the OR gate for the SUM output are those given in Eq. (81.14). The equation for the CARRY output has been modified for use in this PLA which also has programmable output inversions, indicated by the two exclusive-OR gates. The modified equation for the inverse of CARRY, which now shares some products with the first function, is

$$\overline{\text{CARRY}} = A\overline{BC} + \overline{A}\overline{BC} + \overline{AB}C + \overline{ABC} \tag{81.16}$$

Only one new product is now required instead of the three which would have been required without the double negation of the CARRY function.

A PLA is able to implement any set of combinational logic functions, limited only by the number of inputs, number of outputs, and number of product terms. A memory also has this ability, but since in this type of device every combination of inputs is decoded and mapped to a unique set of outputs (via a memory word), the number of inputs handled cannot be as great as with a PLA of similar physical size, since a PLA does not decode every input combination. However, where the set of functions to be implemented would require too many products for a practical PLA, a memory, or a multiple-level network, would have to be used.

An important economy is possible by making use of the fact that for many sets of functions the OR array is not needed for the sharing of products between outputs. Figure 81.43 shows an example of such a function, a multiplexer. Such a function can be implemented by a PLA with only an AND array; the OR array has degenerated into a set of OR gates. The drawback is that the PLA is no longer universal, because a fixed allocation of products to OR gates has to be chosen. PLAs of this structure have become known as PAL devices or just *PALs.* (The term "PAL," which stands for "**programmable array logic**," is a trademark of Advanced Micro Devices, Inc.). There are many applications where the product term sharing capability of the full PLA is wasted, and a PAL-based solution is more economical. Also, because there is only one programmable array, the propagation delay will generally be smaller. Address decoding in microprocessor systems is a very common application of combinational PAL devices.

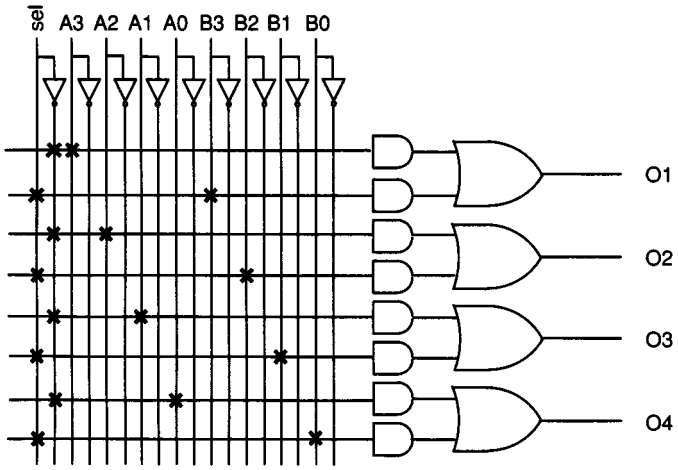

FIGURE 81.43 A four-bit multiplexer implemented in a PAL-structured programmable array.

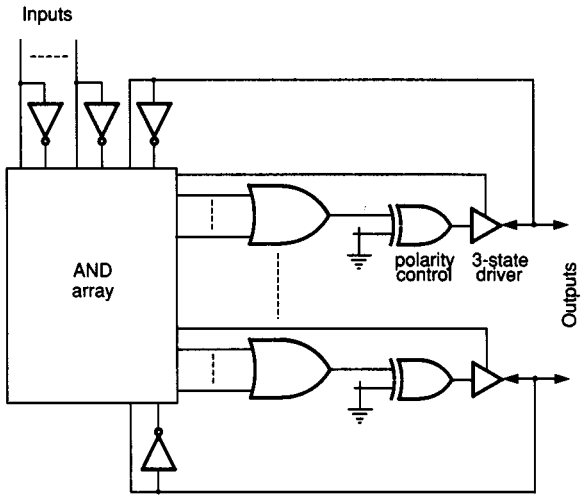

FIGURE 81.44 PAL-structured programmable array with output controls.

PAL devices are available in a wide variety of sizes. Because there is a fixed allocation of products to outputs in a simple PAL device, more different types are needed than in the case of PLAs. This limitation has lately been overcome to some extent in some devices by allowing a limited allocation of products between adjacent outputs.

The flexibility of PAL-structured PLAs can be enhanced by adding controllable three-state output drivers, as shown in Fig. 81.44. The drivers, controlled by additional product terms (or *control terms*), allow those pins to which they are connected to act as either inputs, outputs, or both. This feature allows a single device to be used in a wider range of applications than would be possible with a device with a fixed allocation of inputs and outputs. Note also the polarity control, similar to that in the PLA of Fig. 81.42.

The array structures introduced above can be extended by adding clocked flip-flops to the outputs of the arrays to create general-purpose sequential circuits. A PLA extended in this way is known as a **sequencer**, whose generic structure is shown in Fig. 81.45.

The outputs, which are produced by the OR array, feed either directly to the pins (indicated by Ob in the figure) or to flip-flop inputs (NSa, NSb, and Oa, where "NS" stands for "next state"). The flip-flop outputs are fed back either into the AND array (PSa and PSb, where "PS" stands for "present state") or to pins (PSb and Oa′). The sequencer's primary inputs to the PLA AND array are labeled I. Not every sequencer device will have

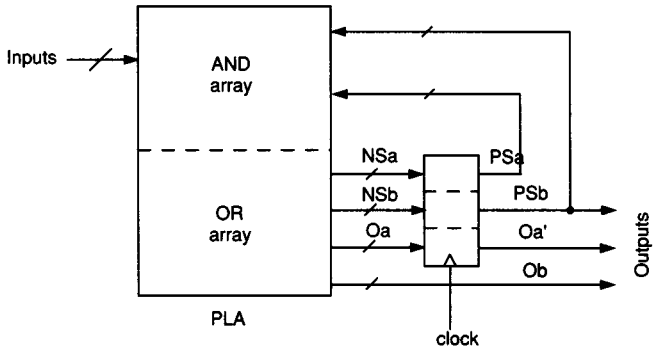

FIGURE 81.45 The structure of a sequencer.

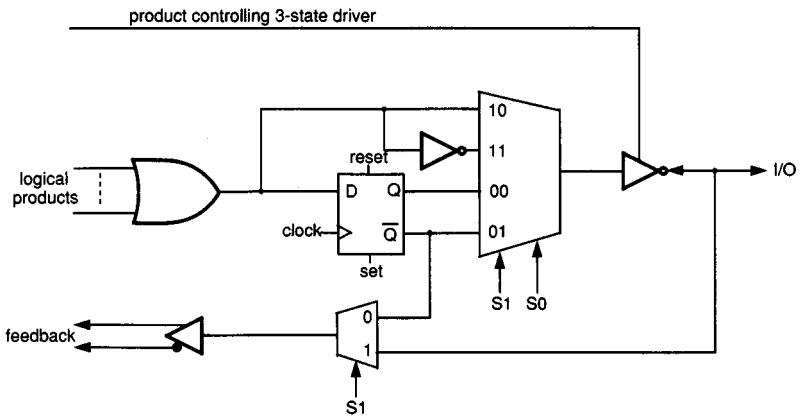

FIGURE 81.46 The output macrocell of the 22V10 PAL device.

all of these paths in its structure. Sequencers are characterized by number of inputs, number of flip-flops, and number of outputs.

A sequencer such as that shown above allows the direct implementation of a synchronous finite state machine with both Moore-type (PSb) or the Mealy-type outputs (Oa′, Ob). The transitions between states in the behavioral specification of the state machine map directly into the product terms of the sequencer.

PAL-structured arrays are also manufactured with clocked flip-flops attached to the array outputs. These are often known as *registered PALs*. State machine descriptions map less naturally into these arrays, but this fact is of less importance nowadays with the reliance on computer-aided design. Registered PALs find wide use in the data paths of digital systems, where special-purpose registers, counters, and data routing functions are needed. Some PAL devices have enhancements such as the exclusive-ORing of outputs to make them more useful in these applications.

Just as a combinational PAL device can be made more general purpose by the addition of a controlled output, a sequential one can be generalized by adding programmable *macrocells* to the array outputs. The output macrocell of the 22V10 device, the first of the *generic* PAL devices to be introduced, is shown in Fig. 81.46.

The modes of this macrocell are controllable by two dedicated bits S1 and S0, programmed into the device, and by a product term controlling the three-state driver. The four possible configurations determined by the programming of S1 and S0 are:

00: registered output, active low, fed back into array
01: registered output, active high, fed back into array
10: combinational input/output, active low
11: combinational input/output, active high

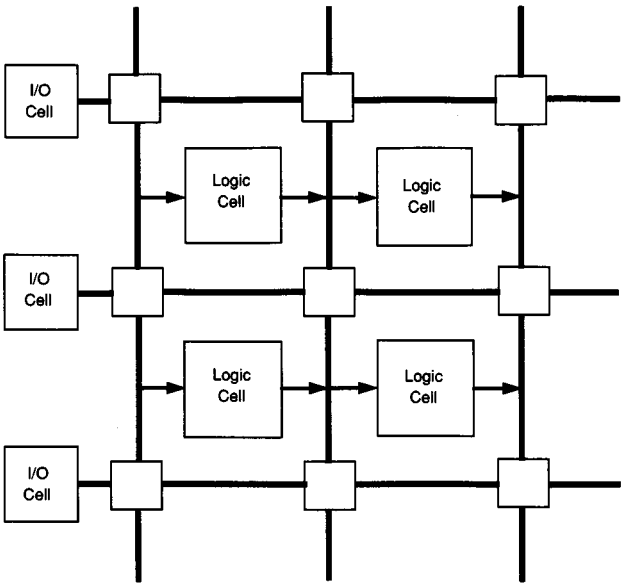

FIGURE 81.47 Interconnection structure in an FPGA.

This form of PAL device is now very widely used and has the advantage that many fewer device types are needed to handle a range of applications. The fastest devices have combinational propagation delays in the 5- to 10-ns range and maximum clock frequencies in excess of 100 MHz.

The single-array devices described so far cannot be extended in size indefinitely; it is difficult to efficiently use large arrays, and the long internal lines required cannot be driven fast enough while maintaining a reasonable power consumption. For these reasons many PLD architectures based on partitioned arrays and switching matrices have been introduced. There is not space to elaborate on these here. A number of these designs are described in Moore and Luk [1991]. However, the most important high-complexity array structure, the FPGA, is introduced in the next section.

Programmable Gate Arrays (FPGAs)

Gate arrays are semicustom devices based on an array of simple cells selected from a library surrounded by an interconnection network. In conventional gate array technology, the interconnection pattern is defined by metallization layers applied at the final stage of manufacture. FPGAs dispense with this final stage by possessing a fixed interconnection network which includes programmable crosspoint switches, as shown in Fig. 81.47. The cells, instead of being selected from a library, are generic and have programmable function. The price for doing this is a lower logic density and higher resistance interconnections, with concomitant effect on speed of operation. Nevertheless, this disadvantage is more than overcome by the short design turnaround times achievable. A major tradeoff in gate array architecture is between cell complexity and interconnection channel capacity. This remains the case with FPGAs.

Each logic cell in an FPGA is a small programmable logic block which will usually contain one or more flip-flops. Typically these cells will have up to ten inputs and a smaller number of outputs.

Computer-Aided Design for Programmable Arrays

As programmable devices become more complex, the capabilities of the computer-aided design support become more and more important. Small PLA and PAL devices can be programmed from a manually created table, but this method is error-prone and cannot be recommended. The earliest widely available design aid for programmable logic was the compiler known as PALASM. This was able to translate the functional specification of a device, expressed in the form of Boolean equations, into the device programming specification for a PAL

device. It also allowed the function of the device to be simulated. Other manufacturer-specific compilers for the simpler PLDs have been produced, but nowadays these needs can be served by one of the very capable Boolean language-based universal compilers.

Recognizing the need for design entry based on schematics, the manufacturers of the more complex PLDs and FPGAs began to offer this alternative; in fact for FPGAs this is an easier option for the design tool writer. Schematics for a PLD describe the interconnection of a collection of notional primitive cells.

Converting a language-based description into the layout of an FPGA is an application of *logic synthesis,* a technology which has evolved independently of programmable logic design tools, but which has now converged with them. However, programmable devices offer new problems to the designer of general-purpose design tools due to the great variety of architectures now existing for the complex devices. Programmable logic design tools are now becoming more integrated into mainstream computer-aided design systems and are starting to adopt the same standards, for example use of the VHDL language for specification.

Defining Terms

Field-programmable gate array (FPGA): A PLD which consists of a matrix of programmable cells embedded in a programmable routing mesh. The combined programming of the cell functions and routing network define the function of the device.

Programmable array logic (PAL) device: A PLA with no OR array, but instead a fixed set of OR gates into which are fed sets of product terms. ("PAL" is a trademark of Advanced Micro Devices, Inc.)

Programmable logic array (PLA): A PLD which consists of an AND array forming logical products of the input literals and an OR array which sums these products to form a set of output functions.

Programmable logic device (PLD): An integrated circuit which is able to implement combinational and/or sequential digital functions which are defined by the designer and programmed into the device.

Sequencer: A PLA which has a set of flip-flops for storage of outputs which can be fed back into the PLA as inputs, enabling the implementation of a finite state machine.

Further Information

Programmable logic is a fast-moving field, with many vendors continually introducing new devices and improved versions of existing architectures. The magazines *Electronic Design, EDN,* and *Computer Design* carry regular announcements of new programmable logic hardware and software products and often print articles illustrating applications and design methods. All of the vendors publish application notes which are the best source of device-specific design information.

81.5 Arithmetic Logic Units

Bill D. Carroll

Arithmetic logic units (ALUs) are combinational logic circuits that can perform basic arithmetic (addition or subtraction) or logical (AND, OR, NOT, etc.) operations on two m-bit operands. ALUs may be constructed from standard integrated circuits or programmable logic devices and are available as single-chip medium-scale integrated circuits. Integrated ALUs may be cascaded to form longer word lengths than are available in a single device.

This section covers the design of arithmetic and logic circuits in sufficient detail for the reader to design and implement basic arithmetic logic units and to understand the operation and utilization of commercial ALU chips. The reader wanting more details or more in-depth discussion of the subject is referred to the References and other sources given at the end of the section.

In the material that follows, it is assumed that operands are signed n-bit binary numbers with the left-most bit representing the sign (0 for positive and 1 for negative) when discussing arithmetic operations/circuits. Negative numbers will be represented in two's complement form. Recall that the two's complement of an n-bit number A is $A' + 1$ where A' represents the bit-wise complement of A. Unsigned n-bit binary numbers are assumed for logic operations/circuits.

Basic Adders and Subtracters

The basic building block for most arithmetic circuits is the **full adder**. A full adder is a logic circuit that produces the two-bit sum (S and C) of three one-bit binary numbers (X, Y, and Z). Table 81.6 shows the truth table and logic equations of a full adder. A logic symbol and a gate-level realization of a full adder are shown in Fig. 81.48.

The addition of two n-bit binary numbers ($X = x_{n-1} \ldots x_1 x_0$ and $Y = y_{n-1} \ldots y_1 y_0$) can be accomplished with n full adders cascaded as shown in Fig. 81.49. Such a circuit is called a **ripple-carry adder** since carries produced

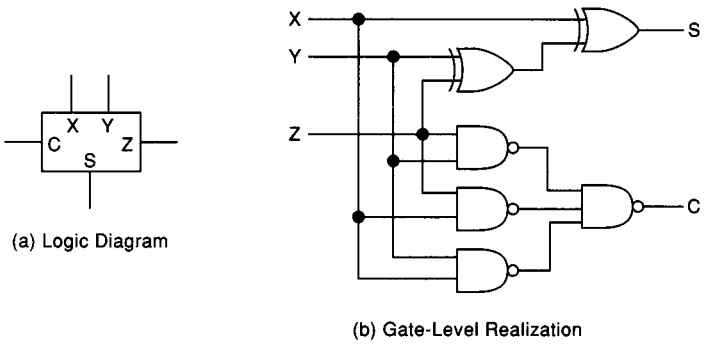

FIGURE 81.48 Full adder.

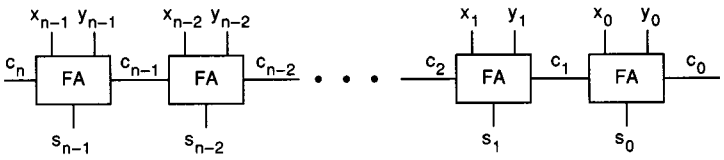

FIGURE 81.49 Ripple-carry adder for two n-bit binary numbers.

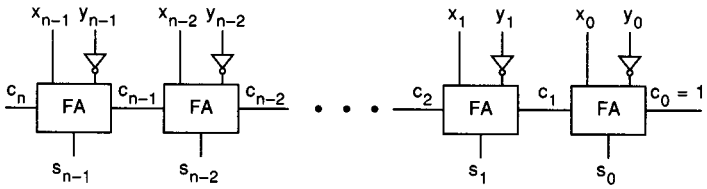

FIGURE 81.50 Two's complement subtracter.

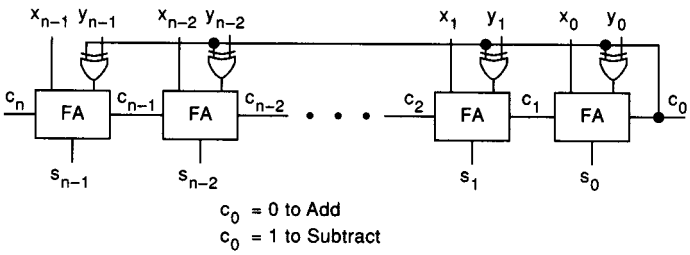

FIGURE 81.51 Two's complement adder/subtracter.

by lower-order stages must propagate or ripple through the higher-order stages before the addition operation is complete.

Ripple-carry adders are simple in both operation and structure but are slow since in the worst case ($X = 1 \ldots 11$ and $Y = 0 \ldots 01$) a carry produced in the least significant full adder must propagate through all the more significant ones. The worst-case add time, t_{add}, is given below where t_{pd} is the propagation delay introduced at each stage.

$$t_{add} = nt_{pd}$$

This assumes that all addend bits are presented to the adder simultaneously. It is important to note that in the least significant full adder, t_{pd} represents the time to compute c_1 from x_0 and y_0 and in the most significant full adder the time to compute s_{n-1} after c_{n-1} is received. In the intermediate stages, t_{pd} is the time needed to compute c_{i+1} from c_i. The propagation delay is approximately equal to the delay of a three-level logic circuit which is consistent with the realization of a full adder given in Fig. 81.48.

Subtraction can easily be performed by adding the minuend to the negative of the subtrahend. In a two's complement number system, $X - Y$ can thus be obtained by computing $X + Y' + 1$. The ripple-carry adder described above can be easily modified to perform this computation by placing inverters on the Y inputs of each full adder and by making the carry-in (c_0) equal to 1. The resulting two's complement subtracter is shown in Fig. 81.50.

A device that can perform either addition or subtraction can be built by replacing the inverters in the subtracter with exclusive-OR gates and using the carry-in (c_0) as a control signal. The resulting two's complement adder/subtracter is shown in Fig. 81.51. The device will function as a ripple-carry adder when $c_0 = 0$ and as a two's complement subtracter when $c_0 = 1$.

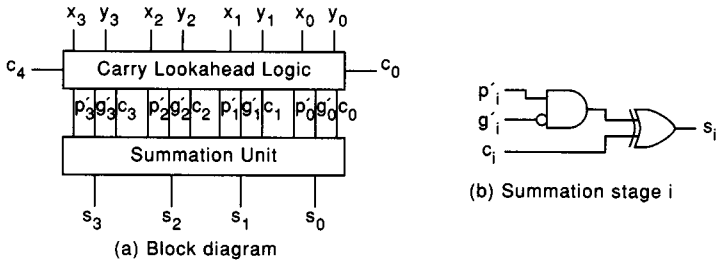

FIGURE 81.52 Carry lookahead adder.

High-Speed Adders

Several different adder designs have been developed for performing high-speed addition. These include **carry lookahead adders (CLAs)**, carry-completion adders, conditional-sum adders, and carry-select adders. Carry lookahead adders have gained wide acceptance in the design of ALUs due to the speed obtained and because they can be conveniently implemented in integrated circuit form.

This material covers only the carry lookahead approach. However, before beginning that discussion, let's briefly explain why fully parallel adders are not feasible. Addition is a combinational process so it is theoretically possible to construct a $2n$-bit "full-adder" that can be realized by a three-level combinational logic circuit and that can perform addition of two n-bit numbers in the time equal to the delay of the circuit. However, such circuits are too costly in terms of gate fan-in to be implemented for reasonable values of n. Carry lookahead is a practical and effective compromise between fully parallel adders and ripple-carry adders. The block diagram of a four-bit CLA is shown in Fig. 81.52(a).

CLAs are based on the observation that a carry-out (c_i) of the ith stage of a full adder is produced by either the propagation of the carry-in (c_{i-1}) through the ith stage or the generation of a carry in the ith stage. This can be seen in the following logic equations for c_i:

$$\begin{aligned} c_i &= x_{i-1}y_{i-1} + x_{i-1}c_{i-1} + y_{i-1}c_{i-1} \\ &= x_{i-1}y_{i-1} + (x_{i-1} + y_{i-1})c_{i-1} \\ &= g_{i-1} + p_{i-1}c_{i-1} \end{aligned}$$

where $g_i = x_i y_i$ and $p_i = x_i + y_i$ are the generate and propagate terms, respectively, for stage i for $i = 0$ to $n - 1$.

The carry equations for an n-bit adder can be derived by repeatedly applying the above equation. The following set of equations results for the $n = 4$ case:

$$c_1 = g_0 + p_0c_0$$

$$c_2 = g_1 + p_1g_0 + p_1p_0c_0$$

$$c_3 = g_2 + p_2g_1 + p_2p_1g_0 + p_2p_1p_0c_0$$

$$c_4 = g_3 + p_3g_2 + p_3p_2g_1 + p_3p_2p_1g_0 + p_3p_2p_1c_0$$

The carry equations can be realized by three-level combinational logic circuits to form the carry lookahead logic block shown in Fig. 81.52(a). The sum (s_i) bits for the ith stage of an adder can be written in terms of g_i, p_i, and c_i and generated by the logic circuit given in Fig. 81.52(b). This completes the description of the four-bit CLA.

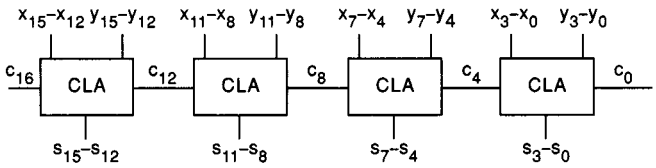

FIGURE 81.53 Cascaded carry lookahead adders.

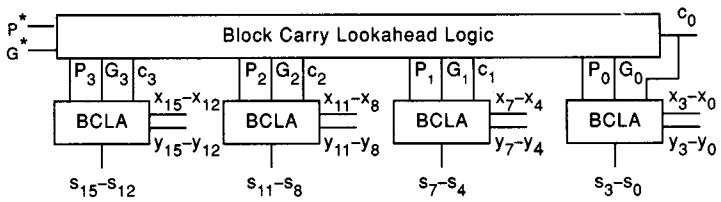

FIGURE 81.54 Block carry lookahead adders.

Now let's examine the add-time, t_{add}, for a CLA. Assume that both addends are applied to the CLA simultaneously and that $c_0 = 0$. Also, let t_{pd} represent the propagation delay of a three-level logic circuit. There are two components that contribute to the add time. First, the three-level carry lookahead logic must produce the carries. This takes t_{pd}. Then, the summation unit must produce the final values of the sum bits. This step takes a time equal to the propagation delay of the exclusive-OR gate in the summation unit which is t_{pd} since an exclusive-OR gate can be realized as a three-level combinational logic circuit. Hence, the add time for a CLA is

$$t_{add} = 2t_{pd}$$

The above result indicates that the add time of a CLA is not only much faster than a ripple-carry adder but is also independent of the length (n) of the addends. Hence, one might conclude that CLAs are the final answer to the high-speed adder problem. However, a closer look at the set of carry equations given above quickly reveals that the equations become progressively more complex in the number of product terms and literals. Therefore, fan-in constraints will eventually limit the practicality of realizing the equations in three-level logic. The actual limit is technology dependent. Standard single-chip medium-scale ALUs typically handle four-bit operands, although longer lengths are certainly feasible with today's technology.

CLAs may be cascaded to produce an adder for longer operands. Figure 81.53 shows a cascade of four 4-bit CLAs to produce a 16-bit adder. Carries are produced using carry lookahead logic within each CLA stage but must propagate between stages in a manner reminiscent of a ripple-carry adder. Hence the add time of cascaded CLAs is dependent on the number of stages in the cascade. The four-stage adder shown in Fig. 81.53 has a worst-case add time of $5t_{pd}$. In general, the add time of an m-stage cascade is $(m + 1)t_{pd}$.

The carry lookahead approach can be applied at a higher level to eliminate the propagation of carries between CLA stages or blocks. This approach uses **block carry lookahead adders** (BCLAs) and block carry lookahead (BCL) logic as shown in Fig. 81.54. A BCLA is a CLA modified to produce block carry propagate (P) and block carry generate (G) outputs instead of a carry-out. BCL logic is a combinational logic circuit that generates block carries (C_j) for each BCLA from the P and G outputs of lower-order BCLAs and c_0. Logic equations for the block carry logic can be derived by repeated application of the following equations for a typical block:

$$C_j = G_j + P_j C_{j-1}$$

where

$$G_j = [g_3 + p_3 g_2 + p_3 p_2 g_1 + p_3 p_2 p_1 g_0]_j$$

and

$$P_j = [p_3 p_2 p_1 p_0]_j$$

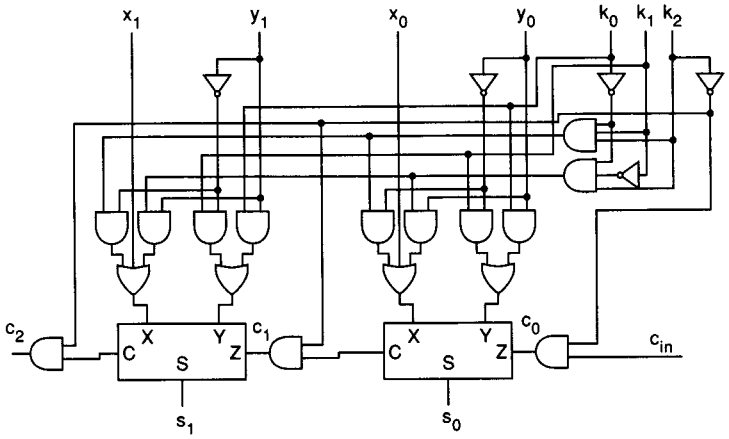

FIGURE 81.55 Multifunction ALU.

TABLE 81.7 Functions Performed by the Multifunction ALU

Control Inputs					
*k*2	*k*1	*k*0	*cin*	Result	Function
0	0	0	0	$S = X$	Transfer X
0	0	0	1	$S = X + 1$	Increment X
0	0	1	0	$S = X + Y$	Addition
0	0	1	1	$S = X + Y + 1$	Add with carry in
0	1	0	0	$S = X - Y - 1$	Subtract with borrow
0	1	0	1	$S = X - Y$	Subtraction
0	1	1	0	$S = X - 1$	Decrement X
0	1	1	1	$S = X$	Transfer X
1	0	0	. . .	$S = X$ OR Y	Logical OR
1	0	1	. . .	$S = X$ OR Y	Exclusive-OR
1	1	0	. . .	$S = X$ AND Y	Logical AND
1	1	1	. . .	$S =$ NOT X	Bit-wise complement

BCLAs and block carry logic units are available in standard medium-scale integrated circuits. Extension of the carry lookahead concept to k levels is possible in theory. However, more than three levels is usually not practical.

Multifunction Arithmetic Logic Units

Devices that can provide a variety of addition, subtraction, and logical operations can be easily designed around the adders/subtracters presented in the previous sections. The logic diagram of the first two stages of an n-bit multifunction ALU is given in Fig. 81.55. Operand inputs for the device are $X = x_{n-1} \ldots x_1 x_0$ and $Y = y_{n-1} \ldots y_1 y_0$ and the output is $S = s_{n-1} \ldots s_1 s_0$. The function performed on the operand(s) is determined by the values of the control inputs k_2, k_1, k_0, and c_{in} as shown in Table 81.7. The given realization is based on a ripple-carry adder for simplicity of presentation. However, the same design approach can be used with other adders such as carry lookahead.

Standard Integrated Circuit ALUs

The devices described above are generic in nature but are similar in function and realization to many commercially available integrated circuit products. Representative products are summarized in Table 81.8.

TABLE 81.8 Typical Integrated Circuit Arithmetic and Logic Devices

Part Number	Function	Features
74LS181	4-bit multifunction (16) ALU	BCL outputs
74LS182	Carry lookahead generator	Use with 74LS181 for BCL
74LS183	Full adder	Two per package
74LS283	4-bit binary adder	Internal CL
74LS381	4-bit multifunction (8) ALU	BCL outputs
74LS382	4-bit multifunction (8) ALU	Ripple-carry output

Defining Terms

Arithmetic logic unit (ALU): A combinational logic circuit that can perform basic arithmetic and logical operations on *n*-bit binary operands.

Block carry lookahead adder (BCLA): An adder that uses two levels of carry lookahead logic.

Carry lookahead adder (CLA): A high-speed adder that uses extra combinational logic to generate all carries in an *m*-bit block in parallel.

Full adder (FA): A combinational logic circuit that produces the two-bit sum of three one-bit binary numbers.

Ripple-carry adder (RCA): A basic *n*-bit adder that is characterized by the need for carries to propagate from lower- to higher-order stages.

82.1 Practical Microprocessors

John Staudhammer and Sue-Ling Chen

A **microprocessor** (μP) is a semiconductor die containing the components of a computer central processor, complete with instruction processing unit, arithmetic, interrupt, and basic communication facilities. Such devices have been around since the early 1970s and have greatly benefitted from the continuing improvements in electronics. As microelectronic technology allows the **feature sizes** of components to be shrunk, more powerful μP systems are being put on single **dies**. One of the early microprocessors, the Intel 8080, is still a widely used controller; its understanding and study are recommended for all designers of microprocessor systems [see Gaonkar, 1984]. Early processors contained a few thousands of transistors, while the top-end microprocessor has over 1.5 million. The early processors were 4-bit machines, initially intended for hand-held calculator use; the largest chips today are intended for use as full central processing units of large computers. What makes these devices *micro* is that they are microelectronic devices. These devices are typically built of NMOS (N-type metal-oxide semiconductor) or CMOS (complementary metal-oxide semiconductor) circuits; the CMOS version is typically a bit more expensive and requires less power. An excellent overview of microprocessors and systems using them is found in Raffiquzzaman [1990].

Application of a microprocessor involves adding memory for program and data, and input/output circuitry, which may involve analog/digital and digital/analog converters. As feature sizes of electronic components shrink, the manufacturer of the chip has three options:

1. Reduce the chip size (the die size)—this may result in a cheaper device of the same capability.
2. Increase the processing power at the same cost.
3. Add **peripheral** circuits to the processor, thus putting on-chip devices normally added to the μP. Adding the right combination of peripherals has the greatest benefit for system cost.

A **microcontroller** (μC) is a microprocessor with peripherals on the same chip. These include various types of memory, interrupt structures, communication means, timing and data acquisition circuits.

All three chip developments listed above occur simultaneously, thus keeping a successful product line going for many years. For example, the Motorola 6800 processor was introduced over 20 years ago; today it is still available, but the manufacturer steers designers to the successor chips, the 6809 μP and the 68HC11 μC.

A μP chip communicates to its peripherals by means of three sets of lines: the bidirectional data bus, the memory address bus, and the control bus. In addition, the μP will also send/receive data on communication

lines; the number and types of these vary greatly among chips. A μC will have on the same chip a number of memory elements, timers, communication ports and buffers, counters, and analog/digital converters in addition to a processor; communication to the peripheral circuits is through ports assigned to these devices, as well as any needed external memories. A discussion of general μC systems is given in Clements [1987], while Myers and Budde [1988] present the details of a very-high-performance μC.

All processors require an external clock, typically a crystal. The processor internal circuits run at this speed, but external devices usually use a submultiple of this rate, the bus clock, which is usually 2 to 4 times slower. The advertised clock rate is usually the external clock rate, not the bus cycle speed.

There are well over a hundred different μP systems on the market. They each have peculiarities and may have some advantages. They differ by the kind of data they handle, the amount of processing they do, and the software support they enjoy. What makes μP practical is not so much its claimed prowess, typically stated in peak instruction execution capability (MIPS, millions of instructions per second), but rather its ease of use in a given application, determined to a large degree by the kind and amount of support software available from the manufacturer.

Types of Microprocessors and Microcontrollers

The yearly compendium of μP/μC chips [Markowitz, 1997] categorizes these chips by the width of the data path: 4, 8, 16, 32, and 64 bits. In addition, high-performance chips include bit/word slice chips—these are meant to implement the functions of a central processing unit for a limited number of bits (4 or 8 bits) and are meant to be concatenated for handling an entire computer word. For a discussion of these chips and their uses, see Mick and Brick [1980].

The most precious resource in a μP chip is the number of connection pins. Great efforts are made to utilize the ones used by various control lines and mode selections for the processor. Hence, a given μP chip may have four or more modes of operation: it is simply cheaper to build a flexible system, rather than several different ones.

The vast majority of μPs possess a richness of data access means (addressing modes); they support many different ways of working with memory and external data items. They are complex instruction set computers (CISC). A prime example is the Motorola 68000 with five data groupings and nine addressing modes.

Even the simplest 4-bit processor in wide use (National Semiconductor COP400) has a 10-bit address bus (and a 4-bit data bus). The device can have up to 1 K words (1024 bytes) of memory on the chip, which is often enough for a simple dedicated task. Thus, these chips often appear as single items in simple computer-controlled devices. Most of these chips are found in embedded applications, in kitchen appliances, and in toys.

By far the largest volume of μPs are 8-bit devices; they use 8-bit-wide (1 byte) data paths, but have address busses usually 16 (or more) bits. Often the data bus is time-multiplexed with the lower byte of the address bus. These types of devices can access as much as 65 K memory locations. The typical instruction execution time is 3 to 7 bus cycles. A widely used 8-bit processor is the Zilog Z-80.

The 16-bit μP chips have 16 data and address lines. The typical execution time is 2 to 5 bus cycles.

The 32-bit and 64-bit μP chips are the high end of these devices and find application in advanced personal computers, high-performance workstations, and digital controllers. They are characterized by high cost (compared to most μC chips) and extensive support circuitry. The typical execution time is 1 to 2 bus cycles. They represent the developing efforts in μP technology.

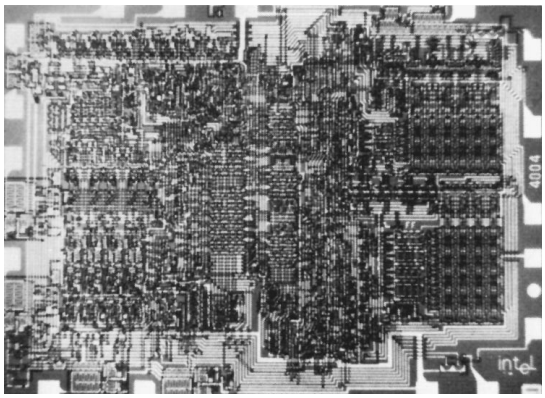
Microcontroller chips contain a μP and various items that make up a μP-based system: there is usually some random access memory (RAM) for holding volatile data, at least one kind of read only memory (ROM) for holding the control program, communication peripherals, including parallel interface(s), serial communication adapter(s), various counting and timing circuits for measuring input pulses, and analog/digital converters. Because each processor has an external clock, usually a crystal clock, timing intervals can be determined to great precision. Many procedures have been developed to take advantage of this precision: voltage-to-frequency converters are used externally to bring pulses to the μP system, which then proceeds to accurately count them. The timing and counting capabilities of μP systems gives them their ubiquitous applicability.

Software for μP/μC Systems

Manufacturers of μP/μC devices have gone to extraordinary efforts to make their devices attractive to system designers. Much software is offered for use with the chips and to support the design effort. ROM-based monitor

The Integrated Circuit

Microelectronics has been the most significant area of development in electrical technology in recent years and has had a profound effect on the course of electrical engineering. The integrated circuit was one of the major developments of its time.



The Intel 4004, the first commercial microprocessor, was originally designed for a programmable calculator. It represented the first consolidation of the arithmetic and logic functions of several chips onto a single integrated circuit. (Photo courtesy of the IEEE Center for the History of Electrical Engineering.)

The increasing complexity of electronic devices meant that even transistorized circuits could be too large and heavy, especially for aerospace applications. In addition, the reliability of such circuits was limited by the ever-increasing number of interconnections. The integrated circuit was a solution to both of these problems. They actually changed the way electrical circuits were designed. Engineers had grown accustomed to creating circuits with a minimum of active components, since transistors and diodes were relatively more expensive than resistors and capacitors. However, active components are both smaller and easier to put on a silicon chip than inactive ones. Thus, the circuits most adaptable to integration are digital circuits, with many active components performing "yes-no" logic functions. Since these are the types of circuits used in computers, it actually encouraged engineers to look for digital solutions to design problems.

The blending of microelectronics and computers has produced the microprocessor, the computer on a chip. This has made possible tremendous reductions in computer size and cost, and consequently has made computers far more available for previously undreamed-of applications. Not since the development of electric power systems began over one hundred years ago have engineers produced such a fundamental and far-reaching tool for change. (Courtesy of the IEEE Center for the History of Electrical Engineering.)

programs are available in most chips so that normal communication tasks can be accomplished easily; programs for usual input/output tasks, data acquisition, timing, and program examples are distributed so that (relatively) error-free software is available for the designers. Most of these are distributed through public-access dial-up bulletin boards. Programming then becomes largely an adaptation of these programs to the tasks that the system is to perform. Of course, the system task analysis and program system design are still the designer's responsibilities, as is the conduct of a software validation.

The μP receives instructions, from its internal or external memory, and data, as a combination of zeros and ones; it is this machine code instruction that controls the operation of the system. The writing of such machine code is far too tedious. An English-like language, machine mnemonics, is used to describe each machine operation and this is then translated to the 0's and 1's which are stored in the memory. For example ADD 123 may stand for the machine code necessary to perform the addition of the number contained in memory location 123 to the content of the computer's arithmetic register, leaving the result in the arithmetic register. The manufacturers supply assemblers to accomplish the mnemonic language assembly into code that may be loaded into the μP memory. These assemblers typically will run on personal computers and various minicomputer systems. Programs that monitor the operation of an actual chip through the μP serial port(s) are effective development tools.

