The ASIC designer's task is to translate the desired VLSI logic function into a physical design using the basic gate cells provided on the noncustomized IC. To avoiding the routing of intercell interconnections around long rows of logic cells, some of the "cells" along the row are feedthrough cells, allowing routing of interconnections to other logic cell rows. Included in the designer's toolset are library functions predefining the construction of more-complex logic functions (e.g., adders, registers, multipliers, etc.) from the gate cells on the noncustomized gate array IC.

The gate array technology shares the costs of masks among all ASIC customers and exploits high-volume production of the noncustomized wafers. On the other hand, construction of higher-level functions must adhere to the predefined positions and type of gate cells, leading to less-efficient and lower-performance designs than in the standard cell approach. In addition, the width of the wiring channel is fixed, limiting the number of parallel interconnections in the channel and imposing wasted area if all available wires are not used.

Sea-of-Gates ASIC Technology

The *sea-of-gates* technology also uses premanufactured, noncustomized gate arrays. However, additional metallization layers are provided, with lower-level metallization layer(s) used to program the internal function of the cells and the upper-level layer(s) used for over-the-cell routing [Sherwani et al., 95] of signals among cells, such as illustrated earlier in Fig. 25.30(b). This eliminates the need for wiring channels and feedthrough cells, leading to denser arrays of transistors.

CMOS Circuits Using Megacell Elements

The examples above have focused on low-level logic functions. However, as the complexity of VLSI ICs has increased, it has become increasingly important to include standard, high-level functions (e.g., microprocessors, DSPs, PCI interfaces, MPEG coders, RAM arrays, etc.) within an ASIC. For example, an earlier generation of microprocessor may offer the necessary performance and would occupy only a small portion of the area of a present-generation ASIC. Including such a standard microprocessor has the advantages of allowing the ASIC design to be completed more quickly as well as providing users with the microprocessor standard instruction set and software development tools. Such large cells are called *megacells*. As VLSI technologies advance and as standards increasingly impact design decisions, the use of standard megacells will become increasingly common.

Field-Programmable Gate Arrays: Evolving to an ASIC Technology

The *field-programmable gate array* (FPGA), like the gate array, places fixed cells on the wafer, and the FPGA designer constructs more-complex functions from these cells. However, the cells provided on the FPGA can be substantially more complex than the simple gates provided on the gate array. In addition, the term *field programmable* highlights the customizing of the ASIC by the user, rather than by the foundry manufacturing the FPGA. The *mask-programmable gate array* (MPGA) is similar to the FPGA (using more-complex cells than the gate array), but the programming is performed by addition of the metal layer by the FPGA manufacturer.

Figure 25.33 shows an example of cells and programmable interconnections for a representative FPGA technology [Actel, 1995]. The array of cells is constructed from two types of cell, which alternate along the logic cell rows of the FPGA. The combinational logic cell — "C-module" in Fig. 25.33(a) — provides a ROM-based lookup table (LUT) able to efficiently implement a complex logic function (with four data inputs and two control signals). The sequential cell (S-module) adds a flip-flop to the combinational module, allowing efficient realization of sequential circuits. The interconnection approach illustrated in Fig. 25.33(c) is based on (1) short vertical interconnections directly connecting adjacent modules, (2) long vertical interconnections extending through the overall array, (3) long horizontal interconnections extending across the overall array, (4) points at which the long vertical interconnections can be connected to cells, and (5) points at which the long vertical and horizontal lines can be used for general routing. The long horizontal and vertical lines are broken into segments, with programmable links between successive segments. The programmer can then connect a set of adjacent line segments to create the desired interconnection line. In addition, programmable connection points allow the programmer to make transitions between the long vertical lines and the long horizontal lines. By connecting various inputs the cell of an FPGA to either V_{dd} or *GND*, the cell can be "programmed" to perform one of its possible functions. The basic array is complemented by additional driver and other circuitry around the perimeter of the FPGA for interfacing to the "external world."

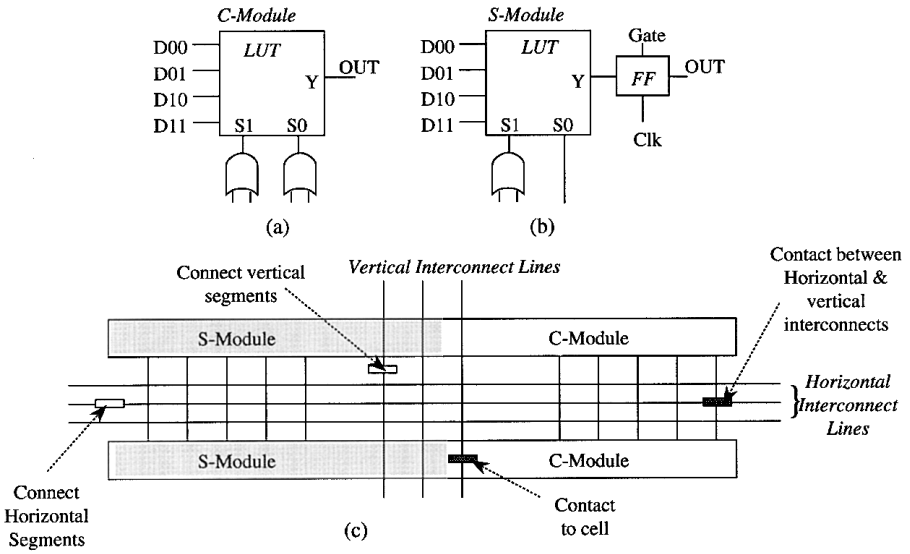

FIGURE 25.33 Example of FPGA elements (Actel FPGA family [Actel, 1995]). Combinational cells (a) and sequential cells (b). (c) Programmable wiring organization.

Different FPGA manufacturers have developed different basic cells, seeking to provide the most useful functionality in the cells for generation of overall FPGA functions. Cells range from fine-grained cells consisting of basic gates through medium-grained cells providing more complex programmable functions to large-grained cells. Different FPGA manufacturers also provide different approaches to the programming step. FPGA programming technologies include one-time programming or multiple-time programming capabilities with the programming either nonvolatile (i.e., programming is retained when power is turned off) or volatile (i.e., programming is lost when power is turned off). Physical programming includes antifuse (fuse) approaches in which the programming nodes are normally off (on) and are "blown" into a permanently on (off) state, providing one-time, nonvolatile programming. Electrical switches also can be used for programming, with an electrical control signal setting the state of the switch. The state control signal can be provided by an EPROM (one-time, nonvolatile), an EEPROM (multiple-time, nonvolatile), or an SRAM (multiple-time, volatile), with different approaches having different advantages and disadvantages.

Interconnection Performance Modeling

Accurate estimation of signal timing is increasingly important in contemporary VLSI ASICs and will become even more important as feature sizes decrease further. Higher clock rates impose tighter timing margins, requiring more accurate modeling of the signal delays. In addition, more-sophisticated models are required for smaller feature size VLSI.

Perhaps of greatest impact is the rapid increase in the importance of interconnect delay relative to gate delay. In the earlier 1 μm VLSI technologies, typical gate delays were about six times the average interconnection delays. For the 0.5 μm technologies, gate delays had decreased while interconnect delays had increased, becoming approximately equal. At 0.3 μm, the decreasing gate delay and increasing interconnect delays have led to average interconnect delays about six times greater than typical gate delays. Accurate estimation of signal delays early in the design is therefore increasingly difficult, since the designer does not have a detailed knowledge of interconnection lengths and nearby lines, which can cause coupling noise, until much of the design has been completed. As the design proceeds and the interconnection lengths become better specified, parameters related to the signal performance can be fed back (back-annotated) to the earlier design steps, allowing the design to be adapted to reflect necessary changes to achieve desired performance.

In earlier VLSI technologies, a linear delay model was adequate, representing the overall delay τ from the input to one cell (cell A in Fig. 25.34) to the input to the connected cell (cell B in Fig. 25.34) by an analytic

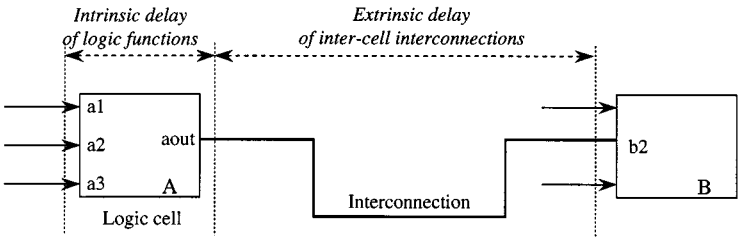

FIGURE 25.34 Logic cell delay (intrinsic delay) and intercell interconnection delay (extrinsic delay).

form such as $\tau = \tau(0) + k1 \cdot C(\text{out}) + k2 \cdot t(s)$, where $\tau(0)$ is the intrinsic (internal) delay of the cell with no loading, $C(\text{out})$ is the output capacitance seen by the output driver of the cell, $t(s)$ is the **rise/fall time** of the signal, and the parameters $k1$ and $k2$ are constants. In the case of deep submicron CMOS technologies, the overall delay must be divided into the **intrinsic delay** of the gate and the **extrinsic delay** of the interconnect, each having substantially more-complex models than the linear model.

Factors impacting the intrinsic delay of gates include the following, with the input and output signals referring to logic cell A in Fig. 25.34.

1. A 0-to-1 change in an input to cell A may cause a different delay to the output of cell A than a 1-to-0 change in that input.
2. Starting from the time when the input starts to change, slower transition times lead to a longer delays before the threshold voltage is reached, leading to longer delays to the output.
3. Once the input passes the threshold voltage, a slower changing input may lead to a longer delay to the output transition.
4. The delay from a change in a given input to a change in the output may depend on the state of other inputs to the circuit.

These are merely representative examples of the more-complex behavior seen in the gates as the feature sizes decrease. Together, those complexities lead to a nonlinear delay model, which is typically implemented as a LUT, rather than with an analytic expression.

The models used for interconnections [Tewksbury, 1994] have also changed, reflecting the changing interconnection parameters and increasing clock rates. The three primary models are as follows.

Lumped RC Model: If the rise/fall times of the signal are substantially greater than the round-trip propagation delay of the signal, then the voltage and current are approximately constant across the length of the interconnection. The interconnection is modeled as a single lumped resistance and a single lumped capacitance. The signal does not incur a propagation delay, and at all points along the line the signal has the same rise/fall times.

Distributed RC Model: If the line is sufficiently long, the signal sees a decreasing resistance and capacitance toward the destination as the signal traverses the line. To represent this changing *RC,* the distributed RC model divides the overall line into shorter segments, each of which can be represented by the lumped RC model above. The transfer function of the overall line is then the product of the transfer functions of the sections. The propagation delay is negligible, though the rise/fall times increase as the signal propagates toward the far-end gates (significant if the line is tapped along its length to drive multiple gates).

Distributed RLC Model: As the rise/fall times become shorter, the relative contributions of capacitance and inductance change. In particular, the impedance of the capacitance is inversely proportional to frequency while that of the inductance is proportional to frequency. At sufficiently high data rates, the inductance effects become significant. In this case, the signal is delayed as it propagates toward the far-end gates, with the rise/fall times increasing along the line. Different terminal points of a net will see the signal at different times with different rise/fall times.

Given the wide range of lengths of signal interconnections, all three models above are relevant; the lumped RC model suitable for short interconnections, the distributed RC model for low-to-moderate speed signals on longer-length interconnections, and the distributed RLC model for high-speed signals on longer interconnections.

Accurate modeling of signals propagating on an interconnection requires detailed knowledge of the capacitance C^* and inductance L^* per unit length along the length of the line. As additional metal layers have been provided, capacitance to neighboring lines (on different or the same metal layer) has become increasingly important, even exceeding the capacitance to ground in some cases. Extraction of accurate interconnect delay parameters may require the use of three-dimensional field solvers, with two-dimensional analysis used for less-accurate modeling of signal behavior.

In addition to the effects noted above, crosstalk (increasingly problematic for buses whose parallel lines run long distances) and reflections (of increasing importance as the signal frequencies increase) degrade signals. This broad range of effects impacting signal delay, distortion, and noise have made *signal integrity* an increasingly important issue in VLSI design. Signal integrity effects also appear on the "dc" power and ground lines, due to large transient currents caused by switching gates and switching drivers of output lines.

Clock Distribution

Signals are increasingly distorted not only by long line lengths, but also by the higher clock frequency in present-day VLSI circuits, with the combination of long lines and high clock rates of particular concern. Present-day VLSI circuits include a vast number of flip-flops (often as registers) distributed across the area of the VLSI circuit. *Synchronous ASICs* use a common clock, distributed to each of these flip-flops. With the clock signal being the longest interconnection on the VLSI circuit and the highest-frequency signal, design of the clock distribution network is critical for highest performance.

Complex synchronous ASICs are designed assuming that all flip-flops are clocked simultaneously. *Clock skew* is the maximum difference between the times of clock transitions at any two flip-flops of the overall VLSI circuit. The clock network must deliver clock signals to each of the flip-flops within the margins set by the allowed clock skew, margins which are substantially less than the clock period. For example, part of the 2-ns clock period of a high-speed VLSI circuit operating with a 500-MHz clock is consumed by the rise/fall times of the signals appearing at the input to the flip-flop and by the specified setup and hold times of the flip-flop. The result is that the clock must be applied to the flip-flop within a time interval small as compared with the clock period.

The distance over which the clock signal can travel before incurring a delay greater than the clock skew defines *isochronous* regions (illustrated in Fig. 25.35(a) as shaded regions) within the IC. If the external clock can be provided to such regions with zero clock skew, then clock routing within the isochronous region is not critical. Figure 25.35(a) illustrates the H-tree approach, whose clock paths have equal lengths to terminal points, ideally delivering clock pulses to each of the terminal points (leaf nodes) of the tree simultaneously (zero skew). In a real circuit, precisely zero clock skew is not achieved since different network segments encounter different environments of data lines coupled electrically to the clock line segment.

In Fig. 25.35(a), a single buffer drives the entire H-tree network, requiring a large area buffer and wide clock lines toward the connection of the clock line to the external clock signal. Such a large buffer can account for up to 30% or more of the total VLSI circuit power dissipation. Figure 25.35(b) illustrates a distributed buffer approach, with a given buffer only having to drive those clock line segments to the next level of buffers. In this case, the buffers can be smaller and the clock lines can be narrower. The 300-MHz DEC Alpha microprocessor, for example, uses an H-tree clock distribution network with multiple stages of buffering extending to the final legs of the H-tree network. Another approach to relax the clock distribution problem uses multiple input/output (I/O) pins for the clock. In this case, a number of smaller H-trees can be driven separately, one starting at each clock I/O pin.

The constraint on clock timing is a bound on clock skew, not a requirement for zero clock skew. In Fig. 25.35(c), the clock network uses multiple buffers but allows different path lengths consistent with clock skew margins. For tight margins, an H-tree can be used to deliver clock pulses to local regions in which distribution proceeds using a different buffered network approach such as that in Fig. 25.35(c).

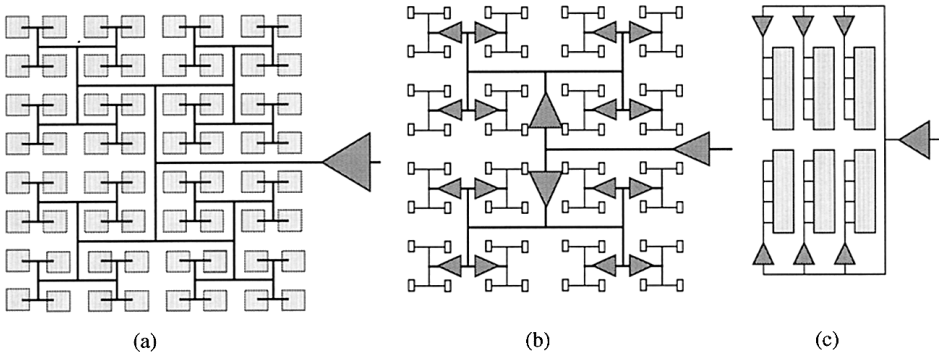

FIGURE 25.35 H-tree clock distribution. (a) Example of single driver and isochronous (shaded) regions. (b) Example of distributed drivers. (c) Example of clock distribution with unequal line lengths but within skew tolerances.

Other approaches for clock distribution are gaining in importance. For example, a lower frequency clock can be distributed across the VLSI circuit, with phase-locked loops (PLLs) used to multiply the clock rate at various sites on the circuit. In addition to multiplying the low clock rate, the PLL can also adjust the phase of the high rate clock, correcting clock skew which may have been introduced in the routing of the low rate clock to that PLL. Another approach is to generate a local clock at a local register when the register input data changes. This *self-timed circuit* approach leads to *asynchronous circuits* but can be quite effective for register-transfer logic (generating a local clock for a large register).

Power Distribution

Present-day VLSI ASICs consume considerable power, unless specifically designed for battery-operated, low-power portable electronics [Chandrakasan and Broderson, 1995]. A 40-W IC operating at 3.3 V requires a current of 12 A, with currents increasing in future generations of high-power VLSI (due not only to the higher power dissipation but also to lower V_{dd}).

Voltage and ground lines must be properly sized to prevent the peak current density exceeding the level at which the power lines will be physically "blown out," leading to rapid and catastrophic failure of the circuit. An equally serious problem is gradual deterioration of a voltage or ground line, eventually leading to failure as a result of *electromigration*. Electromigration failure affects both signal and power lines, but is particularly important in power lines because of the constant direction of the current. As current flows through an aluminum interconnection, the average force exerted on the metal atoms by the electrons leads to a slow migration of those atoms in the direction of electron flow, causing the line to migrate in the direction of the electrons (opposite to the current flow). In regions of the metal line where discontinuities occur (e.g., at the naturally occurring grain boundaries), a void can develop, creating an open in the line. Fortunately, there is a current density threshold level (about 1 mA/μm) below which electromigration is insignificant. Notably, copper, in addition to having a lower resistivity than aluminum, has greater resistance to electromigration. Accurate estimates of power dissipation due to logic switching within logic blocks of the ASIC are also necessary to assess thermal heating within the IC.

Another issue in power distribution concerns *ground bounce* (or *simultaneous switching noise*), which is increasingly problematic as the number of ASIC I/O data pins increases. Consider M output lines switching simultaneously to the 1 state, each of those lines outputting a current transient I(out) within a time t(out). (If M output lines switch simultaneously to the 0 state, then a corresponding input current transient is produced.) The net output current $M \cdot I$(out) is fed through the V_{dd} pin (returned to ground in the case of outputs switching to 0). With an inductance L associated with the V_{dd} pin, a transient voltage $DV \approx L \cdot M \cdot I(\text{out})/t(\text{out})$ is imposed on V_{dd}. A similar effect occurs on the ground connection for outputs switching to 0. With a total output current of 200 mA/ns and a ground pin inductance of 5 nH, the voltage transient is about 1 V. The voltage transient propagates through the IC, potentially causing logic blocks to fail to produce the correct outputs. The transient voltage can be reduced by reducing the power line inductance L, for example by replacing

the single V_{dd} and *Gnd* pins by multiple V_{dd} and *Gnd* pins, with *K* voltage pins reducing the inductance by a factor of *K*.

With power distribution and power line noise problems growing in importance, EDA/CAD tools are rapidly evolving to provide the designer with early estimates and final accurate assessments of various measures of current and of power dissipation.

Analog and Mixed-Signal ASICs

One of the exciting ASIC areas undergoing rapid development is the addition of analog integrated circuits [Geiger et al., 1990; Ismail and Fiez, 1994; Laker and Sansen, 1994] to the standard digital VLSI ASIC, corresponding to *mixed-signal* VLSI. **Mixed-signal ICs** allow the IC to interact directly with the real physical (and analog) world. Library cells representing various analog circuit functions supplement the usual digital circuit cells of the library, allowing the ASIC designer to add needed analog circuits within the same general framework as the addition of digital circuit cells. Automotive electronics is a representative example, with many sensors providing analog information which is converted into a digital format and analyzed using microcomputers or other digital circuits. Mixed-signal library cells include A/D and D/A converters, comparators, analog switches, sample-and-hold circuits, etc., while analog library cells include op amps, precision voltage sources, and phase-locked loops.

As such mixed-signal VLSI ASICs evolve, EDA/CAD tools will also evolve to address the performance and design issues related to analog circuits and their behavior in a digital circuit environment. In addition, analog high-level description languages (AHDLs) are being developed to support high-level specifications of both analog and mixed-signal circuits.

Summary

For about three decades, microelectronics technologies have been evolving, starting with primitive digital logic functions and evolving to the extraordinary capabilities available in present-day VLSI ASICs. This evolution promises to continue for at least another decade, leading to VLSI ICs containing complex systems and vast memory on a single IC. ASIC technologies (including the EDA/CAD tools which guide design to a final IC) deliver this complex technology to the systems designers, including those not associated with a company having a microfabrication facility. This delivery of a highly complex technology to the average electronic systems designer is the result of a steady migration of specialized skill to very powerful EDA/CAD tools which control the complexity of the design process and the result of a need to provide a wide variety of electronics designers with access to technologies which earlier had been available only within large, vertically integrated companies.

Defining Terms

ASIC: Application-specific integrated circuit — an integrated circuit designed for a specific application.

CAD: Computer-aided design — software programs which assist the design of electronic, mechanical, and other components and systems.

CMOS: Complementary metal-oxide semiconductor transistor circuit composed of PMOS and NMOS transistors.

EDA: Electronics design automation — software programs which automate various steps in the design of electronics components and systems.

Extrinsic Delay: Also called *point-to-point delay,* the delay from the transition of output of a logic cell to the transition at the input of another logic cell.

HDL: High-level description language — a software "language" used to describe the function performed by a circuit (or collection of circuits).

IC: Integrated circuit — a normally silicon substrate in which electronic devices and interconnections have been fabricated.

Intrinsic delay: Also called *pin-to-pin delay,* the delay between the transition of an input to a logic cell to the transition at the output of that logic cell.

Mixed-signal ICs: Integrated circuits including circuitry performing digital logic functions as well as circuitry performing analog circuit functions.

NMOS transistor: A metal-oxide semiconductor transistor which is in the on state when the voltage input is high and in the off state when the voltage input is low.

PMOS Transistor: A metal-oxide semiconductor transistor which is in the off state when the voltage input is high and in the on state when the voltage input is low.

Rise/(fall) time: The time required for a signal (normally voltage) to change from a low (high) value to a high (low) value.

V_{dd}**:** The supply voltage used to drive logic within an IC.

VLSI: Very large scale integration — microelectronic integrated circuits containing large (presently millions) of transistors and interconnections to realize a complex electronic function.

Wiring channel: A region extending between the power and ground lines on an IC and dedicated for placement of interconnections among logic cells.

Further Information

The *Institute for Electrical and Electronics Engineers, Inc.* (IEEE) publishes several professional journals which describe the broad range of issues related to contemporary VLSI circuits, including the *IEEE Journal of Solid-State Circuits* and the *IEEE Transactions on Very Large Scale Integration Systems.* Other applications-related journals from the IEEE cover VLSI-related topics. Representative examples include the *IEEE Transactions on Signal Processing,* the *IEEE Transactions on Computers,* the *IEEE Transactions on Image Processing,* and the *IEEE Transactions on Communications.* Several conferences also highlight VLSI circuits, including the *IEEE Solid-State Circuits Conference,* the *IEEE Custom Integrated Circuits Conference,* and several others.

Commercial software tools and experiences related to ASIC designs are changing rapidly, but are well covered in several trade journals including *Integrated System Design* (the Verecom Group, Los Altos, Calif.), *Computer Design* (PennWell Publishing Co., Nashua, N.H.), *Electronics Design News* (Cahners Publishing Co., Highlands Ranch, Colo.), and *Electronic Design* (Penton Publishing Inc., Cleveland, Ohio).

There are also many superb books covering the many topics related to IC design and VLSI design. The references for this chapter consist mainly of books, all of which are well-established treatments of various aspects of VLSI circuits and VLSI design automation.

26.1 Introduction

This section on surface mount technology (SMT) will familiarize the reader with the process steps in a successful SMT design. The new user of SMT is referred to Mims [1987] and Leibson [1987] for introductory material. Being successful with the implementation of SMT means the engineers involved must commit to the principles of concurrent engineering. It also means that a continuing commitment to a quality techniques is necessary, whether that is Taguchi, TQM, SPC, DOE, another technique, or a combination of several quality techniques, lest you too have quality problems with SMT (Fig. 26.1).

26.2 Definition and Considerations

SMT is a collection of scientific and engineering methods needed to design, build, and test products made with electronic components that mount to the surface of the printed circuit board without holes for leads [Higgins, 1991]. This definition notes the breadth of topics necessary to understand SMT, and also clearly says that the successful implementation of SMT will require the use of concurrent engineering [Classon, 1993; Shina, 1991]. Concurrent engineering means that a team of design, manufacturing, test, and marketing people will concern themselves with board layout, parts and parts placement issues, soldering, cleaning, test, rework, and packaging, before any product is made. The careful control of all these issues improves both yield and reliability of the final product. In fact, SMT cannot be reasonably implemented without the use of concurrent engineering, and/or the principles contained in Design for Manufacturability (DFM) and Design for Testability (DFT), and therefore any facility that has not embraced these principles should do so if implementation of SMT is its goal.

Considerations in the Implementation of SMT

Main reasons to consider implementation of SMT include:

- reduction in circuit board size
- reduction in circuit board weight
- reduction in number of layers in the circuit board
- reduction in trace lengths on the circuit board, with correspondingly shorter signal transit times and potentially higher-speed operation

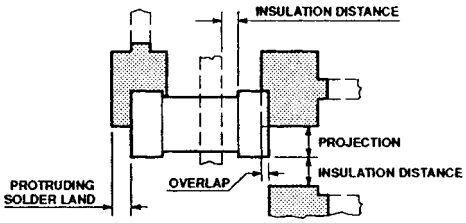

FIGURE 26.1 Placement misalignment of an SMT chip resistor. (*Source:* Phillips Semiconductors, *Surface Mount Process and Application Notes,* Sunnyvale, Calif.: Phillips Semiconductors, 1991. With permission.)

However, not all these reductions may occur in any given product redesign from **through-hole technology** (THT) to SMT.

Most companies that have not converted to SMT are considering doing so. All is of course not golden in SMT Land. During the assembly of a **through-hole** board, either the component leads go through the holes or they do not, and the component placement machines can typically detect the difference in force involved. During SMT board assembly, the placement machine does not have such direct feedback, and accuracy of final soldered placement becomes a stochastic (probability-based) process, dependent on such items as component pad design, accuracy of the PCB artwork and fabrication which affects the accuracy of trace location, accuracy of solder paste deposition location and deposition volume, accuracy of adhesive deposition location and volume if adhesive is used, accuracy of placement machine vision system(s), variations in component sizes from the assumed sizes, and thermal issues in the solder reflow process. In THT test, there is a through-hole at every potential test point, making it easy to align a bed-of-nails tester. In SMT designs, there are not holes corresponding to every device lead. The design team must consider form, fit and function, time-to-market, existing capabilities, testing, rework capabilities, and the cost and time to characterize a new process when deciding on a change of technologies.

26.3 SMT Design, Assembly, and Test Overview

- Circuit design (not covered in this chapter)
- Substrate [typically Printed Circuit Board (PCB)] design
- Thermal design considerations
- Bare PCB fabrication and tests (not covered in this chapter)
- Application of adhesive, if necessary
- Application of solder paste
- Placement of components in solder paste
- Reflowing of solder paste
- Cleaning, if necessary
- Testing of populated PCB (not covered in this chapter)

Once circuit design is complete, substrate design and fabrication, most commonly of a printed circuit board (PCB), enters the process. Generally, PCB assembly configurations using surface mount devices (SMDs) are classified as shown in Fig. 26.2.

Type I — only SMDs are used, typically on both sides of the board. No through-hole components are used. Top and bottom may contain both large and small active and passive SMDs. This type board uses reflow soldering only.

Type II — a double-sided board, with SMDs on both sides. The top side may have all sizes of active and passive SMDs, as well as through-hole components, while the bottom side carries passive SMDs and

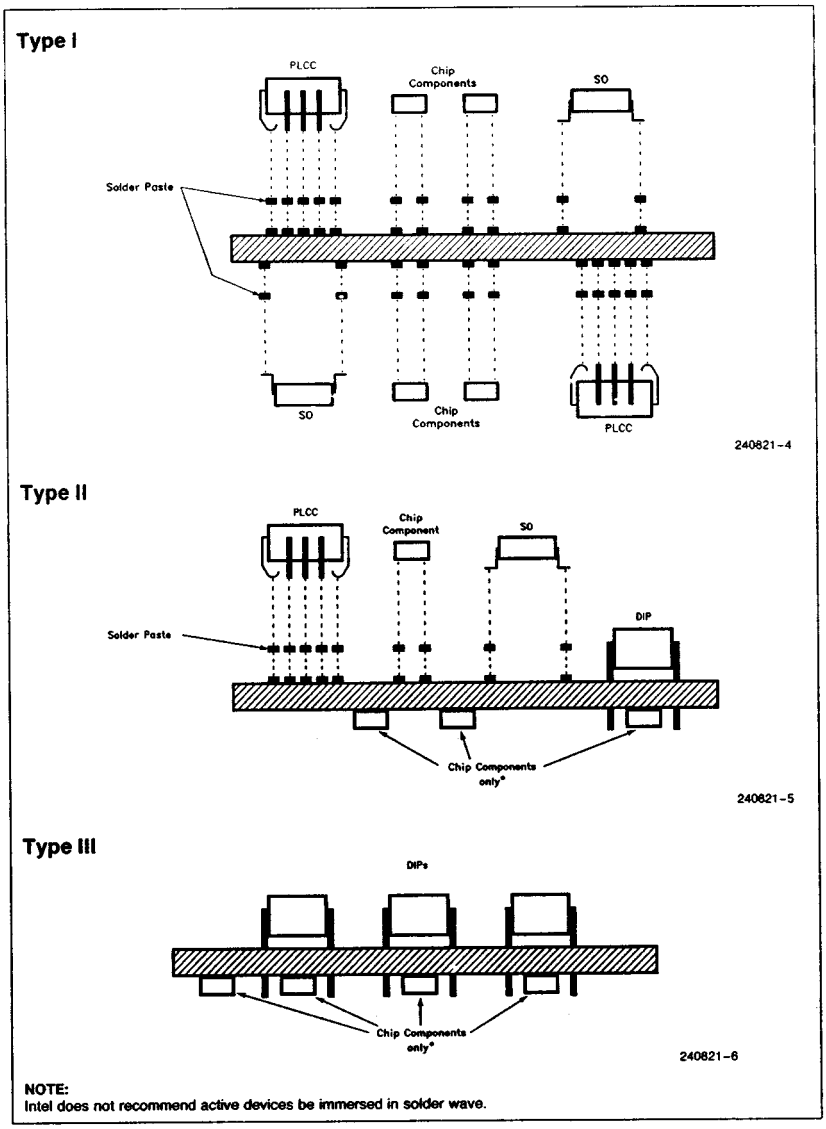

FIGURE 26.2 Type I, II, and III SMT circuit boards. (*Source:* Intel Corporation, *Packaging*, Santa Clara, Calif.: Intel Corporation, 1994. With permission.)

small active components such as transistors. This type board requires both reflow and wave soldering, and will require placement of bottom-side SMDs in adhesive.

Type III — top side has only through-hole components, which may be active and/or passive, while the bottom side has passive and small active SMDs. This type board uses wave soldering only, and also requires placement of the bottom-side SMDs in adhesive.

It should be noted that with the ongoing increase in usage of various techniques to place IC dice directly on circuit boards, Type III in some articles means a mix of packaged SMT ICs and bare die on the same board.

A Type I bare board will first have solder paste applied to the component pads on the board. Once solder paste has been deposited, active and passive parts are placed in the paste. For prototype and low-volume lines this can be done with manually guided X–Y tables using vacuum needles to hold the components, while in medium and high-volume lines automated placement equipment is used. This equipment will pick parts from

reels, sticks, or trays, then place the components at the appropriate pad locations on the board, hence the term "pick and place" equipment.

After all parts are placed in the solder paste, the entire assembly enters a reflow oven to raise the temperature of the assembly high enough to reflow the solder paste and create acceptable solder joints at the component lead/pad transitions. Reflow ovens most commonly use convection and IR heat sources to heat the assembly above the point of solder liquidus, which for 63/37 tin-lead eutectic solder is 183°C. Due to the much higher thermal conductivity of the solder paste compared to the IC body, reflow soldering temperatures are reached at the leads/pads before the IC chip itself reaches damaging temperatures. The board is inverted and the process repeated.

If mixed-technology Type II is being produced, the board will then be inverted, an adhesive will be dispensed at the centroid of each SMD, parts placed, the adhesive cured, the assembly re-righted, through-hole components mounted, and the circuit assembly will then be wave-soldered which will create acceptable solder joints for both the through-hole components and bottom-side SMDs.

A Type III board will first be inverted, adhesive dispensed, SMDs placed on the bottom-side of the board, the adhesive cured, the board re-righted, through-hole components placed, and the entire assembly wave-soldered. It is imperative to note that only passive components and small active SMDs can be successfully bottom-side wave-soldered without considerable experience on the part of the design team and the board assembly facility. It must also be noted that successful wave soldering of SMDs requires a dual-wave machine with one turbulent wave and one laminar wave.

It is common for a manufacturer of through-hole boards to convert first to a Type II or Type III substrate design before going to an all-SMD Type I design. This is especially true if amortization of through-hole insertion and wave-soldering equipment is necessary. Many factors contribute to the reality that most boards are mixed-technology Type II or Type III boards. While most components are available in SMT packages, through-hole connectors are still commonly used for the additional strength the through-hole soldering process provides, and high-power devices such as three-terminal regulators are still commonly through-hole due to off-board heat-sinking demands. Both of these issues are actively being addressed by manufacturers and solutions exist which allow Type I boards with connectors and power devices [Holmes, 1993].

Again, it is imperative that all members of the design, build, and test teams be involved from the design stage. Today's complex board designs mean that it is entirely possible to exceed the ability to adequately test a board if the test is not designed-in, or to robustly manufacture the board if in-line inspections and handling are not adequately considered. Robustness of both test and manufacturing are only assured with full involvement of all parties to overall board design and production.

It cannot be overemphasized that the speed with which packaging issues are moving requires anyone involved in SMT board or assembly issues to stay current and continue to learn about the processes. Subscribe to one or more of the industry-oriented journals noted in the "Further Information" section at the end of this Chapter, obtain any IC industry references, and purchase several SMT reference books.

26.4 Surface Mount Device (SMD) Definitions

The new user of SMDs must rapidly learn the packaging sizes and types for SMDs. Resistors, capacitors, and most other passive devices come in two-terminal packages which have end-terminations designed to rest on substrate pads/lands (Fig. 26.3).

SMD ICs come in a wide variety of packages, from 8-pin Small Outline Packages (SOLs) to 1000+ connection packages in a variety of sizes and lead configurations, as shown in Fig. 26.4. The most common commercial packages currently include **Plastic Leaded Chip Carriers** (PLCCs), Small Outline packages (SOs), **Quad Flat Packs** (QFPs), and Plastic Quad Flat Packs (PQFPs) also know as Bumpered Quad Flat Packs (BQFPs). Add in Tape Automated Bonding (TAB), Ball Grid Array (BGA) and other newer technologies, and the IC possibilities become overwhelming. Space prevents examples of all these technologies from being included here. The reader is referred to the standards of the Institute for Interconnecting and Packaging Electronic Circuits (IPC)[1] to find the latest package standards, and to the proceedings of the most recent National Electronics Production and

[1]IPC, 7380 N. Lincoln Ave, Lincolnwood, IL 60646-1705, 708-677-2850.

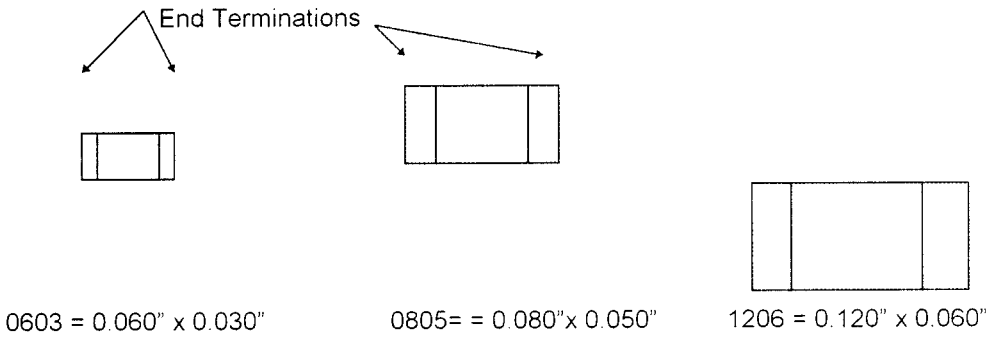

FIGURE 26.3 Example of passive component sizes (top view)(not to scale).

Productivity (NEPCON) Conference[1] for information on industry uses of the latest SMT packages. A good overview of package styles is found in Appendix A of Hollomon [1995] and (for ICs only) in Signetics [1991b] which is being updated as of this writing.

Each IC manufacturer's data books will have packaging information for their products. The engineer should be familiar with the term "lead pitch", which means the center-to-center distance between IC leads. Pitch may be in thousandths of an inch, also known as mils, or in millimeters. Common pitches are 0.050 in. (50 mil pitch), 0.025 in. (25 mil pitch) frequently called "fine pitch", and 0.020 in. and smaller frequently called "ultra-fine pitch". Metric equivalents are 1.27 mm, 0.635 mm, and 0.508 mm and smaller. Conversions from metric to inches are easily approximated if one remembers that 1 mm approximately equals 40 mils.

For process control, design teams must consider the minimum and maximum package size variations allowed by their part suppliers, the moisture content of parts as-received, and the relative robustness of each lead type. Incoming inspection should consist of both electrical and mechanical tests. Whether these are spot checks, lot checks, or no checks will depend on the relationship with the vendor.

26.5 Substrate Design Guidelines

As noted previously, substrate (typically PCB) design has an effect not only on board/component layout, but also on the actual manufacturing process. Incorrect land design or layout can negatively affect the placement process, the solder process, the test process or any combination of the three. Substrate design must take into account the mix of SMDs that are available for use in manufacturing.

The considerations noted here as part of the design process are neither all-encompassing, nor in sufficient detail for a true SMT novice to adequately deal with all the issues involved in the process. They are intended to guide an engineer through the process, allowing him/her to access more detailed information as necessary. General references are noted at the end of this chapter, and specific references will be noted as applicable. In addition, conferences such as the NEPCON, and SMI[2] are invaluable sources of information for both the beginner and the experienced SMT engineer. Although these guidelines are noted as "steps", they are not necessarily in an absolute order, and may require several iterations back-and-forth among the steps to result in a final satisfactory process and product.

After the circuit design (schematic capture) and analysis, Step 1 in the process is to determine whether all SMDs will be used in the final design making a Type I board, or whether a mix of SMDs and through-hole parts will be used, leading to a Type II or Type III board. This decision will be governed by some or all of the following considerations:

- Current parts stock
- Existence of current through-hole placement and/or wave solder equipment

(**b**) QFP footprint. (*Source:* Intel Corporation, *Packaging,* Santa Clara, Calif.: Intel Corporation, 1994. With permission.)

- Amortization of current through-hole placement and solder equipment
- Existence of reflow soldering equipment, or cost of new reflow soldering equipment
- Desired size of the final product
- Panellization of smaller Type I boards
- Thermal issues related to high power circuit sections on the board

It may be desirable to segment the board into areas based on function: RF, low power, high power, etc. using all SMDs where appropriate, and mixed-technology components as needed. Power and connector portions of the circuit may point to the use of through-hole components, although as mentioned both these issues are being addressed by circuit board material and connector manufacturers. Using one solder technique (reflow or wave) simplifies processing, and may outweigh other considerations.

Step 2 in the SMT process is to define all the footprints of the SMDs under consideration for use in the design. The footprint is the copper pattern or "land", on the circuit board upon which the SMD will be placed. Footprint examples are shown in Figs. 26.5a and 26.5b, and footprint recommendations are available from IC manufacturers and in the appropriate data books. They are also available in various ECAD packages used for the design process, or in several references that include an overview of the SMT process [Electronic Packaging and Production, 1994]. However, the reader is seriously cautioned about using the general references for anything other than the most common passive and active packages. Even the position of pin 1 may be different among IC manufacturers of the "same" chip. The footprint definition may also include the position of the solder resist pattern surrounding the copper pattern. Footprint definition sizing will vary depending on whether reflow or wave solder process is used. Wave solder footprints will require recognition of the direction of travel of the board through the wave, to minimize solder shadowing in the final fillet, as well as requirements for solder thieves. The copper footprint must allow for the formation of an appropriate, inspectable solder fillet.

If done as part of the EDA process (electronic design automation, using appropriate electronic CAD software), the software will automatically assign copper directions to each component footprint, as well as appropriate coordinates and dimensions. These may need adjustment based on considerations related to wave soldering, test points, RF and/or power issues, and board production limitations. Allowing the software to select 5 mil traces when the board production facility to be used can only reliably do 10 mil traces would be inappropriate. Likewise, the solder resist patterns must be governed by the production capabilities.

Final footprint and trace decisions will:

- allow for optimal solder fillet formation
- minimize necessary trace and footprint area
- allow for adequate test points
- minimize board area, if appropriate
- set minimum inter-part clearances for placement and test equipment to safely access the board (Fig. 26.6)

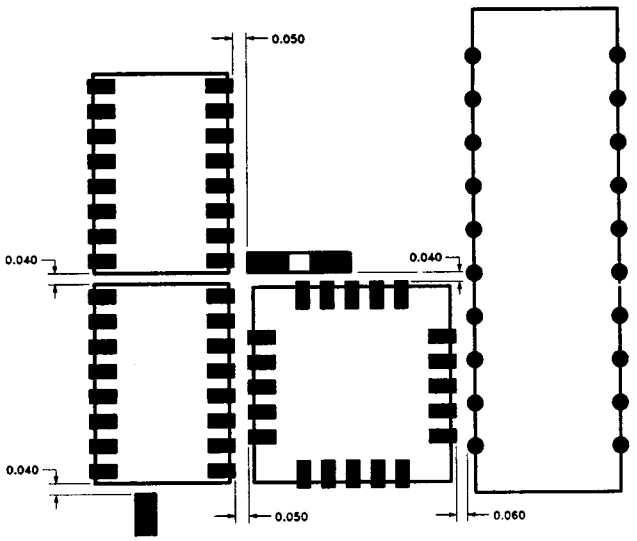

FIGURE 26.6 Minimum land-to-land clearance examples. (*Source:* Intel Corporation, *Packaging*, Santa Clara, Calif.: Intel Corporation, 1994. With permission.)

- allow adequate distance between components for post-reflow operator inspections
- allow room for adhesive dots on wave-soldered boards
- minimize solder bridging

Decisions that will provide optimal footprints include a number of mathematical issues, including:

- component dimension tolerances
- board production capabilities, both artwork and physical tolerances across the board relative to a 0–0 fiducial
- how much artwork/board shrink or stretch is allowable
- solder deposition volume consistencies with respect to fillet sizes
- placement machine accuracies
- test probe location controls and bed-of-nails grid pitch

Design teams should restrict wave-solder-side SMDs to passive components and transistors. While small SMT ICs can be successfully wave-soldered, this is inappropriate for an initial SMT design, and is not recommended by some IC manufacturers (Fig. 26.2).

These decisions may require a statistical computer program, if available to the design team. The stochastic nature of the overall process suggests a statistical programmer will be of value.

26.6 Thermal Design Considerations

Thermal management issues remain major concerns in the successful design of an SMT board and product. Consideration must be taken of the variables affecting both board temperature and junction temperature of the IC. The reader is referred to Chapter 33 in this Handbook for the basics of Thermal Management, and to Bar-Cohen and Kraus [1988] for a more detailed treatment on thermal issues affecting ICs and PCB design.

The design team must understand the basic heat transfer characteristics of most SMT IC packages [Capillo, 1993]. Since the silicon chip of an SMD is equivalent to the chip in an identical-function DIP package, the smaller SMD package means the internal lead frame metal has a smaller mass than the lead frame in a DIP package. This lesser ability to conduct heat away from the chip is somewhat offset by the leadframe of many SMDs being constructed of copper, which has a lower thermal resistance than the Kovar and Alloy 42 materials

commonly used for DIP packages. However, with less metal and shorter lead lengths to transfer heat to ambient air, more heat is typically transferred to the circuit board itself. Several board thermal analysis software packages are available, and are highly recommended for boards that are expected to develop high thermal gradients [Flotherm, 1995].

Since all electronics components generate heat in use, and elevated temperatures negatively affect the reliability and failure rate of semiconductors, it is important that heat generated by SMDs be removed as efficiently as possible. The design team needs to have expertise with the variables related to thermal transfer:

- junction temperature: T_j
- thermal resistances: Θ_{jc}, Θ_{ca}, Θ_{cs}, Θ_{sa}
- temperature sensitive parameter (TSP) method of determining Θs
- power dissipation: P_D
- thermal characteristics of substrate material

SMT packages have been developed to maximize heat transfer to the substrate. These include PLCCs with integral heat spreaders, the SOT-89 power transistor package, the DPAK power transistor package, and many others. Analog ICs are also available in power packages. Note that all of these devices are designed primarily for processing with the solder paste process, and some specifically recommend against their use with wave-solder applications. Heat sinks and heat pipes should also be considered for high-power ICs.

In the conduction process, heat is transferred from one element to another by direct physical contact between the elements. Ideally the material to which heat is being transferred should not be adversely affected by the transfer. As an example, the **glass transition temperature** T_g of FR-4 is 125°C. Heat transferred to the board has little or no detrimental affect as long as the board temperature stays at least 50°C below T_g. Good heat sink material exhibits high thermal conductivity, which is not a characteristic of fiberglass. Therefore, the traces must be depended on to provide the thermal transfer path [Choi et al., 1994]. Conductive heat transfer is also used in the transfer of heat from IC packages to heat sinks, which also requires use of thermal grease to fill all air gaps between the package and the "flat" surface of the sink.

The previous discussion of lead properties of course does not apply to leadless devices such as Leadless Ceramic Chip Carriers (LCCCs). Design teams using these and similar packages must understand the better heat transfer properties of the alumina used in ceramic packages, and must match TCEs between the LCCC and the substrate, since there are no leads to bend and absorb mismatches of expansion.

Since the heat transfer properties of the system depend on substrate material properties, it is necessary to understand several of the characteristics of the most common substrate material, FR-4 fiberglass. The glass transition temperature has already been noted, and board designers must also understand that multi-layer FR-4 boards do not expand identically in the X-, Y-, and Z-directions as temperature increases. Plate-through-holes will constrain z-axis expansion in their immediate board areas, while non-through-hole areas will expand further in the z-axis, particularly as the temperature approaches and exceeds T_g [Lee et al., 1984]. This unequal expansion can cause delamination of layers and plating fracture.

If the design team knows that there will be a need for higher abilities to dissipate heat and/or a need for higher glass transition temperatures and lower coefficients of thermal expansion (TCE) than FR-4 possesses, many other materials are available, examples of which will follow.

Note in Table 26.1 that copper-clad Invar has both variable T_g and variable thermal conductivity depending on the volume mix of copper and Invar in the substrate. Copper has a high TCE and Invar has a low TCE, so the TCE increases with the thickness of the copper layers. In addition to heat transfer considerations, board material decisions must also be based on the expected vibration, stress, and humidity in the application.

Convective heat transfer involves transfer due to the motion of molecules, typically airflow over a heat sink, and depends on the relative temperatures of the two media involved. It also depends on the velocity of air flow over the boundary layer of the heat sink. Convective heat transfer is primarily effected when forced air flow is provided across a substrate, and when convection effects are maximized through the use of heat sinks. The rules that designers are familiar with when designing THT heat-sink device designs also apply to SMT design.

The design team must consider whether passive conduction and convection will be adequate to cool a populated substrate or whether forced-air cooling or liquid cooling will be needed. Passive conductive cooling

TABLE 26.1

Substrate Material (Units)	T_g – Glass Transition Temperature (°C)	TCE – Thermal Coefficient of X–Y Expansion (PPM/°C)	Thermal Conductivity (W/M°C)	Moisture Absorption (%)
FR-4 Epoxy glass	125	13–18	0.16	0.10
Polymide glass	250	12–16	0.35	0.35
Copper-clad invar	Depends on resin	5–7	160XY — 15–20Z	NA
Poly Aramid fiber	250	3–8	0.15	1.65
Alumina/ceramic	NA	5–7	20–45	NA

is enhanced with thermal layers in the substrate, such as the previously mentioned copper/Invar. There will also be designs that will rely on the traditional through-hole device with heat sink to maximize heat transfer. An example of this would be the typical three-terminal voltage regulator mounted on a heat sink or directly to a metal chassis for heat conduction, for which standard calculations apply [Lee et al., 1993].

Many specific examples of heat transfer may need to be considered in board design, and of course most examples involve both conductive and convective transfer. For example, the air gap between the bottom of a standard SMD and the board effects the thermal resistance from the case to ambient, Θ_{ca}. A wider gap will result in a higher resistance, due to poorer convective transfer, whereas filling the gap with a thermal-conductive epoxy will lower the resistance by increasing conductive heat transfer. Thermal-modeling software is the best way to deal with these types of issues, due to the need for rigorous application of computational fluid dynamics (CFD) [Lee, 1994].

26.7 Adhesives

In the surface mount assembly process, Type II and Type III boards will always require adhesive to mount the SMDs for passage through the solder wave. This is apparent when one envisions components on the bottom side of the substrate with no through-hole leads to hold them in place. Adhesives will stay in place after the soldering process, and throughout the life of the substrate and the product, since there is no convenient means for adhesive removal once the solder process is complete. This means the adhesive used must meet a number of both physical and chemical characteristics that should be considered during the three phases of adhesive use in SMT production: pre-application properties relating to storage and dispensing issues, curing properties relating to time and temperature needed for cure, and post-curing properties: relating to final strength, mechanical stability, and reworkability. Among these characteristics are:

- electrically non-conductive
- thermal coefficient of expansion similar to the substrate and the components
- stable in both storage and after application, prior to curing
- stable physical drop shape — retains drop height and fills z-axis distance between the board and the bottom of the component; thixotropic with no adhesive migration
- non-corrosive to substrate and component materials
- chemically inert to flux, solder, and cleaning materials used in the process
- cureable as appropriate to the process: UV, oven, or air-cure
- removable for rework and repair
- once cured, unaffected by temperatures in the solder process
- adhesive color, for easy identification by operators

One-part adhesives are easier to work with than two-part adhesives because an additional process step is not required. The user must verify that the adhesive has sufficient shelf life and pot life for the user's perceived process requirements. Both epoxy and acrylic adhesives are available as one- or two-part systems, and must be cured thermally. Generally, epoxy adhesives are cured by oven-heating, while acrylics may be formulated to be cured by long-wave UV light or heat.

Adhesive can be applied by screening techniques similar to solder paste screen application, by pin transfer techniques, and by syringe deposition. Screen and pin-transfer techniques are suitable for high-volume production lines with few product changes over time. Syringe deposition using an X–Y table riding over the board with a volumetric pump and syringe tip is more suitable for lines with a varying product mix, prototype lines, and low-volume lines where the open containers of adhesive necessary in pin-transfer and screen techniques are avoided. Newer syringe systems are capable of handling high-volume lines. See Fig. 26.8 for methods of adhesive deposition.

If Type II or Type III assemblies are used, and thermal transfer between components and the substrate is a concern, the design team should consider thermally conductive adhesives.

Regardless of the type of assembly, the type of adhesive used, or the curing technique used, adhesive volume and height must be carefully controlled. Slump of adhesive after application is undesirable because the adhesive must stay high enough to solidly contact the bottom of the component, and must not spread and contaminate any pad associated with the component.

If adhesive dot height = X, substrate metal height = Y, and SMD termination thickness = Z, then X>Y+Z, allowing for all combinations of potential errors, e.g., end termination min and max thickness, adhesive dot min and max height, and substrate metal min and max height:

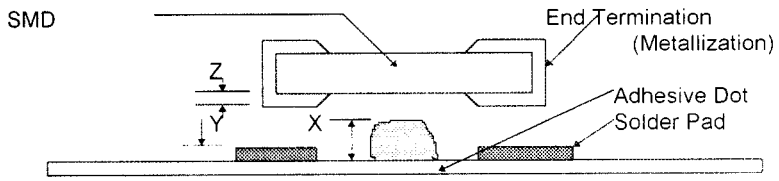

FIGURE 26.7 Relation of adhesive dot, substrate, and component. (*Source:* Phillips Semiconductors, *Surface Mount Process and Application Notes,* Sunnyvale, Calif.: Phillips Semiconductors, 1991. With permission.)

Typically, end termination thickness variations are available from the part manufacturer. Solder pad thickness variations are a result of the board manufacturing process, and will vary not only on the type of board metallization (standard etch vs. plated-through-hole) but also on the variations within each type. For adequate dot height, which will allow for some dot compression by the part, X should be between 1.5X and 2.5X of the total Y+Z, or just Z when dummy tracks are used. If adhesive dots are placed on masked areas of the board, mask thickness must also be considered.

A common variation on the above design is to place "dummy" copper pads under the center of the part. Since these pads are etched and plated at the same time as the actual solder pads, the variation in metal height Y is eliminated as an issue. Adhesive dots are placed on the dummy pads and X > Z is the primary concern.

Adhesive dispensing quality issues are addressed by considerations of:

- type of adhesive to be used
- process-area ambient temperature and humidity
- incoming quality control
- no voids in cured adhesive to prevent trapping of flux, dirt, etc.
- volume control
- location control
- as in Fig. 26.7, all combinations of termination, dot, and substrate height/thicknesses

Prasad [1997] has an excellent in-depth discussion of adhesives in SMT production.

26.8 Solder Paste and Joint Formation

Solder joint formation is the culmination of the entire process. Regardless of the quality of the design, or any other single portion of the process, if high-quality reliable solder joints are not formed, the final product is not reliable. It is at this point that PPM levels take on their finest meaning. For a medium-size substrate (nominal

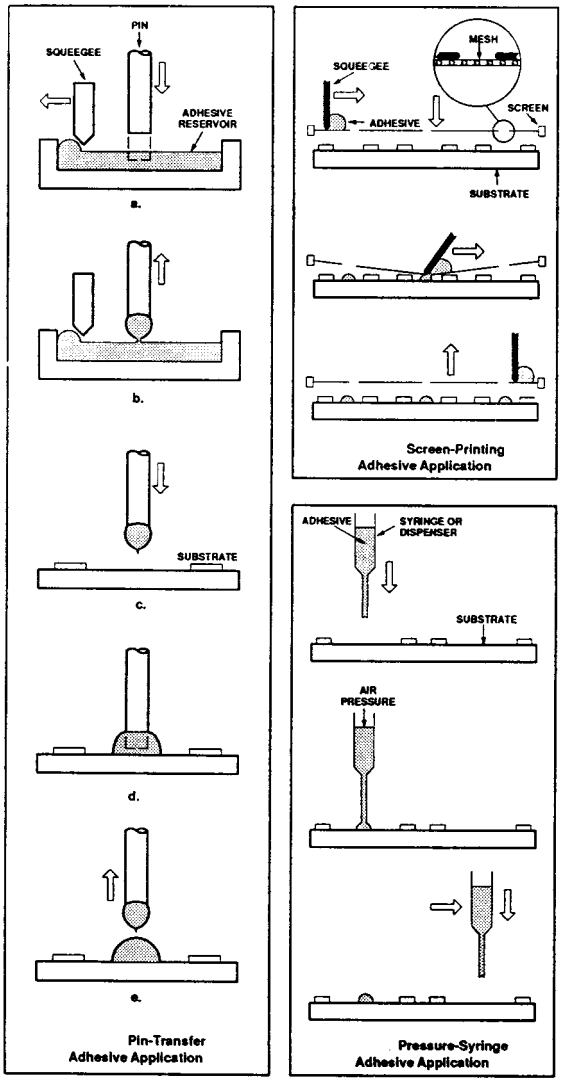

FIGURE 26.8 Methods of adhesive deposition.

6" X 8"), with a medium density of components, a typical mix of active and passive parts on the topside and only passive and 3- or 4-terminal active parts on bottomside, there may be in excess of 1000 solder joints per board. If solder joints are manufactured at the 3 sigma level (99.73% good joints, or 0.27% defect rate, or 2700 defects per 1 million joints), *there will be 2.7 defects per board*!! At the 6 sigma level, of 3.4 PPM, there will be a defect on 1 board out of every 294 boards produced. If your anticipated production level is 1000 units per day, you will have 3.4 rejects based solely on solder joint problems, not counting other sources of defects.

Solder paste may be deposited by syringe, or by screen or stencil printing techniques. Stencil techniques are best for high-volume/speed production although they do require a specific stencil for each board design. Syringe and screen techniques may be used for high-volume lines and are also suited to mixed-product lines where only small volumes of a given board design are to have solder paste deposited. Syringe deposition is the only solder paste technique that can be used on boards which already have some components mounted. It is also well suited for prototype lines and for any use requires only software changes to develop a different deposition pattern.

Solder joint defects have many possible origins:

- poor or inconsistent solder paste quality
- inappropriate solder pad design/shape/size/trace connections
- substrate artwork or production problems, e.g., mismatch of copper and mask, warped substrate
- solder paste deposition problems, e.g., wrong volume or location
- component lead problems, e.g., poor coplanarity or poor tinning of leads
- placement errors, e.g., part rotation or X–Y offsets
- reflow profile, e.g., preheat ramp too fast or too slow; wrong temperatures created on substrate
- board handling problems, e.g., boards getting jostled prior to reflow.

Once again, a complete discussion of all of the potential problems that can affect solder joint formation is beyond the scope of this chapter. Many references are available which address the issues. An excellent overview of solder joint formation theory is found in Lau [1991]. Update information this and all SMT topics is available each year at conferences such as SMI and NEPCON.

While commonly used solder paste for both THT and SMT production contains 63-37 eutectic tin-lead solder, other metal formulations are available, including 96-4 tin-silver (a.k.a. silver solder). The fluxes available include RMA, water-soluble, and no-clean. The correct decision rests as much on the choice of flux as it does on the proper metal mixture. A solder paste supplier can best advise on solder pastes for specific needs. Many studies are in process to determine a no-lead replacement for lead-based solder in commercial electronic assemblies. The design should investigate the current status of these studies as well as the status of no-lead legislation as part of the decision-making process.