Hence, the typical software includes an assembler, a loader, and a monitor. More user-oriented software for these tasks is available from third-party vendors; many of these extra-cost software packages are highly cost effective. Interactive assemblers and debugging tools are particularly good investments.

Packaging and Cost

The simplest processors are housed in normal dual in-line packages (DIP) of 16 pins or more, spaced 0.3 inches wide. Thus, they resemble conventional transistor-transistor logic (TTL) packages. The mid-range ones are usually in large DIP packages, 0.8 inches wide, with 40 to 68 pins (2 to 4 inches long.) The high-performance ones come in multirow pin packages and may require 200 connections and may use unusual chip sockets. The high performance chips may require special cooling.

Virtually all processors are multisourced, i.e., they are available from more than one manufacturer. This is an important consideration for continued product support. The processors come in various speed grades; the higher speed ones may be 3 to 5 times as costly as the slow-speed versions.

The low-end processors, with no memory and a few communication ports, cost less than $1 in quantity. The widely used Z-80, developed about 20 years ago, costs about $1, while the high-end processors (i860, Pentium Pro) cost around $1000, in low quantities.

Programming of μPs

Most μP systems are programmed in assembly language. Each of the instructions that the processor can execute is given an English-like name (i.e., ADD for the instruction to add two numbers) and translator programs are available from the μP manufacturers to translate the English-like statements (the source code) into the machine codes (which are streams of zeros/ones that the μP interprets). Such assemblers are available from public-access bulletin boards maintained by several vendors; however, convenient assemblers for specific μP systems are usually bought from third-party vendors. Almost all μP assemblers are meant to be used on personal computers; some are available for minicomputer systems. One should check with the chip manufacturer for current software.

High-level language compilers are also available for most μPs, typically from third-party vendors. These are usually C-language compilers, but Pascal compilers also may be available. Here again, the best guide is the chip manufacturer.

The programming of μP systems usually involves carefully tailored code to control signals that interact with the processor chip. Usually the functions that are required of the processor are time-critical real-time control actions. Programs for such applications can easily become highly intricate and require detailed knowledge of all the functions of the processor chip. For a discussion of these problems, see Chapters 3 and 4 of Peatman [1988].

Development Support

Complex μP/μC systems are designed top-down: the task statements are successively refined to a set of smaller tasks, until they can be implemented in relatively short subroutines. The design approach for micro-based systems is described and illustrated in Peatman [1988].

The most important support software for a designer is programs for checking the system, both for logical flow and for cycle-by-cycle activity. Often subtle errors and data dependencies will occur; finding them may be a daunting task. Simulators are the first-level checkout tools for programs. Simulators do not use the actual hardware; rather they use a software model of it. They calculate and show the contents of all computer registers, of ports and selected memory locations, so that an effective check of the internal operations can be made. Most simulators are from third-party vendors.

The actual operation of the μP/μC system may be checked with an in-circuit emulator (ICE), an expensive but effective tool that replaces the μP or μC pin-for-pin in the actual circuit. The ICE typically uses a more powerful computer to mimic the performance of the μP/μC being developed. The ICE tracks signals (including many transients) and can be used to effectively show the behavior of the system, as well as the expected response from the μP and its associated software.

Comparison of μP/μC Chips

As with all computer devices, the advertised speeds and performance figures must be carefully interpreted. These numbers tend to measure only the performance of the manufacturer's test cases and may not be directly comparable [see Hennessey and Patterson, 1990]. These numbers may not be applicable to any one user's requirements. Since the market for μP/μC chips is highly competitive, small differences become amplified in advertising.

Unfortunately, getting a valid number for comparison purposes requires an extensive effort at benchmarking. The advertised performance figures may be taken as a guide, if the task is similar to the benchmark programs. If the processor does not pass the comparison with a comfortable margin, however, one should opt for a higher-performance version of the same chip (if much programming already has been done) or select a clearly superior other candidate.

Trends in μP/μC Developments

An entire microprocessor may be used as a building block in an application-specific integrated circuit (ASIC), available from various vendors. ASIC and VLSI design tools may be used to design such systems, tailored to specific user applications. The μP manufacturers are developing μC chips extending the use of their basic processors. For any application, the best procedure is to invite several vendors to propose alternate systems. Current chips are merely indications of devices to come.

High-performance μP systems are becoming more RISC (reduced instruction set computer) oriented. The object is to execute one instruction per clock period (versus the prevailing 3 to 7 cycles) and to obtain a more regular processor structure. The most popular μP/μC systems are CISC processors. For a user it makes little difference what the internal structure of the processor is; the availability of user support software is far more critical. The trend is to make processors simpler, thus speeding up program execution, even if some programs may have to use more program steps in replacing many "convenience" instructions.

Nevertheless, the very high end μP systems have such a wide data path (32 or 64 bits) that more than one instruction may be accessed at one time. These machines are termed very long instruction word (VLIW) machines. They are able to execute more than one instruction per clock cycle, but they will be more complex internally. For users, both the simpler RISC and the complex VLIW machines will provide increased performance.

Microelectronics is able to produce 2 million transistor chips. While they are expensive, they will replace virtually all of the peripheral chips: memory, timers, and communication channels can all be controlled from a single chip. However, the humble 8-bit chip is still be the most cost-effective workhorse of the bulk of μC applications.

Defining Terms

Die: The piece a silicon wafer containing all electronics.

Feature size: The characteristic size of electronic components on a die.

Microcontroller (μC): A microelectronic chip incorporating a μP and memory, communication, as well as other computer support functions.

Microprocessor (μP): A microelectronic chip that carries out all operations of a computer central processing unit: instruction fetch, execution, interrupt and management of address, data and control lines which are connected to the chip.

Peripheral: Device that supports the functions of the processor. The peripheral may be all electronic (a communications adapter) or may contain mechanical parts (a disk memory). To the processor a peripheral appears as electronics with timing constraints.

Further Information

The magazine *EDN* runs an annual microprocessor/microcontroller review, typically late in the year (i.e., September 25, 1997). These are handy compendia of characteristics.

The IEEE magazine *Micro* presents detailed articles on device development and applications of microprocessors and systems which embed them. At mid-year the magazine carries a set of articles based on the Hot Chips Symposium, presenting developments in μP and chip technology for high-performance workstations and systems.

Specifics of various microprocessor and microsystem chips are found in the respective manufacturer's reference literature; for any design one must become familiar with the applicable manual and design notes. Even for a modest chip the reference manual may run 300 pages; in addition, the manufacturer's free-of-charge support software is of comparable size. For example the Motorola 68HC11 reference manual is 512 pages, and there is over 1 megabyte of design support software available from the manufacturer. The Intel i860 data book is 150 pages, hardware and programmer reference manuals are over 300 pages, and the support software is several megabytes.

82.2 Applications

Phillip J. Windley and James F. Frenzel

Microprocessors are cheap, small, and consume little power. In addition, in recent years their performance has increased at a greater rate than the performance of larger computers. These factors have led to an explosion in the application of microprocessors. A short section could never do justice to every application; therefore, we will view representative applications in three broad areas:

- Data collection, where microprocessors are used to monitor sensors and either record the collected information or communicate the information to some other computer.
- Control, where microprocessors have largely replaced analog electronics for controlling everything from manufacturing robots to home appliances.
- Computing, where microprocessors have transformed the concept of computer and made parallel processing possible.

Admittedly, these categories are not strictly disjoint. They do, however, represent the most pervasive uses for microprocessors at an abstract level.

Data Collection

In data collection the microprocessor-based system serves primarily as a low-cost data recorder. Basic functions include the polling of sensors, acceptance of data, data storage, and data transmission or display. Additional features might include preprocessing of the raw data. Such a classification spans a broad range of applications, from automotive diagnostics to space-born monitoring stations.

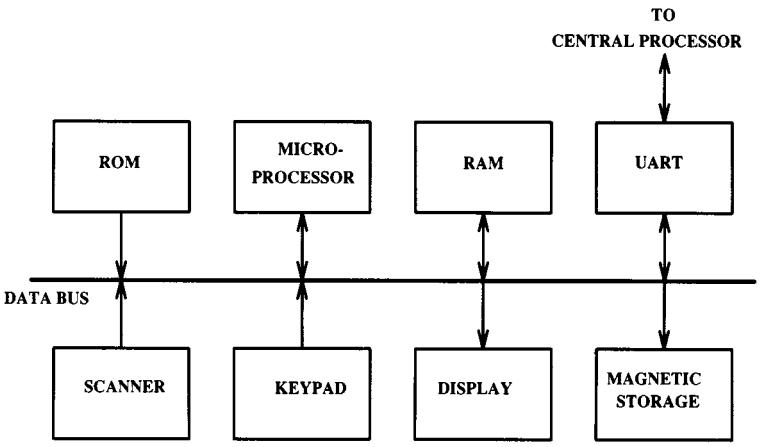

FIGURE 82.1 Point-of-sale terminal system.

Microprocessors are well suited as the controller for such tasks because of their cost and flexibility. Sufficient numbers of processors may be used to allow real-time data acquisition. Because the microprocessor is programmable, sensors may be added, removed, or rearranged without major system impact. Finally, because the microprocessor is a computational device, calculations may be performed on the recorded data to produce useful information, such as calculating speed from distance and time. In the next section we will examine the components of one such system, the retail point-of-sale terminal [Hordeski, 1984].

Point-of-Sale Terminal

The function of a point-of-sale (POS) terminal is characteristic of the applications under the category of data collection. The microprocessor is not being used for intensive computations, nor for controlling a complex process, but rather to collect data, perform some processing, and then pass the results on to a central collector. The cost and flexibility of the microprocessor make it an excellent choice over special-purpose hardware.

System Components. In addition to the microprocessor and storage capability, the typical retail terminal has one or more input devices for entering prices (e.g., keyboard, bar code scanner) and one or more output devices for displaying totals (e.g., paper tape, display). Often these terminals are part of a large network of terminals and may support additional features beyond totaling purchases such as automated inventory control and credit checking. A complete system is shown in Fig. 82.1, including magnetic tape for storing transactions and a **universal asynchronous receiver/transmitter (UART)** for communication with a central processing facility. Because of the high unit volume, it is desirable to keep the cost and complexity low. Typically, each terminal will have limited storage capability, relying on a central processor for maintaining store inventory and credit checks. In order to reduce communication traffic with the central processor, however, each terminal generally has in storage the current price for all items.

Universal Product Code. The use of the Universal Product Code (UPC) has enabled the development of intelligent POS terminals which can "read" the UPC symbol and determine the identity of the item. The UPC symbol consists of ten decimal digits, split into two fields of five digits each. Each digit is encoded using a 7-bit binary number, represented by a group of 7 dark (binary 1) and light (binary 0) bars. The five left-hand digits are encoded using odd parity and the right-hand digits are encoded using even parity. This allows correct recognition of the symbol, independent of its orientation.

For groceries, the first five decimal digits identify the manufacturer and the second group of five digits identify the specific product. There are additional codes in use as well, such as the National Drug Code. By using a microprocessor-based system, a POS terminal can be quickly reconfigured to recognize a different code (or multiple codes) through a simple software change.

Operation. A typical sale might involve the following steps. The clerk inquires whether the sale is to be a cash purchase or charged to an account. If the latter, the clerk enters the necessary information and the terminal

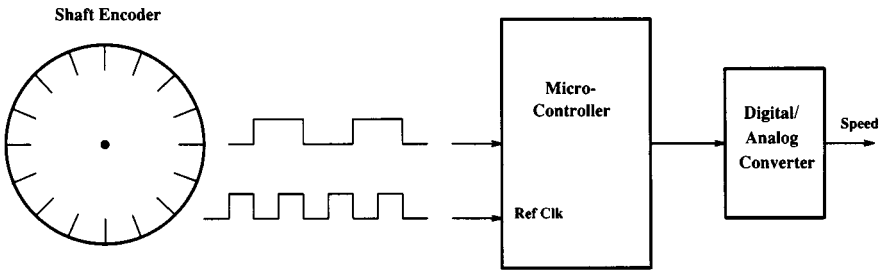

FIGURE 82.2 Digital tachometer.

transmits a request to a central processor, inquiring as to the available credit. In the interim, items are entered, either through the bar code scanner or the keypad, and the price and running total are displayed. The identity of the items purchased is also stored for later transmission to the central processor responsible for inventory control. Finally, the terminal checks the available credit against the total and records the transaction for later transmission to the central processor.

Digital Tachometer

Another example of using a microprocessor for data collection is the implementation of a digital tachometer [Bonert, 1989]. The microprocessor samples the output of a shaft **encoder** and compares it with a reference signal to determine the rotational speed. The calculated value is passed to a digital-to-analog converter to generate an analog speed signal. The system is shown in Fig. 82.2.

Speed Evaluation Methods. Various methods may be used to evaluate the speed value, all of which involve some combination of pulse counting and time measurement. The constant elapsed time (CET) method provides a good compromise between measurement accuracy and response time. The CET method records the number of encoder pulses observed during a fixed time interval. The rotational speed, n, is then given by

$$n = C_p/(C_t m/T_c)$$

where C_p is the number of encoder pulses, C_t is the number of clock pulses, m is the number of encoder marks per turn, and T_c is the clock pulse period.

Implementation. Rather than continuously stopping and resetting external counters, it is possible to take advantage of features often found in modern **microcontrollers**, microprocessors containing additional interface circuitry. Microcontrollers often contain counters, timers, and **capture registers**. Capture registers allow the storing of timer or counter values triggered by an external signal. At the start of evaluation, the rising edge of the next encoder pulse triggers the capture of the timer count and the pulse count. After a minimum evaluation time has elapsed, the next encoder pulse again triggers the capture of the current counter values. The rotational speed can then be computed using the difference between the captured values. A flowchart of the algorithm is shown in Fig. 82.3.

Performance. Using an encoder with 1024 marks per revolution, a 2-MHz reference clock, and an evaluation period of 2.3 ms resulted in a measurable speed range of 25.5–4883 rpm. The maximum relative error was 0.123%, induced primarily by the encoder tolerance [Bonert, 1989].

Control

Microprocessors are ubiquitous in control applications. While some custom analog controllers are still built, the advantages of cost and flexibility inherent in microprocessors make them a natural choice. The advantages of microprocessors are particularly obvious in mass-produced goods where time-to-market can be a significant driving force.

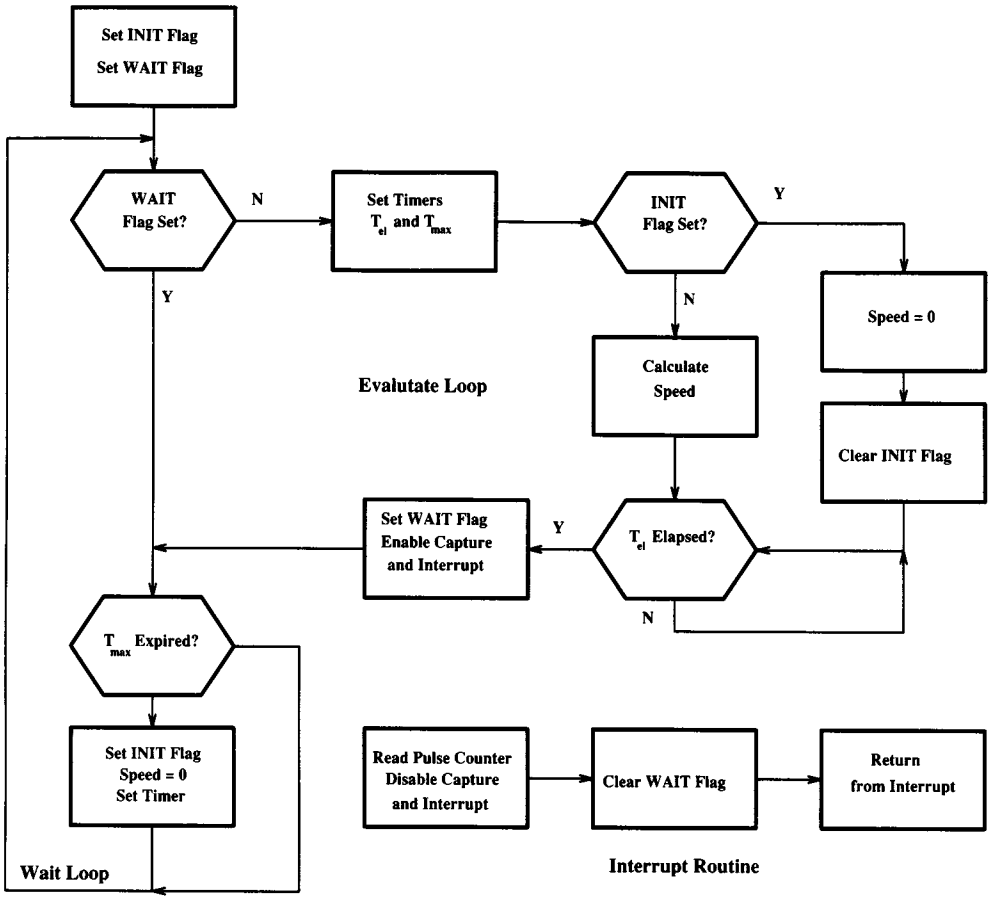

FIGURE 82.3 Tachometer program. (*Source:* Bonert, 1989.)

Microcontrollers

Microprocessors designed especially for use in control applications are called *microcontrollers*. Typically, the major difference between a microcontroller and a standard microprocessor is the presence of scratchpad RAM, input and output ports, timers, and even analog-to-digital (**A/D**) and digital-to-analog (**D/A**) converters on-chip.

Figure 82.4 shows a simplified microcontroller architecture. The process to be controlled is monitored by means of sensors. The outputs from the sensors are fed to A/D converters which convert the analog signals from the sensors to digital signals appropriate for use in the microprocessor. The microprocessor reads the digital signal from the A/D converter and uses it for input to a control program stored in the microprocessor memory. The program produces digital outputs which are fed to D/A converters. The analog outputs from the D/A converters (which are typically low power) are fed to amplifiers, and the amplified signal is used to control actuators that affect the process being controlled.

Control Applications

Consumer Electronics. A survey of the typical home will show numerous microprocessors where 10 years ago, there were none. Microprocessors are used for controlling VCRs, TVs, stereo equipment, microwave ovens, sprinkler systems, telephone equipment, heating systems, and virtually every other appliance using electricity.

Manufacturing. Microprocessors have found numerous applications in manufacturing. Perhaps none is better known than the robot. Microprocessor technology has made the modern robot possible. Robot arms used in

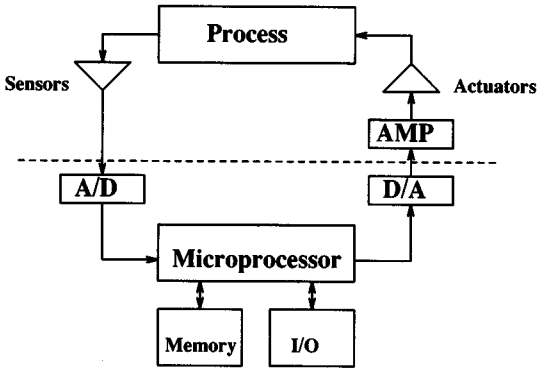

FIGURE 82.4 Typical microcontroller design.

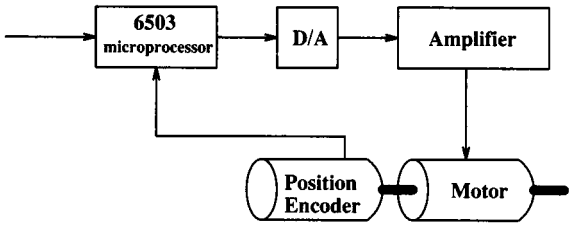

FIGURE 82.5 Microprocessor-controlled servomechanism from a PUMA 560 robot.

manufacturing typically have five or six joints. Current practice is to treat each joint in the robot arm as a separate servomechanism with its own control system. For example, the PUMA 560 robot arm, manufactured by Unimation, has six rotating joints. Each joint is controlled by an individual microcontroller system. Another computer calculates paths and sends individual joint motion information to the six joint servomechanisms [Fu et al., 1987].

The servomechanism system shown in Fig. 82.5 consists of an 8-bit Rockwell 6503 microprocessor, a D/A converter, an amplifier, a joint motor, and an encoder. The 6503 microprocessor receives joint position information from the supervisory computer every 28 ms. The microprocessor calculates the joint error information by comparing the current position to the desired joint position using the PID (proportional-integral-derivative) control method. The error is converted to an analog signal by the D/A converter and amplified before going to the joint motor. The encoder is connected to the motor shaft and provides a digital signal to the microprocessor.

The microprocessor performs the following functions:

1. Receives the desired joint position from the supervisory computer every 28 ms
2. Reads the position signal from the encoder every 0.875 ms
3. Calculates the error every 0.875 ms
4. Sends the error to the D/A converter

The microprocessor calculates joint error and sends the correction signal to the joint motor 32 times for every joint position received from the supervisory computer.

Transportation. Microprocessors are used for control applications in every facet of the transportation industry. Microprocessors are used to control the operation of the vehicles themselves such as controlling engines, air surfaces in aircraft, antilock brakes in automobiles, and rudders in ships. Microprocessors are also used in wide-area applications such as traffic control.

In controllers for motor traffic, the microprocessor has replaced hardwired logic and analog systems to provide systems which are much more capable and typically more reliable [Hordeski, 1984]. A typical traffic light controller is shown in Fig. 82.6. The microprocessor provides the CPU, memory, and I/O ports. The system

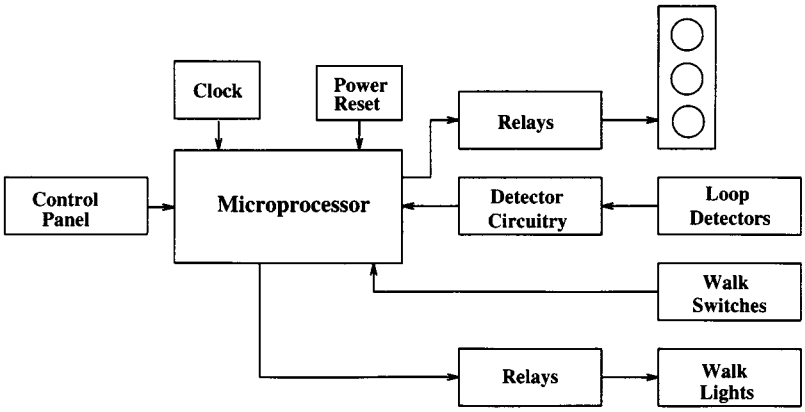

FIGURE 82.6 Traffic control system. (*Source:* M. Hordeski, *Microprocessors in Industry*, New York: Van Nostrand Reinhold, 1984, p. 398. With permission.)

includes a real-time clock for timing external events and a power-fail restart unit which restarts the system after a power failure (including restoring volatile data). The system monitors traffic at the intersection through the use of loop detectors and controls the traffic by changing the traffic lights. Other components of the system monitor and control pedestrian traffic and provide an interface to the system for human operators.

The loop detectors are paired coils of wire placed under the pavement. The impedance of the loop detectors changes in response to the presence of a car on the roadway. The change in impedance changes the frequency of an RC oscillator, which is converted to a digital signal reported to the microprocessor. Loop detectors can be used to monitor the presence of a car at a traffic light, the length of a line of cars, and the speed of traffic.

The function of the traffic controller is to optimize traffic flow. For example, during busy periods of the day, the goal may be to optimize flow through an intersection. Another goal may be to ensure that traffic flows smoothly in certain directions to effectively feed larger roads. Traffic lights can be synchronized to provide a highway through a busy network of roads by ensuring that a car that enters the roadway and maintains a recommended speed can travel along the entire length without stopping at a traffic light. On the other hand, during periods of low use, such as night and early morning, the system may monitor for the presence of a car at an intersection and immediately switch the light to let it pass.

Microprocessors offer advantages in traffic control situations in addition to optimized traffic flow. When properly designed, the system can provide a certain degree of fault tolerance. When a loop detector is giving a faulty value, the system can be programmed to ignore its value and use values from adjoining lanes. An error report can be forwarded to a central traffic facility and after repairs are made, the loop brought automatically on-line. The system can also monitor feedback information from the traffic light to ensure that the lights are actually lit. When a problem is detected, the system can enter an emergency mode and report the problem.

Social Issues

The explosive growth in the use of microprocessors in control applications has caused discussion about the utility and safety of such devices.

An issue many people can identify with is feature overload. The advent of cheap microprocessors has turned design upside-down. Designers can add additional features for very little additional increased manufacturing cost. Competition spurs even more features until even the simplest of consumer items come with thick instruction manuals. Naturally, consumers become frustrated with features that are difficult to use.

Perhaps more important are the safety hazards that may be engendered by replacing analog control systems with digital control systems. Most analog systems are based on physical properties with continuous behavior. Digital systems, on the other hand, are discrete and are thus much more prone to problems where small errors can result in large changes in behavior due to the digital representation of value; a single bit change can result in a large change in magnitude. Digital control systems are becoming more and more prevalent in systems controlling aircraft, automobiles, nuclear power plants, and other safety-critical systems. Engineers who design

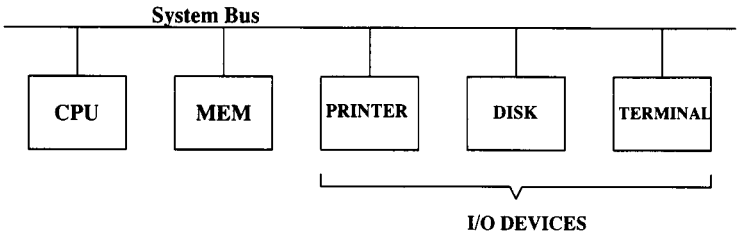

FIGURE 82.7 Major components of a simple microcomputer.

the systems and officials charged with ensuring their safety are still coming to grips with the implications of this trend. New techniques for analyzing computer system designs for errors are being developed which promise to alleviate some of these concerns [Windley, 1995].

Computing

While microprocessors have been put to a plethora of interesting special-purpose uses such as data collection and control, perhaps the most visible use of microprocessors has been in the area of general-purpose computing.

Microcomputers

The advent of microprocessors has resulted in a personal computer on virtually every desktop. Even the slowest of these computers rival the performance of the largest computers available 15 years ago.

Figure 82.7 shows the major hardware components of a simple microcomputer. The central processing unit (CPU) is the execution engine of the microcomputer and is most often a microprocessor. One popular family of microprocessors used as the CPU in microcomputers is manufactured by Intel. These chips, with names such as the 8088, 80286, 80386, 80486, and Pentium are used in microcomputers such as the IBM personal computer. Another important family of microprocessors is the Motorola Power Pc series, which is used in microcomputers manufactured by Apple Computer [Matloff, 1992].

In addition to the CPU, there are a number of other components in a microcomputer. General-purpose memory is not typically part of the microprocessor but must be added as a separate component. In simple microcomputers, the memory may be directly attached to the microprocessor. In more complex designs, the memory is attached to the microprocessor by a system bus that allows system components other than the microprocessor to access memory as well. In addition, the memory may have its own controller, called a memory management unit.

Other components in the system include input/output (I/O) interfaces to devices such as printers, terminals, disks, mice, and so on. The common feature of all of these devices is that they interface the microprocessor to the outside world. All of the components in the microcomputer are connected together by a system bus. The bus is a set of parallel wires that carry information from one component to another.

Multiprocessing

The desire for greatly increased computer performance has fueled research in using microprocessors as the computing engines in multiprocessors which would achieve performance gains over single-processor computers through the use of numerous low-cost microprocessors.

There are numerous multiprocessor architectures. An example architecture that is well suited to using large numbers of microprocessors is the hypercube. The hypercube architecture was originally developed by Charles Seitz and others at California Institute of Technology in the early 1980s. The hypercube depends on using large numbers of commodity microprocessors, each with private memory, in a hypercube network [Bell, 1989].

In a hypercube network, N microprocessors are arranged in an n-dimensional cube, where $N = 2^n$. Each processor is connected to n other processors and the longest communications path from any processor to any other is n links. For example, a three-dimensional hypercube contains eight processors and is arranged as a standard cube, where the nodes are the processors and the edges of the cube are the communication paths.

Figure 82.8 shows a four-dimensional hypercube represented as a tesseract. A four-dimensional hypercube has 16 processors, each is connected to 4 other processors, and the longest path between any two processors (shown in bold in Fig. 82.8) is 4. Thus, doubling the number of processors results in a unit increase in the communications path length. This logarithmic relationship results in the great advantage of the hypercube: it scales well. A system with 1024 processors has a maximum communications path length of just 10.

There are several manufacturers of hypercube systems including NCUBE and Intel. Most of these systems have between 32 and 1024 processors. NCUBE has a hypercube architecture with 8192 nodes operating at 2.4 megaflops each.

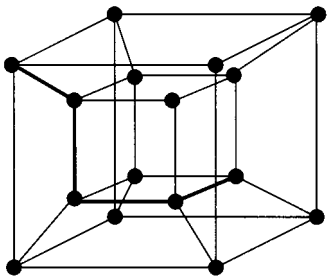

FIGURE 82.8 A four-dimensional hypercube.

Digital Signal Processing

Digital signal processing (DSP) may be considered a specific example belonging to the category of computation. Specialized microprocessors are finding widespread application in many areas of digital signal processing such as telecommunications, speech processing, medical imaging, and radar [Aliphas and Feldman, 1987]. These microprocessors are designed for very high data rates and contain specialized circuitry to accelerate computations that are specific to signal processing. Figure 82.9 illustrates the architectural differences between digital signal processors and conventional microprocessors.

Architectural Features. A common task among most signal processing algorithms is the summation of multiple products. The most notable distinction between general-purpose microprocessors and digital signal processors is the existence of a high-speed multiplier-accumulator [Allen, 1985]. This circuitry can complete a multiply-add operation in one cycle, as opposed to roughly 25 cycles for a conventional microprocessor. Traditionally, only fixed-point arithmetic was available, but newer DSP chips provide floating-point arithmetic with 32 bits of precision.

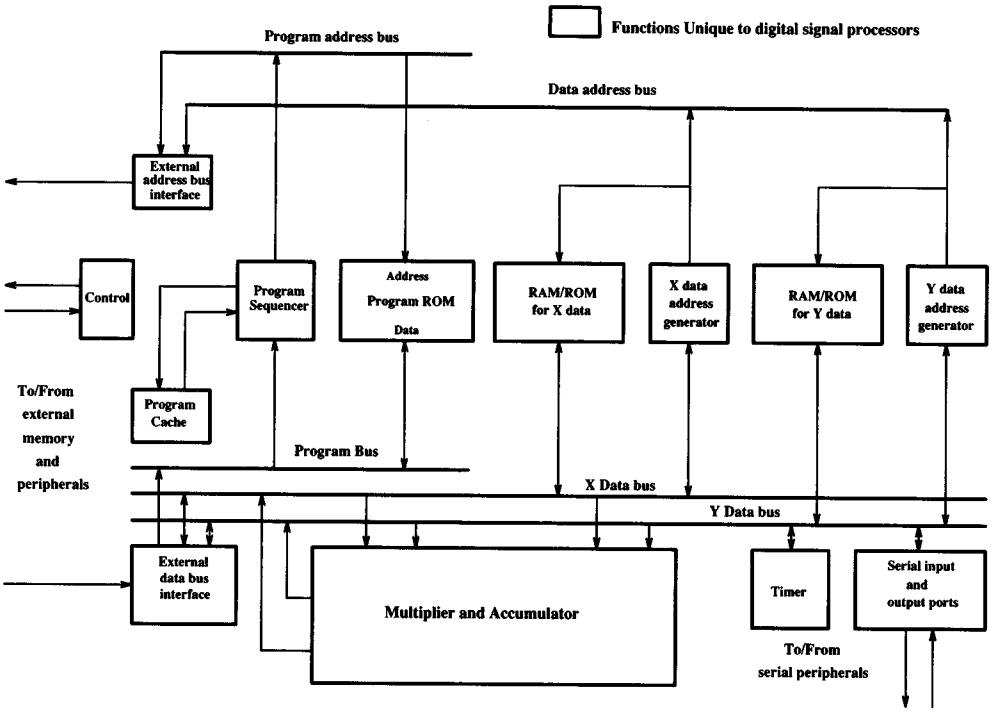

FIGURE 82.9 Digital signal processor architecture. (*Source:* Aliphas and Feldman, 1987.)

The second most noticeable feature on DSP chips is the existence of multiple data buses and memories. Many chips have two data memories, each with a data bus, allowing the simultaneous fetch of two operands for the multiply-accumulate operation. Furthermore, most chips use the Harvard architecture, characterized by separate program and data memories, so that instructions and data can be fetched simultaneously. Others use a modified Harvard architecture, where data can be stored in slower, cheaper program memory and moved to the faster data memory as needed.

Finally, DSP chips typically have separate arithmetic-logic units (ALU) for data arithmetic and address calculations. This serves two purposes: (1) data calculations can proceed unhindered by address calculations, maintaining a high throughput, and (2) each unit can be specialized for its particular task. For example, the data ALU may have additional circuitry to support saturation arithmetic, whereas the ALU used for address calculations may provide indexing, auto-increment, or even bit-reversal, an operation required for the fast Fourier transform (FFT).

Dedicated digital signal processors offer an excellent alternative or supplement to general-purpose microprocessors for signal processing applications. As a slave to a conventional processor, the DSP chip is freed from communicating with peripherals, increasing throughput. For additional performance, DSP chips may be operated in a multiprocessor configuration, controlled by a central processor. Such an arrangement would be appropriate for applications such as phased-array radar, where the volume of data and uniformity of the calculations lend themselves to distributed processing.

Defining Terms

A/D: Analog to digital. Usually a device that changes an analog signal to a digital signal of corresponding magnitude.

Capture registers: Internal registers which, triggered by a specified internal or external signal, store or "capture" the contents of an internal timer or counter.

D/A: Digital to analog. Usually a device that changes a digital signal to an analog signal of corresponding magnitude.

Encoder: A sensor that directly creates a digital signal for use in a control application. An example is a shaft encoder that turns an angular shaft position into a digital signal.

Interrupts: Special hardware on a computer that suspends the executing program so that another procedure can be run to service an external device.

Microcontroller: A special-purpose microprocessor with scratchpad RAM, input and output ports, timers, and even analog to digital (A/D) and digital-to-analog (D/A) converters on-chip used in control applications.

Universal asynchronous receiver/transmitter (UART): Circuitry (often a separate module), which provides all of the interface functions necessary for a microprocessor to communicate with a serial device.

83.1 Light-Emitting Diodes

James E. Morris

The light-emitting diode (LED) has found a multitude of roles as the field of optoelectronics has bloomed. Infrared devices are used in conjunction with spectrally matched phototransistors in optoisolation couplers, hand-held remote controllers, interruptive, reflective and fiber-optic sensing techniques, etc. Visible spectrum applications include simple status indicators and dynamic power level bar graphs on a stereo or tape deck. This section will concentrate on digital display applications of visible output devices.

Semiconductor Device Principles

The operation of an LED is based on the recombination of electrons and holes in a semiconductor. As an electron carrier in the conduction band recombines with a hole in the valence band, it loses energy ΔE equal to the bandgap E_g with the emission of a photon of frequency

$$\upsilon = c/\lambda = \Delta E/h \tag{83.1}$$

where λ is the radiation wavelength and h is Planck's constant.

The incidence of recombination under equilibrium conditions is insufficient for practical applications but can be enhanced by increasing the minority carrier density. In an LED, this is accomplished by forward biasing the diode, the injected minority carriers recombining with the majority carriers within a few diffusion lengths of the junction edge. Figure 83.1 illustrates the process. The potential barrier eV_o is reduced by forward bias eV, leading to net forward current and the minority carrier distributions shown on either side of the depletion layer. As the carriers diffuse away from the junction edges, these distributions decay exponentially because of recombination with the majority carriers. Each recombination event shown on either side of the junction gives off a photon. This process is called **injection electroluminescence.**

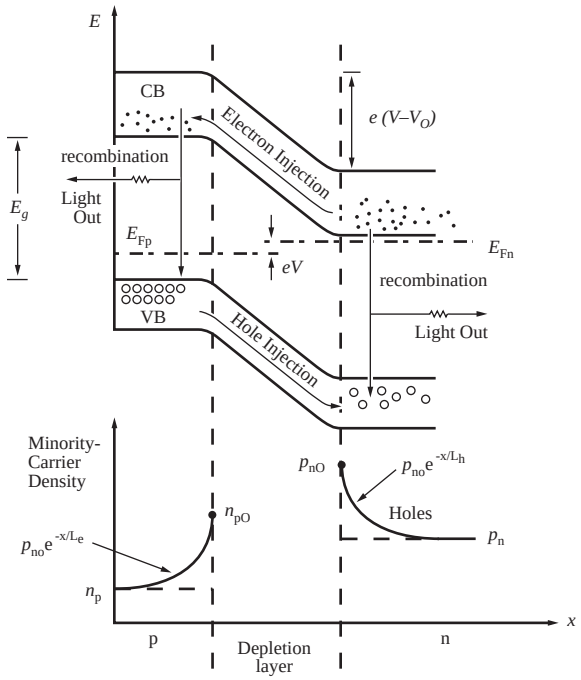

FIGURE 83.1 Light emission due to radiative recombination of injected carriers in a forward-biased *pn* junction.

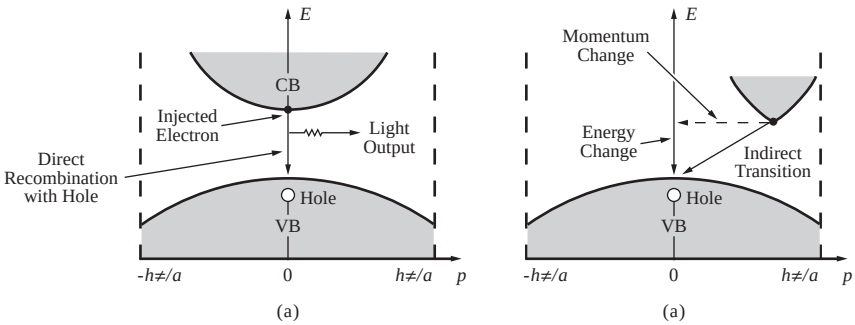

FIGURE 83.2 (a) Interband recombination in a direct-bandgap semiconductor; (b) recombination in an indirect-gap semiconductor also involves a momentum change.

Equation (83.1) implies that the radiation emitted will be monochromatic, but in practice $\Delta E > E_g$, and there is a spectral distribution corresponding to the energy distributions of the carriers in the conduction and valence bands.

Semiconductor Materials

Silicon is the most common material used in current semiconductor technologies, but it is not at all suitable for an LED. The reason is that silicon has an indirect bandgap, and a direct bandgap is required for process efficiency. Direct and indirect bandgaps are compared in Fig. 83.2, where carrier energy is plotted versus momentum for both cases. The photon momentum

$$p = h\lambda = h\upsilon/c \tag{83.2}$$

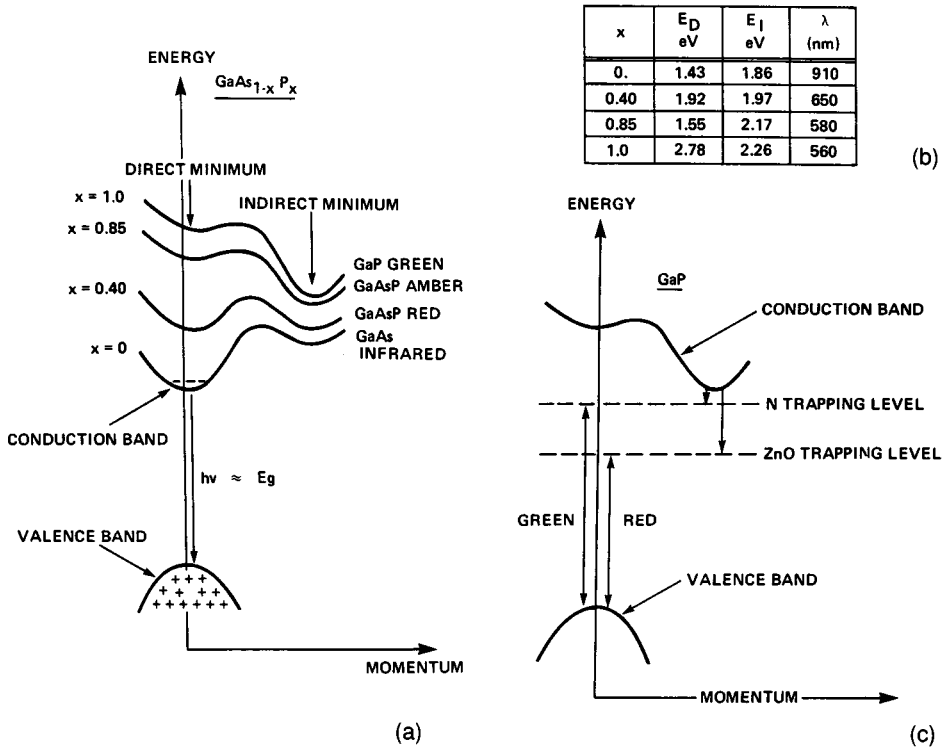

FIGURE 83.3 (a) Plot of momentum versus bandgap energy, and (b) corresponding semiconductor parameters for various compounds of the GaAs/GaP system; (c) plot of momentum versus bandgap energy for indirect GaP materials showing special trapping levels. (*Source:* S. Gage et al., *Optoelectronics/Fiber-Optics Applications Manual,* 2nd ed., New York: Hewlett-Packard/McGraw-Hill, 1981, pp. 1.3–4. With permission.)

(where c is the velocity of light) is very small, and conservation of momentum can be readily accommodated by small deviations from the vertical transition shown in Fig. 83.2(a). For the indirect case illustrated in Fig. 83.2(b), the energy change ΔE defines the photon energy and momentum, again according to Eqs. (83.1) and (83.2), but conservation of momentum additionally requires that the much greater electron momentum on the order of $h/2a$ be accounted for. For lattice dimensions, a, on the order of 10^{-10} m and wavelengths, λ, on the order of 10^{-6} m, it is clearly not possible for both conservation criteria to be met without the participation of a third body, i.e., a phonon. The two consequences of this result are that the indirect transition is inefficient (in that it must transfer momentum and hence thermal energy to the lattice) and less likely to occur than the direct transition (because of the requirement for all three particles to simultaneously meet the energy and momentum conditions). Indirect bandgaps therefore lead to long diffusion lengths and recombination times, which produce good transistors but poor LEDs.

The most common direct-bandgap semiconductor is GaAs, but the photon wavelength calculated for $E_g = E_D = 1.43$ eV as listed in Fig. 83.3(b) is in the infrared. Such a material may be ideal for communications and sensory optoelectronic applications but is unsuitable for display purposes. The bandgap may be adjusted, however, by the substitution of phosphorus for arsenic in the lattice as shown in Fig. 83.3(a). The color range listed corresponds to the range of LED colors commonly available: red, yellow, and green. The direct and indirect bandgaps, E_D and E_I, of $GaAs_{1-x}P_x$ vary with x as

$$E_D = 1.441 + 1.091x + 0.210x^2 \tag{83.3}$$

and

$$E_I = 1.977 + 0.144x + 0.211x^2 \tag{83.4}$$

[Wang, 1989], enabling one to design the material to produce the required LED color.

Note the continuous transition from the direct GaAs to the indirect GaP. The materials have an indirect bandgap for $x > 0.4$ and have the same problems as light emitters as silicon. The efficiency of an indirect-gap emitter can be greatly enhanced by the introduction of appropriate impurity recombination centers, as shown in Fig. 83.3(c). In the process shown, an injected minority carrier electron (in *p*-type material) is first trapped by the localized impurity (which is itself electrically neutral but which introduces a local potential to the lattice which attracts electrons). The center is then negatively charged and attracts a hole to complete the recombination process, which produces the photon. The recombination center solves the momentum transfer problem, because the trapped electron is localized to the impurity lattice site and has a momentum range according to the Heisenberg Uncertainty Principle of

$$\Delta p \sim h/2\pi a \tag{83.5}$$

that is, sufficient to include the processes shown in the diagram at $p \sim 0$. In the cases used as examples, a nitrogen atom substitutes for a phosphorus, or a zinc–oxygen pair substitutes for adjacent gallium–phosphorus atoms in the $GaAs_{1-x}P_x$ lattice.

The $GaAs_{1-x}P_x$ system is well established, but can only produce wavelengths defined by the range of energy gap widths, i.e., down to green. Blue LEDs require higher band-gap materials:

(a) SiC technology is well developed for high temperature semiconductor applications, but it has an indirect band gap, so its emission efficiency is very poor [Pierret, 1996].

(b) GaN (and In/Al GaN alloys) is a direct band gap material system producing successful blue and blue-green devices [Jiles, 1994; Nakamura, 1995; Pierret, 1996].

(c) II-IV compounds such as ZnS and ZnSe possess direct band gaps in the 1.5–3.6eV range, offering the possibility of full spectrum LEDs within the single materials system [Jiles, 1994].

Device Efficiency

In considering LED efficiencies, it is convenient to consider the emission process to consist of three distinct steps: (a) excitation, (b) recombination, and (c) extraction. These will be discussed with reference to Fig. 83.4.

(a) Photons created by minority electron recombination on the *p*-type side of the junction are more likely to be successfully emitted from the surface of the device, for the structure shown in Fig. 83.4(a) and (b) if the *p*-type region is a thin surface layer. For a given total LED current, I, made up of electron, hole, and space-charge region recombination components, I_n, I_p, and I_r, respectively, the electron injection efficiency (which provides the excitation) is

$$\gamma_n = I_n/(I_n + I_p + I_r) \tag{83.6}$$

In principle, all the physical processes described above apply equally to both electrons and holes. However, the electron mobility, μ_n, is greater than that of a hole, μ_p, and since

$$I_n/I_p = N_d\,\mu_n/N_a\,\mu_p \tag{83.7}$$

(where N_d, N_a are *n*-type donor and *p*-type acceptor doping densities, respectively) greater γ_n is attainable for a given doping ratio than hole injection efficiency, γ_p. Consequently, LEDs are usually p-n^+ diodes constructed as in Fig. 83.4, with the *p*-layer at the surface.

(b) Some of the recombinations undergone by the excess electron distribution, Δn, in the *p*-type region will lead to radiation of the photon desired, but others will not, because of the existence of doping and various impurity levels in the bandgap. The total recombination rate, R, can be written in terms of the radiative and nonradiative rates, R_r and R_{nr}, as

$$R = R_r + R_{nr} \tag{83.8}$$

where

$$R_r = \Delta n/\tau_r, \qquad R_{nr} = \Delta n/\tau_{nr}, \qquad R = \Delta n/\tau \tag{83.9}$$

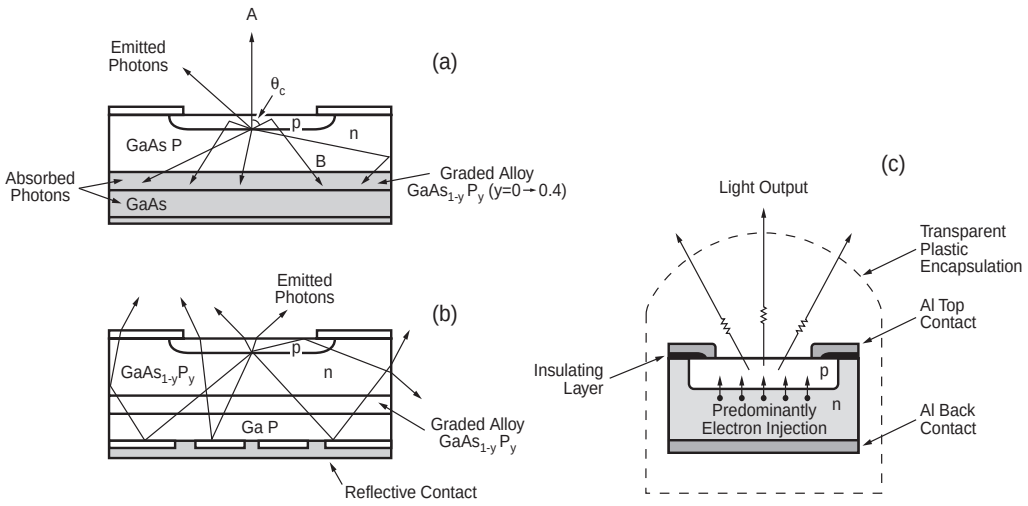

FIGURE 83.4 Effect of (a) opaque substrate, (b) transparent substrate, and (c) encapsulation on photons emitted at the *pn* junction.

and where τ_r and τ_{nr} are the minority carrier lifetimes associated with the radiative and nonradiative recombination processes, and τ is the effective lifetime. The radiative efficiency is defined as

$$\eta = R_r/(R_r + R_{nr}) = \tau/\tau_r \tag{83.10}$$

and the **internal quantum efficiency** is

$$\eta_i = \eta\gamma \tag{83.11}$$

(c) It is clear from Fig. 83.4 that many of the photons generated on either side of the junction will pass through sufficient bulk semiconductor to be reabsorbed. In fact the photon energy may be ideally suited to reabsorption if it exceeds the semiconductor direct bandgap. It is obvious, then, why GaAs is opaque and GaP transparent to photons from Ga(As:P) junctions. Clearly, a greater efficiency might be expected from the transparent substrate with reflecting contact [Fig. 83.4(b)].

The photon must strike the LED surface at an angle less than the critical angle for total internal reflection, θ_c, where

$$\sin\theta_c = n_{\text{ext}}/n_{\text{LED}} = 1/n \tag{83.12}$$

and n_{ext}, n_{LED} are the external and internal refractive indices, respectively. For air, $n_{\text{ext}} = 1$, but critical angle loss can be reduced by encapsulating the device in an epoxy lens cap [Fig. 83.4(c)] to increase both $n_{\text{ext}} > 1$ and the angle of incidence at the air interface.

Even within angles less than θ_c, there is Fresnel loss, with transmission ratio

$$T = 4n/(1 + n)^2 \tag{83.13}$$

The total **external quantum efficiency** is then the fraction of photons emitted [Neamen, 1992], given by [Yang, 1988]

$$\eta_e = 1/(1 + \alpha v_o/AT) \tag{83.14}$$

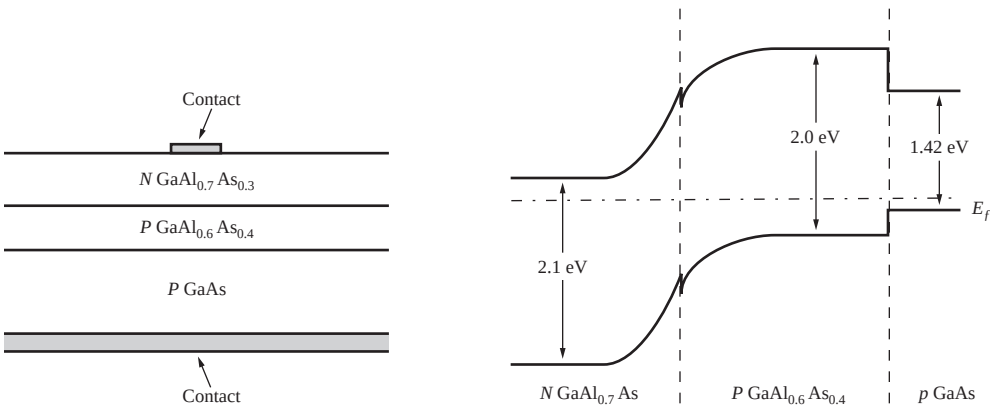

FIGURE 83.5 A GaAlAs heterojunction LED: (a) cross-sectional diagram; (b) energy-band diagram.

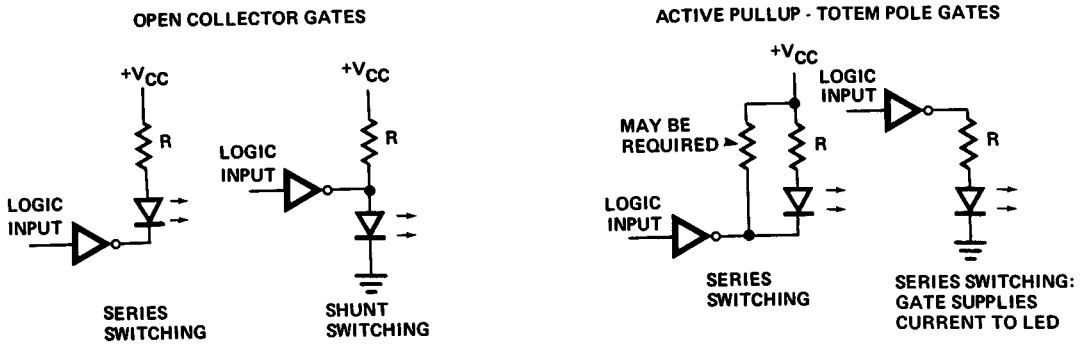

FIGURE 83.6 Digital logic can interface directly to LED lamps. (*Source:* S. Gage et al., *Optoelectronics/Fiber-Optics Applications Manual*, 2nd ed., New York: Hewlett-Packard/McGraw-Hill, 1981, p. 2.20. With permission.)

where α is the average absorption coefficient, v_o is the LED volume, and A is the emitting area.

In considering LED effectiveness for display purposes, one must also include radiation wavelength in relation to the spectral response of the human eye [Sze, 1985]. Although the GaP green LED is intrinsically less efficient than the GaAsP red LED, the eye compensates for the deficiency with a greater sensitivity to green.

More recently developed heterojunction LEDs (Fig. 83.5) offer two mechanisms to improve LED efficiencies [Yang, 1988]. The electron injection efficiency can be enhanced, but, in addition, absorption losses through the wider 2.1-eV bandgap *n*-type layer are essentially eliminated for photons emitted by recombination in the lower 2.0-eV bandgap *p*-type region.

Interfacing

In circuit design applications, the LED may be treated much as a regular diode, but with a much greater forward voltage, V_P. Since one usually seeks maximum brightness from the device, it is usually conducting heavily and V_F approaches the contact potential. As one moves from GaAs to GaP [Fig. 83.3(a)], V_F varies from about 1.5 to around 2.0 V. The variation in V_F with temperature (at constant current) follows similar rules as apply to conventional diodes, but radiant power and wavelengths also change [Gage et al., 1981].

Single LEDs are commonly driven by logic gates, perhaps as status indicators, and some of the simplest interface circuits are shown in Fig. 83.6. In many cases, the gate output will not be able to source or sink sufficient current for visibility, and an amplifier will be required, as in Fig. 83.7. Bar graph displays are commonly

used to indicate signal level on audio equipment, with a modification of the position indicator seen in Fig. 83.8 to guide fine tuning. Matrix LED arrays can be used for flexible, high-density panel displays [Fig. 83.9(a)] and are conventionally controlled by row or column strobing [Fig. 83.9(b)] controlled by a microprocessor interface.

Multiple LEDs are commonly packaged together in a single integrated device, organized in one of the standard display fonts [Fig. 83.10(a)], with decoding often included within the package [Fig. 83.10(b)]. The 7-segment

display is adequate for hexadecimal applications, but the 16-segment is required for alphanumerics. To limit pin-out requirements, the LEDs of a single package are connected in either the common anode or common cathode configuration [Fig. 83.11(a)], with multiple display digits multiplexed as illustrated in Fig. 83.11(b).

Gage et al., *Optoelectronics/Fiber-Optics Applications Manual,* 2nd ed., New York: Hewlett-Packard/McGraw-Hill, 1981, pp. 5.25, 5.23. With permission.)

Defining Terms

External quantum efficiency: The proportion of the photons emitted from the *pn* junction that escape the device structure (but sometimes alternatively defined as $\eta_i\eta_e$).

Injection electroluminescence: *Electroluminescence* is the general term for optical emission resulting from the passage of electric current; *injection electroluminescence* refers to the case where the mechanism involves the injection of carriers across a *pn* junction.

Internal quantum efficiency: The product of injection efficiency and radiative efficiency corresponds to the ratio of power radiated from the junction to electrical power supplied.

Further Information

More extensive semiconductor device treatments of the LED are contained in *Semiconductor Devices and Integrated Circuits* by A. G. Milnes (Van Nostrand Reinhold, New York) and in *Introduction to Optical Electronics* by K. A. Jones (Harper and Row, New York). E. Uiga provides more interfacing and design detail for the LED as a circuit element in optoelectronics (Prentice-Hall, Englewood Cliffs, NJ, 1995). Wang [1989] considers second-order effects extensively. In *Semiconductor Optoelectronics* by J. Singh (McGraw-Hill, New York, 1996), the emphasis is on communications applications, but the temperature dependence and frequency response issues covered there are also relevant to displays.

Chapter 2 of Gage et al. [1981] contains detailed information on the optical and thermal design constraints on the LED package and on LED back-lit display systems. Chapter 6 considers filtering and other techniques for the contrast enhancement required for direct sunlight viewing.

Professional society magazines are good sources of up-to-date information at the non-specialist level, especially the occasional special issues devoted to topic reviews. *IEEE Spectrum* is a good example, as is the *IEEE Circuits & Devices* magazine.

83.2 Liquid-Crystal Displays

James E. Morris

In a low-power CMOS digital system, the dissipation of a light-emitting diode (LED) or other comparable display technology can dominate the total system's power requirements. In such circumstances the low-power dissipation advantage of CMOS technology can be completely lost. This is the situation in which liquid-crystal display (LCD) technology must be used. The LED (or other active system, such as a plasma or vacuum fluorescent display) emits optical power supplied (comparatively inefficiently) by the system battery or other source. The passive LCD is fundamentally different in that the optical power is supplied externally (by sunlight or room lighting typically) and the system source need supply only the relatively minute amount of power (microwatts per square centimeter) required to change the device's reflective optical properties.

Principle of Operation

Materials classed as liquid crystals are typically liquid at high temperatures and solid at low temperatures, but in the intermediate temperature range they display characteristics of both. Although there are many different types of liquid crystals used, we will concentrate here on the use of **nematic** crystals in **twisted nematic** devices, the most common by far.

The essential feature of a liquid crystal is the long rod-like molecule. In a nematic crystal, the molecules align as shown in Fig. 83.12. If the container surface is microscopically grooved, the interface molecules will be aligned by the grooves and intermolecular forces will maintain that orientation across the liquid crystal [Fig. 83.12(a)]. The molecules will align in an electric field, and beyond a critical value, the field may be sufficient to overcome the alignment with the grooves [Fig. 83.12(b)]. (In practice, the transition is not so abrupt, and groove alignment persists at the interface itself [Fig. 83.13].)

The process of alignment in the electric field is the result of the anisotropic dielectric constant characteristic of liquid crystals. For the electric field parallel to the molecular alignment, $\varepsilon_r = \varepsilon_{\parallel}$, and for a perpendicular field, $\varepsilon_r = \varepsilon_{\perp}$. In a "positive" liquid crystal, $\varepsilon_{\parallel} > \varepsilon_{\perp}$, and the molecules align parallel to the field as described above in order to minimize the system's potential energy.

The principle of the twisted nematic cell is illustrated in Fig. 83.14. The confining plates, typically 10 μm apart, are grooved orthogonally, forcing the molecular orientation to spiral through 90 degrees [Fig. 83.14(a)]. In the LCD, two polarizers and a mirror are added as shown in Fig. 83.14(b). Incident ambient light is polarized and enters the liquid-crystal cell with the plane of polarization parallel to the molecular orientation. As the light traverses the cell, the plane of polarization is rotated by the twist in the liquid crystal, so that it reaches the opposite face with a polarization 90 degrees to the original direction, but parallel now to the direction of the second polarizer, through which it may therefore pass. The light is then reflected from the mirror and passes back through the cell, reversing the prior sequence.

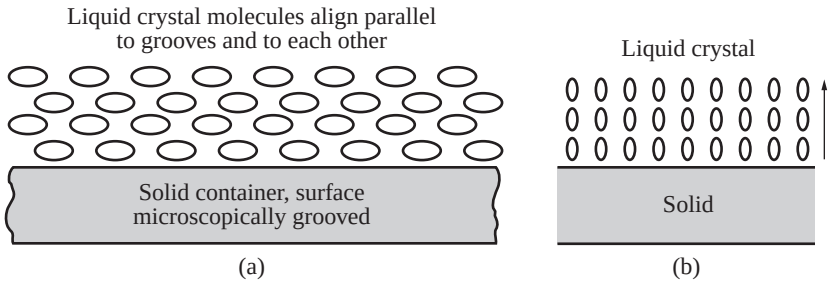

FIGURE 83.12 Liquid-crystal/grooved interface: (a) with no field applied, and (b) with an electric field ε > a critical value.

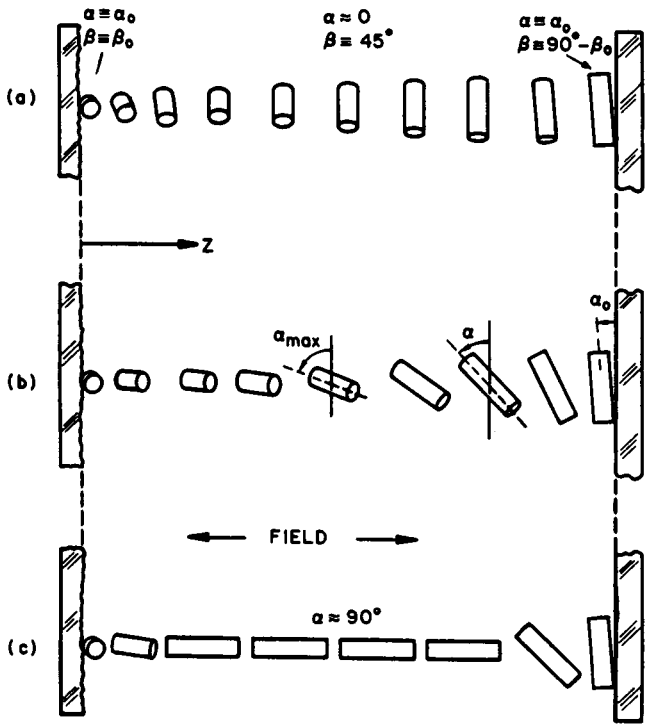

FIGURE 83.13 Diagram of the orientation of the liquid-crystal axis in a cell (a) with no applied field, (b) with about twice the critical field, and (c) with several times the critical field. Note slight permanent tilt (α_0) and turn (β_0) at the surfaces. (*Source:* G. Baur, in *The Physics and Chemistry of Liquid Crystal Devices,* G.J. Sprokel, Ed., New York: Plenum, 1980, p. 62. With permission.)

When an electric field (greater than the critical field) is applied between the transparent electrodes, usually conductive **indium–tin oxide (ITO)** thin films, the 90-degree twist in the crystal is destroyed as the molecules align parallel to the field, so that the rotation of the light's plane of polarization cannot be sustained. Consequently, the crossed polarizers effectively block reflection of the incident light from the backing mirror, and the surface appears to be dark, with excellent contrast to the light gray color of the device in the reflecting mode. The contrast ratio can be further enhanced by the use of the *super twisted nematic* crystal, where the molecular orientation is rotated through 270 degrees rather than 90 degrees.

Transmission LCDs function very similarly to the devices just described, but without the mirror, which is replaced by a powered backlighting source. Obviously, the low-power advantage of the passive device is lost in

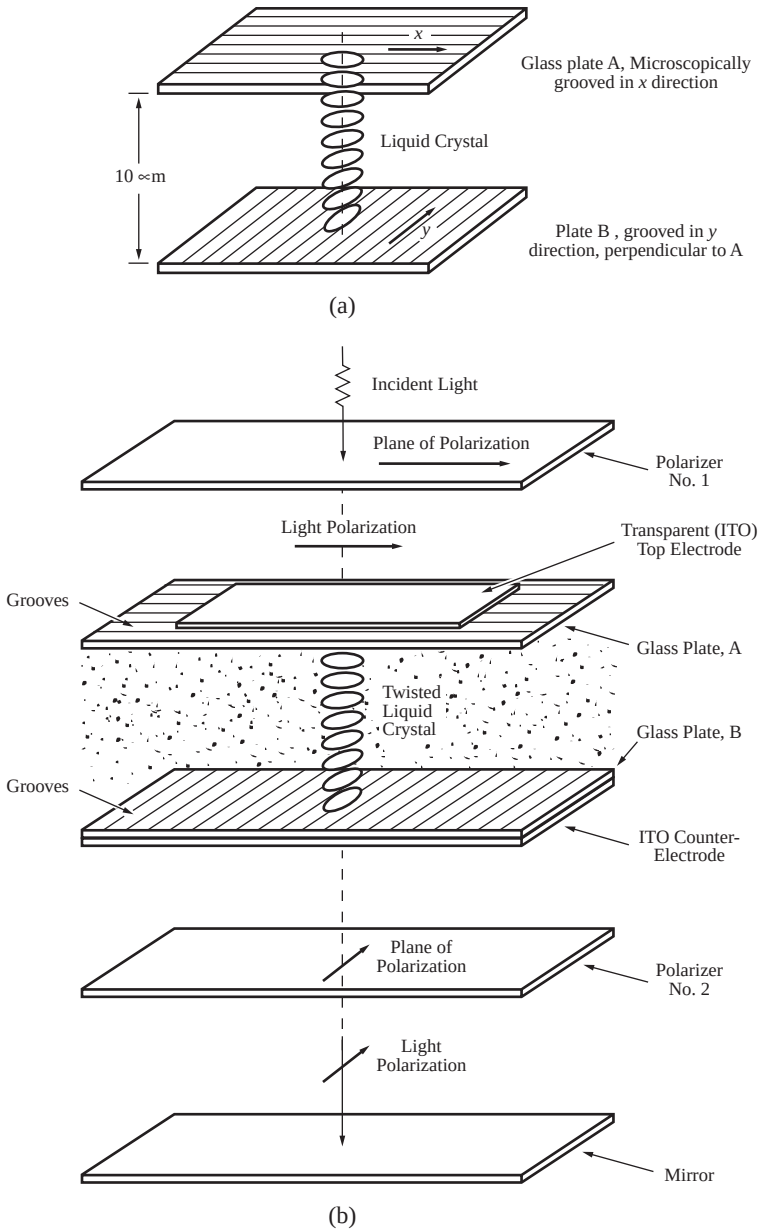

FIGURE 83.14 (a) Twisted nematic cell, $\varepsilon = 0$. (b) Liquid-crystal display element.

this active alternative, but monochromatic backlighting does provide one means of constructing displays with varied background colors.

Another form of color display is provided by **cholesteric** crystals. The three main types of liquid crystals, nematic, cholesteric, and smectic, are distinguished by the different types of molecular ordering they display. In the cholesteric crystal, the direction of molecular alignment rotates in each successive parallel plane (Fig. 83.15). The spatial period of the rotation, p, is called the pitch, and Bragg reflections occur when the wavelength of incident light meets the condition

$$\lambda = p/n \tag{83.15}$$

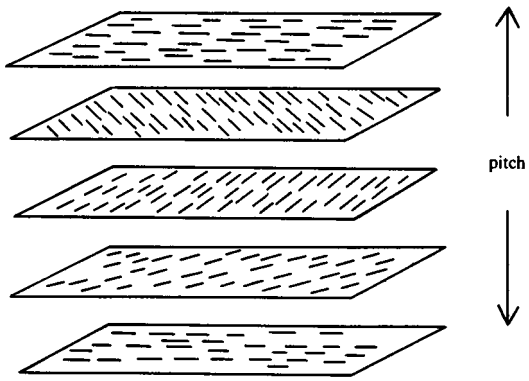

FIGURE 83.15 Cholesteric ordering: a large number of planes of nematic ordering are formed where the directors rotate as we move along a direction perpendicular to the planes. (*Source:* J. Wilson and J.F.B. Hawkes, *Optoelectronics: An Introduction,* London: Prentice-Hall, 1989, p. 145. With permission.)

where n is an integer. The liquid crystal can thus appear to be colored in incident white light. In practice, the color is strongly temperature dependent and the effect is more appropriate to temperature-sensing applications than to digital displays.

In practice, the color pixels of a large area display will be organized in the traditional television RGB format, with the colors defined by external filters or internal dyes [Braithwaite and Weaver, 1995]. The dye molecules align with the LCD molecules, and absorb correctly polarized light.

There is current interest in the development of liquid-crystal color switches where an electrical control signal would be able to change the device color, whether from white to monochromatic or continuously through the spectrum.

Uiga [1995] discusses some LCD problems, in particular the slow response times and the variation of effective critical voltages with limited viewing angles, and the temperature dependences of both.

Interfacing

LCDs can be organized in all the ways available to competing technologies, e.g., LEDs (see Section 83.1), including seven-segment, alphanumeric, and dot matrix. The LCD differs from LED displays, where each pixel or segment must be a separate device, because the LCD segment or pixel areas are defined by transparent electrodes separated from a common overlapping backplane by a single liquid crystal [Fig. 83.16(a)]. In a large matrix array, it may take a significant period to scan all pixels, and the simple addressing scheme of Fig. 83.16(b) may lead to noticeable flicker. The high off resistance of the MOSFETs of Fig. 83.16(c) can reduce this problem by increasing the discharge time to hold the LCD on after the address pulse has gone. The MOSFETs in this **active matrix** technology are implemented in practice in the form of polysilicon or hydrogenated amorphous silicon (a-Si:H) thin film transistors (TFT) [Shur, 1990; Braithwaite and Weaver, 1990].

The interfacing requirements, which are otherwise similar in multiplexing techniques, etc., are complicated by the requirement for zero net dc bias across the cell in order to avoid electrochemical degradation of the material. LCDs require ac drive signals, and square waves of frequency between 25 Hz and 1 kHz are typically used [Wilson and Hawkes, 1989]. A square wave is applied to the backplane, with in-phase and antiphase signals to the counter electrode determining whether the given pixel or segment is on or off. In practice, the state is determined by the root-mean-square (rms) value of the differential voltage applied.

Figure 83.18 illustrates the additional complexity that would be required by even a simple multiplexed addressing system. The backplane and segment drivers might correspond to rows and columns of a dot matrix, as implied in the diagram, or the backplanes may identify specific characters of an alphanumeric display. Calculating the rms values of the difference voltages shown gives 0.42 V_{tc} for the *on* pixels and 0.24 V_{tc} for *off*, from which V_{tc} can be calculated for reliable operation if the critical voltage is known for the LCD to be used.

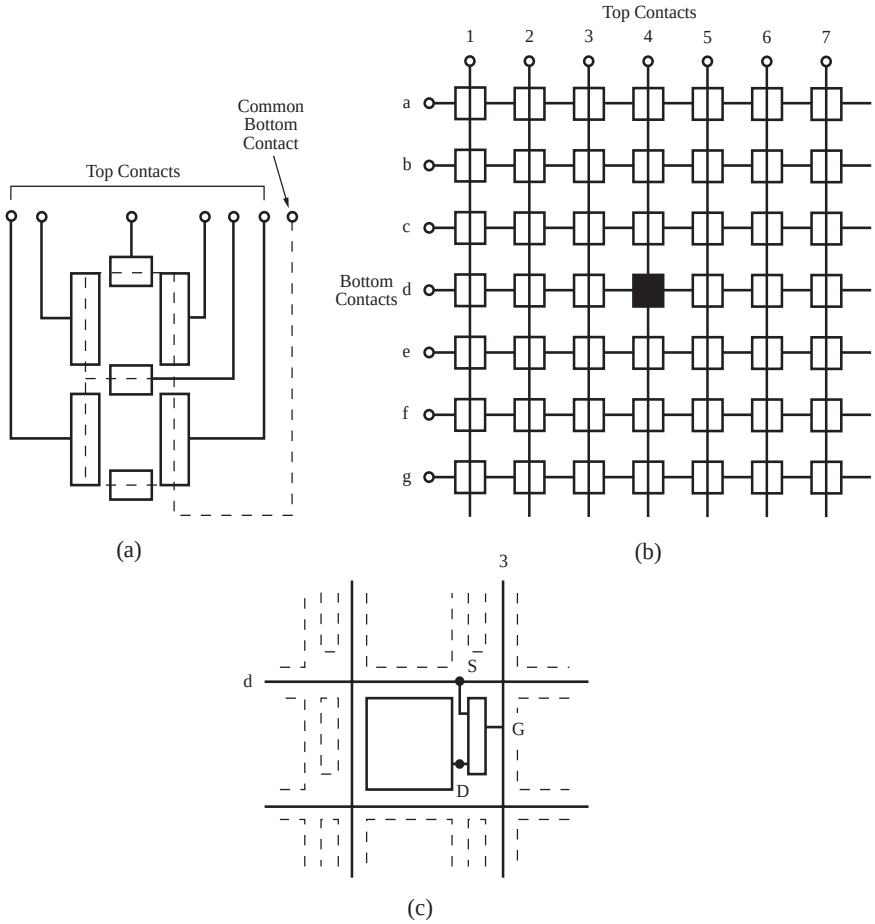

FIGURE 83.16 LCD addressing: (a) simple (seven-segment) addressing; (b) matrix addressing; and (c) matrix addressing with MOSFETs.

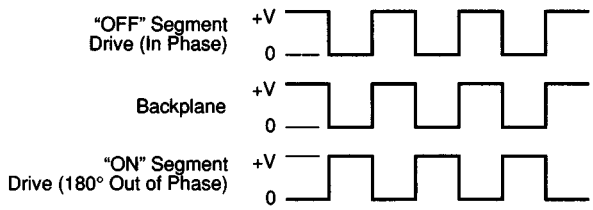

FIGURE 83.17 Drive signals from a direct connect LCD driver. (*Source:* R. Lutz, Application Note 350, in *Interface Databook,* Santa Clara, Calif.: National Semiconductor Corporation, 1990, p. 4–109. With permission.)

Defining Terms

Active matrix: Each pixel in a high density display matrix, such as for flat-screen television, requires its own active (switching element) driver (e.g., a TFT).

Cholesteric: In the cholesteric liquid crystal, successive layers of aligned molecules are rotated naturally.

Indium–tin oxide (ITO): A mixture of the semiconducting oxides SnO_2 and In_2O_3; the most common transparent conductor.

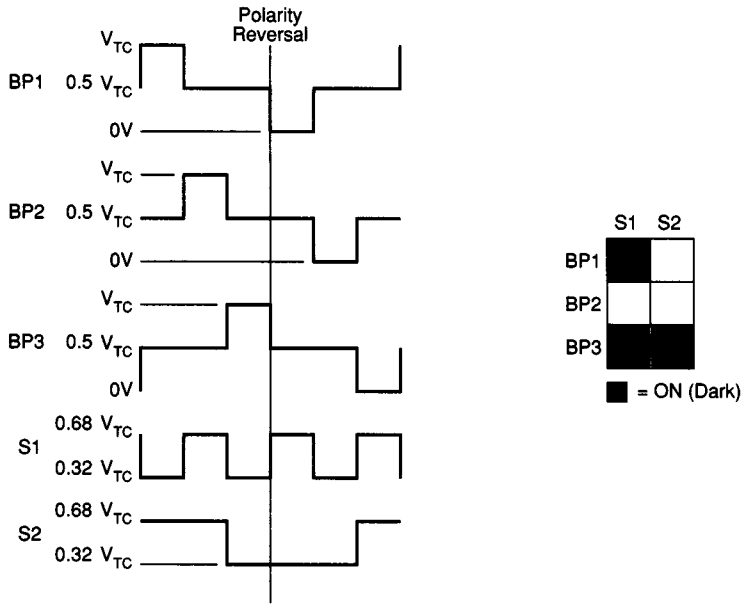

FIGURE 83.18 Example of backplane and segment patterns. (*Source:* R. Lutz, Application Note 350, in *Interface Databook,* Santa Clara, Calif.: National Semiconductor Corporation, 1990, p. 4–109. With permission.)

Nematic: The type of liquid crystal in which the molecular chains align; such alignment can be controlled across the liquid crystal if it can be constrained at the boundaries.

Twisted nematic: The alignments of the nematic planes are rotated through 90 degrees across the crystal by constraining alignments to be orthogonal at the boundaries.

Further Information

Nematic liquid-crystal molecules typically incorporate two separated benzene rings in a complex chain molecule [Wilson and Hawkes, 1989]. The organic chemistry of liquid-crystal compounds will lie outside the interests of most readers but is briefly reviewed in "Liquid Crystal Materials for Display Devices," by J. A. Castellano and K. J. Harrison in *The Physics and Chemistry of Liquid Crystal Devices,* edited by G. J. Sprokel [Plenum, 1980].

One technique used in liquid-crystal color switches requires the use of electrically controlled birefringence. This topic is covered at an elementary level by Wilson and Hawkes [1989].

An interesting historical perspective on the development of LCD technology is provided by the extensive reviews of 150 patents in the field contained in *Liquid Crystal Devices,* edited by T. Kallard (*State of the Art Review,* Vol. 7, Optosonic Press, New York, 1973). The book also contains a bibliography of more than 1100 entries.

The various professional societies' magazines are excellent sources of material for recent developments in this field (and others). These publications regularly devote a special issue to research developments in a single field, at a level intended for the non-specialist. A good example in the LCD area is provided by two articles on TFT silicon for active matrix displays contained in the *Materials for Flat-Panel Displays* issue of the *MRS Bulletin,* 21(3), March 1996 (Materials Research Society), which cover the transition from a-Si:H to polysilicon, to the prospects for single crystals.