To better understand solder joint formation, one must understand the make-up of solder paste used for SMT soldering. The solder paste consists of microscopic balls of solder, most commonly tin-lead with the accompanying oxide film, flux, and activator and thickener solvents as shown in Fig. 26.9.

The fluxes are an integral part of the solder paste, and are discussed further in Section 26.11. RMA, water soluble, and no-clean flux/pastes are available. An issue directly related to fluxes, cleaning and fine-pitch components (25 mil pitch and less) is reflowing in an inert environment. Inert gas blanketing the oven markedly reduces the development of oxides in the elevated temperatures present. Oxide reduction needs are greater with the smaller metal balls in paste designed for fine-pitch parts because there is more surface area on which oxides can form. No-clean fluxes are not as active as other fluxes and therefore have a lesser ability to reduce the oxides formed on both the paste metal and substrate metallizations. Inerting the oven tends to solve these problems. However, it brings with it control issues that must be considered.

Regardless of the supplier, frequent solder paste tests are advisable, especially if the solder is stored for prolonged periods before use. At a minimum, viscosity, percent metal, and solder sphere formation should be tested [Capillo, 1990]. Solder sphere formation is particularly important because acceptable particle sizes will vary depending on the pitch of the smallest-pitch part to be used, and the consistency of solder sphere formation will effect the quality of the final solder joint. Round solder spheres have the smallest surface area for a given

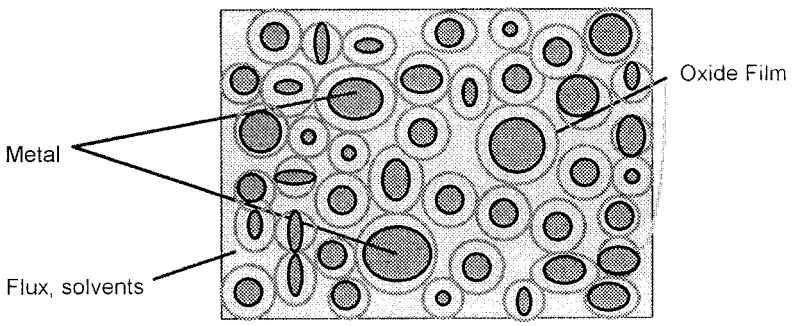

FIGURE 26.9 Make-up of SMT solder paste.

volume. Therefore, they will have the least amount of oxide formation. Uneven distribution of sphere sizes within a given paste can lead to uneven heating during the reflow process, with the result that the unwanted solder balls will be expelled from the overall paste mass at a given pad/lead site. Fine-pitch paste has smaller ball sizes and consequently more surface area on which oxides can form.

It should be noted at this point that there are three distinctly different "solder balls" referred to in this chapter and in publications discussing SMT. The solder sphere test refers to the ability of a volume of solder to form a ball shape due to its inherent surface tension when reflowed (melted) on a non-wettable surface. This ball formation is dependent on minimum oxides on the microscopic metal balls which make up the paste — the second type of "solder ball". It is also dependent on the ability of the flux to reduce the oxides that are present, as well the ramp-up of temperature during the preheat and drying phases of the reflow oven profile. Too steep a time/temperature slope can cause rapid escape of entrapped volatile solvents, resulting in expulsion of small amounts of metal that will form undesirable "solder balls" of the third type, small metal balls scattered around the solder joint(s) on the substrate itself rather than on the tinned metal of the joint. This third type of ball can also be formed by excess solder paste on the pad, and by mis-deposition on non-wettable areas of the substrate.

The reader is referred to Lau [1991] for discussions of finite element modeling of solder joints, and detailed analytical studies of most aspects of basic joints and of joint failures. Various articles by Engelmaier et al. also address many solder joint reliability issues and their analytical analysis. These and other sources will discuss in detail the quality issues that effect solder paste:

- viscosity and its measurement
- printability
- open time
- slump
- metal content
- particle/ball size in mesh
- particle/ball size consistency
- wetting
- storage conditions

Note with regard to viscosity measurements, some paste manufacturers will prefer the spindle technique and some the spiral technique. To properly compare the paste manufacturer's readings with your tests, the same technique must be used.

26.9 Parts Inspection and Placement

Briefly, all parts must be inspected prior to use. Functional parts testing should be performed on the same basis as for through-hole devices. Each manufacturer of electronic assemblies is familiar with the various processes used on through-hole parts, and similar processes must be in place on SMDs. Problems with solderability of leads and lead planarity are two items that can lead to the largest number of defects in the finished product. Solderability is even more important with SMDs than with through- hole parts because all electrical and mechanical strength rests within the solder joint, there being no hole-with-lead to add mechanical strength.

Lead coplanarity is defined as follows. If a multi-lead part, e.g., IC, is placed on a planar surface, lack of ideal coplanarity exists if the lowest solderable part of any lead does not touch that surface. **Coplanarity** requirements vary depending on the pitch of the component leads and their shape, but generally out-of-plane measurements should not exceed 4 mils (0.004 in.) for 50-mil pitch devices, and 2 mils for 25-mil pitch devices.

All SMDs undergo thermal shocking during the soldering process, particularly if the SMDs are to be wave-soldered (Type II or Type III boards), which means they will be immersed in the molten solder wave for 2 to 4 s. Therefore, all plastic-packaged parts must be controlled for moisture content. If the parts have not been stored in a low-humidity environment (<25%RH), then the absorbed moisture will expand during the solder process and crack the package — a phenomenon know as "popcorning" because the crack is accompanied by a loud "pop" and the package expands due to the expansion of moisture, just like real popcorn. IC suppliers have strict recommendations on storage ambient humidity and temperature, and also on the baking procedures

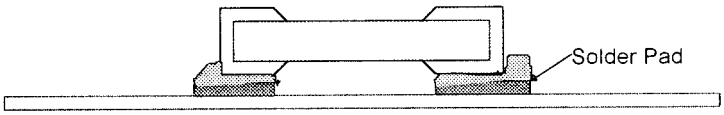

FIGURE 26.10a Part placed *into* solder paste with a passive part.

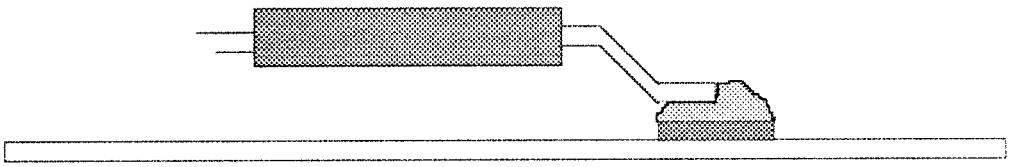

FIGURE 26.10b Part placed *into* solder paste with an active part.

necessary to allow safe reflow soldering if those recommendations are not heeded. Follow them carefully. Typically if storage RH is above 20%, baking must be considered prior to reflow.

Parts Placement

Proper parts placement not only places the parts within an acceptable window relative to the solder pad pattern on the substrate, but the placement machine will apply enough downward pressure on the part to force it halfway into the solder paste as well (Fig. 26.10a and 26.10b). This assures both that the part will sit still when the board is moved, and that coplanarity offsets within limits will still result in an acceptable solder joint. The effects of coplanarity can be done mathematically by considering:

- the thickness of the solder paste deposit
- maximum coplanarity offsets among leads
- lead penetration in paste

If T is the thickness of paste, C is maximum allowable coplanarity, and P is penetration in paste (as a percentage of overall average paste thickness), then:

$$P = \frac{C}{T} \times 100\%$$

Parts placement may be done manually for prototype or low-volume operations, although this author suggests the use of guided X–Y tables with vacuum part pickup for even the smallest operation. Manual placement of SMDs does not lend itself to repeatable work. For medium and high volume work, a multitude of machines are available. See Fig. 26.11 for the four general categories of automated placement equipment.

One good source for manufacturer's information on placement machines and most other equipment used in the various SMT production and testing phases is the annual "Directory of Suppliers to the Electronics Manufacturing Industry", published by Electronic Packaging and Production. Among the elements to consider in the selection of placement equipment, whether fully automated or X–Y-vacuum assist tables, are:

- volume of parts to be placed per hour
- conveyorized links to existing equipment
- packaging of components to be handled: tubes, reels, trays, bulk, etc.
- ability to download placement information from CAD/CAM systems
- ability to modify placement patterns by the operator
- vision capability needed, for board fiducials and/or fine-pitch parts

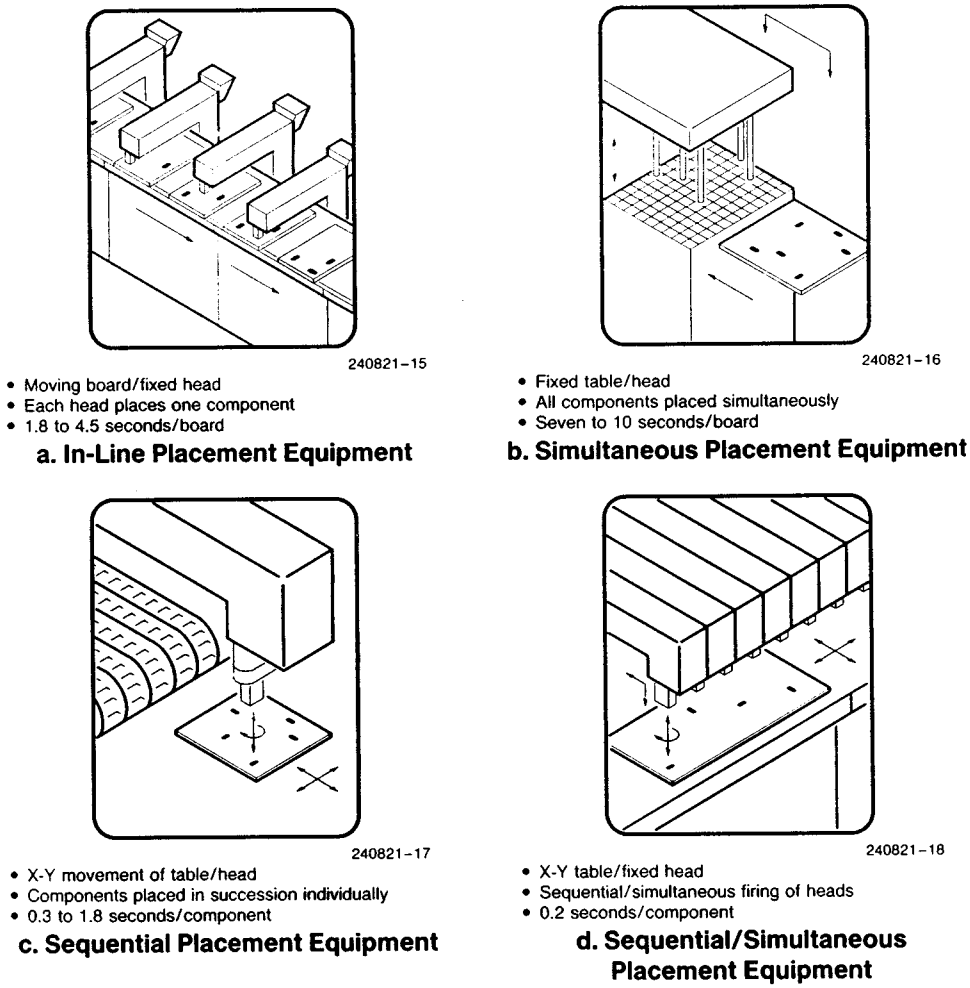

FIGURE 26.11 Four major categories of placement equipment. (*Source:* Intel Corporation, *Packaging,* Santa Clara, Calif.: Intel Corporation, 1994. With permission.)

Checks of new placement equipment, or in-place equipment when problems occur, should include:

- X-accuracy
- Y-accuracy
- Z-accuracy
- placement pressure
- vision system checks both downward and upward

It must be emphasized that placement accuracy checks cannot be made using standard circuit boards. Special glass plates with engraved measurement patterns and corresponding glass parts must be used because standard circuit boards and parts vary too widely to allow accurate X-, Y-, and Θ-measurements.

26.10 Reflow Soldering

Once SMDs have been placed in solder paste, the assembly will be reflow soldered. This can be done in either batch-type ovens or conveyorized continuous-process ovens. The choice depends primarily on the board throughput per hour required. While many early ovens were of the vapor phase type, most ovens today use

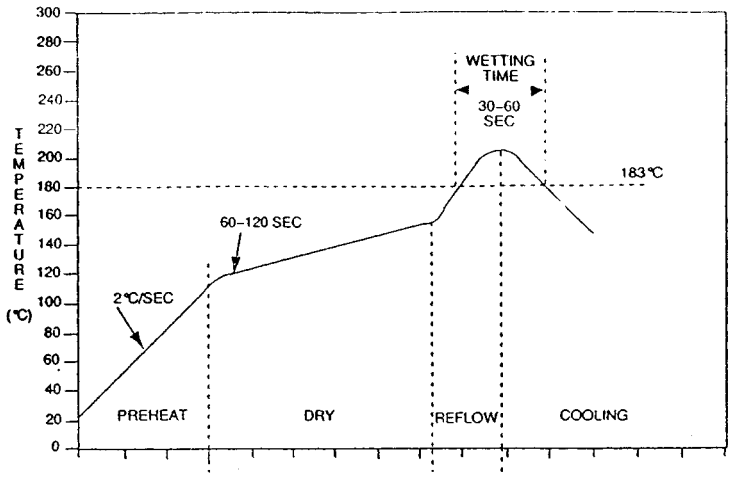

FIGURE 26.12 Typical thermal profile for SMT reflow soldering (Type I or II assemblies). (*Source:* Cox, N.R., *Reflow Technology Handbook,* Minneapolis, Minn.: Research, Inc., 1992. With permission.)

infrared (IR) heating, convection heating, or a combination of the two. In IR ovens the absorbance of the paste, parts, glue, etc. as a function of color should considered. Convection ovens tend to be more forgiving with variations in color and thermal masses on the substrates. This author does not recommend vapor phase (condensation heating) ovens to new users of SMT. All ovens are zoned to provide a thermal profile necessary for successful SMD soldering. An example of an oven profile is shown in Fig. 26.12, and the phases of reflow soldering that are reflected in that example include:

- Preheat: The substrate, components and solder paste preheat.
- Dry: Solvents evaporate from the solder paste. Flux activates, reduces oxides, and evaporates. Both low- and high-mass components have enough soak time to reach temperature equilibrium.
- Reflow: The solder paste temperature exceeds the liquidus point and reflows, wetting both the component leads and the board pads. Surface tension effects occur, minimizing wetted volume.
- Cooling: The solder paste cools below the liquidus point, forming acceptable (shiny and appropriate volume) solder joints.

The setting of the reflow profile is not trivial. It will vary on whether the flux is RMA, water soluble, or no clean, and it will vary depending on both the mix of low- and high-thermal mass components, and on how those components are laid out on the board. The profile should exceed the liquidus temperature of the solder paste by 20 to 25°C. While final setting of the profile will depend on actual quality of the solder joints formed

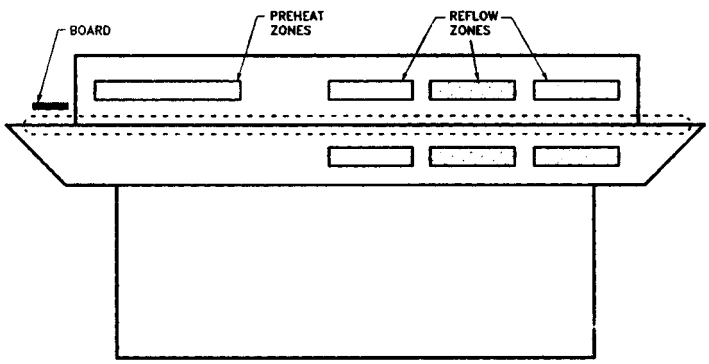

FIGURE 26.13 Conveyorized reflow oven showing zones which create the profile. (*Source:* Intel Corporation, *Packaging,* Santa Clara, Calif.: Intel Corporation, 1994. With permission.)

in the oven, initial profile setting should rely heavily on information from the solder paste vendor, as well as the oven manufacturer. Remember that the profile shown is the profile to be developed on the substrate, and the actual control settings in various stages of the oven itself may be considerably different, depending on the thermal inertia of the product in the oven and the heating characteristics of the particular oven being used. This should be determined not by the oven settings but by instrumenting actual circuit boards with thermocouples and determining that the profiles at various locations on the circuit board meet the specifications necessary for good soldering.

Defects as a result of poor profiling may include:

- component thermal shock
- solder splatter
- solder balls formation
- dewetted solder
- cold or dull solder joints

It should be noted that many other problems may contribute to defective solder joint formation. One example would be placement misalignment which contributes to the formation of solder bridges, as shown in Fig. 26.14.

Other problems that may contribute to defective solder joints include poor solder mask adhesion, and unequal solder land areas at opposite ends of passive parts, which creates unequal moments as the paste liquifies and develops surface tension. Wrong solder paste volumes, whether too much or too little, will create defects, as will board shake in placement machines and coplanarity problems in IC components. Many of these problems should be covered and compensated for during the design process and the qualification of SMT production equipment.

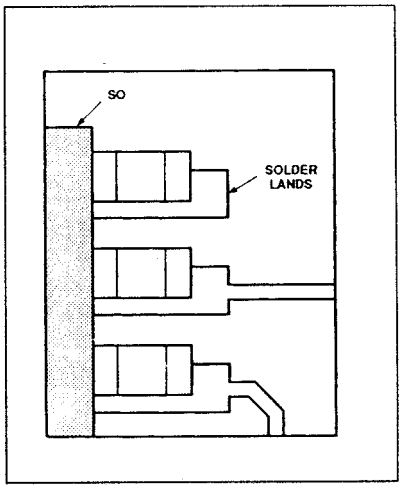

FIGURE 26.14 Solder bridge risk due to misalignment. (*Source:* Phillips Semiconductors, *Surface Mount Process and Application Notes,* Sunnyvale, Calif.: Phillips Semiconductors, 1991. With permission.)

Post-Reflow Inspection

Final analysis of the process is performed based on the quality of the solder joints formed in the reflow process. Whatever criteria may have been followed during the overall process, solder joint quality is the final determining factor of the correctness of the various process steps. As noted earlier, the quality level of solder joint production is a major factor in successful board assembly. A primary criteria is the indication of wetting at the junction of the reflowed solder and the part termination. This same criteria shown in Fig. 26.15 applies to both through-hole and SMDs, with only the inspection location being different.

Note that criteria shown in Fig. 26.15 are for any solderable surface, whether component or board, SMT or THT. Some lead surfaces are defined as not solderable, e.g., the cut and not-tinned end of an SO or QFP lead is not considered solderable. Parts manufacturers will define whether a given surface is designed to be solderable.

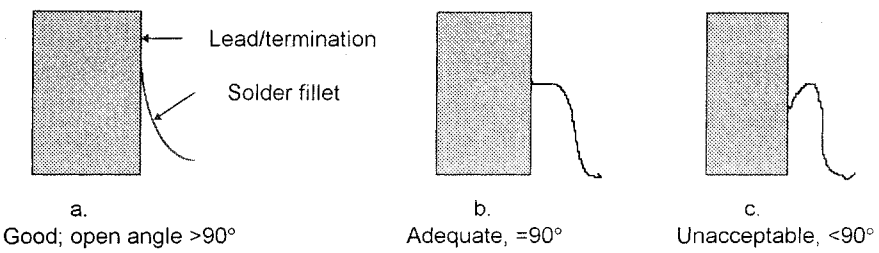

FIGURE 26.15 Solder joint inspection criteria.

Presentation of criteria for all the various SMD package types and all the possible solder joint problems is beyond the scope of this chapter. The reader is directed to Hollomon [1995], Hwang [1989], Lau [1991], Klein-Wassink [1989], and Prasad [1997] for an in-depth discussion of these issues.

26.11 Cleaning

Cleaning, like all other parts of the process, should be considered during the design phase. Cleaning requirements are determined largely by the flux in the solder paste, and should be determined before production is ever started. Design issues may effect the choice of flux, which determines cleaning. For example, low clearance (close to the substrate) parts are difficult to clean under, and the use of no-clean flux may be suggested.

Rosin Mildly Activated (RMA) is the old standard, and if cleaning is needed with RMA, either solvent-based cleaners or water with saponifiers must be used. (Saponifiers are alkaline materials that react with the rosin so that it becomes water-soluble.) RMA tends to be non-active at "room" temperatures, and may not need to be cleaned on commercial products designed for indoor use. The major limitation on RMA at this point is the need for chemicals in the cleaning process.

Water-soluble fluxes are designed to be cleaned with pure water. They remain active at room temperatures, and therefore *must* be cleaned when used. Beyond their activity, the other disadvantage to water soluble fluxes is that their higher surface tension relative to solvent-based cleaners means there is more difficulty cleaning under low-clearance components.

No-clean fluxes are designed to not be cleaned, and this means they are of low activity (they don't reduce oxides as well as other types of flux) and when used they should *not* be cleaned. No-clean fluxes are designed so that after reflow they microscopically encapsulate themselves, sealing in any active components. If the substrate is subsequently cleaned, the encapsulants may be destroyed, leaving the possibility of active flux components remaining on the board.

26.12 Prototype Systems

Systems for all aspects of SMT assembly are available to support low-volume/prototype needs. These systems will typically have manual solder-paste deposition and parts placement systems, with these functions being assisted for the user. Syringe solder paste deposition may be as simple as a manual medical-type syringe dispenser which must be guided and squeezed freehand. More sophisticated systems will have the syringe mounted on an X–Y arm to carry the weight of the syringe, and will apply air pressure to the top of the syringe with a foot-pedal control, freeing the operator's arm to guide the syringe to the proper location on the substrate and perform the negative z-axis maneuver which will bring the syringe tip into the proper location and height above the substrate. Dispensing is then accomplished by a timed air pressure burst applied to the top of the syringe under foot-pedal control. Paste volume is likewise determined by trial-and-error with the time/pressure relation and depends on the type and manufacturer of paste being dispensed.

Parts placement likewise may be as simple as tweezers and may progress to hand-held vacuum probes to allow easier handling of the components. As mentioned in the Section 26.9, X–Y arm/tables are available which have vacuum-pick nozzles to allow the operator to pick a part from a tray, reel, or stick, and move the part over the correct location on the substrate. The part is then moved down into the solder paste, the vacuum is turned off manually or automatically, and the nozzle is raised away from the substrate.

Soldering of prototype/low-volume boards may be done by contact soldering of each component, by a manually guided hot-air tool, or in a small batch or conveyorized oven. Each step up in soldering sophistication is, of course, accompanied by an increase in the investment required.

For manufacturers with large prototype requirements, it is possible to set up an entire line that would involve virtually no hardware changes from one board to another:

- ECAD design and analysis, producing Gerber files.
- CNC circuit board mill takes Gerber files and mills out two-sided boards.
- Software translation package generates solder-pad centroid information.

- Syringe solder paste deposition system takes translated Gerber file and dispenses appropriate amount at each pad centroid.
- Software translation package generates part centroid information.
- Parts placement equipment places parts based on translated part centroid information
- Assembly is reflow soldered.

The only manual process in the above system is adjustment of the reflow profile based on the results of soldering an assembly. The last step in the process would be to test the finished prototype board. This system could also be used for very small volume production runs, and all components as described are available. With a change from milled boards to etched boards, the system can be used as a flexible assembly system.

Defining Terms

Coefficient of thermal expansion (CTE, a.k.a. TCE): A measure of the ratio between the measure of a material and its expansion as temperature increases. May be different in X-, Y-, and Z-axes. Expressed in PPM/°C. A measure that allows comparison of materials that are to be joined.

Coplanarity: A simplified definition of planarity, which is difficult to measure. Coplanarity is the distance between the highest and lowest leads, and is easily measured by placing the IC on a flat surface such as a glass plate. The lowest leads will then rest on the plate, and the measured difference to the lead highest above the plate is the measurement of coplanarity.

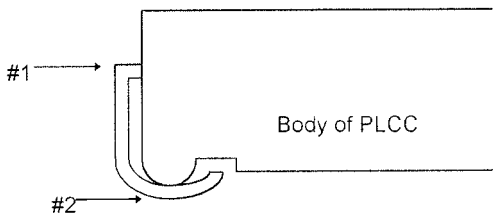
Glass transition temperature (T_g): Below T_g a polymer substance, such as fiberglass, is relatively linear in its expansion/contraction due to temperature changes. Above T_g, the expansion rate increases dramatically and becomes non-linear. The polymer will also lose its stability, i.e., an FR-4 board "droops" above T_g.

Gull wing: An SMD lead shape as shown in Fig. 26.4 for SOPs and QFPs, and in Fig. 26.11b. So called because it looks like a gull's wing in flight.

J-Lead: An SMD lead shape as shown in the PLCC definition. So called because it is in the shape of the capital letter J.

Land: A metallized area intended for the placement of one termination of a component. Lands may be tinned with solder, or be bare copper in the case of SMOBC circuit board fabrication.

PLCC: Plastic leaded chip carrier. Shown in Fig. 26.4, it is a common SMT IC package and is the only package that has the leads bent back under the IC itself.



Planarity: Lying in the same plane. A plane is defined by the exit of the leads from the body of the IC (arrow #1 above). A second plane is defined as the average of the lowest point all leads are below the first plane (arrow #2 above). Non-planarity is the maximum variation in mils or mm of any lead of an SMD from the lowest point plane.

Quad flat pack: Any flat pack IC package that has gull-wing leads on all four sides.

Through-hole: Also a plate-through-hole (PTH). A via that extends completely through a substrate and is solder-plated.

SMOBC: An acronym for "solder mask on bare copper", a circuit board construction technique that does not tin the copper traces with solder prior to the placement of the solder mask on the board.

Through-Hole Technology (THT): The technology of using leaded components that require holes through the substrate for their mounting (insertion) and soldering.

27.1 Ideal and Practical Models

E.J. Kennedy

The concept of the **operational amplifier** (usually referred to as an *op amp*) originated at the beginning of the Second World War with the use of vacuum tubes in dc amplifier designs developed by the George A. Philbrick Co. [some of the early history of operational amplifiers is found in Williams, 1991]. The op amp was the basic building block for early electronic servomechanisms, for synthesizers, and in particular for analog computers used to solve differential equations. With the advent of the first monolithic integrated-circuit (IC) op amp in 1965 (the μA709, designed by the late Bob Widlar, then with Fairchild Semiconductor), the availability of op amps was no longer a factor, while within a few years the cost of these devices (which had been as high as $200 each) rapidly plummeted to close to that of individual discrete transistors.

Although the digital computer has now largely supplanted the analog computer in mathematically intensive applications, the use of inexpensive operational amplifiers in instrumentation applications, in pulse shaping, in filtering, and in signal processing applications in general has continued to grow. There are currently many commercial manufacturers whose main products are high-quality op amps. This competitiveness has ensured a marketplace featuring a wide range of relatively inexpensive devices suitable for use by electronic engineers, physicists, chemists, biologists, and almost any discipline that requires obtaining quantitative analog data from instrumented experiments.

Most operational amplifier circuits can be analyzed, at least for first-order calculations, by considering the op amp to be an "ideal" device. For more quantitative information, however, and particularly when frequency response and dc offsets are important, one must refer to a more "practical" model that includes the internal limitations of the device. If the op amp is characterized by a really complete model, the resulting circuit may be quite complex, leading to rather laborious calculations. Fortunately, however, computer analysis using the program **SPICE** significantly reduces the problem to one of a simple input specification to the computer. Today, nearly all the op amp manufacturers provide SPICE models for their line of devices, with excellent correlation obtained between the computer simulation and the actual measured results.

The Ideal Op Amp

An **ideal operational amplifier** is a dc-coupled amplifier having two inputs and normally one output (although in a few infrequent cases there may be a differential output). The inputs are designated as noninverting (designated + or NI) and inverting (designated – or Inv.). The amplified signal is the *differential* signal, v_e, between the two inputs, so that the output voltage as indicated in Fig. 27.1 is

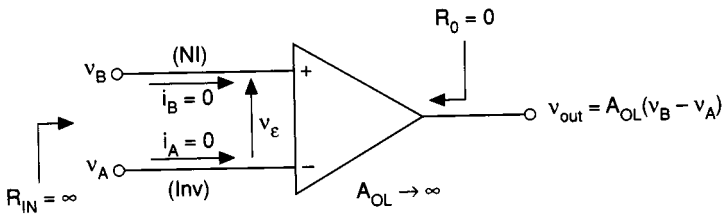

FIGURE 27.1 Configuration for an ideal op amp.

$$v_{out} = A_{OL}(v_B - v_A) \tag{27.1}$$

The general characteristics of an ideal op amp can be summarized as follows:

1. The open-loop gain A_{OL} is infinite. Or, since the output signal v_{out} is finite, then the differential input signal v_ε must approach zero.
2. The input resistance R_{IN} is infinite, while the output resistance R_O is zero.
3. The amplifier has zero current at the input (i_A and i_B in Fig. 27.1 are zero), but the op amp can either sink or source an infinite current at the output.
4. The op amp is not sensitive to a common signal on both inputs (i.e., $v_A = v_B$); thus, the output voltage change due to a common input signal will be zero. This common signal is referred to as a common-mode signal, and manufacturers specify this effect by an op amp's *common-mode rejection ratio* (CMRR), which relates the ratio of the open-loop gain (A_{OL}) of the op amp to the common-mode gain (A_{CM}). Hence, for an ideal op amp CMRR = ∞.
5. A somewhat analogous specification to the CMRR is the *power-supply rejection ratio* (PSRR), which relates the ratio of a power supply voltage change to an equivalent input voltage change produced by the change in the power supply. Because an ideal op amp can operate with any power supply, without restriction, then for the ideal device PSRR = ∞.
6. The gain of the op amp is not a function of frequency. This implies an infinite bandwidth.

Although the foregoing requirements for an ideal op amp appear to be impossible to achieve practically, modern devices can quite closely approximate many of these conditions. An op amp with a field-effect transistor (FET) on the input would certainly not have zero input current and infinite input resistance, but a current of <10 pA and an $R_{IN} = 10^{12}\ \Omega$ is obtainable and is a reasonable approximation to the ideal conditions. Further, although a CMRR and PSRR of infinity are not possible, there are several commercial op amps available with values of 140 dB (i.e., a ratio of 10^7). Open-loop gains of several precision op amps now have reached values of $>10^7$, although certainly not infinity. The two most difficult ideal conditions to approach are the ability to handle large output currents and the requirement of a gain independence with frequency.

Using the ideal model conditions it is quite simple to evaluate the two basic op amp circuit configurations, (1) the inverting amplifier and (2) the noninverting amplifier, as designated in Fig. 27.2.

For the ideal inverting amplifier, since the open-loop gain is infinite and since the output voltage v_o is finite, then the input differential voltage (often referred to as the *error signal*) v_ε must approach zero, or the input current is

$$i_I = \frac{v_I - v_\varepsilon}{R_1} = \frac{v_I - 0}{R_1} \tag{27.2}$$

The feedback current i_F must equal i_I, and the output voltage must then be due to the voltage drop across R_F, or

$$v_o = -i_F R_F + v_\varepsilon = -i_I R_F = -\left(\frac{R_F}{R_1}\right) v_I \tag{27.3}$$

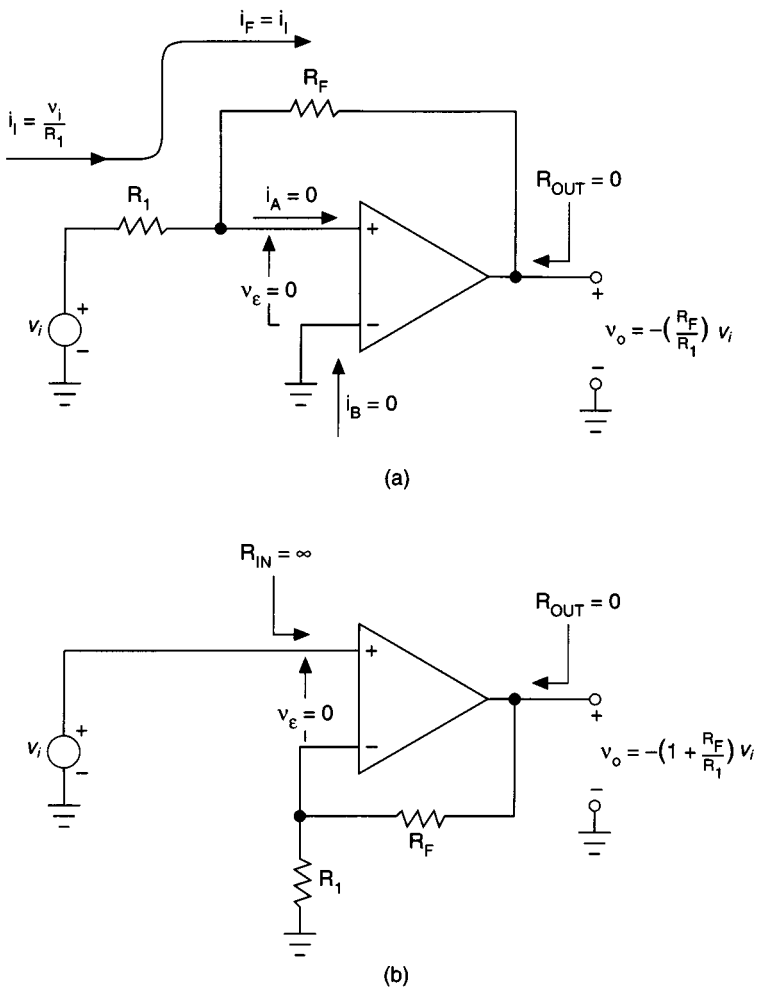

FIGURE 27.2 Illustration of (a) the inverting amplifier and (b) the noninverting amplifier. (*Source:* E.J. Kennedy, *Operational Amplifier Circuits, Theory and Applications,* New York: Holt, Rinehart and Winston, 1988, pp. 4, 6. With permission.)

The inverting connection thus has a voltage gain v_o/v_I of $-R_F/R_1$, an input resistance seen by v_I of R_1 ohms [from Eq. (27.2)], and an output resistance of 0 Ω. By a similar analysis for the noninverting circuit of Fig. 27.2(b), since v_ε is zero, then signal v_I must appear across resistor R_1, producing a current of v_I/R_1, which must flow through resistor R_F. Hence the output voltage is the sum of the voltage drops across R_F and R_1, or

$$v_o = R_F\left(\frac{v_I}{R_1}\right) + v_I = \left(1 + \frac{R_F}{R_1}\right)v_I \tag{27.4}$$

As opposed to the inverting connection, the input resistance seen by the source v_I is now equal to an infinite resistance, since R_{IN} for the ideal op amp is infinite.

Practical Op Amps

A nonideal op amp is characterized not only by finite open-loop gain, input and output resistance, finite currents, and frequency bandwidths, but also by various nonidealities due to the construction of the op amp circuit or external connections. A complete model for a practical op amp is illustrated in Fig. 27.3. The nonideal

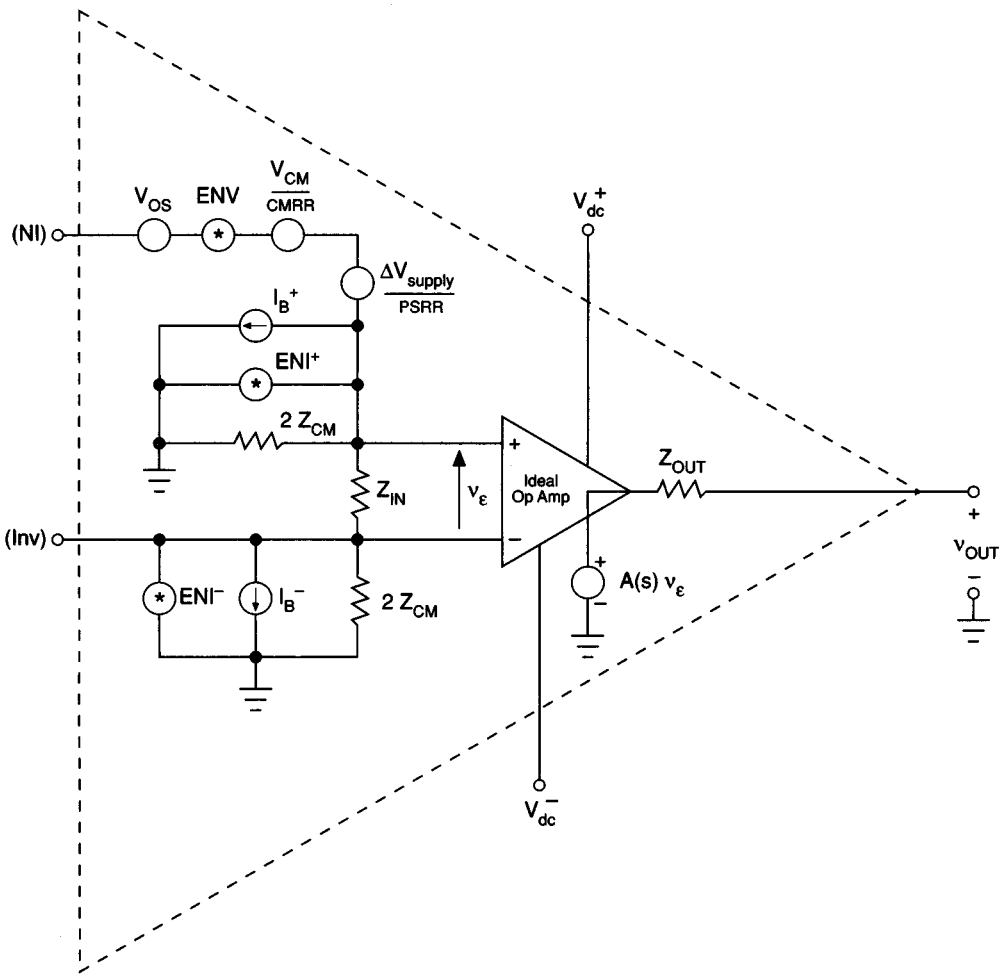

FIGURE 27.3 A model for a practical op amp illustrating nonideal effects. (*Source:* E.J. Kennedy, *Operational Amplifier Circuits, Theory and Applications,* New York: Holt, Rinehart and Winston, 1988, pp. 53, 126. With permission.)

effects of the PSRR and CMRR are represented by the input series voltage sources of ΔV_{supply}/PSRR and V_{CM}/CMRR, where ΔV_{supply} would be any total change of the two power supply voltages, V_{dc}^+ and V_{dc}^-, from their nominal values, while V_{CM} is the voltage common to both inputs of the op amp. The open-loop gain of the op amp is no longer infinite but is modeled by a network of the output impedance Z_{out} (which may be merely a resistor but could also be a series *R-L* network) in series with a source $A(s)$, which includes all the open-loop poles and zeroes of the op amp as

$$A(s) = \frac{A_{OL}\left(1 + \dfrac{s}{\omega_{Z_1}}\right)(1 + \cdots)}{\left(1 + \dfrac{s}{\omega_{p1}}\right)\left(1 + \dfrac{s}{\omega_{p2}}\right)(1 + \cdots)} \tag{27.5}$$

where A_{OL} is the finite dc open-loop gain, while poles are at frequencies ω_{p1}, ω_{p2}, . . . and zeroes are at ω_{Z1}, etc. The differential input resistance is Z_{IN}, which is typically a resistance R_{IN} in parallel with a capacitor C_{IN}. Similarly, the common-mode input impedance Z_{CM} is established by placing an impedance $2Z_{CM}$ in parallel

with each input terminal. Normally, Z_{CM} is best represented by a parallel resistance and capacitance of $2R_{CM}$ (which is >> R_{IN}) and $C_{CM}/2$. The dc bias currents at the input are represented by I_B^+ and I_B^- current sources that would equal the input base currents if a differential bipolar transistor were used as the input stage of the op amp, or the input gate currents if FETs were used. The fact that the two transistors of the input stage of the op amp may not be perfectly balanced is represented by an equivalent input *offset voltage* source, V_{OS}, in series with the input.

The smallest signal that can be amplified is always limited by the inherent random noise internal to the op amp itself. In Fig. 27.3 the noise effects are represented by an *equivalent input voltage source* (ENV), which when multiplied by the gain of the op amp would equal the total output noise present if the inputs to the op amp were shorted. In a similar fashion, if the inputs to the op amp were open circuited, the total output noise would equal the sum of the noise due to the *equivalent input current sources* (ENI^+ and ENI^-), each multiplied by their respective current gain to the output. Because noise is a random variable, this summation must be accomplished in a squared fashion, i.e.,

$$E_O^2\left(\text{rms volt}^2/\text{Hz}\right) = (\text{ENV})^2 A_v^2 + (\text{ENI}^+)^2 A_{I1}^2 + (\text{ENI}^-)^2 A_{12}^2 \tag{27.6}$$

Typically, the correlation (C) between the ENV and ENI sources is low, so the assumption of $C \approx 0$ can be made.

For the basic circuits of Fig. 27.2(a) or (b), if the signal source v_I is shorted then the output voltage due to the nonideal effects would be (using the model of Fig. 27.3)

$$v_o = \left(V_{OS} + \frac{V_{CM}}{\text{CMRR}} + \frac{\Delta V_{\text{supply}}}{\text{PSRR}}\right)\left(1 + \frac{R_F}{R_1}\right) + I_B^- R_F \tag{27.7}$$

provided that the loop gain (also called loop transmission in many texts) is related by the inequality

$$\left(\frac{R_1}{R_1 + R_F}\right) A(s) >> 1 \tag{27.8}$$

Inherent in Eq. (27.8) is the usual condition that $R_1 \ll Z_{IN}$ and Z_{CM}. If a resistor R_2 were in series with the noninverting input terminal, then a corresponding term must be added to the right hand side of Eq. (27.7) of value $-I_B^+ R_2 (R_1 + R_F)/R_1$. On manufacturers' data sheets the individual values of I_B^+ and I_B^- are not stated; instead the average input bias current and offset current are specified as

$$I_B = \frac{I_B^+ + I_B^-}{2}; \qquad I_{\text{offset}} = \left|I_B^+ - I_B^-\right| \tag{27.9}$$

The output noise effects can be obtained using the model of Fig. 27.3 along with the circuits of Fig. 27.2 as

$$\begin{aligned} E_{\text{out}}^2(\text{rms volts}^2/\text{Hz}) = {} & E_1^2\left(\frac{R_F}{R_1}\right)^2 + E_F^2 + (\text{ENV}^2 + E_2^2) \times \\ & \left(1 + \frac{R_F}{R_1}\right)^2 + (\text{ENI}^-)^2 R_F^2 + (\text{ENI}^+)^2 R_2^2 \left(1 + \frac{R_F}{R_1}\right)^2 \end{aligned} \tag{27.10}$$

where it is assumed that a resistor R_2 is also in series with the noninverting input of either Fig. 27.2(a) or (b). The thermal noise (often called Johnson or Nyquist noise) due to the resistors R_1, R_2, and R_F is given by (in rms volt^2/Hz)

$$E_1^2 = 4kT\,R_1$$
$$E_2^2 = 4kT\,R_2 \qquad (27.11)$$
$$E_F^2 = 4kT\,R_F$$

where k is Boltzmann's constant and T is absolute temperature (°Kelvin). To obtain the total output noise, one must multiply the E_{out}^2 expression of Eq. (27.10) by the noise bandwidth of the circuit, which typically is equal to $\pi/2$ times the –3 dB signal bandwidth, for a single-pole response system [Kennedy, 1988].

SPICE Computer Models

The use of op amps can be considerably simplified by computer-aided analysis using the program SPICE. SPICE originated with the University of California, Berkeley, in 1975 [Nagel, 1975], although more recent user-friendly commercial versions are now available such as HSPICE, HPSPICE, IS-SPICE, PSPICE, and ZSPICE, to mention a few of those most widely used. A simple macromodel for a near-ideal op amp could be simply stated with the SPICE subcircuit file (* indicates a comment that is not processed by the file)

```
.SUBCKT IDEALOA 1 2 3
*A near-ideal op amp: (1) is noninv, (2) is inv, and (3) is output.
RIN 1 2 1E12
E1 (3, 0) (1, 2) 1E8
.ENDS IDEALOA
```
(27.12)

The circuit model for IDEALOA would appear as in Fig. 27.4(a). A more complete model, but not including nonideal offset effects, could be constructed for the 741 op amp as the subcircuit file OA741, shown in Fig. 27.4(b).

```
.SUBCKT OA741 1 2 6
*A linear model for the 741 op amp: (1) is noninv, (2) is inv, and
*(6) is output. RIN = 2MEG, AOL = 200,000, ROUT = 75 ohm,
*Dominant open - loop pole at 5 Hz, gain - bandwidth product
*is 1 MHz.
RIN 1 2 2MEG
E1 (3, 0) (1, 2) 2E5
R1 3 4 100K
C1 4 0 0.318UF ; R1 × C1 = 5HZPOLE
E2 (5, 0) (4, 0) 1.0
ROUT 5 6 75
.ENDS OA741
```
(27.13)

The most widely used op amp macromodel that includes dc offset effects is the **Boyle model** [Boyle et al., 1974]. Most op amp manufacturers use this model, usually with additions to add more poles (and perhaps zeroes). The various resistor and capacitor values, as well as transistor, and current and voltage generator, values are intimately related to the specifications of the op amp, as shown earlier in the nonideal model of Fig. 27.3. The appropriate equations are too involved to list here; instead, the interested reader is referred to the article by Boyle in the listed references. The Boyle model does not accurately model noise effects, nor does it fully model PSRR and CMRR effects.

A more circuits-oriented approach to modeling op amps can be obtained if the input transistors are removed and a model formed by using passive components along with both fixed and dependent voltage and current sources. Such a model is shown in Fig. 27.5. This model not only includes all the basic nonideal effects of the op amp, allowing for multiple poles and zeroes, but can also accurately include ENV and ENI noise effects.

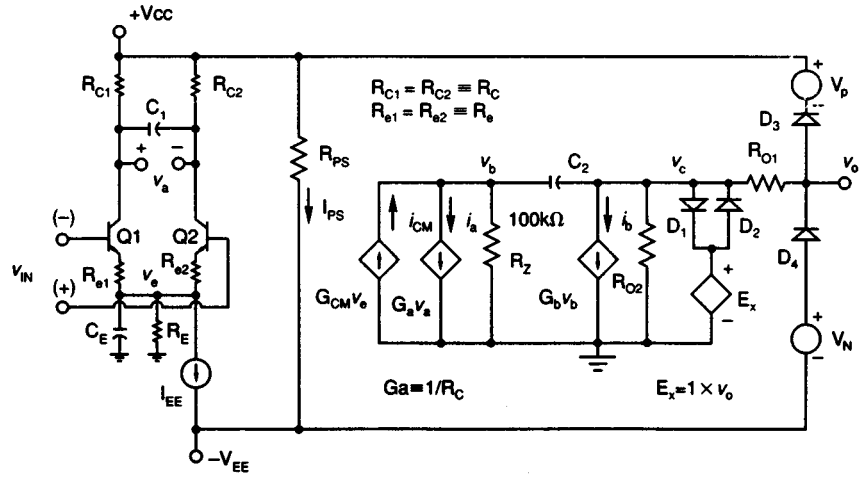
(b)



(c)

FIGURE 27.4 Some simple SPICE macromodels. (a) A near ideal op amp. (b) A linear model for a 741 op amp. (c) The *Boyle* macromodel.

The circuits-approach macromodel can also be easily adapted to current-feedback op amp designs, whose input impedance at the noninverting input is much greater than that at the inverting input [see Williams, 1991]. The interested reader is referred to the text edited by J. Williams, listed in the references, as well as the SPICE modeling book by Connelly and Choi [1992].

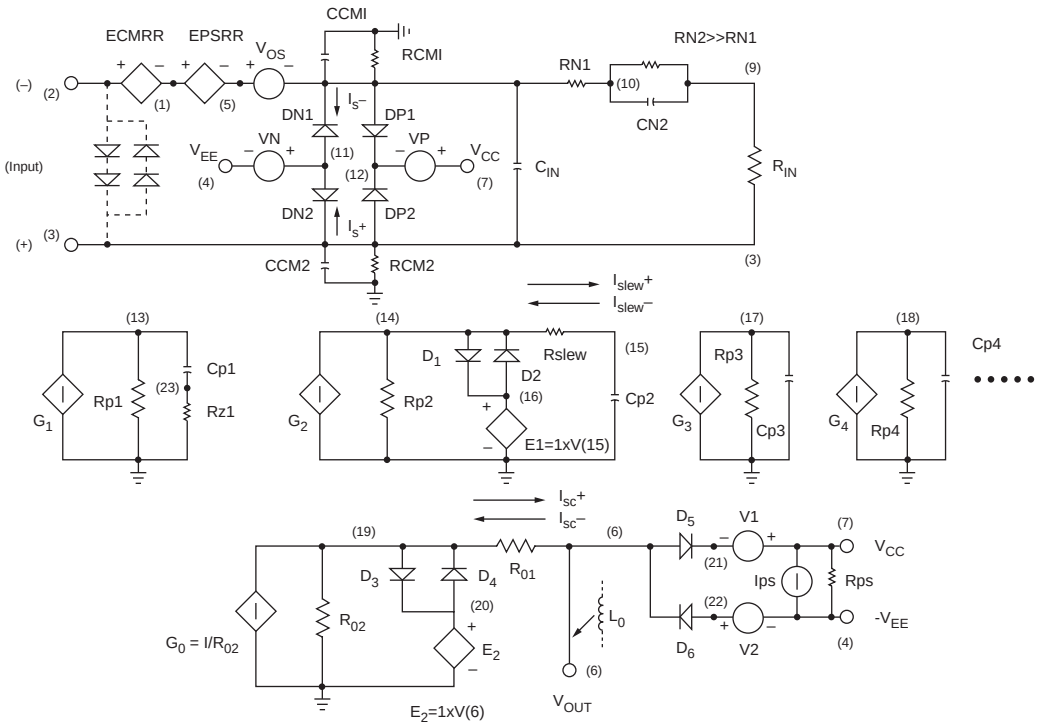


FIGURE 27.5 A SPICE circuits-approach macromodel.

A comparison of the SPICE macromodels with actual manufacturer's data for the case of an LM318 op amp is demonstrated in Fig. 27.6, for the open-loop gain versus frequency specification.

Defining Terms

Boyle macromodel: A SPICE computer model for an op amp. Developed by G.R. Boyle in 1974.

Equivalent noise current (ENI): A noise current source that is effectively in parallel with either the noninverting input terminal (ENI^+) or the inverting input terminal (ENI^-) and represents the total noise contributed by the op amp if either input terminal is open circuited.

Equivalent noise voltage (ENV): A noise voltage source that is effectively in series with either the inverting or noninverting input terminal of the op amp and represents the total noise contributed by the op amp if the inputs were shorted.

Ideal operational amplifier: An op amp having infinite gain from input to output, with infinite input resistance and zero output resistance and insensitive to the frequency of the signal. An ideal op amp is useful in first-order analysis of circuits.

Operational amplifier (op amp): A dc amplifier having both an inverting and noninverting input and normally one output, with a very large gain from input to output.

SPICE: A computer simulation program developed by the University of California, Berkeley, in 1975. Versions are available from several companies. The program is particularly advantageous for electronic circuit analysis, since dc, ac, transient, noise, and statistical analysis is possible.

27.2 Applications

John V. Wait

In microminiature form (epoxy or metal packages or as part of a VLSI mask layout) the **operational amplifier** (op amp) is usually fabricated in integrated circuit (IC) form. The general environment is shown in Fig. 27.7. A pair of + and – regulated power supplies (or batteries) may supply all of the op amp in a system, typically with $\pm 10 - \pm 15$ V. The ground and power supply buses are usually assumed, and an individual op-amp symbol is shown in Fig. 27.8. Such amplifiers feature:

1. A high voltage gain, down to and including dc, and a dc open loop gain of perhaps 10^5 (100 dB) or more
2. An inverting (–) and noninverting (+) symbol
3. Minimized dc offsets, a high input impedance, and a low output impedance
4. An output stage able to deliver or absorb currents over a dynamic range approaching the power supply voltages

It is important *never* to use the op amp without feedback between the output and inverting terminals at all frequencies. A simple inverting amplifier is shown in Fig. 27.9. Here the voltage gain is

$$V_{\text{out}} / V_{\text{in}} = -K = -R_F / R_1$$

The circuit gain is determined essentially by the external resistances, within the bandwidth and output-driving capabilities of the op amp (more later). If $R_F = R_1 = R$, we have the simple *unity gain inverter* of Fig. 27.10.

Figure 27.11 shows a more flexible *summer-inverter* circuit with

$$v_0 = -(K_1 v_1 + K_2 v_2 + \ldots + K_n v_n)$$

where $K_i = R_F / R_i$.

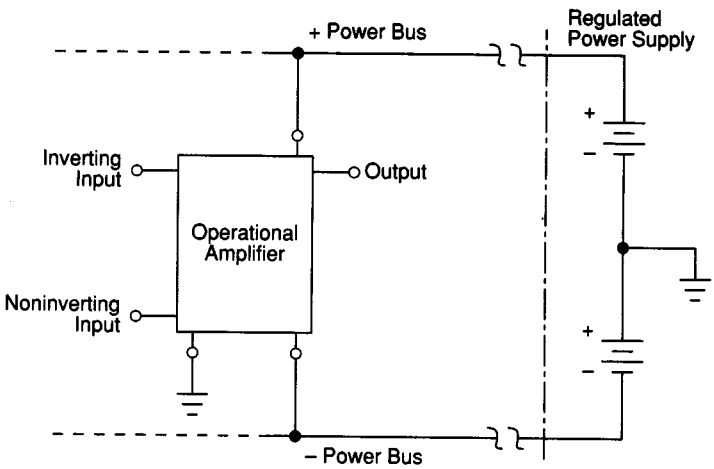

FIGURE 27.7 Typical operational amplifier environment.

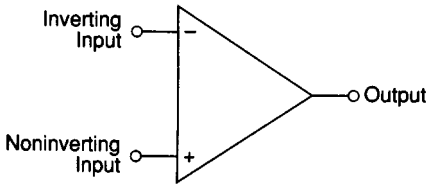

FIGURE 27.8 Conventional operational amplifier symbol. Only active signal lines are shown, and all signals are referenced to ground.

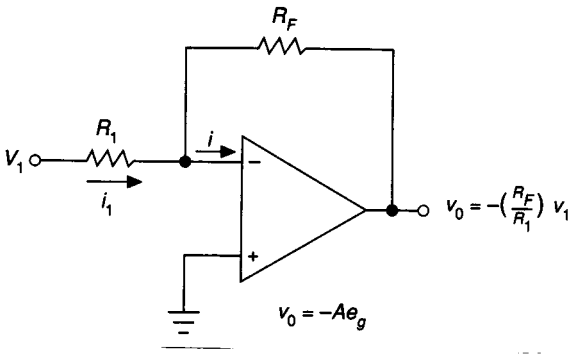

FIGURE 27.9 Simple resistive inverter-amplifier.

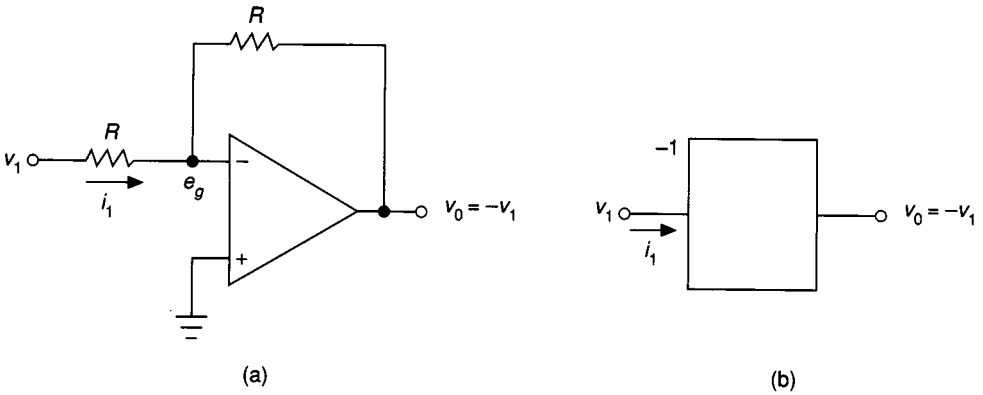

FIGURE 27.10 A simple unity gain inverter, showing (a) detailed circuit; (b) block-diagram symbol.

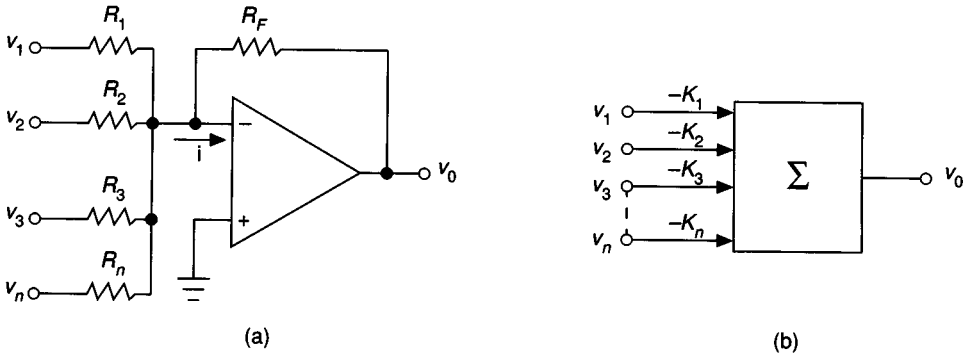

FIGURE 27.11 The summer-inverter circuit, showing (a) complete circuit; (b) block-diagram symbol.

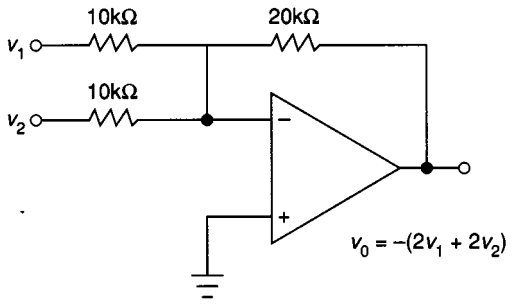

FIGURE 27.12 Simple summer-inverter.