83.3 The Cathode Ray Tube

André Martin

The **cathode ray tube** (CRT) is the element which, in a display, converts an electrical signal into visual information using an electron beam adequately intensity modulated and deflected to impinge on a cathodoluminescent screen surface, in a glass envelope under vacuum.

Because of the extensive growth of electronic communication since the Second World War, information is very often presented on CRTs, mainly when the information content exceeds 100,000 picture elements (pixels).

Monochrome CRTs are widely used for computer terminals, radars, oscilloscopes, projection systems, etc., while high resolution color CRTs are preferred for imaging from computers, such as multimedia, CAD-CAM systems and digital image processors [Keller, 1991].

In 1991, the worldwide market for CRT monitors was 37 million units [Stanford Resources, 1992a], of which 20 million units were high-resolution color monitors. These 37 million do not take into account the oscilloscope, radar, projection, and other special-purpose tubes that would add a few hundred thousand to the figures. In 1996, high resolution color CRT monitors in current use are in excess of 200 million units and mroe than 50 million monitors are being produced.

The importance of the CRT in the display world can be explained by two key factors:

- The CRT is using a single serial data input to generate a picture.
- The CRT is a very efficient light-emitting display.

For example, a typical high-resolution 20-inch diagonal color monitor requires 70 W from the main ac 50/60-Hz power supply and generates a picture visible in any office environment with a luminous efficiency of 6 to 8 lm/W. These two factors, high luminous efficiency and convenience of addressing, make the CRT difficult to replace by any other type of display for large image contents.

We will describe first the monochrome CRT and then discuss the color CRTs.

Monochrome CRTs

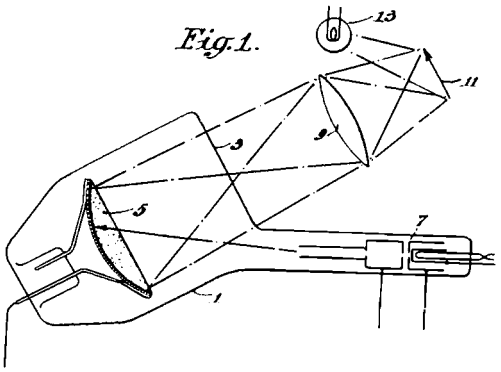
General

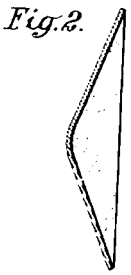
The monochrome CRT [Martin, 1986] is composed of:

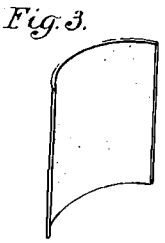
- A glass envelope with the necessary glass-to-metal seals for anode and electron gun connections. This envelope is under vacuum (about 10^{-7} mm Hg).
- A cathodoluminescent screen deposited on the faceplate, usually aluminized to improve brightness and obtain good screen potential uniformity.
- An electron gun using a hot cathode to emit electrons that are accelerated toward the screen and deflected either by electrostatic plates or by an electromagnetic deflection coil.
- Various outside and inside conductive coatings to normalize the potentials.

The Electron Gun

A typical electron gun is composed of (Fig. 83.19):







Cathode Ray Tube

Vladimir K. Zworykin
Patented December 6, 1938
#2,139,296

An excerpt from Zworykin's patent application:

I claim as my invention:

1. In combustion, a cathode ray image transmitting tube provided with an electrode in the form of a mosaic photosensitive target and with means for developing a ray of electrons and directing the ray at a surface of said target for scanning the same, a lens system for focusing an optical image of an object on the scanning portion of the surface of the target, such portion of said surface being concave toward the lens system with the curvature corresponding substantially to that of an imaginary spherical surface on which the lens system is able to focus the optical image sharply.

A spherical (or possibly hyperbolic) photosensitive cathode helped correct for the distortion inherent in aiming the electron beam over a relatively wide dispersion to scan the whole "screen". The basic principles behind Zworykin's CRT, first demonstrated in 1929, have been used in hundreds of millions of radar screens, television tubes, and now computer monitors.

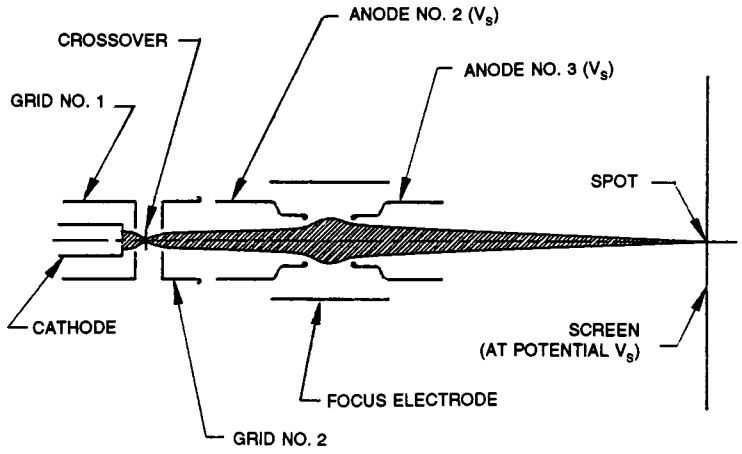


FIGURE 83.19 A typical electron gun with unipotential lens structure.

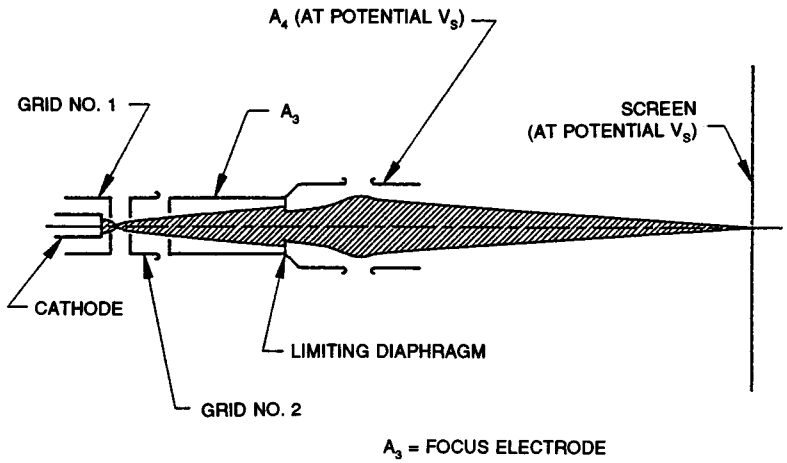

FIGURE 83.20 A typical electron gun with bipotential lens structure.

- A hot cathode that emits electrons when heated to ≈800°C and a suitable potential is applied to the adjacent electrodes G_1 and G_2.
- An apertured grid No. 1, also called G_1, which is maintained negative with respect to the cathode and whose potential controls the flow of electrons from the cathode.
- An apertured grid No. 2 placed close to G_1 (usually a few thousandths of an inch) and set at a positive voltage of a few hundred volts with respect to the cathode. This G_2 attracts the electrons controlled by the G_1 aperture potential and shapes the beam.
- An anode composed of metal cylinders to accelerate the electron beam toward the focus electrode and a final anode to further accelerate the beam toward the screen, where it focuses into a spot.

Figure 83.19 describes the unipotential lens focus structure, also called an EINZEL lens design. Another structure, widely used in modern CRTs, is the bipotential lens focus structure represented in Fig. 83.20. The bipotential structure is theoretically a better performer than the unipotential focus structure, because the lenses have less curvature of the line forces and less spherical aberration.

When optimum resolution is required, electromagnetic focus is used instead of the electrostatic focus systems described previously. Because this magnetic focus lens just bends the electron trajectories without changing the electron's speed, and because of its large diameter, the spherical aberration is reduced and the spot size is optimized.

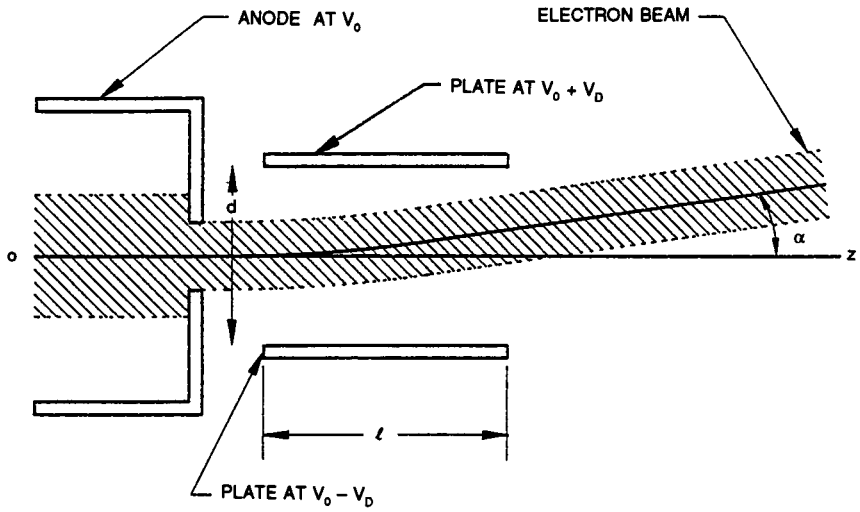

FIGURE 83.21 Principle of electrostatic deflection.

The Cathode

The cathode used on most CRTs is the oxide cathode, which consists typically of a heated nickel substrate coated with barium, strontium, and calcium oxides. This cathode works at a temperature of ≈800°C and provides a dc emission density up to 0.2 amp/cm^2 and 2 amp/cm^2 peak current density. When higher current densities are required, a tungsten-impregnated cathode (porous tungsten matrix heated at ≈1000°C and impregnated with barium and calcium aluminates) can be used. The impregnated cathode operates at higher temperature than the oxide cathode and requires sophisticated materials and techniques for its processing. The impregnated cathode, also known as a dispenser cathode, is commonly used on projection tubes and on other tubes where high beam currents are required, typically above 1.5 mA.

The Electrostatic Deflection System

An electrostatic deflection system (Fig. 83.21) consists of two sets of metal plates of length l symmetrically located with respect to the electron beam axis at a distance d of each other. At the anode outlet aperture (at potential V_0), the beam enters the deflection plates whose potentials are, respectively, $V_0 + V_D$, $V_0 - V_D$. The deflection angle α at the exit of plates is such that

$$\tan \alpha = \frac{1}{2} \frac{V_D}{V_0} \frac{l}{d}$$

In order to increase the deflection sensitivity, plates are often flared to have an optimum contour. High-frequency deflection systems incorporate delay lines to match the electron beam speed in the deflection zone with the signal propagation speed in the delay line.

The Electromagnetic Deflection System

An electromagnetic deflection coil is composed of two perpendicular windings generating electromagnetic fields perpendicular to the trajectory of the electron beam in the vertical and horizontal planes. Figure 83.22 shows the principle of electromagnetic deflection where a field of length l is applied perpendicularly to the electron beam accelerated at V_B. The beam, assuming the field intensity is uniform and of length l, is deflected onto a circular path of radius r. The corresponding angle of deflection is θ such as:

$$\sin \theta = \frac{Nil}{2.68D\sqrt{V_B}}$$

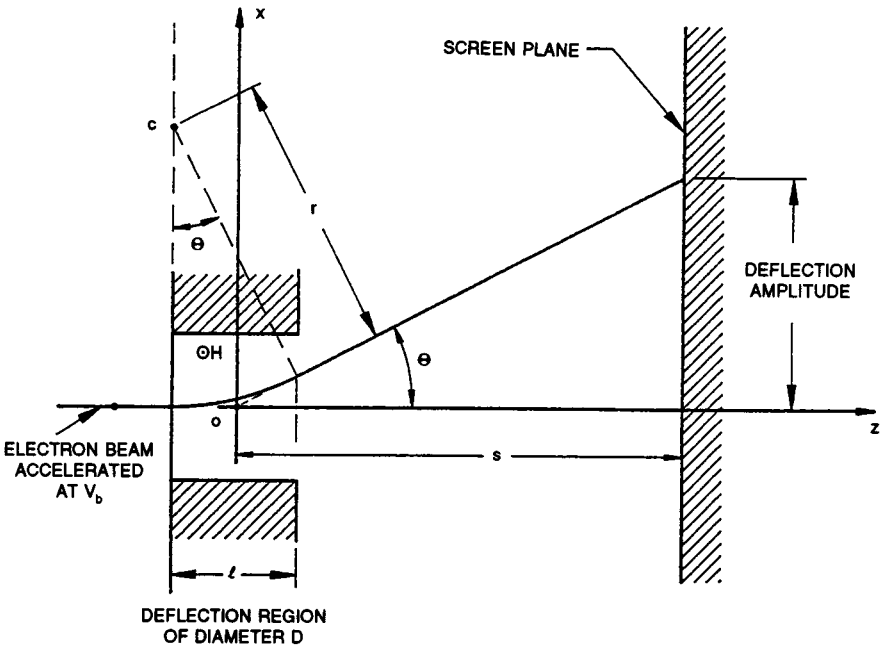

FIGURE 83.22 Principle of electromagnetic deflection.

where *Ni* is the number of ampere turns generating the magnetic field, *D* the diameter of the cylindrical winding generating the field, l is its length, and V_B the accelerating voltage expressed in volts. From the above, the deflection angle is conversely proportional to the coil diameter. As the coil diameter is limited by the tube neck diameter, it is preferable to use a small neck diameter to increase sensitivity to reduce deflection power. Because a small neck diameter cannot accommodate the large electrostatic focusing lenses required to reduce spherical aberration and spot size, a compromise must then be found between spot size and deflection power to achieve the best CRT performance when electrostatic focus is required.

The Screen

A cathodoluminescent material is characterized by several parameters:

- Color, usually expressed by its spectral distribution curve and also measured by color coordinates *xy* or $u'v'$
- Temporal characteristics, such as decay time, usually measured at 10% of initial excitation

These parameters, as well as the chemical composition of the luminescent materials, are listed in the E.I.A. Publication TEP 116 C [Publ. TEP].

Other parameters such as luminous efficiency (expressed in lumens/watt) or energy conversion efficiency (expressed in watts/watt) are also necessary and have to be required from manufacturers.

Color CRTs

The Shadow-Mask CRT

Color CRTs are widely used in commercial television and for computer displays. The shadow-mask CRT [Morrell et al., 1974] uses three electron beams deflected by one deflection coil. The beams traverse a perforated metal mask before impinging on the selected luminescent screen material, which is usually made of stripes or dots of red, blue, and green phosphors. The arrangement of the electron optics and of the deflection system is such that the three electron beams converge on the screen after passing through the shadow-mask, each beam impinging on one color, red, blue, or green, only.

Shadow-mask tubes use a mechanical selection of colors. The thin perforated steel or invar shadow-mask is welded onto a metallic frame suspended by supports in the tube glass faceplate. This structure is sensitive to shock and vibration, which may affect the position of the mask in the faceplate and the registration of the beam on the appropriate phosphor dots. These types of CRTs need specialized damping when ruggedization is required. Another type of shadow-mask CRT, the flat tension mask (FTM), is much more resistant to shock and vibration because of the thin shadow-mask foil tension sealed to the face plate. Suspended weight is minimal and the CRT can withstand high shock and vibration levels [Taki et al., 1996]. The shadow-mask tube is by far the most widespread tube for computer and high-resolution monitor displays.

Two other types of color CRTs are practically immune to shock and vibration. These are the beam index tube and the penetration tube.

The Beam Index CRT

In the beam index tube, the RGB striped screen is intermixed with indexing stripes of a UV emitting luminescent material with very fast decay time. When excited by the electron beam, the index stripes emit a light pulse that is detected by photosensors located on the transparent bulb. The signals are then digitally processed, permitting video signals to be fired at the correct position of the electron beam on the screen.

Beam index CRTs are basically used for avionic applications. A typical 150×150 mm^2 (6×6 in.) CRT can display images with a white brightness around 3400 cd/m^2 (1000 fL).

The Penetration CRT

With the penetration CRT, operation is based on the variation in depth of penetration of an electron beam in successive layers of different luminescent materials, typically red and green emitting.

At low voltage, such as 9 kV, the first layer of luminescent material is excited and a red color is obtained. At high voltage, such as 18 kV, the electrons penetrate the red layer without losing much of their energy and excite the green layer to produce a slightly desaturated green. Typically, only four colors can be produced.

These tubes can be built in any size and can also use a variety of short and long persistence luminescent materials to achieve variable persistence. This is convenient for radar or other specific limited color applications.

The Beam Matrix Flat CRT [Tully, 1994]

This flat panel CRT combines electron beams provided by a hot cathode, like a conventional CRT, and beam modulation and addressing thanks to a matrix of conductive metallic rows and columns. The electron beam generated impinges on a fluorescent screen identical to that of a standard CRT.

Such tubes are, as of 1996, still in the development stage.

Another type of flat panel using an electron beam is the field emission device (FED); these FEDs are in fact using electron beams generated in a very high vacuum by field emission, then these beams are modulated and addressed by sets of matrixed conductive electrodes, arranged in rows and columns, and impinged on a fluorescent screen [Kumar et al., 1994]. These FEDs are in the early stages of development and samples of 10-in. diagonal color panels have been demonstrated in 1996, during the SID conference.

Although the FEDs are not exactly corresponding to the definition of a CRT, they are emissive devices using an electron beam to illuminate a fluorescent screen and hence can be assimilated to the family of CRTs.

Contrast and Brightness

Contrast ratio is defined as the ratio of the luminance L_1 of the picture element to the luminance L_2 of the background as follows:

$$C_R = \frac{L_1}{L_2}$$

Brightness contrast, important to the observer, is defined as the ratio of the luminance of the picture element plus background $L_1 + L_2$ to the background luminance L_2

$$C = \frac{L_1 + L_2}{L_2} = 1 + C_R$$

In order to improve contrast, the usual technique is to use an absorbing faceplate or spectrally matched filter to absorb the light emitted by the luminescent screen once and the ambient incident light twice. In addition, antireflection coatings and antiglare treatments can be applied to the CRT face to reduce the reflections from the front surface. Depending upon the ambient lighting conditions, a compromise must usually be found between light output required and the contrast need.

Measurements on CRTs

Line Width and Modulation Transfer Function

The emitted phosphor spot of a CRT usually presents a Gaussian energy distribution. The measurement is usually performed at the 50% height of the Gaussian curve and is called $L_{0.5}$. It can be done also at the σ point of the Gaussian curve and called $L_{0.6}$, with $L_{0.5} = 1.175\ L_{0.6} = 1.175\ L\sigma$.

Spot size is related to modulation transfer function (MTF) [E.I.A., 1986] by

$$L_{0.5} = \sqrt{\frac{1}{3.56(N)^2}\ L\frac{1}{MTF}} = \frac{0.53}{N}\sqrt{L\frac{1}{MTF}}$$

where MTF is fractional, L is the neperian logarithm, N is the number of cycles/millimeter, and $L_{0.5}$ is expressed in millimeters, and can be related to $L\sigma$ by the formula

$$L_{0.5} = 1.175L\sigma$$

The spot image is normally measured using a microscope with a suitable detector such as a fiber-optic probe coupled to a photomultiplier or a CCD array.

Another method widely used is the shrinking **raster** technique. After a raster of n horizontal lines is scanned on the CRT screen, the vertical size of the screen is reduced until the line structure disappears and produces a uniform luminance to the observer. The number of raster lines is then divided into the raster height:

$$L_{SR} = \frac{\text{compressed raster height}}{n}$$

Comparing L_{SR} to $L\sigma$, authors find values of L_{SR} between 1.17 and 1.23 $L\sigma$.

Brightness

Brightness is measured as area brightness (raster luminance) L_R or peak line brightness L_p. Peak line brightness is an inverse function of the writing speed, a direct function of the refresh rate of the displayed line and, of course, of the beam current. Raster luminance L_R is related to the raster emitting surface (S), to the beam current (I), to the screen efficiency (ε), transmission (T) of the faceplate, and to the screen voltage (V_s) by the formula

$$L_R = \frac{V_S I}{\pi S} T\varepsilon$$

where ε is lumens/watt, I is amperes, S is in square meters, T is fractional, and $\pi = 3.1416$. There is no convenient relation between peak line brightness and raster brightness.

Illumination

Illumination is usually measured by illuminance in lux where: 1 lux = 1 lumen/m^2. The S.I. units are the candela/square meter or nit for luminance and the lux for illuminance. They are related to the commonly used footlambert (fL) and footcandle (fC) by the relations:

$$1\ \text{fL} = \frac{1}{\pi}\ \text{cd/ft}^2 = 3.42\ \text{cd/m}^2$$
$$1\ \text{fC} = 1\ \text{lm/ft}^2 = 10.8\ \text{lux}$$
$$1\ \text{lux} = 1\ \text{lm/m}^2$$

The notion of illumination has to be differentiated from the notion of brightness. The footcandle is often used for illuminance and is produced approximately by a source having a luminance of 1 fL (when the reflectance of the surface is 1), which makes the contrast calculation easy. However, these units must not be confused.

Projection Screen

Very often a CRT is used to project an image onto a screen. For a lambertian screen, which rediffuses the incident light in all directions, we can write

$$B = L\frac{T}{4n^2(m+1)^2}$$

where B is the luminance off the projection screen, L is the luminance of the CRT, f is the focal length of the lens used, m is the magnification factor, d is lens diameter, n is aperture, f/d, and T is the transmission of the optics.

The maximum **flux** F (lumens) from the CRT can be expressed by

$$F = \pi\ LS$$

where L is the CRT screen brightness (candelas/square meters) and S the emitting screen surface (square meters), $\pi = 3.1416$.

Conclusion

The worldwide market for 1996 CRTs is at a yearly level of 50 million units compared to 38 million units in 1991 [Stanford Resources, 1992]. High resolution color CRTs are the mainstream of this growth because there is progressive symbiosis between multimedia and high resolution color television with the upcoming of digital television and the development of the Internet. The growth of this market is presently foreseen by the electron tube community up to 100 million units yearly. It is now obvious that the competitive technologies have still to progress to be able to replace the CRT in many applications and that this progress is much slower than the sometimes optimistic predictions of the scientific and industrial community.

It is also important to note that the Electronics Industries Association is monitoring several standard committees for CRTs and that proposals for standards are submitted by the industry and by laboratories such as the National Information Display Laboratory (see Further Information). These standards are following the evolution of measurement techniques. The adoption of these standards by the industry will make it possible for display users to choose their equipment according to criteria uniformly approved around the world.

The CRT is widely used aboard commercial and military aircraft for cockpit displays, aboard surface ships and submarines, and aboard military and commercial vehicles. Because of its wide range of capabilities, versatility of use, brightness and contrast, image quality, and efficiency, the qualities of the CRT largely offset

its bulkiness and weight for most applications. CRTs are still dominating high-resolution applications ranging from 12-mm helmet-mounted displays to 1000-mm diagonal 2000×2000 pixels color monitors and, according to P. Brody [1980], will continue to dominate the market for a few decades.

Defining Terms

Cathode ray tube: A vacuum tube which uses *cathode rays* to generate a picture on a fluorescent screen. These cathode rays are in fact the electron beam deflected and modulated, which impinges on a phosphor screen to generate a picture according to a repetitive pattern refreshed at a frequency usually between 25 and 72 Hz. The term cathode rays stems from the discovery by Plücker [1858] and Hittorf [1869] of a blue glow present at some spots on a glass tube when studying high-voltage discharge in a low-pressure gas. Crookes [1879] showed that these cathode rays were deflected by a magnetic field and were in fact electrons emitted by the negative electrode. The more poetic term *cathode rays* has been kept instead of electron beam for the cathode ray tube.

Contrast: For a cathode ray tube, contrast is the evaluation of the visibility of the picture presented on the phosphor screen in a given ambient lighting. Contrast is usually measured by the contrast ratio, which is the ratio of the luminance of the picture element under evaluation to the background luminance.

Flux: Also called *radiant flux*, the radiant power emitted by a source. It can be expressed in watts for a radiometric source or in lumens when the source spectral energy distribution is between 400 and 700 nm.

Illumination: The effect of a visible radiation flux received on a given surface. Illumination is measured by the illuminance, which is the luminous flux received by surface unit, usually expressed in lux. One lux equals 1 lumen/m^2.

Raster: Also called *television raster;* it is developed by a moving spot of light generated by an electron beam scanning a CRT phosphor screen in a predetermined and repetitive pattern. A picture is generated by modulating the beam intensity, hence the spot light output, when scanning the screen surface. Usually, horizontal lines are generated scanning in a left-to-right sequence and developed top-to-bottom of the image surface.

83.4 Color Plasma Displays

Larry F. Weber

Introduction

The last few years have seen an explosive growth in manufacturing capacity and interest in full color **plasma** displays. This is fueled by the realization that plasma displays can fulfill the long sought after goal of consumer-affordable hang-on-the-wall flat-panel television displays with diagonals in the range of 20 to 60 in. Color plasma displays operate on the same physical principle as fluorescent lamps. A gas discharge generates ultraviolet light which excites a phosphor layer that fluoresces visible light. Differing phosphors are used for the red, green, and blue primaries and a full color moving image is obtained by modulating each primary color sub-pixel to one of typically 256 intensity levels at 60 times a second.

One quantitative measurement of industrial activity is the list of major corporate efforts on the three distinct structures shown in Fig. 83.23. Each of these companies is now manufacturing or has demonstrated 40-in. or larger color plasma panels. Many of these companies are looking to plasma displays as the next display device opportunity that will follow the success model of the active matrix liquid crystal displays (AMLCDs).

Color Plasma Display Markets

The plasma display manufacturers have adopted the strategy of a strong attack on the greater than 40-in. diagonal NTSC television and high definition television (HDTV) markets. Display diagonals smaller than 20 in. are specifically avoided in this strategy. Plasma displays have found their proper place in the market by evading the fierce competition from the smaller diagonal LCDs and CRTs since both of these technologies have difficulty with 40- to 60-in. diagonals. In this diagonal range, plasma displays will compete primarily with projection displays.

While projection systems have recently shown a very high level of achievement they are especially vulnerable to plasma because of their limited viewing angle and bulk. It is clear that projection systems have not found

1.	Diagonals of 20 to 60 in.
2.	Full 16 million colors
3.	Very strong non-linearity
4.	Inherent memory
5.	Long lifetime
6.	Very wide viewing angle
7.	Instant update time
8.	Good luminance and luminous efficiency
9.	CRT-like manufacturing model
10.	Tolerant to shock, vibration, and temperature extremes
11.	Reasonable impedance characteristics
12.	Precise digital grey scale
13.	CRT-like color gamut

much success in diagonal ranges where there is a wide viewing angle CRT alternative. Thus, a wide angle and thin plasma display alternative at a competitive price will easily dominate this large diagonal market. This market is quite large because of the expectation that many HDTV viewers will prefer the wide screen theater-like effect of the high resolution image. The challenge to the plasma displays will be to achieve prices competitive to those of projection systems.

The potential market for large plasma displays is enormous. The most optimistic market projections show annual world-wide sales of about 10 million plasma displays in the year 2002. While this projection shows a very rapid growth, it is still only 5% of the slightly less than 200 million television sets that will be sold that year. More conservative projections still show $5 billion world-wide sales for plasma displays in 2002.

Color Plasma Display Attributes

Table 83.1 shows some of the attributes of color plasma displays which make them successful. The following reviews each attribute.

1. The electrical characteristics of the gas discharge allow plasma displays to be made with diagonals in the 20- to 60-in. range. Such large diagonals are facilitated by very strong non-linearity and inherent **memory** of the discharge, as discussed in Items 3 and 4 below, which present no practical limitations to the number of lines that can be multiplexed. Also, the high impedance characteristic (covered below in Item 11) coupled with the ability to use highly conductive opaque electrodes, greatly reduces electrode loss limitations to size. Monochrome plasma displays have been sold with sizes as great as 60-in. diagonal,

having over 4 million pixels. By 1996 full color plasma displays had been demonstrated with 46-in. diagonals and 4 million sub-pixels.

2. The all-digital gray scale technique used in color plasma displays allows each primary sub-pixel to display 256 or more intensity levels. This allows full 24-bit color or 16 million colors. These 256 intensity levels are not the limit of the plasma displays but rather a convenient design point for software and system compatibility.
3. The plasma display has a very large non-linearity due to the electrical characteristic of the gas discharge used in all plasma displays. This is an electrical non-linearity, meaning that below a certain threshold voltage, the gas discharge will emit no light. Of course, above that threshold voltage the gas discharge fires and emits a desired color. Very sharp non-linearity allows plasma displays to be multiplexed without limit which makes very large plasma displays practical. This is demonstrated by a number of recently developed $1280 \times 1024 \times 3$ sub-pixel color plasma displays. This is a considerable advantage when compared to other display technologies such as the liquid crystal. The liquid crystal display does not have a very good non-linearity and, therefore, some other non-linear element, such as a thin film transistor, is sometimes added in series with each liquid crystal element to increase the display non-linearity. Of course, this greatly complicates and adds cost to this active matrix liquid crystal.
4. Most color plasma displays have inherent memory which is stored directly in the glass plasma panel. Memory is very desirable for flat panel displays because it allows the display to be very bright even for very large sizes. This is because a display with memory has a pixel duty cycle of one. Displays without memory have a pixel duty cycle of one divided by the number of scanned lines. Thus, as the non-memory displays get bigger and the number of scanned lines increases, the duty cycle and, therefore, the brightness of the display decrease. An additional value of memory is the elimination of flicker because the pixels are on all of the time.
5. The lifetime of color plasma displays can be long. Full color plasma display products have been delivered with specified lifetimes to half luminance of 10,000 to 30,000 h. While this is comparable to some CRT products, there is considerable effort to extend this lifetime further. The failure mode is usually a slow degradation in the phosphor that gradually decreases the display luminance. If all of the pixels are aged uniformly, with perhaps a randomly moving television image, the display will still be usable after the specified lifetime but at reduced luminance. However, displays used for computer images require a much tougher life specification because images such as icons may be left on the same screen location for long periods and burn in an image. These problems are very similar to the phosphor degradation observed on a CRT.
6. One of the major advantages of all plasma displays over liquid crystals is the very wide viewing angle. Plasma displays can even get brighter when viewed off axis and, therefore, have the widest viewing angle of any display technology.
7. Gas discharges switch in microseconds and so plasma displays can be updated instantly. Speed is especially important for the very popular mouse and cursor operations where the cursor would disappear when moving on a liquid crystal display. Full motion television images are not a challenge for plasma displays.
8. The luminance and **luminous efficiency** of color plasma displays are good. Displays having 450 candelas per meter squared at 1 lumen per watt have been demonstrated. Some other display technologies such as ac electroluminescence have a higher material luminous efficiency but this performance must be tempered by the fact that the plasma panel has 1000 times less electrical capacitance than the ac electroluminescent devices. The plasma panel frequently takes less power than the EL devices when the switching loss of the EL panel is considered. This favors plasma panels for larger numbers of scanned lines and favors EL panels for smaller numbers of scanned lines. The crossover point is somewhere in the region of a few hundred scanned lines.
9. Color plasma displays are manufactured in a plant that has considerable commonalty with CRT manufacturing plants. This contrasts sharply with the semiconductor-like manufacturing plant of AMLCDs. Therefore, the plasma display plant will cost much less than the AMLCD plant.
10. The structure can withstand very high levels of shock and vibration when properly mounted. Military plasma displays have been designed for in excess of 150 Gs of shock. Plasma displays can easily operate at both high and low temperature extremes. **ac plasma displays** have a temperature limit dependent

almost solely on the drive circuit characteristics. **dc plasma displays**, which use mercury, should not be operated for long periods at low temperatures without an external heater. All recently introduced color dc plasma displays do not have mercury and do not have this limitation.

11. Plasma displays have a high input impedance characteristic that makes them easy to drive. The dielectric constant of the gas is equal to one, which means that plasma displays have virtually the lowest possible electrode capacitance. This is 1000 times smaller than electroluminescent displays and about 100 times smaller than liquid crystal displays. This translates to lower current requirements and, therefore, smaller drive circuit silicon area for the plasma displays. While plasma displays do require 100-volt address drivers, it is frequently easier to design high voltage circuits than high current circuits. Also, 40-in. and larger displays can be designed with little power dissipation in panel electrodes.
12. The gray scale technique used in color plasma displays is 100% digital, which allows design of an all digital image system having reduced noise and increased stability in the color representations. This will become more important as signal sources with very high quality digital signals, such as those from digital video disks and HDTV, become widely available.
13. The color gamut of the available plasma display phosphors is very good. While the color coordinates do not yet exactly match those used in the CRT, future process adjustments are expected to produce the desired close match.

Gas Discharge Physics

A brief account of gas discharge physics will be covered below. A more detailed discussion of this material is presented in Weber [1985].

Figure 83.24 shows the important reactions that occur in a gas discharge for the monochrome gas mixture of neon and argon. The reactions in the gas volume include ionization (I), excitation (E), metastable generation (M), and Penning ionization (P). The three surface reactions that occur at the cathode cause ejection of electrons from the cathode by a bombarding neon ion, a neon **metastable atom** or by a high energy photon. The most important volume reaction is ionization (I), which can cause the generation of an avalanche in the gas volume as shown in Fig. 83.24. This avalanche is started by an electron near the cathode and as it grows toward the anode, it generates a large number of electron-ion pairs. The number of electron-ion pairs increases with increasing applied voltage across the gas. Ions, photons, or metastable atoms that are transported to the cathode can then eject electrons with a cathode surface-dependent probability and these ejected electrons will initiate further avalanches. These mechanisms act as a positive feedback system that becomes unstable when the loop gain is greater than 1. The onset of the unstable condition is defined as the gas firing voltage. Above this firing voltage the discharge current will continue to grow without bounds if the initial avalanche is primed with at least a single electron.

Figure 83.25 shows the I-V characteristic of a typical gas discharge found in plasma displays. Note that the current is plotted on a log scale over nine orders of magnitude. The most striking feature is the very strong non-linearity at the firing voltage, which is a major attribute of gas discharges that allows matrix addressing. When the discharge current has sufficient magnitude, space charge distortion sets in and the characteristic achieves a negative resistance region. Most plasma displays operate near the junction of the normal and the abnormal glow regions of the characteristic.

One critical aspect of gas discharges is the requirement for external priming as shown in the lower part of Fig. 83.25. The avalanche process shown in Fig. 83.24 needs at least one electron to start the discharge growth. Without this first electron, the discharge will not start at any voltage. Priming electrons can come from a number of different active particles created either by a prior discharge or by neighboring discharging pixels. Active particles include free electrons, free ions, metastable atoms, and ultraviolet photons.

Figure 83.26 shows the characteristics of the glow discharge commonly found in operating plasma displays. The light comes from two luminous regions: the negative glow and the positive column. All plasma displays on the market today use light from the negative glow but a few research displays have used the light from the positive column. These regions are caused by the space charge distribution of the electrons and ions that distort the electric field and voltage distribution.

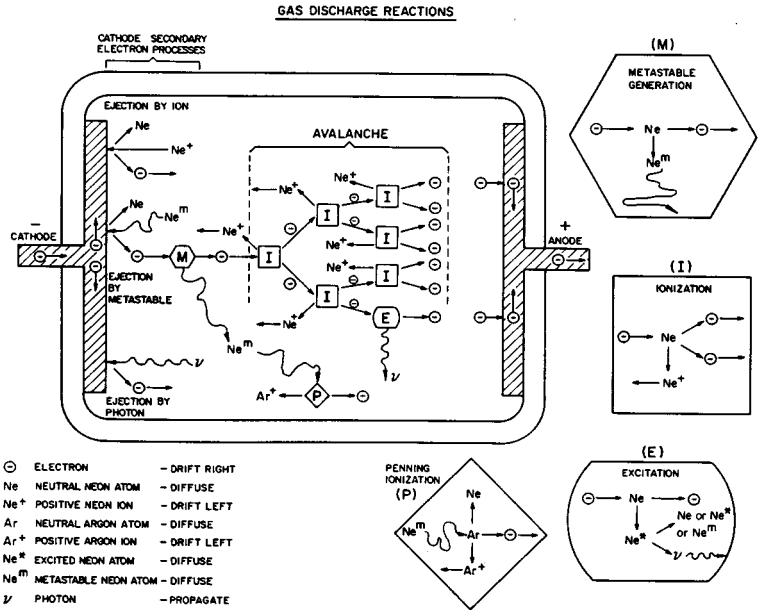

FIGURE 83.24 Model of important gas discharge reactions.

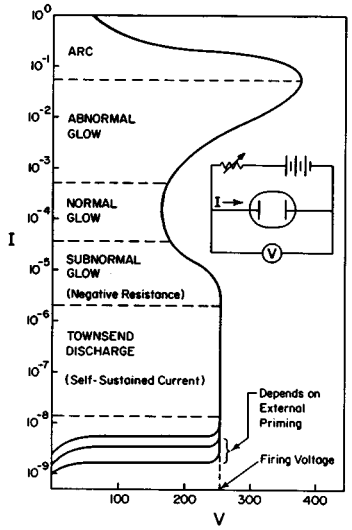

FIGURE 83.25 The I-V characteristic of a gas discharge.

Current Limiting for Plasma Displays

To avoid a catastrophic arc, the current in a gas discharge must be limited by some means. There are a number of ways of accomplishing this, but only two, shown in Fig. 83.27, have achieved commercial success. dc plasma displays use a resistor, a semiconductor current source, or a short applied voltage pulse to limit the current and have the electrodes in intimate contact with the gas discharge. ac plasma displays limit the current with an internal glass dielectric that couples the electrodes capacitively to the gas discharge.

Most of the commercially successful monochrome dc displays have the resistors or current sources connected to a display electrode external to the panel which allows only one discharge to be ignited along that electrode at any one time. This works well for scanned displays. Multiple discharges and dc memory require placing the

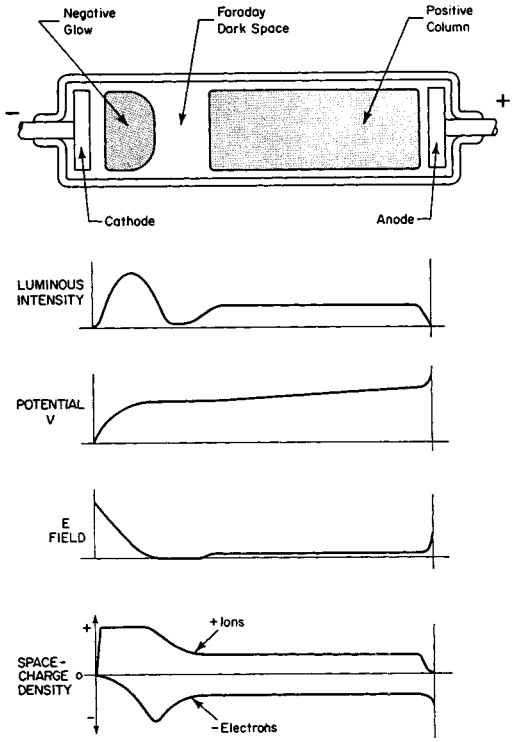

FIGURE 83.26 Luminous regions of a gas discharge.

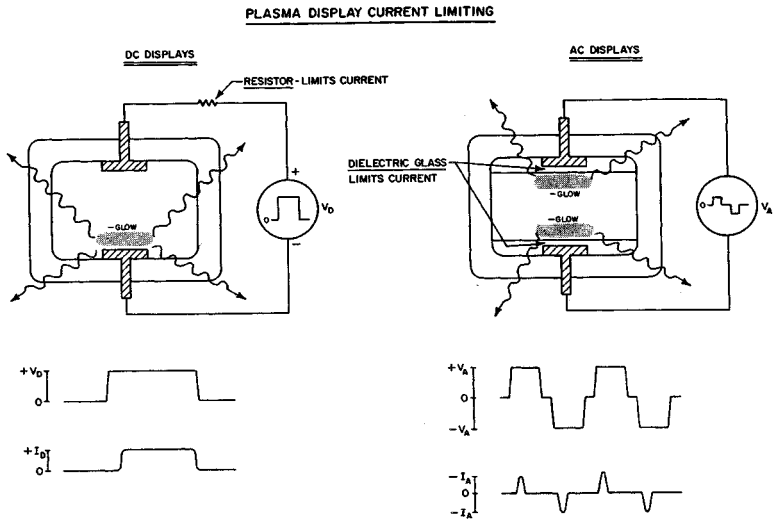

FIGURE 83.27 The two current limiting techniques used in plasma display products.

resistor internal to the panel in series with each pixel. Recent materials and process advances have allowed practical dc color displays with memory to be made having a resistor per sub-pixel.

The ac displays can achieve memory and the necessary current limiting with a simple dielectric layer that forms a capacitor in series with each pixel. When a voltage pulse is applied to an ac panel, the discharge deposits

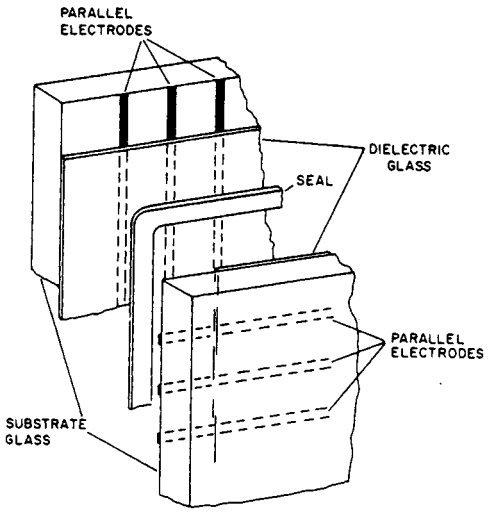

FIGURE 83.28 Monochrome ac plasma display structure.

a charge on the wall that reduces the voltage across the gas. After a short time, the discharge will extinguish and the light output will end until the applied voltage reverses polarity and a new discharge pulse occurs. This wall charge allows the ac plasma displays to operate in a memory mode, which greatly increases the brightness of large displays.

ac Plasma Displays

Figure 83.23 shows that currently, color plasma displays are dominated by the ac technology, so it is worth examining the ac monochrome structure shown in Fig. 83.28 [Criscimagna and Pleshko, 1980]. These panels are made by depositing thin film electrodes on the front and back substrates and then covering those electrodes with a thin dielectric glass. Recall from Fig. 83.27 that this dielectric glass makes a capacitor that is used to limit the discharge current. This dielectric also is used to store the charge that gives these panels inherent memory. The two substrates are then sealed together around the perimeter and filled with neon gas. The ac panels have a very simple structure that allows the pixels to be isolated simply by the action of electric fields.

The ac plasma panels require the inner surface of the dielectric that is in contact with the gas to have a special coating of magnesium oxide. This MgO layer is necessary for the panel to have low operating voltages and long life. Being a refractory oxide, MgO sputters away at a very low rate and it is also well known for its high secondary electron emission.

The largest plasma display product ever manufactured (prior to 1997) uses the Fig. 83.28 structure and has a diagonal of 60 in. with a 2048×2048 array of more than 4 million pixels [Wedding et. al., 1987]. This display operates at a very high update rate so that it will work with a standard NTSC video source. The memory feature allows this display to have the same luminance as the smaller page sized displays.

ac displays require that an ac signal, called the sustain voltage, be applied during operation as shown on the right side of Fig. 83.27. A typical sustain frequency is 50 kHz. Figure 83.29 shows the details of this operation for a pixel in both the on and off states. When a pixel is discharging, charge collects on the dielectric glass walls and influences the voltage across the gas. The component of voltage due to this charge is called the wall voltage. When a pixel is on, the wall voltage changes for each polarity reversal of the sustain voltage. This change in wall voltage coincides with a pulse of light due to the gas discharge. When the pixel is off, there are no light pulses, and the wall voltage remains at a zero level.

Pixel addressing is achieved through a partial discharge by introducing an address pulse timed between the sustain pulses. A write pulse causes the wall voltage to transit from zero volts to the final equilibrium wall voltage level. Likewise, an erase pulse causes the wall voltage to return to zero.

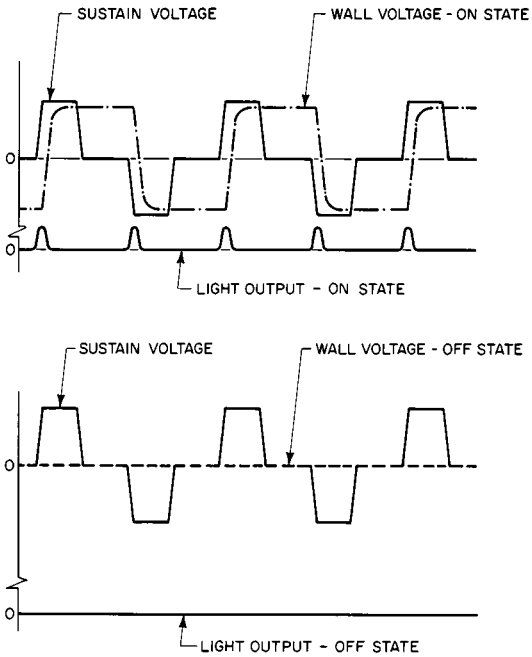

FIGURE 83.29 Sustain voltage, wall voltage, and light output for ac plasma pixels in the on and off states.

Color Plasma Display Devices

Color is achieved by placing phosphors in the plasma panel and then exciting those phosphors with the ultraviolet light of the gas discharge. This is the same principle as used in the fluorescent lamp. Xenon is the active UV generating gas which provides atomic resonance radiation at 147 nm and a molecular band centered at 173 nm. Neon or helium buffer gases are always mixed with the xenon.

Figure 83.23 indicates the companies who are making a serious effort at developing the three dominant full color structures. The basic concepts of the two ac structures are shown in Fig. 83.30. The double substrate structure is very similar to the monochrome ac structure shown in Fig. 83.28. The single substrate structure separates the discharge cathode areas from the phosphor by applying the sustain voltage only to the lower electrodes while the phosphor is on the top. The single substrate approach promises longer phosphor life because it is not directly sputtered by the energetic ions that are directed toward the cathodes.

The structure for the single substrate ac plasma displays is shown in Fig. 83.31 [Shinoda et al., 1993]. Note that the front and back substrates each have simple one dimensional features. Since the two substrate structures are positioned orthogonally, there is no critical alignment between the two substrates because the pixels will automatically occur wherever the orthogonal electrodes intersect. This allows for straightforward manufacture of large panels.

The phosphors are placed on the rear substrate of the panel in Fig. 83.31 and are excited by the ultraviolet light generated by the electrodes on the top substrate. In this case, both sets of ac sustain electrodes are on the upper substrate. The ac voltage is applied to these electrodes in the normal way and the fringing fields from these electrodes reach into the gas and create a discharge. Note that the structure in Fig. 83.31 has glass barrier rib separators between each sub-pixel. This is necessary to reduce cross-talk between the different colors that will reduce the color purity. These barrier ribs do not transmit the 147-nm or 173-nm radiation generated by the xenon gas used in color plasma displays. The phosphors are placed on all walls of the sub-pixel channel except for the front plate which has the phosphor damaging **sputtering** activity at the cathodes. This nearly complete phosphor coverage of the walls maximizes luminance while minimizing sputtering damage.

Other important features of the structure in Fig. 83.31 are the address electrodes buried beneath the phosphors of the rear substrate. These are the column electrodes that are selectively pulsed depending on the input image data. While these address operations do create discharge activity that could potentially sputter damage

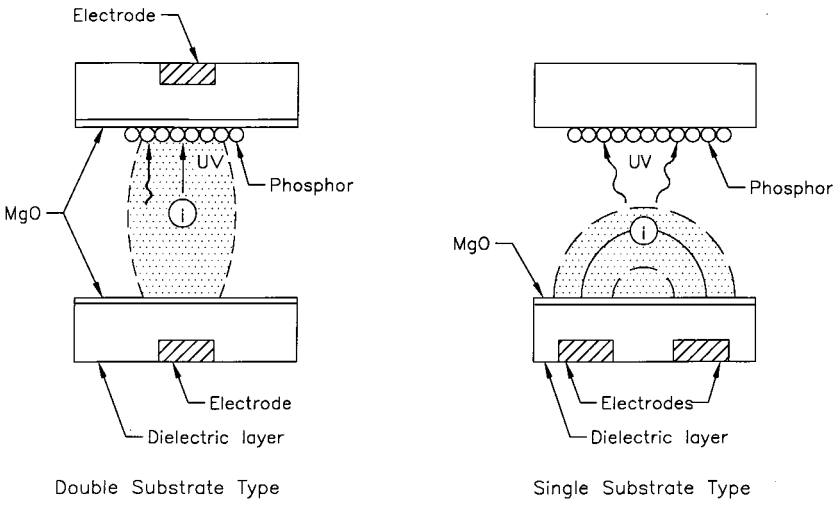

FIGURE 83.30 Two major structural designs of color ac plasma displays.

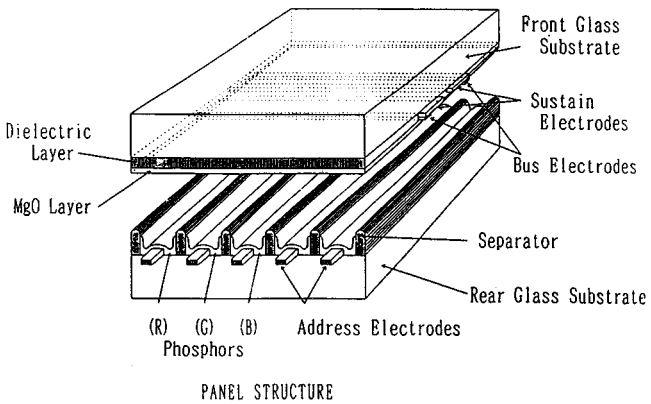

FIGURE 83.31 Structure of single substrate color ac panel.

the phosphor, the address pulse frequency is orders of magnitude lower than the sustain frequency and so the amount of address damage is minimal.

The sustain electrodes shown in Fig. 83.31 are made of a conductive transparent material such as tin oxide. Unfortunately, the resistance is orders of magnitude too high. To correct this problem, narrow bus electrodes of high conductivity materials, such as silver or chrome-copper-chrome, are placed over the tin oxide to reduce the electrode resistance to values on the order of 100 ohms.

The ac double substrate device shown on the left of Fig. 83.30 has a structure very similar to the monochrome device of Fig. 83.28 [Doyeux and Deschamps, 1995]. The major differences are the introduction of glass barrier ribs to maintain color purity and the introduction of color phosphors. The phosphors are placed on one substrate and are carefully positioned to avoid the location directly over the electrode since the sputtering action over the electrode will cause significant phosphor degradation.

Figure 83.32 shows the color dc plasma display structure [Koike et al., 1995]. The major difference between the dc and ac structures is the placement of resistors in series with each sub-pixel to limit the discharge current for the dc case as shown in Fig. 83.27. Another difference is the requirement for the dc device to have barrier ribs on all four edges of each sub-pixel. This is needed to prevent the dc discharge from spreading to neighboring sub-pixels in addition to the color purity issue discussed above for ac panels. Unlike the single substrate ac structure shown in Fig. 83.31, the alternate color phosphors are patterned along each row and each column in

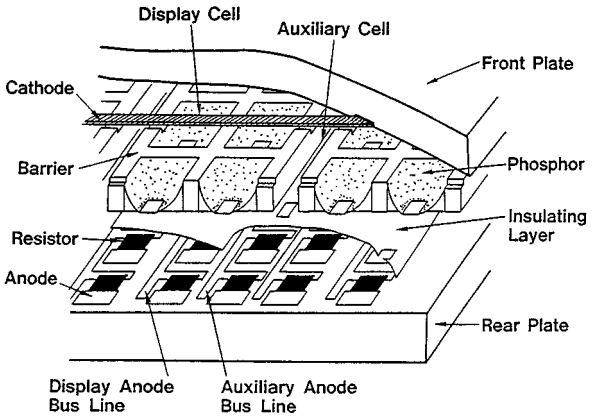

FIGURE 83.32 Structure of color dc panel.

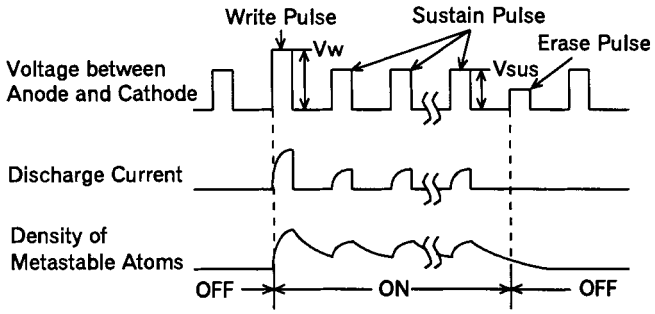

FIGURE 83.33 Pulsed memory mode for dc plasma panels.

a two-dimensional structure. This requires careful alignment between the front and the rear substrates. Priming is achieved by means of the auxiliary cells and anodes placed between the sub-pixels that generate a discharge that is not visible to the viewer.

Inherent memory is achieved for the dc plasma structure of Fig. 83.32 with the pulsed memory mode waveforms shown in Fig. 83.33 [Takano et al., 1994]. This operates on the principle that if there is metastable priming from the preceding discharge pulse, then the discharge will build up in a sufficiently short time to fully mature during the very short electrode voltage pulse. The electrode voltage pulse is adjusted to be sufficiently short to inhibit a sequence of discharges if there has not been an initiating higher amplitude address pulse. The pulse memory mode was invented over 25 years ago [Holz, 1972], and is the most widely studied technique for achieving memory in dc plasma displays. It was just recently introduced to commercial production.

Gray Scale

The ac or dc memory displays cannot use pulse intensity or pulse width modulation for gray scale because the pixels in memory mode are either on or off and such pulse perturbations would, in many cases, have the undesirable effect of changing the state of the pixel. Instead these memory displays achieve gray scale by modulating the percentage of time that the pixel is on in a given frame. This means that the pixels must be addressed multiple times per frame. In the sequence shown in Fig. 83.34 for 256 intensity levels, each frame is divided into eight sub-fields and each sub-field consists of an address period and a sustain period [Yoshikawa, 1992]. During a given address period, address pulses are applied to all pixels in the panel according to the sub-field image data. Each of the eight sub-fields has a sustain period with a different number of sustain cycles which emits an amount of light proportional to the number of sustain cycles. If each data bit of a given pixel

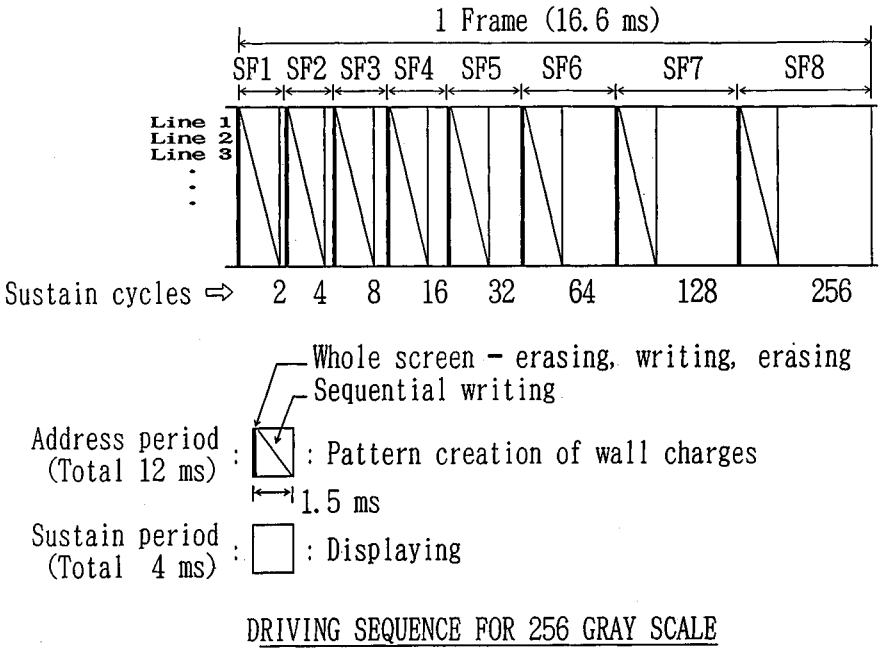

FIGURE 83.34 Addressing sequence for 256 intensity gray scale in ac memory plasma displays.

intensity word is allowed to control one of the sub-fields, then the total number of sustain cycles (and light) per frame will be proportional to the 8-bit intensity value. This results in a precise inherently digital gray scale.

Defining Terms

ac plasma displays: These employ an internal capacitive dielectric layer to limit the gas discharge current.

dc plasma displays: These employ an internal or external resistor to limit the gas discharge current.

Luminous efficiency: The measure of the display output light luminance for a given input power, usually measured in lumens per watt, which is equivalent to the nit.

Memory: The property of a display pixel that allows it to remain stable in an initially established state of luminance. Memory gives a display high luminance and absence of flicker.

Metastable atom: An atom in a temporary but long lived excited state in which photon emission is forbidden by electrodynamic theory. Metastables can give up their energy by ionizing other atoms or through wall collisions.

Plasma: The fourth state of matter comprised of positive ions and negative electrons of equal and sufficiently high density to nearly cancel out any applied electric field. Not to be confused with blood plasma.

Sputtering: The physical process whereby an ion with kinetic energy in the gas collides with a solid surface ejecting an atom from the solid into the gas.

84.1 Introduction

Data acquisition includes everything from gathering data, to transporting it, to storing it. The term *data acquisition* is described as the "phase of data handling that begins with sensing of variables and ends with a magnetic recording of raw data, may include a complete telemetering link" (McGraw-Hill, *Dictionary of Scientific and Technical Terms,* Second Edition, 1978). Here, the term *variables* refers to those physical quantities that are associated with a natural or artificial process. A data acquisition phase involves a real-time computing environment where the computer must be keyed to the time scale of the process. Figure 84.1 gives a simplified block diagram of a data acquisition system current in the early 1990s.

The path the data travels through the system is called the data acquisition channel. Data are first captured and subsequently translated into usable signals using transducers. In this discussion, usable signals are assumed to be electrical voltages, either unipolar (that is, single ended, with a common ground so that we need just one lead wire to carry the signal) or bipolar (that is, common mode, with the signal carried by a wire pair, so that the reference of the rest of the system is not part of the output). These voltages can be either analog or digital, depending on the nature of the measurand (the quantity being captured). When there is more than one analog input, they are subsequently sent to an analog **multiplexer** (MUX). Both the analog and the digital signals are then conditioned using signal conditioners. There are two additional steps for those conditioned analog signals. First they must be sampled (see Chapter 73.4) and next converted to digital data. This conversion is done by **analog-to-digital converters** (ADC) (see Chapter 32).

Once the analog-to-digital conversion is done, the rest of the steps have to deal with digital data only. The calendar/clock block shown in Fig 84.1 is used to add the time-of-date information, an important parameter of a real-time processing environment, into the half-processed data. The digital processor performs the overall system control tasks using a software program, which is usually called system software. These control tasks also include display, printer, data recorder, and communication interface management. A well-regulated **power supply unit** (PSU) and a stable clock are essential components in many data acquisition systems. There are systems where massive amounts of data points are produced within a very short period of time, and they are equipped with *on-board memory* so that a considerable amount of data points can be stored locally. Data are transmitted to the host computer once the local storage has reached its full capacity. Historically, data acquisition evolved in modular form, until monolithic silicon came along and reduced the size of the modules.

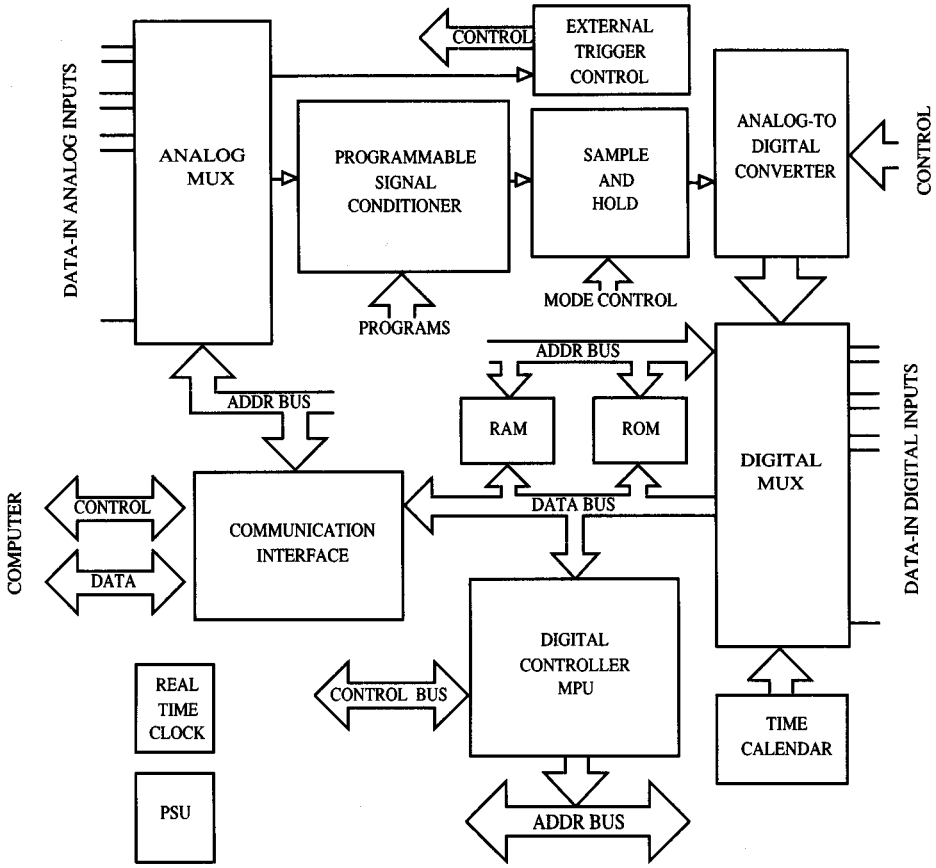

FIGURE 84.1 The block diagram of a data acquisition system.

The analysis and design of data acquisition systems is a discipline that has roots in the following subject areas: signal theory, transducers, analog signal processing, noise, sampling theory, quantizing and encoding theory, analog-to-digital conversion theory, analog and digital electronics, data communication, and systems engineering. Cost, accuracy, bit resolution, speed of operation, on-board memory, power consumption, stability of operation under various operating conditions, number of input channels and their ranges, on-board space, supply voltage requirements, compatibility with existing bus interfaces, and the types of data recording instruments involved are some of the prime factors that must be considered when designing or buying a data acquisition system. Data acquisition systems are involved in a wide range of applications, such as machine control, robot control, medical and analytical instrumentation, vibration analysis, spectral analysis, correlation analysis, transient analysis, digital audio and video, seismic analysis, test equipment, machine monitoring, and environmental monitoring.

84.2 The Analog and Digital Signal Interface

The data acquisition system must be designed to match the process being measured as well as the end-user requirements. The nature of the process is mainly characterized by its speed and number of measuring points, whereas the end-user requirement is mainly the flexibility in control. Certain processes require data acquisition with no interruption where computers are used in controlling. On the other hand, there are cases where the acquisition starts at a certain instance and continues for a definite period. In this case the acquisition cycle is repeated in a periodic manner, and it can be controlled manually or by software. Controllers access the process via the analog and digital interface submodules, which are sometimes called analog and digital front ends.

Many applications require information capturing from more than one channel. The use of the analog MUX in Fig. 84.1 is to cater to multiple analog inputs. A detailed diagram of this input circuitry is shown in Fig. 84.2

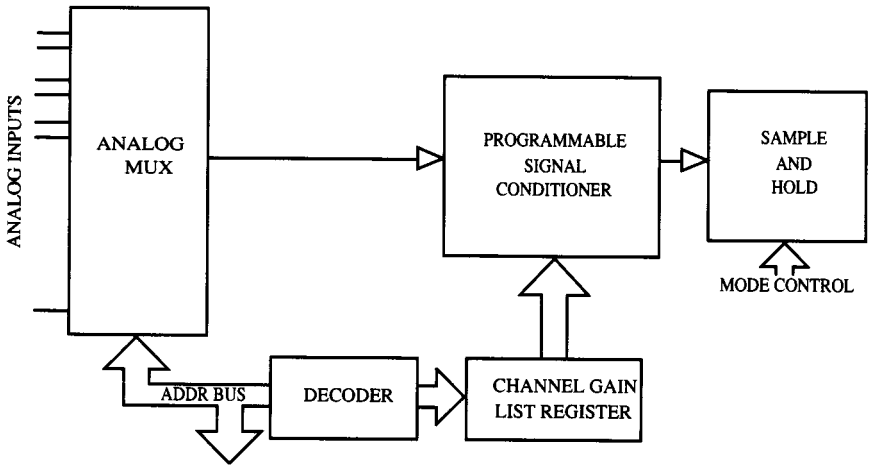

FIGURE 84.2 Analog input circuitry—the analog front end.

and the functional description is as follows. When the MUX is addressed to select an input, say, $x_i(t)$, the same address will be decoded by the decoding logic to generate another address, which is used in addressing the programmable register. The programmable register contains further information regarding how to handle $x_i(t)$. The outcome of the register is then used in subsequent tuning of the signal conditioner. Complex programmable control tasks might include automatic gain selection for each channel, and hence the contents of this register are known as the channel gain list. The MUX address generator could be programmed in many ways, and one simple way is to scan the input channels in a cyclic fashion where the address can be generated by means of a binary counter. Microprocessors are also used in addressing MUXs in applications where complex channel selection tasks are involved. Multiplexers are available in integrated circuit form, though relay MUXs are widely used because they minimize errors due to cross talk and bias currents. Relay MUX modules are usually designed as plugged-in units and can be connected according to the requirements.

There are applications where the data acquisition cycle is triggered by the process itself. In this case an analog or digital trigger signal is sent to the unit by the process, and a separate external trigger interface circuitry is supplied. The internal controller assumes its duties once it has been triggered. It takes a finite time to settle the signal $x_i(t)$ through the MUX up to the signal conditioner once it is addressed. Therefore, it is possible to process $x_{i-1}(t)$ during the selection time of $x_i(t)$ for greater speeds. This function is known as pipelining and will be illustrated in Section 84.3.

In some data acquisition applications the data acquisition module is a plugged-in card in a computer, which is installed far away from the process. In such cases, transducers—the process sensing elements—are connected to the data acquisition module using transmission lines or a radio link. In the latter case a complete demodulating unit is required at the input. When transmission lines are used in the interconnection, care must be taken to minimize electromagnetic interference since transmission lines pick up noise easily. In the case of a single-ended transducer output configuration, a single wire is adequate for the signal transmission, but a common ground must be established between the two ends as given in Fig. 84.3(a). For the transducers that have common mode outputs, a shielded twisted pair of wires will carry the signal. In this case, the shield, the transducer's encasing chassis, and the data acquisition module's reference may be connected to the same ground as shown in Fig. 84.3(c). In high-speed applications the transmission line impedance should be matched with the output impedance of the transducer in order to prevent reflected traveling waves. If the transducer output is not strong enough to transmit for a long distance, then it is best to amplify it before transmission.

Transducers that produce digital outputs may be first connected to Schmitt trigger circuits for pulse shaping purposes, and this can be considered as a form of digital signal conditioning. This becomes an essential requirement when such inputs are connected through long transmission lines where the line capacitance significantly affects the rising and falling edges of the incoming wave. Opto-isolators are sometimes used in coupling when the voltage levels of the two sides of the transducer and the input circuit of the data acquisition unit do not match each other. Special kinds of connectors are designed and widely used in interconnecting

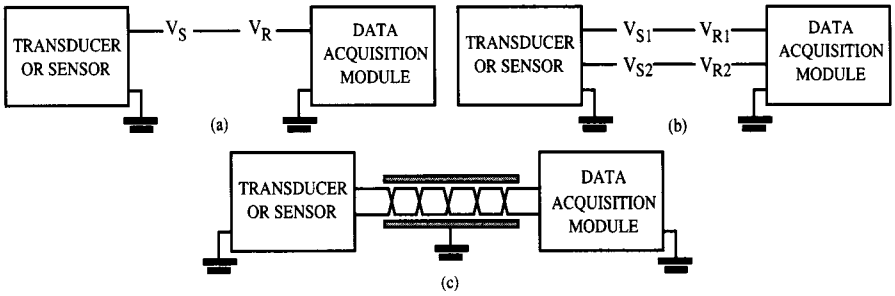

FIGURE 84.3 (a) Connecting transducers to the data acquisition unit, (b) single-ended (unipolar) output, and (c) common-mode (bipolar) output.

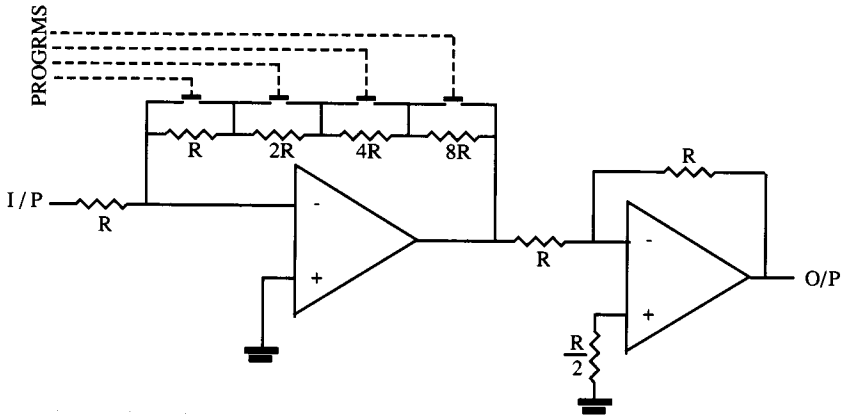

FIGURE 84.4 Programmable gain instrumentation amplifier.

transmission lines and data acquisition equipment in order to screen the signals from noise. Analog and digital signal grounds should be kept separate where possible to prevent digital signals from flowing in the analog ground circuit and including spurious analog signal noise.

84.3 Analog Signal Conditioning

The objective of an analog signal conditioner is to increase the quality of the transducer output to a desired level before analog-to-digital conversion. A signal conditioner mainly consist of a preamplifier, which is either an instrumentation amplifier or an operational amplifier and/or a filter. Coupling more and more circuits to the data acquisition channel has to be done taking great care that these signal conditioning circuits do not add more noise or unstable behavior to the data acquisition channel. General purpose signal conditioner modules are commercially available for applications. Some details were given in the previous section about programmable signal conditioners and the discussion is continued here.

Figure 84.4 shows an instrumentation amplifier with programmable gain where the programs are stored in the channel-gain list. The reason for having such sophistication is to match transducer outputs with the maximum allowable input range of the ADC. This is very important in improving accuracy in cases where transducer output voltage ranges are much smaller than the full-scale input range of an ADC, as is usually the case. Indeed, this is equally true for signals that are larger than the full-scale range, and in such cases the amplifier functions as an attenuator. Furthermore, the instrumentation amplifier converts a bipolar voltage signal into a unipolar voltage with respect to the system ground. This action will reduce a major control task as far as the ADC is concerned; that is, the ADC is always sent unipolar voltages, and hence it is possible to maintain unchanged the mode control input which toggles the ADC between the unipolar and bipolar modes of an ADC.

Values of the **signal-to-noise ratio**

$$\text{SNR} = \left[\frac{\text{RMS signal}}{\text{RMS noise}}\right]^2 \tag{84.1}$$

at the input and the output of the instrumentation amplifier are related to its **common-mode rejection ratio** (CMRR) given by

$$\text{CMRR} = \sqrt{\frac{\text{SNR}_{\text{output}}}{\text{SNR}_{\text{input}}}} \tag{84.2}$$

Hence, higher values of $\text{SNR}_{\text{output}}$ indicate low noise power. Therefore, instrumentation amplifiers are designed to have very high CMRR figures. The existence of noise will result in an error in the ADC output. The allowable error is normally expressed as a fraction of the **least significant bit** (LSB) of the code such as $\pm(1/X)$LSB. The amount of error voltage (V_{error}) corresponding to this figure can be found considering the bit resolution (N) and the ADC's maximum analog input voltage (V_{max}) as given in

$$V_{\text{error}} = \pm\left[\frac{V_{\text{max}}}{2^N - 1} \times \frac{1}{X}\right] \text{ volts} \tag{84.3}$$

Other specifications of amplifiers include the temperature dependence of the input offset voltage (V_{offset}, μV/°C) and the current (I_{offset}, pA/°C) associated with the operational amplifiers in use. High slew rate (V/μs) amplifiers are recommended in high-speed applications. Generally, the higher the bandwidth, the better the performance.

Cascading a filter with the preamplifier will result in better performance by eliminating noise. Active filters are commonly used because of their compact design, but passive filters are still in use. The cut-off frequency, f_c, is one of the important performance indices of a filter that has to be designed to match the channel's requirements. The value f_c is a function of the preamplifier bandwidth, its output SNR, and the output SNR of the filter.

84.4 Sample-and-Hold and A/D Techniques in Data Acquisition

Sample-and-hold systems are primarily used to maintain a constant magnitude representing the input, across the input of the ADC throughout a precisely known period of time. Such systems are called **sample-and-hold amplifiers** (SHA), and their characteristics are crucial to the overall system accuracy and reliability of digital data. The SHA is not an essential item in applications where the analog input does not vary more than $\pm(1/2)$LSB of voltage. As the name indicates, a SHA operates in two different modes, which are digitally controlled. In the sampling mode it acts as an input voltage follower, where, once it is triggered into its hold mode, it should ideally retain the signal voltage level at the time of the trigger. When it is brought back into the sampling mode, it instantly assumes the voltage level at the input.

Figure 84.5 shows the simplified circuit diagram of a monolithic sampling-and-hold circuit and the associated switching waveforms. The differential amplifiers function as input and output buffers, and the capacitor acts as the storage mechanism. When the mode control switch is at its *on* position, the two buffers are connected in series and the capacitor follows the input with minimum time delay, if it is small. Now, if the mode control is switched *off*, the feedback loop is interrupted, and the capacitor ideally retains its terminal voltage until the next sampling signal occurs. Leakage and bias currents usually cause the capacitor to discharge and or charge in the hold mode and the fluctuation of the hold voltage is called *droop*, which could be minimized by having a

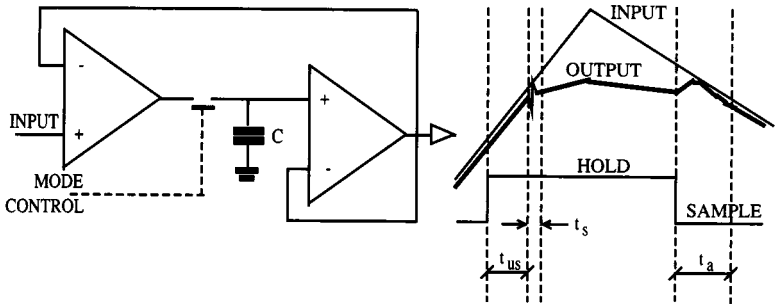

FIGURE 84.5 Sample-and-hold circuit diagram and switching waveforms.

large capacitor. Therefore, the capacitance has to be selected such that the circuit performs well in both modes. Several time intervals are defined relative to the switching waveform of SHAs. The *acquisition time* (t_a) is the time taken by the device to reach its final value after the sample command has been given. The *setting time* (t_s) is the time taken to settle the output. The *aperture uncertainty* or *aperture jitter* (t_{us}) is the range of variation of the aperture time. It is important to note here that the sampling techniques have a well-formulated theoretical background.

ADCs perform a key function in the data acquisition process. The application of various ADC technologies in a data acquisition system depends mainly on the cost, bit resolution, and speed. Successive approximation types are more common at high resolution at moderate speeds (<1 MHz). This kind of ADC offers the best trade-offs among bit resolution, accuracy, speed, and cost. Flash converters, on the other hand, are best suited for high-speed applications. Integrating-type converters are suitable for high-resolution and -accuracy applications.

Many techniques have been developed in coupling sample-hold circuits and ADCs in data acquisition systems because no single ADC or sampling technology is able to satisfy the ever increasing requirements of data acquisition applications. Figure 84.6 illustrates the various sampling and ADC configurations used in practice. It can be seen that the sampling frequencies are increased because of pipelining, parallelism, or concurrent architecture. The increase in the sampling frequency improves the bandwidth, improving in turn the SNR in the channel.

84.5 The Communication Interface of a Data Acquisition System

The communication interface is the module through which the acquired data are sent as well as other control tasks are established between the data acquisition module and the host computer (Fig. 84.1). There are basically two different ways of establishing a data link between the two. One way is to use interrupts and the other is through **direct memory access** (DMA). In the case of an interrupt-driven mode, an interrupt-request signal is sent to the computer. Upon receiving it, the computer will first finish the execution of the current instruction, suspend the next, and then send an interrupt-acknowledge signal asking the module to send data. The operation is asynchronous since the sender sends data when it wants to do so. Getting the computer ready to receive data is known as handshaking. In the case of a DMA transfer, the DMA controller is given the starting address of the memory location where the data have to be written. The DMA controller asks the computer to freeze its operations until it has finished writing data directly into the memory. The operation does not need any waiting time and therefore it is fast.