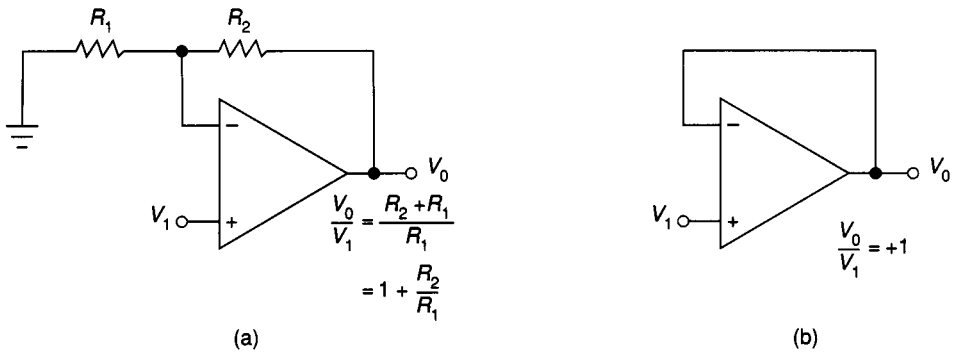

FIGURE 27.13 Noninverting amplifier circuit with resistive elements. (a) General circuit; (b) simple unity gain follower.

The summer-inverter is generally useful for precisely combining or mixing signals, e.g., summing and inverting. The signal levels must be appropriately limited but may generally be *bipolar* (+/–).

The resistance values should be in a proper range since (a) too low resistance values draw excessive current from the signal source, and (b) too high resistance values make the circuit performance too sensitive to stray capacitances and dc offset effects.

Typical values are from 1 MΩ and 10 kΩ. The circuit of Fig. 27.12 shows a circuit to implement

$$v_0 = -4v_1 - 2v_2$$

Noninverting Circuits

Figure 27.13(a) shows the useful *noninverting* amplifier circuit. It has a voltage gain

$$V_0/V_1 = (R_2 + R_1)/R_1$$
$$= 1 + (R_2/R_1)$$

Figure 27.13(b) shows the important unity gain follower circuit, which has a *very high input impedance,* which lightly loads the signal source but which can provide a reasonable amount of output current milliamps.

It is fairly easy to show that the *inverting first-order low-pass filter* of Fig. 27.14 has a dc gain or $-R_2/R_1$ and a –3-dB frequency = $1/(2\pi R_2 C)$.

Figure 27.15 shows a two-amplifier differentiator and high-pass filter circuit with a resistive input impedance and a low-frequency cutoff determined by R_1 and C.

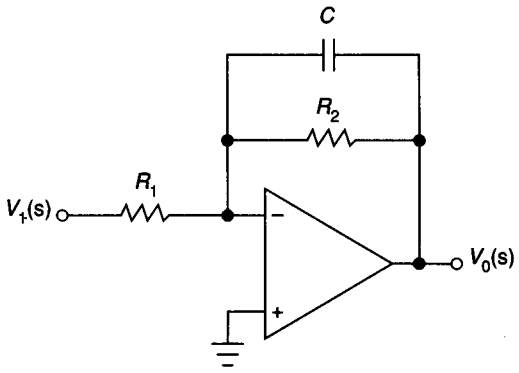

FIGURE 27.14 First-order low-pass filter circuit.

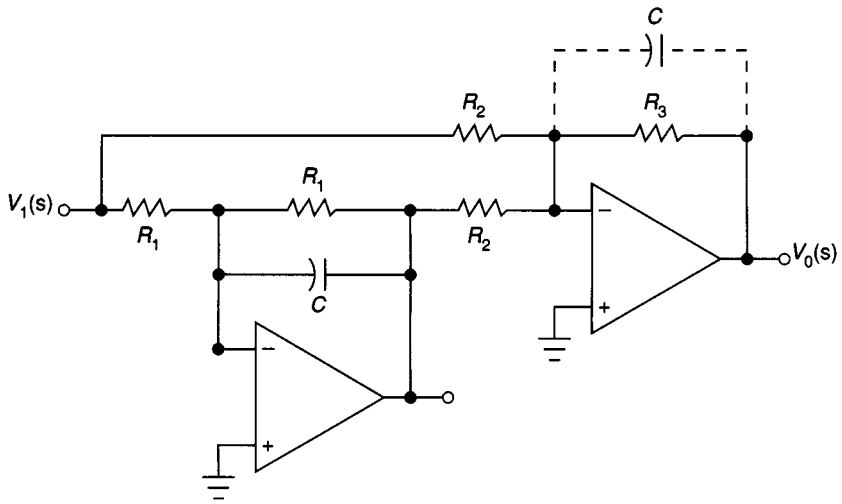

FIGURE 27.15 A two-amplifier high-pass circuit.

Op amps provide good differential amplifier circuits. Figure 27.16 is a single amplifier circuit with a differential gain

$$A_d = R_0/R_1$$

Good resistance matching is required to have good common-mode rejection of unwanted common-mode signals (static, 60-Hz hum, etc.). The one-amplifier circuit of Fig. 27.16 has a differential input impedance of $2R_1$. R_1 may be chosen to provide a good load for a microphone, phono-pickup, etc.

The improved three-amplifier instrumentation amplifier circuit of Fig. 27.17, which several manufacturers provide in a single module, provides

1. Very high voltage gain
2. Good common-mode rejection
3. A differential gain
4. High input impedance

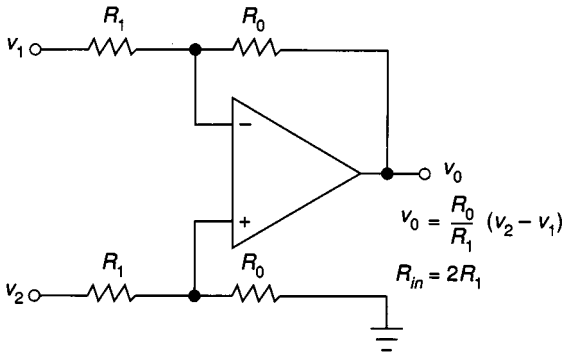

FIGURE 27.16 Single-output differential-input amplifier circuit.

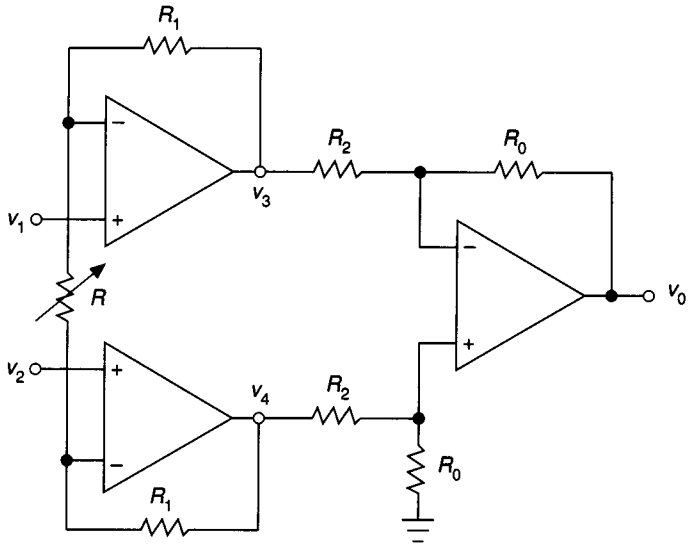

FIGURE 27.17 A three-amplifier differential-input instrumentation amplifier featuring high input impedance and easily adjustable gain.

$$A_d = -\frac{R_0}{R_2}\left(1 + \frac{2R_1}{R}\right)(V_2 - V_1)$$

Operational amplifier circuits form the heart of many precision circuits, e.g., regulated power supplies, precision comparators, peak-detection circuits, and waveform generators [Wait et al., 1992]. Another important area of application is **active RC filters** [Huelsman and Allen, 1980]. Microminiature electronic circuits seldom use inductors. Through the use of op amps, resistors, and capacitors, one can implement precise filter circuits (low-pass, high-pass, and bandpass). Figures 27.18 and 27.19 show second-order low-pass and bandpass filter circuits that feature relatively low sensitivity of filter performance to component values. Details are provided in Wait et al. [1992] and Huelsman and Allen [1980].

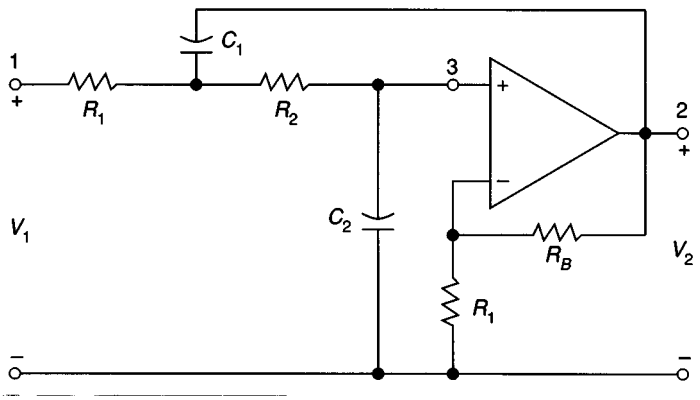

FIGURE 27.18 Sallen and Key low-pass filter.

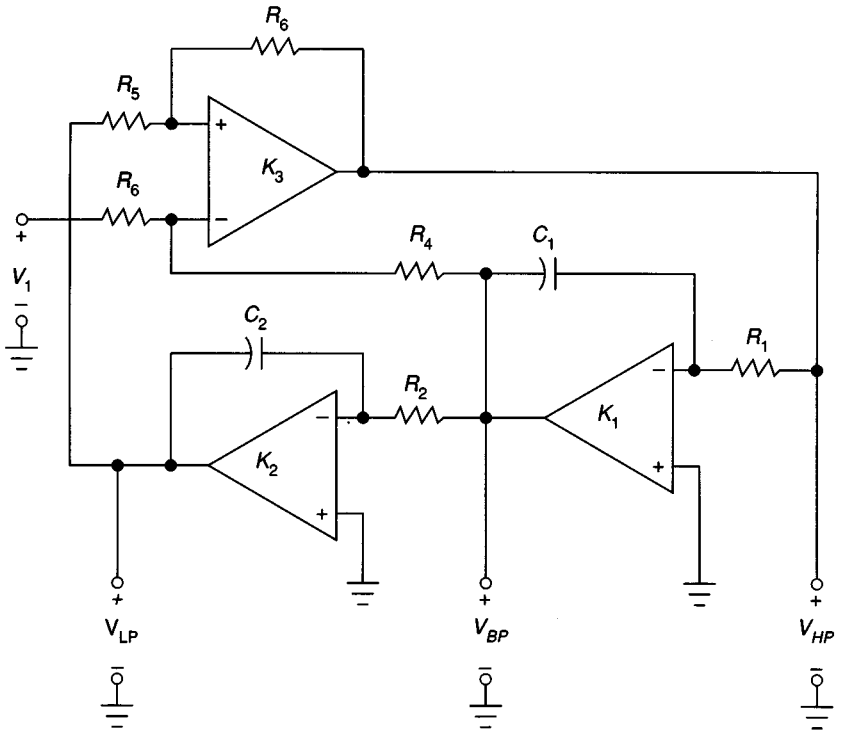

FIGURE 27.19 State-variable filter.

Of course, the op amp does not have infinite bandwidth and gain. An important op-amp parameter is the unity-gain frequency, f_u. For example, it is fairly easy to show the actual bandwidth of a constant gain amplifier of nominal gain G is approximately

$$f_{-3\text{ dB}} = f_u/G$$

Thus, an op amp with f_u = 1 MHz will provide an amplifier gain of 20 up to about 50 kHz.

When a circuit designer needs to accurately explore the performance of an op-amp circuit design, modern circuit simulation programs (SPICE, PSPICE, and MICRO-CAP) permit a thorough study of circuit design, as related to op-amp performance parameters. We have not here treated nonlinear op-amp performance limitations such as *slew rate, full-power bandwidth,* and *rated output.* Surely, the op-amp circuit designer must be careful not to exceed the output rating of the op amp, as related to *maximum output voltage* and *current* and *output rate-of-change.*

Nevertheless, op-amp circuits provide the circuit designer with a handy and straightforward way to complete electronic system designs with the use of only a few basic circuit components plus, of course, the operational amplifier.

Defining Terms

Active RC filter: An electronic circuit made up of resistors, capacitors, and operational amplifiers that provide well-controlled linear frequency-dependent functions, e.g., low-, high-, and bandpass filters.

Analog-to-digital converter (ADC): An electronic circuit that receives a magnitude-scaled analog voltage and generates a binary-coded number proportional to the analog input, which is delivered to an interface subsystem to a digital computer.

Digital-to-analog converter (DAC): An electronic circuit that receives an *n*-bit digital word from an interface circuit and generates an analog voltage proportional to it.

Electronic switch: An electronic circuit that controls analog signals with digital (binary) signals.

Interface: A collection of electronic modules that provide data transfer between analog and digital systems.

Operational amplifier: A small (usually integrated circuit) electronic module with a bipolar (+/–) output terminal and a pair of differential input terminals. It is provided with power and external components, e.g., resistors, capacitors, and semiconductors, to make amplifiers, filters, and wave-shaping circuits with well-controlled performance characteristics, relatively immune to environmental effects.

28.1 Large Signal Analysis

Gordon L. Carpenter

Large signal amplifiers are usually confined to using bipolar transistors as their solid state devices because of the large linear region of amplification required. One exception to this is the use of VMOS for large power outputs due to their ability to have a large linear region. There are three basic configurations of amplifiers: common emitter (CE) amplifiers, common base (CB) amplifiers, and common collection(CC) amplifiers. The basic configuration of each is shown in Fig. 28.1.

In an amplifier system, the last stage of a voltage amplifier string has to be considered as a large signal amplifier, and generally EF amplifiers are used as large signal amplifiers. This then requires that the dc bias or dc operating point (quiescent point) be located near the center of the load line in order to get the maximum output voltage swing. Small signal analysis can be used to evaluate the amplifier for voltage gain, current gain, input impedance, and output impedance, all of which are discussed later.

DC Operating Point

Each transistor connected in a particular amplifier configuration has a set of characteristic curves, as shown in Fig. 28.2.

When amplifiers are coupled together with capacitors, the configuration is as shown in Fig. 28.3. The load resistor is really the input impedance of the next stage. To be able to evaluate this amplifier, a dc equivalent circuit needs to be developed as shown in Fig. 28.4. This will result in the following dc bias equation:

$$I_{CQ} = \frac{V_{BB} - V_{BE}}{R_B/\text{beta} + R_E} \qquad \text{Assume } h_{FE} >> 1$$

where beta (h_{FE}) is the current gain of the transistor and V_{BE} is the conducting voltage across the base-emitter junction. This equation is the same for all amplifier configurations. Looking at Fig. 28.3, the input circuit can be reduced to the dc circuit shown in Fig. 28.4 using circuit analysis techniques, resulting in the following equations:

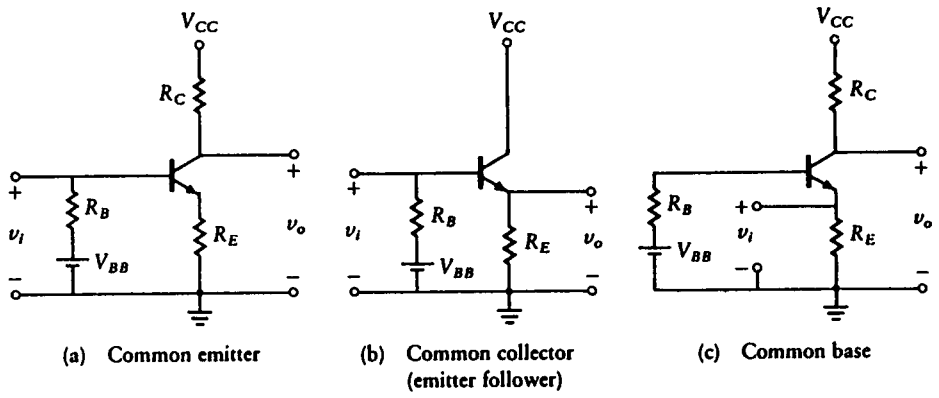

FIGURE 28.1 Amplifier circuits. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 80. With permission.)

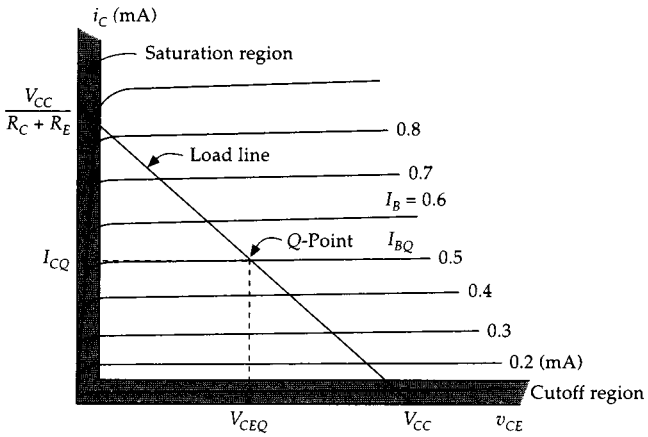

FIGURE 28.2 Transistor characteristic curves. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 82. With permission.)

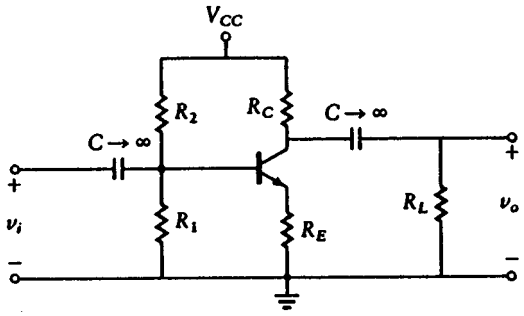

FIGURE 28.3 Amplifier circuit. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 92. With permission.)

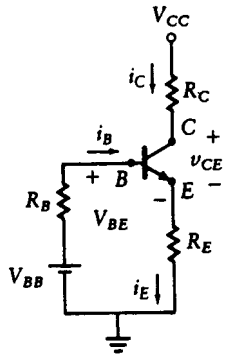

FIGURE 28.4 Amplifier equivalent circuit. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 82. With permission.)

$$V_{BB} = V_{TH} = V_{CC}(R_1)/(R_1 + R_2)$$

$$R_B = R_{TH} = R_1//R_2$$

For this biasing system, the Thévenin equivalent resistance and the Thévenin equivalent voltage can be determined. For design with the biasing system shown in Fig. 28.3, then:

$$R_1 = R_B/(1 - V_{BB}/V_{CC})$$

$$\mathrm{R_2 = R_B\ (V_{CC}/V_{BB})}$$

Graphical Approach

To understand the graphical approach, a clear understanding of the dc and ac load lines is necessary. The dc load line is based on the Kirchhoff's equation from the dc power source to ground (all capacitors open)

$$V_{CC} = v_{CE} + i_C R_{DC}$$

where R_{DC} is the sum of the resistors in the collector-emitter loop.

The ac load line is the loop, assuming the transistor is the ac source and the source voltage is zero, then

$$V'_{CC} = v_{ce} + i_C R_{ac}$$

where R_{ac} is the sum of series resistors in that loop with all the capacitors shorted. The load lines then can be constructed on the characteristic curves as shown in Fig. 28.5. From this it can be seen that to get the maximum output voltage swing, the quiescent point, or Q point, should be located in the middle of the ac load line. To place the Q point in the middle of the ac load line, I_{CQ} can be determined from the equation

$$I_{CQ} = V_{CC}/(R_{DC} + R_{ac})$$

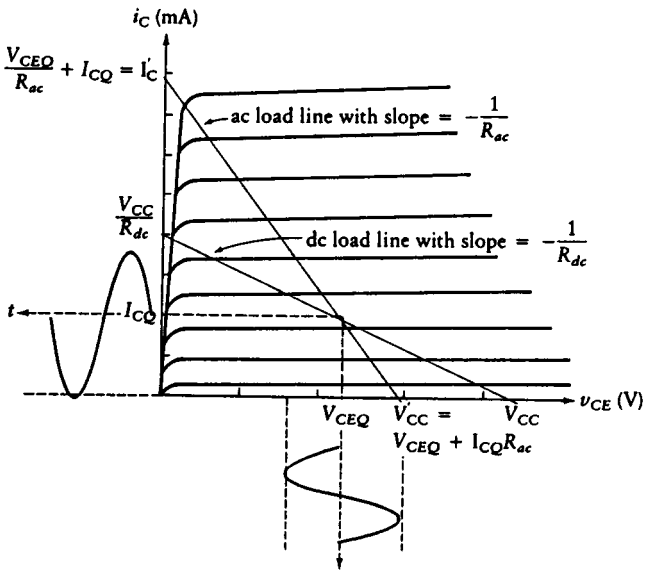

FIGURE 28.5 Load lines. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 94. With permission.)

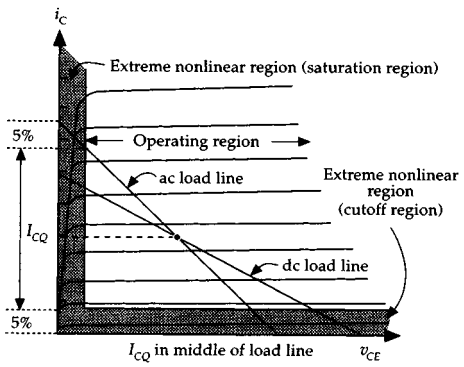

FIGURE 28.6 *Q* point in middle of load line. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 135. With permission.)

To minimize distortion caused by the cutoff and saturation regions, the top 5% and the bottom 5% are discarded. This then results in the equation (Fig. 28.6):

$$V_o \text{ (peak to peak)} = 2\ (0.9)\ I_{CQ}\ (R_C//R_L)$$

If, however, the *Q* point is not in the middle of the ac load line, the output voltage swing will be reduced. Below the middle of the ac load line [Fig. 28.7(a)]:

$$V_o \text{ (peak to peak)} = 2\ (I_{CQ} - 0.05\ I_{C\text{Max}})\ R_C//R_L$$

Above the middle of the ac load line [Fig. 28.7(b)]:

$$V_o \text{ (peak to peak)} = 2\ (0.95\ I_{C\text{Max}} - I_{CQ})\ R_C//R_L$$

These values allow the highest allowable input signal to be used to avoid any distortion by dividing the voltage gain of the amplifier into the maximum output voltage swing. The preceding equations are the same for the CB configuration. For the EF configurations, the R_C is changed to R_E in the equations.

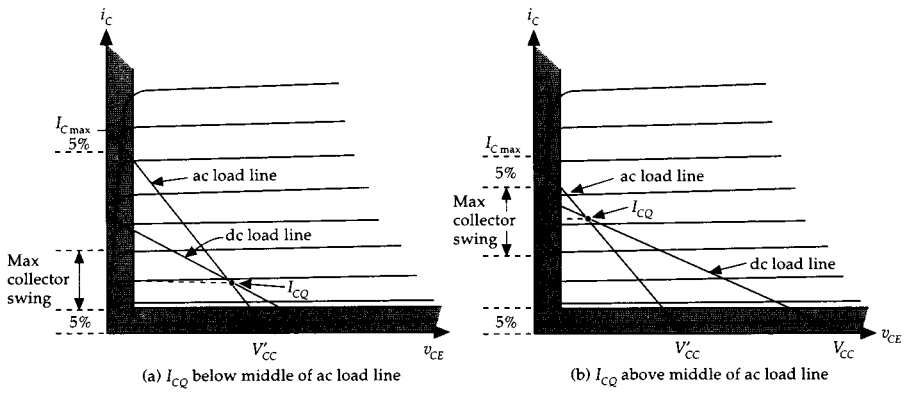

FIGURE 28.7 Reduced output voltage swing. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 136. With permission.)

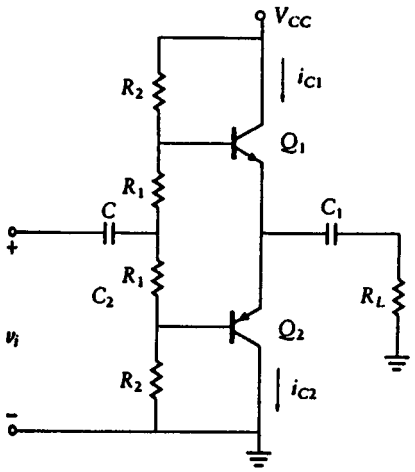

FIGURE 28.8 Complementary symmetry power amplifier. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 248. With permission.)

Power Amplifiers

Emitter followers can be used as power amplifiers. Even though they have less than unity voltage gain they can provide high current gain. Using the standard linear EF amplifier for a maximum output voltage swing provides less than 25% efficiency (ratio of power in to power out). The dc current carrying the ac signal is where the loss of efficiency occurs. To avoid this power loss, the Q point is placed at I_{CQ} equal to zero, thus using the majority of the power for the output signal. This allows the efficiency to increase to as much as 70%. Full signal amplification requires one transistor to amplify the positive portion of the input signal and another transistor to amplify the negative portion of the input signal. In the past, this was referred to as push-pull operation. A better system is to use an NPN transistor for the positive part of the input signal and a PNP transistor for the negative part. This type of operation is referred to as Class B complementary symmetry operation (Fig. 28.8).

In Fig. 28.8, the dc voltage drop across R_1 provides the voltage to bias the transistor at cutoff. Because these are power transistors, the temperature will change based on the amount of power the transistor is absorbing. This means the base-emitter junction voltage will have to change to keep $I_{CQ} = 0$. To compensate for this change in temperature, the R_1 resistors are replaced with diodes or transistors connected as diodes with the same turn-on characteristics as the power transistors. This type of configuration is referred to as the complementary symmetry diode compensated (CSDC) amplifier and is shown in Fig. 28.9. To avoid crossover distortion, small resistors can be placed in series with the diodes so that I_{CQ} can be raised slightly above zero to get increased amplification in the cutoff region. Another problem that needs to be addressed is the possibility of thermal runaway. This can be easily solved by placing small resistors in series with the emitters of the power transistors. For example, if the load is an 8-Ω speaker, the resistors should not be greater than 0.47 Ω to avoid output signal loss.

To design this type of amplifier, the dc current in the bias circuit must be large enough so that the diodes remain on during the entire input signal. This requires the dc diode current to be equal to or larger than the zero to peak current of the input signal, or

$$I_D \geq I_{ac}\,(0 \text{ to peak})$$

$$(V_{CC}/2 - V_{BE})/R_2 = I_B\,(0 \text{ to peak}) + V_L\,(0 \text{ to peak})/R_2$$

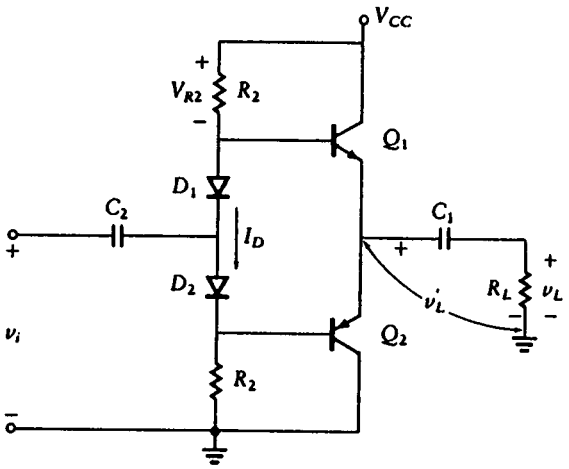

FIGURE 28.9 Complimentary symmetry diode compensated power amplifier. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 251. With permission.)

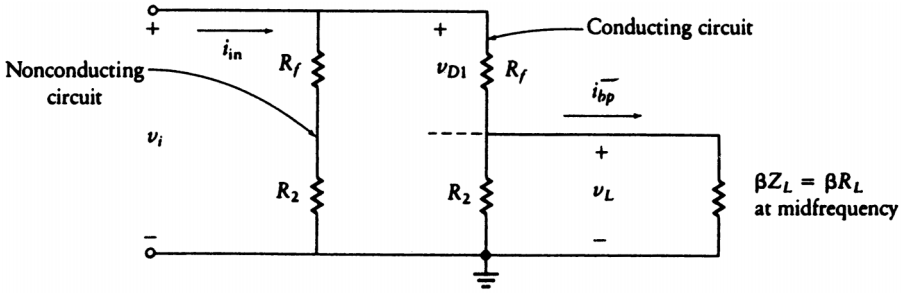

FIGURE 28.10 AC equivalent circuit of the CSDC amplifier. (*Source:* C.J. Savant, M. Roden, and G. Carpenter, *Electronic Design, Circuits and Systems,* 2nd ed., Redwood City, Calif.: Benjamin-Cummings, 1991, p. 255. With permission.)

When designing to a specific power, both I_B and V_L can be determined. This allows the selection of the value of R_2 and the equivalent circuit shown in Fig. 28.10 can be developed. Using this equivalent circuit, both the input resistance and the current gain can be shown. R_f is the forward resistance of the diodes.

$$R_{\text{in}} = (R_f + R_2)//[R_f + (R_2//\text{Beta}\, R_L)]$$

$$P_o = I_{\text{Cmax}} R_L/2$$

The power rating of the transistors to be used in this circuit should be greater than

$$P_{\text{rating}} = V_{CC}^2/(4\text{Pi}^2 R_L)$$

$$\text{C}_1 = 1/(2\text{Pi}\, f_{\text{low}} R_L)$$

$$C_2 = 10/[2\text{Pi}\, f_{\text{low}}(R_{\text{in}} + R_i)]$$

where R_i is the output impedance of the previous stage and f_{low} is the desired low frequency cutoff of the amplifier.

28.2 Small Signal Analysis

John Choma, Jr.

This section introduces the reader to the analytical methodologies that underlie the design of small signal, analog bipolar junction transistor (BJT) amplifiers. Analog circuit and system design entails complementing basic circuit analysis skills with the art of architecting a circuit topology that produces acceptable input-to-output (I/O) electrical characteristics. Because design is not the inverse of analysis, analytically proficient engineers are not necessarily adept at design. However, circuit and system analyses that conduce an insightful understanding of meaningful topological structures arguably foster design creativity. Accordingly, this section focuses more on the problems of interpreting analytical results in terms of their circuit performance implications than it does on enhancing basic circuit analysis skills. Insightful interpretation breeds engineering understanding. In turn, such an understanding of the electrical properties of circuits promotes topological refinements and innovations that produce reliable and manufacturable, high performance electronic circuits and systems.

Hybrid-Pi Equivalent Circuit

In order for a BJT to function properly in linear amplifier applications, it must operate in the forward active region of its volt–ampere characteristic curves. Two conditions ensure BJT operation in the forward domain. First, the applied emitter-base terminal voltage must forward bias the intrinsic emitter-base junction diode at all times. Second, the instantaneous voltage established across the base-collector terminals of the transistor must preclude a forward biased intrinsic base-collector diode. The simultaneous satisfaction of these two conditions requires appropriate biasing subcircuits, and it imposes restrictions on the amplitudes of applied input signals [Clarke and Hess, 1978].

The most commonly used BJT equivalent circuit for investigating the dynamical responses to small input signals is the **hybrid-pi model** offered in Fig. 28.11 [Sedra and Smith, 1987]. In this model, R_b, R_c, and R_e respectively, represent the *internal base, collector,* and *emitter resistances* of the considered BJT. Although these series resistances vary somewhat with quiescent operating point [de Graaf, 1969], they can be viewed as constants in first-order manual analyses.

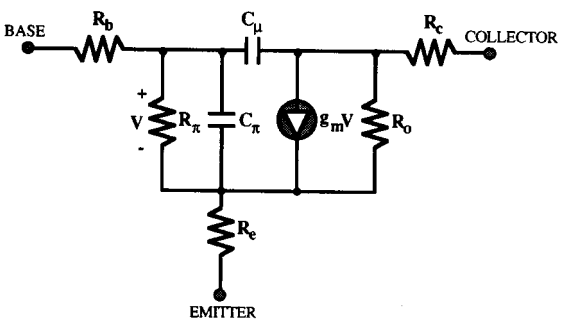

FIGURE 28.11 The small signal equivalent circuit (hybrid-pi model) of a bipolar junction transistor.

The *emitter-base junction diffusion resistance,* R_π, is the small signal resistance of the emitter-base junction diode. It represents the inverse of the slope of the common emitter static input characteristic curves. Analytically, R_π is given by

$$R_\pi = \frac{h_{FE} N_F V_T}{I_{CQ}} \tag{28.1}$$

where h_{FE} is the *static common emitter current gain* of the BJT, N_F is the *emitter-base junction injection coefficient*, V_T is the *Boltzmann voltage corresponding to an absolute junction operating temperature of T*, and I_{CQ} is the *quiescent collector current.*

The expression for the resistance, R_o, which accounts for *conductivity modulation* in the neutral base, is

$$R_o = \frac{V'_{CEQ} + V_{AF}}{I_{CQ}\left(1 - \dfrac{I_{CQ}}{I_{KF}}\right)} \tag{28.2}$$

where V_{AF} is the *forward Early voltage,* V'_{CEQ} is the quiescent voltage developed across the internal collector-emitter terminals, and I_{KF} symbolizes the *forward knee current.* The knee current is a measure of the onset of *high injection effects* [Gummel and Poon, 1970] in the base. In particular, a collector current numerically equal to I_{KF} implies that the forward biasing of the emitter-base junction promotes a net minority carrier charge injected into the base from the emitter that is equal to the background majority charge in the neutral base. The Early voltage is an inverse measure of the slope of the common emitter output characteristic curves.

The final low frequency parameter of the hybrid-pi model is the *forward transconductance*, g_m. This parameter, which is a measure of the forward small signal gain available at a quiescent operating point, is given by

$$g_m = \frac{I_{CQ}}{N_F V_T}\left(\frac{1 - \dfrac{I_{CQ}}{I_{KF}}}{1 + \dfrac{V_{CEQ'}}{V_{AF}}}\right) \tag{28.3}$$

Two capacitances, C_π and C_μ, are incorporated in the small signal model to provide a first-order approximation of steady-state transistor behavior at high signal frequencies. The capacitance, C_π, is the *net capacitance of the emitter-base junction diode* and is given by

$$C_\pi = \frac{C_{JE}}{\left(1 - \dfrac{V_E}{V_{JE} - 2V_T}\right)^{M_{JE}}} + \tau_f g_m \tag{28.4}$$

where the first term on the right-hand side represents the *depletion component* and the second term is the *diffusion component* of C_π. In Eq. (28.4), τ_f is the *average forward transit time of minority carriers in the field-neutral base*, C_{JE} is the *zero bias value of emitter-base junction depletion capacitance,* V_{JE} is the *built-in potential of the junction,* V_E is the *forward biasing voltage developed across the intrinsic emitter-base junction,* and M_{JE} is the *grading coefficient of the junction.* The capacitance, C_μ, has only a depletion component, owing to the reverse

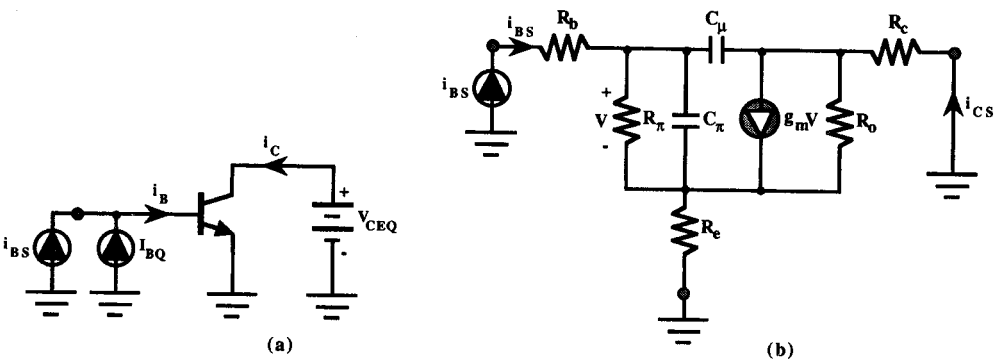

FIGURE 28.12 (a) Schematic diagram pertinent to the evaluation of the short circuit, common emitter, small signal current gain. (b) High frequency small signal model of the circuit in part (a).

(or at most zero) bias impressed across the internal base-collector junction. Accordingly, its analytical form is analogous to the first term on the right-hand side of Eq. (28.4). Specifically,

$$C_{\mu} = \frac{C_{JC}}{\left(1 - \dfrac{V_C}{V_{JC} - 2V_T}\right)^{M_{JC}}} \tag{28.5}$$

where the physical interpretation of C_{JC}, V_{JC}, and M_{JC} is analogous to C_{JE}, V_{JE}, and M_{JE}, respectively.

A commonly invoked figure of merit for assessing the high speed, small signal performance attributes of a BJT is the *common emitter,* **short circuit gain-bandwidth product,** ω_T, which is given by

$$\omega_T = \frac{g_m}{C_{\pi} + C_{\mu}} \tag{28.6}$$

The significance of Eq. (28.6) is best appreciated by studying the simple circuit diagram of Fig. 28.12(a), which depicts the grounded emitter configuration of a BJT biased for linear operation at a quiescent base current of I_{BQ} and a quiescent collector-emitter voltage of V_{CEQ}. Note that the battery supplying V_{CEQ} grounds the collector for small signal conditions. The small signal model of the circuit at hand is resultantly seen to be the topology offered in Fig. 28.12(b), where i_{BS} and i_{CS}, respectively, denote the signal components of the net instantaneous base current, i_B, and the net instantaneous collector current, i_C.

For negligibly small internal collector (R_c) and emitter (R_e) resistances, it can be shown that the *small signal, short circuit, high frequency common emitter current gain,* $\beta_{ac}(j\omega)$, is expressible as

$$\beta_{ac}(j\omega) \triangleq \frac{i_{CS}}{i_{BS}} = \frac{\beta_{ac}\left(1 - \dfrac{j\omega C_{\mu}}{g_m}\right)}{1 + \dfrac{j\omega}{\omega_{\beta}}} \tag{28.7}$$

where β_{ac}, the low frequency value of $\beta_{ac}(j\omega)$, or simply the *low frequency beta,* is

$$\beta_{ac} = \beta_{ac}(0) = g_m R_\pi \tag{28.8}$$

and

$$\omega_\beta = \frac{1}{R_\pi(C_\pi + C_\mu)} \tag{28.9}$$

symbolizes the so-called *beta cutoff frequency* of the BJT. Because the frequency, g_m/C_μ, is typically much larger than ω_β, ω_β is the approximate **3-dB bandwidth** of $\beta_{ac}(j\omega)$; that is,

$$\left|\beta_{ac}(j\omega_\beta)\right| \cong \frac{\beta_{ac}}{\sqrt{2}} \tag{28.10}$$

It follows that the corresponding *gain-bandwidth product*, ω_T, is the product of β_{ac} and ω_β, which, recalling Eq. (28.8), leads directly to the expression in Eq. (28.6). Moreover, in the neighborhood of ω_T,

$$\beta_{ac}(j\omega) \cong \frac{\beta_{ac}\omega_\beta}{j\omega} = \frac{\omega_T}{j\omega} \tag{28.11}$$

which suggests that ω_T is the approximate frequency at which the magnitude of the small signal, short circuit, common emitter current gain degrades to unity.

Hybrid-Pi Equivalent Circuit of a Monolithic BJT

The conventional hyprid-pi model in Fig. 28.11 generally fails to provide sufficiently accurate predictions of the high frequency response of monolithic diffused or implanted BJTs. One reason for this modeling inaccuracy is that the hybrid-pi equivalent circuit does not reflect the fact that monolithic transistors are often fabricated on lightly doped, noninsulating substrates that establish a distributed, large area, *pn* junction with the collector region. Since the substrate-collector *pn* junction is back biased in linear applications of a BJT, negligible static and low frequency signal currents flow from the collector to the substrate. At high frequencies, however, the depletion capacitance associated with the reverse biased substrate-collector junction can cause significant susceptive loading of the collector port. In Fig. 28.13, the lumped capacitance, C_{bb}, whose mathematical definition is similar to that of C_μ in Eq. (28.5), provides a first-order account of this collector loading. Observe that this substrate capacitance appears in series with a substrate resistance, R_{bb}, which reflects the light doping nature of the substrate material. For monolithic transistors fabricated on insulating or semi-insulating substrates, R_{bb} is a very large resistance, thereby rendering C_{bb} unimportant with respect to the problem of predicting steady-state transistor responses at high signal frequencies.

A problem that is even more significant than parasitic substrate dynamics stems from the fact that the hybrid-pi equivalent circuit in Fig. 28.11 is premised on a uniform transistor structure whose emitter-base and base-collector junction areas are identical. In a monolithic device, however, the effective base-collector junction area is much larger than that of the emitter-base junction because the base region is diffused or implanted into the collector [Glaser and Subak-Sharpe, 1977]. The effect of such a geometry is twofold. First, the actual value of C_μ is larger than the value predicated on the physical considerations that surround a simplified uniform structure BJT. Second, C_μ is not a single lumped capacitance that is incident with only the intrinsic base-collector junction. Rather, the effective value of C_μ is distributed between the intrinsic collector and the entire base-collector junction interface. A first-order account of this capacitance distribution entails partitioning C_μ in Fig. 28.11 into two capacitances, say $C_{\mu 1}$ and $C_{\mu 2}$, as indicated in Fig. 28.13. In general, $C_{\mu 2}$ is 3 to 5 times larger than $C_{\mu 1}$. Whereas $C_{\mu 1}$ is proportional to the emitter-base junction area, $C_{\mu 2}$ is proportional to the net base-collector junction area, less the area of the emitter-base junction.

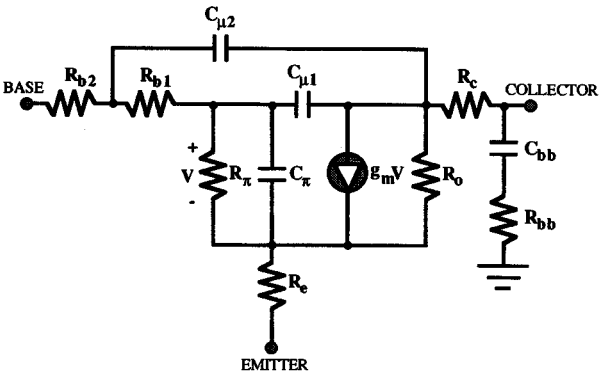

FIGURE 28.13 The hybrid-pi equivalent circuit of a monolithic bipolar junction transistor.

Just as $C_{\mu 1}$ and $C_{\mu 2}$ superimpose to yield the original C_μ in the simplified high frequency model of a BJT, the effective base resistances, R_{b1} and R_{b2}, sum to yield the original base resistance, R_b. The resistance, R_{b1}, is the *contact resistance* associated with the base lead and the inactive BJT base region. It is inversely proportional to the surface area of the base contact. On the other hand, R_{b2}, which is referred to as the *active base resistance*, is nominally an inverse function of emitter finger length. Because of submicron base widths and the relatively light average doping concentrations of active base regions, R_{b2} is significantly larger than R_{b1}.

Common Emitter Amplifier

The most commonly used canonic cell of linear BJT amplifiers is the *common emitter amplifier*, whose basic circuit schematic diagram is depicted in Fig. 28.14(a). In this diagram, R_{ST} is the Thévenin resistance of the applied signal source, V_{ST}, and R_{LT} is the effective, or Thévenin, load resistance driven by the amplifier. The signal source has zero average, or dc, value. Although requisite biasing is not shown in the figure, it is tacitly assumed that the transistor is biased for linear operation. Hence, the diagram at hand is actually the **ac schematic diagram**; that is, it delineates only the signal paths of the circuit. Note that in the common emitter orientation, the input signal is applied to the base of the transistor, while the resultant small signal voltage response, V_{OS}, is extracted at the transistor collector.

The hybrid-pi model of Fig. 28.11 forms the basis for the small signal equivalent circuit of the common emitter cell, which is given in Fig. 28.14(b). In this configuration, the capacitance, C_o, represents an effective output port capacitance that accounts for both substrate loading of the collector port (if the BJT is a monolithic device) and the net effective shunt capacitance associated with the load.

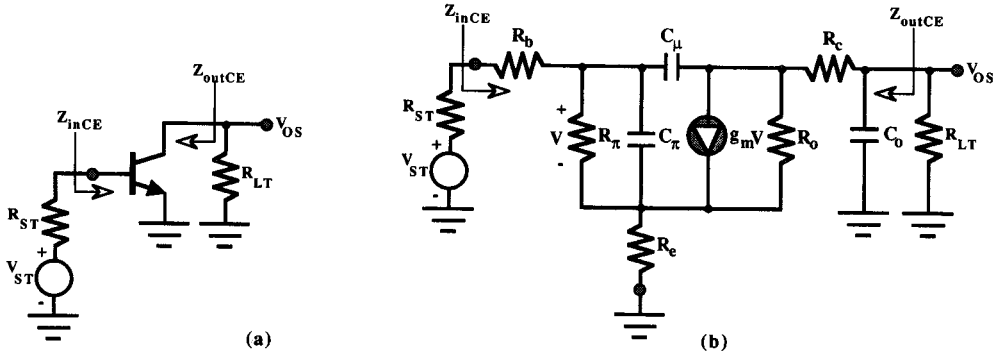

FIGURE 28.14 (a) AC schematic diagram of a common emitter amplifier. (b) Modified small signal, high frequency equivalent circuit of common emitter amplifier.

At low signal frequencies, the capacitors, C_π, C_μ, and C_o in the model of Fig. 28.14(b), can be replaced by open circuits. A straightforward circuit analysis of the resultantly simplified equivalent circuit produces analytical expressions for the low frequency values of the small signal *voltage gain*, $A_{vCE} = V_{OS}/V_{ST}$; the *driving point input impedance*, $Z_{\text{in}CE}$; and the *driving point output impedance*, $Z_{\text{out}CE}$. Because the Early resistance, R_o, is invariably much larger than the resistance sum $(R_c + R_e + R_{LT})$, the low frequency voltage gain of the common emitter cell is expressible as

$$A_{vCE}(0) \cong -\left[\frac{\beta_{ac} R_{LT}}{R_{ST} + R_b + R_\pi + (\beta_{ac} + 1)R_e}\right] \tag{28.12}$$

For large R_o, conventional circuit analyses also produce a low frequency driving point input resistance of

$$R_{\text{in}CE} = Z_{\text{in}CE}(0) \cong R_b + R_\pi + (\beta_{ac} + 1)R_e \tag{28.13}$$

and a low frequency driving point output resistance of

$$R_{\text{out}CE} = Z_{\text{out}CE}(0) \cong \left(\frac{\beta_{ac} R_e}{R_e + R_b + R_\pi + R_{ST}} + 1\right) R_o \tag{28.14}$$

At high signal frequencies, the capacitors in the small signal equivalent circuit of Fig. 28.14(b) produce a third-order voltage gain frequency response whose analytical formulation is algebraically cumbersome [Singhal and Vlach, 1977; Haley, 1988]. However, because the poles produced by these capacitors are real, lie in the left half complex frequency plane, and generally have widely separated frequency values, the dominant pole approximation provides an adequate estimate of high frequency common emitter amplifier response in the usable passband of the amplifier. Accordingly, the high frequency voltage gain, say $A_{vCE}(s)$, of the common emitter amplifier can be approximated as

$$A_{vCE}(s) \cong A_{vCE}(0)\left[\frac{1 + sT_{zCE}}{1 + sT_{pCE}}\right] \tag{28.15}$$

In this expression, T_{pCE} is of the form,

$$T_{pCE} = R_{C\pi} C_\pi + R_{C\mu} C_\mu + R_{Co} C_o \tag{28.16}$$

where $R_{C\pi}$, $R_{C\mu}$, and R_{Co}, respectively, represent the Thévenin resistances seen by the capacitors, C_π, C_μ, and C_o, under the conditions that (1) all capacitors are supplanted by open circuits and (2) the independent signal generator, V_{ST}, is reduced to zero. Analogously, T_{zCE} is of the form

$$T_{zCE} = R_{C\pi o} C_\pi + R_{C\mu o} C_\mu + R_{Coo} C_o \tag{28.17}$$

where $R_{C\pi o}$, $R_{C\mu o}$, and R_{Coo}, respectively, represent the Thévenin resistances seen by the capacitors, C_π, C_μ, and C_o, under the conditions that (1) all capacitors are supplanted by open circuits and (2) the output voltage response, V_{OS}, is constrained to zero while maintaining nonzero input signal source voltage. It can be shown that when R_o is very large and R_c is negligibly small,

$$R_{C\pi} = \frac{R_\pi \| (R_{ST} + R_b + R_e)}{1 + \dfrac{\beta_{ac} R_e}{R_{ST} + R_b + R_\pi + R_e}} \tag{28.18}$$

$$R_{C\mu} = (R_{LT} + R_c) + \{(R_{ST} + R_b) \| [R_\pi + (\beta_{ac} + 1)R_e]\} \left[1 + \frac{\beta_{ac}(R_{LT} + R_c)}{R_\pi + (\beta_{ac} + 1)R_e}\right] \tag{28.19}$$

and

$$R_{Co} = R_{LT} \tag{28.20}$$

Additionally, $R_{C\pi o} = R_{Coo} = 0$, and

$$R_{C\mu o} = -\frac{R_\pi + (\beta_{ac} + 1)R_e}{\beta_{ac}} \tag{28.21}$$

Once T_{pCE} and T_{zCE} are determined, the 3-dB voltage gain bandwidth, B_{CE}, of the common emitter amplifier can be estimated in accordance with

$$B_{CE} \cong \frac{1}{T_{pCE}\sqrt{1 - 2\left(\dfrac{T_{zCE}}{T_{pCE}}\right)^2}} \tag{28.22}$$

The high frequency behavior of both the driving point input and output impedances, $Z_{\text{in}CE}(s)$ and $Z_{\text{out}CE}(s)$, respectively, can be approximated by mathematical functions whose forms are analogous to the gain expression in Eq. (28.15). In particular,

$$Z_{\text{in}CE}(s) \cong R_{\text{in}CE}\left[\frac{1 + sT_{zCE1}}{1 + sT_{pCE1}}\right] \tag{28.23}$$

and

$$Z_{\text{out}CE}(s) \cong R_{\text{out}CE}\left[\frac{1 + sT_{zCE1}}{1 + sT_{pCE2}}\right] \tag{28.24}$$

where $R_{\text{in}CE}$ and $R_{\text{out}CE}$ are defined by Eqs. (28.13) and (28.14). The dominant time constants, T_{pCE1}, T_{zCE1}, T_{pCE2}, and T_{zCE2}, derive directly from Eqs. (28.16) and (28.17) in accordance with [Choma and Witherspoon, 1990]

$$T_{pCE1} = \lim_{R_{ST} \to \infty} [T_{pCE}] \tag{28.25}$$

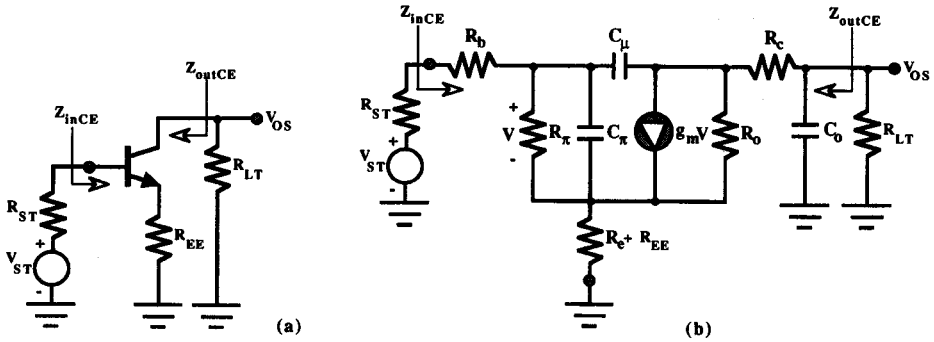

FIGURE 28.15 (a) AC schematic diagram of a common emitter amplifier using an emitter degeneration resistance. (b) Small signal, high frequency equivalent circuit of amplifier in part (a).

$$T_{zCE1} = \lim_{R_{ST} \to 0} [T_{pCE}] \tag{28.26}$$

$$T_{pCE2} = \lim_{R_{LT} \to \infty} [T_{pCE}] \tag{28.27}$$

and

$$T_{zCE2} = \lim_{R_{LT} \to 0} [T_{pCE}] \tag{28.28}$$

For reasonable values of transistor model parameters and terminating resistances, $T_{pCE1} > T_{zCE1}$, and $T_{pCE2} > T_{zCE2}$. It follows that both the input and output ports of a common emitter canonic cell are capacitive at high signal frequencies.

Design Considerations for the Common Emitter Amplifier

Equation (28.12) underscores a serious shortcoming of the canonical common emitter configuration. In particular, since the internal emitter resistance of a BJT is small, the low frequency voltage gain is sensitive to the processing uncertainties that accompany the numerical value of the small signal beta. The problem can be rectified at the price of a diminished voltage gain magnitude by inserting an *emitter degeneration resistance*, R_{EE}, in series with the emitter lead, as shown in Fig. 28.15(a). Since R_{EE} appears in series with the internal emitter resistance, R_e, as suggested in Fig. 28.15(b), the impact of emitter degeneration can be assessed analytically by replacing R_e in Eqs. (28.12) through (28.28) by the resistance sum $(R_e + R_{EE})$. For sufficiently large R_{EE}, such that

$$R_e + R_{EE} \cong R_{EE} >> \frac{R_{ST} + R_b + R_\pi}{\beta_{ac} + 1} \tag{28.29}$$

the low frequency voltage gain becomes

$$A_{vCE}(0) \cong -\frac{\alpha_{ac} R_{LT}}{R_{EE}} \tag{28.30}$$

where α_{ac}, which symbolizes the *small signal, short circuit, common base current gain*, or simply the *ac alpha*, of the transistor is given by

$$\alpha_{ac} = \frac{\beta_{ac}}{\beta_{ac} + 1} \tag{28.31}$$

Despite numerical uncertainties in β_{ac}, minimum values of β_{ac} are much larger than one, thereby rendering the voltage gain in Eq. (28.30) almost completely independent of small signal BJT parameters.

A second effect of emitter degeneration is an increase in both the low frequency driving point input and output resistances. This contention is confirmed by Eq. (28.13), which shows that if R_o remains much larger than $(R_c + R_e + R_{EE} + R_{LT})$, a resistance in the amount of $(\beta_{ac} + 1)R_{EE}$ is added to the input resistance established when the emitter of a common emitter amplifier is returned to signal ground. Likewise, Eq. (28.14) verifies that emitter degeneration increases the low frequency driving point output resistance. In fact, a very large value of R_{EE} produces an output resistance that approaches a limiting value of $(\beta_{ac} + 1)R_o$. It follows that a common emitter amplifier that exploits emitter degeneration behaves as a voltage-to-current converter at low signal frequencies. In particular, its high input resistance does not incur an appreciable load on signal voltage sources that are characterized by even moderately large Thévenin resistances, while its large output resistance comprises an almost ideal current source at its output port.

A third effect of emitter degeneration is a decrease in the effective pole time constant, T_{pCE}, as well as an increase in the effective zero time constant, T_{zCE}, which can be confirmed by reinvestigating Eqs. (28.18) through (28.21) for the case of R_e replaced by the resistance sum $(R_e + R_{EE})$. The use of an emitter degeneration resistance therefore promotes an increased 3-dB circuit bandwidth. Unfortunately, it also yields a diminished circuit gain-bandwidth product; that is, a given emitter degeneration resistance causes a degradation in the low frequency gain magnitude that is larger than the corresponding bandwidth increase promoted by this resistance. This deterioration of circuit gain-bandwidth product is a property of all *negative feedback circuits* [Choma, 1984].

For reasonable values of the emitter degeneration resistance, R_{EE}, the Thévenin time constant, $R_{C\mu}C_\mu$, is likely to be the dominant contribution to the effective first-order time constant, T_{pCE}, attributed to the poles of a common emitter amplifier. Hence, C_μ is the likely device capacitance that dominantly imposes an upper limit to the achievable 3-dB bandwidth of a common emitter cell. The reason for this substantial bandwidth sensitivity to C_μ is the so-called Miller multiplication factor, say M, which appears as the last bracketed term on the right-hand side of Eq. (28.19), namely,

$$M = 1 + \frac{\beta_{ac}(R_{LT} + R_c)}{R_\pi + (\beta_{ac} + 1)R_e} \tag{28.32}$$

The Miller factor, M, which effectively multiplies C_μ in the expression for $R_{C\mu}C_\mu$, increases sharply with the load resistance, R_{LT}, and hence with the gain magnitude of the common emitter amplifier. Note that in the limit of a large emitter degeneration resistance (which adds directly to R_e), Eq. (28.30) reduces Eq. (28.32) to the factor

$$M \cong 1 + \left|A_{vCE}(0)\right| \tag{28.33}$$

Common Base Amplifier

A second canonic cell of linear BJT amplifiers is the *common base amplifier*, whose ac circuit schematic diagram appears in Fig. 28.16(a). In this diagram, R_{ST}, V_{ST}, R_{LT}, and V_{OS} retain the significance they respectively have in the previously considered common emitter configuration. Note that in the common base orientation, the input signal is applied to the base, while the resultant small signal voltage response is extracted at the collector of a transistor.

The relevant small signal model is shown in Fig. 28.16(b). A straightforward application of Kirchhoff's circuit laws gives, for the case of large R_o, a low frequency voltage gain, $A_{vCB}(0) = V_{OS}/V_{ST}$, of

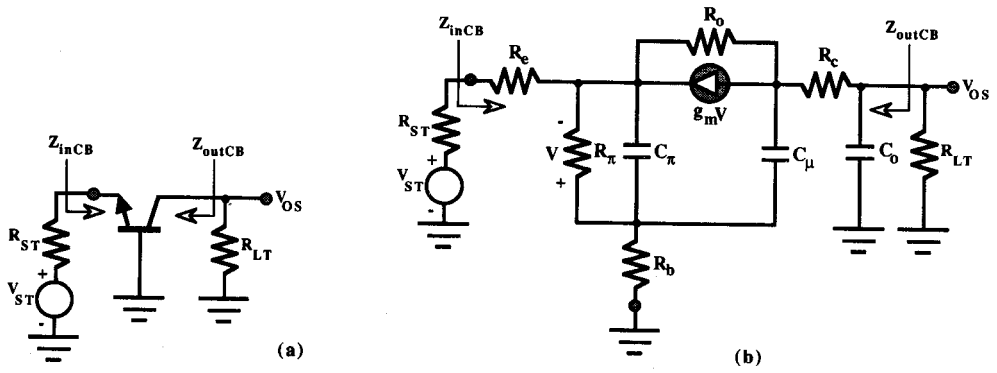

FIGURE 28.16 (a) AC schematic diagram of a common base amplifier. (b) Small signal, high frequency equivalent circuit of amplifier in part (a).

$$A_{vCB}(0) \cong \frac{\alpha_{ac} R_{LT}}{R_{ST} + R_{\text{in}CB}} \tag{28.34}$$

where $R_{\text{in}CB}$ is the low frequency value of the common base driving point input impedance,

$$R_{\text{in}CB} = Z_{\text{in}CB}(0) \cong R_e + \frac{R_b + R_\pi}{\beta_{ac} + 1} \tag{28.35}$$

Moreover, it can be shown that the low frequency driving point output resistance is

$$R_{\text{out}CB} = Z_{\text{out}CB}(0) \cong \left[\frac{\beta_{ac}(R_e + R_{ST})}{R_e + R_b + R_\pi + R_{ST}} + 1 \right] R_o \tag{28.36}$$

The preceding three equations underscore several operating characteristics that distinguish the common base amplifier from its common emitter counterpart. For example, Eq. (28.35) suggests a low frequency input resistance that is significantly smaller than that of a common emitter unit. To underscore this contention, consider the case of two identical transistors, one used in a common emitter amplifier and the other used in a common base configuration, that are biased at identical quiescent operating points. Under this circumstance, Eqs. (28.35) and (28.13) combine to deliver

$$R_{\text{in}CB} \cong \frac{R_{\text{in}CE}}{\beta_{ac} + 1} \tag{28.37}$$

which shows that the common base input resistance is a factor of $(\beta_{ac} + 1)$ times smaller than the input resistance of the common emitter cell. The resistance reflection factor, $(\beta_{ac} + 1)$, in Eq. (28.37) represents the ratio of small signal emitter current to small signal base current. Accordingly, Eq. (28.37) is self-evident when it is noted that the input resistance of a common base stage is referred to an input emitter current, whereas the input resistance of its common emitter counterpart is referred to an input base current.