Data acquisition systems are usually designed to couple with existing computer systems, and many computer systems provide standard bus architecture, allowing users to connect various peripherals that are compatible with its bus. Data acquisition systems are computer peripherals that follow the above description. Since ADCs produce parallel data, many data acquisition systems provide outputs compatible with parallel instrument buses such as the IEEE-488 (HP-IB or GPIB) or the VMEbus. Personal computer-based data acquisition boards must have communication interfaces compatible with the computer bus in order to share resources. The RS-232 standard communication interfaces are widely used in serial data transfer. Communication interfaces for data acquisition systems are normally designed to satisfy the electrical, mechanical, and protocol standards of the interface bus. Electrical standards include power supply requirements, methods of supply, the data transfer rate (baud rate), the width of the address, and the line terminating impedance. Mechanical requirements are the

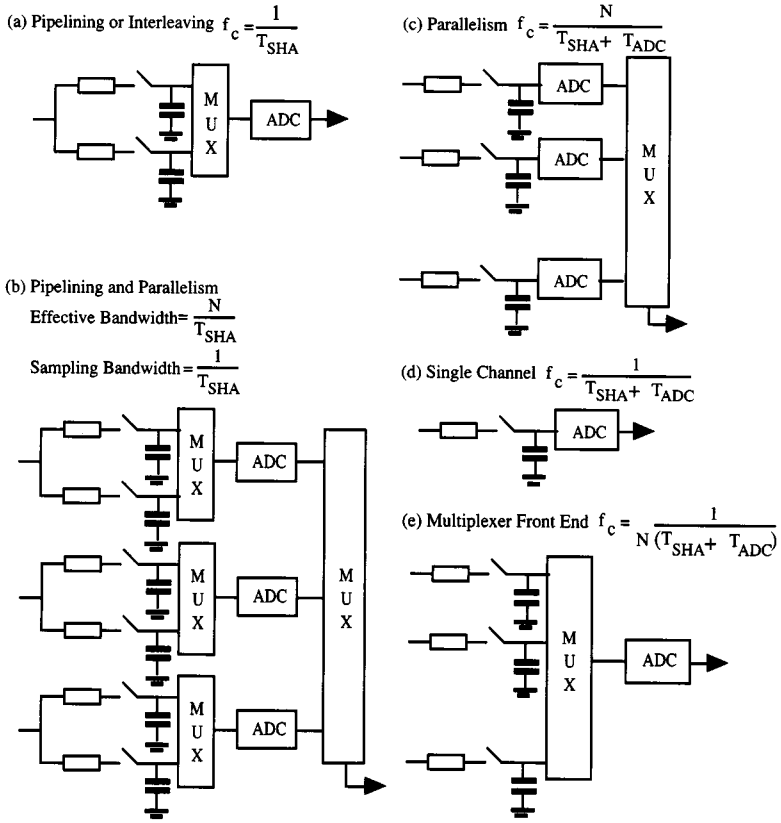

FIGURE 84.6 Coupling techniques for SHA and ADC systems.

type, size, and the pin assignments of the connectors. The data transfer protocol determines the procedure of data transfer between the two systems. A definition of the timing and input–output philosophy—whether the transfer is in synchronous, asynchronous, or quasi-synchronous mode and how errors are detected and handled—are important factors to be considered.

84.6 Data Recording

It is important to provide storage media to cater to large streams of data being produced. Data acquisition systems use graph paper, paper tapes, magnetic tapes, magnetic floppy disks, hard disks, or any combination of these as their data recorders. Paper and magnetic tape storage schemes are known as sequential access storage, whereas disk storage is called direct access storage. Tapes are cost-effective media compared to disk drives and are still in wide use. In many laboratory situations it will be much more cost effective to network a number of systems to a single, high-capacity hard drive, which acts as a file server. This adoption of digital recording provides the ultimate in signal-to-noise ratio, accuracy of signal waveform and freedom from tape transfer flutter. Data storage capacity, access time, transfer rate, and error rate are some of the performance indices that are associated with these devices.

84.7 Software Aspects

So far the discussion has been mainly on the hardware side of the data acquisition system. The other most important part is the software system associated with a data acquisition system, which can generally be divided into two—the system software and the user-interface program. Both must be designed properly in order to achieve the maximum use of the system. The system software is mainly written in assembly language with many

lines of code, whereas the user interface is built using a high-level software development tool. One main part of system software is written to handle the input–output (I/O) operations. The use of assembly language results in the fast execution of I/O commands. The I/O software has to deal with how the basic input–output programming tasks such as interrupt and DMA handling are done. The other aspects of system software are to perform the internal control tasks such as providing trigger pulses for the ADC and SHA, addressing the input multiplexer, the accessing and editing of the channel-gain list, transferring data into the on-board memory, and the addition of the clock/calendar information into data. Multitasking software programs are best suited for many data acquisition systems because it may be necessary to read data from the data acquisition module and display and print it at the same time. Menu-driven user interfaces are common and have a variety of functions built into them.

Defining Terms

Analog-to-digital converter (ADC): A device that converts analog input voltage signals into digital form.

Common-mode rejection ratio (CMRR): A measure of quality of an amplifier with differential inputs and defined as the ratio between the common-mode gain and the differential gain.

Direct memory access (DMA): The process of sending data from an external device into the computer memory with no involvement of the computer's central processing unit.

Least significant bit (LSB): The 2^0th bit in a digital word.

Multiplexer (MUX): A combinational logic device with many input channels and usually just one output. The function performed by the device is connecting one and only one input channel at a time to the output. The required input channel is selected by sending the channel address to the MUX.

Power supply unit (PSU): The one that generates the necessary voltage levels required by a system.

Sample-and-hold amplifier (SHA): A unity gain amplifier with a mode control switch where the input of the amplifier is connected to a time-varying voltage signal. A trigger pulse at the mode control switch causes it to read the input at the instance of the trigger and maintain that value until the next trigger pulse.

Signal-to-noise ratio (SNR): The ratio between the signal power and the noise power at a point in the signal traveling path.

85.1 Digital IC Testing

Micaela Serra

In this section we give an overview of digital testing techniques with appropriate reference to material containing all details of the methodology and algorithms. First, we present a general introduction of terminology and a taxonomy of testing methods. Next, we present a definition of fault models, and finally we discuss the main approaches for test pattern generation and data compaction, respectively.

Taxonomy of Testing

The evaluation of the reliability and quality of a digital IC is commonly called *testing*, yet it comprises distinct phases that are mostly kept separate both in the research community and in industrial practice.

1. *Verification* is the initial phase in which the first prototype chips are "tested" to ensure that they match their functional specification, that is, to verify the correctness of the design. Verification checks that all design rules are adhered to, from layout to electrical parameters; more generally, this type of functional testing checks that the circuit: (a) implements what it is supposed to do *and* (b) does not do what it is not supposed to do. Both conditions are necessary. This type of evaluation is done at the design stage and uses a variety of techniques, including logic verification with the use of hardware description languages, full functional simulation, and generation of functional test vectors. We do not discuss verification techniques here.
2. *Testing* correctly refers to the phase when one must ensure that only defect-free production chips are packaged and shipped and detect faults arising from manufacturing and/or wear-out. Testing methods must (a) be fast enough to be applied to large amounts of chips during production, (b) take into consideration whether the industry concerned has access to large expensive external tester machines, and (c) consider whether the implementation of **built-in self-test (BIST)** proves to be advantageous. In BIST, the circuit is designed to include its own self-testing extra circuitry and thus can signal directly, during testing, its possible failure status. Of course, this involves a certain amount of overhead in area, and trade-offs must be considered. The development of appropriate testing algorithms and their tool support can require a large amount of engineering effort, but one must note that it may need to be done only once per design. The speed of application of the algorithm (applied to many copies of the chips) can be of more importance.

3. *Parametric testing* is done to ensure that components meet design specification for delays, voltages, power, etc. Lately much attention has been given to **I_{DDq} testing,** a parametric technique for CMOS testing. I_{DDq} testing monitors the current I_{DD} that a circuit draws when it is in a quiescent state. It is used to detect faults such as bridging faults, transistor stuck-open faults, or gate oxide leaks, which increase the normally low I_{DD} [Jacomino et al., 1989].

The density of circuitry continues to increase, while the number of I/O pins remains small. This causes a serious escalation of complexity, and testing is becoming one of the major costs to industry (estimated up to 30%). ICs should be tested before and after packaging, after mounting on a board, and periodically during operation. Different methods may be necessary for each case. Thus by testing we imply the means by which some qualities or attributes are determined to be fault-free or faulty. The main purpose of testing is the detection of malfunctions (Go/NoGo test), and only subsequently one may be interested in the actual location of the malfunction; this is called *fault diagnosis* or *fault location.*

Most testing techniques are designed to be applied to combinational circuits only. While this may appear a strong restriction, in practice it is a realistic assumption based on the idea of designing a sequential circuit by partitioning the memory elements from the control functionality such that the circuit can be reconfigured as combinational at testing time. This general approach is one of the methods in *design for testability* (DFT) (see Section 85.2). DFT encompasses any design strategy aimed at enhancing the testability of a circuit. In particular, scan design is the best-known implementation for separating the latches from the combinational gates such that some of the latches can also be reconfigured and used as either tester units or as input generator units (essential for built-in testing).

Figure 85.1(a) shows the general division for algorithms in testing. *Test pattern generation* implies a fair amount of work in generating an appropriate subset of all input combinations, such that a desired percentage of faults is activated and observed at the outputs. *Output response analysis* encompasses methods which capture only the output stream, with appropriate transformations, with the assumption that the circuit is stimulated by either an exhaustive or a random set of input combinations. Both methodologies are introduced below.

Moreover a further division can be seen between *on-line* and *off-line* methods [see Fig. 85.1(b)]. In the former, each output word from the circuit is tested during normal operation. In the latter, the circuit must suspend normal operation and enter a "test mode," at which time the appropriate method of testing is applied. While **off-line testing** can be executed either through external testing (a tester machine external to the circuitry) or through the use of BIST, **on-line testing** (also called *concurrent checking*) usually implies that the circuit contains some coding scheme which has been previously embedded in the design of the circuitry.

If many defects are present during the manufacturing process, the manufacturing yield is lowered, and testing becomes of paramount importance. Some estimation can be given about the relationship between manufacturing yield, effectiveness of testing and defect level remaining after test [Williams, 1986]. Let Y denote the yield, where Y is some value between 1 (100% defect-free production) and 0 (all circuits faulty after testing).

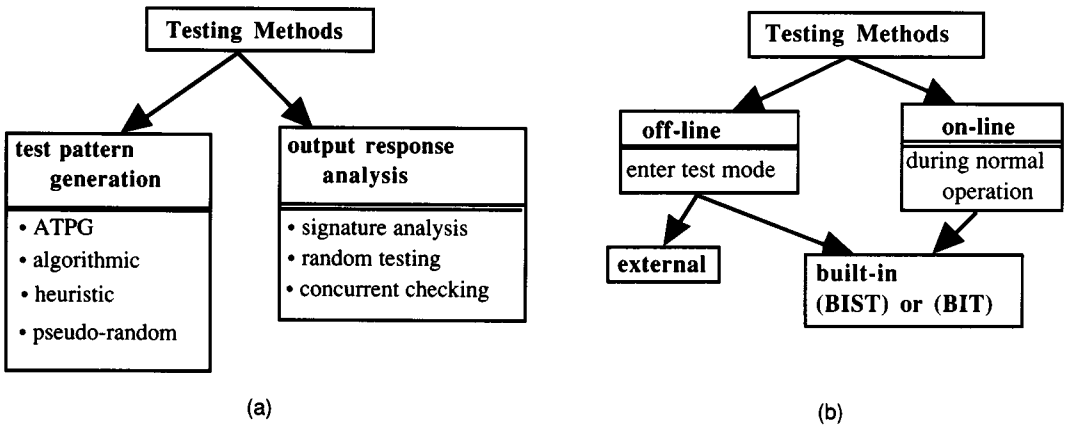

FIGURE 85.1 Taxonomy of testing methods. (a) Test pattern generation; (b) on-line and off-line methods.

Let *FC* be the **fault coverage**, calculated as the percentage of detected faults over the total number of detectable modeled faults (see below for fault models). The value of *FC* ranges from 1 (all possible faults detected) to 0 (no testing done). We are interested in the final defect level (*DL*), after test, defined as the probability of shipping a defective product. It has been shown that tests with high fault coverage (for certain fault models, see below) also have high defect coverage. The empirical equation is

$$DL = (1 - Y^{1-FC})\ 100\%$$

Plotting this equation gives interesting and practical results. Table 85.1 shows only a few examples of some practical values of *Y* and *FC*. The main conclusion to be drawn is that a very high fault coverage must be achieved to obtain any acceptable defect level value, and manufacturing yield must be continually improved to maintain reliability of shipped products.

Fault Models

At the defect level, an enormous number of different failures could be present, and it is totally infeasible to analyze them as such. Thus failures are grouped together with regards to their logical fault effect on the functionality of the circuit, and this leads to the construction of logical fault models as the basis for testing algorithms [Abramovici et al., 1992]. More precisely, a *fault* denotes the physical failure mechanism, the *fault effect* denotes the logical effect of a fault on a signal-carrying net, and an *error* is defined as the condition (or state) of a system containing a fault (deviation from correct state). Faults can be further divided into classes, as shown in Fig. 85.2. Here we discuss only *permanent* faults, that is, faults in existence long enough to be observed at test time, as opposed to *temporary* faults (transient or intermittent), which appear and disappear in short intervals of time, or *delay* faults, which affect the operating speed of the circuit. Moreover we do not discuss **sequential faults**, which cause a combinational circuit to behave like a sequential one, as they are mainly restricted to certain technologies (e.g., CMOS).

The most commonly used fault model is that of a **stuck-at fault**, which is modeled by having a line segment stuck at logic 0 or 1 (stuck-at 1 or stuck-at 0). One may consider single or multiple stuck-at faults and Fig. 85.3 shows an example for a simple circuit. The fault-free function is shown as *F*, while the faulty functions, under

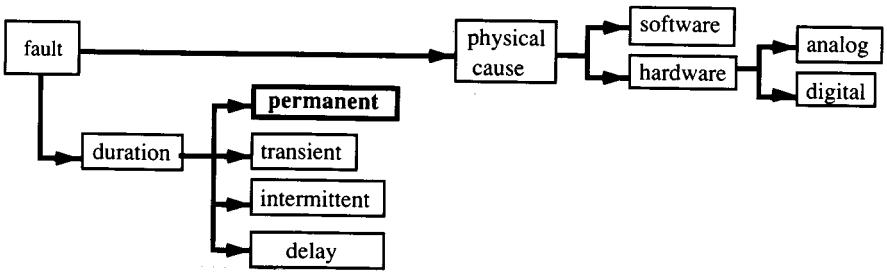

FIGURE 85.2 Fault characteristics.

FIGURE 85.4 Test set example.

the occurrence of the single stuck-at faults of either line 1 stuck-at 0 (1/0) or of line 2 stuck-at 1 (2/1), are shown as F^*.

Bridging faults occur when two or more lines are shorted together. There are two main problems in the analysis of bridging faults: (1) the theoretical number of possible such faults is extremely high and (2) the operational effect is of a wired logic AND or OR, depending on technology, and it can even have different effects in complex CMOS gates.

CMOS stuck-open faults have been examined recently, as they cannot be modeled from the more classical fault models and are restricted to the CMOS technology. They occur when the path through one of the *p*-channel or one of the *n*-channel transistors becomes an open circuit. The main difficulty in detecting this type of fault is that it changes the combinational behavior of a cell into a sequential one. Thus the logical effect is to retain, on a given line, the previous value, introducing a memory state. To detect such a fault, one must apply two stimuli: the first to set a line at a certain value and the second to try and change that value. This, of course, increases the complexity of fault detection.

Test Pattern Generation

Test pattern generation is the process of generating a (minimal) set of input patterns to stimulate the inputs of a circuit such that detectable faults can be exercised (if present) [Abramovici et al., 1992]. The process can be divided in two distinct phases: (1) derivation of a test and (2) application of a test. For (1), one must first select appropriate models for the circuit (gate or transistor level) and for faults; one must construct the test such that the output signal from a faulty circuit is different from that of a good circuit. This can be computationally very expensive, but one must remember that the process is done only once at the end of the design stage. The generation of a test set can be obtained either by manual methods, by algorithmic methods (with or without heuristics), or by pseudo-random methods. On the other hand, for (2), a test is subsequently applied many times to each IC and thus must be efficient both in space (storage requirements for the patterns) and in time. Often such a set is not minimal, as near minimality may be sufficient. The main considerations in evaluating a test set are the time to construct a minimal test set; the size of the test pattern generator, i.e., the software or hardware module used to stimulate the circuit under test; the size of the test set itself; the time to load the test patterns; and the equipment required (if external) or the BIST overhead.

Most algorithmic test pattern generators are based on the concept of sensitized paths. Given a line in a circuit, one wants to find a *sensitized* path to take a possible error all the way to an observable output. For example, to sensitize a path that goes through one input of an AND gate, one must set all other inputs of the gate to logic 1 to permit the sensitized signal to carry through. Figure 85.4 summarizes the underlying principles of trying to construct a test set. Each column shows the expected output for each input combination of a NAND gate. Columns 3 to 8 show the output under the presence of a stuck-at fault as per label. The output bits that permit detection of the corresponding fault are shown in a square, and thus at the bottom the minimal test set is listed, comprising the minimal number of distinct patterns necessary to detect all single stuck-at faults.

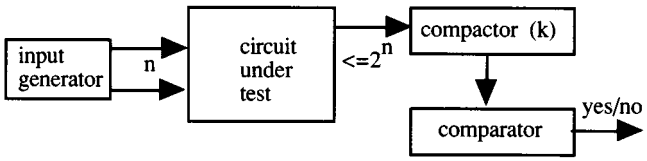

FIGURE 85.5 Data compaction testing.

The best-known algorithms are the D-algorithm (precursor to all), PODEM, and FAN [Abramovici, 1992]. Three steps can be identified in most automatic test pattern generation (ATPG) programs: (1) listing the signals on the inputs of a gate controlling the line on which a fault should be detected, (2) determining the primary input conditions necessary to obtain these signals (back propagation) and sensitizing the path to the primary outputs such that the signals and fault can be observed, and (3) repeating this procedure until all detectable faults in a given fault set have been covered. PODEM and FAN introduce powerful heuristics to speed the three steps by aiding in the sequential selection of faults to be examined and by cutting the amount of back and forward propagation necessary.

Notwithstanding heuristics, algorithmic test pattern generation is very computationally expensive and can encounter numerous difficulties, especially in certain types of networks. Newer alternatives are based on **pseudo-random pattern generation** [Bardell et al., 1987] and **fault simulation**. In this strategy, a large set of patterns is generated pseudo-randomly with the aid of an inexpensive (hardware or software) generator. Typical choices for these are linear feedback shift registers and linear cellular automata registers (see below). The pseudo-random set is used to stimulate a circuit, and, using a fault simulator, one can evaluate the number of faults that are covered by this set. An algorithmic test pattern generator is then applied to find coverage for the remaining faults (hopefully, a small number), and the pseudo-random set is thus augmented. The disadvantages are that the resulting set is very large and fault simulation is also computationally expensive. However, this method presents an alternative for circuits where the application of deterministic algorithms for all faults is infeasible.

Output Response Analysis

Especially when designing a circuit including some BIST, one must decide how to check the correctness of the circuit's responses [Bardell et al., 1987]. It is infeasible to store on-chip all expected responses, and thus a common solution is to reduce the circuit responses to relatively short sequences: this process is called *data compaction* and the short, compacted resulting sequence is called a *signature*. The normal configuration for data compaction testing is shown in Fig. 85.5. The n-input circuit is stimulated by an input pattern generator (pseudo-random or exhaustive if $n < 20$); the resulting output vector(s), of length up to $2''$, is compacted to a very short signature of length $k << 2''$ (usually k is around 16 to 32 bits). The signature is then compared to a known good value. The main advantages of this method are that (1) the testing can be done at circuit speed, (2) there is no need to generate test patterns, and (3) the testing circuitry involves a very small area, especially if the circuit has been designed using scan techniques (see Section 85.2). The issues revolve around designing very efficient input generators and compactors.

The main disadvantage of this method is the possibility of **aliasing**. When the short signature is formed, a loss of information occurs, and it can be the case that a faulty circuit produces the same signature of a fault-free circuit, thus remaining undetected. The design method for data compaction aims at minimizing the probability of aliasing. Using the compactors explained below, the probability of aliasing has been theoretically proven to be 2^{-k}, where k is the length of the compactor (and thus the length of the signature). It is important to note that (1) the result is asymptotically independent of the size and complexity of the circuit under test; (2) for $k = 16$, the probability of aliasing is only about 10^{-6} and thus quite acceptable; and (3) the empirical results show that in practice this method is even more effective. Most of all, this is the chosen methodology when BIST is required for its effectiveness, speed, and small area overhead.

A secondary issue in data compaction is in the determination of the expected "good" signature. The best way is to use fault-free simulation for both the circuit and the compactor, and then the appropriate comparator can be built as part of the testing circuitry [Bardell et al., 1987; Abramovici, 1992].

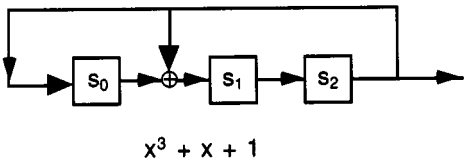

FIGURE 85.6 Autonomous LFSR.

The most important issue is in the choice of a compactor. Although no "perfect" compactor can be found, several have been shown to be very effective. Several compaction techniques have been researched: *counting techniques*, as in one's count, syndrome testing, transition count, and Walsh spectra coefficients; and *signature analysis techniques* based on linear feedback shift registers (**LFSRs**) or linear cellular automata registers (LCARs). Only these latter ones are discussed here. LFSRs and LCARs are also the preferred implementation for the input pattern generators.

LFSRs as Pseudo-Random Pattern Generators

An autonomous LFSR is a clocked synchronous shift register augmented with appropriate feedback taps and receiving no external input [Bardell et al., 1987; Abramovici, 1992]. It is an example of a general linear finite state machine, where the memory cells are simple *D* flip-flops and the next state operations are implemented by EXOR gates only. Figure 85.6 shows an example of an autonomous LFSR of length $k = 3$. An LFSR of length k can be described by a polynomial with binary coefficients of degree k, where the nonzero coefficients of the polynomial denote the positions of the respective feedback taps. In Fig. 85.6, the high-order coefficient for x^3 is 1, and thus there is a feedback tap from the rightmost cell s_2; the coefficient for x^2 is 0, and thus no feedback tap exists after cell s_1; however, taps are present from cell s_0 and to the leftmost stage since x and x^0 have nonzero coefficients. Since this is an autonomous LFSR, there is no external input to the leftmost cell.

The state of the LFSR is denoted by the binary state of its cells. In Fig. 85.6, the next state of each cell is determined by the implementation given by its polynomial and can be summarized as follows: $s_0^+ = s_2$, $s_1^+ = s_0 \oplus s_2$, $s_2^+ = s_1$, where the s_i^+ denotes the next state of cell s_i at each clock cycle. If the LFSR is initialized in a nonzero state, it cycles through a sequence of states and eventually comes back to the initial state, following the functionality of the next-state rules implemented by its polynomial description. An LFSR that goes through all possible $2^k - 1$ nonzero states is said to be described by a *primitive* polynomial (see theory of Galois fields for the definition of primitive), and such polynomials can be found from tables [Bardell et al., 1987].

By connecting the output of each cell to an input of a circuit under test, the LFSR implements an ideal input generator, as it is inexpensive in its implementation and it provides the stimuli in pseudo-random order for either exhaustive or pseudo-exhaustive testing.

LFSRs as Signature Analyzer

If the leftmost cell of an LFSR is connected to an external input, as shown in Fig. 85.7, the LFSR can be used as a compactor [Bardell et al., 1987; Abramovici, 1992]. In general, the underlying operation of the LFSR is to compute polynomial division over a finite field, and the theoretical analysis of the effectiveness of **signature analysis** is based on this functionality. The polynomial describing the LFSR implementation is seen to be the divisor polynomial. The binary input stream can be seen to represent the coefficients (high order first) of a dividend polynomial. For example, if the input stream is 1001011 (bits are input left to right in time), the dividend polynomial is $x^6 + x^3 + x + 1$. After seven clock cycles for all the input bits to have entered the LFSR, the binary output stream exiting from the right denotes the quotient polynomial, while the last state of the cells in the LFSR denotes the remainder polynomial.

In the process of computing a signature for testing the circuit, the input stream to the LFSR used as a compactor is the output stream from the circuit under test. At the end of the testing cycles, only the last state of the LFSR is examined and considered to be the compacted signature of the circuit. In most real cases, circuits have many outputs, and the LFSR is converted into a multiple-input shift register (**MISR**). A MISR is constructed by adding EXOR gates to the input of some or all the flip-flop cells; the outputs of the circuit are then fed through these gates into the compactor. The probability of aliasing for a MISR is the same as that of an LFSR;

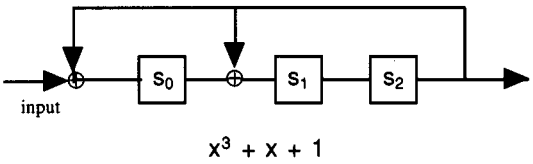

FIGURE 85.7 LFSR for signature analysis.

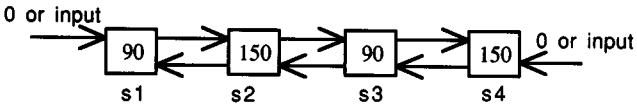

FIGURE 85.8 LCAR for signature analysis.

however, some errors are missed due to cancellation. This is the case when an error in one output at time t is canceled by the EXOR operation with the error in another output at time $t+1$. Given an equally likely probability of errors occurring, the probability of error cancellation has been shown to be 2^{1-m-N}, where m is the number of outputs compacted and N is the length of the output streams.

Given that the normal length of signatures used varies between $k = 16$ and $k = 32$, the probability of aliasing is minimal and considered acceptable in practice. In MISR, the length of the compactor also depends on the number of outputs tested. If the number of outputs is greater than the length of the MISR, algorithms or heuristics exist for combining outputs with EXOR trees before feeding them to the compactor. If the number of outputs is much smaller, various choices can be evaluated. The amount of aliasing that actually occurs in a particular circuit can be computed by full fault simulation, that is, by injecting each possible fault into a simulated circuit and computing the resulting signature. Changes in aliasing can be achieved by changing the polynomial used to define the compactor. It has been shown that primitive polynomials, essential for the generation of exhaustive input generators (see above), also possess better aliasing characteristics.

Data Compaction with Linear Cellular Automata Registers

LCARs are one-dimensional arrays composed of two types of cells: rule 150 and rule 90 cells [Cattell et al., 1996]. Each cell is composed of a flip-flop that saves the current state of the cell and an EXOR gate used to compute the next state of the cell. A rule 150 cell computes its next state as the EXOR of its present state and of the states of its two (left and right) neighbors. A rule 90 cell computes its next state as the EXOR of the states of its two neighbors only. As can be seen in Fig. 85.8, all connections in an LCAR are near-neighbor connections, thus saving routing area and delays (common for long LFSRs).

Up to two inputs can be trivially connected to an LCAR, or it can be easily converted to accept multiple inputs fed through the cell rules. There are some advantages of using LCARs instead of LFSRs: first, the localization of all connections, and second, and most importantly, it has been shown that LCARs are much "better" pseudo-random pattern generators when used in autonomous mode, as they do not show the correlation of bits due to the shifting of the LFSRs. Finally, the better pattern distribution provided by LCARs as input stimuli has been shown to provide better detection for delay faults and open faults, normally very difficult to test.

As for LFSRs, LCARs are fully described by a characteristic polynomial, and through it any linear finite state machine can be built either as an LFSR or as an LCAR. It is, however, more difficult, given a polynomial, to derive the corresponding LCAR, and tables are now used. The main disadvantage of LCARs is in the area overhead incurred by the extra EXOR gates necessary for the implementation of the cell rules. This is offset by their better performance. The corresponding multiple-output compactor is called a MICA.

Summary

Accessibility to internal dense circuitry is becoming a greater problem, and thus it is essential that a designer consider how the IC will be tested and incorporate structures in the design. Formal DFT techniques are

concerned with providing access points for testing (see *controllability* and *observability* in Section 85.2). As test pattern generation becomes even more prohibitive, probabilistic solutions based on compaction and using fault simulation are more widespread, especially if they are supported by DFT techniques and they can avoid the major expense of dedicated external testers. However, any technique chosen must be incorporated within the framework of a powerful CAD system providing semiautomatic analysis and feedback, such that the *rule of ten* can be kept under control: if one does not find a failure at a particular stage, then detection at the next stage will cost 10 times as much!

Defining Terms

Aliasing: Whenever the faulty output produces the same signature as a fault-free output.
Built-in self-test (BIST): The inclusion of on-chip circuitry to provide testing.
Fault coverage: The fraction of possible failures that the test technique can detect.
Fault simulation: An empirical method used to determine how faults affect the operation of the circuit and also how much testing is required to obtain the desired fault coverage.
***I_{DDq}* testing:** *A parametric technique to monitor the current* I_{DD} that a circuit draws when it is in a quiescent state. It is used to detect faults which increase the normally low I_{DD}.
LFSR: A shift register formed by *D* flip-flops and EXOR gates, chained together, with a synchronous clock, used either as input pattern generator or as signature analyzer.
MISR: Multiple-input LFSR.
Off-line testing: Testing process carried out while the tested circuit is not in use.
On-line testing: Concurrent testing to detect errors while circuit is in operation.
Pseudo-random pattern generator: Generates a binary sequence of patterns where the bits appear to be random in the local sense (1 and 0 are equally likely), but they are repeatable (hence only pseudo-random).
Random testing: The process of testing using a set of pseudo-randomly generated patterns.
Sequential fault: A fault that causes a combinational circuit to behave like a sequential one.
Signature analysis: A test where the responses of a device over time are compacted into a characteristic value called a signature, which is then compared to a known good one.
Stuck-at fault: A fault model represented by a signal stuck at a fixed logic value (0 or 1).
Test pattern (test vector): Input vector such that the faulty output is different from the fault-free output (the fault is stimulated and detected).

Further Information

The author would like to recommend reading the book by Abramovici et al. [1992] that, at the present time, gives the most comprehensive view of testing methods and design for testability. More information on deterministic pattern generation can also be found in *Fault Tolerant Computing,* edited by D.K. Pradhan, and for

newer approaches of random testing the book by Bardell et al. contains basic information. The latest state-of-the-art research is to be found mainly in proceedings of the IEEE International Test Conference.

85.2 Design for Test

Bulent I. Dervisoglu

Testing of electronic circuits, which has long been pursued as an activity that follows the design and manufacture of (at least) the prototype product, has currently become a topic of up-front investigation and commitment. Today, it is not uncommon to list the *design for testability* (DFT) features of a product among the so-called *functional* requirements in the definition of a new product to be developed. Just how such a major transformation has occurred can be understood by examining the testability problems faced by manufacturing organizations and considering their impact on time to market (TTM).

The Testability Problem

The primary objective of testing digital circuits at chip, board, or system level is to detect the presence of hardware failures induced by faults in the manufacturing processes or by operating stress or wearout mechanisms. Furthermore, during manufacturing, a secondary but equally important objective is to accurately determine which component or physical element (e.g., connecting wire) is faulty so that quick diagnosis/repair of the product becomes possible. These objectives are necessary due to imperfections in the manufacturing processes used in building digital electronic components/systems. All digital circuits must undergo appropriate level testing to avoid shipping faulty components/systems to the customer. Analog circuits may have minimum and maximum allowable input signal values (e.g., input voltage) as well as infinitely many values in between these that the component has to be able to respond to. Testing of analog circuits is often achieved by checking the circuit response at the specified upper and lower bounds as well as observing/quantifying the change of the output response with varying input signal values. On the other hand, the behavior of a digital system is characterized by discrete (as opposed to continuous) responses to discrete operating state/input signal permutations such that testing of digital circuits may be achieved by checking their behavior under every operating mode and input signal permutation. In principle this approach is valid. However, in practice, most digital circuits are too complex to be tested using such a brute force technique. Instead, test methods have been developed to test digital circuits using only a fraction of all possible test conditions without sacrificing test coverage. Here, *test coverage* is used to refer to the ratio of faults that can be detected to all faults which are taken into consideration, expressed as a percentage. At the present time the most popular *fault model* is the so-called *stuck-at* fault model that refers to individual nets being considered to be fault-free (i.e., *good network*) or considered to be permanently stuck at either one of the logic 1 or logic 0 values. For example, if the *device under test* (DUT) contains several components (or building blocks), where the sum of all input and output terminals (*nodes*) of the components is k, there are said to be $2k$ possible stuck-at faults, corresponding to each of the circuit nodes being permanently stuck at one of the two possible logic states. In general, a larger number of possible stuck-at faults leads to increased difficulty of testing the digital circuit.

For the purpose of *test pattern* (i.e., input stimulus) generation it is often assumed that the *circuit under test* (CUT) is either fault-free or it contains only one node which is permanently stuck at a particular logic state. Thus, the most widely used fault model is the so-called *single stuck-at fault* model. Using this model each fault is tested by applying a specific test pattern that, in a good circuit, drives the particular node to the logic state which has the opposite value from the state of the fault assumed to be present in the faulty circuit. For example, to test if node v is stuck at logic state x (denoted by v/x or v-x), a test pattern must be used that would cause node v to be driven to the opposite of logic state x if the circuit is not faulty. Thus, the test pattern attempts to show that node v is not stuck at x by driving the node to a value other than x, which for a two-valued digital circuit must be the opposite of x (denoted by $\sim x$). This leads to the requirement that to detect any stuck-at fault v/x, it is necessary to be able to control the logic value at node v so that it can be set to $\sim v$. If the signal value at node v can be observed directly by connecting it to a test equipment, the particular fault v/x can be detected readily. However, in most cases, node v may be an *internal* node, which is inaccessible for direct

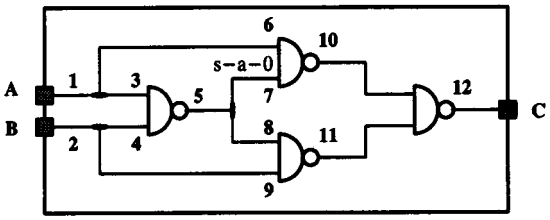

FIGURE 85.9 Example logic circuit with internal node 7 stuck at 0 (7/0).

TABLE 85.2 Test Pattern for Node 7/0 for the Circuit in Fig. 85.9

A	*B*	1	2	3	4	5	6	7	8	9	10	11	12	C
1	0	1	0	1	0	1	1	1	1	0	0	1	1	1 good circuit
1	0	1	0	1	0	1	1	**0**	1	0	**1**	1	**0**	**0** with fault 7/0

observation from outside the component package. In that case, it is necessary to create a condition where the value of the signal on an externally observable node, say node *t*, will be different for each of the two possible values that node *v* can take on, that is, node *t* shall be driven to logic state *y* or $\sim y$ depending upon whether node *v* is at logic state *x* or $\sim x$, respectively. Note that *x* and *y* may represent the same or different logic states.

The external pins of a component are the only means of applying the stimuli and observing the behavior of that component. During testing, a test pattern is used as the stimulus to detect the presence of a particular fault by causing at least one output pin of the component to take on a different value depending upon whether the targeted fault is present or not. Thus, a test pattern is used for *controlling* the circuit's nodes so that the presence of a fault on a circuit node can be *observed* on at least one of the circuit's external pins. Solving the dual problems of *controllability* and *observability* is the primary objective of all test methods. The *logic-to-pin ratio* of a digital circuit is a relative measure of the ratio of possible faults in the circuit to the number of signal pins (i.e., not including the constant power/ground pins) of that component. A large-value logic-to-pin ratio implies that logic states of a large number of circuit nodes must be controlled using a small number of external pins. As a result, conflicting requirements for controllability and observability become harder to satisfy, and the circuit is considered to be more difficult to test.

Consider Fig. 85.9, which depicts a single (hypothetical) *integrated circuit* (IC) component and shows its internal circuitry which uses four NAND gates. The nodes of the circuit are numbered 1 through 12 and the external pins of the component are labeled *A, B,* and *C*. To detect if node 7 is stuck at logic 0 (i.e., 7/0), a test pattern must be found that sets node 7 (and hence, node 5) to the logic 1 state. This can be achieved by setting either or both of the external pins *A* and *B* to the logic 0 state. Furthermore, to observe (or deduce) the value of node 7 at the only externally visible circuit pin, *C*, it is necessary to create a condition where the logic state of node 12 becomes dependent on the value of node 7. The only path from node 7 to node 12 passes through node 10, and since node 10 is the output of a NAND gate the second input to that gate (i.e., node 6) must be set to the logic 1 state by setting input pin *A* to the logic 1 state. Therefore, the only possible test pattern for 7/0 is $A = 1$ and $B = 0$. At this point, we must still continue the analysis to see if indeed node 12 will reflect the value of node 7. With input terminals *A* and *B* set to logic 1 and logic 0, respectively, node 9 will be set to logic 0, which causes node 11 to become logic 1. With these settings, the value at node 12 will be determined by the value at node 10 and the test pattern is valid. Table 85.2 shows the values of all circuit nodes when this test pattern is applied to the circuit of Fig. 85.9.

It should be evident from the simple example of a *combinational circuit* described above that test pattern generation for digital circuits can be very difficult and involved. The problem becomes much more complex when dealing with *sequential circuits,* where the *internal state variables* (i.e., bistable memory storage elements such as latches and flip-flops) must be treated as *pseudo-inputs* and *pseudo-outputs* that must be controlled and observed using the external pins of the component. In this case test patterns become *test sequences* that must be applied in precise order, and outputs must be observed only at prescribed times. Thus, the testing of sequential

circuits is much harder to achieve compared to the testing of combinational circuits. Computer programs, called automatic test pattern generation (ATPG) programs, have been developed for generating test patterns for combinational or sequential circuits. By far, the generation of test patterns for combinational circuits is better understood and automated than doing the same for sequential circuits.

Before discussing the various techniques that may be used to improve testability of digital circuits, it is necessary to mention the related problem of determining test effectiveness. A typical digital system contains a very large number of possible stuck-at faults. This and the logical complexity of the circuits make it unacceptable to "guess" how effective the test patterns (or the diagnostic program) will be in detecting all possible faults. This problem is often approached in a formal manner by using a class of test tool called a *fault simulator* program. A fault simulator uses the given set of test patterns to simulate the given circuit first when there are no faults assumed present (i.e., good circuit simulation). Next, the circuit is simulated with the same set of test patterns, but this time the effects of each possible stuck-at fault are considered one at a time. For a given test pattern, and given stuck-at-type fault, if the output of the good circuit simulation differs from the output obtained during fault simulation, then the given fault will be detected by the given test pattern. This way, it is possible to determine the percentage of all possible stuck-at faults that may be present in a digital circuit which will be covered by the given set of test patterns.