A second difference between the common emitter and common base amplifiers is that the voltage gain of the latter displays no phase inversion between source and response voltages. Moreover, for the same load and source terminations and for identical transistors biased identically, the voltage gain of the common base cell is likely to be much smaller than that of the common emitter unit. This contention is verified by substituting Eq. (28.37) into Eq. (28.34) and using Eqs. (28.31), (28.13), and (28.12) to write

$$A_{vCB}(0) \cong \frac{|A_{vCE}(0)|}{1 + \dfrac{\beta_{ac} R_{ST}}{R_{ST} + R_{\text{in}CE}}} \tag{28.38}$$

At high signal frequencies, the voltage gain, driving point input impedance, and driving point output impedance can be approximated by functions whose analytical forms mirror those of Eqs. (28.15), (28.23), and (28.24). Let T_{pCB} and T_{zCB} designate the time constants of the effective dominant pole and the effective dominant zero, respectively, of the common base cell. An analysis of the structure of Fig. 28.16(b) resultantly produces, with R_o and R_c ignored,

$$T_{pCB} = R_{C\pi} C_\pi + R_{C\mu} C_\mu + R_{Co} C_o \tag{28.39}$$

where

$$R_{C\pi} = \frac{R_\pi \,||\, (R_{ST} + R_b + R_e)}{1 + \dfrac{\beta_{ac}(R_{ST} + R_e)}{R_{ST} + R_b + R_\pi + R_e}} \tag{28.40}$$

$$R_{C\mu} = R_b \,||\, [R_\pi + (\beta_{ac} + 1)(R_{ST} + R_e)] + R_{LT}\left[1 + \frac{\beta_{ac} R_b}{R_b + R_\pi + (\beta_{ac} + 1)(R_{ST} + R_e)}\right] \tag{28.41}$$

and R_{Co} remains given by Eq. (28.20). Moreover,

$$T_{zCB} = \frac{R_b C_\mu}{\alpha_{ac}} \tag{28.42}$$

Design Considerations for the Common Base Amplifier

An adaptation of Eqs. (28.25) through (28.28) to the common base stage confirms that the driving point input impedance is capacitive at high signal frequencies. On the other hand, $g_m R_b > 1$ renders a common base driving point input impedance that is inductive at high frequencies. This impedance property can be gainfully exploited to realize monolithic shunt peaked amplifiers in which the requisite circuit inductance is synthesized as the driving point input impedance of a common base stage (or the driving point output impedance of a common collector cell) [Grebene, 1984].

The common base stage is often used to broadband the common emitter amplifier by forming the *common emitter–common base cascode*, whose ac schematic diagram is given in Fig. 28.17. The broadbanding afforded by the cascode structure stems from the fact that the effective low frequency load resistance, say R_{Le}, seen by the common emitter transistor, QE, is the small driving point input resistance of the common base amplifier, QB. This effective load resistance, as witnessed by C_μ of the common emitter transistor, is much smaller than the actual load resistance that terminates the output port of the amplifier, thereby decreasing the Miller multiplication of the C_μ in QE. If the time constant savings afforded by decreased Miller multiplication is larger than the sum of the additional time constants presented to the circuit by the common base transistor, an enhancement of common emitter bandwidth occurs. Note that such bandwidth enhancement is realized without compromising the common emitter gain-bandwidth product, since the voltage gain of the common emitter–common base unit is almost identical to that of the common emitter amplifier alone.

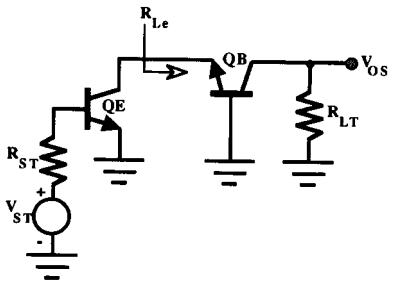

FIGURE 28.17 AC schematic diagram of a common emitter–common base cascode amplifier.

Common Collector Amplifier

The final canonic cell of linear BJT amplifiers is the *common collector amplifier*. The ac schematic diagram of this stage, which is often referred to as an *emitter follower*, is given in Fig. 28.18(a). In emitter followers, the input signal is applied to the base, and the resultant small signal output voltage is extracted at the transistor emitter.

The small signal equivalent circuit corresponding to the amplifier in Fig. 28.18(a) is shown in Fig. 28.18(b). A straightforward circuit analysis gives, for the case of large R_o, a low frequency voltage gain, $A_{vCC}(0) = V_{OS}/V_{ST}$, of

$$A_{vCC}(0) \cong \frac{R_{LT}}{R_{LT} + R_{\text{out}CC}} \tag{28.43}$$

where $R_{\text{out}CC}$ is the low frequency value of the driving point output impedance,

$$R_{\text{out}CC} = Z_{\text{out}CC}(0) \cong R_e + \frac{R_b + R_\pi + R_{ST}}{\beta_{ac} + 1} \tag{28.44}$$

The low frequency driving point output resistance is

$$R_{\text{in}CC} = Z_{\text{in}CC}(0) \cong R_b + R_\pi + (\beta_{ac} + 1)(R_e + R_{LT}) \tag{28.45}$$

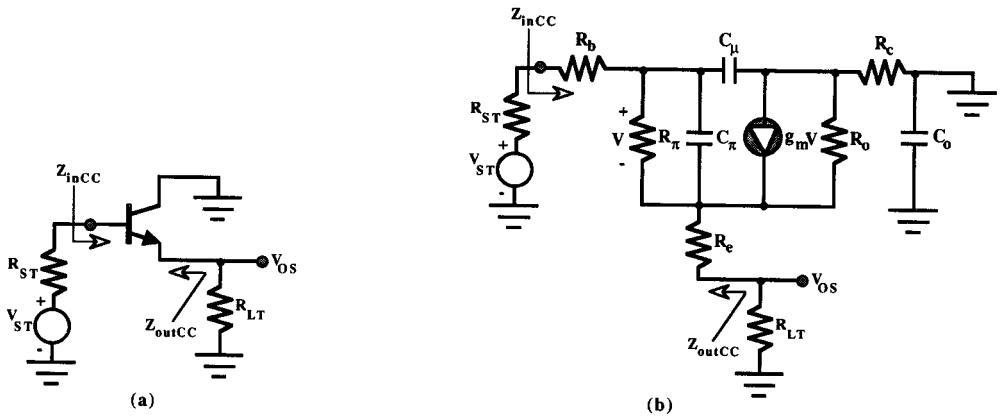

FIGURE 28.18 (a) AC schematic diagram of a common collector (emitter follower) amplifier. (b) Small signal, high frequency equivalent circuit of amplifier in part (a).

The facts that the voltage gain is less than one and is without phase inversion, the output resistance is small, and the input resistance is large make the emitter follower an excellent candidate for impedance buffering applications.

As in the cases of the common emitter and the common base amplifiers, the high frequency voltage gain, driving point input resistance, and driving point output resistance can be approximated by functions having analytical forms that are similar to those of Eqs. (28.15), (28.23), and (28.24). Let T_{pCC} and T_{zCC} designate the time constants of the effective dominant pole and the effective dominant zero, respectively, of the emitter follower. Since the output port capacitance, C_o, appears across a short circuit, T_{pCC} is expressible as

$$T_{pCC} = R_{C\pi}C_{\pi} + R_{C\mu}C_{\mu} \tag{28.46}$$

With R_o ignored,

$$R_{C\pi} = \frac{R_{\pi} \,||\, (R_{ST} + R_b + R_{LT} + R_e)}{1 + \dfrac{\beta_{ac}(R_{LT} + R_e)}{R_{ST} + R_b + R_{\pi} + R_{LT} + R_e}} \tag{28.47}$$

and

$$R_{C\mu} = (R_{ST} + R_b) \,||\, [R_{\pi} + (\beta_{ac} + 1)(R_{LT} + R_e) + \left[1 + \frac{\beta_{ac}(R_{ST} + R_b)}{R_{ST} + R_b + R_{\pi} + (\beta_{ac} + 1)(R_{LT} + R_e)}\right] R_c \tag{28.48}$$

The time constant of the effective dominant zero is

$$T_{zCC} = \frac{R_{\pi}C_{\pi}}{\beta_{ac} + 1} \tag{28.49}$$

Although the emitter follower possesses excellent wideband response characteristics, it should be noted in Eq. (28.48) that the internal collector resistance, R_c, incurs some Miller multiplication of the base-collector junction capacitance, C_{μ}. For this reason, monolithic common collector amplifiers work best in broadband impedance buffering applications when they exploit transistors that have collector sinker diffusions and buried collector layers, which collectively serve to minimize the parasitic internal collector resistance.

Defining Terms

ac schematic diagram: A circuit schematic diagram, divorced of biasing subcircuits, that depicts only the dynamic signal flow paths of an electronic circuit.

Driving point impedance: The effective impedance presented at a port of a circuit under the condition that all other circuit ports are terminated in the resistances actually used in the design realization.

Hybrid-pi model: A two-pole linear circuit used to model the small signal responses of bipolar circuits and circuits fabricated in other device technologies.

Miller effect: The deterioration of the effective input impedance caused by the presence of feedback from the output port to the input port of a phase-inverting voltage amplifier.

Short circuit gain-bandwidth product: A measure of the frequency response capability of an electronic circuit. When applied to bipolar circuits, it is nominally the signal frequency at which the magnitude of the current gain degrades to one.

Three-decibel bandwidth: A measure of the frequency response capability of low-pass and bandpass electronic circuits. It is the range of signal frequencies over which the maximum gain of the circuit is constant to within a factor of the square root of two.

Passive and Active Filters

There are formal definitions of activity and passivity in electronics, but it is sufficient to observe that passive filters are built from passive components; resistors, capacitors, and inductors are the commonly encountered building blocks although distributed RC components, quartz crystals, and surface acoustic wave devices are used in filters working in the high-megahertz regions. **Active filters** also use resistors and capacitors, but the inductors are replaced by active devices capable of producing power gain. These devices can range from single transistors to integrated circuit (IC) -controlled sources such as the operational amplifier (op amp), and more exotic devices, such as the operational transconductance amplifier (OTA), the generalized impedance converter (GIC), and the frequency-dependent negative resistor (FDNR).

The theory of filter synthesis, whether active or passive, involves the determination of a suitable circuit topology and the computation of the circuit component values within the topology, such that a required network response is obtained. This response is most commonly a voltage transfer function (VTF) specified in the frequency domain. Circuit analysis will allow the performance of a filter to be evaluated, and this can be done by obtaining the VTF, $H(s)$, which is, in general, a rational function of s, the complex frequency variable. The *poles* of a VTF correspond to the roots of its denominator polynomial. It was established early in the history of filter theory that a network capable of yielding complex-conjugate transfer function (TF) pole-pairs is required to achieve high selectivity. A highly selective network is one that gives a rapid transition between passband and stopband regions of the frequency response. Figure 29.1(a) gives an example of a passive low-pass LCR ladder network capable of producing a VTF with the necessary pole pattern.

The network of Fig. 29.1(a) yields a VTF of the form

$$H(s) = \frac{V_{\text{out}}(s)}{V_{\text{in}}(s)} = \frac{1}{a_5 s^5 + a_4 s^4 + a_3 s^3 + a_2 s^2 + a_1 s + a_0} \tag{29.1}$$

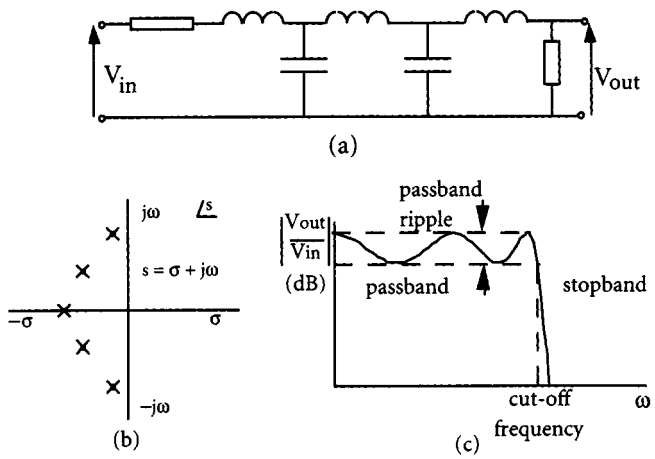

FIGURE 29.1 (a) Passive LCR filter; (b) typical pole plot; (c) typical frequency response.

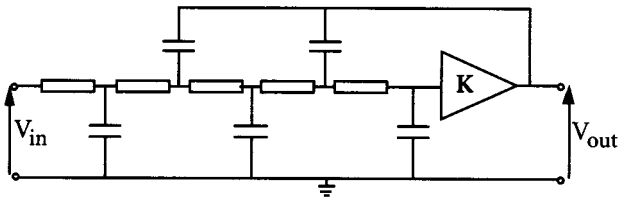

FIGURE 29.2 RC-active filter equivalent to circuit of Fig. 29.1(a).

Figure 29.1(b) shows a typical pole plot for the fifth-order VTF produced by this circuit. Figure 29.1(c) gives a sample sinusoidal steady-state frequency response plot. The frequency response is found by setting $s = j\omega$ in Eq. (29.1) and taking $|H(j\omega)|$. The LCR low-pass ladder structure of Fig. 29.1(a) can be altered to higher or lower order simply by adding or subtracting reactances, preserving the series-inductor/shunt-capacitor pattern. In general terms, the higher the filter order, the greater the selectivity.

This simple circuit structure is associated with a well-established design theory and might appear the perfect solution to the filter synthesis problem. Unfortunately, the problems introduced by the use of the inductor as a circuit component proved a serious difficulty from the outset. Inductors are intrinsically nonideal components, and the lower the frequency range of operation, the greater these problems become. Problems include significant series resistance associated with the physical structure of the inductor as a coil of wire, its ability to couple by electromagnetic induction into fields emanating from external components and sources and from other inductors within the filter, its physical size, and potential mechanical instability. Added to these problems is the fact that the inductor tends not to be an off-the-shelf component but has instead to be fabricated to the required value as a custom device. These serious practical difficulties created an early pressure to develop alternative approaches to electrical filtering. After the emergence of the electronic amplifier based on vacuum rules, it was discovered that networks involving resistors, capacitors, and amplifiers—*RC-active filters*—were capable of producing TFs exactly equivalent to those of LCR ladders. Figure 29.2 shows a single-amplifier multiloop ladder structure that can produce a fifth-order response identical to that of the circuit of Fig. 29.1(a).

The early active filters, based as they were on tube amplifiers, did not constitute any significant advance over their passive counterparts. It required the advent of solid-state active devices to make the RC-active filter a viable alternative. Over the subsequent three decades, active filter theory has developed to an advanced state, and this development continues as new IC technologies create opportunities for novel network structures and applications.

Active Filter Classification and Sensitivity

There are two major approaches to the synthesis of RC-active filters. In the first approach, a TF specification is factored into a product of second-order terms. Each of these terms is realized by a separate RC-active

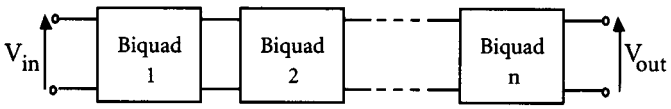

FIGURE 29.3 Biquad cascade realizing high-order filter.

subnetwork designed to allow for non-interactive interconnection. The subnetworks are then connected in cascade to realize the required overall TF, as shown in Fig. 29.3. A first-order section is also required to realize odd-order TF specifications. These second-order sections may, depending on the exact form of the overall TF specification, be required to realize numerator terms of up to second order. An RC-active network capable of realizing a biquadratic TF (that is, one whose numerator *and* denominator polynomials are second-order) is called a **biquad**.

This scheme has the advantage of design ease since simple equations can be derived relating the components of each section to the coefficients of each factor in the VTF. Also, each biquad can be independently adjusted relatively easily to give the correct performance. Because of these important practical merits, a large number of alternative biquad structures have been proposed, and the newcomer may easily find the choice overwhelming.

The second approach to active filter synthesis involves the use of RC-active circuits to simulate passive LCR ladders. This has two important advantages. First, the design process can be very straightforward: the wealth of design data published for passive ladder filters (see Further Information) can be used directly so that the sometimes difficult process of component value synthesis from specification is eliminated. Second, the LCR ladder offers optimal **sensitivity** properties [Orchard, 1966], and RC-active filters designed by ladder simulation share the same low sensitivity features. Chapter 4 of Bowron and Stephenson [1979] gives an excellent introduction to the formal treatment of circuit sensitivity.

Sensitivity plays a vital role in the characterization of RC-active filters. It provides a measure of the extent to which a change in the value of any given component affects the response of the filter. High sensitivity in an RC-active filter should also alert the designer to the possibility of oscillation. A nominally stable design will be unstable in practical realization if sensitivities are such that component value errors cause one or more pairs of poles to migrate into the right half plane. Because any practical filter will be built with components that are not exactly nominal in value, sensitivity information provides a practical and useful indication of how different filter structures will react and provides a basis for comparison.

Cascaded Second-Order Sections

This section will introduce the cascade approach to active filter design. As noted earlier, there are a great many second-order RC-active sections to choose from, and the present treatment aims only to convey some of the main ideas involved in this strategy. The references provided at the end of this section point the reader to several comprehensive treatments of the subject.

Sallen and Key Section

This is an early and simple example of a second-order section building block [Sallen and Key, 1955]. It remains a commonly used filter despite its age, and it will serve to illustrate some key stages in the design of all such RC-active sections. The circuit is shown in Fig. 29.4. A straightforward analysis of this circuit yields a VTF

$$H(s) = \frac{K\dfrac{1}{C_1C_2R_1R_2}}{s^2 + s\left[\dfrac{1}{C_2R_2} + \dfrac{1}{C_2R_1} + \dfrac{1-K}{C_1R_1}\right] + \dfrac{1}{C_1C_2R_1R_2}} \tag{29.2}$$

This is an all-pole low-pass form since the numerator involves only a constant term.

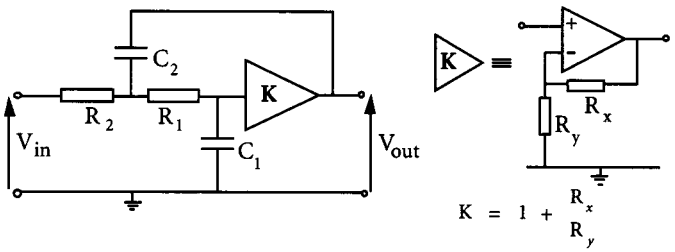

FIGURE 29.4 Sallen and Key second-order filter section.

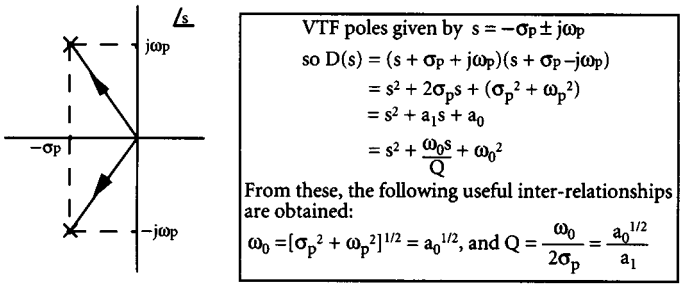

FIGURE 29.5 VTF pole relationships.

Specifications for an all-pole second-order section may arise in coefficient form, where the required *s*-domain VTF is given as

$$H(s) = \frac{k}{s^2 + a_1 s + a_0} \tag{29.3}$$

or in Q-ω_0 standard second-order form

$$H(s) = \frac{k}{s^2 + \dfrac{\omega_0}{Q} s + \omega_0} \tag{29.4}$$

Figure 29.5 shows the relationship between these VTF forms.

As a design example, the VTF for an all-pole fifth-order Chebyshev filter with 0.5-dB passband ripple [see Fig. 29.1(c)] has the factored-form denominator

$$D(s) = (s + 0.36232)(s^2 + 0.22393\,s + 1.0358)(s^2 + 0.58625s + 0.47677) \tag{29.5}$$

Taking the first of the quadratic factors in Eq. (29.5) and comparing like coefficients from Eq. (29.2) gives the following design equations:

$$\frac{1}{C_1 C_2 R_1 R_2} = 1.0358; \qquad \frac{1}{C_2 R_2} + \frac{1}{C_2 R_1} + \frac{1 - K}{C_1 R_1} = 0.22393 \tag{29.6}$$

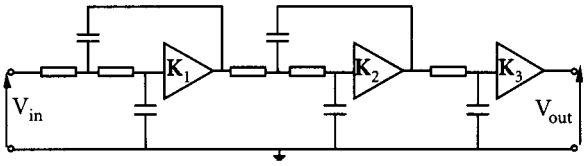

FIGURE 29.6 Form of fifth-order Sallen and Key cascade.

Clearly, the designer has some degrees of freedom here since there are two equations in five unknowns. Choosing to set both (normalized) capacitor values to unity, and fixing the dc stage gain $K = 5$, gives

$$C_1 = C_2 = 1\text{F};\ R_1 = 1.8134\ \Omega;\ R_2 = 1.3705\ \Omega;\ R_x = 4\ \Omega;\ R_y = 1\ \Omega$$

Note that Eq. (29.5) is a normalized specification giving a filter cut-off frequency of 1 rad s^{-1}. These normalized component values can now be denormalized to give a required cut-off frequency and practical component values. Suppose that the filter is, in fact, required to give a cut-off frequency $f_c = 1$ kHz. The necessary shift is produced by multiplying all the capacitors (leaving the resistors fixed) by the factor ω_N/ω_D where ω_N is the normalized cut-off frequency (1 rad s^{-1} here) and ω_D is the required denormalized cut-off frequency ($2\pi \times 1000$ rad s^{-1}). Applying this results in denormalized capacitor values of 159.2 μF. A useful rule of thumb [Waters, 1991] advises that capacitor values should be on the order of magnitude of $(10/f_c)$ μF, which suggests that the capacitors should be further scaled to around 10 nF. This can be achieved without altering of the filter's f_c by means of the impedance scaling property of electrical circuits. Providing all circuit impedances are scaled by the same amount, current and voltage TFs are preserved. In an RC-active circuit, this requires that all resistances are multiplied by some factor while all capacitances are divided by it (since capacitive impedance is proportional to $1/C$). Applying this process yields final values as follows:

$$C_1,\ C_2 = 10\ \text{nF};\ R_1 = 29.86\ \text{k}\Omega;\ R_2 = 21.81\ \text{k}\Omega;\ R_x = 63.66\ \text{k}\Omega;\ R_y = 15.92\ \text{k}\Omega$$

Note also that the dc gain of each stage, $|H(0)|$, is given by K [see Eq. (29.2) and Fig. 29.4] and, when several stages are cascaded, the overall dc gain of the filter will be the product of these individual stage gains. This feature of the Sallen and Key structure gives the designer the ability to combine easy-to-manage amplification with prescribed filtering.

Realization of the complete fifth-order Chebyshev VTF requires the design of another second-order section to deal with the second quadratic term in Eq. (29.5), together with a simple circuit to realize the first-order term arising because this is an odd-order VTF. Figure 29.6 shows the form of the overall cascade. Note that the op amps at the output of each stage provide the necessary interstage isolation. It is finally worth noting that an extended single-amplifier form of the Sallen and Key network exists—the circuit shown in Fig. 29.2 is an example of this—but that the saving in op amps is paid for by higher component spreads, sensitivities, and design complexity.

State-Variable Biquad

The simple Sallen and Key filter provides only an all-pole TF; many commonly encountered filter specifications are of this form—the Butterworth and Chebyshev approximations are notable examples—so this is not a serious limitation. In general, however, it will be necessary to produce sections capable of realizing a second-order denominator together with a numerator polynomial of up to second-order:

$$H(s) = \frac{b_2 s^2 + b_1 s + b_0}{s^2 + a_1 s + a_0} \tag{29.7}$$

The other major filter approximation in common use—the elliptic (or Cauer) function filter—involves quadratic numerator terms in which the b_1 coefficient in Eq. (29.7) is missing. The resulting numerator

polynomial, of the form $b_2\ s^2 + b_0$, gives rise to *s*-plane zeros on the $j\omega$ axis corresponding to points in the stopband of the sinusoidal frequency response where the filter's transmission goes to zero. These notches or *transmission zeros* account for the elliptic's very rapid transition from passband to stopband and, hence, its optimal selectivity.

A filter structure capable of producing a VTF of the form of Eq. (29.7) was introduced as a state-variable realization by its originators [Kerwin et al., 1967]. The structure comprises two op amp integrators and an op amp summer connected in a loop and was based on the integrator-summer analog computer used in control/analog systems analysis, where system state is characterized by some set of so-called state variables. It is also often referred to as a ring-of-three structure. Many subsequent refinements of this design have appeared (Schaumann et al., [1990] gives a useful treatment of some of these developments) and the state-variable biquad has achieved considerable popularity as the basis of many commercial universal packaged active filter building blocks. By selecting appropriate chip/package output terminals, and with the use of external trimming components, a very wide range of filter responses can be obtained.

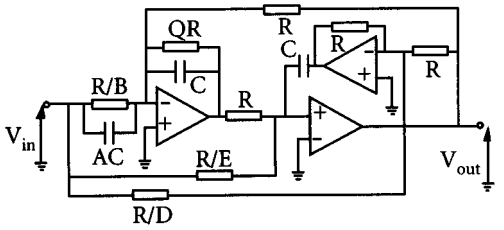

FIGURE 29.7 Circuit schematic for state-variable biquad.

Figure 29.7 shows a circuit developed from this basic state-variable network and described in Schaumann et al. [1990]. The circuit yields a VTF

$$H(s) = \frac{V_{out}(s)}{V_{in}(s)} = -\frac{As^2 + \omega_0(B - D)s + E\omega_0^2}{s^2 + \dfrac{\omega_0}{Q}s + \omega_0^2}, \text{ with } \omega_0 \triangleq 1/RC \tag{29.8}$$

By an appropriate choice of the circuit component values, a desired VTF of the form of Eq. (29.8) can be realized.

Consider, for example, a specification requirement for a second-order elliptic filter cutting off at 10 kHz. Assume that a suitable normalized (1 rad/s) specification for the VTF is

$$H(s) = -\frac{0.15677(s^2 + 7.464)}{s^2 + 0.9989s + 1.1701} \tag{29.9}$$

From Eq. (29.8) and Eq. (29.9), and referring to Fig. 29.7, normalized values for the components are computed as follows. As the *s* term in the numerator is to be zero, set $B = D = 0$ (which obtains if resistors R/B and R/D are simply removed from the circuit). Setting $C = 1$ F gives the following results:

$$\text{AC} = 0.15677\text{F};\ \text{R} = 1/C\omega_0 = 0.92446\ \Omega;\ \text{QR} = 1.08290\ \Omega;\ \text{R/E} = 0.92446\ \Omega$$

Removing the normalization and setting $C = (10/10\text{ k})\ \mu\text{F} = 1$ nF requires capacitors to be multiplied by 10^{-9} and resistors to be multiplied by 15.9155×10^3. Final denormalized component values for the 10-kHz filter are thus:

$$\text{C} = 1\text{ nF};\ \text{AC} = 0.15677\text{ nF};\ \text{R} = \text{R/E} = 14.713\ \text{k}\Omega;\ \text{QR} = 17.235\ \text{k}\Omega$$

Passive Ladder Simulation

As for the biquad approach, numerous different ladder-based design methods have been proposed. Two representative schemes will be considered here: inductance simulation and ladder transformation.

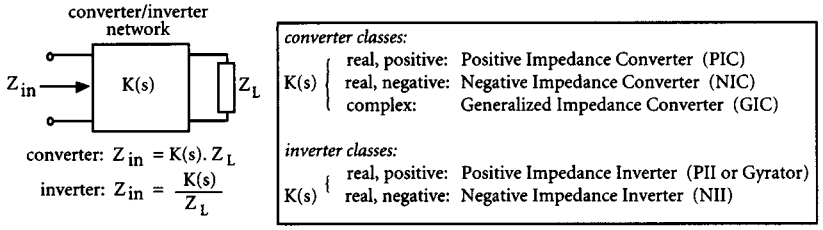

FIGURE 29.8 Generic impedance converter/inverter networks.

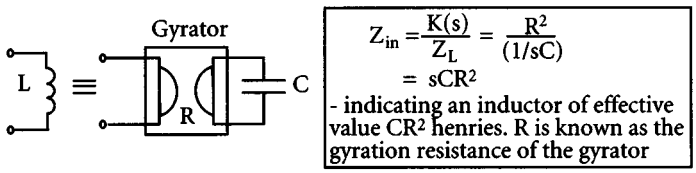

FIGURE 29.9 Gyrator simulation of an inductor.

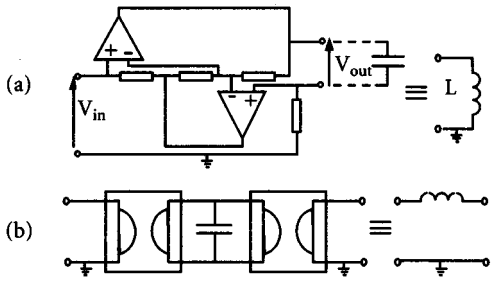

FIGURE 29.10 (a) Practical gyrator and (b) simulation of floating inductor. (Source: A. Antoniou, Proc. IEE, vol. 116, pp. 1838–1850, 1969. With permission.)

Inductance Simulation

In the inductance simulation approach, use is made of impedance converter/inverter networks. Figure 29.8 gives a classification of the various generic forms of device. The NIC enjoyed prominence in the early days of active filters but was found to be prone to instability. Two classes of device that have proved more useful in the longer term are the GIC and the gyrator.

Figure 29.9 introduces the symbolic representation of a gyrator and shows its use in simulating an inductor.

The gyrator can conveniently be realized by the circuit of Fig. 29.10(a), but note that the simulated inductor is grounded at one end. This presents no problem in the case of high-pass filters and other forms requiring a grounded shunt inductor but is not suitable for the low-pass filter. Figure 29.10(b) shows how a pair of back-to-back gyrators can be configured to produce a floating inductance, but this involves four op amps per inductor.

The next section will introduce an alternative approach that avoids the op amp count difficulty associated with simulating the floating inductors directly.

Ladder Transformation

The other main approach to the RC-active simulation of passive ladders involves the transformation of a prototype ladder into a form suitable for active realization. A most effective method of this class is based on the use of the Bruton transformation [Bruton, 1969], which involves the complex impedance scaling of a prototype passive LCR ladder network. All prototype circuit impedances $Z(s)$ are transformed to $Z_T(s)$ with

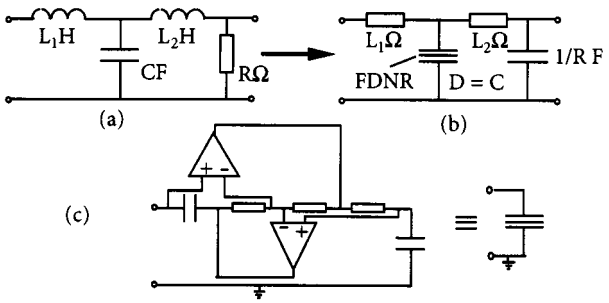

FIGURE 29.11 FDNR active filter.

$$Z_T(s) = \frac{K}{s} \cdot Z(s) \tag{29.10}$$

where K is a constant chosen by the designer and which provides the capacity to scale component values in the final filter. Since impedance transformations do not affect voltage and current transfer ratios, the VTF remains unaltered by this change. The Bruton transformation is applied directly to the elements in the prototype network, and it follows from Eq. (29.10) that a resistance R transforms into a capacitance $C = K/R$, while an inductance L transforms into a resistance $R = KL$. The elimination of inductors in favor of resistors is the key purpose of the Bruton transform method. Applying the Bruton transform to a prototype circuit capacitance C gives

$$Z_T(s) = \frac{K}{s} \cdot \frac{1}{sC} = \frac{K}{s^2C} = \frac{1}{s^2D} \tag{29.11}$$

where $D = C/K$ is the parameter value of a new component produced by the transformation, which is usually referred to as a frequency-dependent negative resistance (FDNR). This name results from the fact that the sinusoidal steady-state impedance $Z_T(j\omega) = -(1/\omega^2 D)$ is frequency-dependent, negative, and real, hence, resistive. In practice, the FDNR elements are realized by RC-active subnetworks using op amps, normally two per FDNR. Figure 29.11(a) and (b) shows the sequence of circuit changes involved in transforming from a third-order LCR prototype ladder to an FDNR circuit. Figure 29.11(c) gives an RC-active realization for the FDNR based on the use of a GIC, introduced in the previous subsection.

Active Filters for ICs

It was noted earlier that the advent of the IC op amp made the RC-active filter a practical reality. A typical state-of-the-art 1960–70s active filter would involve a printed circuit board-mounted circuit comprising discrete passive components together with IC op amps. Also appearing at this time were hybrid implementations, which involve special-purpose discrete components and op amp ICs interconnected on a ceramic or glass substrate. It was recognized, however, that there were considerable benefits to be had from producing an all-IC active filter.

Production of a quality on-chip capacitor involves substantial chip area, so the scaling techniques referred to earlier must be used to keep capacitance values down to the low picofarad range. The consequence of this is that, unfortunately, the circuit resistance values become proportionately large so that, again, there is a chip-area problem. The solution to this dilemma emerged in the late 1970s/early 1980s with the advent of the switched-capacitor (SC) active filter. This device, a development of the active-RC filter that is specifically intended for use in IC form, replaces prototype circuit resistors with arrangements of switches and capacitors that can be shown to simulate resistances, under certain circumstances. The great merit of the scheme is that the values of the capacitors involved in this process of resistor simulation are inversely proportional to the values of the prototype resistors; thus, the final IC structure involves principal and switched capacitors that are

small in magnitude and hence ideal for IC realization. A good account of SC filters is given, for example, in Schaumann et al. [1990] and in Taylor and Huang [1997]. Commonly encountered techniques for SC filter design are based on the two major design styles (biquads and ladder simulation) that have been introduced in this section.

Many commercial IC active filters are based on SC techniques, and it is also becoming usual to find custom and semicustom IC design systems that include active filter modules as components within a macrocell library that the system-level design can simply invoke where analog filtering is required within an all-analog or mixed-signal analog/digital system.

Defining Terms

Active filter: An electronic filter whose design includes one or more active devices.

Biquad: An active filter whose transfer function comprises a ratio of second-order numerator and denominator polynomials in the frequency variable.

Electronic filter: An electronic circuit designed to transmit some range of signal frequencies while rejecting others. Phase and time-domain specifications may also occur.

Sensitivity: A measure of the extent to which a given circuit performance measure is affected by a given component within the circuit.

Further Information

Tabulations of representative standard filter specification functions appear in the sources in the References by Schaumann et al. [1990] and Bowron and Stephenson [1979], but more extensive tabulations, including prototype passive filter component values, are given in A. I. Zverev, *Handbook of Filter Synthesis* (New York: John Wiley, 1967). More generally, the Schaumann text provides an admirable, up-to-date coverage of filter design with an extensive list of references as does Taylor and Huang [1997].

The field of active filter design remains active, and new developments appear in *IEEE Transactions on Circuits and Systems* and *IEE Proceedings Part G (Circuits and Systems)*. The IEE publication *Electronic Letters* provides for short contributions. A number of international conferences (whose proceedings can be borrowed through technical libraries) feature active filter and related sessions, notably the *IEEE International Symposium on Circuits and Systems* (ISCAS) and the *European Conference on Circuit Theory and Design* (ECCTD).

29.2 Realization

J. W. Steadman and B. M. Wilamowski

After the appropriate low-pass form of a given **filter** has been synthesized, the designer must address the realization of the filter using **operational amplifiers**. If the required filter is not low-pass but high-pass, bandpass, or bandstop, transformation of the prototype function is also required [Budak, 1974; Van Valkenburg, 1982]. While a detailed treatment of the various transformations is beyond the scope of this work, most of the filter designs encountered in practice can be accomplished using the techniques given here.

When the desired filter function has been determined, the corresponding electronic circuit must be designed. Many different circuits can be used to realize any given transfer function. For purposes of this handbook, we present several of the most popular types of realizations. Much more detailed information on various circuit realizations and the advantages of each may be found in the literature, in particular Van Valkenburg [1982], Huelseman and Allen [1980], and Chen [1986]. Generally the design trade-offs in making the choice of circuit to be used for the realization involve considerations of the number of elements required, the sensitivity of the circuit to changes in component values, and the ease of tuning the circuit to given specifications. Accordingly, limited information is included about these characteristics of the example circuits in this section.

Each of the circuits described here is commonly used in the realization of **active filters**. When implemented as shown and used in the appropriate gain and bandwidth specifications of the amplifiers, they will provide excellent performance. Computer-aided filter design programs are available which simplify the process of obtaining proper element values and simulation of the resulting circuits [Krobe et al., 1989; Wilamowski et al., 1992].

Transformation from Low-Pass to Other Filter Types

To obtain a high-pass, bandpass, or bandstop filter function from a low-pass prototype, one of two general methods can be used. In one of these, the circuit is realized and then individual circuit elements are replaced by other elements or subcircuits. This method is more useful in **passive filter** designs and is not discussed further here. In the other approach, the transfer function of the low-pass prototype is transformed into the required form for the desired filter. Then a circuit is chosen to realize the new filter function. We give a brief description of the transformation in this section, then give examples of circuit realizations in the following sections.

Low-Pass to High-Pass Transformation

Suppose the desired filter is, for example, a high-pass Butterworth. Begin with the low-pass Butterworth transfer function of the desired order and then *transform* each pole of the original function using the formula

$$\frac{1}{S - S_j} \rightarrow \frac{Hs}{s - s_j} \tag{29.12}$$

which results in one complex pole and one zero at the origin for each pole in the original function. Similarly, each zero of the original function is transformed using the formula

$$S - S_j \rightarrow \frac{s - s_j}{Hs} \tag{29.13}$$

which results in one zero on the imaginary axis and one pole at the origin. In both equations, the scaling factors used are

$$H = \frac{1}{S_j} \quad \text{and} \quad s_j = \frac{\omega_0}{S_j} \tag{29.14}$$

where ω_0 is the desired cut-off frequency in radians per second.

Low-Pass to Bandpass Transformation

Begin with the low-pass prototype function in factored, or *pole-zero*, form. Then each pole is transformed using the formula

$$\frac{1}{S - S_j} \rightarrow \frac{Hs}{(s - s_1)(s - s_2)} \tag{29.15}$$

resulting in one zero at the origin and two conjugate poles. Each zero is transformed using the formula

$$S - S_j \rightarrow \frac{(s - s_1)(s - s_2)}{Hs} \tag{29.16}$$

resulting in one pole at origin and two conjugate zeros. In Eqs. (29.15) and (29.16)

$$H = -B; \quad s_{1,2} = \omega_c\left(\alpha \pm \sqrt{\alpha^2 - 1}\right); \text{ and } \alpha = \frac{BS_j}{2\omega_c} \tag{29.17}$$

where ω_c is the center frequency and B is the bandwidth of the bandpass function.

Low-Pass to Bandstop Transformation

Begin with the low-pass prototype function in factored, or pole-zero, form. Then each pole is transformed using the formula

$$\frac{1}{S - S_j} \rightarrow \frac{H(s - s_1)(s - s_2)}{(s - s_3)(s - s_4)} \tag{29.18}$$

transforming each pole into two zeros on the imaginary axis and into two conjugate poles. Similarly, each zero is transformed into two poles on the imaginary axis and into two conjugate zeros using the formula

$$S - S_j \rightarrow \frac{(s - s_3)(s - s_4)}{H(s - s_1)(s - s_2)} \tag{29.19}$$

where

$$H = \frac{1}{S_j}; \; s_{1,2} = \pm j\omega_c; \; s_{3,4} = \omega_c\left(\beta \pm \sqrt{\beta^2 - 1}\right); \text{ and } \beta = \frac{B}{2\omega_c S_j} \tag{29.20}$$

Once the desired transfer function has been obtained through obtaining the appropriate low-pass prototype and transformation, if necessary, to the associated high-pass, bandpass or bandstop function, all that remains is to obtain a circuit and the element values to realize the transfer function.

Circuit Realizations

Various electronic circuits can be found to implement any given transfer function. Cascade filters and ladder filters are two of the basic approaches for obtaining a practical circuit. Cascade realizations are much easier to find and to tune, but ladder filters are less sensitive to element variations. In cascade realizations, the transfer function is simply factored into first- and second-order parts. Circuits are built for the individual parts and then cascaded to produce the overall filter. For simple to moderately complex filter designs, this is the most common method, and the remainder of this section is devoted to several examples of the circuits used to obtain

the first- and second-order filters. For very high-order transfer functions, ladder filters should be considered, and further information can be obtained by consulting the literature.

In order to simplify the circuit synthesis procedure, very often ω_0 is assumed to be equal to one and then after a circuit is found, the values of all capacitances in the circuit are divided by ω_0. In general, the following magnitude and frequency transformations are allowed:

$$R_{\text{new}} = K_M R_{\text{old}} \text{ and } C_{\text{new}} = \frac{1}{K_F K_M} C_{\text{old}} \tag{29.21}$$

where K_M and K_F are magnitude and frequency scaling factors, respectively.

Cascade filter designs require the transfer function to be expressed as a product of first- and second-order terms. For each of these terms a practical circuit can be implemented. Examples of these circuits are presented in Figs. 29.12–29.22. In general the following first- and second-order terms can be distinguished:

(a) First-order low-pass:

$$T(s) = \frac{H\omega_0}{s + \omega_0}$$

Assumption : $r_1 = 1$

$$c_1 = \frac{1}{\omega_0} \qquad r_2 = |H|\,\omega_0$$

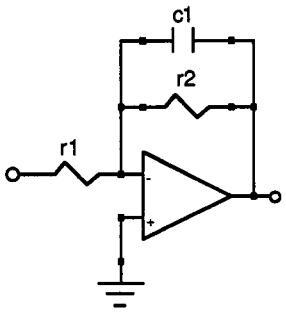

FIGURE 29.12 First-order low-pass filter.

This filter is inverting, i.e., H must be negative, and the scaling factors shown in Eq. (29.21) should be used to obtain reasonable values for the components.

(b) First-order high-pass:

$$T(s) = \frac{Hs}{s + \omega_0}$$

Assumption : $r_1 = 1$

$$c_1 = \frac{1}{\omega_0} \qquad r_2 = |H|$$

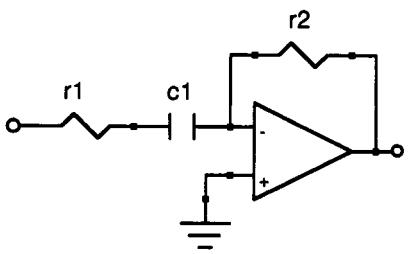

FIGURE 29.13 First-order high-pass filter.

This filter is inverting, i.e., H must be negative, and the scaling factors shown in Eq. (29.21) should be used to obtain reasonable values for the components.

While several passive realizations of first-order filters are possible (low-pass, high-pass, and lead-lag), the active circuits shown here are inexpensive and avoid any loading of the other filter sections when the individual circuits are cascaded. Consequently, these circuits are preferred unless there is some reason to avoid the use of the additional operational amplifier. Note that a second-order filter can be realized using one operational amplifer as shown in the following paragraphs, so it is common practice to choose even-order transfer functions, thus avoiding the use of any first-order filters.

(c) There are several second-order low-pass circuits:

$$T(s) = \frac{H\omega_0^2}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2}$$

$$\text{Assumption}: \quad r_1 = r_2 = 1$$

$$c_1 = \frac{2Q}{\omega_0} \qquad c_2 = \frac{1}{2Q\omega_0}$$

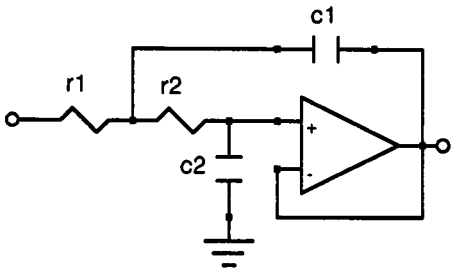

FIGURE 29.14 Second-order low-pass Sallen-Key filter.

This filter is noninverting and unity gain, i.e., H must be one, and the scaling factors shown in Eq. (29.21) should be used to obtain reasonable element values. This is a very popular filter for realizing second-order functions because it uses a minimum number of components and since the operation amplifier is in the unity gain configuration it has very good bandwidth.

Another useful configuration for second-order low-pass filters uses the operational amplifier in its inverting "infinite gain" mode as shown in Fig. 29.15.

$$T(s) = \frac{H\omega_0^2}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2}$$

$$\text{Assumption}: \quad r_1 = r_2 = r_3 = 1$$

$$c_1 = \frac{3Q}{\omega_0} \qquad c_2 = \frac{1}{3Q\omega_0}$$

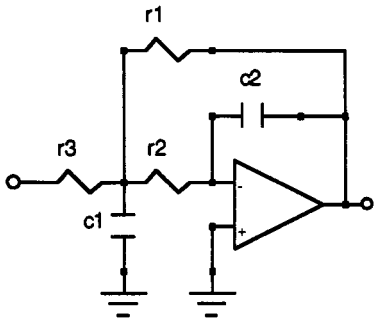

FIGURE 29.15 Second-order low-pass filter using the inverting circuit.

This circuit has the advantage of relatively low sensitivity of ω_0 and Q to variations in component values. In this configuration the operational amplifier's gain-bandwidth product may become a limitation for high-Q and high-frequency applications [Budak, 1974]. There are several other circuit configurations for low-pass filters. The references given at the end of the section will guide the designer to alternatives and the advantages of each.

(d) Second-order high-pass filters may be designed using circuits very much like those shown for the low-pass realizations. For example, the Sallen-Key low-pass filter is shown in Fig. 29.16.

$$T(s) = \frac{Hs^2}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2}$$

$$\text{Assumption}: \quad r_3 = 1$$

$$c_1 = c_2 = 1$$

$$r_1 = r_2 = \frac{1}{\omega_0} \qquad r_4 = 2 - \frac{1}{Q}$$

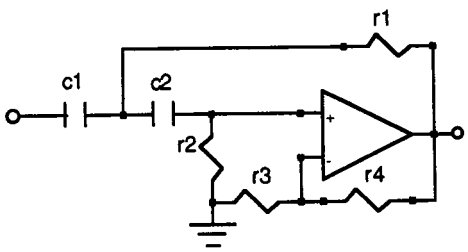

FIGURE 29.16 A second-order high-pass Sallen-Key filter.

As in the case of the low-pass Sallen-Key filter, this circuit is noninverting and requires very little gain from the operational amplifier. For low to moderate values of Q, the **sensitivity functions** are reasonable and the circuit performs well.

The inverting *infinite gain* high-pass circuit is shown in Fig. 29.17 and is similar to the corresponding low-pass circuit.

$$T(s) = \frac{Hs^2}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2}$$

Assumption: $r_1 = 1$

$$r_2 = 9Q^2 \quad c_1 = c_2 = c_3 = \frac{1}{3Q^2}$$

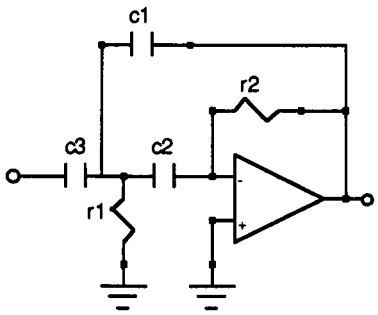

FIGURE 29.17 An inverting second-order high-pass circuit.

This circuit has relatively good sensitivity figures. The principal limitation occurs with high-Q filters since this requires a wide spread of resistor values.

Both low-pass and high-pass frequency response circuits can be achieved using three operational amplifier circuits. Such circuits have some sensitivity function and tuning advantages but require far more components. These circuits are used in the sections describing bandpass and bandstop filters. The designer wanting to use the three-operational-amplifier realization for low-pass or high-pass filters can easily do this using simple modifications of the circuits shown in the following sections.

(e) Second-order bandpass circuits may be realized using only one operational amplifier. The Sallen-Key filter shown in Fig. 29.18 is one such circuit.

$$T(s) = \frac{H\frac{\omega_0}{Q}s}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2}$$

Assumption: $c_1 = c_2 = 1; \quad r_5 = 1$

$$r_2 = r_3 = \frac{\sqrt{2}}{\omega_0} \qquad r_1 = \frac{\frac{4Q}{\sqrt{2}} - 1}{H}$$

$$r_4 = \frac{\frac{4Q}{\sqrt{2}} - 1}{\frac{4Q}{\sqrt{2}} - 1 - H} \qquad r_6 = 3 - \frac{\sqrt{2}}{\omega_0}$$

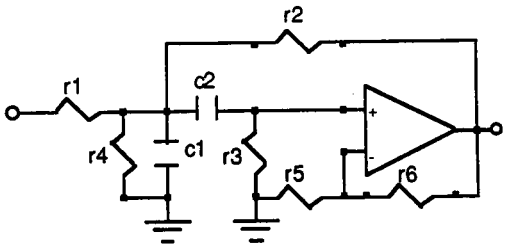

FIGURE 29.18 A Sallen-Key bandpass filter.

This is a noninverting amplifier which works well for low- to moderate-Q filters and is easily tuned [Budak, 1974]. For high-Q filters the sensitivity of Q to element values becomes high, and alternative circuits are recommended. One of these is the bandpass version of the inverting amplifier filter as shown in Fig. 29.19.

$$T(s) = \frac{H\frac{\omega_0}{Q}s}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2}$$

$$\text{Assumption}: \quad c_1 = c_2 = \frac{1}{2Q\omega_0}$$

$$r_1 = \frac{2Q^2}{H} \qquad r_2 = 4Q^2 \qquad r_3 = \frac{1}{1 - \frac{H}{2Q^2}}$$

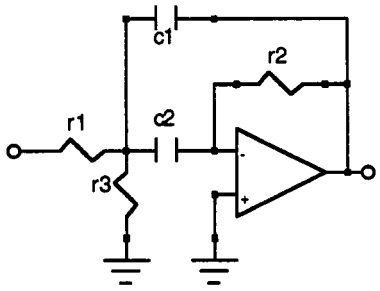

FIGURE 29.19 The inverting amplifier bandpass filter.

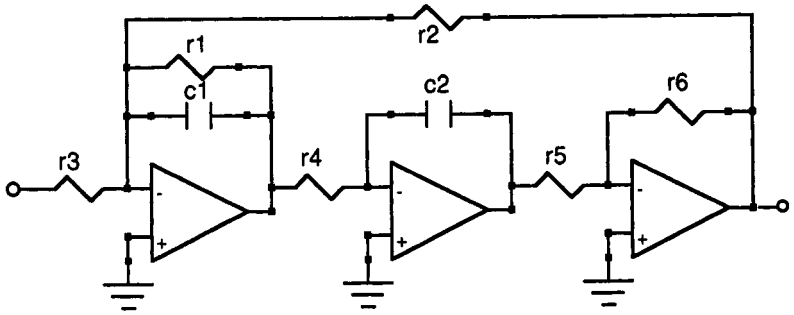
This circuit has few components and relatively small sensitivity of ω_0 and Q to variations in element values. For high-Q circuits, the range of resistor values is quite large as r_1 and r_2 are much larger than r_3.

When ease of tuning and small sensitivities are more important than the circuit complexity, the three-operational-amplifier circuit of Fig. 29.20 may be used to implement the bandpass transfer function.



$$T(s) = \frac{H\frac{\omega_0}{Q}s}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2} \qquad c_1 = c_2 = \frac{1}{\omega_0} \qquad r_1 = Q \qquad r_2 = r_4 = r_5 = r_6 = 1 \qquad r_3 = \frac{Q}{|H|}$$

FIGURE 29.20 The three-operational-amplifier bandpass filter.

The filter as shown in Fig. 29.20 is inverting. For a noninverting realization, simply take the output from the middle amplifier rather than the right one. This same configuration can be used for a three-operational-amplifier low-pass filter by putting the input into the summing junction of the middle amplifier and taking the output from the left operational amplifier. Note that Q may be changed in this circuit by varying r_1 and that this will not alter ω_0. Similarly, ω_0 can be adjusted by varying c_1 or c_2 and this will not change Q. If only variable resistors are to be used, the filter can be tuned by setting ω_0 using any of the resistors other than r_1 and then setting Q using r_1.

(f) Second-order bandstop filters are very useful in rejecting unwanted signals such as line noise or carrier frequencies in instrumentation applications. Such filters are implemented with methods very similar to the bandpass filters just discussed. In most cases, the frequency of the zeros is to be the same as the frequency of the poles. For this application, the circuit shown in Fig. 29.21 can be used.

$$T(s) = \frac{H(s^2 + \omega_z^2)}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2}$$

Assumption : $c_1 = c_2 = 1$

$$r_1 = \frac{1}{2Q\omega_0} \qquad r_3 = \frac{1}{Q\omega_0} \qquad r_2 = r_4 = \frac{2Q}{\omega_0}$$

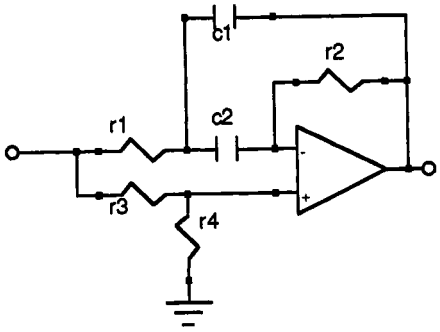


FIGURE 29.21 A single operational-amplifier bandstop filter.

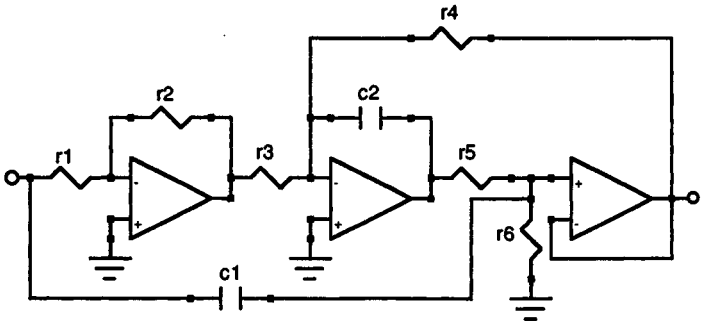
The primary advantage of this circuit is that it requires a minimum number of components. For applications where no tuning is required and the Q is low, this circuit works very well. When the bandstop filter must be tuned, the three-operational-amplifier circuit is preferable.



$$T(s) = \frac{H(s^2 + \omega_z^2)}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2} \quad c_1 = c_2 = \frac{1}{\omega_0} \quad r_1 = 1 \quad r_2 = H \quad r_5 = r_6 = 2Q \quad r_3 = \frac{H\omega_0^2}{2Q\omega_z^2} \quad r_4 = \frac{1}{2Q}$$

FIGURE 29.22 A three-operational-amplifier bandstop filter.

The foregoing circuits provide a variety of useful first- and second-order filters. For higher-order filters, these sections are simply cascaded to realize the overall transfer function desired. Additional detail about these circuits as well as other circuits used for active filters may be found in the references.

Defining Terms

Active filter: A filter circuit which uses active components, usually operational amplifiers.

Filter: A circuit which is designed to be frequency selective. That is, the circuit will emphasize or "pass" certain frequencies and attenuate or "stop" others.

Operational amplifier: A very high-gain differential amplifier used in active filter circuits and many other applications. These monolithic integrated circuits typically have such high gain, high input impedance, and low output impedance that they can be considered "ideal" when used in active filters.

Passive filter: Afilter circuit which uses only passive components, i.e., resistors, inductors, and capacitors. These circuits are useful at higher frequencies and as prototypes for ladder filters that are active.

Sensitivity function: A measure of the fractional change in some circuit characteristic, such as center frequency, to variations in a circuit parameter, such as the value of a resistor. The sensitivity function is normally defined as the partial derivative of the desired circuit characteristic with respect to the element value and is usually evaluated at the nominal value of all elements.

29.3 Generalized Impedance Convertors and Simulated Impedances

James A. Svoboda

The problem of designing a circuit to have a given transfer function is called filter design. This problem can be solved using passive circuits, that is, circuits consisting entirely of resistors, capacitors, and inductors. Further, these passive filter circuits can be designed to have some attractive properties. In particular, passive filters can be designed so that the transfer function is relatively insensitive to variations in the values of the resistances, capacitances, and inductances. Unfortunately, passive circuits contain inductors. Inductors are frequently large, heavy, expensive, and nonlinear.

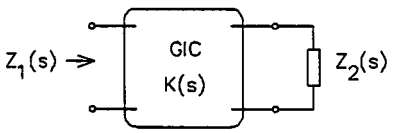

FIGURE 29.23 The GIC converts the impedance $Z_2(s)$ to the impedance $Z_1(s)$.

Generalized impedance convertors (GIC) are electronic circuits used to convert one impedance into another impedance [Bruton, 1981; Van Valkenburg, 1982]. GICs provide a way to get the advantages of passive circuits without the disadvantages of inductors. Figure 29.23 illustrates the application of a GIC. The GIC converts the impedance $Z_2(s)$ to the impedance $Z_1(s)$. The impedances are related by

$$Z_1(s) = K(s)Z_2(s) \tag{29.22}$$

The function $K(s)$ is called the conversion function or, more simply, the gain of the GIC.

Figure 29.24 shows two ways to implement a GIC using operational amplifiers (op amps). The GIC shown in Fig. 29.24a has a gain given by

$$K(s) = -\frac{Z_A(s)}{Z_B(s)} \tag{29.23}$$

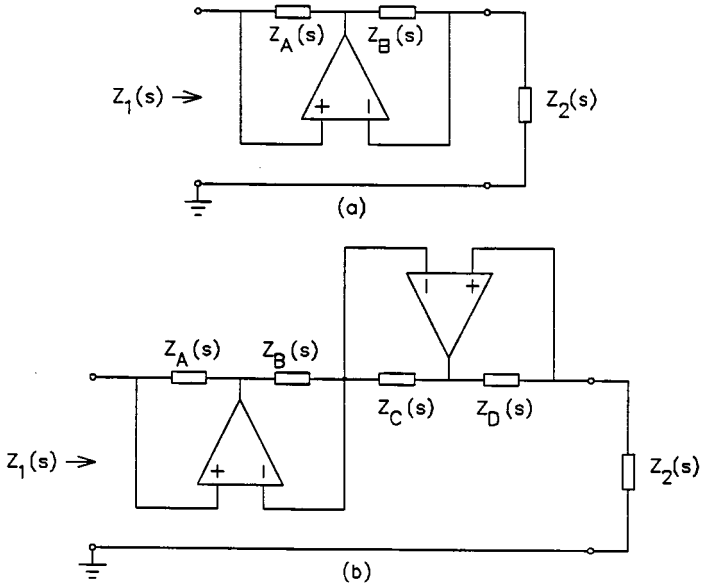

FIGURE 29.24 (a) An inverting GIC and (b) a noninverting GIC.

This GIC is called an inverting GIC because $K(s)$ is negative.

A **negative resistor** is an electronic circuit that acts like a resistor having a negative value of resistance. The inverting GIC can be used to design a negative resistor by taking $Z_A(s) = R_A$, $Z_B(s) = R_B$, and $Z_2(s) = R_2$. Figure 29.25(a) shows the op amp circuit that implements a negative resistor, and Fig. 29.25(b) shows the equivalent circuit. The resistance of the negative resistor is given by

$$R = -\frac{R_A}{R_B} R_2 \tag{29.24}$$

Figure 29.24(b) shows another op amp circuit that implements a GIC. The gain of this GIC is given by

$$K(s) = \frac{Z_A(s)Z_C(s)}{Z_B(s)Z_D(s)} \tag{29.25}$$

This GIC is called a noninverting GIC because $K(s)$ is positive.

A **simulated inductor** is circuit consisting of resistors, capacitors, and amplifiers that acts like an inductor. The noninverting GIC can be used to design a simulated inductor by taking $Z_A(s) = R_A$, $Z_B(s) = R_B$, $Z_C(s) = R_C$, $Z_D(s) = 1/(sC_D)$, and $Z_2(s) = R_2$. Figure 29.25(c) shows the op amp circuit that implements a simulated inductor, and Fig. 29.25(d) shows the equivalent circuit. The inductance of the simulated inductor is given by

$$L = \frac{R_A R_C C_D}{R_B} R_2 \tag{29.26}$$

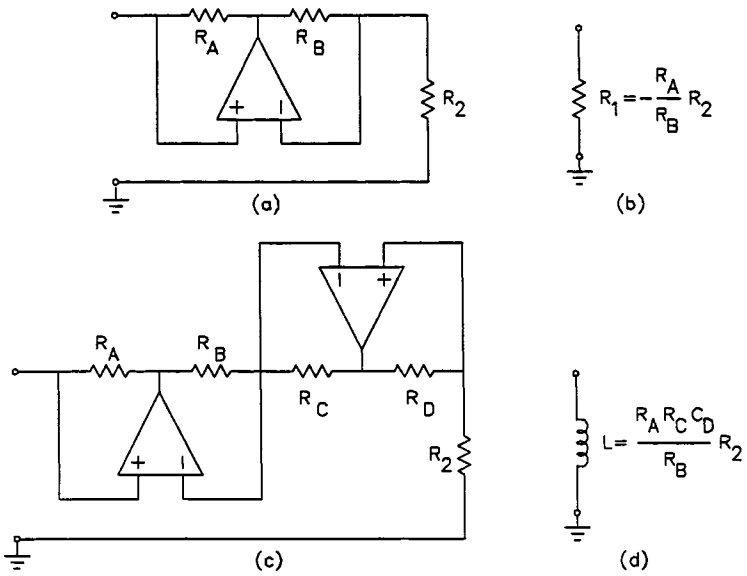

FIGURE 29.25 (a) A grounded negative resistor and (b) its equivalent circuit. (c) A grounded simulated inductor and (d) its equivalent circuit.

Notice that one node of the negative resistor shown in Fig. 29.25(b) and of the simulated inductor shown in Fig. 29.25(d) is grounded. This ground is the ground of the power supplies used to bias the op amp. Op amp circuits implementing floating negative resistors and simulated inductors are more difficult to design [Reddy, 1976]. Floating negative resistors and simulated inductors can be more easily designed using an electronic device called a **current conveyor**. The symbol for the current conveyor is shown in Fig. 29.26. The terminal voltages and currents of the "second-generation" current conveyor [Sedra and Smith, 1971] are represented by

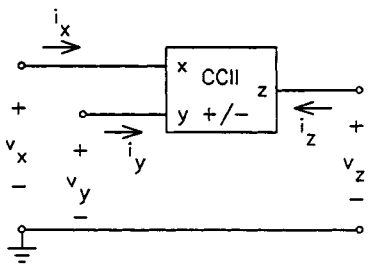

FIGURE 29.26 A CCII current conveyor.

$$\begin{pmatrix} i_y \\ v_x \\ i_z \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & \pm 1 & 0 \end{pmatrix} \begin{pmatrix} v_y \\ i_x \\ v_z \end{pmatrix} \tag{29.27}$$

There are two kinds of second-generation current conveyor, corresponding to the two possible signs of the ±1 entry in the third row of Eq. (29.27). The + indicates a CCII$^+$ current conveyor while the – indicates a CCII$^-$ current conveyor.

Current conveyors are related to **transimpedance amplifiers** [Svoboda, 1991]. Figure 29.27(a) indicates that a transimpedance amplifier consists of a CCII$^+$ current conveyor and a voltage buffer. Several transimpedance amplifiers, e.g., the AD844, AD846, and AD811, are commercially available. Figure 29.27(b) shows that a CCII$^-$ current conveyor can be constructed from two CCII$^+$ current conveyors.

Figure 29.28(a) presents a current conveyor circuit that implements a floating negative resistor. The resistance of the negative resistor is given simply as

$$R = -R_2 \tag{29.28}$$

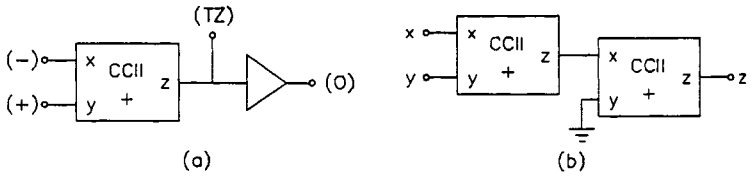

FIGURE 29.27 (a) A transimpedance amplifier consists of a CCII+ current conveyor and a voltage buffer. (b) A CCII− implemented using two CCII+ current conveyors.

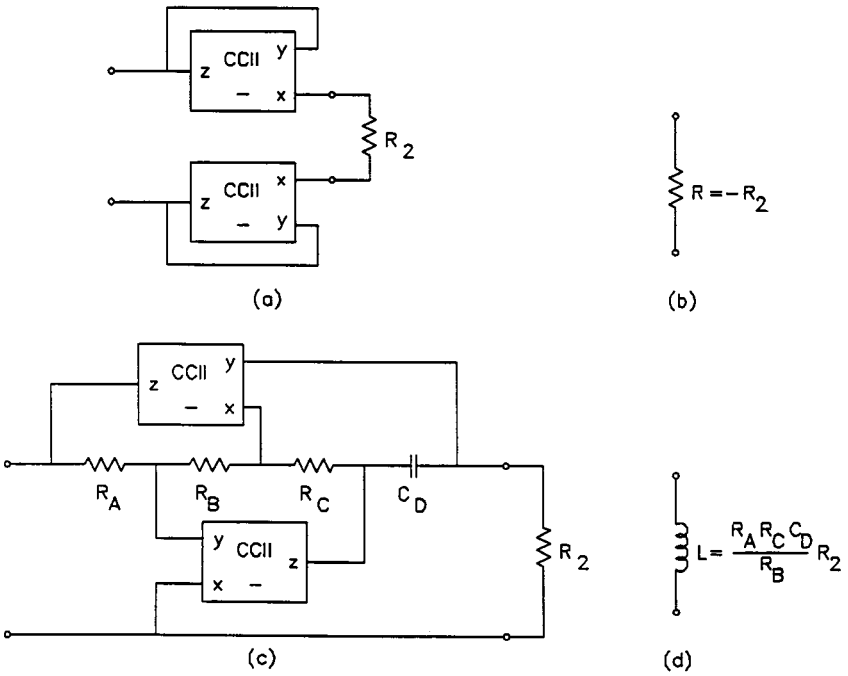

FIGURE 29.28 (a) A floating negative resistor and (b) its equivalent circuit. (c) A floating simulated inductor and (d) its equivalent circuit.

Figure 29.28(b) shows the equivalent circuit of the current conveyor negative resistor. Notice that in Fig. 29.28(b) neither node is required to be ground, in contrast to the equivalent circuit for the op amp negative resistor in Fig. 29.25(b).

Figure 29.28(c) shows a current conveyor circuit that implements a floating simulated inductor. The inductance of this simulated inductor is given by

$$L = \frac{R_A R_C C_D}{R_B} R_2 \tag{29.29}$$

Figure 29.28(d) shows the equivalent circuit of the current conveyor simulated inductor. The current conveyor circuit can simulate a floating inductor, so neither node of the equivalent inductor is required to be grounded.

Figure 29.29 illustrates an application of simulated impedances. The circuit shown in Fig. 29.29(a) implements a voltage-controlled current source (VCCS). This particular VCCS has the advantage of perfect regulation. In other words, the output current, i_o, is completely independent of the load resistance, R_L. The circuit in Fig. 29.29(a) requires a negative resistor, the resistor labeled $-R$. Since one node of this resistor is grounded,

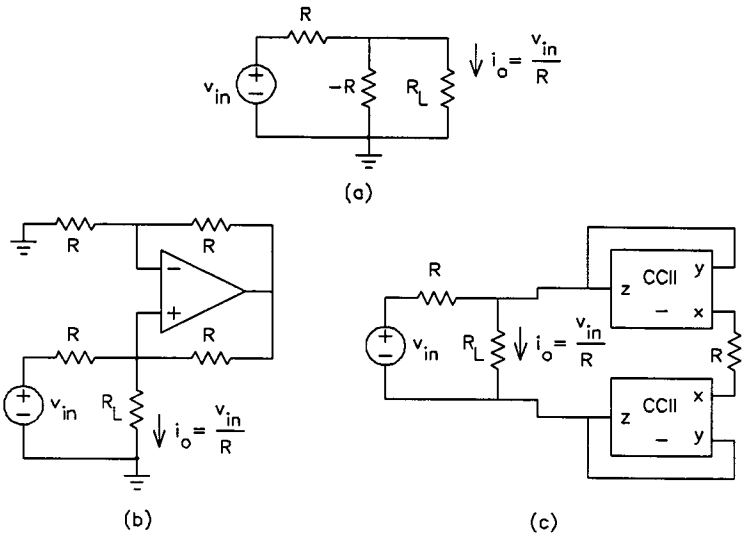

FIGURE 29.29 Three versions of a VCCS: (a) using a negative resistor, (b) using an op amp, and (c) using current conveyors.

this resistor can be implemented using the op amp negative resistor shown in Fig. 29.25(a). The resulting circuit is shown in Fig. 29.29(b).

In Fig. 29.29(a), one node of the load resistor is grounded. As a consequence, one node of the negative resistor was grounded and it was appropriate to use the op amp negative resistor. Sometimes a VCCS is needed to cause a current in an ungrounded load resistance. In this case the negative resistor must also be ungrounded so the current conveyor negative resistor is used. In Fig. 29.29(c) the current conveyor negative resistor is used to implement a VCCS that supplies current to an ungrounded resistor R_L.

Figure 29.30 illustrates the application of a simulated inductor. The circuit shown in Fig. 29.30(a) is a low-pass filter. The transfer function of this filter is

$$\frac{V_o(s)}{V_{\text{in}}(s)} = \frac{\dfrac{1}{LC}}{s^2 + \dfrac{R}{L}s + \dfrac{1}{LC}} \tag{29.30}$$

The filter in Fig. 29.30(a) contains an inductor. This inductor can be implemented as a simulated inductor. Since neither node of the inductor is grounded, it is necessary to use the current conveyor simulated inductor. The resulting circuit is shown in Fig. 29.30(b). The inductance of the simulated inductor is given by Eq. (29.29). Substituting this equation into Eq. (29.30) gives the transfer function of the circuit in Fig. 29.30(b)

$$\frac{V_o(s)}{V_{\text{in}}(s)} = \frac{\dfrac{R_B}{R_A R_C R_2 C_D C}}{s^2 + \dfrac{RR_B}{R_A R_C R_2 C_D}s + \dfrac{R_B}{R_A R_C R_2 C_D C}} \tag{29.31}$$

Similarly, high-pass, bandpass, and notch filters can be designed by rearranging the resistor, capacitor, and inductor in Fig. 29.30(a) to get the desired transfer function and then simulating the inductor. When the inductor is grounded, it can be simulated using the op amp–simulated inductor, but when the inductor is floating, the current conveyor–simulated inductor must be used.

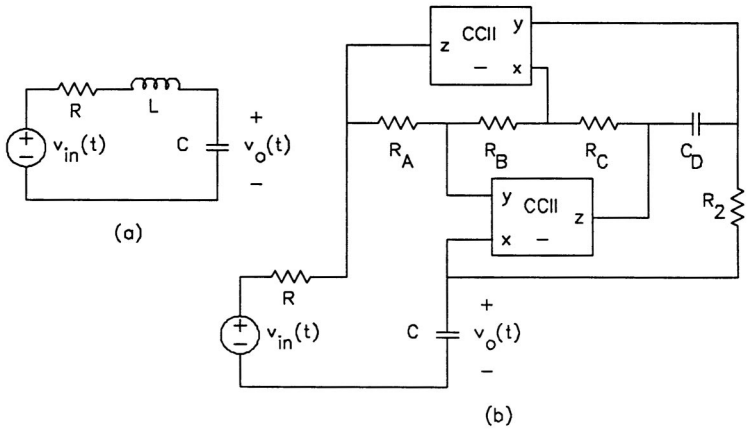

FIGURE 29.30 (a) A low-pass RLC filter and (b) the same low-pass filter implemented using a floating simulated inductor.

Defining Terms

Current conveyor: An electronic device represented by Fig. 29.26 and Eq. (29.27).
Generalized impedance convertors (GIC): Electronic circuits used to convert one impedance into another impedance.
Negative resistor: An electronic circuit that acts like a resistor having a negative value of resistance.
Transimpedance amplifier: An amplifier consisting of a CCII$^+$ current conveyor and a voltage buffer.
Simulated inductor: A circuit consisting of resistors capacitors and amplifiers that acts like an inductor.

30.1 Power Semiconductor Devices

Kaushik Rajashekara

The modern age of power electronics began with the introduction of thyristors in the late 1950s. Now there are several types of power devices available for high-power and high-frequency applications. The most notable power devices are gate turn-off thyristors, power Darlington transistors, power MOSFETs, and insulated-gate bipolar transistors (IGBTs). Power semiconductor devices are the most important functional elements in all power conversion applications. The power devices are mainly used as switches to convert power from one form to another. They are used in motor control systems, uninterrupted power supplies, high-voltage dc transmission, power supplies, induction heating, and in many other power conversion applications. A review of the basic characteristics of these power devices is presented in this section.

Thyristor and Triac

The thyristor, also called a silicon-controlled rectifier (SCR), is basically a four-layer three-junction *pnpn* device. It has three terminals: anode, cathode, and gate. The device is turned on by applying a short pulse across the gate and cathode. Once the device turns on, the gate loses its control to turn off the device. The turn-off is achieved by applying a **reverse voltage** across the anode and cathode. The thyristor symbol and its volt-ampere characteristics are shown in Fig. 30.1. There are basically two classifications of thyristors: converter grade and inverter grade. The difference between a converter-grade and an inverter-grade thyristor is the low turn-off time (on the order of a few microseconds) for the latter. The converter-grade thyristors are slow type and are used in natural commutation (or phase-controlled) applications. Inverter-grade thyristors are used in forced commutation applications such as dc-dc choppers and dc-ac inverters. The inverter-grade thyristors are turned off by forcing the current to zero using an external commutation circuit. This requires additional commutating components, thus resulting in additional losses in the inverter.

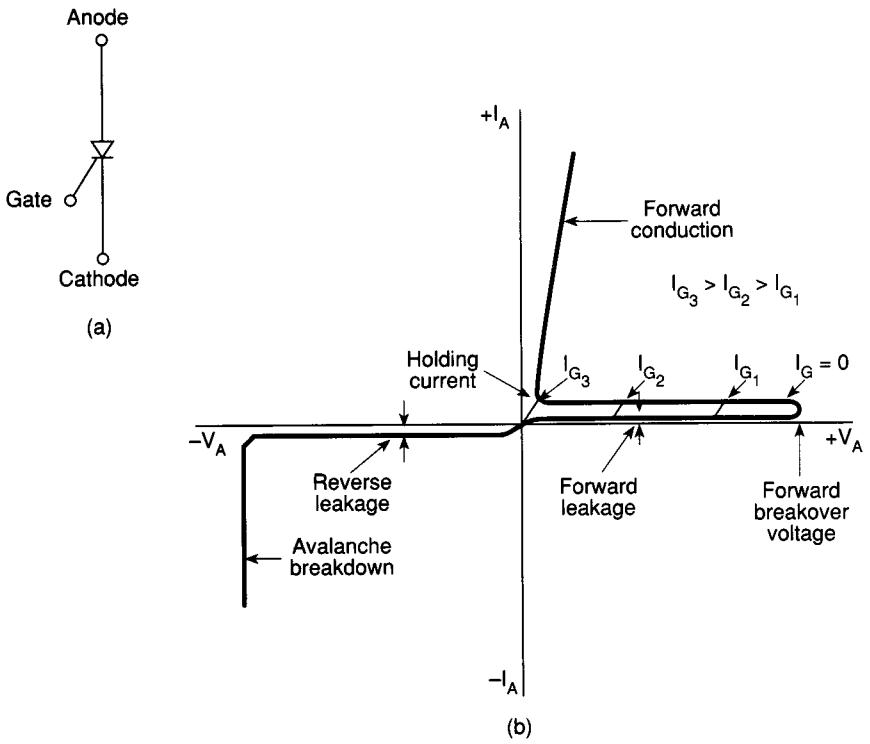

FIGURE 30.1 (a) Thyristor symbol and (b) volt-ampere characteristics. (*Source:* B.K. Bose, *Modern Power Electronics: Evaluation, Technology, and Applications,* p. 5. © 1992 IEEE.)

Thyristors are highly rugged devices in terms of transient currents, ***di/dt,*** and ***dv/dt*** capability. The **forward voltage** drop in thyristors is about 1.5 to 2 V, and even at higher currents of the order of 1000 A, it seldom exceeds 3 V. While the forward voltage determines the on-state power loss of the device at any given current, the switching power loss becomes a dominating factor affecting the device junction temperature at high operating frequencies. Because of this, the maximum switching frequencies possible using thyristors are limited in comparison with other power devices considered in this section.

Thyristors have I^2t withstand capability and can be protected by fuses. The nonrepetitive surge current capability for thyristors is about 10 times their rated root mean square (rms) current. They must be protected by snubber networks for *dv/dt* and *di/dt* effects. If the specified *dv/dt* is exceeded, thyristors may start conducting without applying a gate pulse. In dc-to-ac conversion applications it is necessary to use an antiparallel diode of similar rating across each main thyristor. Thyristors are available up to 6000 V, 3500 A.

A triac is functionally a pair of converter-grade thyristors connected in antiparallel. The triac symbol and volt-ampere characteristics are shown in Fig. 30.2. Because of the integration, the triac has poor reapplied *dv/dt*, poor gate current sensitivity at turn-on, and longer turn-off time. Triacs are mainly used in phase control applications such as in ac regulators for lighting and fan control and in solid-state ac relays.

Gate Turn-Off Thyristor (GTO)

The GTO is a power switching device that can be turned on by a short pulse of gate current and turned off by a reverse gate pulse. This reverse gate current amplitude is dependent on the anode current to be turned off. Hence there is no need for an external commutation circuit to turn it off. Because turn-off is provided by bypassing carriers directly to the gate circuit, its turn-off time is short, thus giving it more capability for high-frequency operation than thyristors. The GTO symbol and turn-off characteristics are shown in Fig. 30.3.

GTOs have the I^2t withstand capability and hence can be protected by semiconductor fuses. For reliable operation of GTOs, the critical aspects are proper design of the gate turn-off circuit and the snubber circuit.

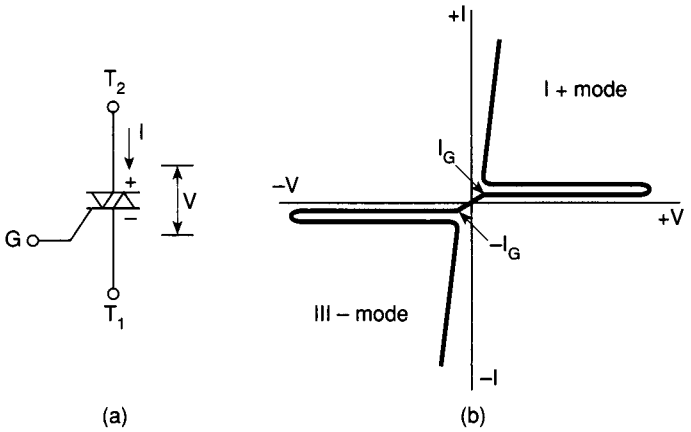

FIGURE 30.2 (a) Triac symbol and (b) volt-ampere characteristics. (*Source:* B.K. Bose, *Modern Power Electronics: Evaluation, Technology, and Applications,* p. 5. © 1992 IEEE.)

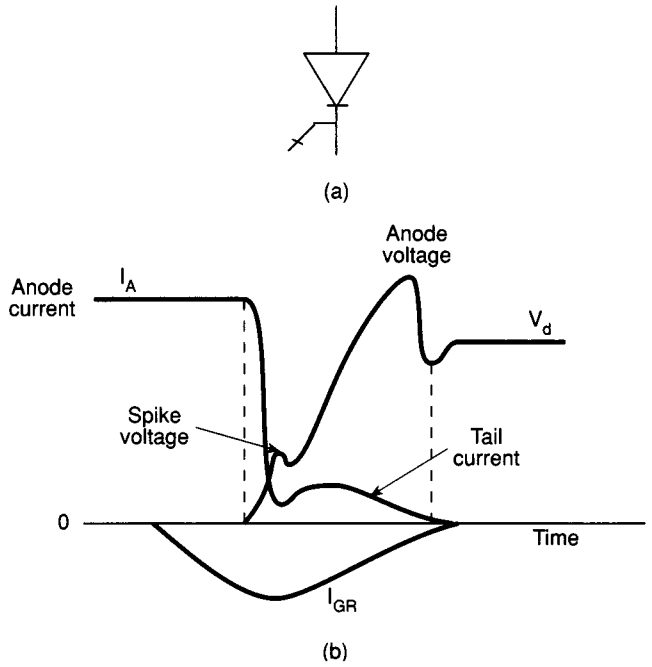

FIGURE 30.3 (a) GTO symbol and (b) turn-off characteristics. (*Source:* B.K. Bose, *Modern Power Electronics: Evaluation, Technology, and Applications,* p. 5. © 1992 IEEE.)

A GTO has a poor turn-off current gain of the order of 4 to 5. For example, a 2000-A peak current GTO may require as high as 500 A of reverse gate current. Also, a GTO has the tendency to latch at temperatures above 125°C. GTOs are available up to about 4500 V, 2500 A.

Reverse-Conducting Thyristor (RCT) and Asymmetrical Silicon-Controlled Rectifier (ASCR)

Normally in inverter applications, a diode in antiparallel is connected to the thyristor for commutation/freewheeling purposes. In RCTs, the diode is integrated with a fast switching thyristor in a single silicon chip. Thus,

the number of power devices could be reduced. This integration brings forth a substantial improvement of the static and dynamic characteristics as well as its overall circuit performance.

The RCTs are designed mainly for specific applications such as traction drives. The antiparallel diode limits the reverse voltage across the thyristor to 1 to 2 V. Also, because of the reverse recovery behavior of the diodes, the thyristor may see very high reapplied *dv/dt* when the diode recovers from its reverse voltage. This necessitates use of large RC snubber networks to suppress voltage transients. As the range of application of thyristors and diodes extends into higher frequencies, their reverse recovery charge becomes increasingly important. High reverse recovery charge results in high power dissipation during switching.

The ASCR has a similar forward blocking capability as an inverter-grade thyristor, but it has a limited reverse blocking (about 20–30 V) capability. It has an on-state voltage drop of about 25% less than an inverter-grade thyristor of a similar rating. The ASCR features a fast turn-off time; thus it can work at a higher frequency than an SCR. Since the turn-off time is down by a factor of nearly 2, the size of the commutating components can be halved. Because of this, the switching losses will also be low.

Gate-assisted turn-off techniques are used to even further reduce the turn-off time of an ASCR. The application of a negative voltage to the gate during turn-off helps to evacuate stored charge in the device and aids the recovery mechanisms. This will in effect reduce the turn-off time by a factor of up to 2 over the conventional device.

Power Transistor

Power transistors are used in applications ranging from a few to several hundred kilowatts and switching frequencies up to about 10 kHz. Power transistors used in power conversion applications are generally *npn* type. The power transistor is turned on by supplying sufficient base current, and this base drive has to be maintained throughout its conduction period. It is turned off by removing the base drive and making the base voltage slightly negative (within $-V_{BE(\max)}$). The saturation voltage of the device is normally 0.5 to 2.5 V and increases as the current increases. Hence the on-state losses increase more than proportionately with current. The transistor off-state losses are much lower than the on-state losses because the leakage current of the device is of the order of a few milliamperes. Because of relatively larger switching times, the switching loss significantly increases with switching frequency. Power transistors can block only forward voltages. The reverse peak voltage rating of these devices is as low as 5 to 10 V.

Power transistors do not have I^2t withstand capability. In other words, they can absorb only very little energy before breakdown. Therefore, they cannot be protected by semiconductor fuses, and thus an electronic protection method has to be used.

To eliminate high base current requirements, Darlington configurations are commonly used. They are available in monolithic or in isolated packages. The basic Darlington configuration is shown schematically in Fig. 30.4. The Darlington configuration presents a specific advantage in that it can considerably increase the current switched by the transistor for a given base drive. The $V_{CE(\text{sat})}$ for the Darlington is generally more than that of a single transistor of similar rating with corresponding increase in on-state power loss. During switching, the reverse-biased collector junction may show hot spot breakdown effects that are specified by reverse-bias safe operating area (RBSOA) and forward bias safe operating area (FBSOA). Modern devices with highly interdigited emitter base geometry force more uniform current distribution and therefore considerably improve second breakdown effects. Normally, a well-designed switching aid network constrains the device operation well within the SOAs.

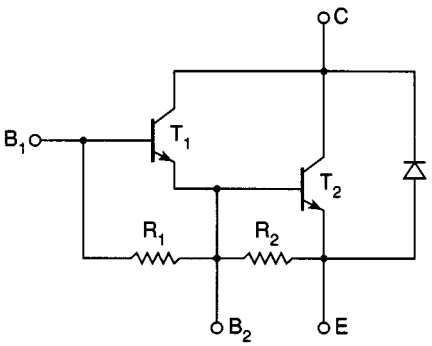

FIGURE 30.4 A two-stage Darlington transistor with bypass diode. (*Source:* B.K. Bose, *Modern Power Electronics: Evaluation, Technology, and Applications,* p. 6. © 1992 IEEE.)

Power MOSFET

Power MOSFETs are marketed by different manufacturers with differences in internal geometry and with different names such as MegaMOS, HEXFET, SIPMOS, and TMOS. They have unique features that make them potentially attractive for switching applications. They are essentially voltage-driven rather than current-driven devices, unlike bipolar transistors.

The gate of a MOSFET is isolated electrically from the source by a layer of silicon oxide. The gate draws only a minute leakage current of the order of nanoamperes. Hence the gate drive circuit is simple and power loss in the gate control circuit is practically negligible. Although in steady state the gate draws virtually no current, this is not so under transient conditions. The gate-to-source and gate-to-drain capacitances have to be charged and discharged appropriately to obtain the desired switching speed, and the drive circuit must have a sufficiently low output impedance to supply the required charging and discharging currents. The circuit symbol of a power MOSFET is shown in Fig. 30.5.

Power MOSFETs are majority carrier devices, and there is no minority carrier storage time. Hence they have exceptionally fast rise and fall times. They are essentially resistive devices when turned on, while bipolar transistors present a more or less constant $V_{CE(\text{sat})}$ over the normal operating range. Power dissipation in MOSFETs is $Id^2R_{DS(\text{on})}$, and in bipolars it is $I_CV_{CE(\text{sat})}$. At low currents, therefore, a power MOSFET may have a lower conduction loss than a comparable bipolar device, but at higher currents, the conduction loss will exceed that of bipolars. Also, the $R_{DS(\text{on})}$ increases with temperature.

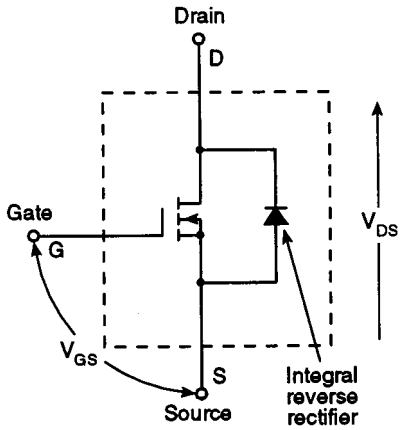

FIGURE 30.5 Power MOSFET circuit symbol. (*Source:* B.K. Bose, *Modern Power Electronics: Evaluation, Technology, and Applications,* p. 7. © 1992 IEEE.)

An important feature of a power MOSFET is the absence of a secondary breakdown effect, which is present in a bipolar transistor, and as a result, it has an extremely rugged switching performance. In MOSFETs, $R_{DS(\text{on})}$ increases with temperature, and thus the current is automatically diverted away from the hot spot. The drain body junction appears as an antiparallel diode between source and drain. Thus power MOSFETs will not support voltage in the reverse direction. Although this inverse diode is relatively fast, it is slow by comparison with the MOSFET. Recent devices have the diode recovery time as low as 100 ns. Since MOSFETs cannot be protected by fuses, an electronic protection technique has to be used.

With the advancement in MOS technology, ruggedized MOSFETs are replacing the conventional MOSFETs. The need to ruggedize power MOSFETs is related to device reliability. If a MOSFET is operating within its specification range at all times, its chances for failing catastrophically are minimal. However, if its absolute maximum rating is exceeded, failure probability increases dramatically. Under actual operating conditions, a MOSFET may be subjected to transients — either externally from the power bus supplying the circuit or from the circuit itself due, for example, to inductive kicks going beyond the absolute maximum ratings. Such conditions are likely in almost every application, and in most cases are beyond a designer's control. Rugged devices are made to be more tolerant for over-voltage transients. Ruggedness is the ability of a MOSFET to operate in an environment of dynamic electrical stresses, without activating any of the parasitic bipolar junction transistors. The rugged device can withstand higher levels of diode recovery *dv/dt* and static *dv/dt.*

Insulated-Gate Bipolar Transistor (IGBT)

The IGBT has the high input impedance and high-speed characteristics of a MOSFET with the conductivity characteristic (low saturation voltage) of a bipolar transistor. The IGBT is turned on by applying a positive voltage between the gate and emitter and, as in the MOSFET, it is turned off by making the gate signal zero or slightly negative. The IGBT has a much lower voltage drop than a MOSFET of similar ratings. The structure of an IGBT is more like a thyristor and MOSFET. For a given IGBT, there is a critical value of collector current

that will cause a large enough voltage drop to activate the thyristor. Hence, the device manufacturer specifies the peak allowable collector current that can flow without latch-up occurring. There is also a corresponding gate source voltage that permits this current to flow that should not be exceeded.

Like the power MOSFET, the IGBT does not exhibit the secondary breakdown phenomenon common to bipolar transistors. However, care should be taken not to exceed the maximum power dissipation and specified maximum junction temperature of the device under all conditions for guaranteed reliable operation. The on-state voltage of the IGBT is heavily dependent on the gate voltage. To obtain a low on-state voltage, a sufficiently high gate voltage must be applied.

In general, IGBTs can be classified as punch-through (PT) and nonpunch-through (NPT) structures, as shown in Fig. 30.6. In the PT IGBT, an N^+ buffer layer is normally introduced between the P^+ substrate and the N^- epitaxial layer, so that the whole N^- drift region is depleted when the device is blocking the off-state voltage, and the electrical field shape inside the N^- drift region is close to a rectangular shape. Because a shorter N^- region can be used in the punch-through IGBT, a better trade-off between the forward voltage drop and turn-off time can be achieved. PT IGBTs are available up to about 1200 V.

High voltage IGBTs are realized through non-punch-through process. The devices are built on a N^- wafer substrate which serves as the N^- base drift region. Experimental NPT IGBTs of up to about 4 KV have been reported in the literature. NPT IGBTs are more robust than PT IGBTs particularly under short circuit conditions. But NPT IGBTs have a higher forward voltage drop than the PT IGBTs.

The PT IGBTs cannot be as easily paralleled as MOSFETs. The factors that inhibit current sharing of parallel-connected IGBTs are (1) on-state current unbalance, caused by $V_{CE}(sat)$ distribution and main circuit wiring resistance distribution, and (2) current unbalance at turn-on and turn-off, caused by the switching time difference of the parallel connected devices and circuit wiring inductance distribution. The NPT IGBTs can be paralleled because of their positive temperature coefficient property.

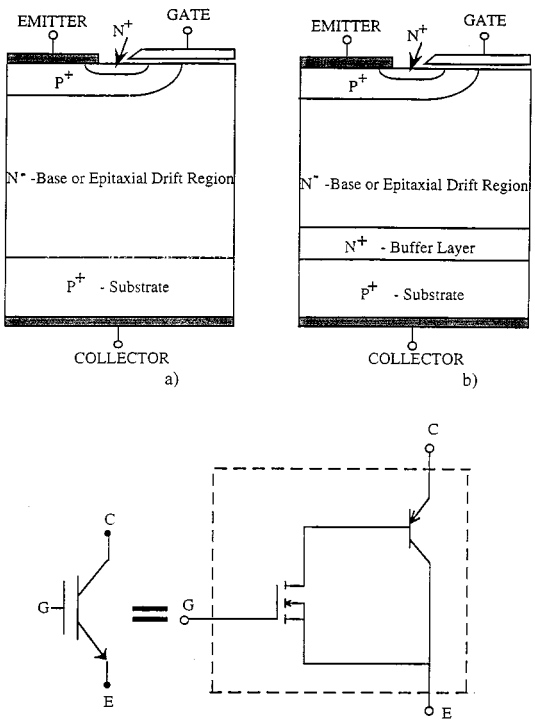

FIGURE 30.6 Nonpunch-through IGBT, (b) Punch-through IGBT, (c) IGBT equivalent circuit.

MOS-Controlled Thyristor (MCT)

The MCT is a new type of power semiconductor device that combines the capabilities of thyristor voltage and current with MOS gated turn-on and turn-off. It is a high power, high frequency, low conduction drop and a rugged device, which is more likely to be used in the future for medium and high power applications. A cross sectional structure of a p-type MCT with its circuit schematic is shown in Fig. 30.7. The MCT has a thyristor type structure with three junctions and PNPN layers between the anode and cathode. In a practical MCT, about 100,000 cells similar to the one shown are paralleled to achieve the desired current rating. MCT is turned on by a negative voltage pulse at the gate with respect to the anode, and is turned off by a positive voltage pulse.

The MCT was announced by the General Electric R & D Center on November 30, 1988. Harris Semiconductor Corporation has developed two generations of p-MCTs. Gen-1 p-MCTs are available at 65 A/1000 V and 75A/600 V with peak controllable current of 120 A. Gen-2 p-MCTs are being developed at similar current and voltage ratings, with much improved turn-on capability and switching speed. The reason for developing p-MCT is the fact that the current density that can be turned off is 2 or 3 times higher than that of an n-MCT; but n-MCTs are the ones needed for many practical applications. Harris Semiconductor Corporation is in the process of developing n-MCTs, which are expected to be commercially available during the next one to two years.

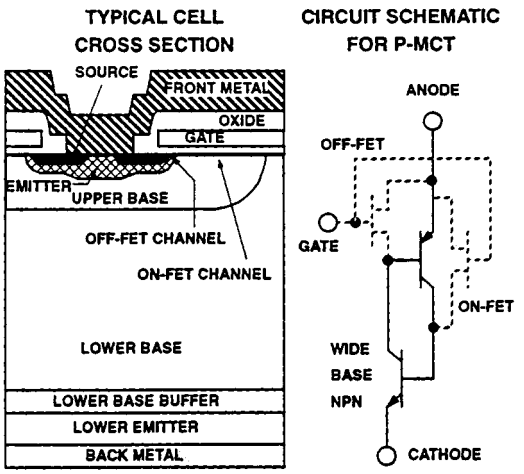

FIGURE 30.7 (*Source:* Harris Semiconductor, *User's Guide of MOS Controlled Thyristor,* With permission.)

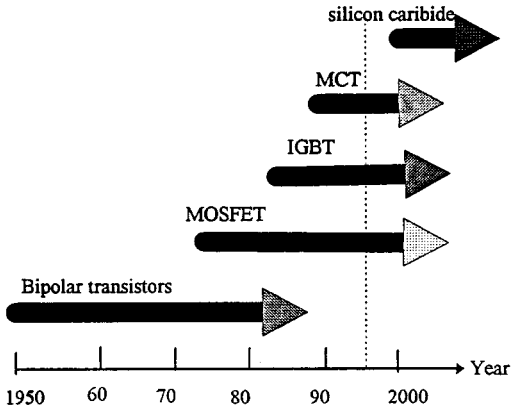

FIGURE 30.8 Current and future pwer semiconductor devices development direction (*Source:* A.Q. Huang, *Recent Developments of Power Semiconductor Devices,* VPEC Seminar Proceedings, pp. 1–9. With permission.)

The advantage of an MCT over-IGBT is its low forward voltage drop. N-type MCTs will be expected to have a similar forward voltage drop, but with an improved reverse bias safe operating area and switching speed. MCTs have relatively low switching times and storage time. The MCT is capable of high current densities and blocking voltages in both directions. Since the power gain of an MCT is extremely high, it could be driven directly from logic gates. An MCT has high *di/dt* (of the order of 2500 A/μs) and high *dv/dt* (of the order of 20,000 V/μs) capability.

The MCT, because of its superior characteristics, shows a tremendous possibility for applications such as motor drives, uninterrupted power supplies, static VAR compensators, and high power active power line conditioners.

The current and future power semiconductor devices developmental direction is shown in Fig. 30.8. High temperature operation capability and low forward voltage drop operation can be obtained if silicon is replaced by silicon carbide material for producing power devices. The silicon carbide has a higher band gap than silicon. Hence higher breakdown voltage devices could be developed. Silicon carbide devices have excellent switching characteristics and stable blocking voltages at higher temperatures. But the silicon carbide devices are still in the very early stages of development.

Defining Terms

di/dt limit: Maximum allowed rate of change of current through a device. If this limit is exceeded, the device may not be guaranteed to work reliably.
dv/dt: Rate of change of voltage withstand capability without spurious turn-on of the device.
Forward voltage: The voltage across the device when the anode is positive with respect to the cathode.
I^2t: Represents available thermal energy resulting from current flow.
Reverse voltage: The voltage across the device when the anode is negative with respect to the cathode.

30.2 Power Conversion

Kaushik Rajashekara

Power conversion deals with the process of converting electric power from one form to another. The power electronic apparatuses performing the power conversion are called *power converters.* Because they contain no moving parts, they are often referred to as *static* power converters. The power conversion is achieved using power semiconductor devices, which are used as switches. The power devices used are SCRs (silicon controlled rectifiers, or thyristors), triacs, power transistors, power MOSFETs, insulated gate bipolar transistors (IGBTs), and MCTs (MOS-controlled thyristors). The power converters are generally classified as:

1. ac-dc converters (phase-controlled converters)
2. direct ac-ac converters (cycloconverters)
3. dc-ac converters (inverters)
4. dc-dc converters (choppers, buck and boost converters)

AC-DC Converters

The basic function of a **phase-controlled converter** is to convert an alternating voltage of variable amplitude and frequency to a variable dc voltage. The power devices used for this application are generally **SCR**s. The average value of the output voltage is controlled by varying the conduction time of the SCRs. The turn-on of the SCR is achieved by providing a gate pulse when it is forward-biased. The turn-off is achieved by the **commutation** of current from one device to another at the instant the incoming ac voltage has a higher instantaneous potential than that of the outgoing wave. Thus there is a natural tendency for current to be commutated from the outgoing to the incoming SCR, without the aid of any external commutation circuitry. This commutation process is often referred to as *natural commutation.*

A single-phase half-wave converter is shown in Fig. 30.9. When the SCR is turned on at an angle α, full supply voltage (neglecting the SCR drop) is applied to the load. For a purely resistive load, during the positive half cycle, the output voltage waveform follows the input ac voltage waveform. During the negative half cycle, the SCR is turned off. In the case of inductive load, the energy stored in the inductance causes the current to flow in the load circuit even after the reversal of the supply voltage, as shown in Fig. 30.9(b). If there is no freewheeling diode D_F, the load current is discontinuous. A freewheeling diode is connected across the load to turn off the SCR as soon as the input voltage polarity reverses, as shown in Fig. 30.9(c). When the SCR is off, the load current will freewheel through the diode. The power flows from the input to the load only when the SCR is conducting. If there is no freewheeling diode, during the negative portion of the supply voltage, SCR returns the energy stored in the load inductance to the supply. The freewheeling diode improves the input power factor.

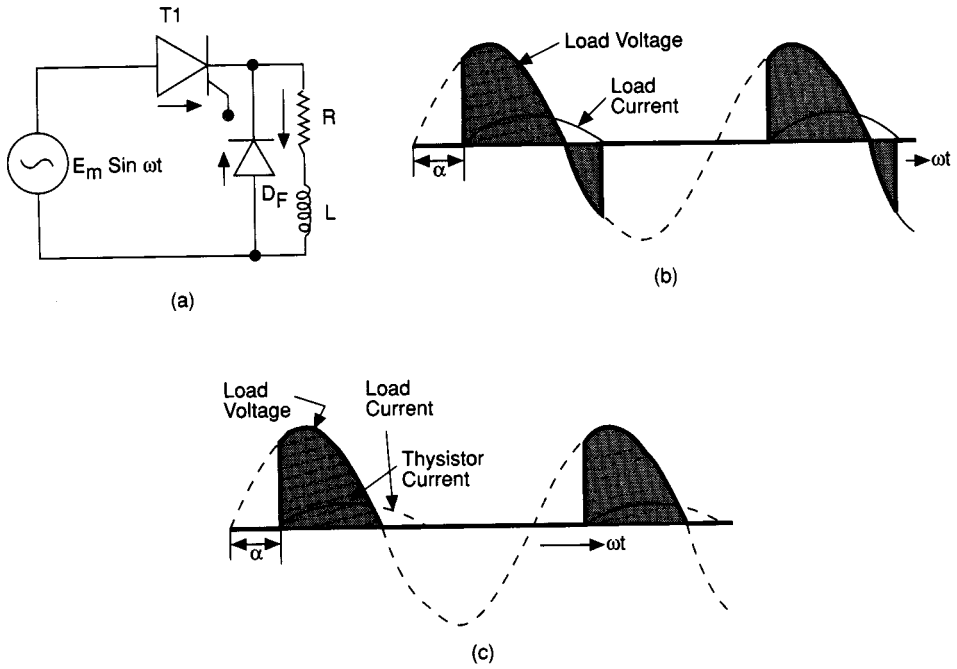

FIGURE 30.9 Single-phase half-wave converter with freewheeling diode. (a) Circuit diagram; (b) waveform for inductive load with no freewheeling diode; (c) waveform with freewheeling diode.

The controlled full-wave dc output may be obtained by using either a center tap transformer (Fig. 30.10) or by bridge configuration (Fig. 30.11). The bridge configuration is often used when a transformer is undesirable and the magnitude of the supply voltage properly meets the load voltage requirements. The average output voltage of a single-phase full-wave converter for continuous current conduction is given by

$$v_{d\alpha} = 2\frac{E_m}{\pi}\cos\alpha$$

where E_m is the peak value of the input voltage and α is the firing angle. The output voltage of a single-phase bridge circuit is the same as that shown in Fig. 30.10. Various configurations of the single-phase bridge circuit can be obtained if, instead of four SCRs, two diodes and two SCRs are used, with or without freewheeling diodes.

A three-phase full-wave converter consisting of six thyristor switches is shown in Fig. 30.12(a). This is the most commonly used three-phase bridge configuration. Thyristors T_1, T_3, and T_5 are turned on during the positive half cycle of the voltages of the phases to which they are connected, and thyristors T_2, T_4, and T_6 are turned on during the negative half cycle of the phase voltages. The reference for the angle in each cycle is at the crossing points of the phase voltages. The ideal output voltage, output current, and input current waveforms are shown in Fig. 30.12(b). The output dc voltage is controlled by varying the firing angle α. The average output voltage under continuous current conduction operation is given by

$$v_o = \frac{3\sqrt{3}}{\pi}E_m\cos\alpha$$

where E_m is the peak value of the phase voltage. At $\alpha = 90°$, the output voltage is zero. For $0 < \alpha < 90°$, v_o is positive and power flows from ac supply to the load. For $90° < \alpha < 180°$, v_o is negative and the converter operates in the inversion mode. If the load is a dc motor, the power can be transferred from the motor to the ac supply, a process known as *regeneration.*

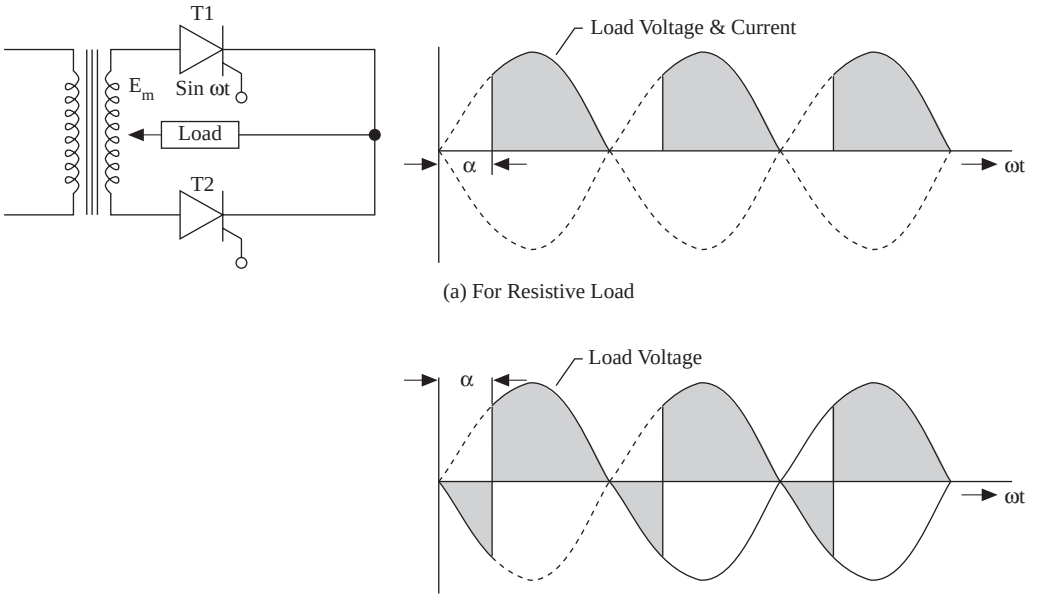

FIGURE 30.10 Single-phase full-wave converter with transformer.

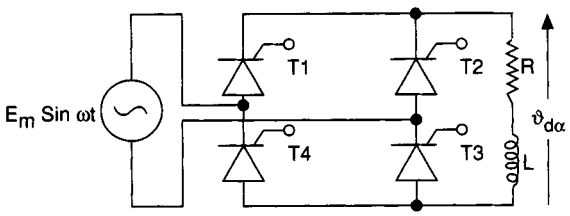

FIGURE 30.11 Single-phase bridge converter.

In Fig. 30.12(a), the top or bottom thyristors could be replaced by diodes. The resulting topology is called a *thyristor semiconverter*. With this configuration, the input power factor is improved, but the regeneration is not possible.

Cycloconverters

Cycloconverters are direct ac-to-ac frequency changers. The term *direct conversion* means that the energy does not appear in any form other than the ac input or ac output. The output frequency is lower than the input frequency and is generally an integral multiple of the input frequency. A cycloconverter permits energy to be fed back into the utility network without any additional measures. Also, the phase sequence of the output voltage can be easily reversed by the control system. Cycloconverters have found applications in aircraft systems and industrial drives. These cycloconverters are suitable for synchronous and induction motor control. The operation of the cycloconverter is illustrated in Section 30.4 of this chapter.

DC-to-AC Converters

The dc-to-ac converters are generally called *inverters*. The ac supply is first converted to dc, which is then converted to a variable-voltage and variable-frequency power supply. This generally consists of a three-phase bridge connected to the ac power source, a dc link with a filter, and the three-phase inverter bridge connected

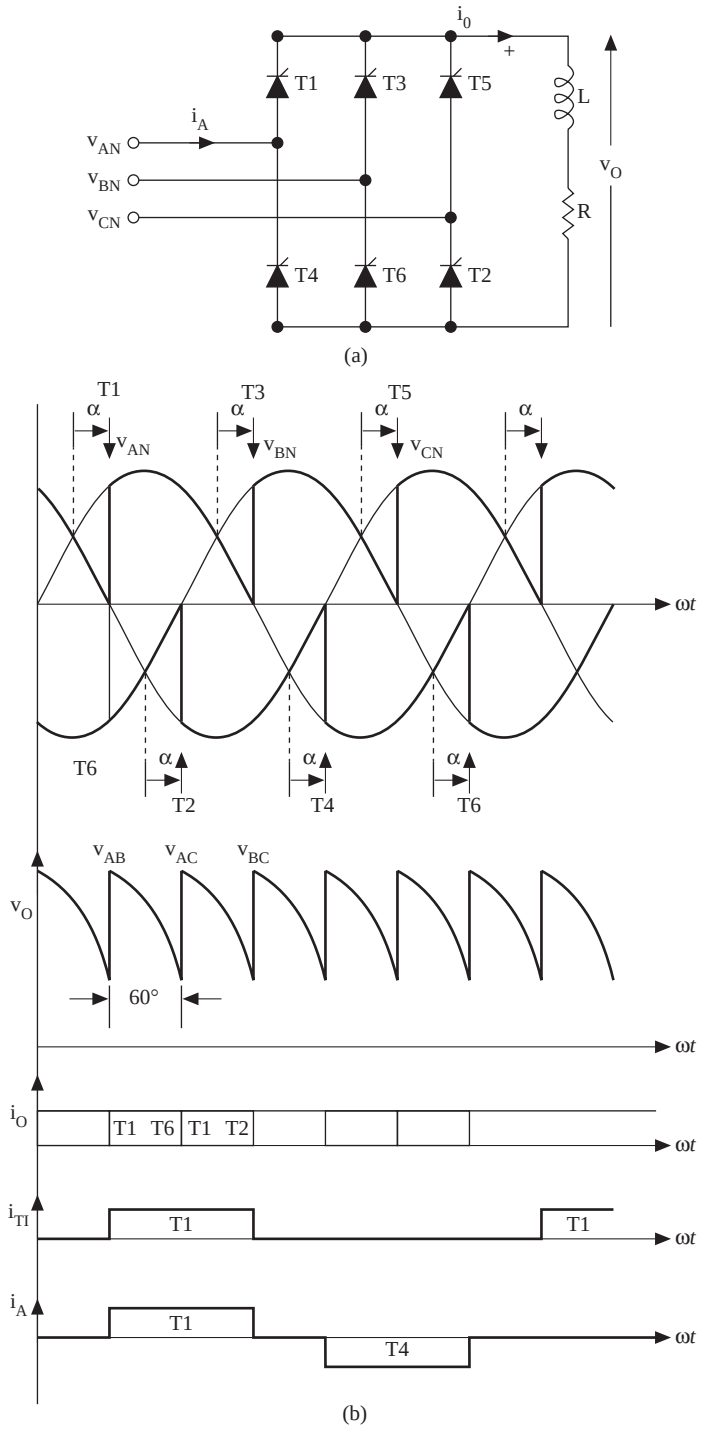

FIGURE 30.12 (a) Three-phase thyristor full bridge configuration; (b) output voltage and current waveforms.

to the load. In the case of battery-operated systems, there is no intermediate dc link. Inverters can be classified as voltage source inverters (VSIs) and current source inverters (CSIs). A voltage source inverter is fed by a stiff dc voltage, whereas a current source inverter is fed by a stiff current source. A voltage source can be converted to a current source by connecting a series inductance and then varying the voltage to obtain the desired current.

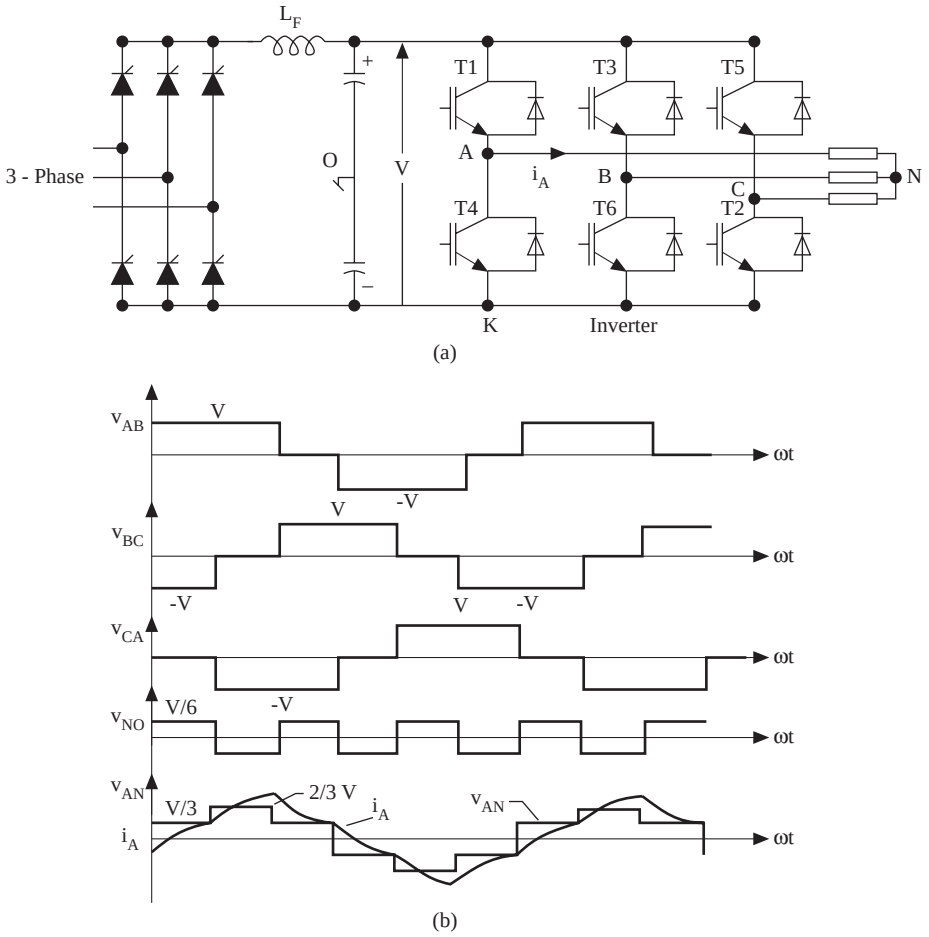

FIGURE 30.13 (a) Three-phase converter and voltage source inverter configuration; (b) three-phase square-wave inverter waveforms.

A VSI can also be operated in current-controlled mode, and similarly a CSI can also be operated in the voltage-control mode. The inverters are used in variable frequency ac motor drives, uninterrupted power supplies, induction heating, static VAR compensators, etc.

Voltage Source Inverter

A three-phase voltage source inverter configuration is shown in Fig. 30.13(a). The VSIs are controlled either in square-wave mode or in pulsewidth-modulated (PWM) mode. In square-wave mode, the frequency of the output voltage is controlled within the inverter, the devices being used to switch the output circuit between the plus and minus bus. Each device conducts for 180 degrees, and each of the outputs is displaced 120 degrees to generate a six-step waveform, as shown in Fig. 30.13(b). The amplitude of the output voltage is controlled by varying the dc link voltage. This is done by varying the firing angle of the thyristors of the three-phase bridge converter at the input. The square-wave-type VSI is not suitable if the dc source is a battery. The six-step output voltage is rich in harmonics and thus needs heavy filtering.