Most ATPG programs operate by picking a possible fault from among the possible faults, generating a specific test pattern that covers it, simulating the logic circuit with the newly generated test pattern to determine which other faults are incidentally covered by the same pattern, and continuing the process until all faults have been considered. Of the two related processes of *test pattern generation* and *fault simulation*, the latter is by far the more time-consuming one.

A different approach is taken in some testability analysis tools whereby rather than determining which faults are covered by a given test pattern, the analysis program assigns a numeric value to indicate the degree of difficulty of controlling and observing the digital circuit's nodes. This analysis, which can be done much more quickly compared to performing fault simulation, should be done prior to attempting to generate the test patterns for a circuit so that time will not be spent unnecessarily on digital circuits which are likely to present difficulties for the ATPG/fault-simulation process to deal with.

Design for Testability

Low-cost/high-volume manufacturing requires that product testability be considered up front since a product which is inherently hard to test will cost both time and money to achieve a desired level of quality. There are many steps that can be taken to improve the testability of digital circuits and systems. The following subsections describe some of the techniques that can be used.

Ad-Hoc Techniques [Abramovici et al., 1990; Bardell et al., 1978]

Circuit/System Reset Requirements. A simple and straightforward mechanism for resetting a digital circuit to a known state is an essential requirement for testability. It should be noted that the requirement is not only for having the reset function provided but further that it should be simple to execute. For example, applying a defined sequence of external signals to a circuit which must be synchronized with a free-running clock signal would not be considered a simple reset mechanism. Instead, keeping an external signal at some logic value for a minimum duration is a much more desirable approach. It is very desirable that the reset function be asynchronous (i.e., not require system clock pulses to execute) since during power-up a circuit may need to be reset even before free-running clock pulses can be started.

Clock Control Requirements. Another very important requirement for implementing DFT is the ability to control the clocking of the internal logic of the digital circuit. If the external clock signal is gated with some other signals such that it is necessary to determine how to set these other signals to their required values to allow the externally applied clock pulse to reach the internal flip-flop clock terminals, then the ATPG program has another level of constraints to resolve in generating the test patterns. Furthermore, some of these additional requirements may pose difficulties in satisfying them during component and/or system testing. Most ATPG programs assume that once the test pattern has been applied to the pins of the component, the system's response to that pattern can be captured by applying an external clock pulse which enables the internal flip-flops to

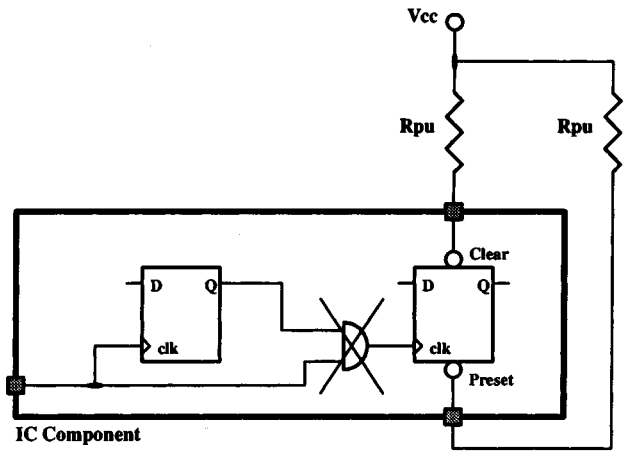

FIGURE 85.10 Using pull-up resistor to tie off unused preset/clear inputs of flip-flops.

respond to the test pattern. Thus, the ATPG programs assume that the internal flip-flop clock inputs are controlled directly from an external pin of the component. This very desirable characteristic is often expressed by stating that *externally applied clock pulses are not allowed to be gated by other signals before these reach the clock terminals of the internal flip-flops.* A side benefit of this design rule is that it prevents glitches (i.e., undesirable pulses) which might be generated at the flip-flop clock terminals due to changing the other inputs to the clock gating circuit while the clock pulse is present.

Managing "Unused" Inputs of Components. When designing digital systems from existing components there may be inputs of those components that, for the current implementation, are not needed. For example, if a two-input AND gate is needed to implement a logic circuit on a printed circuit board, it may be possible to use one of the unused three-input AND gate elements from an IC package already present on that board. In this case, the unused third input of that AND gate must be connected to the logic 1 level in order that a three-input AND function may be implemented using the other two inputs to that gate. Thus, the unused input to the AND gate may be connected directly to the V_{cc} (i.e, power supply) signal. Similarly, if a flip-flop contains unused *preset* or *clear* terminals, these may be tied off to their respective deasserted states. In many cases printed circuit boards are tested using an *in-circuit tester* which uses a *bed-of-nails* test fixture to make physical contact with selected nets on the board so that their values can be observed or controlled by the tester. For the in-circuit tester to control the value of a net it has to backdrive the output of the component which normally drives that net. Since IC components have limited output drive capabilities, the in-circuit tester can overcome the electrical drive from that component and can force that net to a value opposite the value which the driving IC is trying to achieve. By keeping such backdriving conditions to last only a very short period, damage to the opposing IC component is prevented. However, if the net is driven not by an IC but directly from the V_{cc} or ground (*Gnd*) signals, then the in-circuit tester may not be able to overcome their drive. Furthermore, back-driving the V_{cc} or *Gnd* levels would prevent the other IC components from being able to perform their normal functions. Instead, if the logic signals to such unused terminals are applied using *pull-up* or *pull-down* resistors when connecting these to the V_{cc} or *Gnd* levels, respectively, these signals may be controlled by the in-circuit tester. For example, this way it becomes possible to set/reset a flip-flop value by using the normally "unused" preset/clear terminal of that flip-flop. Note that if the flip-flop contains both a preset and a clear input which are unused, these must be pulled up (or pulled down) through separate resistors so that each can be controlled by the in-circuit tester independent of the other. This is illustrated in Fig. 85.10.

Synchronous versus Asynchronous Design Style. More than any other issue, discussions concerning synchronous versus asynchronous design style create the most disagreements concerning design for testability. Many logic designers who are experienced in using SSI and MSI IC chips have adapted a design style where synchronous (e.g., clocked) and asynchronous (e.g., self-timed) designs are freely mixed together. Using clocked flip-flops

with asynchronous preset/clear inputs is a typical example of this design style. Similarly, building latches out of, say, cross-coupled NAND gates and using these as state variables in implementing finite-state machines used to be a very common technique. However, concerns about system initialization and pattern generation have made this style undesirable for implementing DFT. Indeed, most of the so-called *structured* design styles described below make it a requirement that all internal storage elements be constructed from clocked flip-flops, and feedback loops in combinational circuits are broken with the insertion of such flip-flops, along the feedback paths. Asynchronous circuits suffer from combinational circuit hazards that are glitches created as a result of delay differences along circuit paths. Some hazards may be prevented by constraining the manner (i.e., sequence) in which circuit inputs are allowed to be changed. Whereas such constraints may be met during regular system operation, often test pattern generation algorithms cannot take such constraints into account. Therefore, asynchronous logic may create severe problems during testing.

Avoiding Redundant Logic. Technically speaking, redundancy is the only reason why a given stuck-at fault might not be detectable by any test. For example, if an INVERTER function is implemented by tying both inputs of a two-input NAND gate together, then a stuck-at 1 fault on either one of the inputs becomes undetectable since the output signal can still be determined correctly by the remaining nonfaulty input signal. This creates two problems. First, conventional ATPG programs might spend a lot of time trying to generate a test pattern for such a fault before they declare the fault untestable. Second, the presence of an undetectable fault can cause a detectable fault to become undetectable (it may also cause an undetectable fault to become detectable). For example, consider a parity checking circuit in which an existing stuck-at fault may cause the wrong parity to be generated, and the existence of a second fault may correct the parity and hence hide both failures. The remedy for these situations is to try to avoid redundancy in the first place, and when this is not possible provide additional circuit modes where the redundant circuits might be isolated. Alternately (or in addition) it may be useful to provide additional test points, as described below.

Providing Test Points. A test point is an input or output signal to control or observe intermediate signals in a logic circuit. For example, if triple redundancy has been used to implement a fault-tolerant circuit, additional output signals might be provided so that signal values from the identical functional units become individually observable, improving the testability of the overall circuit. Similarly, control signals might be provided so that, during testing, outputs from some functional units may be forced into certain states which allow easier observation of the outputs from other circuits. Recommended sites for inserting test points include redundant nets, nets with large fan-outs, preset and clear inputs of flip-flops, nets that carry system clock signals, (at least some of the) inputs to logic circuit gates with large number of inputs (i.e., large fan-in), data and/or address lines of bus lines, as well as intermediate points in cascaded circuits (such as long ripple counters, shift registers).

Logic Partitioning. Traditionally logic partitioning has been used as a strategy when the circuit is too large/complex for the test generation tools to handle. Thus, its objective is to reduce the number of circuit nodes that must be considered jointly in order to generate test patterns. The partitioning process identifies the *logic cones*, which are sections of logic receiving inputs from multiple input sources and generating a single output. Thus, a digital circuit would be broken into as many individual logic cones as there are individually observable output signals. Obviously, the logic cones may (and often do) overlap with each other since they share common input signals or intermediate signals generated from inside one partition and used in another partition. This is illustrated in Fig. 85.11(a), where two overlapping cones of logic are shown. Here, logic cones O_1 and O_2 contain primary inputs I_1, I_2, I_3, I_4 and I_3, I_4, I_5, I_6, respectively. When either partition is dependent on more inputs than what the ATPG tools or the tester can accommodate, it is possible to insert an additional gate, controlled by a tester input in order to test each partition independently of the other. This is illustrated in Fig. 85.11(b), where an additional input pin I_t has been added such that with I_t set to logic 0 by the tester, it is possible to test either partition without requiring to control shared inputs I_3 or I_4. Logic partitioning has become more important as a result of increased use of *pseudo-exhaustive testing* (to be described later).

Testing Embedded Memory Blocks. A major testability problem arises when a regular-structure memory block such as random-access memory (RAM) or read-only memory (ROM) is embedded into a logic circuit. This creates three problems:

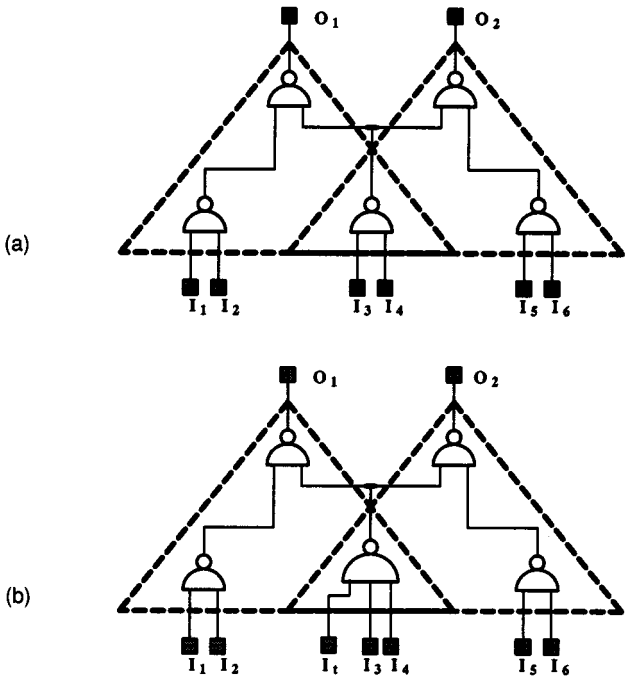

FIGURE 85.11 (a) Logic partitioning with overlapping logic cones. (b) Adding an additional test point to reduce dependence on primary inputs.

1. Testing logic that is downstream from the RAM block (i.e., output of RAM block drives the downstream logic) is difficult since this requires setting the test pattern at the RAM outputs. This problem is usually solved by providing a bypass mode where data inputs to the RAM (or ROM) block are channeled directly to the RAM (or ROM) outputs without (or in addition to) being stored inside the RAM block. This way the RAM data outputs can be controlled by controlling the data inputs as desired.
2. Testing logic that is upstream from the RAM block (i.e., outputs from logic circuit are captured by the RAM block) is difficult since the observation point is the RAM block. That is, it is necessary to access the RAM block in order to observe the test results. This problem might be solved by improving the observability of the RAM inputs and/or making the RAM outputs more easily observable as well as providing the *bypass* capability. This way, inputs to the RAM might be bypassed directly to the RAM outputs where they may be observed. This may require adding an *observe-only* register to capture the RAM outputs.
3. Testing of the RAM block itself is difficult since controlling its inputs and observing its outputs require manipulating the upstream and downstream logic circuit blocks, which may be difficult to achieve. Solution to this problem involves providing adequate control of the RAM block inputs (data, address, and read/write control) as well as providing observability of the RAM outputs. In effect, the embedded RAM block can be made testable as if it was a stand-alone block where established memory test algorithms can be applied [Breuer and Friedman, 1976].

Figure 85.12 illustrates how to improve testability of an embedded RAM structure.

Structured Techniques

An alternate approach to improving the testability of digital circuits is to carry out the circuit design by following certain rules that, by construction, assure high testability of the resulting circuits. Since the main problem in achieving testability of a digital circuit is achieving adequate controllability/observability of its internal nodes, structured DFT approaches [Bardell and McAnney, 1978] follow strict design rules that are aimed at achieving this goal. Furthermore, most structured DFT approaches require/recommend additional design rules aimed at preventing incorrect circuit operation as a result of signal races and hazards.

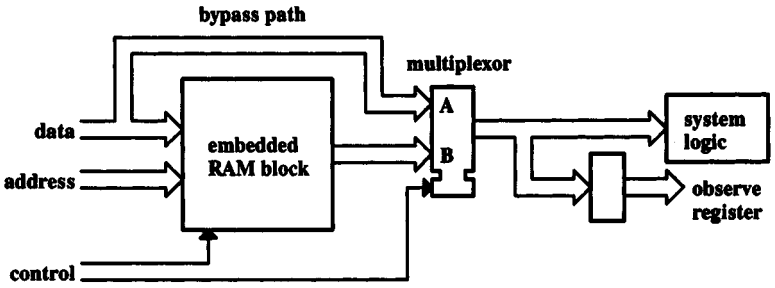

FIGURE 85.12 Providing testability in a design containing an embedded memory block.

Level-Sensitive Scan Design (LSSD). Level-sensitive **scan design** [Eichelberger and Williams, 1978] imposes strict rules on clock signal usage and allows implementing sequential behavior to be implemented only using the shift-register latch (SRL). In the first place, by not allowing any feedback involving combinational circuit elements alone, the LSSD approach prevents timing failures that might be present in purely asynchronous designs. Furthermore, rigid clocking rules are stated in order to prevent SRL data inputs from changing while the clock pulse(s) is (are) transitioning. Hence, the digital circuit is separated into two sections: (1) a robust (i.e., level-sensitive) multi-input/multi-output combinational circuit and (2) a set of SRL elements with which sequential behavior is implemented. In addition to their normal system interconnections each SRL is also connected to its two neighboring SRLs to form a shift-register structure. The serial shift input and shift output signals are labeled *scan-in* and *scan-out,* respectively, and treated as primary input/output terminals. Figure 85.13

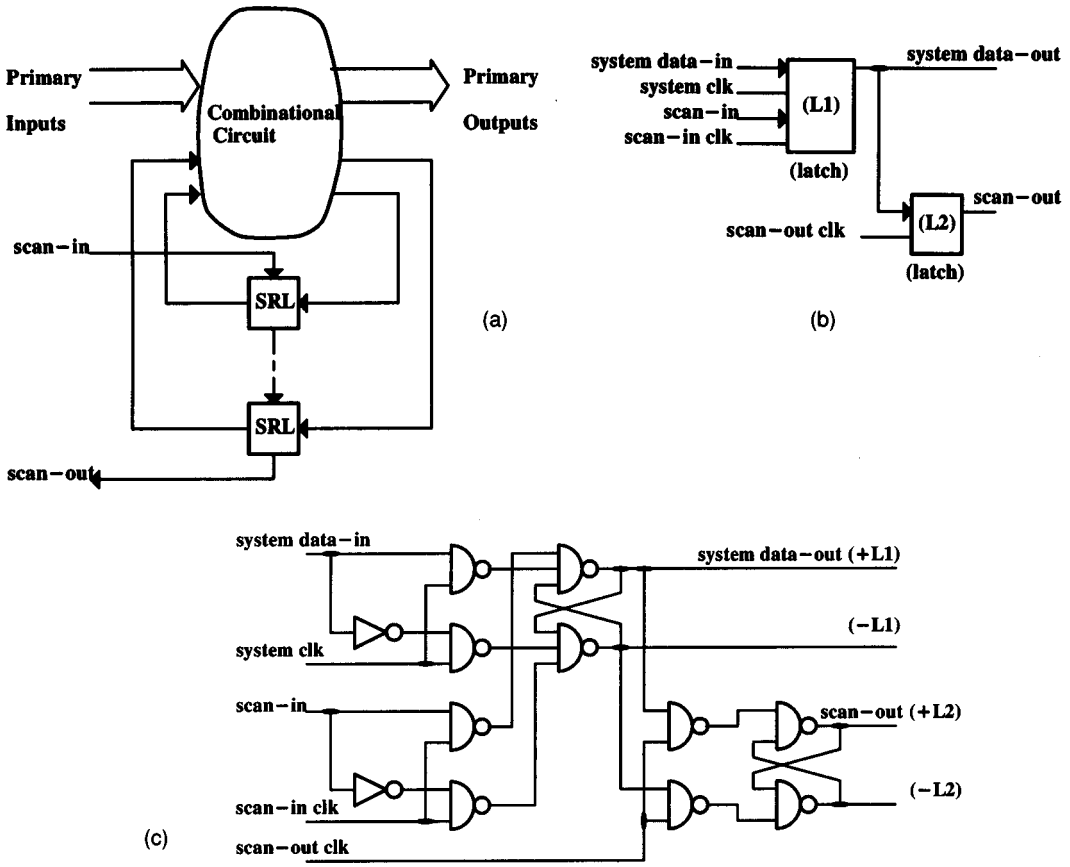

FIGURE 85.13 (a) LSSD circuit model. (b) SRL block diagram. (c) SRL logic diagram.

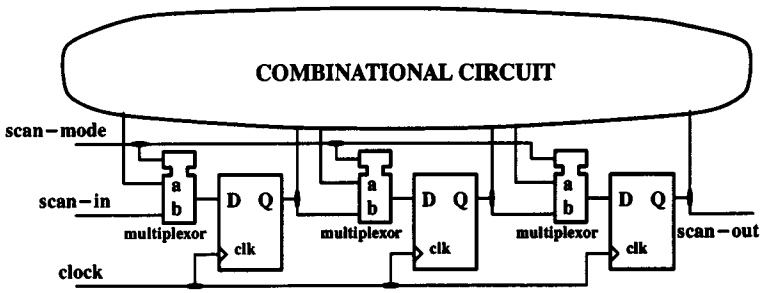

FIGURE 85.14 Model of a digital circuit with scan path.

shows an LSSD circuit model and the general form of an SRL. The significance of the shift-register (often referred to as the *scan-register*) structure is that, during testing, it allows each SRL's value to be individually controllable and observable by shifting (i.e., scanning) a serial vector into/out of the scan register. Hence, the SRLs can be treated as *pseudo-input/output terminals,* and the testing of the digital circuit is reduced to that of a combinational circuit only. Figure 85.13(a) shows an LSSD circuit model, and the general form of an SRL is given in Fig. 85.13(b). A possible gate-level circuit implementation of an SRL is shown in Fig. 85.13(c).

Among the most important LSSD design rules are the following:

1. All internal storage is implemented using SRLs. Each SRL operates such that the L1 latch accepts one or the other of the system data-in or the scan-in data values depending upon whether the system clk or the scan-in clk clock pulse is applied, respectively. The L2 latch accepts the L1 latch value when the scan-out clk clock pulse is applied. The L1 and L2 latches are stable (i.e., cannot change) when the clocks are off.
2. The SRL clocks system clk, scan-in clk, and scan-out clk must be controlled from primary circuit terminals and must be operated in nonoverlapping fashion. This eliminates dependency on minimum circuit delay and assures hazard-free (i.e, level-sensitive) operation.
3. System data-out from SRL_1 may feed the system data-in terminal of SRL_2 only if the system clk which feeds SRL_1 does not overlap with the system clk which feeds SRL_2. This rule prevents the data input to a latch from changing while its clock signal is transitioning.
4. All SRLs are interconnected into one or multiple shift registers by connecting the scan-out terminal from one SRL to the scan-in terminal of the next one in series. If multiple shift registers are implemented, each must be capable of being shifted simultaneously with the others and must have its own scan-in and scan-out primary terminals.

Scan Path. The *scan-path* [Funatsu et al., 1975] approach can be seen as a generalization of the LSSD approach since it follows the same principles but uses standard *D*-type flip-flops as the storage elements instead of the SRLs. The scannable flip-flops can be implemented using dual-ported latches (similar to the L1 latch in the SRL) or using a multiplexor to select between the scan-in and system data-in signals to feed the *D* input of a standard *D*-type flip-flop, as shown in Fig. 85.14.

Scan/Set Logic. Scan/set [Stewart, 1977] is another form of implementing scan technology whereby the sequential circuit structure is separated from its accompanying scan/set register. This is illustrated in Fig. 85.15. A variation on this scheme is the so-called shadow-register concept that has been implemented in some off-the-shelf IC components [AMDI, 1987].

Random-Access Scan. Random-access scan [Ando, 1980] uses a technique akin to addressing locations in a memory (e.g., RAM) block in order to make the states of all storage elements controllable and observable from primary input/output terminals. Using this approach, each storage element is made individually addressable (i.e., accessible) so that in order to control and/or observe the value of an individual storage element it is not necessary to shift in/shift out all other storage elements as well. Figure 85.16(a) shows the general model of a digital circuit employing the random-access scan approach. A possible gate-level circuit implementation of an addressable latch is given in Fig. 85.16(b).

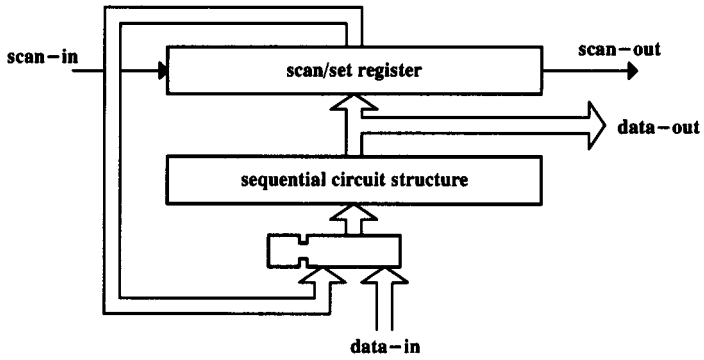

FIGURE 85.15 Generic scan/set circuit design.

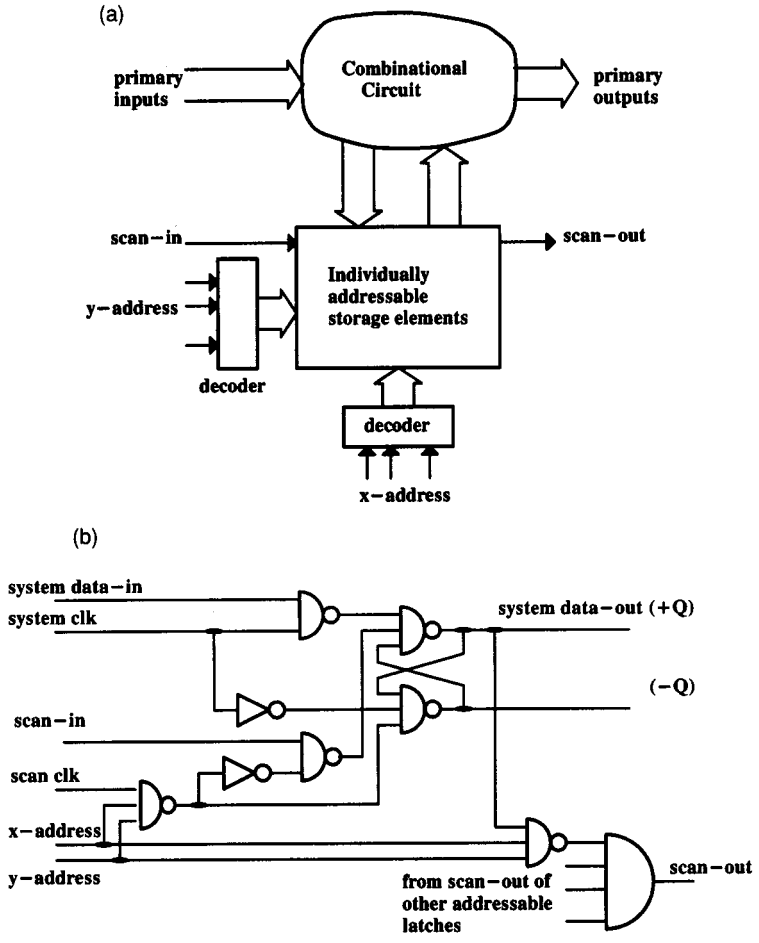

FIGURE 85.16 (a) General model for digital circuit implementing random-access scan. (b) Logic diagram for addressable latch.

Using this approach, each storage element in the circuit is given a unique *x*/*y* address and the decoded address signals are connected to the *x*/*y* address inputs of the latches. As seen in the circuit of Fig. 85.16(b), each latch can then be individually written into using the *scan-in* terminal or its output can be observed using the *scan-out* terminal, provided that the pair of *x*/*y* address lines connected to the current latch are both asserted (i.e.,

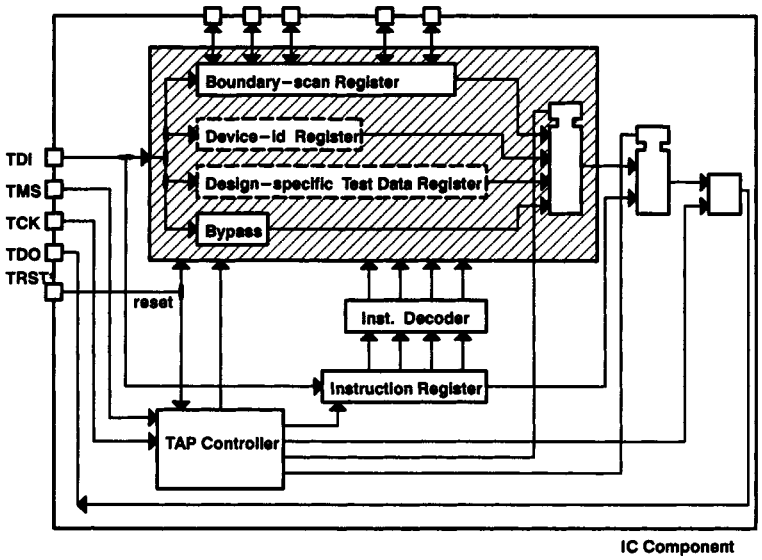

FIGURE 85.17 Architecture of IEEE 1149.1 boundary-scan standard.

set to logic 1). Furthermore, whereas it is also necessary to apply the *scan-in clk* in order to write into the latch, no clock is necessary to observe the latch output. This is a convenient feature that allows the latch values to be selectively observable even while the regular system operations are being executed. The *scan-out* values from the individual latches are combined together into a single AND gate and brought out to a primary output terminal of the circuit. This arrangement works since for any given address only one of the addressable latches will be selected and the scan-out from all other latches will be forced to the logic 1 state. On the other hand, a disadvantage of this approach is that before addressing each latch its proper address must first be applied to the circuit.

Boundary Scan. Unlike the other scan-based techniques described above, **boundary scan** [IEEE, 1990] is intended primarily for testing the board-level interconnections among the IC components on a printed circuit board (PCB). In effect, boundary scan is a special form of scan path that is implemented around every I/O pin of an IC component in order to provide controllability and observability of the I/O pin values during testing. Test control signals provided by an on-chip controller are used to disable the boundary-scan cells during regular system operation so that signal values can flow in/out of the IC component without interference from the test circuits. During testing, *output* pin values can be controlled using values preloaded into the boundary-scan register. Similarly, signal values received on the *input* pins can be captured into the boundary-scan register and subsequently shifted out to be observed on an external tester.

Boundary scan has become an important tool in achieving design for testability following the adoption of the IEEE 1149.1 Test Access Port and Boundary-Scan Architecture in 1990. The IEEE 1149.1 Standard defines a mandatory four-pin (plus an optional fifth pin) test access port (TAP) for providing the interface between the IC component and a digital tester. TAP signals comprise test data input (TDI), test data output (TDO), test clock (TCK), and test mode select (TMS) plus an optional asynchronous tap reset (TRST*) signal. The overall IEEE 1149.1 test architecture (see Fig. 85.17) includes:

- The TAP
- The TAP controller
- The instruction register (IR)
- A group of mandatory and optional test data registers (TDRs)

The TAP controller is characterized by a 16-state finite-state machine (FSM) whose behavior is defined by the IEEE 1149.1 Standard. State transitions of the TAP FSM are controlled by the TMS input line and the dedicated test clock, TCK. Figure 85.18 shows the state-transition diagram for the TAP FSM.

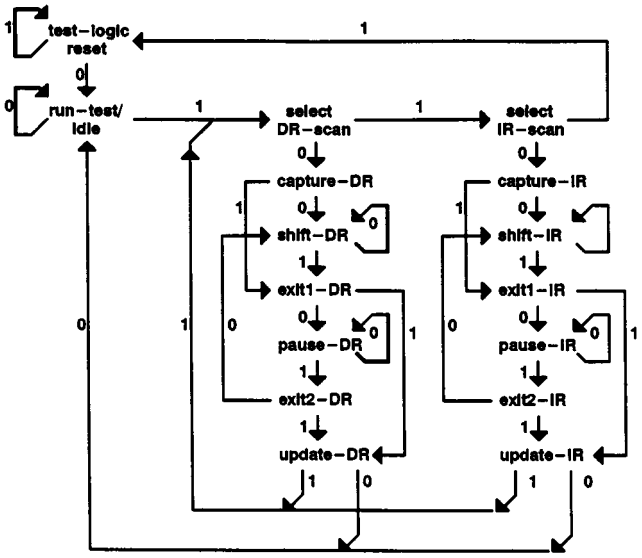

FIGURE 85.18 State-transition diagram for the TAP FSM.

A most important test data register defined by the IEEE 1149.1 Standard is the boundary-scan register that has individual cells associated with each I/O pin of the IC component. Mandatory and permissible features of the boundary-scan register cells are defined by the standard. In addition, a special single-bit register called the BYPASS register has been provided to furnish a more efficient way to shift data through IC components when multiple ICs are chained together by connecting the TDO output from one component to the TDI input of another.

Another mandatory feature of the IEEE 1149.1 Standard is the instruction register and an associated list of mandatory/permissible instructions that govern the behavior of the IC component during testing. The three mandatory instructions are called SAMPLE/PRELOAD, BYPASS, and EXTEST. SAMPLE allows taking a snapshot of the normal operation of the IC, whereas PRELOAD is used for shifting the captured values out while new values are loaded into the boundary-scan register. BYPASS allows shortening the (electrical) distance between the TDI and TDO pins by providing a single-bit register as a shortcut during scan operations involving multiple IC components that are connected in series. EXTEST is the "workhorse" instruction that allows driving the signal values on the component's output pads from the boundary register while capturing the input values into their respective cells in the boundary register. This is followed by shifting the captured values out (using the TDO output) while simultaneously shifting in the new driving values (using the TDI input).

An alternative to using boundary scan is to use a "traditional" in-circuit tester that uses a special "bed-of-nails" fixture. In this approach [Parker, 1987], every net on a PCB would be probed using a tester pin which comes in physical contact with that net such that the current signal value of the net can be observed by the tester. The tester can also be used to control the signal values of the individual nets by injecting appropriate currents through the tester pins. However, since each net is already connected to an output pin of a component on the PCB, this approach amounts to *backdriving* the output drivers of IC components and therefore poses a potential risk of damage to the IC components. This approach is becoming more difficult and/or costly to implement as the number of nets goes up and IC pin spacing is reduced. Furthermore, due to fixturing difficulties, double-sided PCBs cannot be tested in this manner. The IEEE 1149.1 boundary-scan standard [IEEE, 1990] helps solve these problems by providing convenient direct access to the I/O pins of an IC component without requiring the traditional bed-of-nails fixture.

The "CrossCheck" Technique. The CrossCheck approach [Gheewala, 1989] uses cells with built-in test points to observe critical signal values. The test points are connected to an underlining grid structure using very small FETs called *cross-point switches.* An on-chip test control circuit generates the necessary signals to address the individual probe lines and capture the results in a *multi-input signature register* (MISR). Test patterns can be

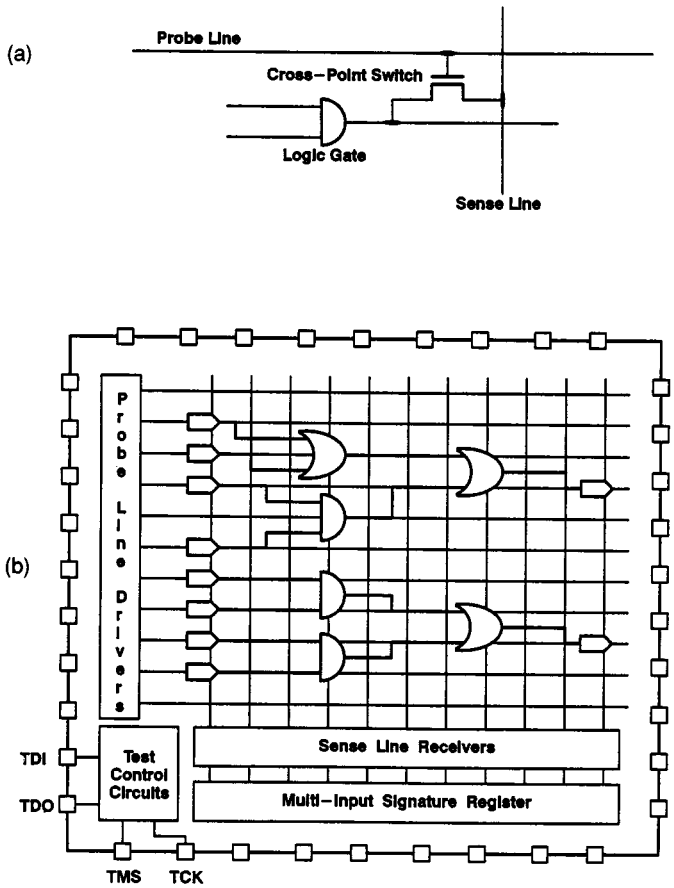

FIGURE 85.19 (a) Cross-point switch implementation. (b) Overview of the CrossCheck technique.

generated externally or by using an on-chip pattern generator, and the final test signature (i.e., contents of MISR) can be accessed using dedicated test pins, such as by providing an IEEE 1149.1 TAP (see previous subsection). Figure 85.19 shows how the CrossCheck technique is implemented on an ASIC.

CrossCheck methodology provides a high degree of observability of the ASIC. Since it is not possible to provide observability of all signals of a design, careful analysis must be performed to determine the most effective points for inserting the cross-point switches. Similarly, the size of the grid structure for the probe lines might be chosen to be design-dependent. However, in many instances it may be better to implement the probe lines as part of the IC master slice in order to reduce the amount of customization to a minimum.

The benefit offered by the CrossCheck technique is due to the potential for the reduced number of test patterns necessary to test an ASIC. This is due to the fact that as observability of internal nodes is increased it becomes easier to generate efficient test patterns which can detect many faults simultaneously. Furthermore, increased observability of internal nodes also improves diagnosability and may help determine the root cause of a failure sooner. On the negative side, the CrossCheck technique does not help improve controllability of internal nodes as achieved using scan-path techniques. Also, a primary disadvantage of the CrossCheck methodology is area penalty due to routing channels that must be set aside for the grid structure. Furthermore, added capacitance of the cross-point switches may affect performance, especially in high-speed applications. In addition, since the technique offers very good observability but no controllability of the internal nodes, it lacks the advantage offered by scan-based approaches for system debug and internal **path-delay testing** [Dervisoglu and Stong, 1991]. However, recent advances have been made that improve the controllability of internal nodes using the CrossCheck technique in gate-array ICs.

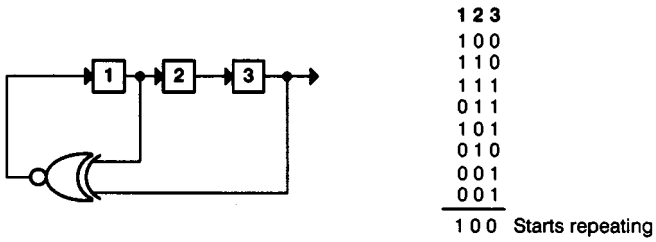

FIGURE 85.20 Three-bit maximal-length LFSR.

Built-in Self-Test (BIST) Techniques. The term **built-in self-test** (or BIST) is a generic name given to any test technique in which an external test resource (e.g., component tester) is not needed to apply test patterns and check a circuit's response to those patterns. This implies that the test patterns must be preloaded into the target device or be generated by the target device itself, in real time. For example, dedicating a section of an IC component for implementing a ROM-based sequencer to apply prestored patterns to test another section of that IC would be classified as a BIST technique. It is often more cost effective to generate the test patterns in real time (i.e., during testing), but in general it is not possible to develop real-time test pattern generation techniques that generate arbitrarily selected test patterns without additionally generating unnecessary ones. Note that whereas storing the test patterns in a ROM might be acceptable in some cases, the size of ROM necessary to store the test patterns prevents this technique being used for implementing BIST in large/complex digital circuits.

One approach to test vector generation is to ignore the specifics of the target circuit and enumerate all possible permutations of inputs. Thus, using *exhaustive* testing, an *n*-input combinational logic cone would be tested by checking its response to all 2**n permutations of input values. In this case, a binary counter can be used as the test pattern generator (TPG). Other, more efficient counter forms (such as a *maximal-length linear feedback shift register,* LFSR) may also be used as the TPG. An LFSR is a special kind of circular-shift register where the serial data input is determined by an EXCLUSIVE-OR function of some of the bit positions. Bit positions which are included in the feedback EXCLUSIVE-OR function are referred to as the tap positions. For any given *degree* (i.e., number of bits) n of LFSR there is at least one set of tap positions that result in the LFSR going through all nonzero n-bit permutations when it is started in any nonzero state. An LFSR that can go through all 2**n states is called a maximal-length LFSR. Figure 85.20 shows a 3-bit maximal-length LFSR and the state sequence that it produces. Exhaustive testing guarantees that all *detectable* faults which do not transform a combinational circuit into a sequential circuit will be detected. Depending upon the clock frequency, this approach becomes impractical to apply when the number of input variables goes up (usually above 22) [McCluskey, 1984].