In PWM inverters, the output voltage and frequency are controlled within the inverter by varying the width of the output pulses. Hence at the front end, instead of a phase-controlled thyristor converter, a diode bridge rectifier can be used. A very popular method of controlling the voltage and frequency is by sinusoidal pulsewidth modulation. In this method, a high-frequency triangle carrier wave is compared with a three-phase sinusoidal waveform, as shown in Fig. 30.14. The power devices in each phase are switched on at the intersection of sine

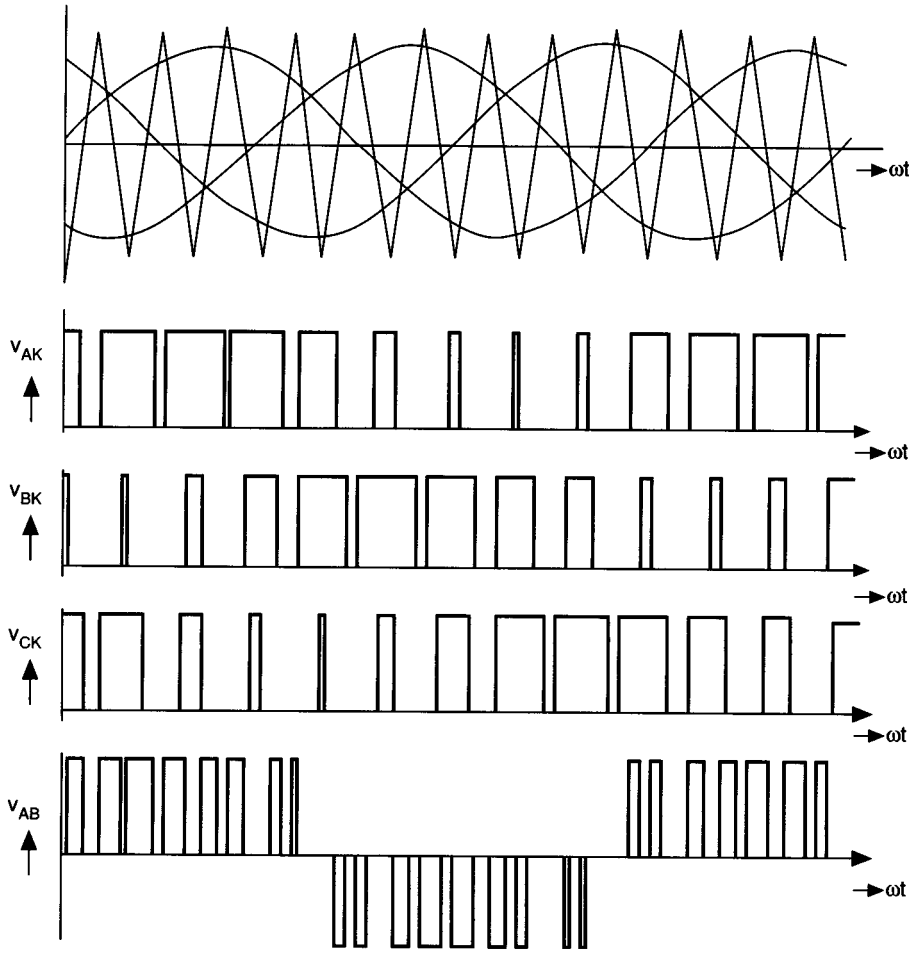

FIGURE 30.14 Three-phase sinusoidal PWM inverter waveforms.

and triangle waves. The amplitude and frequency of the output voltage are varied, respectively, by varying the amplitude and frequency of the reference sine waves. The ratio of the amplitude of the sine wave to the amplitude of the carrier wave is called the *modulation index*.

The harmonic components in a PWM wave are easily filtered because they are shifted to a higher-frequency region. It is desirable to have a high ratio of carrier frequency to fundamental frequency to reduce the harmonics of lower-frequency components. There are several other PWM techniques mentioned in the literature. The most notable ones are selected harmonic elimination, hysteresis controller, and space vector PWM technique.

In inverters, if SCRs are used as power switching devices, an external forced commutation circuit has to be used to turn off the devices. Now, with the availability of **IGBT**s above 1000-A, 1000-V ratings, they are being used in applications up to 300-kW motor drives. Above this power rating, GTOs are generally used. Power Darlington transistors, which are available up to 800 A, 1200 V, could also be used for inverter applications.

Current Source Inverter

Contrary to the voltage source inverter where the voltage of the dc link is imposed on the motor windings, in the current source inverter the current is imposed into the motor. Here the amplitude and phase angle of the motor voltage depend on the load conditions of the motor. The current source inverter is described in detail in Section 30.4.

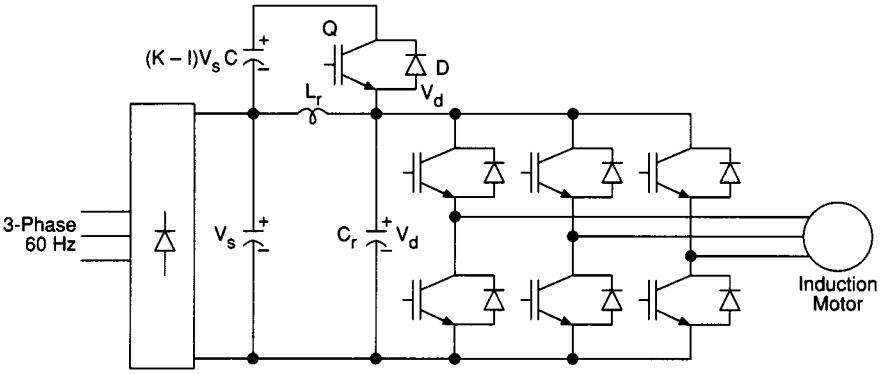

FIGURE 30.15 Resonant dc-link inverter system with active voltage clamping.

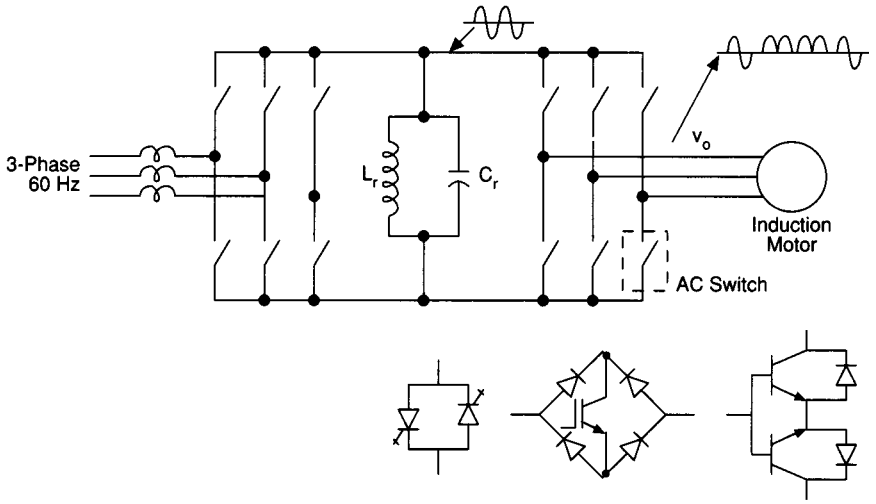

FIGURE 30.16 Resonant ac-link converter system showing configuration of ac switches.

Resonant-Link Inverters

The use of resonant switching techniques can be applied to inverter topologies to reduce the switching losses in the power devices. They also permit high switching frequency operation to reduce the size of the magnetic components in the inverter unit. In the resonant dc-link inverter shown in Fig. 30.15, a resonant circuit is added at the inverter input to convert a fixed dc voltage to a pulsating dc voltage. This resonant circuit enables the devices to be turned on and turned off during the zero voltage interval. Zero voltage or zero current switching is often termed *soft switching*. Under soft switching, the switching losses in the power devices are almost eliminated. The electromagnetic interference (EMI) problem is less severe because resonant voltage pulses have lower *dv/dt* compared to those of hard-switched PWM inverters. Also, the machine insulation is less stretched because of lower *dv/dt* resonant voltage pulses. In Fig. 30.15, all the inverter devices are turned on simultaneously to initiate a resonant cycle. The commutation from one device to another is initiated at the zero dc-link voltage. The inverter output voltage is formed by the integral numbers of quasi-sinusoidal pulses. The circuit consisting of devices *Q*, *D*, and the capacitor *C* acts as an active clamp to limit the dc voltage to about 1.4 times the diode rectifier voltage V_s.

There are several other topologies of resonant link inverters mentioned in the literature. There are also resonant link ac-ac converters based on bidirectional ac switches, as shown in Fig. 30.16. These resonant link converters find applications in ac machine control and uninterrupted power supplies, induction heating, etc. The resonant link inverter technology is still in the development stage for industrial applications.

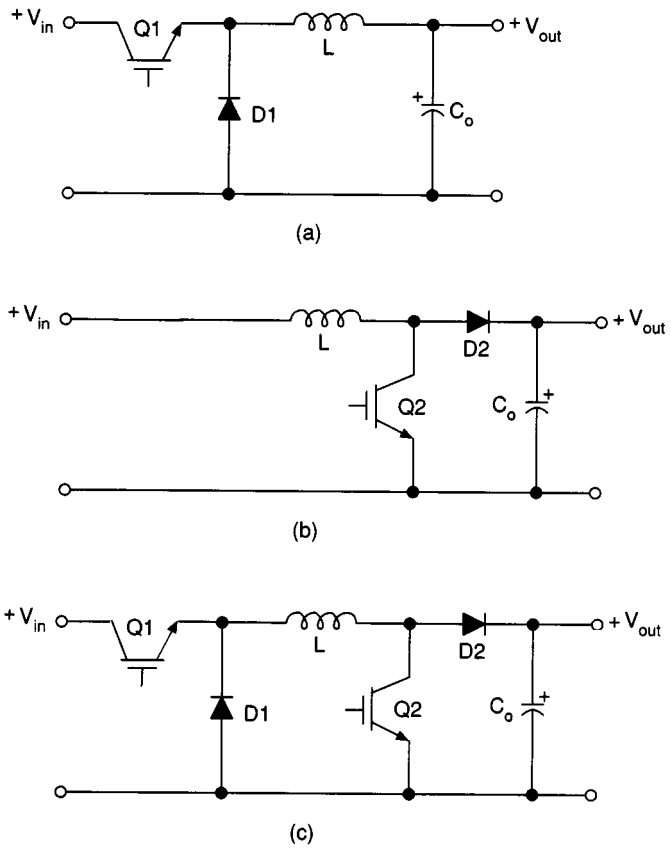

FIGURE 30.17 DC-DC converter configurations: (a) buck converter; (b) boost converter; (c) buck-boost converter.

DC-DC Converters

DC-dc converters are used to convert unregulated dc voltage to regulated or variable dc voltage at the output. They are widely used in switch-mode dc power supplies and in dc motor drive applications. In dc motor control applications, they are called *chopper-controlled drives.* The input voltage source is usually a battery or derived from an ac power supply using a diode bridge rectifier. These converters are generally either hard-switched PWM types or soft-switched resonant-link types. There are several dc-dc converter topologies, the most common ones being buck converter, boost converter, and buck-boost converter, shown in Fig. 30.17.

Buck Converter

A buck converter is also called a *step-down* converter. Its principle of operation is illustrated by referring to Fig. 30.17(a). The IGBT acts as a high-frequency switch. The IGBT is repetitively closed for a time t_{on} and opened for a time t_{off}. During t_{on}, the supply terminals are connected to the load, and power flows from supply to the load. During t_{off}, load current flows through the freewheeling diode D_1, and the load voltage is ideally zero. The average output voltage is given by

$$V_{out} = DV_{in}$$

where D is the **duty cycle** of the switch and is given by $D = t_{on}/T$, where T is the time for one period. $1/T$ is the switching frequency of the power device IGBT.

Boost Converter

A boost converter is also called a *step-up* converter. Its principle of operation is illustrated by referring to Fig. 30.17(b). This converter is used to produce higher voltage at the load than the supply voltage. When the

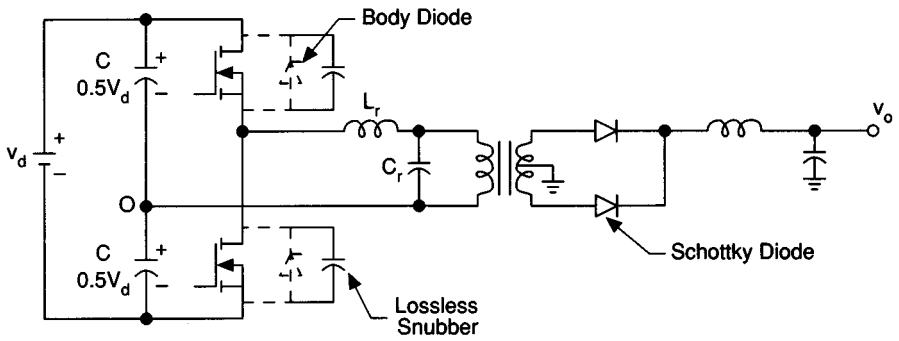

FIGURE 30.18 Resonant-link dc-dc converter.

power switch is on, the inductor is connected to the dc source and the energy from the supply is stored in it. When the device is off, the inductor current is forced to flow through the diode and the load. The induced voltage across the inductor is negative. The inductor adds to the source voltage to force the inductor current into the load. The output voltage is given by

$$V_{\text{out}} = \frac{V_{\text{in}}}{1 - D}$$

Thus for variation of D in the range $0 < D < 1$, the load voltage V_{out} will vary in the range $V_{\text{in}} < V_{\text{out}} < \infty$.

Buck-Boost Converter

A buck-boost converter can be obtained by the cascade connection of the buck and the boost converter. The steady-state output voltage V_{out} is given by

$$V_{\text{out}} = V_{\text{in}} \frac{D}{1 - D}$$

This allows the output voltage to be higher or lower than the input voltage, based on the duty cycle D. A typical buck-boost converter topology is shown in Fig. 30.17(c). When the power device is turned on, the input provides energy to the inductor and the diode is reverse biased. When the device is turned off, the energy stored in the inductor is transferred to the output. No energy is supplied by the input during this interval. In dc power supplies, the output capacitor is assumed to be very large, which results in a constant output voltage. In dc drive systems, the chopper is operated in step-down mode during motoring and in step-up mode during regeneration operation.

Resonant-Link DC-DC Converters

The use of resonant converter topologies would help to reduce the switching losses in dc-dc converters and enable the operation at switching frequencies in the megahertz range. By operating at high frequencies, the size of the power supplies could be reduced. There are several types of resonant converter topologies. The most popular configuration is shown in Fig. 30.18. The dc power is converted to high-frequency alternating power using the MOSFET half-bridge inverter. The resonant capacitor voltage is transformer-coupled, rectified using the two Schottky diodes, and then filtered to get output dc voltage. The output voltage is regulated by control of the inverter switching frequency.

Instead of parallel loading as in Fig. 30.18, the resonant circuit can be series-loaded; that is, the transformer in the output circuit can be placed in series with the tuned circuit. The series resonant circuit provides the short-circuit limiting feature.

There are other forms of resonant converter topologies mentioned in the literature such as quasi-resonant converters and multiresonant converters. These resonant converter topologies find applications in high-density power supplies.

Defining Terms

Commutation: Process of transferring the current from one power device to another.
Duty cycle: Ratio of the on-time of a switch to the switching period.
Full-wave control: Both the positive and negative half cycle of the waveforms are controlled.
IGBT: Insulated-gate bipolar transistor.
Phase-controlled converter: Converter in which the power devices are turned off at the natural crossing of zero voltage in ac to dc conversion applications.
SCR: Silicon-controlled rectifier.

30.3 Power Supplies

Ashoka K. S. Bhat

Power supplies are used in many industrial and aerospace applications and also in consumer products. Some of the requirements of power supplies are small size, light weight, low cost, and high power conversion efficiency. In addition to these, some power supplies require the following: electrical isolation between the source and load, low harmonic distortion for the input and output waveforms, and high power factor (PF) if the source is ac voltage. Some special power supplies require controlled direction of power flow.

Basically two types of power supplies are required: dc power supplies and ac power supplies. The output of dc power supplies is regulated or controllable dc, whereas the output for ac power supplies is ac. The input to these power supplies can be ac or dc.

DC Power Supplies

If an ac source is used, then ac-to-dc **converters** explained in Section 30.2 can be used. In these converters, electrical isolation can only be provided by bulky line frequency transformers. The ac source can be rectified with a diode rectifier to get an uncontrolled dc, and then a dc-to-dc converter can be used to get a controlled dc output. Electrical isolation between the input source and the output load can be provided in the dc-to-dc converter using a high-frequency (HF) transformer. Such HF transformers have small size, light weight, and low cost compared to bulky line frequency transformers. Whether the input source is dc (e.g., battery) or ac, dc-to-dc converters form an important part of dc power supplies, and they are explained in this subsection.

DC power supplies can be broadly classified as linear and switching power supplies.

A *linear power supply* is the oldest and simplest type of power supply. The output voltage is **regulated** by dropping the extra input voltage across a series transistor (therefore, also referred to as a series regulator). They have very small output ripple, theoretically zero noise, large hold-up time (typically 1–2 ms), and fast response. Linear power supplies have the following disadvantages: very low efficiency, electrical isolation can only be on 60-Hz ac side, larger volume and weight, and, in general, only a single output possible. However, they are still used in very small regulated power supplies and in some special applications (e.g., magnet power supplies). Three terminal linear regulator integrated circuits (ICs) are readily available (e.g., μA7815 has +15-V, 1-A output), are easy to use, and have built-in load short-circuit protection.

Switching power supplies use power semiconductor switches in the *on* and *off* switching states resulting in high efficiency, small size, and light weight. With the availability of fast switching devices, HF magnetics and capacitors, and high-speed control ICs, switching power supplies have become very popular. They can be further classified as **pulsewidth-modulated (PWM) converters** and **resonant converters**, and they are explained below.

Pulsewidth-Modulated Converters

These converters employ square-wave pulsewidth modulation to achieve voltage regulation. The average output voltage is varied by varying the duty cycle of the power semiconductor switch. The voltage waveform across the switch and at the output are square wave in nature [refer to Fig. 30.13(b)] and they generally result in higher switching losses when the switching frequency is increased. Also, the switching stresses are high with the generation of large electromagnetic interference (EMI), which is difficult to filter. However, these converters are easy to control, well understood, and have wide load control range.

The methods of control of PWM converters are discussed next.

The Methods of Control. The PWM converters operate with a fixed-frequency, variable duty cycle. Depending on the duty cycle, they can operate in either continuous current mode (CCM) or discontinuous current mode (DCM). If the current through the output inductor never reaches zero (refer to Fig. 30.13), then the converter operates in CCM; otherwise DCM occurs.

The three possible control methods [Severns and Bloom, 1988; Hnatek, 1981; Unitrode Corporation, 1984; Motorola, 1989; Philips Semiconductors, 1991] are briefly explained below.

1. *Direct duty cycle control* is the simplest control method. A fixed-frequency ramp is compared with the control voltage [Fig. 30.19(a)] to obtain a variable duty cycle base drive signal for the transistor. This is the simplest method of control. Disadvantages of this method are (a) provides no voltage feedforward to anticipate the effects of input voltage changes, slow response to sudden input changes, poor audio susceptibility, poor open-loop line regulation, requiring higher loop gain to achieve specifications; (b) poor dynamic response.
2. *Voltage feedforward control.* In this case the ramp amplitude varies in direct proportion to the input voltage [Fig. 30.19(b)]. The open-loop regulation is very good, and the problems in 1(a) above are corrected.
3. *Current mode control.* In this method, a second inner control loop compares the peak inductor current with the control voltage which provides improved open-loop line regulation [Fig. 30.19(c)]. All the problems of the direct duty cycle control method 1 above are corrected with this method. An additional advantage of this method is that the two-pole second-order filter is reduced to a single-pole (the filter capacitor) first-order filter, resulting in simpler compensation networks.

The above control methods can be used in all the PWM converter configurations explained below.

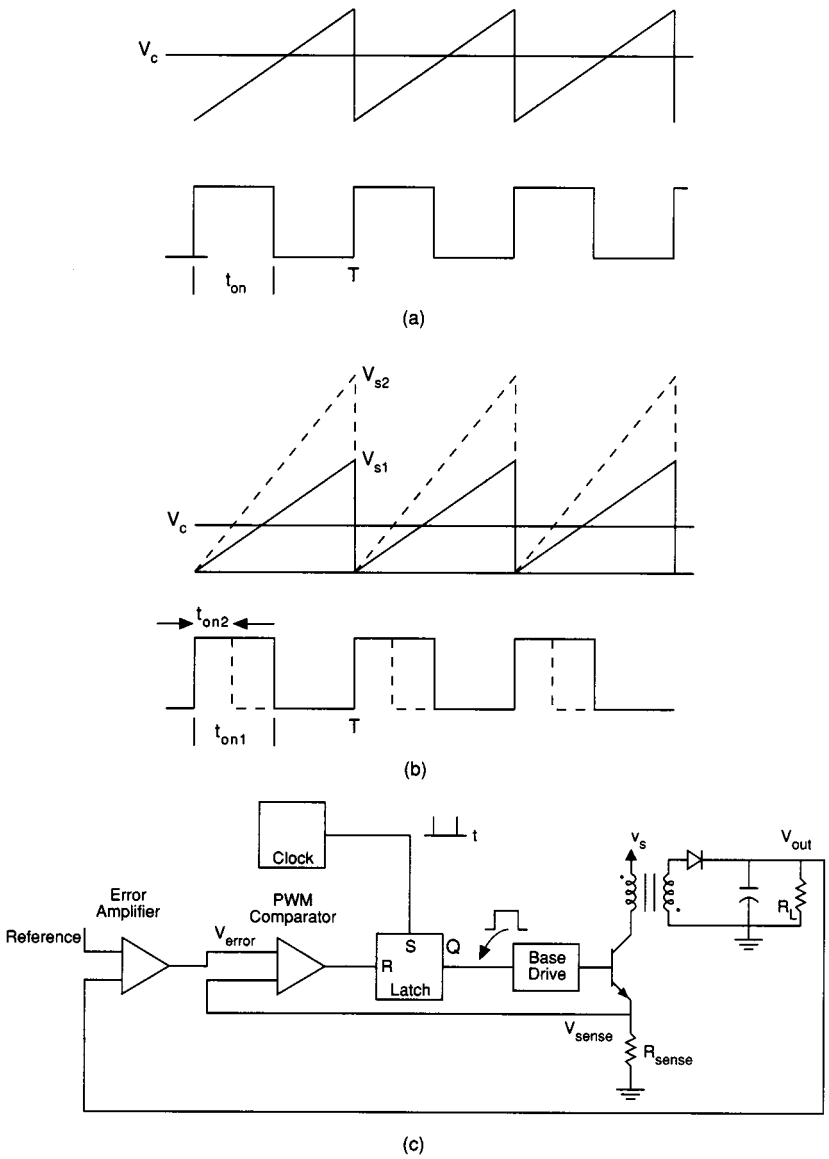

FIGURE 30.19 PWM converter control methods: (a) direct duty cycle control; (b) voltage feedforward control; (c) current mode control (illustrated for flyback converter).

PWM converters can be classified as single-ended and double-ended converters. These converters may or may not have a high-frequency transformer for isolation.

Nonisolated Single-Ended PWM Converters. The basic nonisolated single-ended converters are (a) buck (step-down), (b) boost (step-up), (c) buck-boost (step-up or step-down, also referred to as flyback), and (d) ´Cuk converters (Fig. 30.20). The first three of these converters have been discussed in Section 30.2. The ´Cuk converter provides the advantage of nonpulsating input-output current ripple requiring smaller size external filters. Output voltage expression is the same as the buck-boost converter (refer to Section 30.2) and can be less than or greater than the input voltage. There are many variations of the above basic nonisolated converters, and most of them use a high-frequency transformer for ohmic isolation between the input and the output. Some of them are discussed below.

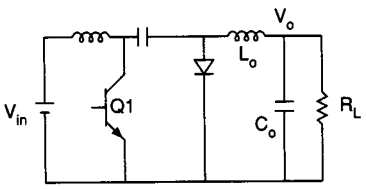

FIGURE 30.20 Nonisolated Ćuk converter.

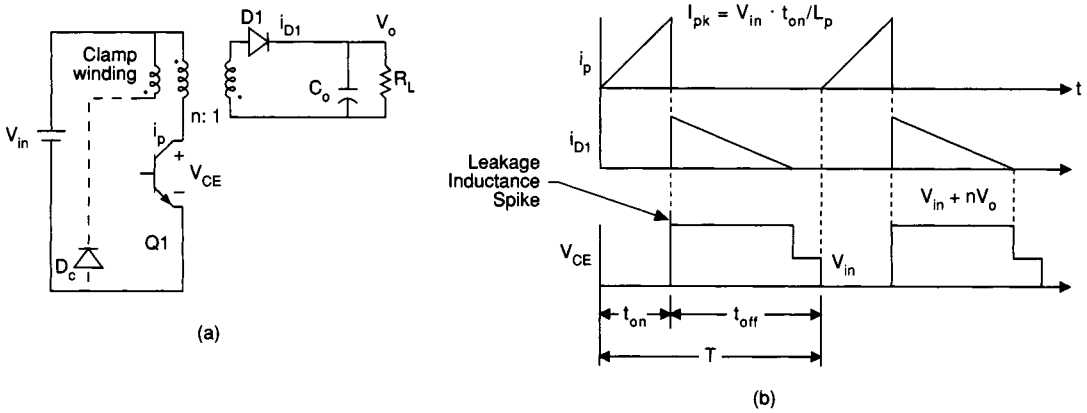

FIGURE 30.21 (a) Flyback converter. The clamp winding shown is optional and is used to clamp the transistor voltage stress to $V_{in} + nV_o$. (b) Flyback converter waveforms without the clamp winding. The leakage inductance spikes vanish with the clamp winding.

Isolated Single-Ended Topologies

1. The flyback converter (Fig. 30.21) is an **isolated** version of the buck-boost converter. In this converter (Fig. 30.21), when the transistor is on, energy is stored in the coupled inductor (not a transformer), and this energy is transferred to the load when the switch is off.

   Some of the advantages of this converter are that the leakage inductance is in series with the output diode when current is delivered to the output, and, therefore, no filter inductor is required; cross regulation for multiple output converters is good; it is ideally suited for high-voltage output applications; and it has the lowest cost.

   Some of the disadvantages are that large output filter capacitors are required to smooth the pulsating output current; inductor size is large since air gaps are to be provided; and due to stability reasons, flyback converters are usually operated in the DCM, which results in increased losses. To avoid the stability problem, flyback converters are operated with current mode control explained earlier. Flyback converters are used in the power range of 20 to 200 W.
2. The forward converter (Fig. 30.22) is based on the buck converter. It is usually operated in the CCM to reduce the peak currents and does not have the stability problem of the flyback converter. The HF transformer transfers energy directly to the output with very small stored energy. The output capacitor size and peak current rating are smaller than they are for the flyback. Reset winding is required to remove the stored energy in the transformer. Maximum duty cycle is about 0.45 and limits the control range. This topology is used for power levels up to about 1 kW.

The flyback and forward converters explained above require the rating of power transistors to be much higher than the supply voltage. The two-transistor flyback and forward converters shown in Fig. 30.23 limit the voltage rating of transistors to the supply voltage.

The Sepic converter shown in Fig. 30.24 is another isolated single-ended PWM converter.

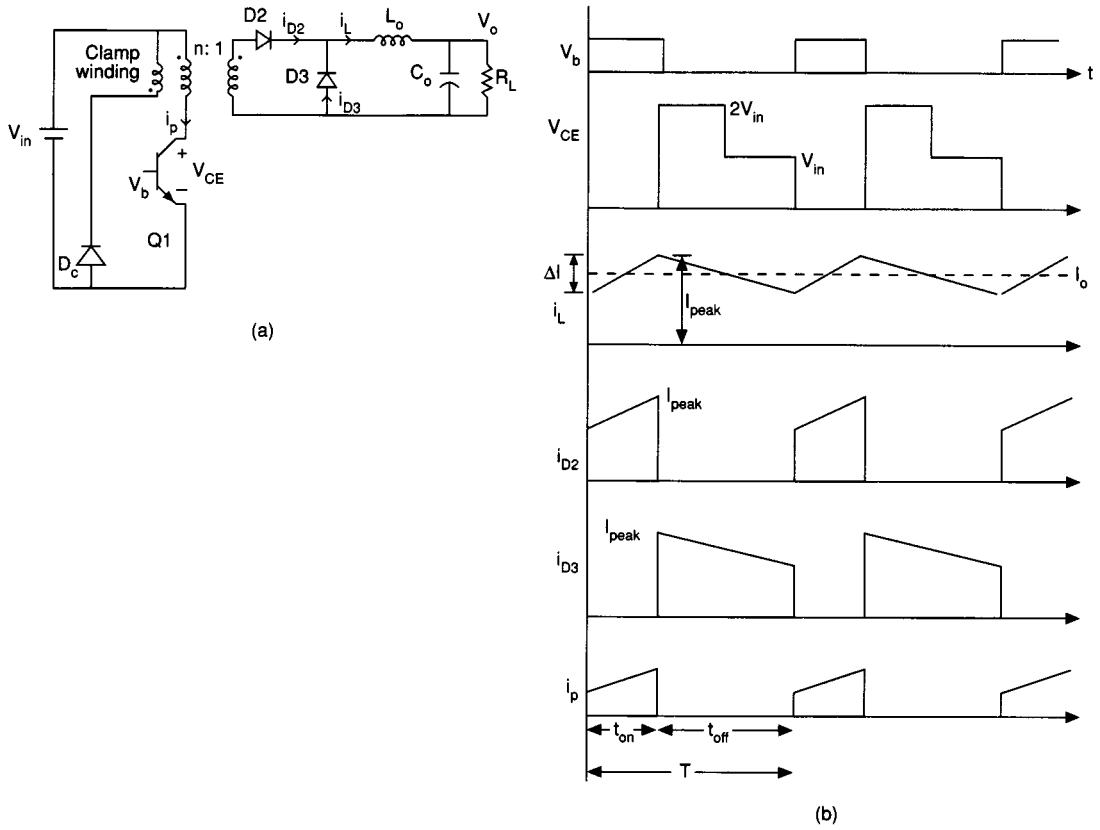

FIGURE 30.22 (a) Forward converter. The clamp winding shown is required for operation. (b) Forward converter waveforms.

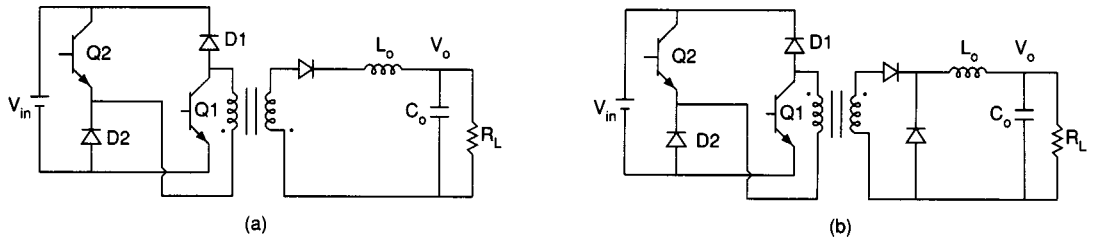

FIGURE 30.23 (a) Two-transistor single-ended flyback converter. (b) Two-transistor single-ended forward converter.

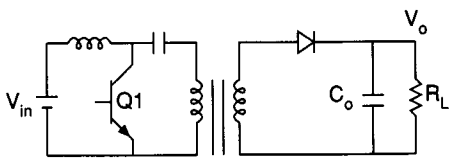

FIGURE 30.24 Sepic converter.

Double-Ended PWM Converters. Usually, for power levels above 300 W, double-ended converters are used. In double-ended converters, full-wave rectifiers are used and the output voltage ripple will have twice the switching frequency. Three important double-ended PWM converter configurations are push-pull (Fig. 30.25), half-bridge (Fig. 30.26), and full-bridge (Fig. 30.27).

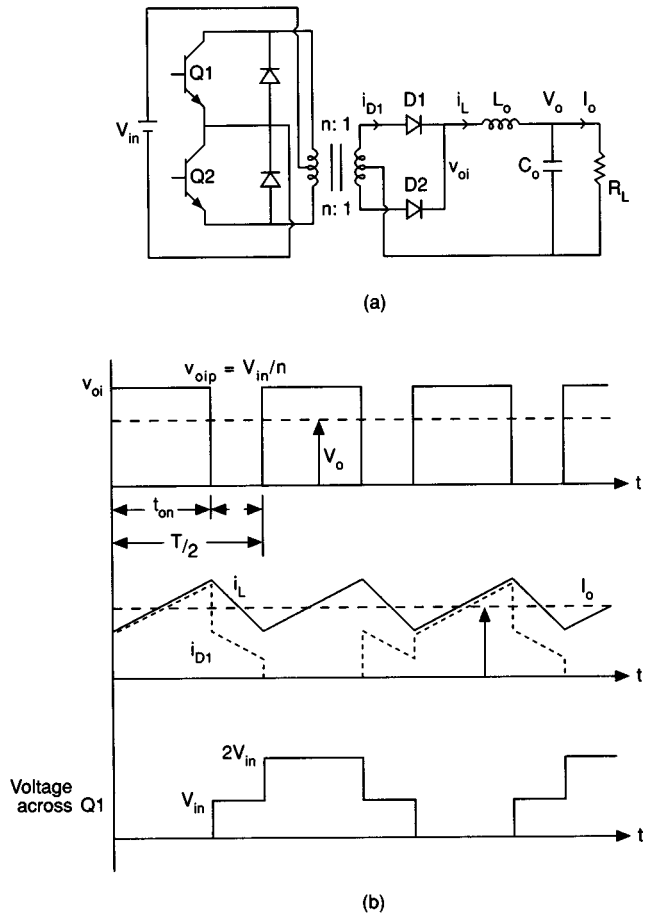

FIGURE 30.25 (a) Push-pull converter and (b) its operating waveforms.

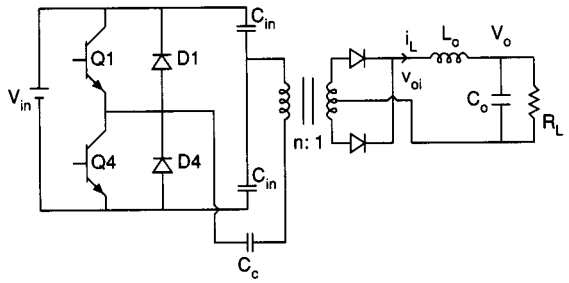

FIGURE 30.26 Half-bridge converter. Coupling capacitor C_c is used to avoid transformer saturation.

1. *The push-pull converter.* The duty ratio of each transistor in a push-pull converter (Fig. 30.25) is less than 0.5. Some of the advantages are that the transformer flux swings fully, thereby the size of the transformer is much smaller (typically half the size) than single-ended converters, and output ripple is twice the switching frequency of transistors, allowing smaller filters.

   Some of the disadvantages of this configuration are that transistors must block twice the supply voltage, flux symmetry imbalance can cause transformer saturation and special control circuitry is required to avoid this problem, and use of center-tap transformer requires extra copper resulting in higher volt-ampere (VA) rating.

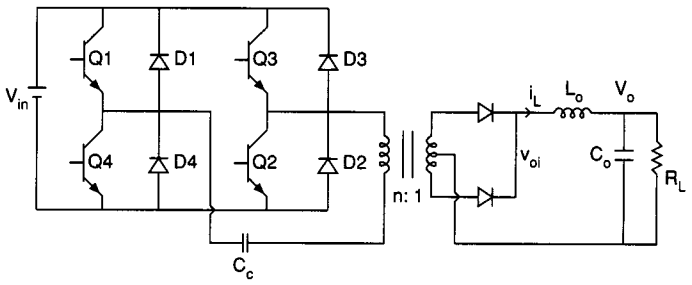

FIGURE 30.27 Full-bridge converter.

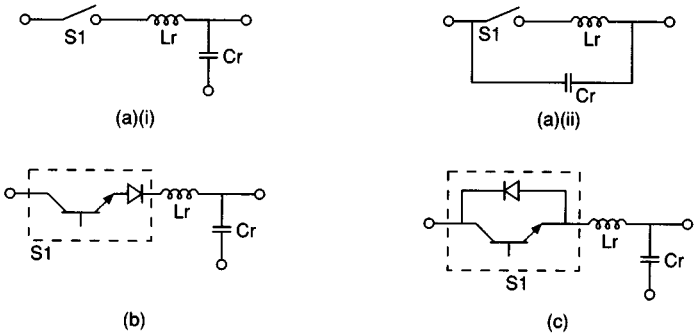

FIGURE 30.28 (a) Zero-current resonant switch: (i) L-type and (ii) M-type. (b) Half-wave configuration using L-type ZC resonant switch. (c) Full-wave configuration using L-type ZC resonant switch.

Current mode control (for the primary current) can be used to overcome the flux imbalance. This configuration is used in 100- to 500-W output range.

2. *The half-bridge.* In the half-bridge configuration (Fig. 30.26) center-tapped dc source is created by two smoothing capacitors (C_{in}), and this configuration utilizes the transformer core efficiently. The voltage across each transistor is equal to the supply voltage (half of push-pull) and, therefore, is suitable for high-voltage inputs. One salient feature of this configuration is that the input filter capacitors can be used to change between 110/220-V mains as selectable inputs to the supply.

   The disadvantage of this configuration is the requirement for large-size input filter capacitors. The half-bridge configuration is used for power levels of the order of 500 to 1000 W.

3. The full-bridge configuration (Fig. 30.27) requires only one smoothing capacitor, and for the same transistor type as that of half-bridge, output power can be doubled. It is usually used for power levels above 1 kW, and the design is more costly due to increased number of components (uses four transistors compared to two in push-pull and half-bridge converters).

   One of the salient features of a full-bridge converter is that by using proper control technique it can be operated in zero-voltage switching (ZVS) mode. This type of operation results in negligible switching losses. However, at reduced load currents, the ZVS property is lost. Recently, there has been a lot of effort to overcome this problem.

Resonant Power Supplies

Similar to the PWM converters, there are two types of resonant converters: single-ended and double-ended. Resonant converter configurations are obtained from the PWM converters explained earlier by adding LC (inductor-capacitor) resonating elements to obtain sinusoidally varying voltage and/or current waveforms. This approach reduces the switching losses and the switch stresses during switching instants, enabling the converter to operate at high switching frequencies, resulting in reduced size, weight, and cost. Some other advantages of resonant converters are that leakage inductances of HF transformers and the junction capacitances of semiconductors can

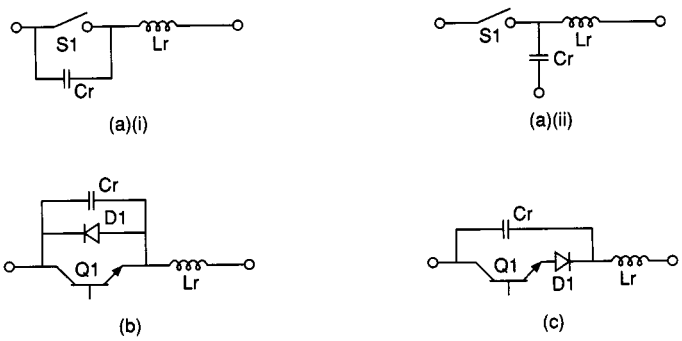

FIGURE 30.29 (a) Zero-voltage resonant switches. (b) Half-wave configuration using ZV resonant switch shown in Fig. (a)(i). (c) Full-wave configuration using ZV resonant switch shown in Fig. (a)(i).

be used profitably in the resonant circuit, and reduced EMI. The major disadvantage of resonant converters is increased peak current (or voltage) stress.

Single-Ended Resonant Converters. They are referred to as quasi-resonant converters (QRCs) since the voltage (or current) waveforms are quasi-sinusoidal in nature. The QRCs can operate with zero-current switching (ZCS) or ZVS or both. All the QRC configurations can be generated by replacing the conventional switches by the resonant switches shown in Figs. 30.28 and 30.29. A number of configurations are realizable. Basic principles of ZCS and ZVS are explained briefly below.

1. *Zero-current switching QRCs* [Sum, 1988; Liu et al., 1985]. Figure 30.30(a) shows an example of a ZCS QR buck converter implemented using a ZC resonant switch. Depending on whether the resonant switch is half-wave type or full-wave type, the resonating current will be only half-wave sinusoidal [Fig. 30.30(b)] or a full sine-wave [Fig. 30.30(c)]. The device currents are shaped sinusoidally, and, therefore, the switching losses are almost negligible with low turn-on and turn-off stresses. ZCS QRCs can operate at frequencies of the order of 2 MHz. The major problems with this type of converter are high peak currents through the switch and capacitive turn-on losses.
2. *Zero-voltage switching QRCs* [Sum, 1988; Liu and Lee, 1986]. ZVS QRCs are duals of ZCS QRCs. The auxiliary LC elements are used to shape the switching device's voltage waveform at off time in order to create a zero-voltage condition for the device to turn on. Fig. 30.31(a) shows an example of ZVS QR boost converter implemented using a ZV resonant switch. The circuit can operate in the half-wave mode [Fig. 30.31(b)] or in the full-wave mode [Fig. 30.31(c)] depending on whether a half-wave or full-wave ZV resonant switch is used, and the name comes from the capacitor voltage waveform. The full-wave mode ZVS circuit suffers from capacitive turn-on losses. The ZVS QRCs suffer from increased voltage stress on the switch. However, they can be operated at much higher frequencies compared to ZCS QRCs.

Double-Ended Resonant Converters. These converters [Sum, 1988; Bhat, 1991; Steigerwald, 1988; Bhat, 1992] use full-wave rectifiers at the output, and they are generally referred to as resonant converters. A number of resonant converter configurations are realizable by using different resonant tank circuits, and the three most popular configurations, namely, the series resonant converter (SRC), the parallel resonant converter (PRC), and the series-parallel resonant converter (SPRC) (also called LCC-type PRC), are shown in Fig. 30.32.

Series resonant converters [Fig. 30.32(a)] have high efficiency from full load to part load. Transformer saturation is avoided due to the series blocking resonating capacitor. The major problems with the SRC are that it requires a very wide change in switching frequency to regulate the load voltage and the output filter capacitor must carry high ripple current (a major problem especially in low output voltage, high output current applications).

Parallel resonant converters [Fig. 30.32(b)] are suitable for low output voltage, high output current applications due to the use of filter inductance at the output with low ripple current requirements for the filter capacitor. The major disadvantage of the PRC is that the device currents do not decrease with the load current, resulting in reduced efficiency at reduced load currents.

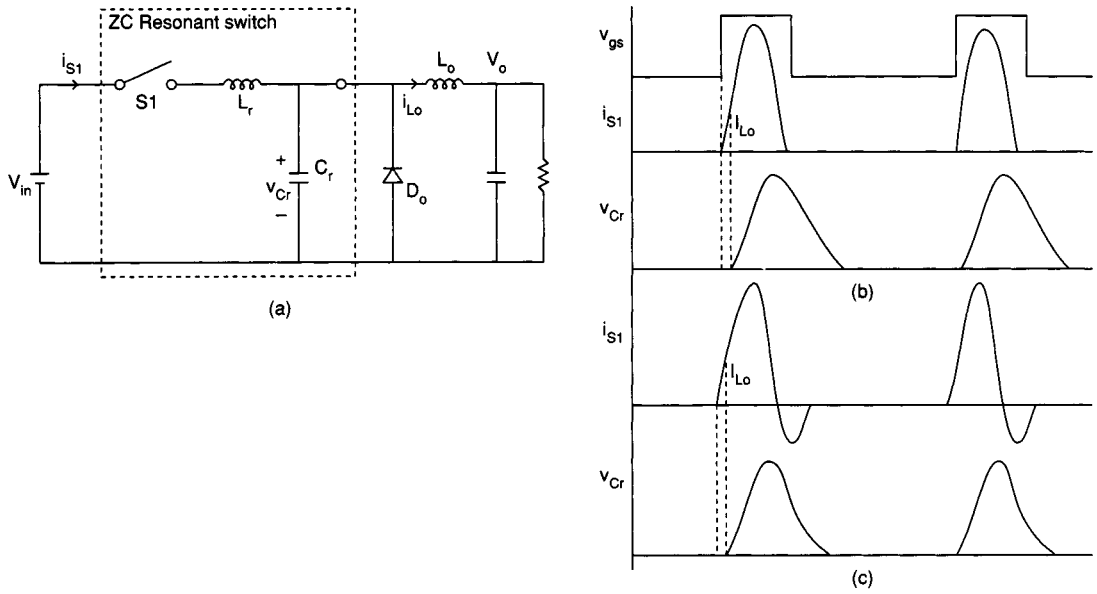

FIGURE 30.30 (a) Implementation of ZCS QR buck converter using L-type resonant switch. (b) Operating waveforms for half-wave mode. (c) Operating waveforms for full-wave mode.

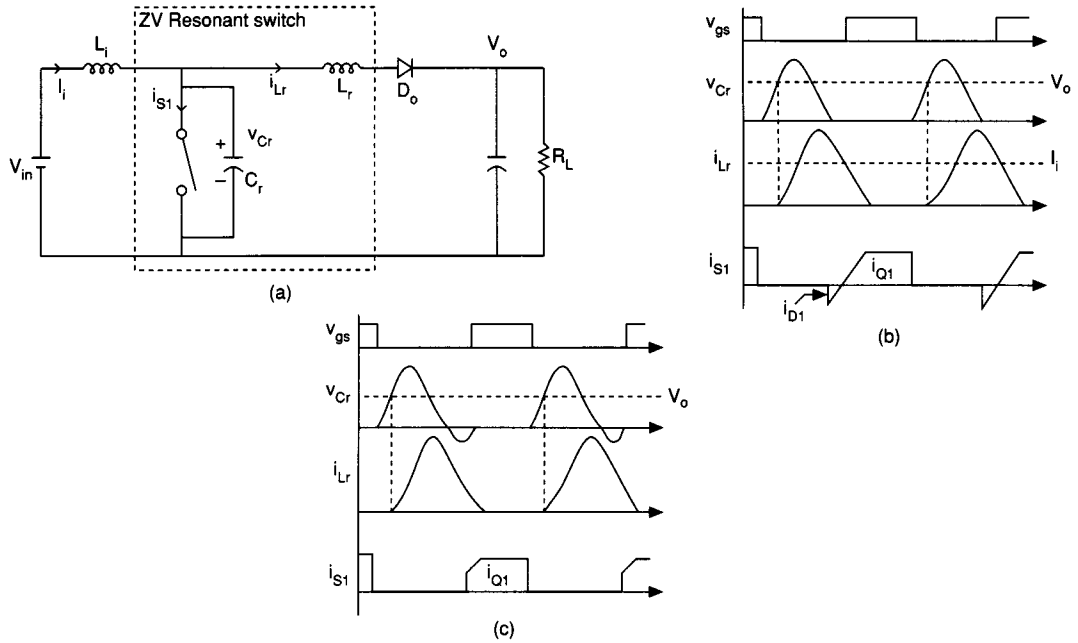

FIGURE 30.31 (a) Implementation of ZVS QR buck converter using resonant switch shown in Fig. 30.28(a)(i). (b) Operating waveforms for half-wave mode. (c) Operating waveforms for full-wave mode.

The SPRC [Fig. 30.32(c)] takes the desirable features of SRC and PRC.

Load voltage regulation in resonant converters for input supply variations and load changes is achieved by either varying the switching frequency or using fixed-frequency (variable pulsewidth) control.

1. *Variable-frequency operation.* Depending on whether the switching frequency is below or above the natural resonance frequency (ω_r), the converter can operate in different operating modes as explained below.

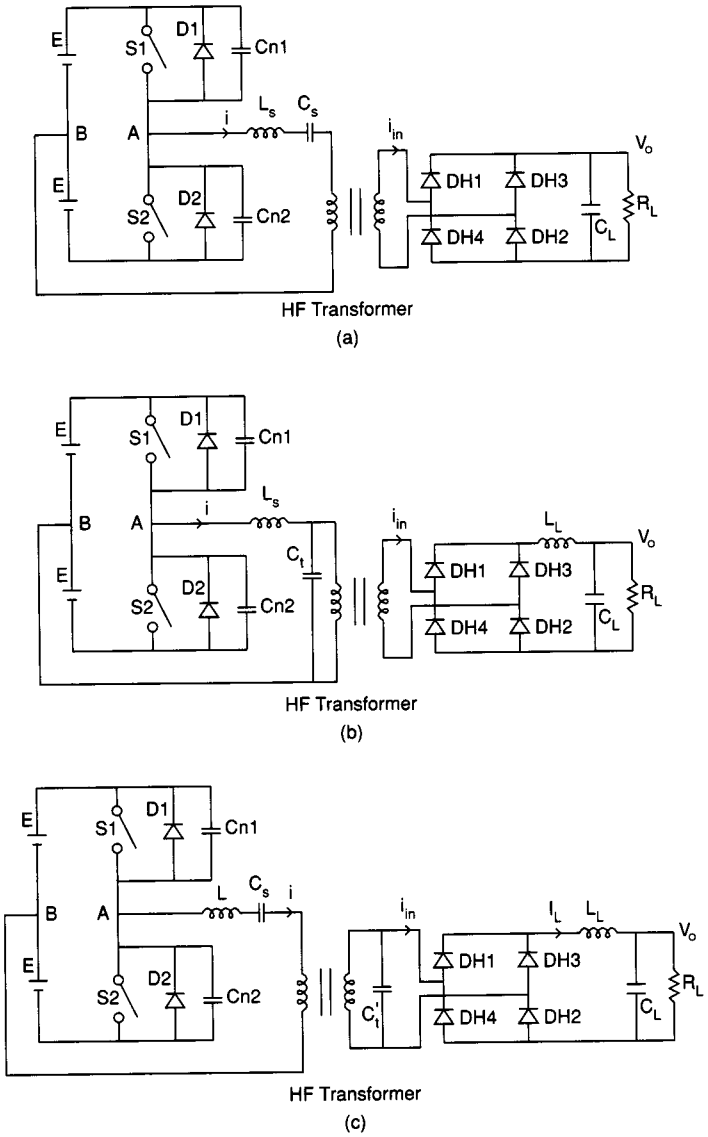

FIGURE 30.32 High-frequency resonant converter (half-bridge version) configurations suitable for operation above resonance. *Cn*1 and *Cn*2 are the snubber capacitors. (*Note:* For operation below resonance, *di/dt* limiting inductors and RC snubbers are required. For operation above resonance, only capacitive snubbers are required as shown.) (a) Series resonant converter. Leakage inductances of the HF transformer can be part of resonant inductance. (b) Parallel resonant converter. (c) Series-parallel (or LCC-type) resonant converter with capacitor C_t placed on the secondary side of the HF transformer.

a. Below-resonance (leading PF) mode. When the switching frequency is below the natural resonance frequency, the converter operates in a below-resonance mode (Fig. 30.33). The equivalent impedance across *AB* presents a leading PF so that natural turn-off of the switches is assured and any type of fast turn-off switch (including asymmetric SCRs) can be used. Depending on the instant of turn-on of switches S_1 and S_2, the converter can enter into two modes of operation, namely, continuous and discontinuous current modes. The steady-state operation in continuous current mode (CCM) [Fig. 30.33(a)] is explained briefly as follows.

Assume that diode D_2 was conducting and switch S_1 is turned on. The current carried by D_2 will be transferred to S_1 almost instantaneously (except for a small time of recovery of D_2 during which input supply is shorted through D_2 and S_1, and the current is limited by the *di/dt* limiting inductors). The

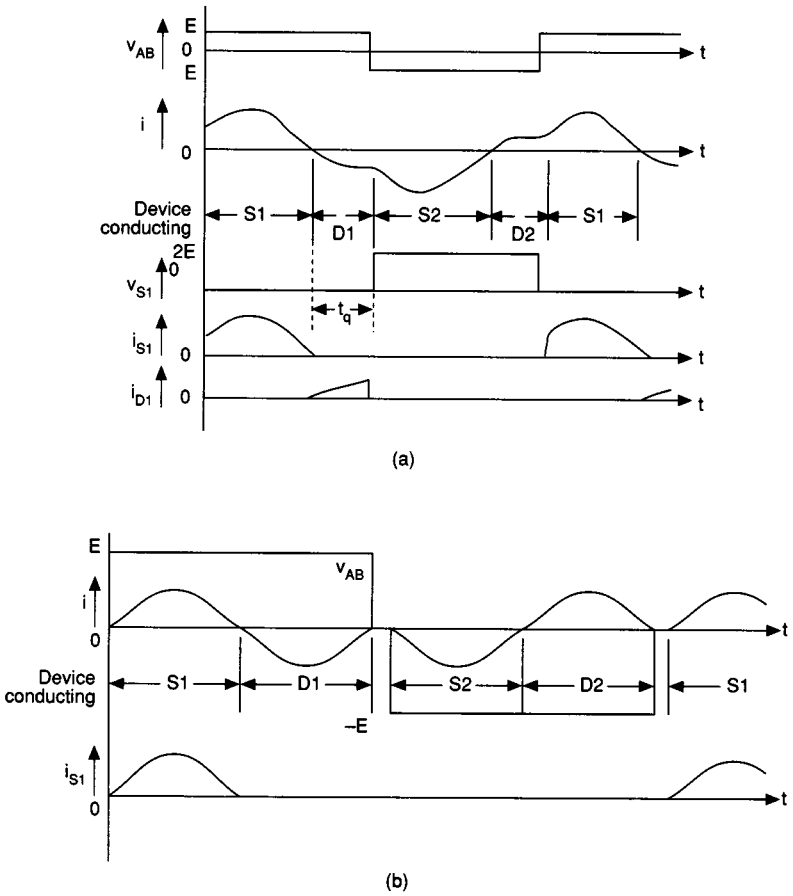

FIGURE 30.33 Typical waveforms at different points of a resonant converter operating below resonance (a) in continuous current mode and (b) in discontinuous current mode.

current i then oscillates sinusoidally and goes to zero in the natural way. The current tries to reverse, and the path for this current is provided by the diode D_1. Conduction of D_1 feeds the reactive energy in the load and the tank circuit back to the supply. The on-state of D_1 also provides a reverse voltage across S_1, allowing it to turn off. After providing a time equal to or greater than the turn-off time of S_1, switch S_2 can be turned on to initiate the second half cycle. The process is similar to the first half cycle, with the voltage across v_{AB} being of opposite polarity, and the functions of D_1, S_1 will be assumed by D_2, S_2. With this type of operation, the converter works in the continuous current mode as the switches are turned on before the currents in the diodes reach zero. If the switching on of S_1 and S_2 is delayed such that the currents through the previously conducting diodes reach zero, then there are zero current intervals and the **inverter** operates in the DCM [Fig. 30.33(b)].

Load voltage regulation is achieved by decreasing the switching frequency below the rated value. Since the inverter output current i leads the inverter output voltage v_{AB}, this type of operation is also called a leading PF mode of operation. If transistors are used as the switching devices, then for operation in DCM, the pulsewidth can be kept constant while decreasing the switching frequency to avoid CCM operation. DCM operation has the advantages of negligible switching losses due to ZCS, lower *di/dt* and *dv/dt* stresses, and simple control circuitry. However, DCM operation results in higher switch peak currents.

From the waveforms shown in Fig. 30.33, the following problems can be identified for operation in the below-resonance mode: requirement of *di/dt* inductors to limit the large turn-on switch currents and a need for lossy RC snubbers and fast recovery diodes. Since the switching frequency is decreased to control the load power, the HF transformer and magnetics must be designed for the lowest switching frequency, resulting in increased size of the converter.

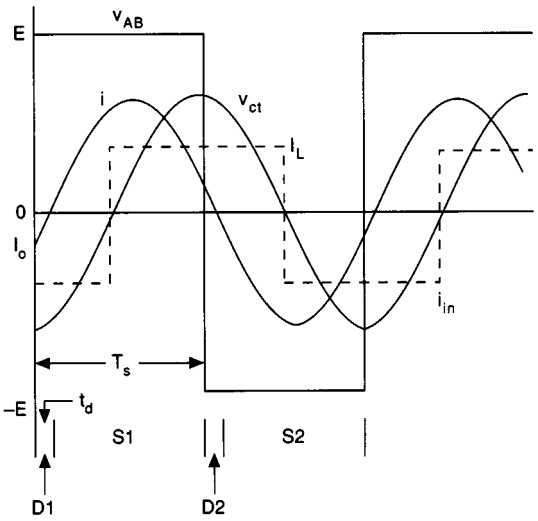

FIGURE 30.34 Typical operating waveforms at different points of an SPRC operating above resonance.

b. Above-resonance (lagging PF) mode. If switches capable of gate or base turn-off (e.g., MOSFETs, bipolar transistors) are used, then the converter can operate in the above-resonance mode (lagging PF mode). Figure 30.34 shows some typical operating waveforms for such type of operation, and it can be noticed that the current i lags the voltage v_{AB}. Since the switch takes current from its own diode across it at zero-current point, there is no need for di/dt limiting inductance, and a simple capacitive snubber can be used. In addition, the internal diodes of MOSFETs can be used due to the large turn-off time available for the diodes. Major problems with the lagging PF mode of operation are that there are switch turn-off losses, and since the voltage regulation is achieved by increasing the switching frequency above the rated value, the magnetic losses increase and the design of a control circuit is difficult.

Exact analysis of resonant converters is complex due to the nonlinear loading on the resonant tanks. The rectifier-filter-load resistor block can be replaced by a square-wave voltage source [for SRC, Fig. 30.32(a)] or a square-wave current source [for PRC and SPRC, Fig. 30.32(b) and (c)]. Using fundamental components of the waveforms, an approximate analysis [Bhat, 1991; Steigerwald, 1988] using a phasor circuit gives a reasonably good design approach. This analysis approach is illustrated next for the SPRC.

2. *Approximate analysis of SPRC.* Figure 30.35 shows the equivalent circuit at the output of the inverter and the phasor circuit used for the analysis. All the equations are normalized using the base quantities

$$\text{Base voltage } V_B = E_{\min}$$

$$\text{Base impedance } Z_B = R'_L = n^2 R_L$$

$$\text{Base current } I_B = V_B/I_B$$

The converter gain [normalized output voltage in per unit (p.u.) referred to the primary-side] can be derived as [Bhat, 1991; Steigerwald, 1988]

$$M = \frac{1}{\left\{\left(\frac{\pi^2}{8}\right)^2\left[1+\left(\frac{C_t}{C_s}\right)\left(1-y_s^2\right)\right]^2 + Q_s^2\left[y_s - \left(\frac{1}{y_s}\right)\right]^2\right\}^{1/2}} \text{ p.u.} \qquad (30.1)$$

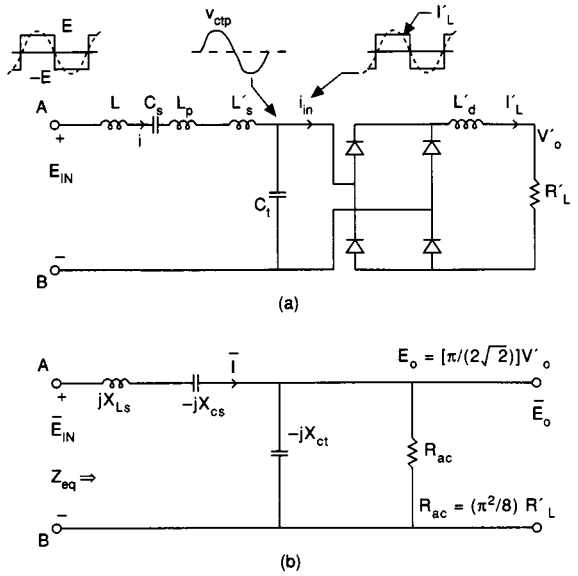

FIGURE 30.35 (a) Equivalent circuit for a SPRC at the output of the inverter terminals (across *AB*) of Fig. 30.31(c), L_p and L'_s are the leakage inductance of the primary and primary referred leakage inductance of the secondary, respectively. (b) Phasor circuit model used for the analysis of the SPRC converter.

where

$$Q_s = \frac{(L_s / C_s)^{1/2}}{R'_L}; L_s = L + L_p + L'_s \tag{30.2}$$

$$y_s = \frac{f_s}{f_r} \tag{30.3}$$

and

$$\begin{aligned} f_s &= \text{switching frequency} \\ f_r &= \text{series resonance frequency} \\ &= \frac{\omega_r}{2\pi} = \frac{1}{2\pi(L_s C_s)^{1/2}} \end{aligned} \tag{30.4}$$

The equivalent impedance looking into the terminals *AB* is given by

$$Z_{eq} = \frac{B_1 + jB_2}{B_3} \quad \text{p.u.} \tag{30.5}$$

where

$$B_1 = \left(\frac{8}{\pi^2}\right)\left(\frac{C_s}{C_t}\right)^2\left(\frac{Q_s}{y_s}\right)^2 \tag{30.6}$$

$$B_2 = Q_s\left(y_s - \frac{1}{y_s}\right)\left[1 + \left(\frac{8}{\pi^2}\right)^2\left(\frac{C_s}{C_t}\right)^2\left(\frac{Q_s}{y_s}\right)^2\right] - \left(\frac{C_s}{C_t}\right)\left(\frac{Q_s}{y_s}\right) \tag{30.7}$$

$$B_3 = 1 + \left(\frac{8}{\pi^2}\right)^2\left(\frac{C_s}{C_t}\right)^2\left(\frac{Q_s}{y_s}\right)^2 \tag{30.8}$$

The peak inverter output (resonant inductor) current can be calculated using

$$I_p = \frac{4}{\pi|Z_{eq}|} \quad \text{p.u.} \tag{30.9}$$

The same current flows through the switching devices.

The value of initial current I_0 is given by

$$I_0 = I_p \sin(-\phi) \text{ p.u.} \tag{30.10}$$

where $\phi = \tan^{-1}(B_2/B_1)$ rad. B_1 and B_2 are given by Eqs. (30.6) and (30.7), respectively.

If I_0 is negative, then forced commutation is necessary and the converter is operating in the lagging PF mode. The peak voltage across the capacitor C'_t (on the secondary side) is

$$V_{\text{ctp}} = \frac{\pi}{2} V_o \quad \text{V} \tag{30.11}$$

The peak voltage across C_s and the peak current through C'_t are given by

$$V_{\text{csp}} = \frac{Q_s}{y_s} I_p \quad \text{p.u.} \tag{30.12}$$

$$I_{\text{ctp}} = \frac{V_{\text{ctp}}}{X_{\text{cptu}} R_L} \quad \text{A} \tag{30.13}$$

$$X_{\text{ctpu}} = \left(\frac{C_s}{C_t}\right)\left(\frac{Q_s}{y_s}\right) \quad \text{p.u.} \tag{30.14}$$

The plot of converter gain versus the switching frequency ratio y_s, obtained using (30.1), is shown for $C_s/C_t = 1$ in Fig. 30.36, for the lagging PF mode of operation. If the ratio C_s/C_t increases, then the converter takes the characteristics of SRC and the load voltage regulation requires a very wide range in the frequency change. Lower values of C_s/C_t take the characteristics of a PRC. Therefore, a compromised value of $C_s/C_t = 1$ is chosen.

It is possible to realize higher-order resonant converters with improved characteristics and many of them are presented in Bhat [1991].

3. *Fixed-frequency operation.* To overcome some of the problems associated with the variable frequency control of resonant converters, they are operated with fixed frequency [Sum, 1988; Bhat, 1992]. A number of configurations and control methods for fixed-frequency operation are available in the literature (Bhat [1992] gives a list of papers). One of the most popular methods of control is the phase-shift control

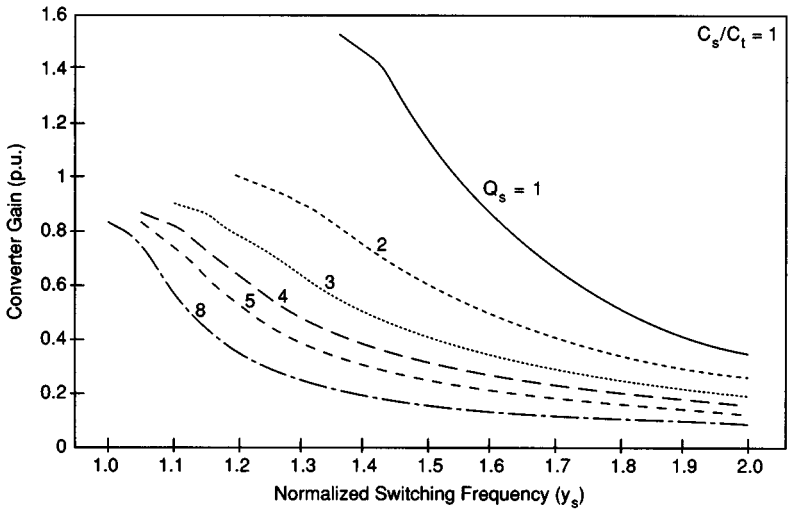

FIGURE 30.36 The converter gain M (p.u.) (normalized output voltage) versus normalized switching frequency y_s of SPRC operating above resonance for $C_s/C_t = 1$.

(also called clamped-mode or PWM operation) method. Figure 30.37 illustrates the clamped-mode fixed-frequency operation of the SPRC. The load power control is achieved by changing the phase-shift angle ϕ between the gating signals to vary the pulsewidth of v_{AB}.

4. *Design example.* Design a 500-W output SPRC (half-bridge version) with secondary-side resonance (operation in lagging PF mode and variable-frequency control) with the following specifications:

$$\text{Minimum input supply voltage} = 2E_{\min} = 230 \text{ V}$$

$$\text{Load voltage, } V_o = 48 \text{ V}$$

$$\text{Switching frequency, } f_s = 100 \text{ kHz}$$

$$\text{Maximum load current} = 10.42 \text{ A}$$

As explained in item 2, $C_s/C_t = 1$ is chosen. Using the constraints (1) minimum kVA rating of tank circuit per kW output power, (2) minimum inverter output peak current, and (3) enough turn-off time for the switches, it can be shown that [Bhat, 1991] $Q_s = 4$ and $y_s = 1.1$ satisfy the design constraints. From Fig. 30.36, $M = 0.8$ p.u.

Average load voltage referred to the primary side of the HF transformer $= 0.8 \times 115\,\text{V} = 92\,\text{V}$. Therefore, the transformer turns ratio required $\simeq 1.84$.

$$R_L' = n^2\left(\frac{V_o^2}{P_o}\right) = 15.6\ \Omega$$

The values of L_s and C_s can be obtained by solving

$$\left(\frac{L_s}{C_s}\right)^{1/2} = 4 \times 15.6\,\Omega \text{ and } \omega_r = \frac{1}{(L_sC_s)^{1/2}} = 2\pi\frac{f_s}{y_s}$$

Solving the above equations gives $L_s = 109\,\mu\text{H}$ and $C_s = 0.0281\,\mu\text{F}$. Leakage inductance $(L_p + L'_s)$ of the HF transformer can be used as part of L_s. Typical value for a 100-kHz practical transformer (using Tokin

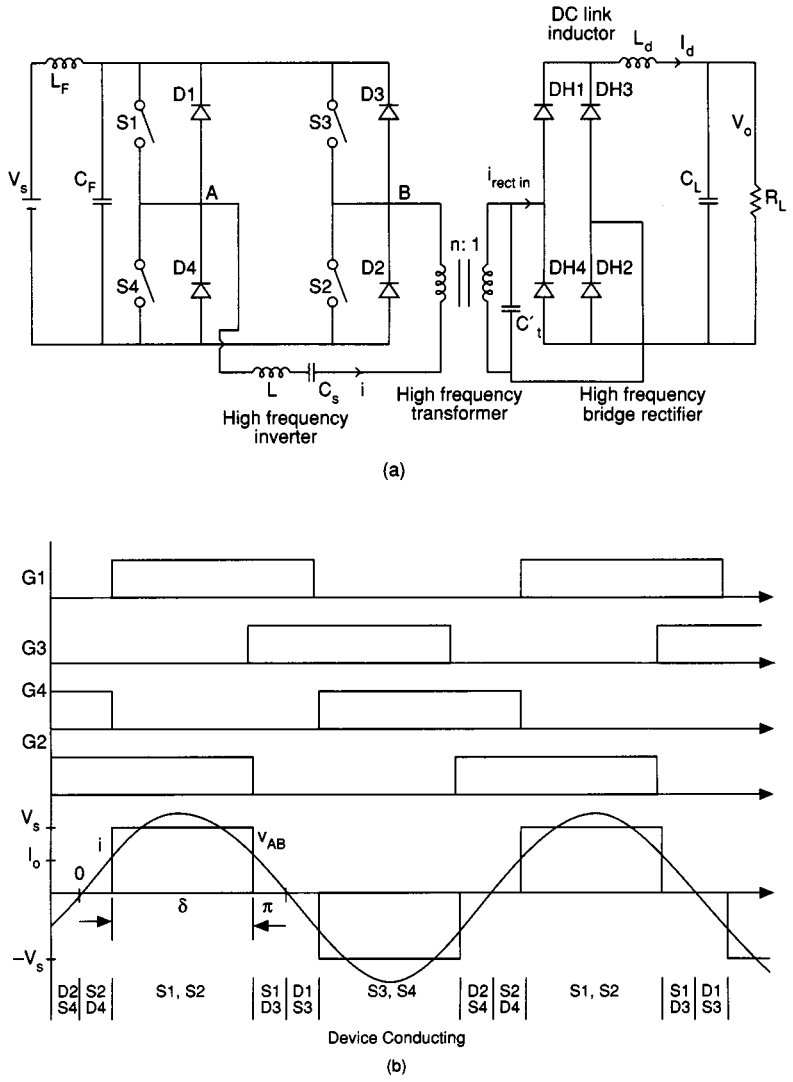

FIGURE 30.37 (a) Basic circuit diagram of series-parallel resonant converter suitable for fixed-frequency operation with PWM (clamped-mode) control. (b) Waveforms to illustrate the operation of fixed-frequency PWM series-parallel resonant converter working with a pulsewidth δ.

Mn-Zn 2500B2 Ferrite, E-I type core) for this application is about 5 μH. Therefore, the external resonant inductance required is $L = 104$ μH.

Since $C_s/C_t = 1$ is chosen, $C_t = 0.0281$ μF. The actual value of C_t used on the secondary side of the HF transformer = $(1.84)^2 \times 0.0281 = 0.09514$ μF. The resonating capacitors must be HF type (e.g., polypropylene) and must be capable of withstanding the voltage and current ratings obtained above (enough safety margin must be provided).

Using Eqs. (30.9) and (30.11) to (30.13):

$$\text{Peak current through switches} = 7.6 \text{ A}$$

$$\text{Peak voltage across } C_s,\ V_{csp} = 430 \text{ V}$$

$$\text{Peak voltage (on secondary side) across } C'_t,\ V_{ctp} = 76 \text{ V}$$

$$\text{Peak current through capacitor } C'_t \text{ (on secondary side)},\ I_{ctp} = 4.54 \text{ A}$$

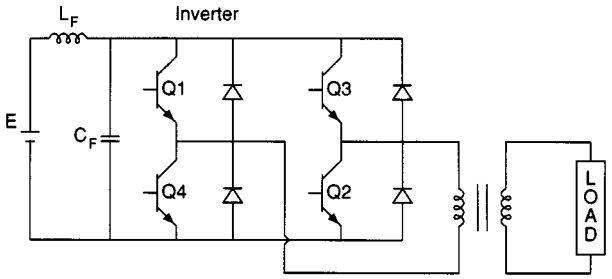

FIGURE 30.38 An inverter circuit to obtain variable-voltage, variable-frequency ac source. Using sinusoidal pulsewidth modulation control scheme, sine-wave ac output voltage can be obtained.

A simple control circuit can be built using PWM IC SG3525 and TSC429 MOSFET driver ICs.

With the development of digital ICs operating on low-voltage (of the order of 3 V) supplies, use of MOSFETs as *synchronous rectifiers* with very low voltage drop (~0.2 V) has become essential [Motorola, 1989] to increase the efficiency of the power supply.

AC Power Supplies

Some applications of ac power supplies are ac motor drives, **uninterruptible power supply (UPS)** used as a standby ac source for critical loads (e.g., in hospitals, computers), and dc source-to-utility interface (either to meet peak power demands or to augment energy by connecting unconventional energy sources like photovoltaic arrays to the utility line). In ac induction motor drives, the ac power main is rectified and filtered to obtain a smooth dc source, and then an inverter (single-phase version is shown in Fig. 30.38) is used to obtain a variable-frequency, variable-voltage ac source. The sinusoidal pulsewidth modulation technique described in Section 30.2 can be used to obtain a sinusoidal output voltage. Some other methods used to get sinusoidal voltage output are [Rashid, 1988] a number of phase-shifted inverter outputs summed in an output transformer to get a stepped waveform that approximates a sine wave and the use of a bang-bang controller in Fig. 30.38. All these methods use line-frequency (60 Hz) transformers for voltage translation and isolation purposes. To reduce the size, weight, and cost of such systems, one can use dc-to-dc converters (discussed earlier) as an intermediate stage. Figure 30.39 shows such a system in block schematic form. One can use an HF inverter circuit (discussed earlier) followed by a **cycloconverter** stage. The major problem with these schemes is the reduction in efficiency due to the extra power stage. Figure 30.40 shows a typical UPS scheme. The battery shown has to be charged by a separate rectifier circuit.

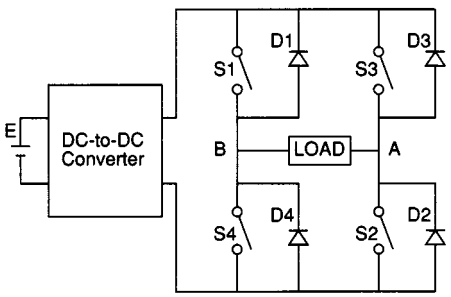

FIGURE 30.39 AC power supplies using HF switching (PWM or resonant) dc-to-dc converter as an input stage. HF transformer isolated dc-to-dc converters can be used to reduce the size and weight of the power supply. Sinusoidal voltage output can be obtained using the modulation in the output inverter stage or in the dc-to-dc converter.

AC-to-ac conversion can also be achieved using cycloconverters [e.g., Rashid, 1988].

Special Power Supplies

Using the inverters and cycloconverters, it is possible to realize bidirectional ac and dc power supplies. In these power supplies [Rashid, 1988], power can flow in both directions, i.e., from input to output or from output to input. It is also possible to control the ac-to-dc converters to obtain sinusoidal line current with unity PF and low harmonic distortion at the ac source.

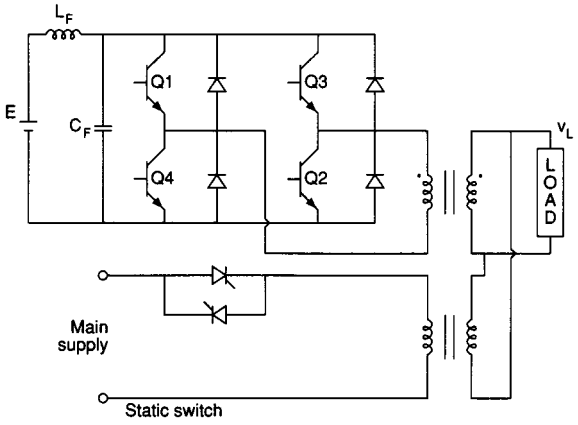

FIGURE 30.40 A typical arrangement of UPS system. The load gets power through the static switch when the ac main supply is present. The inverter supplies power when the main supply fails.

Defining Terms

Converter: A circuit that performs one of the following power conversions — ac to dc, dc to dc, dc to ac, or ac to ac.

Cycloconverter: A power electronic circuit that converts ac input to ac output (generally) of lower frequency than the input source without using any intermediate dc state.

Inverter: A power electronic circuit that converts dc input to ac output.

Isolated: A power electronic circuit that has ohmic isolation between the input source and the load circuit.

Pulsewidth-modulated (PWM) converters: A power electronic converter that employs square-wave switching waveforms with variation of pulsewidth for controlling the load voltage.

Regulated output: Output load voltage is kept at the required value for changes in either the load or the input supply voltage.

Resonant converters: A power electronic converter that employs "LC resonant circuits" to obtain sinusoidal switching waveforms.

Uninterruptible power supply (UPS): A stand-by dc-to-ac inverter used mostly to provide an emergency power to loads at mains frequency (50/60 Hz) in the event of a mains failure.

30.4 Converter Control of Machines

Bimal K. Bose

Converter-controlled electrical machine drives are very important in modern industrial applications. Some examples in the high-power range are metal rolling mills, cement mills, and gas line compressors. In the medium-power range are textile mills, paper mills, and subway car propulsion. Machine tools and computer peripherals are examples of converter-controlled electrical machine drive applications in the low-power range. The converter normally provides a variable-voltage dc power source for a dc motor drive and a variable-frequency, variable-voltage ac power source for an ac motor drive. The drive system efficiency is high because the converter operates in switching mode using power semiconductor devices. The primary control variable of the machine may be torque, speed, or position, or the converter can operate as a solid-state starter of the machine. The recent evolution of high-frequency power semiconductor devices and high-density and economical microelectronic chips, coupled with converter and control technology developments, is providing a tremendous boost in the applications of drives.

Converter Control of DC Machines

The speed of a dc motor can be controlled by controlling the dc voltage across its armature terminals. A phase-controlled thyristor converter can provide this dc voltage source. For a low-power drive, a single-phase bridge converter can be used, whereas for a high-power drive, a three-phase bridge circuit is preferred. The machine can be a permanent magnet or wound field type. The wound field type permits variation and reversal of field and is normally preferred in large power machines.

Phase-Controlled Converter DC Drive

Figure 30.41 shows a dc drive using a three-phase thyristor bridge converter. The converter rectifies line ac voltage to variable dc output voltage by controlling the firing angle of the thyristors. With rated field excitation, as the armature voltage is increased, the machine will develop speed in the forward direction until the rated, or base, speed is developed at full voltage when the firing angle is zero. The motor speed can be increased further by weakening the field excitation. Below the base speed, the machine is said to operate in constant

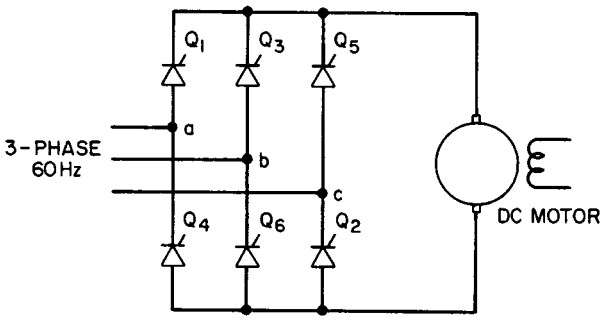

FIGURE 30.41 Three-phase thyristor bridge converter control of a dc machine.

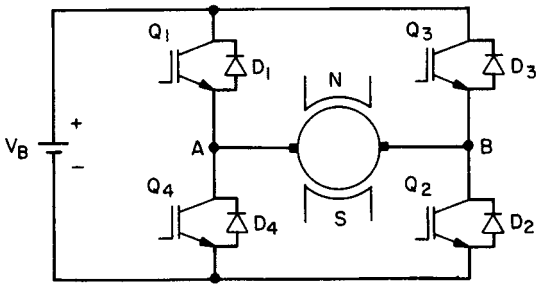

FIGURE 30.42 Four-quadrant dc motor drive using an H-bridge converter.

torque region, whereas the field weakening mode is defined as the constant power region. At any operating speed, the field can be reversed and the converter firing angle can be controlled beyond 90 degrees for **regenerative braking** mode operation of the drive. In this mode, the motor acts as a generator (with negative induced voltage) and the converter acts as an inverter so that the mechanical energy stored in the inertia is converted to electrical energy and pumped back to the source. Such **two-quadrant** operation gives improved efficiency if the drive accelerates and decelerates frequently. The speed of the machine can be controlled with precision by a feedback loop where the command speed is compared with the machine speed measured by a tachometer. The speed loop error generally generates the armature current command through a compensator. The current is then feedback controlled with the firing angle control in the inner loop. Since torque is proportional to armature current (with fixed field), a current loop provides direct torque control, and the drive can accelerate or decelerate with the rated torque. A second bridge converter can be connected in antiparallel so that the dual converter can control the machine speed in all the four quadrants (motoring and regeneration in forward and reverse speeds).

Pulsewidth Modulation Converter DC Machine Drive

Four-quadrant speed control of a dc drive is also possible using an H-bridge pulsewidth modulation (PWM) converter as shown in Fig. 30.42. Such drives (using a permanent magnet dc motor) are popular in low-power applications, such as robotic and instrumentation drives. The dc source can be a battery or may be obtained from ac supply through a diode rectifier and filter. With PWM operation, the drive response is very fast and the armature current ripple is small, giving less harmonic heating and torque pulsation. Four-quadrant operation can be summarized as follows:

Quadrant 1: Forward motoring (buck or step-down converter mode)
- Q_1—on
- Q_3, Q_4—off
- Q_2—chopping
- Current freewheeling through D_3 and Q_1

Quadrant 2: Forward regeneration (boost or step-up converter mode)
- Q_1, Q_2, Q_3—off
- Q_4—chopping
- Current freewheeling through D_1 and D_2

Quadrant 3: Reverse motoring (buck converter mode)
- Q_3—on
- Q_1, Q_2—off
- Q_4—chopping
- Current freewheeling through D_1 and Q_3

Quadrant 4: Reverse regeneration (boost converter mode)
- Q_1, Q_3, Q_4—off
- Q_2—chopping
- Current freewheeling through D_3 and D_4

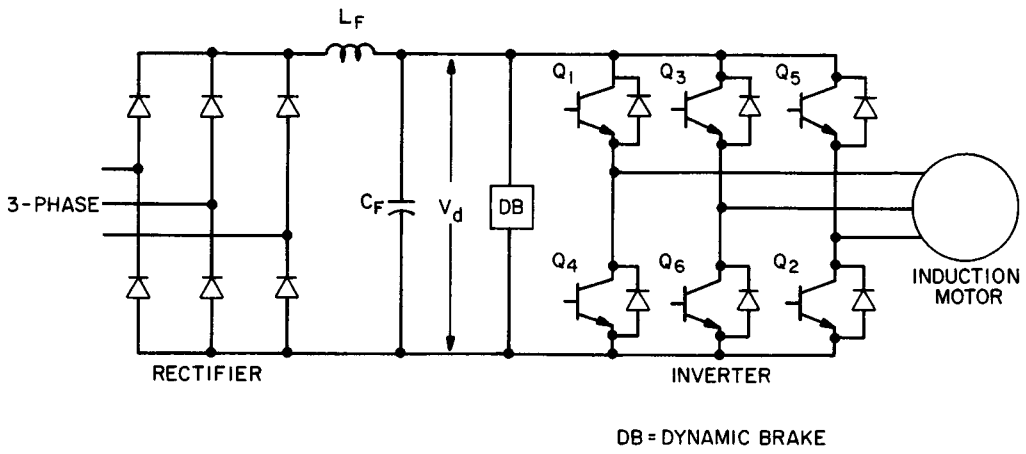

FIGURE 30.43 Diode rectifier PWM inverter control of an induction motor.

Often a drive may need only a one- or two-quadrant mode of operation. In such a case, the converter topology can be simple. For example, in one-quadrant drive, only Q_2 chopping and D_3 freewheeling devices are required, and the terminal A is connected to the supply positive. Similarly, a two-quadrant drive will need only one leg of the bridge, where the upper device can be controlled for motoring mode and the lower device can be controlled for regeneration mode.

Converter Control of AC Machines

Although application of dc drives is quite common, disadvantages are that the machines are bulky and expensive, and the commutators and brushes require frequent maintenance. In fact, commutator sparking prevents machine application in an unclean environment, at high speed, and at high elevation. AC machines, particularly the cage-type induction motor, are favorable when compared with all the features of dc machines. Although converter system, control, and signal processing of ac drives is definitely complex, the evolution of ac drive technology in the past two decades has permitted more economical and higher performance ac drives. Consequently, ac drives are finding expanding applications, pushing dc drives towards obsolescence.

Voltage-Fed Inverter Induction Motor Drive

A simple and popular converter system for speed control of an induction motor is shown in Fig. 30.43. The front-end diode rectifier converts 60 Hz ac to dc, which is then filtered to remove the ripple. The dc voltage is then converted to variable-frequency, variable-voltage output for the machine through a PWM bridge inverter. Among a number of PWM techniques, the sinusoidal PWM is common, and it is illustrated in Fig. 30.44 for one phase only. The stator sinusoidal reference phase voltage signal is compared with a high-frequency carrier wave, and the comparator logic output controls switching of the upper and lower transistors in a phase leg. The phase voltage wave shown refers to the fictitious center tap of the filter capacitor. With the PWM technique, the fundamental voltage and frequency can be easily varied. The stator voltage wave contains high-frequency ripple, which is easily filtered by the machine leakage inductance. The voltage-to-frequency ratio is kept constant to provide constant airgap flux in the machine. The machine voltage-frequency relation, and the corresponding torque, stator current, and slip, are shown in Fig. 30.45. Up to the base or rated frequency ω_b, the machine can develop constant torque. Then, the field flux weakens as the frequency is increased at constant voltage. The speed of the machine can be controlled in a simple open-loop manner by controlling the frequency and maintaining the proportionality between the voltage and frequency. During acceleration, machine-developed torque should be limited so that the inverter current rating is not exceeded. By controlling the frequency, the operation can be extended in the field weakening region. If the supply frequency is controlled to be lower than the machine speed (equivalent frequency), the motor will act as a generator and the inverter will act as a rectifier, and energy from the motor will be pumped back to the dc link. The **dynamic brake** shown is nothing but a buck converter with resistive load that dissipates excess power to maintain the dc bus voltage constant. When

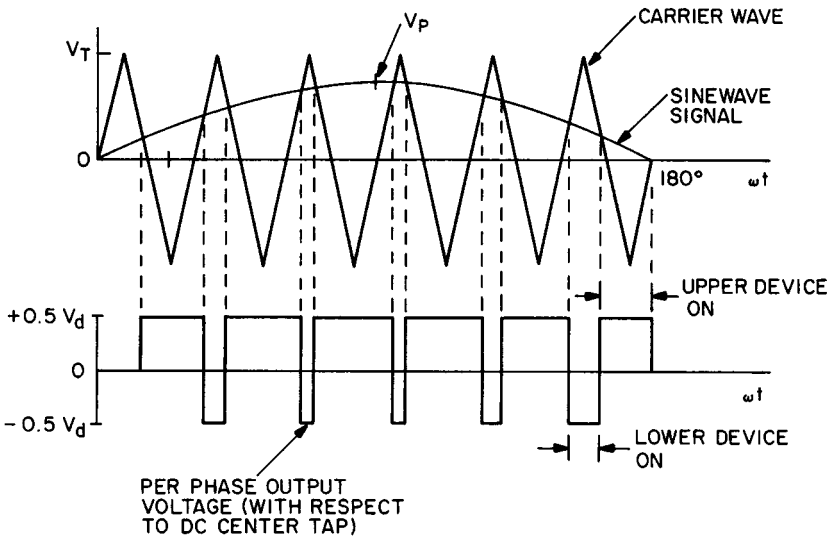

FIGURE 30.44 Sinusoidal pulse width modulation principle.

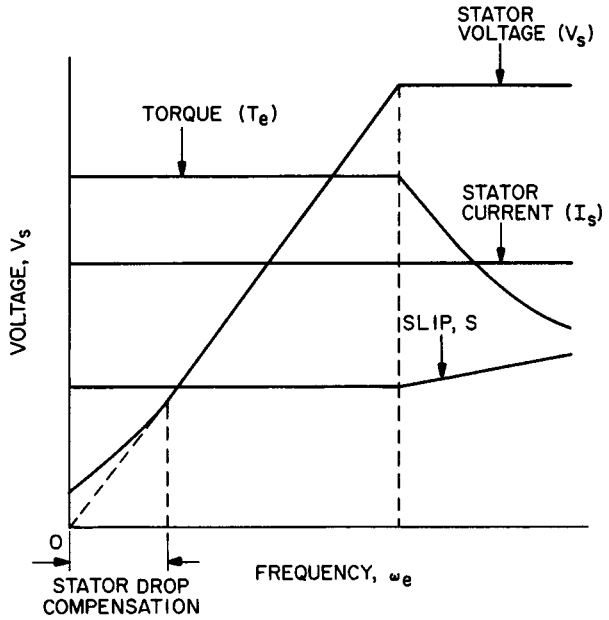

FIGURE 30.45 Voltage-frequency relation of an induction motor.

the motor speed is reduced to zero, the phase sequence of the inverter can be reversed for speed reversal. Therefore, the machine speed can be easily controlled in all four quadrants.

Current-Fed Inverter Induction Motor Drive

The speed of a machine can be controlled by a current-fed inverter as shown in Fig. 30.46. The front-end thyristor rectifier generates a variable dc current source in the dc link inductor. The dc current is then converted to six-step machine current wave through the inverter. The basic mode of operation of the inverter is the same as that of the rectifier, except that it is **force-commutated**, that is, the capacitors and series diodes help commutation of the thyristors. One advantage of the drive is that regenerative braking is easy because the

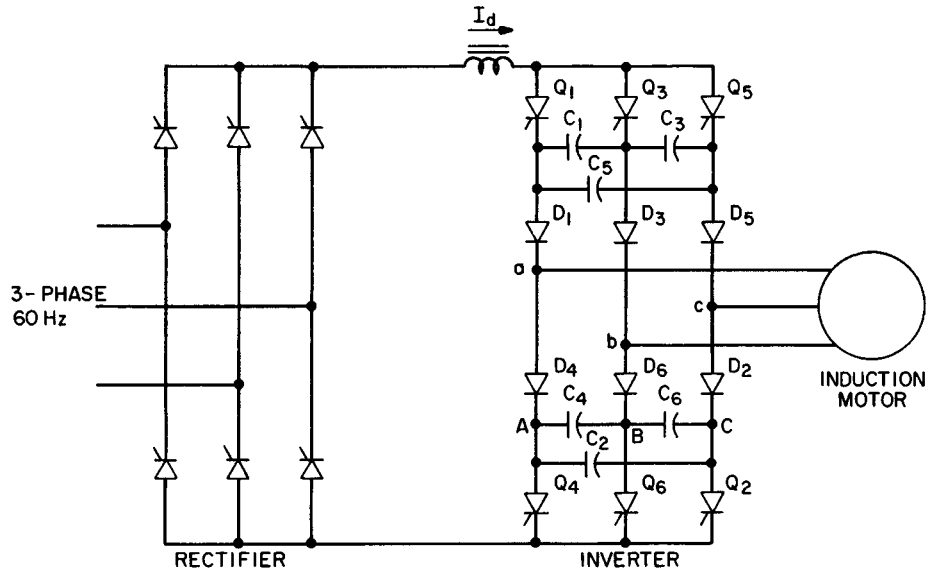

FIGURE 30.46 Force-commutated current-fed inverter control of an induction motor.

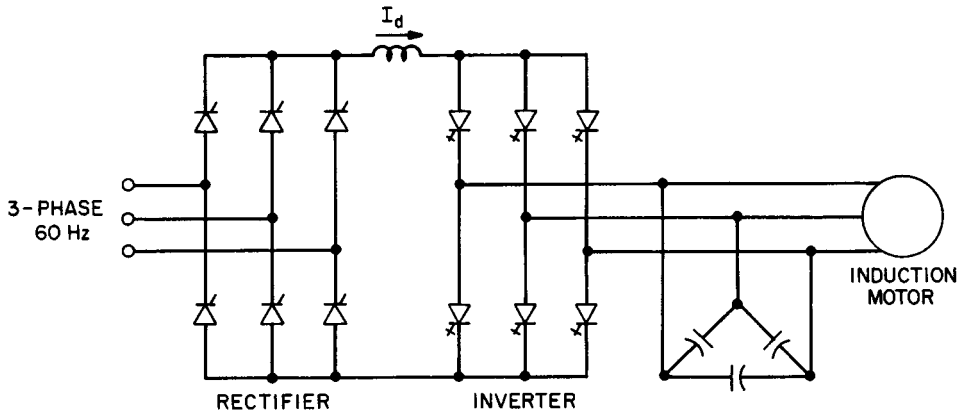

FIGURE 30.47 PWM current-fed inverter control of an induction motor.

rectifier and inverter can reverse their operation modes. Six-step machine current, however, causes large harmonic heating and torque pulsation, which may be quite harmful at low-speed operation. Another disadvantage is that the converter system cannot be controlled in open loop like a voltage-fed inverter.

Current-Fed PWM Inverter Induction Motor Drive

The force-commutated thyristor inverter in Fig. 30.46 can be replaced by a **self-commutating** gate turn-off (GTO) thyristor PWM inverter as shown in Fig. 30.47. The output capacitor bank shown has two functions: (1) it permits PWM switching of the GTO by diverting the load inductive current, and (2) it acts as a low-pass filter causing sinusoidal machine current. The second function improves machine efficiency and attenuates the irritating magnetic noise. Note that the fundamental machine current is controlled by the front-end rectifier, and the fixed PWM pattern is for controlling the harmonics only. The GTO is to be the reverse-blocking type. Such drives are popular in the multimegawatt power range. For lower power, an **insulated gate bipolar transistor (IGBT)** or transistor can be used with a series diode.

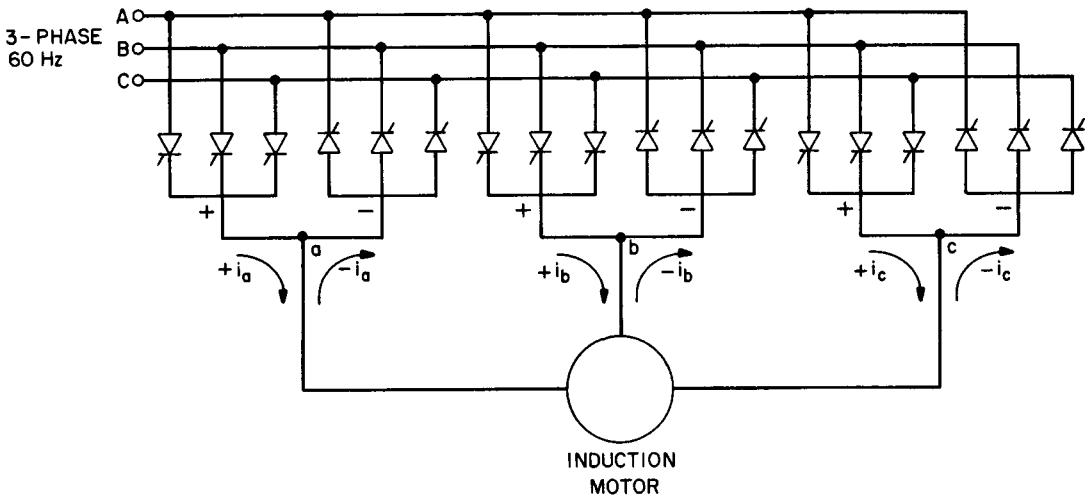

FIGURE 30.48 Cycloconverter control of an induction motor.

Cycloconverter Induction Motor Drive

A phase-controlled cycloconverter can be used for speed control of an ac machine (induction or synchronous type). Figure 30.48 shows a drive using a three-pulse half-wave or 18-thyristor cycloconverter. Each output phase group consists of positive and negative converter components which permit bidirectional current flow. The firing angle of each converter is sinusoidally modulated to generate the variable-frequency, variable-voltage output required for ac machine drive. Speed reversal and regenerative mode operation are easy. The cycloconverter can be operated in blocking or circulating current mode. In blocking mode, the positive or negative converter is enabled, depending on the polarity of the load current. In circulating current mode, the converter components are always enabled to permit circulating current through them. The circulating current reactor between the positive and negative converter prevents short circuits due to ripple voltage. The circulating current mode gives simple control and a higher range of output frequency with lower harmonic distortion.

Slip Power Recovery Drive of Induction Motor

In a cage-type induction motor, the rotor current at slip frequency reacting with the airgap flux develops the torque. The corresponding slip power is dissipated in the rotor resistance. In a wound rotor induction motor, the slip power can be controlled to control the torque and speed of a machine. Figure 30.49 shows a popular slip power-controlled drive, known as a static Kramer drive. The slip power is rectified to dc with a diode rectifier and is then pumped back to an ac line through a thyristor phase-controlled inverter. The method permits speed control in the subsynchronous speed range. It can be shown that the developed machine torque is proportional to the dc link current I_d and the voltage V_d varies directly with speed deviation from the synchronous speed. The current I_d is controlled by the firing angle of the inverter. Since V_d and V_I voltages balance at steady state, at synchronous speed the voltage V_d is zero and the firing angle is 90 degrees. The firing angle increases as the speed falls, and at 50% synchronous speed the firing angle is near 180 degrees. This is practically the lowest speed in static Kramer drive. The transformer steps down the inverter input voltage to get a 180-degree firing angle at lowest speed. The advantage of this drive is that the converter rating is low compared with the machine rating. Disadvantages are that the line power factor is low and the machine is expensive. For limited speed range applications, this drive has been popular.

Wound Field Synchronous Motor Drive

The speed of a wound field synchronous machine can be controlled by a current-fed converter scheme as shown in Fig. 30.46, except that the forced-commutation elements can be removed. The machine is operated at leading power factor by overexcitation so that the inverter can be load commutated. Because of the simplicity of converter topology and control, such a drive is popular in the multimegawatt range.

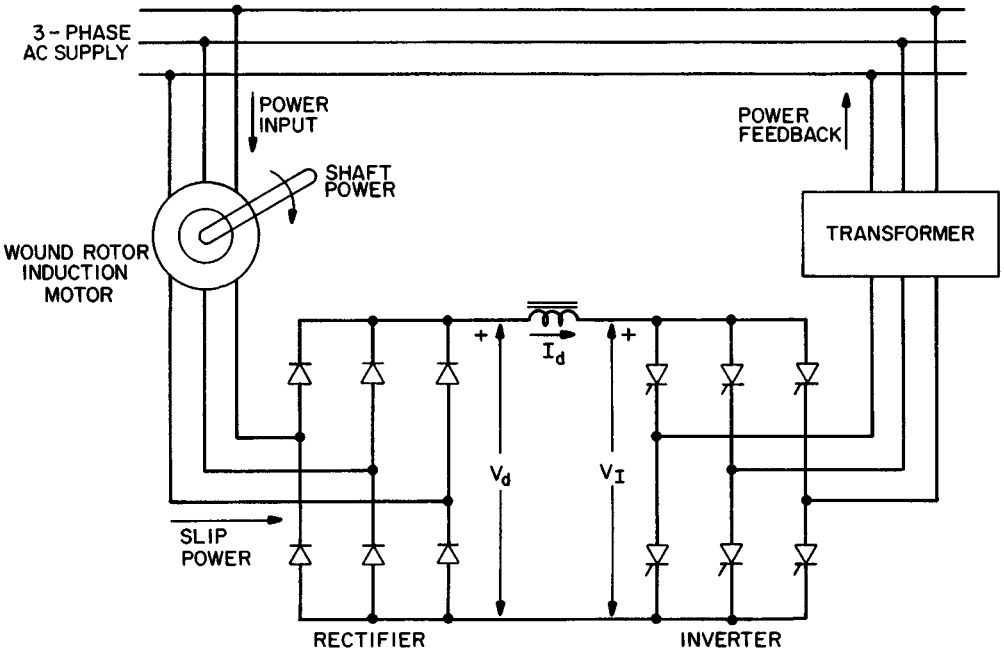

FIGURE 30.49 Slip power recovery control of a wound rotor induction motor.

Permanent Magnet Synchronous Motor Drive

Permanent magnet (PM) machine drives are quite popular in the low-power range. A PM machine can have sinusoidal or concentrated winding, giving the corresponding sinusoidal or trapezoidal induced stator voltage wave. Figure 30.50 shows the speed control system using a trapezoidal machine, and Fig. 30.51 explains the wave forms. The power MOSFET inverter supplies variable-frequency, variable-magnitude six-step current wave to the stator. The inverter is self-controlled, that is, the firing pulses are generated by the machine position sensor through a decoder. It can be shown that such a drive has the features of dc drive and is normally defined as *brushless dc drive*. The speed control loop generates the dc current command, which is then controlled by the **hysteresis-band** method to construct the six-step phase current waves in correct phase relation with the induced voltage waves as shown in Fig. 30.51. The drive can easily operate in four-quadrant mode.

Defining Terms

Dynamic brake: The braking operation of a machine by extracting electrical energy and then dissipating it in a resistor.

Forced-commutation: Switching off a power semiconductor device by external circuit transient.

Four-quadrant: A drive that can operate as a motor as well as a generator in both directions.

Hysteresis-band: A method of controlling current where the instantaneous current can vary within a band.

Insulated gate bipolar transistor (IGBT): A device that combines the features of a power transistor and MOSFET.

Regenerative braking: The braking operation of a machine by converting its mechanical energy into electrical form and then pumping it back to the source.

Self-commutation: Switching off a power semiconductor device by its gate or base drive.

Two-quadrant: A drive that can operate as a motor as well as a generator in one direction.

31.1 Lasers[1]

Jeff Hecht

The word *laser* is an acronym for "light amplification by the stimulated emission of radiation," a phrase that covers most, though not all, of the key physical processes inside a laser. Unfortunately, that concise definition may not be very enlightening to the nonspecialist who wants to *use* a laser and cares less about its internal physics than its external characteristics. From a practical standpoint, a laser can be considered as a source of a narrow beam of **monochromatic**, coherent light in the visible, infrared, or ultraviolet parts of the spectrum. The power in a continuous beam can range from a fraction of a milliwatt to around 25 kilowatts (kW) in commercial lasers, and up to more than a megawatt in special military lasers. Pulsed lasers can deliver much higher peak powers during a pulse, although the power averaged over intervals while the laser is off and on is comparable to that of continuous lasers.

The range of laser devices is broad. The **laser medium**, or material emitting the laser beam, can be a gas, liquid, glass, crystalline solid, or semiconductor crystal and can range in size from a grain of salt to filling the inside of a moderate-sized building. Not every laser produces a narrow beam of monochromatic, coherent light. Semiconductor diode lasers, for example, produce beams that spread out over an angle of 20 to 40 degrees, hardly a pencil-thin beam. Liquid dye lasers emit at a broad or narrow range of wavelengths, depending on the optics used with them. Other types emit at a number of spectral lines, producing light that is neither truly monochromatic nor coherent. Table 31.1 summarizes important commercial lasers.

Practically speaking, lasers contain three key elements. One is the laser medium itself, which generates the laser light. A second in the power supply, which delivers energy to the laser medium in the form needed to excite it to emit light. The third is the optical cavity or **resonator**, which concentrates the light to stimulate the emission of laser radiation. All three elements can take various forms, and although they are not always immediately evident in all types of lasers, their functions are essential. Figure 31.1 shows these elements in a ruby and a helium-neon laser.

Laser-like devices called optical parametric oscillators have come into increasing use. They are more costly and complex than lasers, but can be tuned across a broad range, with wavelengths from 0.2 to 4 micrometers.

1.15	He-Ne	CW, milliwatts
1.2–1.4	InGaAsP diode	CW, to 100 mW
1.313	Nd-YLF	CW or pulsed, to 0.1 W
1.32	Nd-YAG	Pulsed or CW, to a few watts
1.4–1.6	Color center	CW, under 1 W
1.5–1.6	InGaAsP diode	CW, to 100 mW
1.523	He-Ne	CW, milliwatts
1.54	Erbium-glass (bulk)	Pulsed, to 1 W
1.54	Erbium-fiber (amplifier)	CW, milliwatts
1.75–2.5	Cobalt-MgF_2	Pulsed, 1-W range
2.3–3.3	Color center	CW, under 1 W
2.6–3.0	HF chemical	CW or pulsed, to hundreds of watts
3.3–29	Lead-salt diode	CW, milliwatt range
3.39	He-Ne	CW, to tens of milliwatts
3.6–4.0	DF chemical	CW or pulsed, to hundreds of watts
5–6	Carbon monoxide	CW, to tens of watts
9–11	Carbon dioxide	CW or pulsed, to tens of kilowatts
40–100	Far-infrared gas	CW, generally under 1 W

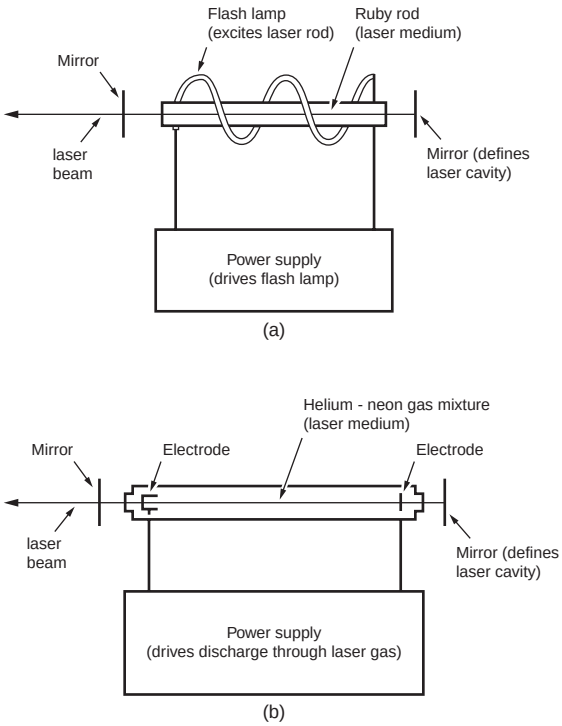

Figure 31.1 Simplified views of two common lasers, (a) ruby and (b) helium-neon, showing the basic components that make a laser.

Several general characteristics are common to most lasers that new users may not expect. Like most other light sources, lasers are inefficient in converting input energy into light. Efficiencies range from less than 0.001 to more than 50%, but except for semiconductor lasers, few types are much above 1% efficient. These low efficiencies can lead to special cooling requirements and duty-cycle limitations, particularly for high-power lasers. In some cases, special equipment may be needed to produce the right conditions for laser operation, such as cryogenic temperatures for lead salt semiconductor lasers. Operating characteristics of individual lasers depend strongly on structural components such as cavity optics, and in many cases a wide range is possible. Packaging can also have a strong impact on laser characteristics and the use of lasers for certain applications. Thus, there are wide ranges of possible characteristics, although single devices will have much more limited ranges of operation.

Differences from Other Light Sources

The basic differences between lasers and other light sources are the characteristics often used to describe a laser: the output beam is narrow, the light is monochromatic, and the emission is coherent. Each of these features is important for certain applications and deserves more explanation.

Most gas or **solid-state lasers** emit beams with divergence angle of about a milliradian, meaning that they spread to about 1 m in diameter after traveling a kilometer. (Semiconductor lasers have much larger beam divergence, but suitable optics can reshape the beam to make it much narrower.) The actual beam divergence depends on the type of laser and the optics used with it. The fact that laser light is contained in a beam serves to concentrate the output power onto a small area. Thus, a modest laser power can produce a high intensity inside the small area of the laser beam; the intensity of light in a 1-mW helium-neon laser beam is comparable to that of sunlight on a clear day, for example. The beams from high-power lasers, delivering tens of watts or more of continuous power or higher peak powers in pulses, can be concentrated to high enough intensities that they can weld, drill, or cut many materials.

The laser beam's concentrated light delivers energy only where it is focused. For example, a tightly focused laser beam can write a spot on a light-sensitive material without exposing the adjacent area, allowing high-resolution printing. Similarly, the beam from a surgical laser can be focused onto a tiny spot for microsurgery, without heating or damaging surrounding tissue. Lenses can focus the parallel rays in a laser beam to a much smaller spot than they can the diverging rays from a point source, a factor that helps compensate for the limited light-production efficiency of lasers.

Most lasers deliver a beam that contains only a narrow range of wavelengths, and thus the beam can be considered monochromatic for all practical purposes. Conventional light sources, in contrast, emit light over much of the visible and infrared spectrum. For most applications, the range of wavelengths emitted by lasers is narrow enough to make life easier for designers by avoiding the need for achromatic optics and simplifying the task of understanding the interactions between laser beam and target. For some applications in spectroscopy and communications, however, that range of wavelengths is not narrow enough, and special line-narrowing options may be required.

One of the beam's unique properties is its **coherence**, the property that the light waves it contains are in phase with one another. Strictly speaking, all light sources have a finite coherence length, or distance over which the light they produce is in phase. However, for conventional light sources that distance is essentially zero. For many common lasers, it is a fraction of a meter or more, allowing their use for applications requiring coherent light. The most important of these applications is probably holography, although coherence is useful in some types of spectroscopy, and there is growing interest in communications using coherent light.

Some types of lasers have two other advantages over other light sources: higher power and longer lifetime. For some high-power semiconductor lasers, lifetime must be traded off against higher power, but for most others the life vs. power trade-off is minimal. The combination of high power and strong directionality makes certain lasers the logical choice to deliver high light intensities to small areas. For some applications, lasers offer longer lifetimes than do other light sources of comparable brightness and cost. In addition, despite their low efficiency, some lasers may be more efficient in converting energy to light than other light sources.

The Laser Industry

Commercial Lasers

There is a big difference between the world of laser research and the world of the commercial laser industry. Unfortunately, many text and reference books fail to differentiate between types of lasers that can be built in the laboratory and those that are readily available commercially. That distinction is a crucial one for laser users.

Laser emission has been obtained from hundreds of materials at many thousands of emission lines in laboratories around the world. Extensive tabulations of these laser lines are available [Weber, 1982], and even today researchers are adding more lines to the list. However, most of these laser lines are of purely academic interest. Many are weak lines close to much stronger lines that dominate the emission in practical lasers. Most of the lasers that have been demonstrated in the laboratory have proved to be cumbersome to operate, low in power, inefficient, and/or simply less practical to use than other types.

Only a couple of dozen types of lasers have proved to be commercially viable on any significant scale; these are summarized in Table 31.1. Some of these types, notably the ruby and helium-neon lasers, have been around since the beginning of the laser era. Others, such as vibronic solid-state, are promising newcomers. The family of commercial lasers is expanding slowly, as new types such as titanium-sapphire come on the market, but with the economics of production a factor to be considered, the number of commercially viable lasers will always be limited.

There are many possible reasons why certain lasers do not find their way onto the market. Some require exotic operating conditions or laser media, such as high temperatures or highly reactive metal vapors. Some emit only feeble powers. Others have only limited applications, particularly lasers emitting low powers in the far-infrared or in parts of the infrared where the atmosphere is opaque. Some simply cannot compete with materials already on the market.

Defining Terms

Coherence: The condition of light waves that stay in the same phase relative to each other; they must have the same wavelength.
Continuous wave (CW): A laser that emits a steady beam rather than pulses.
Laser medium: The material in a laser that emits light; it may be a gas, solid, or liquid.
Monochromatic: Of a single wavelength or frequency.
Resonator: Mirrors that reflect light back and forth through a laser medium, usually on opposite ends of a rod, tube, or semiconductor wafer. One mirror lets some light escape to form the laser beam.
Solid-state laser: A laser in which light is emitted by atoms in a glass or crystalline matrix. Laser specialists do not consider semiconductor lasers to be solid-state types.

31.2 Sources and Detectors

Laurence S. Watkins

Properties of Light

The strict definition of light is electromagnetic radiation to which the eye is sensitive. Optical devices, however, can operate over a larger range of the electromagnetic spectrum, and so the term usually refers to devices which can operate in some part of the spectrum from the near ultraviolet (UV) through the visible range to the near infrared. Figure 31.2 shows the whole spectrum and delineates these ranges.

Optical radiation is electromagnetic radiation and so obeys and can be completely described by Maxwell's equations. We will not discuss this analysis here but just review the important properties of light.

Phase Velocity

In isotropic media light propagates as transverse electromagnetic (TEM) waves. The electric and magnetic field vectors are perpendicular to the propagation direction and orthogonal to each other. The velocity of light propagation in a medium (the velocity of planes of constant phase, i.e., wavefronts) is given by

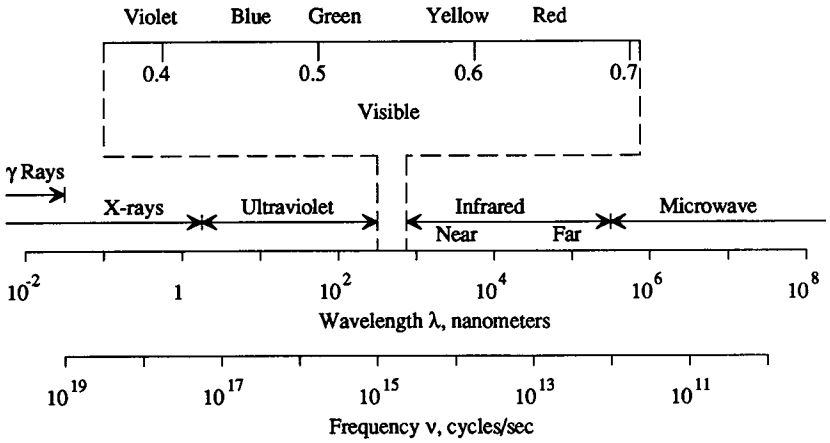

FIGURE 31.2 Electromagnetic spectrum showing visible and optical wavelengths.

$$v = \frac{c}{\sqrt{\varepsilon\mu}} \tag{31.1}$$

where c is the velocity of light in a vacuum (c = 299,796 km/s). The denominator in Eq. (31.1) is a term in optics called the refractive index of the medium

$$n = \sqrt{\varepsilon\mu} \tag{31.2}$$

where ε is the dielectric constant (permittivity) and μ is the magnetic permeability. The wavelength of light, λ, which is the distance between phase fronts is

$$\lambda = \frac{\lambda_0}{n} = \frac{v}{\upsilon} \tag{31.3}$$

where λ_0 is the wavelength in vacuum and υ is the light frequency. The refractive index varies with wavelength, and this is referred to as the dispersive property of a medium.

Another parameter used to describe light frequency is wave number. This is given by

$$\sigma = \frac{1}{\lambda} \tag{31.4}$$

and is usually expressed in cm^{-1}, giving the number of waves in a 1-cm path.

Group Velocity

When traveling in a medium, the velocity of energy transmission (e.g., a light pulse) is less than c and is given by

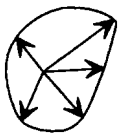
$$u = v - \lambda \frac{dv}{d\lambda} \tag{31.5}$$

In vacuum the phase and group velocities are the same.

Polarization

Light polarization is defined by the direction of the electric field vector. For isotropic media this direction is perpendicular to the propagation direction. It can exist in a number of states, described as follows.

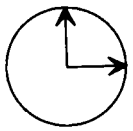
Unpolarized. The electric field vector has a random and constantly changing direction, and when there are multiple frequencies the vector directions are different for each frequency.



Linear. The electric field vector is confined to one direction.

Elliptical. The electric field vector rotates, either left hand or right hand, at the light frequency. The magnitude of the vector (intensity of the light) traces out an ellipse.

Circular. Circular is the special case of the above where the electric field vector traces out a circle.



Absorption

Light in traveling through media can be absorbed. This can be represented in two ways. The light flux propagating through a medium can be written as

$$I = I_0 e^{-\alpha x} \tag{31.6}$$

where x is the distance through the medium with incident light flux I_0. α is the absorption coefficient, usually stated in cm^{-1}. An alternative way of describing absorption is to use the imaginary term in the media refractive index. The complex refractive index is

$$\bar{n} = n(1 + ik) \tag{31.7}$$

where k is the attenuation index. α and k are related as

$$\alpha = \frac{4\pi}{\lambda_0} nk \tag{31.8}$$

Coherence

Light can be partially or fully coherent or incoherent, depending on the source and subsequent filtering operations. Common sources of light are incoherent because they consist of many independent radiators. An example of this is the fluorescent lamp in which each excited atom radiates light independently. There is no fixed phase relationship between the waves from these atoms. In a laser the light is generated in a resonant

cavity using a light amplifier and the resulting coherent light has well-defined phase fronts and frequency characteristics.

Spatial and Temporal Coherence. Spatial coherence describes the phase front properties of light. A beam from a single-mode laser which has one well-defined phase front is fully spatially coherent. A collection of light waves from a number of light emitters is incoherent because the resulting phase front has a randomly indefinable form. Temporal coherence describes the frequency properties of light. A single-frequency laser output is fully temporally coherent. White light, which contains many frequency components, is incoherent, and a narrow band of frequencies is partially coherent.

Laser Beam Focusing

The radial intensity profile of a collimated single-mode TEM_{00} (Gaussian) beam from a laser is given by

$$I(r) = I_0 \exp\left[2\left(\frac{-r^2}{w_0^2}\right)\right] \tag{31.9}$$

where w_0 is the beam radius ($1/e^2$ intensity). This beam will diverge as it propagates out from the laser, and the half angle of the divergence is given by

$$\theta_{1/2} = \frac{\lambda}{\pi w_0} \tag{31.10}$$

When this beam is focused by a lens the resulting light spot radius is given by

$$w_f = \frac{\lambda l}{\pi w_d} \tag{31.11}$$

where l is the distance from the lens to the position of the focused spot and w_d is the beam radius entering the lens. It should be noted that $l \cong f$, the lens focal length, for a collimated beam entering the lens. However, l will be a greater distance than f if the beam is diverging when entering the lens.

Geometric Optics

The wavelength of light can be approximated to zero for many situations. This permits light to be described in terms of light rays which travel in the direction of the wave normal. This branch of optics is referred to geometric optics.

Properties of Light Rays

Refraction. When light travels from one medium into another it changes propagation velocity, Eq. (31.1). This results in refraction (bending) of the light as shown in Fig. 31.3.