In cases where the number of test patterns necessary to achieve exhaustive testing is too large to be applicable, a related technique, called **pseudo-random testing**, may be used. Pseudo-random testing achieves many of the benefits of exhaustive testing but requires much fewer test patterns. This is achieved by generating the test patterns in random fashion from among the 2**n possible patterns. However, the random generation of test patterns is done using a deterministic algorithm that produces test patterns in repeatable sequence. Before pseudo-random testing is chosen, it is necessary to examine the pseudo-random test resistance of the circuit. For example, if 500,000 pseudo-random test patterns are applied to a 20-input AND gate, there is only a 0.00004% probability that an essential test pattern (which sets all 20 inputs to logic 1) will be included among them.

Yet another related technique is to use *pseudo-exhaustive* testing that aims at breaking a circuit into separate partitions and testing each partition exhaustively [Barzilai et al., 1985; Dervisoglu, 1985; Bardell and McAnney, 1984]. Pseudo-exhaustive testing uses the same techniques used in exhaustive testing for testing the individual partitions without generating test patterns that cover the entire circuit. Mathematical considerations for pseudo-random/pseudo-exhaustive testing are too complex to describe here. The following example is presented for illustration purposes only. Figure 85.21 depicts the combinational portion of a digital circuit consisting of a number of overlapping logic cones that each produce a single output signal. All inputs are assumed to be

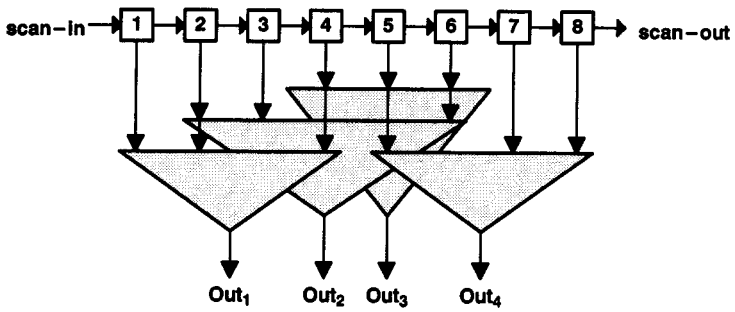

FIGURE 85.21 Overlapping logic cones connected to a common scan path.

connected to scannable flip-flops (i.e., pseudo-inputs) or to primary input pins of the component such that all inputs are 100% controllable either by controlling the values in the flip-flops or the primary input pins. All flip-flops are assumed to be scannable and are arranged into a single *scan path* such that the logic cones have n or fewer inputs all of which lie within k consecutive bits along the scan path. Outputs from the individual logic cones connect (not shown here) to the inputs of flip-flops and/or primary output pins. Thus, all logic cone outputs are also 100% observable. Now, assume that the serial output from the LFSR shown in Fig. 85.20 is connected as the "scan-in" input to the scan-path register shown in Fig. 85.21. In this case any *consecutive* 3-bit partition of the scan-path register will go through the same state sequence as the LFSR itself, delayed from it by the number of flip-flops between that partition and the output bit of the LFSR. For example, the third logic cone that has inputs from flip-flops 4, 5, and 6 will see all input permutations except the all-zeros case which can be applied separately as a special case. On the other hand, the first logic cone, with inputs from flip-flops 1, 2, and 4, will not receive all possible nonzero permutations of three input variables. This is because the first logic cone receives its three inputs from three *nonconsecutive* positions of the scan-path register. In this case only input permutations that have even parity across positions 1, 2, and 4 will be received by the first logic cone. Furthermore, the fourth logic cone that also receives inputs from three nonconsecutive bit positions which are 4 bits apart will receive all 3-bit nonzero input permutations. Analysis of which set of input permutations may be generated across nonconsecutive n bits of a scan-path register which receives the outputs from an mth degree ($m \geq n$) LFSR is based on *linear dependence* and is outside the scope of this section. However, the problem may also be approached statistically by choosing the degree of the LFSR to be higher than n but smaller than k which is the largest span of inputs to any logic cone. For example, in Fig. 85.21 the degree of the LFSR may be chosen as 4. In this case, the probability that a logic cone which has 4 or fewer inputs separated by k bits (here, $k = 5$) may be calculated [Lempel and Cohn, 1985]. It should be noted that a logic cone may be tested in full even when it has not received all 2**n input permutations.

BIST also requires ability to capture the test results without the need for an external tester. This is often achieved by using a *multi-input signature register* (MISR) to capture individual test results and compress these into an overall value called the test *signature*. Figure 85.22 shows a sample signature register that can compress test results captured from four separate outputs into a single 4-bit signature. Provided that the test circuit has deterministic behavior, a signature register can be started in a given starting state, and its final value may be compared to a known good signature to determine pass/fail status. However, compressing test results into a single overall signature may prevent proper fault detection if multiple erroneous outputs (which may result

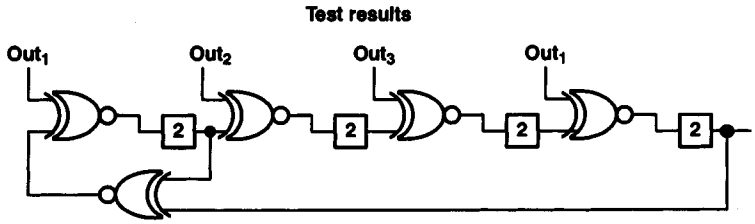

FIGURE 85.22 A four-bit parallel-input signature register.

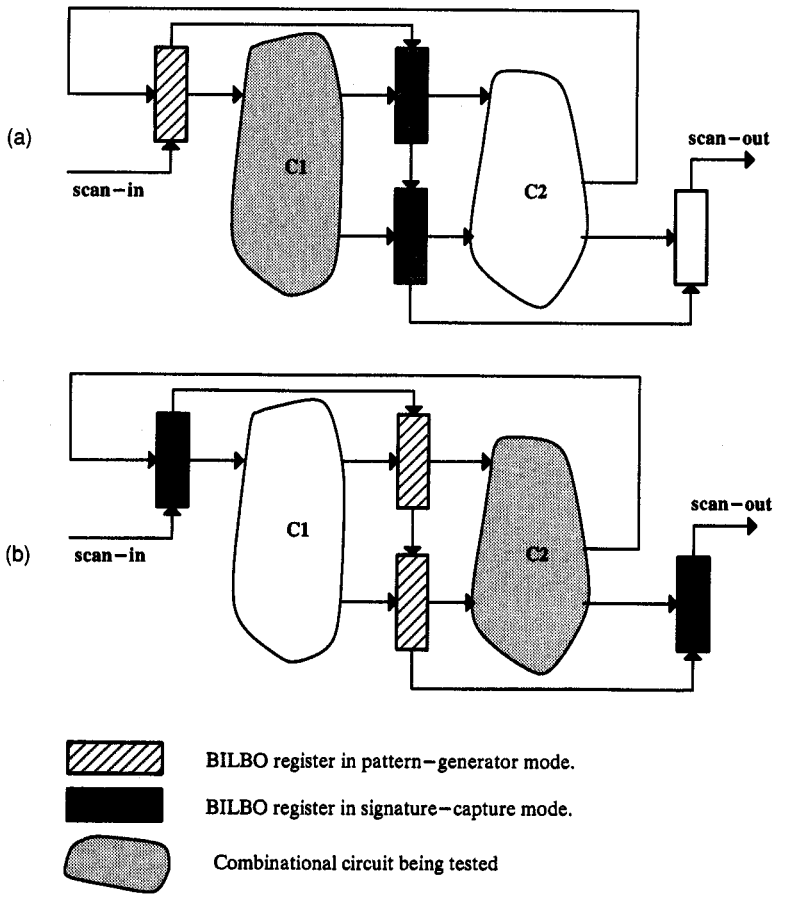

FIGURE 85.23 Using BILBO technique to partition and test a large circuit. (a) Testing combinatorial circuit C_1. (b) Testing combinatorial circuit C_2.

from the same fault being detected on multiple test vectors) causes the final test signature to be correct even though interim signatures were wrong. The probability that a faulty circuit signature will be the same as the good circuit signature is known as aliasing probability. It can be shown that if the test length is sufficiently long, aliasing probability diminishes toward 2^{-t}, where t is the number of bits of the signature register [Dervisoglu, 1985].

The two constructs of LFSR and the MISR can be merged into a single multipurpose register in a *built-in logic block observation* (BILBO) approach [Konemann et al., 1979] where each register can have multiple modes of operation including the LFSR mode, MISR mode, SCAN mode, and NORMAL mode. In this case an on-chip test-control circuit may be used to control the modes of operation of the BILBO registers so that, in turn, each register is used as a test pattern generator or signature register to test a digital component. Figure 85.23 illustrates how to use the BILBO scheme in a stepwise fashion to test a large digital circuit.

Path-Delay Testing

Path-delay testing is aimed at testing whether a given component/system operates at a specified performance level that is often measured as the maximum system clock frequency. For example, the lower bound for the maximum clock frequency which a microprocessor IC is specified that it can reach needs to be verified. However, due to the very large number of different operations that a microprocessor can perform it is not practical to verify correct behavior of such a component operating at maximum clock frequency for every possible single operation or sequence of operations that it is designed to perform. On the other hand, it may be possible to examine the structure of the design to discover its *logic paths* and verify that signals can be propagated along

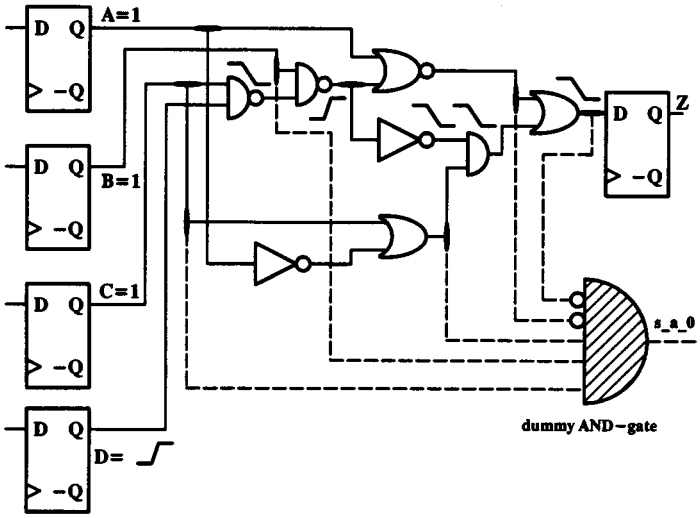

FIGURE 85.24 Circuit example to illustrate path-delay test pattern generation (all flip-flops are clocked using a common clock signal that has not been shown).

these paths within a specified propagational delay time between the initiation of a signal transition at the beginning of the path and the arrival of the final values at the end of that path. This is called *path-delay* testing. A modern IC component with typical complexity would contain many hundreds of thousands of logic paths, so that it becomes impractical to test all of them for at-speed operation. All *synchronous* digital circuits are designed so that there is a fixed clock period resulting from the use-constant frequency clock signals to time their operation. Obviously, the clock period constitutes an upper bound for the propagational delay through any logic path, since otherwise clock pulses may arrive at the flip-flops while their data input signals may still be transitioning. On the other hand, propagational delay through some logic paths may be very close to this upper bound (i.e., clock period) value whereas others may have more slack in them. It is therefore important to identify the *critical* paths and perform path-delay testing on these. Hence path-delay testing can be broken into the two phases of critical-path selection and path-delay test pattern generation.

Several different approaches can be used in identifying the critical paths, including:

1. Select sufficiently large number of paths selected at random from a list of all logic paths.
2. Calculate worst-case timing for all logic paths and select a certain percentage of the slowest paths.
3. First identify certain key nodes and then select paths that pass through those nodes using either of the two approaches listed in (1) and (2) above.

The more challenging problem is to generate the test patterns to verify that none of the signal propagations along a given logic path require longer than the clock-period time to complete. A path-delay test pattern is a pair of patterns that generates the desired signal transition(s) and provides the sensitization of the signal paths whereby the generated transition(s) is (are) sensitized through the combinational circuit to the input of a flip-flop where it will be captured when the system clock is applied. For example, Fig. 85.24 shows a combinational circuit and identifies a specific signal path for which the path delay is to be measured. To determine the appropriate path-delay test patterns, a dummy AND gate is first added to the circuit as shown. An input to the AND gate is derived from the output of the combinational circuit through which the input signal transition is to be propagated. This signal is used in its true or complemented form depending upon whether the final value of the signal transition is a logic 1 or logic 0, respectively. Other inputs to the dummy AND gate come from all remaining inputs of gates through which the desired signal transitions must flow. If the desired signal transition is flowing through an AND or NAND gate, the remaining inputs of these gates are also fed to the inputs of the dummy AND gate, whereas if the desired signal transitions flow through OR or NOR gates, their remaining inputs are inverted and then connected to the inputs of the dummy AND gate. The dummy AND gate is not actually implemented as part of the combinational logic but rather acts as a convenient place to

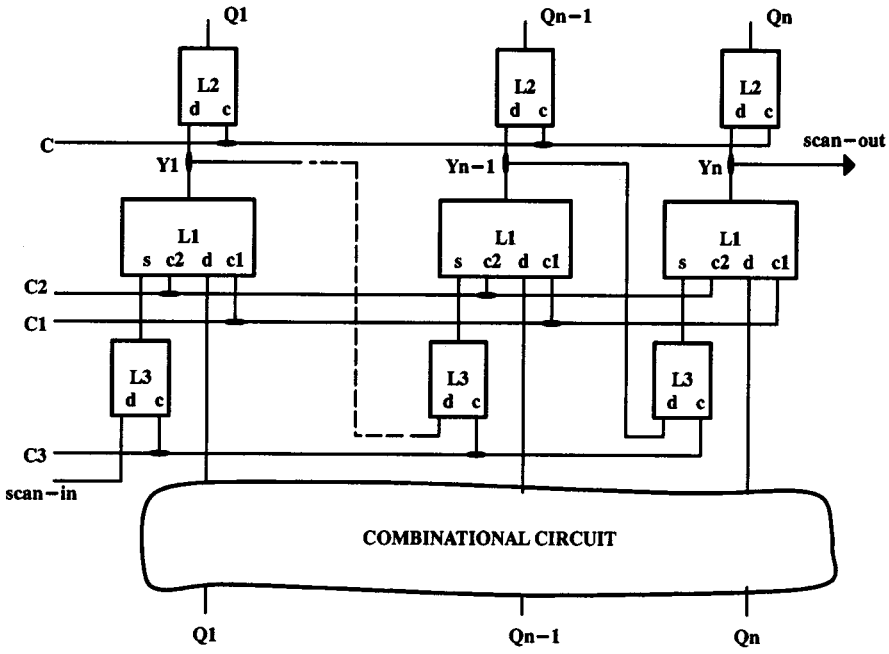

FIGURE 85.25 Using a three-latch flip-flop design to enable path-delay testing.

collect all the necessary conditions for sensitizing the transitions. For example, in the example given above the first pattern requires input flip-flops *A, B,* and *C* all to be set to the logic 1 value in order to sensitize a l*ow-to-high* transition at the *D* input, whereas the second test pattern requires *A, B,* and *C* all to remain at logic 1 while *D* is changed from logic 0 to the logic 1 value. This way the transitions created on input *D* will travel through the identified signal path to reach the destination flip-flop *Z*.

Path-delay test patterns become much easier to generate and also apply to a circuit if the circuit is designed using scannable flip-flops that are additionally capable of storing two arbitrarily selected values in them. This can be done in such a fashion that the initial value available at the flip-flop output will be replaced by the second value when a first clock pulse is applied, and the flip-flop will revert to its normal mode of operation before the second clock pulse is applied. This way the pair of test patterns that form a path-delay test are first loaded into the flip-flops (using scan) and then two clock pulses are applied at speed. The final result captured by the second clock pulse is then scanned out and examined to determine pass/fail status. It is also possible to get an actual measurement of the path delays by repeating the same test over and over again while systematically reducing the time distance between the two clock pulses to determine the minimum separation of the two clock pulses required for proper operation.

Figure 85.25 shows a modified LSSD latch design [Malaiya and Narayanaswamy, 1983] that can be used to enable path-delay testing as described above. Using this design, it is possible to load any two arbitrary test vectors to the combinational circuit in rapid succession. First, test vector Q_1, Q_2,…,Q_n would be scanned into the L1 latches outputs by using clocks C_3 and C_2. Next, the test vector would be moved into the L2 latches by applying a single *C* clock. This way the flip-flop outputs would be set to their initial values defined by Q_1, Q_2,…, Q_n. Following this, the second test vector Y_1, Y_2,…,Y_n would be scanned into the L1 latches using clock signals C_3 and C_2. Now applying the *C* clock causes the first test vector (Q_i) to be replaced by the second test vector (Y_i), and if the C_1 clock is applied next, the response of the combinational circuit will be captured in the L1 latches. This way, the minimum delay between the clock signals *C* and C_1 that is necessary to allow the signals to propagate through the combinational circuit can be determined. Other flip-flop designs with built-in features to support *double-strobe* testing are also possible [Dervisoglu and Stong, 1991].

A different and more difficult-to-use approach for generating test patterns for path-delay measurement is to perform scan-in to load the internal flip-flops with a special pattern that prior circuit analysis will have determined will be transformed into the actually intended test pattern when the first functional clock pulse is

applied. The circuit analysis required to use this approach amounts to performing simulation in reverse time flow to determine what state the device under test should be placed in (using scan) so that its next state corresponds to the desired test pattern.

Future for Design for Test

Present-day trends for striving to achieve shorter time to market while at the same time meeting competitive cost demands are going to continue into the foreseeable future. Design for testability is one of several areas that manufacturers from IC components to complete systems are paying increased emphasis to in order to meet their product goals. Twenty years ago some product managers considered testing as being necessary to weed out the bad from the good but did not consider DFT to be adding value to a product. However, since testing is essential, the value of DFT is seen in reducing the cost of an essential item. Hence DFT adds value to a product at least by an amount equal to the savings in test costs that it brings about. Furthermore, DFT improves time to market by making it possible to identify initial production problems at an earlier point in time. For example, initial productions of high-performance ASIC components may contain flaws that prevent their at-speed operation under certain circumstances. If these flaws are not discovered in a timely manner, they may turn into "showstopper" issues causing serious delays in revenue shipments of products. Whereas no "guaranteed" solutions exist to prevent and/or find a solution for all types of problems, design for testability is a rapidly maturing field of digital design.

Defining Terms

Boundary scan: A technique for applying scan design concepts to control/observe values of signal pins of IC components by providing a dedicated boundary-scan register cell for each signal I/O pin.

Built-in self-test (BIST): Any technique for applying prestored or real-time-generated test cases to a subcircuit, IC component, or system and computing an overall pass/fail signature without requiring external test equipment.

Path-delay testing: Any one of several possible techniques to verify that signal transitions created by one clock event will travel through a particular logic/path in a subcircuit, IC component, or system and will reach their final steady-state values before a subsequent clock event.

Pseudo-random testing: A technique that uses a linear feedback shift register (LFSR) or similar structure to generate binary test patterns with statistical distribution of values (0 and 1) across the bits; these patterns are generated without considering the implementation structure of the circuit to which they will be applied.

Scan design: A technique whereby storage elements (i.e., flip-flops) in an IC are connected in series to form a shift-register structure that can be entered into a test mode to load/unload data values to/from the individual flip-flops.

The ViewSonic® VP140 ViewPanel is about as flat as a board. This new active-matrix LCD flat-panel has a 14-in. viewing area. Measuring at only 2.5 in. deep and weighing just 12.1 lb, the VP140 weighs only a fraction of standard displays and uses 90% less desktop space. The display unit supports a maximum noninterlaced resolution of 1024×768 pixels at a 75-Hz refresh rate. Additionally, the VP140 monitor can be configured for both desktop or slim line wall displays and it supports up to 16.7 million color images for both PC and Macintosh® environments. This revolutionary view panel represents the future of monitors. (Photo courtesy of ViewSonic Corporation.)

COMPUTER ENGINEERING is a discipline that deals with the engineering knowledge required to build digital computers and special systems that communicate and/or process or transmit data. As such, computer engineering is a multi-disciplinary field because it involves many different aspects of engineering that are necessary in designing such complex systems. To illustrate this point one can think of all the various parts of engineering that are involved in a design of a digital computer system. One can start with the knowledge of the material science that is necessary to process the materials of which the integrated circuits are made. One also has to deal with the devices and device physics to make the most efficient transistors of which computing sytems are built. The knowledge of electrical engineering and electronic circuits in particular is necessary in order to design fast and efficient integrated circuits. One level further in the hierarchy of the required knowledge is a logic design which is an implementation of the digital functions. Digital design involves not only an intimate knowledge of electrical engineering but also the use of computer aided design tools and algorithms for efficient implementation of computational structures. Building a complex computer system is similar to building a house — at the very beginning one cannot be bothered with all the details involved in the process, such as plumbing and electrical wiring. Similarly a process of designing an electronic computer starts with an architecture that specifies the functionality and major blocks. Much like building a house, those blocks are later designed by teams of engineers using the architectural specifications of the computer. Computer architecture is on a cross-road between electrical engineering and computer science. On one hand, one does not need to specify all the details of implementation while defining an architecture. However, if one does not know the important aspects of the design which require the knowledge of electrical engineering, the architecture may not be good. Given that the implementation of the architecture has to serve as a platform for various applications, the knowledge of software, compilers, and high-level languages is also necessary.

Computer engineering is not only a very diverse discipline, but as such it is a subject of very rapid changes reflecting high rate of progress in a variety of disciplines encompassed by computer engineering. The performance of digital computers has been doubling steadily every two years while the capacity of the semiconductor memory has been quadrupling every three years. The price-performance figure has dropped for two orders of magnitude in the last ten years. This trend has radically changed the way the computer is perceived today. From exclusive and expensive machines, affordable to only a few, it has become a commodity. For example, an average automobile today contains in the order of 20 processors controlling various aspects of the machine function, brake system, navigation, etc.

Some of the technology-specific aspects of computer engineering were covered in Section VIII. This section, however, is concerned with higher-level aspects which are substantially independent of circuit technology. Chapter 86 reviews organizational matters which particularly affect computer processor design, such as the arithmetic and logical functions required. The next chapter considers the major topic of programming, which may be different in each "layer," using the previous analogy. Programming too has long been dominated by a particular paradigm, the so-called *imperative* model, in which the programmer expresses an algorithm, i.e., a process for solving a problem, as a sequence of instructions—either simple or complex, depending on the type of programming required. Recently others have emerged, such as rule-based programming, which has a *declarative* model, i.e., the user specifies the facts and rules of a situation and poses a question, leaving the computer ("knowledge-engine") to make its own inferences en route to finding a solution or set of solutions.

Computer memory systems are considered in Chapter 88. Early purists preferred the term *storage systems,* since the organization of a computer memory bears little resemblance to what we know of the organization of the human brain. For economic reasons, computer memories have been organized as a hierarchy of different technologies, with decreasing cost per bit as well as increased access times as one moves away from the central processor. The introduction of virtual memory in the Manchester Atlas project (c. 1964) was a major breakthrough in removing memory management from the tasks of the programmer, but recently the availability of vast quantities of semiconductor memory at ultralow prices has reduced the need for this technique.

The topic of Chapter 89 is the input and output of information. Early computers were confined almost exclusively to character information, but "input/output" now refers to any form of *transducer,* to choose an engineering term, which allows any form of information to be sensed whether in analog or digital form, entered

into a computer system, and be output by it in a correspondingly useful form. Information may vary in time such as a temperature indication, in two dimensions such as the user's action in moving a mouse, or even in three dimensions, and output may be as simple as closing a contact or drawing a picture containing a vast range of colors.

Software engineering as discussed in Chapter 90 refers to the serious problem of managing the complexity of the layers of software. This problem has few parallels in other walks of life and is exacerbated by the rate of change in computing. It is dominated by the overall question "Is this computer system reliable?" which will be referred to in Chapter 98. Some parallels can be drawn with other complex human organizations, and, fortunately, the computer itself can be applied to the task.

Graphical input and output is the topic of Chapter 91. Early promise in the mid-1960s led to the pessimistic observation a decade later that this was "a solution looking for a problem," but as computer display technology improved in quality, speed, and, most importantly, cost, attention was focused on visualization algorithms, e.g., the task of producing a two-dimensional representation of a three-dimensional object. This is coupled with the need to provide a natural interface between the user and the computer and has led to the development of interactive graphical techniques for drawing, pointing, etc., as well as consideration of the human factors involved.

As computers have extended their scope, it has become necessary for a computer to communicate with other computers, whether nearby, such as a file server, or across a continent or ocean, such as in electronic mail. Chapter 92 reviews the major concepts of both local and wide area computer networks.

Many engineers were skeptical as to whether early computers would operate sufficiently long before a breakdown would prevent the production of useful results. Little recognition has been given to the pioneers of component and circuit reliability that have made digital systems virtually, but still not totally, fault-free. Critical systems, whether in medicine or national defense, must operate even if components and subsystems fail. The next chapter reviews the techniques employed to make computer systems fault-tolerant.

The idea of a rule-based system, referred to earlier, is covered in Chapter 94. Application software naturally reflects the nature of the application, and the term *knowledge engineering* has been coined to include languages and techniques for particularly demanding tasks, which cannot readily be expressed in a conventional scientific or business programming language.

Parallel systems are emerging as the power of computer systems is extended by using multiple units. The term *unit* may correspond to anything from a rudimentary processor, such as a "smart word" in a massively parallel "fine grain" architecture, to a full-scale computer, in a coarse-grain parallel system with a few tens of parallel units. Chapter 95 discusses the hardware and software approaches to a wide variety of parallel systems.

Operating systems, which are described in the next chapter, turn a "raw" computer into an instrument capable of performing useful, low-level tasks, such as creating a file or starting a process corresponding to an algorithm, or transferring its output to a device such as a printer, which may be busy with other tasks.

As society has become more dependent upon the computer and computer technology, it has become increasingly concerned with protecting the privacy of individuals and maintaining the integrity of computer systems against infiltration—by individuals, groups, and even on occasion by governments. Techniques for protecting the security of a system and ensuring individual privacy are discussed in Chapter 97.

Chapter 98 discusses the overall reliability of computer systems, based on the inevitable limitations of both hardware and software mentioned earlier. Given the inevitability of failure, human or component, what can be said about the probability of a whole computer system failing? This may not be an academic issue for a passenger reading this section while flying in a modern jet airliner, which may spend over 95% of a flight under the control of an automatic pilot. He or she may be reassured to know, however, that the practitioners of reliability engineering have reduced the risk of system failure to truly negligible proportions.

Nomenclature

Symbol	Quantity	Unit
A	area	m2
A_m	main amplifier gain	
A_p	preamplifier gain	
A_v	availability	
BW	bandwidth	Mbyte/s
C	capacitance	F
d	distance	m
E_L	illuminance	
f	proportionality factor	
h	Planck's constant	$6.625 \times 10–34$ J·s
L	latencyns	
λ	failure rate	
μ_f	flip-flop sensitivity	
μ_p	photodetector sensitivity	
μ_s	Schmitt trigger sensitivity	
ν	hardware utilization	
ω	angular velocity	rad/s
P	parallelism	
P_c	character pitch	
q	drop charge	
R	wheel radius	
R_1	shaft radius	
S	sensitivity	fL
S	speed-up ratio	
t_L	optical loss	
V_b	band velocity	m/s
ξ	rotation angle	rad
$z(t)$	hazard rate

86.1 Number Systems

Richard F. Tinder

Number systems provide the basis for conveying and quantifying information. Weather data, stocks, pagination of books, weights and measures—these are just a few examples of the use of numbers that affect our daily lives. For this purpose we find the decimal (or arabic) number system to be reliable and easy to use. This system evolved presumably because early humans were equipped with a crude type of calculator, their ten fingers. A number system that is appropriate for humans, however, may be intractable for use by a machine such as a computer. Likewise, a number system appropriate for a machine may not be suitable for human use.

Before concentrating on those number systems that are useful in computers, it will be helpful to review the characteristics that are desirable in any number system. There are *four* important characteristics in all:

- Distinguishability of symbols
- Arithmetic operations capability
- Error control capability
- Tractability and speed

To one degree or another the decimal system of numbers satisfies these characteristics for hard-copy transfer of information between humans. Roman numerals and **binary** are examples of number systems that do not satisfy all four characteristics for human use. On the other hand, the binary number system is preferable for use in digital computers. The reason is simply put: current digital electronic machines recognize only two identifiable states physically represented by a high voltage level and a low voltage level. These two physical states are logically interpreted as the binary symbols 1 and 0.

A fifth desirable characteristic of a number system to be used in a computer should be that it have a minimum number of easily identifiable states. The binary number system satisfies this condition. However, the digital computer must still interface with humankind. This is done by converting the binary data to a decimal and character-based form that can be readily understood by humans. A minimum number of identifiable characters (say 1 and 0, or true and false) is not practical or desirable for direct human use. If this is difficult to understand, imagine trying to complete a tax form in binary or in any number system other than decimal. On the other hand, use of a computer for this purpose would not only be practical but, in many cases, highly desirable.

Positional and Polynomial Representations

The *positional form* of a number is a set of side-by-side (juxtaposed) digits given generally in *fixed-point* form as

$$N_r = (\underbrace{\overset{\text{MSD}\downarrow}{a_{n-1}} \ldots a_3 a_2 a_1 a_0}_{\text{Integer}} \overset{\text{Radix Point}\downarrow}{.} \underbrace{a_{-1} a_{-2} a_{-3} \ldots \overset{\text{LSD}\downarrow}{a_{-m}}}_{\text{Fraction}})_r \tag{86.1}$$

where the **radix** (or base) r is the total number of digits in the number system and a is a digit in the set defined for radix r. Here, the radix point separates n integer digits on the left from m fraction digits on the right. Notice that a_{n-1} is the most significant (highest-order) digit, called MSD, and that a_{-m} is the least significant (lowest-order) digit, denoted by LSD.

The *value* of the number in Eq. (86.1) is given in *polynomial form* by

$$\begin{aligned} N_r &= \sum_{i=-m}^{n-1} a_i r^i \\ &= \begin{pmatrix} a_{n-1} r^{n-1} + \cdots + a_2 r^2 + a_1 r^1 + a_0 r^0 \\ + a_{-1} r^{-1} + a_{-2} r^{-2} + \cdots + a_{-m} r^{-m} \end{pmatrix}_r \end{aligned} \tag{86.2}$$

where a_i is the digit in the ith position with a *weight* r^i.

Application of Eqs. (86.1) and (86.2) follows directly. For the decimal system $r = 10$, indicating that there are 10 distinguishable characters recognized as decimal numerals $0, 1, 2, \ldots, r - 1 (= 9)$. Examples of the positional and polynomial representations for the decimal system are

$$\begin{aligned} N_{10} &= (d_3 d_2 d_1 d_0 . d_{-1} d_{-2} d_{-3})_{10} \\ &= 3017.528 \end{aligned}$$

and

$$\begin{aligned} N_{10} &= \sum_{i=-3}^{n-1} d_i 10^i \\ &= 3 \times 10^3 + 0 \times 10^2 + 1 \times 10^1 + 7 \times 10^0 + 5 \times 10^{-1} + 2 \times 10^{-2} + 8 \times 10^{-3} \\ &= 3000 + 10 + 7 + 0.5 + 0.02 + 0.008 \end{aligned}$$

where d_i is the decimal digit in the ith position. Exclusive of possible leading and trailing zeros, the MSD and LSD for this number are 3 and 8, respectively. This number could have been written in a form such as $N_{10} =$ 03017.52800 without altering its value but implying greater accuracy of the fraction portion.

Unsigned Binary Number System

Applying Eqs. (86.1) and (86.2) to the binary system requires that $r = 2$, indicating that there are two distinguishable characters, typically 0 and $(r - 1) = 1$, that are used. In positional representation these characters (numbers) are called *binary digits* or *bits*. Examples of the positional and polynomial notations for a binary number are

$$N_2 = (b_{n-1} \ldots b_3 b_2 b_1 b_0 \,.\, b_{-1} b_{-2} b_{-3} \ldots b_{-m})_2$$
$$= 101101.101_2$$

MSB — LSB

and

$$N = \sum_{i=-m}^{n-1} b_i 2^i$$
$$= 1\times 2^5 + 0\times 2^4 + 1\times 2^3 + 1\times 2^2 + 0\times 2^1 + 1\times 2^0 + 1\times 2^{-1} + 0\times 2^{-2} + 1\times 2^{-3}$$
$$= 32 + 8 + 4 + 1 + 0.5 + 0.125$$
$$= 45.625_{10}$$

where b_i is the bit in the ith position. Thus, the bit positions are weighted …, 16, 8, 4, 2, 1, ½, ¼, ⅛, … for any number consisting of integer and fraction portions. Binary numbers so represented are sometimes referred to as *natural* binary. In positional representation the bits on the extreme left and extreme right are called the MSB (most significant bit) and LSB (least significant bit), respectively. Notice that by obtaining the value of a binary number a conversion from binary to decimal has been performed. The subject of radix (base) conversion will be dealt with more extensively later.

For reference purposes Table 86.1 provides the binary-to-decimal conversion for two-, three-, four-, five-, and six-bit binary. The six-bit binary column is only halfway completed for brevity.

TABLE 86.1 Binary-to-Decimal Conversion

Two-Bit Binary	Decimal Value	Three-Bit Binary	Decimal Value	Four-Bit Binary	Decimal Value	Five-Bit Binary	Decimal Value	Six-Bit Binary	Decimal Value
00	0	000	0	0000	0	10000	16	100000	32
01	1	001	1	0001	1	10001	17	100001	33
10	2	010	2	0010	2	10010	18	100010	34
11	3	011	3	0011	3	10011	19	100011	35
		100	4	0100	4	10100	20	100100	36
		101	5	0101	5	10101	21	100101	37
		110	6	0110	6	10110	22	100110	38
		111	7	0111	7	10111	23	100111	39
				1000	8	11000	24	101000	40
				1001	9	11001	25	101001	41
				1010	10	11010	26	101010	42
				1011	11	11011	27	101011	43
				1100	12	11100	28	101100	44
				1101	13	11101	29	101101	45
				1110	14	11110	30	101110	46
				1111	15	11111	31	101111	47

TABLE 86.2 NBCD Bit Patterns and Decimal Equivalent

NBCD Bit Pattern	Decimal	NBCD Bit Pattern	Decimal
0000	0	1000	8
0001	1	1001	9
0010	2	1010	NA
0011	3	1011	NA
0100	4	1100	NA
0101	5	1101	NA
0110	6	1110	NA
0111	7	1111	NA

NA = not allowed.

In the natural binary system the number of bits in a unit of data is commonly assigned a name. Examples are:

- 4-data-bit unit: nibble (or half-byte)
- 8-data-bit unit: byte
- 16-data-bit unit: two bytes (or half-word)
- 32-data-bit unit: word (or four bytes)
- 64-data-bit unit: double-word

  etc.

The word size for a computer is determined by the number of bits that can be manipulated and stored in registers. The foregoing list of names would be applicable to a 32-bit computer.

Unsigned Binary-Coded Decimal, Hexadecimal, and Octal Systems

While the binary system of numbers is most appropriate for use in computers, it has several disadvantages when used by humans who have become accustomed to the decimal system. For example, binary machine code is long, difficult to assimilate, and tedious to convert to decimal. However there exist simpler ways to represent binary numbers for conversion to decimal representation. Three examples, commonly used, are natural binary-coded decimal (NBCD), binary-coded **hexadecimal** (BCH), and binary-coded **octal** (BCO). These number systems are useful in applications where a digital device, such as a computer, must interface with humans. The NBCD code representation is also useful in carrying out computer arithmetic.

The NBCD Representation

The BCD system as used here is actually an 8, 4, 2, 1 weighted code called *natural* BCD or NBCD. This system uses patterns of four bits to represent each decimal position of a number and is one of several such weighted BCD code systems. The NBCD code is converted to its decimal equivalent by polynomials of the form

$$N_{10} = b_3 \times 2^3 + b_2 \times 2^2 + b_1 \times 2^1 + b_0 \times 2^0$$
$$= b_3 \times 8 + b_2 \times 4 + b_1 \times 2 + b_0 \times 1$$

for any $b_3b_2b_1b_0$ code integer. Thus, decimal 6 is represented as $(0\times8) + (1\times4) + (1\times2) + (0\times1)$, or 0110 in NBCD code. Like natural binary, NBCD code is also called "natural" because its bit positional weights are derived from integer powers of 2^n. Table 86.2 shows the NBCD bit patterns for decimal integers 0 through 9.

The NBCD code is currently the most widely used of the BCD codes. There are many excellent sources of information on BCD codes. One, in particular, provides a fairly extensive coverage of both weighted and unweighted BCD codes [Tinder, 1991].

Decimal numbers greater than 9 or less than 1 can be represented by the NBCD code if each digit is given in that code and if the results are combined. For example, the number 63.98 is represented by (or converted to) NBCD code as

$$\begin{aligned} & \quad 6 \quad 3 \quad . \quad 9 \quad 8 \\ 63.98_{10} &= 0110 \;\; 0011 \;\; . \;\; 1001 \;\; 1000)_{\text{NBCD}} \\ &= 1100011.10011_{\text{NBCD}} \end{aligned}$$

Here, the code weights are 80, 40, 20, 10; 8, 4, 2, 1; 0.8, 0.4, 0.2, 0.1; and 0.08, 0.04, 0.02, 0.01 for the tens, units, tenths, and hundredths digits, respectively, representing four decades. Conversion between binary and NBCD requires conversion to decimal as an intermediate step. For example, to convert from NBCD to binary requires that groups of four bits be selected in both directions from the radix point to form the decimal number. If necessary, zeros are added to the leftmost or rightmost ends to complete the groups of four bits as in the above example. Negative NBCD numbers can be represented either in sign-magnitude notation or 1's or 2's **complement** notation as discussed later.

Another BCD code that is used for number representation and manipulation is called excess 3 BCD (or XS3 NBCD, or simply XS3). XS3 is an example of a *biased-weighted* code (a bias of 3). This code is formed by adding 0011_2 ($= 3_{10}$) to the NBCD bit patterns in Table 86.2. Thus, to convert XS3 to NBCD code, 0011 must be subtracted from XS3 code. In four-bit quantities the XS3 code has the useful feature that when adding two numbers together in XS3 notation a carry will result and yield the correct value any time a carry results in decimal (i.e., when 9 is exceeded). This feature is not shared by either natural binary or NBCD addition.

The Hexadecimal and Octal Systems