The change in propagation direction of the light ray is given by Snell's law:

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \tag{31.12}$$

where n_1 and n_2 are the refractive indices of media 1 and 2, respectively.

Critical Angle. When a light ray traveling in a medium is incident on a surface of a less dense medium, there is an incidence angle θ_2, where $\sin\theta_1 = 1$. This is the critical angle; for light incident at angles greater than θ_2 the light is totally internally reflected as shown in Fig. 31.3(b). The critical angle is given by $\theta_c = \sin^{-1}(n_1/n_2)$.

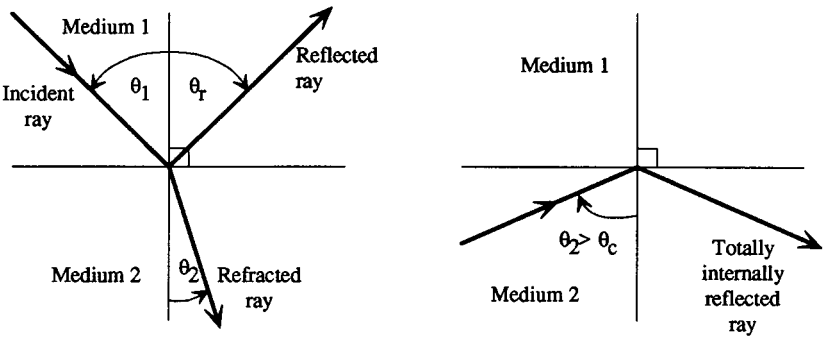


FIGURE 31.3 (a) Diagram of a light ray in medium 1 incident at angle θ_1 on the surface to medium 2. The ray is refracted at angle θ_2. (b) Diagram of the situation when the ray in medium 2 is incident at an angle greater than the critical angle θ_c and totally internally reflected.

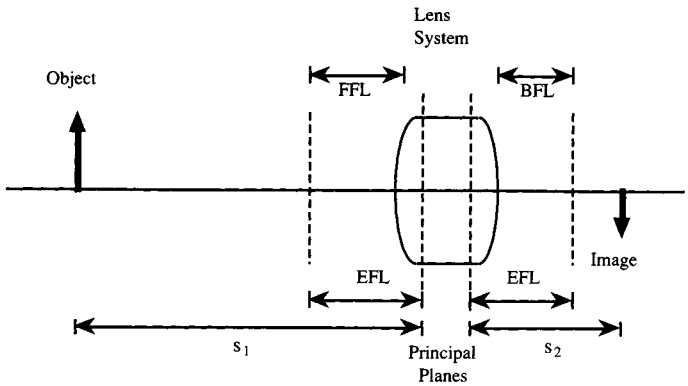

FIGURE 31.4 Schematic of an optical system forming an image of an object. Light rays from the object are captured by the lens which focuses them to form the image. EFL, effective focal length, f, of the lens; FFL and BFL, distances from the focal points to the outer lens surface. Principal planes are the positions to which the focal points, object distance, and image distance are measured; in a simple lens they are coincident.

Image Formation with a Lens

Many applications require a lens to focus light or to form an image onto a detector. A well-corrected lens usually consists of a number of lens elements in a mount, and this can be treated as a black box system. The characteristics of this lens are known as the cardinal points. Figure 31.4 shows how a lens is used to form an image from an illuminated object.

The equation which relates the object, image, and lens system is

$$\frac{1}{f} = \frac{1}{s_1} + \frac{1}{s_2} \tag{31.13}$$

The image magnification is given by $M = s_2/s_1$. When the object is very far away s_1 is infinite and the image is formed at the back focal plane.

Incoherent Light

When two or more incoherent light beams are combined, the resulting light flux is the sum of their energies. For coherent light this is not necessarily true and the resulting light intensity depends on the phase relationships between the electric fields of the two beams, as well as the degree of coherence.

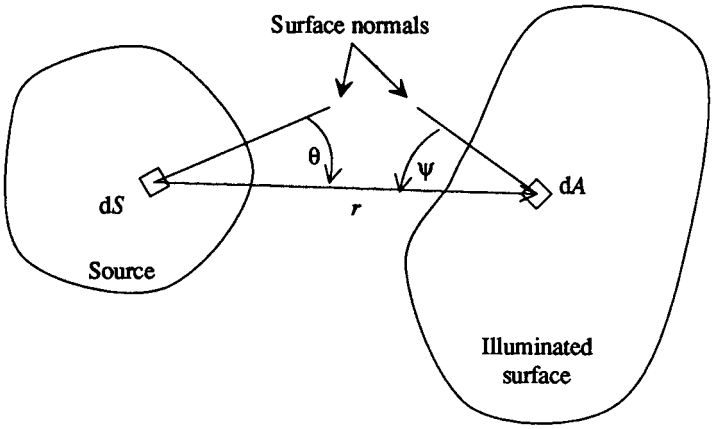

FIGURE 31.5 Surface being illuminated by an extended source. Illumination of surface element *dA* is calculated by summing the effects of elements *dS*.

Brightness and Illumination

The flux density of a light beam emitted from a **point source** decreases with the square of distance from it. Light sources are typically extended sources (being larger than point sources). The illumination of a surface from light emitted from an **extended source** can be calculated using Fig. 31.5.

The flux incident on a surface element *dA* from a source element *dS* is given by

$$dE = \frac{B\,dA\cos\theta\,dS\cos\psi}{r^2} \tag{31.14}$$

The constant *B* is called the luminance or photometric brightness of the source. Its units are candles per square meter (1 stilb = π lamberts) and *dE* is the luminous flux in lumens. The total illumination *E* of the surface element is calculated by integrating over the source. The illuminance or flux density on the surface is thus

$$I = \frac{E}{dA}\ (\text{lumens/cm}^2) \tag{31.15}$$

Two methods are commonly used for quantifying light energy, namely, the radiometric unit of watts and the photometric unit of candelas. The candela is an energy unit which is derived from light emission from a blackbody source. The two can be related using the relative visibility curve $V(\lambda)$, which describes the eye's sensitivity to the visible light spectrum, it being maximum near a wavelength of 550 nm. The constant which relates lumens to watts at this wavelength is 685 lm/W. The luminous flux emitted by a source can therefore be written as

$$F = 685\int V(\lambda)\,P(\lambda)\,d\lambda\ \ (\text{lumens}) \tag{31.16}$$

where *V* is the spectral response of the eye and *P* is the source radiant intensity in watts.

The source radiance is normally stated as luminance in candle per square centimeter (1 lumen per steradian per square centimeter) or radiance in watts per square centimeter per steradian per nanometer. The lumen is defined as the luminous flux emitted into a solid angle of a steradian by a point source of intensity 1/60th that of a 1-cm² blackbody source held at 2042 K temperature (molten platinum).

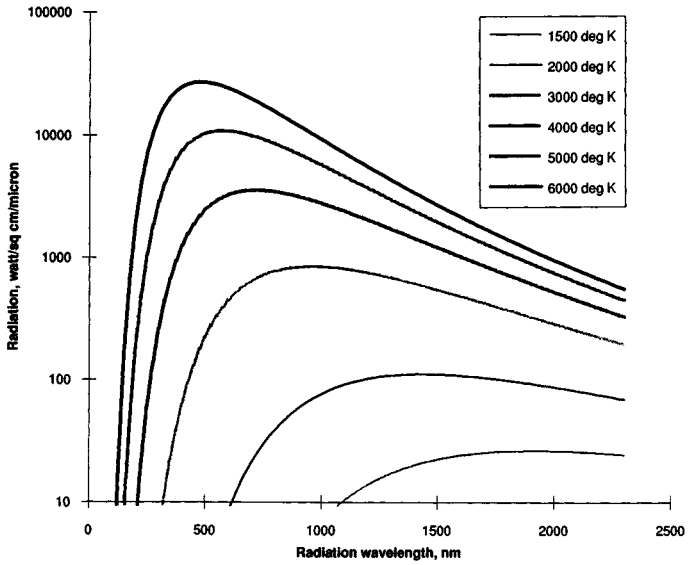

FIGURE 31.6 Plot of blackbody radiation for a series of temperatures. Radiation is in watts into a hemisphere direction from a 1-cm^2 of surface in a 1-μm wavelength band.

Thermal Sources

Objects emit and absorb radiation, and as their temperature is increased the amount of radiation emitted increases. In addition, the spectral distribution changes, with proportionally more radiation emitted at shorter wavelengths. A blackbody is defined as a surface which absorbs all radiation incident upon it, and Kirchhoff's law of radiation is given by

$$\frac{W}{a} = \text{constant} = WB \tag{31.17}$$

stating that the ratio of emitted to absorbed radiation is a constant a at a given temperature.

The energy or wavelength distribution for a blackbody is given by Planck's law

$$W = \frac{c_1}{\lambda^5}\left[\exp\left(\frac{c_2}{\lambda T}\right) - 1\right]^{-1} \quad (\text{watts/cm}^2 \text{ area per } \mu\text{m wavelength})$$
$$c_1 = 3.7413 \times 10^4 \tag{31.18}$$
$$c_2 = 1.4380 \times 10^4$$

T is in degrees Kelvin, λ is in micrometers, and W is the power emitted into a hemisphere direction. Blackbody radiation is incoherent, with atoms or molecules emitting radiation independently. Figure 31.6 is a plot of the blackbody radiation spectrum for a series of temperatures.

Very few materials are true blackbodies; carbon lampblack is one. For this reason a surface emissivity is used which describes the ratio of actual radiation emitted to that from a perfect blackbody. Table 31.2 is a listing of emissivities for some common materials.

Tungsten Filament Lamp

In the standard incandescent lamp a tungsten filament is heated to greater than 2000°C, and it is protected from oxidation and vaporization by an inert gas. In a quartz halogen lamp the envelope is quartz, which allows

TABLE 31.2 Emissivities of Some Common Materials

Material	Temperature (°C)	Emissivity
Tungsten	2000	0.28
Nickel-chromium (80-20)	600	0.87
Lampblack	20–400	0.96
Polished silver	200	0.02
Glass	1000	0.72
Platinum	600	0.1
Graphite	3600	0.8
Aluminum (oxidized)	600	0.16
Carbon filament	1400	0.53

the filament to run at a higher temperature. This increases the light output and gives a whiter wavelength spectrum with proportionally more visible radiation to infrared.

Standard Light Source—Equivalent Black Blackbody

Because the emissivity of incandescent materials is less than 1, an equivalent source is needed for measurement and calibration purposes. This is formed by using an enclosed space which has a small opening in it. Provided the opening is much smaller than the enclosed area, the radiation from the opening will be nearly equal to that from a blackbody at the same temperature, as long as the interior surface emissivity is > 0.5. Blackbody radiation from such a source at the melting point of platinum is defined as 1/60 cd/cm^2.

Arc Lamp

A gas can be heated to temperatures of 6000 K or more by generating an electric arc between two electrodes. The actual resulting temperature is dependent on the current flowing through the arc, the gas pressure and its composition, and other factors. This does provide a light source which is close to the temperature of the sun. Using an inert xenon gas results in essentially a white light spectrum. The use of a gas such as mercury gives more light in the UV as well as a number of strong peak light intensities at certain wavelengths. This is due to excitation and fluorescence of the mercury atoms.

Fluorescent Lamp

A fluorescent source is a container (transparent envelope) in which a gas is excited by either a dc discharge or an RF excitation. The excitation causes the electrons of the gas to move to higher energy orbits, raising the atoms to a higher excited state. When the atoms relax to lower states they give off energy, and some of this energy can be light. The wavelength of the light is characteristically related to the energy levels of the excited states of the gas involved. Typically a number of different wavelengths are associated with a particular gas.

Low-pressure lamps have relatively low luminance but provide light with narrow linewidths and stable spectral wavelengths. If only one wavelength is required, then optical filters can be used to isolate it by blocking the unwanted wavelengths.

Higher luminance is achieved by using higher gas pressures. The fluorescent lamp is very efficient since a high proportion of the input electrical energy is converted to light. White light is achieved by coating the inside of the container with various types of phosphor. The gas, for example a mercury–argon mixture, provides UV and violet radiation which excites the phosphor. Since the light is produced by fluorescence and phosphorescence, the spectral content of the light does not follow Planck's radiation law but is characteristic of the coating (e.g., soft white, cool white).

Light-Emitting Diodes (LED)

Light can be emitted from a semiconductor material when an electron and hole pair recombine. This is most efficient in a direct gap semiconductor like GaAs and the emitted photons have energy close to the bandgap energy E_g. The wavelength is then given by

$$\lambda \cong \frac{hc}{E_g} \tag{31.19}$$

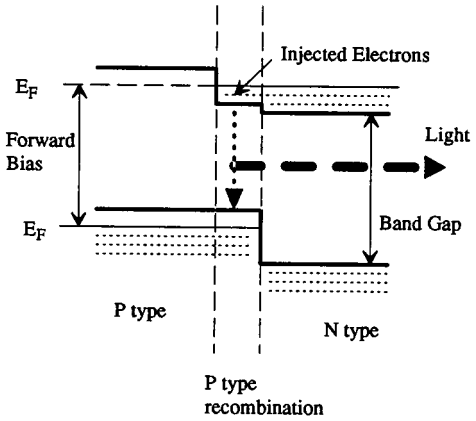

FIGURE 31.7 Band structure of a double heterostructure LED. Forward bias injects holes and electrons into the junction region where they recombine and emit light.

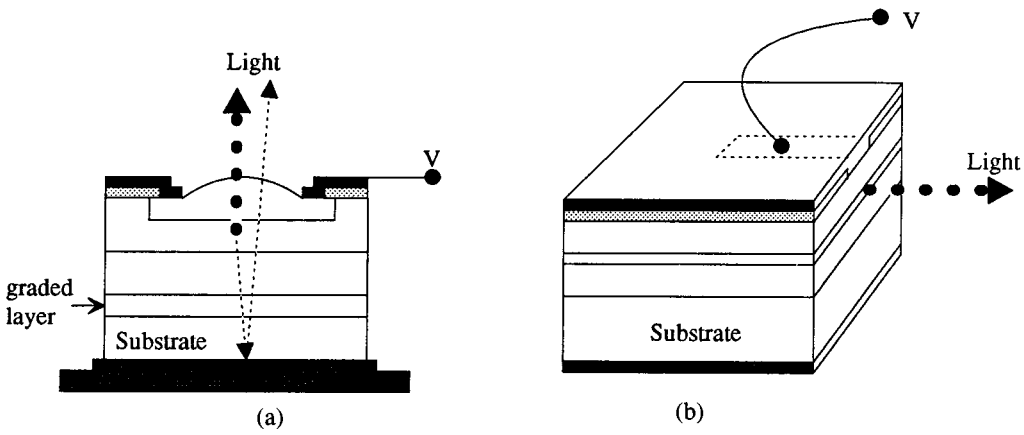

FIGURE 31.8 Cross-sectional diagrams of (a) surface emitting LED and (b) edge emitting LED. The light output from the edge emitter is more directional because of confinement by the junction guide region.

where h is Planck's constant (6.626×10^{-34} J-s) and c the velocity of light in vacuum. The spectral width of the emission is quite broad, a few hundred nanometers, and is a function of the density of states, transition probabilities, and temperature.

For **light emission** to occur, the conduction band must be populated with many electrons. This is achieved by forward biasing a *pn* junction to inject electrons and holes into the junction region as shown in Fig. 31.7.

Figure 31.8(a) shows the cross section of a surface emitting LED with an integral lens fabricated into the surface. The light from the LED is incoherent and emitted in all directions. The lens and the bottom reflecting surface increase the amount of light transmitted out of the front of the device. The output from the LED is approximately linear with current but does decrease with increasing junction temperature.

Figure 31.8(b) shows an edge emitting LED. Here the light is generated in a waveguide region which confines the light, giving a more directional output beam.

Various wavelengths are available and are obtained by using different bandgap semiconductors. This is done by choosing different binary, ternary, and quaternary compositions. Table 31.3 is a listing of the more common ones.

The output power is usually specified in milliwatts per milliamp current obtained in a given measurement situation, e.g., into a fiber or with a 0.5 numerical aperture large area detector. Other parameters are peak wavelength, wavelength band (usually full width half max), and temperature characteristics.

TABLE 31.3 Common Light-Emitting Diode Compounds and Wavelengths

Compound	Wavelength (nm)	Color
GaP	565	Green
GaAsP	590	Yellow
GaAsP	632	Orange
GaAsP	649	Red
GaAlAs	850	Near IR
GaAs	940	Near IR
InGaAs	1060	Near IR
InGaAsP	1300	Near IR
InGaAsP	1550	Near IR

LEDs for Fiber Optic Communications

GaAs and InGaAsP LEDs are commonly used as sources for fiber optic communications. Since they are an incoherent source, it is only practical to use them with multimode fiber. Only multimode fiber has a large enough core diameter and numerical aperture (NA) to couple in enough light to be able to propagate any useful distance. Applications for LEDs in fiber optics are for short distance links using glass or plastic fiber at relatively low bandwidths, typically in the Mb/s rather than Gb/s. Primary applications of these are for low cost datalinks.

The detector can be packaged two ways: first with a fiber pigtail directly attached to the detector package; or a more common package is to have a fiber connector molded in as part of the package so that a connectorized fiber can be plugged in to it. Many LEDs for fiber optics are now packaged with electronic drive circuits to form a transmitter module ready to receive standard format data signals.

Detectors, Semiconductor

When light interacts electronically with a medium, by changing the energy of electrons or creating carriers, for example, it interacts in a quantized manner. The light energy can be quantized according to Planck's theory

$$E = h\upsilon \tag{31.20}$$

where υ is the light frequency and h is Planck's constant. The energy of each photon is very small; however, it does increase with shorter wavelengths.

Photoconductors

Semiconductors can act as photoconductors, where incident light increases the carrier density, thus increasing the conductivity. There are two basic types, intrinsic and extrinsic. Figure 31.9 shows a simple energy diagram containing conduction and valence bands. Also indicated are the levels which occur with the introduction of donor and acceptor impurities.

Intrinsic photoconduction effect is when a photon with energy $h\upsilon$, which is greater than the bandgap energy, excites an electron from the valence band into the conduction band, creating a hole–electron pair. This increases the conductivity of the material. The spectral response of this type of detector is governed by the bandgap of the semiconductor.

In an extrinsic photoconductor (see Fig. 31.9), the photon excites an electron from the valence band into the acceptor level corresponding to the hole of the acceptor atom. The resulting energy $h\upsilon$ is much smaller than the bandgap and is the reason why these detectors have applications for long wavelength infrared sensors. Table 31.4 is a list of commercial photoconductors and their peak wavelength sensitivities.

The doping material in the semiconductor determines the acceptor energy level, and so both the host material and the dopant are named. Since the energy level is quite small it can be populated by a considerable amount by thermal excitation. Thus, for useful detection sensitivity the devices are normally operated at liquid nitrogen and sometimes liquid helium temperatures. The current response, i, of a photoconductor can be written as

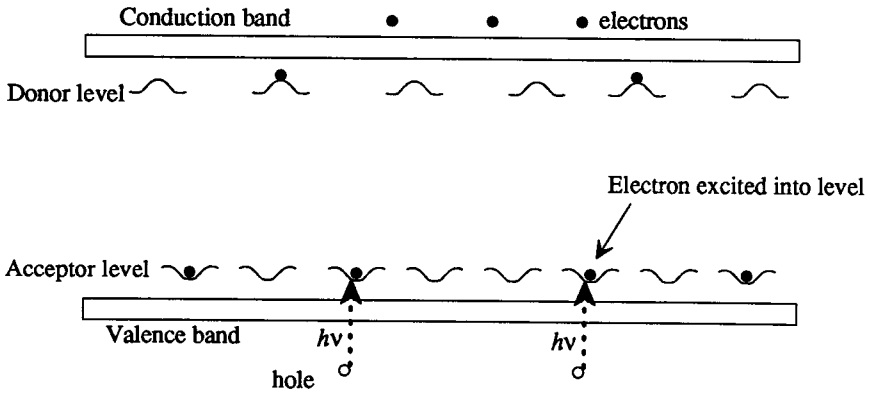

FIGURE 31.9 A simplified energy diagram for a photoconductive semiconductor, showing extrinsic effect of electrons into the acceptor level.

TABLE 31.4 Photoconductor Materials and Their Peak Wavelength Sensitivity

Photoconductor	Peak Wavelength (μm)
PbS	3
PbSe	5
HgCd	4
HgCaTe	10
HgCdTe	11
Si:Ga (4.2 K)	11
Si:As (4.2 K)	20
Si:Sb (4.2 K)	28

$$i = \frac{P\eta\tau_0 ev}{h\upsilon d} \tag{31.21}$$

where P is the optical power at frequency υ; h is Planck's constant; v is drift velocity = μE, where μ is mobility and E is electric field; η is quantum efficiency (at frequency υ); τ_0 is lifetime of carriers; and e is charge on electron.

Charge Amplification. For semiconductor photoconductors like CdS there can be traps. These are holes, which under the influence of a bias field will be captured for a period of time. This allows electrons to move to the anode instead of recombining with a hole, resulting in a longer period for the conduction increase. This provides a photoconductive gain which is equal to the mean time the hole is trapped divided by the electron transit time in the photoconductor. Gains of 10^4 are typical.

The charge amplification can be written as

$$\frac{\tau_0}{\tau_d} \tag{31.22}$$

where $\tau_d = d/v$, the drift time for a carrier to go across the semiconductor. The response time of this type of sensor is consequently slow, ~10 ms, and the output in quite nonlinear.

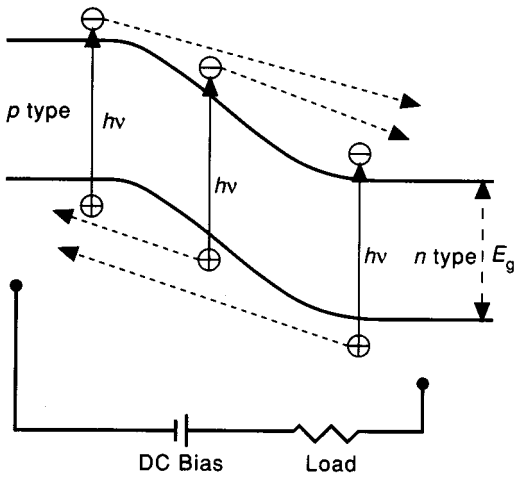

FIGURE 31.10 Energy diagram of a pn junction photodiode showing the three ways electron–hole pairs are created by absorbing photons and the contribution to current flow in the circuit.

Junction Photodiodes

In a simple junction photodiode a *pn* junction is fabricated in a semiconductor material. Figure 31.10 shows the energy diagram of such a device with a reverse voltage bias applied. Incident light with energy greater than the bandgap creates electrons in the *p* region and holes in the *n* region. Those which are within the diffusion length of the junction are swept across by the field. The light also creates electron–hole pairs in the junction region, and these are separated by the field. In both cases an electron charge is contributed to the external circuit. In the case of no bias the carrier movement creates a voltage with *p* region being positive. The maximum voltage is equal to the difference in the Fermi levels in the *p* and *n* regions and approaches the bandgap energy E_g.

PIN Photodiodes. The carriers which are generated in the junction region experience the highest field and so, being separated rapidly, give the fastest time response. The PIN diode has an extra intrinsic high field layer between the p and n regions, designed to absorb the light. This minimizes the generation of slow carriers and results in a fast response detector.

The signal current generated by incident light power *P* is

$$i = \frac{Pe\eta}{h\upsilon} + \text{dark current} \tag{31.23}$$

The output current is linear with incident power plus a constant dark current due to thermal generation of carriers; η is the quantum efficiency.

Avalanche Photodiodes

When the reverse bias of a photodiode is increased to near the breakdown voltage, carriers in the depletion region can be accelerated to the point where they will excite electrons from the valence band into the conduction band, creating more carriers. This current multiplication is called avalanche gain, and typical gains of 50 are available. Avalanche diodes are specially designed to have uniform junction regions to handle the high applied fields.

Detectors for Fiber Optic Communications

A major application for junction photodioldes is detectors for fiber optic communications. Silicon detectors are typically used for short wavelength light such as with GaAs sources. InP detectors are used for the 1.3 and 1.5 μm wavelength bands. The specific type and design of a detector is tailored to the fiber optics application, depending on whether it is low cost lower frequency datalinks or higher cost high frequency bit-rates in the

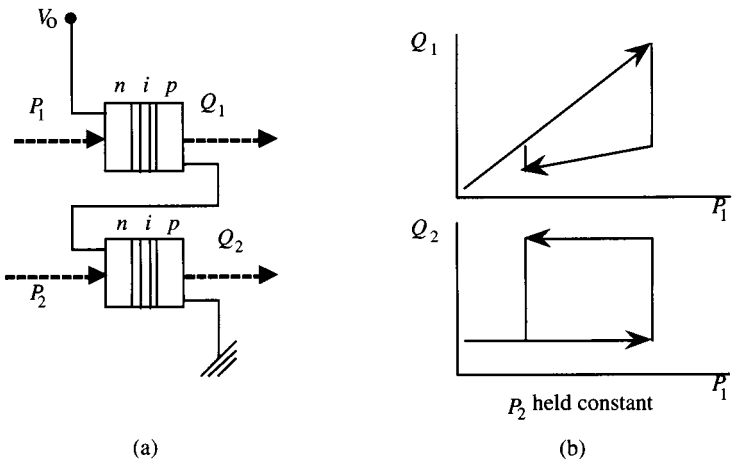

FIGURE 31.11 (a) S-SEED with voltage bias applied; (b) bistable outputs Q as a result of varying the input light power P_1 holding input power P_2 constant.

Gb/s. The detector is packaged either with a fiber pigtail or with a fiber connector receptacle molded as part of the package body.

Fiber optics detectors can also be packaged with pre-amplifier electronics or complete receiver and communications electronics into a module. For very high frequency response it is important to minimize the capacitance of the detector and the attached preamplifier circuit.

Solar Cells

Solar cells are large-area *pn* junction photodiodes, usually in silicon, which are optimized to convert light to electrical power. They are normally operated in the photovoltaic mode without a reverse voltage bias being applied.

Linear Position Sensors

Large-area photodiodes can be made into single axis and two axis position sensors. The single axis device is a long strip detector, and the two axis is normally square. In the single axis device the common terminal is in the middle and there are two signal terminals, one at each end. When a light beam is directed onto the detector, the relative output current from each signal terminal depends on how close the beam is to the terminal. The sum of the output currents from both terminals is proportional to the light intensity.

Phototransistors

For bipolar devices the light generates carriers which inject current into the base of the transistor. This modulates the collector base current, providing a higher output signal. For a field effect device the light generates carriers which create a gate voltage. PhotoFETs can have very high sensitivities.

SEEDs

A self-electro-optic effect device (SEED) is a multiple quantum well semiconductor optical pin device and forms the combination of a photodiode and a modulator. It can operate as a photodetector where incident light will generate a photocurrent in a circuit. It can also act as a modulator where the light transmitted through the device is varied by an applied voltage.

Devices are normally connected in pairs to form symmetric SEEDs as demonstrated in Fig. 31.11(a). These can then be operated as optical logic flip-flop devices. They can be set in one of two bistable states by application of incident light beams. The bistable state can be read out by similar light beams which measure the transmitted intensity. The hysteresis curve is shown in Fig. 31.11(b). These and similar devices are the emerging building blocks for optical logic and are sometimes referred to as smart pixels.

Detectors, Photoemissive

In the photoemissive effect, light falls onto a surface (photocathode) and the light energy causes electrons to be emitted. These electrons are then collected at a positively biased anode. There is a threshold energy required for the electron to be emitted from the surface. This energy is called the work function, f, and is a property of the surface material. The photon energy $h\upsilon$ must be greater than f, and this determines the longest wavelength sensitivity of the photocathode.

Vacuum Photodiodes

A vacuum photodiode comprises a negatively biased photocathode and a positive anode in a vacuum envelope. Light falling on the cathode causes electrons to be emitted, and these electrons are collected at the anode. Not all photons cause photoelectrons to be emitted, and quantum efficiencies, η, typically run 0.5–20%. These devices are not very sensitive; however, they have very good linearity of current to incident light power, P. They are also high-speed devices, with rise time being limited by the transit time fluctuations of electrons arriving at the anode. The photocurrent is given by

$$i = \frac{Pe\eta}{h\upsilon} + \text{dark current} \tag{31.24}$$

This kind of detector exhibits excellent short-term stability. The emissive surface can fatigue with exposure to light but will recover if the illumination is not excessive. Because of these properties, these devices have been used for accurate light measurement, although in many cases semiconductor devices are now supplanting them.

Gas-Filled Tubes

The light sensitivity of vacuum phototubes can be increased by adding 0.1 mm pressure of argon. The photoelectrons under the influence of the anode voltage accelerate and ionize the gas, creating more electrons. Gains of 5–10 can be realized. These devices are both low frequency, in the 10-kHz range, and nonlinear and are suitable only for simple light sensors. Semiconductor devices again are displacing these devices for most applications.

Photomultiplier Tubes

Photomultiplier tubes are the most sensitive light sensors, especially for visible radiation. Figure 31.12 is a schematic showing the electrical circuit used to bias it and form the output voltage signal. Light is incident on the photocathode, and the resulting photoelectrons are accelerated to a series of dynodes to generate secondary electrons and through this **electron multiplication** amplify the signal. Gains of 10^8 can be achieved with only minor degradation of the linearity and speed of vacuum photodiodes. The spectral response is governed by the emission properties of the photocathode.

There are various types of photomultipliers with different physical arrangements to optimize for a specific application. The high voltage supply ranges from 700 to 3000 V, and the electron multiplication gain is normally adjusted by varying the supply voltage. The linearity of a photomultiplier is very good, typically 3% over 3 decades of light level. Saturation is normally encountered at high anode currents caused by space charge effects at the last dynode where most of the current is generated. The decoupling capacitors, C_1, on the last few dynodes are used for high-frequency response and to prevent saturation from the dynode resistors.

Photon Counting

For the detection of very low light levels and for measuring the statistical properties of light, photon counting can be done using photomultipliers. A pulse of up to 10^8 electrons can be generated for each photoelectron emitted from the cathode, and so the arrival of individual photons can be detected. There is a considerable field of study into the statistical properties of light fields as measured by photon counting statistics.

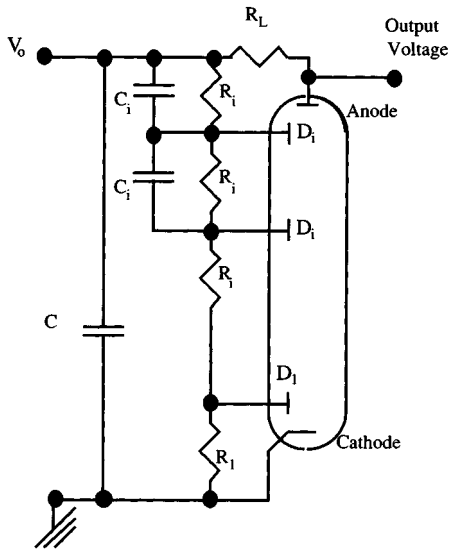

FIGURE 31.12 The basic layout of a photomultiplier tube showing the dynodes and the electrical circuit to bias them.

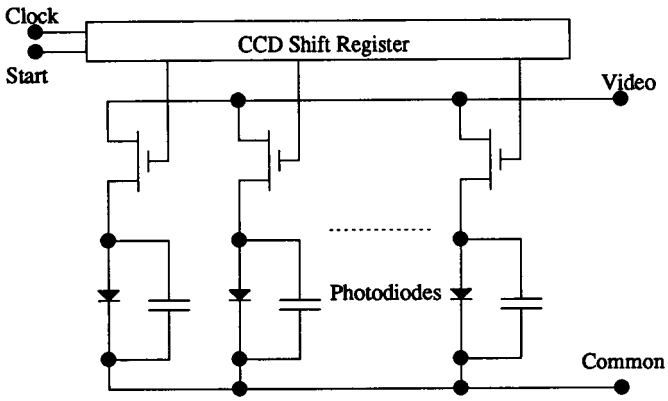

FIGURE 31.13 Schematic diagram of a linear CCD diode array sensor. CCD shift register sequentially clocks out charge from each photodiode to the video line.

Imaging Detectors

A natural extension to single photodetectors is to arrange them in arrays, both linear single dimension and two dimensions. Imaging detectors are made from both semiconductors and vacuum phototubes.

Semiconductor Detector Arrays

Detector arrays have been made using either photodiodes or photoconductors. The applications are for visible and infrared imaging devices. For small-sized arrays each detector is individually connected to an electrical lead on the package. This becomes impossible for large arrays, however, and these contain additional electronic switching circuits to provide sequential access to each diode.

Figure 31.13 show an example of a **charge-coupled device** (CCD) linear photodiode array. The device consists of a linear array of *pn* junction photodiodes. Each diode has capacitance associated with it, and when light falls on the detector the resulting photocurrent charges this capacitance. The charge is thus the time integral of the light intensity falling on the diode. The CCD periodically and sequentially switches the charge to the video line, resulting in a series of pulses. These pulses can be converted to a voltage signal which represents the light pattern incident on the array.

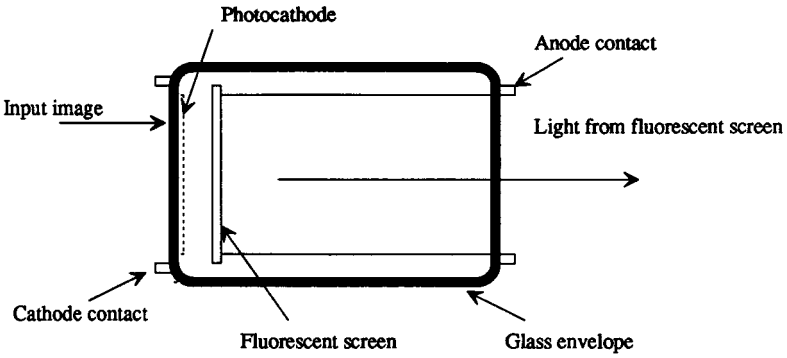

FIGURE 31.14 Diagram of a simple image-intensifier tube. More complex ones use improved electron optics.

The location of the diodes is accurately defined by the lithographic fabrication process and, being solid state, is also a rugged detector. These devices are thus very suitable for linear or two-dimensional optical image measurement. The devices can be quite sensitive and can have variable sensitivity by adjusting the CCD scan speed since the diode integrates the current until accessed by the CCD switch. The spectral sensitivity is that of the semiconductor photodiode, and the majority of devices now available are silicon. Smaller arrays are becoming more available in many types of semiconductors, however.

Image-Intensifier Tubes

An image-intensifier tube is a vacuum device which consists of a photoemissive surface onto which a light image is projected, an electron accelerator, and a phosphor material to view the image. This device, shown in Fig. 31.14, can have a number of applications, for example, brightening a very weak image for night vision or converting an infrared image into a visible one.

Light falling on the cathode causes electrons to be emitted in proportion to the light intensity. These electrons are accelerated and focused by the applied electric field onto the fluorescent screen to form a visible image. Luminance gains of 50–100 times can be achieved, and a sequence of devices can be used to magnify the gain even more.

Image Orthicon Tube (TV Camera)

There are two basic types of **television** (TV) camera tubes, the orthicon and the vidicon. The orthicon uses the photoemissive effect. A light image is focused onto the photocathode, and the electrons emitted are attracted toward a positively based target (see Fig. 31.15). The target is a wire mesh, and the electrons pass through it to be collected on a glass electron target screen. This also causes secondary electrons to be emitted, and they also collect on the screen. This results in a positive charge image which replicates the light image on the photocathode.

A low-velocity electron beam is raster scanned across the target to neutralize the charge. The surplus electrons return to the electron multiplier and generate a current for the signal output. The output current is thus inversely proportional to the light level at the scanning position of the beam. The orthicon tube is very sensitive because there is both charge accumulation between scans and gain from the electron multiplier.

Vidicon Camera Tube

A simple TV camera tube is the vidicon. This is the type used in camcorders and for many video applications where a rugged, simple, and inexpensive camera is required. Figure 31.16 is a schematic of a vidicon tube; the optical image is formed on the surface of a large-area photoconductor, causing corresponding variations in the conductivity. This causes the rear surface to charge toward the bias voltage V_b in relation to the conductivity image. The scanning electron beam periodically recharges the rear side to 0 V, resulting in a recharging current flow in the output. The output signal is a current signal proportional to the light incident at the position of the scanning electron beam.

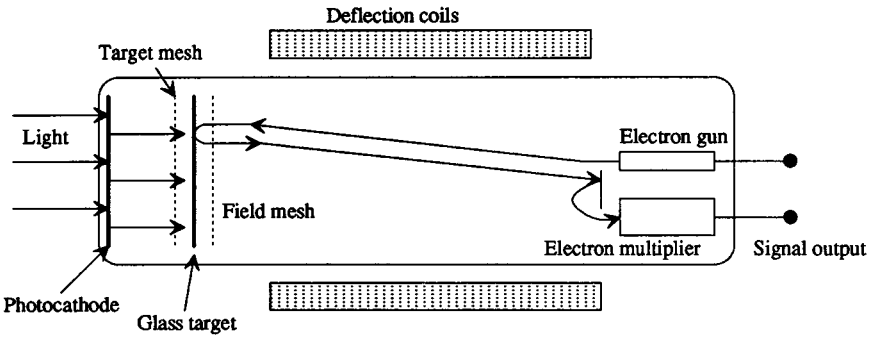

FIGURE 31.15 Schematic diagram of an image orthicon TV camera tube.

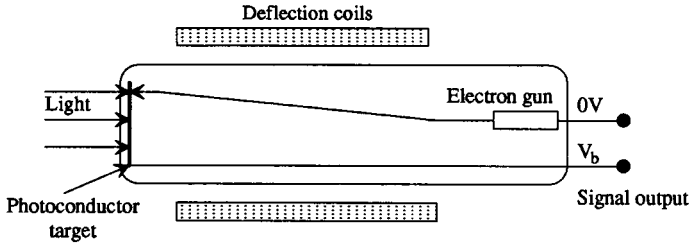

FIGURE 31.16 Schematic of a vidicon TV camera tube.

The primary disadvantages of the vidicon are its longer response time and smaller dynamic range. The recent availability of longer wavelength photoconducting films has resulted in new infrared cameras becoming available.

A recent advance in these types of image sensor is to replace the photoconductor with a dense array of very small semiconductor photodiodes. Photocurrent in the diode charges a capacitor connected to it. The raster scanned electron beam discharges this capacitor in the same way.

Image Dissector Tube

The image dissector tube is a photosensitive device which uses an electron deflection lens to image the electron from the cathode onto a pinhole in front of an electron multiplier. The image can be deflected around in front of the pinhole in a random access manner. The primary application of this kind of device is for tracking purposes.

Noise and Detectivity

Noise

There are two primary sources of noise in photodetectors: Johnson noise due to thermal effects in the resistive components of the device and its circuits, and shot noise or its equivalent, which is due to the quantized nature of electro-optic interactions.

In semiconductor devices noise is usually given in terms of noise current,

$$\delta\bar{i}^2 = 2eiM^{2+x}\Delta f + \frac{4kT\Delta f}{R} \tag{31.25}$$

where i includes signal and dark currents, e is electron charge, M is avalanche gain (x depends on avalanche photodetector characteristics), Δf is frequency bandwidth, k is Boltzmann's constant, T is in degrees Kelvin, and R is the total circuit resistance at temperature, T.

For photoconductor devices (including effects of charge amplification) the noise current is given by

$$\delta\bar{i}^2 = \frac{4ei(\tau_0/\tau_d)\Delta f}{1 + 4\pi^2\upsilon^2\tau_0^2} + \frac{4kT\Delta f}{R} \tag{31.26}$$

The first term is analogous to shot noise but includes the effects of carrier creation and recombination. τ_0 is the carrier lifetime, τ_d is the drift time for a carrier to go across the photoconductor, and υ is the light frequency.

The noise for photoemissive devices is usually written as a noise voltage and is given by

$$\delta_v^{-2} = 2ei\,G^2\Delta f R^2 + 4kT\Delta f R \tag{31.27}$$

where G is the current gain for the photomultiplier.

Detectivity

The performance of a detector is often described using the term D^*, detectivity. This term is useful for comparison purposes by normalizing with respect to detector size and/or noise bandwidth. This is written as

$$D^* = \frac{\sqrt{A\Delta f}}{\text{NEP}} \tag{31.28}$$

where NEP is the noise equivalent power (for signal-to-noise ratio equal to 1) and A is detector area. The term $D^*(\lambda)$ is used for quoting the result using a single-wavelength light source and $D^*(\mathrm{T})$ is used for the unfiltered blackbody radiation source.

Defining Terms

Charge-coupled device (CCD): A series of electronic logic cells in a device in which a signal is represented and stored as an electronic charge on a capacitor. The signal is moved from one cell (memory position or register) to an adjacent cell by electronically switching the charge between the capacitors.

Electron multiplication: The phenomenon where a high-energy electron strikes a surface and causes additional electrons to be emitted from the surface. Energy from the incident electron transfers to the other electrons to cause this. The result is electron gain which is proportional to the incident electron energy.

Extended source: A light source with finite size where the source size and shape can be determined from the emitted light characteristics. The light is spatially incoherent.

Light detection: The conversion of light energy into an electrical signal, either current or voltage.

Light emission: The creation or emission of light from a surface or device.

Point source: A light source which is so small that its size and shape cannot be determined from the characteristics of the light emanating from it. The light emitted has a spherical wave front and is spatially coherent.

Television (TV): The process of detecting an image and converting it to a serial electronic representation. A detector raster scans the image, producing a voltage proportional to the light intensity. The time axis represents the distance along the raster scan. Several hundred horizontal scans make up the image starting at the top. The raster scan is repeated to provide a continuing sequence of images.

31.3 Circuits

R.A. Becker

In 1969, Stewart Miller of AT&T Bell Laboratories published his landmark article on **integrated optics**. This article laid the foundation for what has now developed into optoelectronic circuits. In it he described the concepts of planar **optical guided-wave devices** formed as thin films on various substrates using fabrication techniques similar to those used in the semiconductor integrated circuit (IC) industry. The attributes of these new circuits included small size, weight, power consumption, and mechanical robustness because all components were integrated on a single substrate. The field of optoelectronic circuits began as a hybrid implementation where optical sources (laser diodes) and detectors have historically been fabricated on separate semiconductor substrates, and waveguide devices, such as modulators and switches, have been fabricated on electro-optic single-crystal oxides such as **lithium niobate** ($LiNbO_3$). Often, the two dissimilar substrates have been connected using single-mode polarization preserving optical fiber. Now, although the hybrid concept is finding commercial applications, most active research is performed on monolithic implementations, where all devices are fabricated on a common semiconductor substrate. After a brief summary discussion of semiconductor, glass, and polymer material systems, we will deal exclusively with the most mature hybrid implementation of optoelectronic circuits based on $LiNbO_3$.

Because sources and detectors have been covered in previous sections, in this section the devices that are utilized in between, i.e., modulators and switches, will be discussed.

Integrated Optics

Integrated optics can be defined as the monolithic integration of one or more optical guided-wave structures on a common substrate. These structures can be passive, such as a fixed optical power splitter, or active, such as an optical switch. Active devices are realized by placing metal electrodes in close proximity to the optical waveguides. Applying a voltage to the electrodes changes the velocity of the light within the waveguide. Depending on the waveguide geometry and the electrode placement, a wide variety of technologically useful devices and circuits can be realized.

The technological significance of integrated optics stems from its natural compatibility with two other rapidly expanding technologies: fiber optics and semiconductor laser diodes. These technologies have moved in the past 10 years from laboratory curiosities to large-scale commercial ventures. Integrated optic devices typically use laser diode optical sources, diode-pumped yttrium, aluminum, garnet (YAG) lasers, and transmit the modified optical output on a single-mode optical fiber. Integrated optic devices are typically very high speed, compact, and require only moderate control voltages compared to their bulk-optical counterparts.

In integrated optic devices, the optical channel waveguides are formed on a thin, planar, optically polished substrate using photolithographic techniques similar to those used in the semiconductor IC industry. Waveguide routing is accomplished by the mask used in the photolithographic process, similar to the way electrically conductive paths are defined in semiconductor ICs. The photolithographic nature of device fabrication offers the potential of readily scaling the technology to large volumes, as is done in the semiconductor IC industry. For example, the typical device is 0.75 in. × 0.078 in. in size. Dividing the substrate size by the typical device size and assuming a 50% area usage indicates that one can achieve 50 devices per 3-in. wafer.

Substrate materials for integrated optics include semiconductors, such as GaAs and InP, glass, polymer coated glass or Si, and $LiNbO_3$. Recently, primarily passive glass-based devices have been commercially introduced as replacements for passive all-fiber devices such as splitters and combiners. In addition, there are slow-speed switches (millisecond) now available that utilize the thermooptic effect in glass. Glass-based devices are fabricated by either depositing glass waveguiding layers on Si, or through the indiffusion of dopants into glass which results in a waveguiding layer. Both fabrication approaches are used in commercially available devices.

Very recently, low-speed polymer-on-Si switches have been commercially introduced. These also operate via the thermooptic effect. However, since polymers can be engineered with electrooptic properties, high-speed devices may also be available in the future. The primary impediment to market penetration of polymer-based devices has been their relatively poor stability, especially at temperatures above 100°C. However, if polymers can be produced with both strong electrooptic properties and enhanced stability with temperature, they could be the material system of choice for many applications because of their low-cost potential.

The area of semiconductor-based integrated optics has attracted much attention worldwide because if offers the potential of integrating electronic circuitry, optical sources and detectors, and optical waveguides on a single substrate. While being quite promising, the technology is still 5 years away from commercialization. Technical problems in semiconductor-based integrated optics include low electrooptic coefficients, higher optical waveguide attenuation, and an incompatibility of the processing steps needed to fabricate the various types of devices on a single substrate. However, considerable attention is being paid to these problems, and improvements are continually occurring.

The primary substrate material in integrated optics is the widely available synthetic crystal, lithium niobate ($LiNbO_3$), which has been commercially produced in volume for more than 20 years. This material is transparent to optical wavelengths between 400 and 4500 nm, has a hardness similar to glass, and is nontoxic.

$LiNbO_3$-based devices have been commercially available since 1985 and have been incorporated in a large number of experimental systems. The basic $LiNbO_3$ waveguide fabrication technique was developed in 1974 and has been continually refined and improved during subsequent years. The material itself finds wide application in a number of electrical and optical devices because of its excellent optical, electrical, acoustic, and electro- and acousto-optic properties. For example, almost all color television sets manufactured today incorporate a surface-acoustic-wave (SAW) electrical filter based on $LiNbO_3$.

In $LiNbO_3$-based integrated optics, optical waveguides are formed in one of two ways. The first uses photolithographically patterned lines of titanium (Ti), several hundred angstroms thick, on the substrate surface. The titanium is then diffused into the substrate surface at a temperature of about 1000°C for several hours. This process locally raises the refractive index in the regions where titanium has been diffused, forming high-refractive index stripes that will confine and guide light. Because the diffusion is done at exceedingly high temperatures, the waveguide stability is excellent. The waveguide mechanism used is similar to that used in fiber optics, where the higher-index, doped cores guide the light. The exact titanium stripe width, the titanium thickness, and diffusion process are critical parameters in implementing a low-loss single-mode waveguide. Different fabrication recipes are required to optimize the waveguides for operation at the three standard diode laser wavelengths: 800 nm, 1300 nm, and 1500 nm. The second approach uses a technique known as proton exchange. In this approach, a mask is used to define regions of the substrate where hydrogen will be exchanged for lithium, resulting in an increase in the refractive index. This reaction takes place at lower temperatures (200–250°C) but has been found to produce stable waveguides if an anneal at 350–400°C is performed. Waveguides formed using the proton exchange method support only one polarized mode of propagation, whereas those formed using Ti indiffusion support two. Proton exchange waveguides are also capable of handling much higher optical power densities, especially at the shorter wavelengths, than are those formed by Ti indiffusion. More fabrication detail will be provided later.

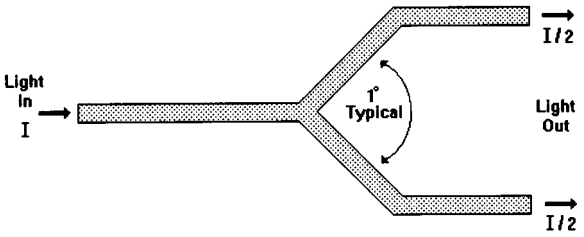

FIGURE 31.17 Passive Y-splitter.

Light modulation is realized via the electro-optic effect, i.e., inducing a small change in the waveguide refractive index by applying an electric field within the waveguide. On an atomic scale the applied electric field causes slight changes in the basic crystal unit cell dimensions, which changes the crystal's refractive index. The magnitude of this change depends on the orientation of the applied electric field and the optical polarization. As a result, only certain crystallographic orientations are useful for device fabrication and devices are typically polarization dependent. The electro-optic coefficients of $LiNbO_3$ are among the highest (30.8 pm/V) of any inorganic material, making the material very attractive for integrated optic applications.

Combining the concepts of optical waveguides and electro-optic modulation with the geometric freedom of photolithographic techniques leads to an extremely diverse array of passive and active devices.

Passive components do not require any electric fields and are used for power splitting and combining functions. Two types of passive power division structures have been fabricated: Y-junctions and directional couplers. A single waveguide can be split into two by fabricating a shallow-angle Y-junction as shown in Fig. 31.17.

An optical signal entering from the single-waveguide side of the junction is split into two optical signals with the same relative phase but one-half the original intensity. Conversely, light incident on the two-waveguide side of the junction will be combined into the single waveguide with a phase and intensity dependent on the original inputs. Directional couplers consist of two or more waveguides fabricated in close proximity to each other so that the optical fields overlap as shown in Fig. 31.18. As a result, optical power is transferred between the waveguides. The extent of the power transfer is dependent on the waveguide characteristics, the waveguide spacing, and the interaction length.

A different type of passive component is an optical polarizer, which can be made using several different techniques. One such method is the metal-clad, dielectric-buffered waveguide shown in Fig. 31.19. In this passive device, the TM polarization state is coupled into the absorbing metal and is thus attenuated, while the TE polarization is virtually unaffected. Measurements of a 2-mm-long polarizer of this type have demonstrated TM attenuations exceeding 50 dB (100,000:1). Polarizers can also be fabricated in others ways. One interesting technique involves the diffusion of hydrogen ions into the $LiNbO_3$. This results in a waveguide which, as discussed earlier, will only support the TE-polarized mode and, thus, is a natural polarizer.

Active components are realized by placing electrodes in close proximity to the waveguide structures. Depending on the substrate crystallographic orientation, the waveguide geometry, and the electrode geometry, a wide variety of components can be demonstrated. The simplest active device is the **phase modulator**, which is a single waveguide with electrodes on either side as shown in Fig. 31.20. Applying a voltage across the electrodes induces an electric field across the waveguide, which changes its refractive index via the electro-optic effect. For 800-nm wavelength operation, a typical phase modulator would be 6 mm long and would induce a π-phase shift for an applied voltage of 4 V. The transfer function (light out versus voltage in) can be expressed as

$$I_0(V) = I_i \exp(j\omega t + \pi V/V_\pi) \tag{31.29}$$

where V_π is the voltage required to cause a 180-degree phase shift. Note that there is no change in the intensity of the light. Coherent techniques are used to measure the amount of phase change.

Optical **intensity modulators** can be fabricated by combining two passive Y-junctions with a phase modulator situated between them. The result, which is shown in Fig. 31.21, is a guided-wave implementation of the classic Mach–Zehnder interferometer. In this device the incoming light is split into two equal components by the first

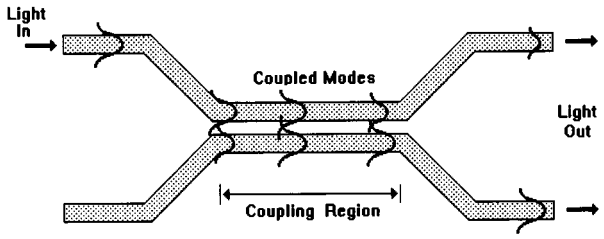

FIGURE 31.18 Directional coupler power splitter.

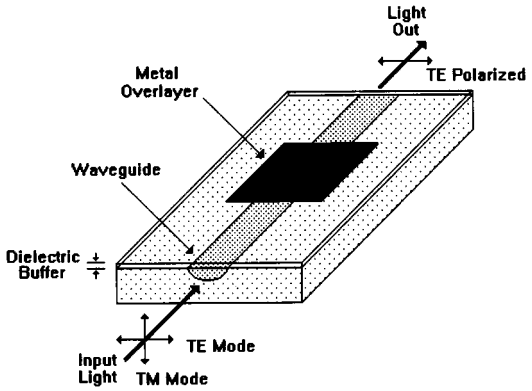

FIGURE 31.19 Thin-film optical polarizer.

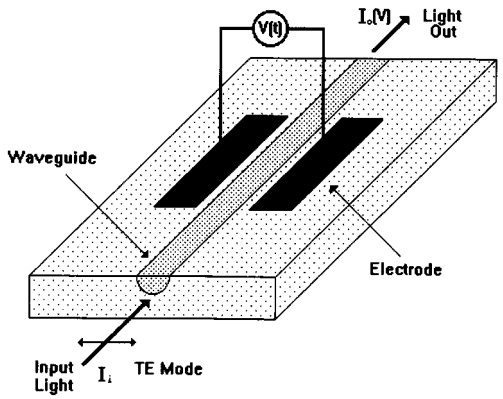

FIGURE 31.20 Electro-optic integrated optic phase modulator.

Y-junction. An electrically controlled differential phase shift is then introduced by the phase modulator, and the two optical signals are recombined in the second Y-junction. If the two signals are exactly in phase, then they recombine to excite the lowest-order mode of the output waveguide and the intensity modulator is turned fully on. If instead there exists a π-phase shift between the two signals, then they recombine to form the second mode, which is radiated into the substrate and the modulator is turned fully off. Contrast ratios greater than 25 dB (300:1) are routinely achieved in commercial devices. The transfer function for the Mach–Zehnder modulator can be expressed as

$$I_0(V) = I_i \cos^2(\pi V/2V_\pi + \phi) \tag{31.30}$$

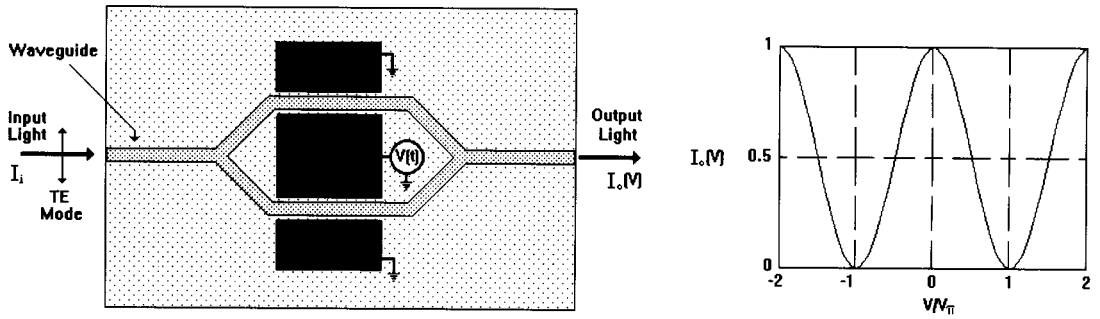

FIGURE 31.21 Mach–Zehnder intensity modulator and transfer function.

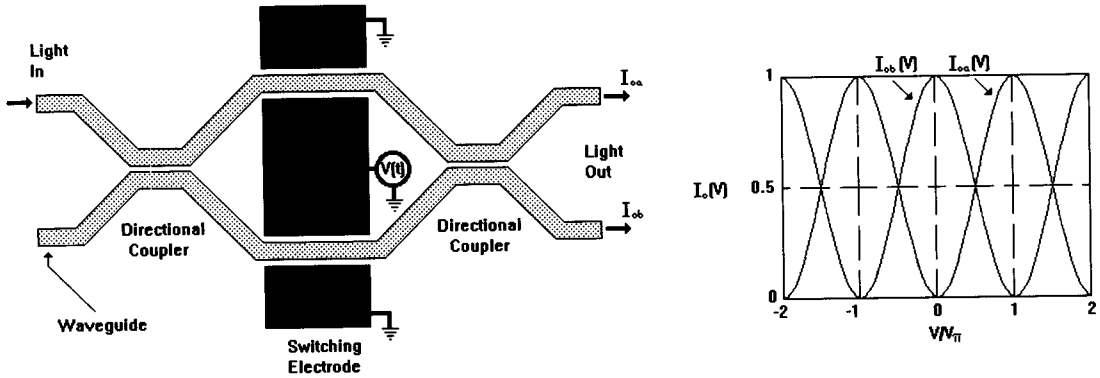

FIGURE 31.22 Balanced-bridge modulator/switch and transfer function.

where V_π is the voltage required to turn the modulator from on to off, and ϕ is any static phase imbalance between the interferometer arms. This transfer function is shown graphically in Fig. 31.21. Note that the modulator shown in Fig. 31.21 has push-pull electrodes. This means that when a voltage is applied, the refractive index is changed in opposite directions in the two arms, yielding a twice-as-efficient modulation.

Optical switches can be realized using a number of different waveguide, electrode, and substrate orientations. Two different designs are used in commercially available optical switches: the balanced-bridge and the $\Delta\beta$ directional coupler. The balanced-bridge design is similar to that of the Mach–Zehnder interferometer, except that the Y-junctions have been replaced by 3-dB directional couplers as shown in Fig. 31.22.

Similar to the Mach–Zehnder, the first 3-dB coupler splits the incident signal into two signals, ideally of equal intensity. Once again, if a differential phase shift is electro-optically induced between these signals, then when they recombine in the second 3-dB coupler, the ratio of power in the two outputs will be altered. Contrast ratios greater than 20 dB (100:1) are routinely achieved in commercial devices. The transfer function for this switch can be expressed as

$$I_{0a} = I_i \cos^2(\pi V/2V_\pi + \pi/2) \tag{31.31}$$

$$I_{0b} = I_i \sin^2(\pi V/2V_\pi + \pi/2) \tag{31.32}$$

and is graphically depicted in Fig. 31.22. In the other type of switch, the $\Delta\beta$ directional coupler, the electrodes are placed directly over the directional coupler as shown in Fig. 31.23. The applied electric field alters the power transfer between the two adjacent waveguides. Research versions of this switch have demonstrated contrast ratios greater than 40 dB (10,000:1); however, commercial versions typically achieve 20 dB, which is competitive

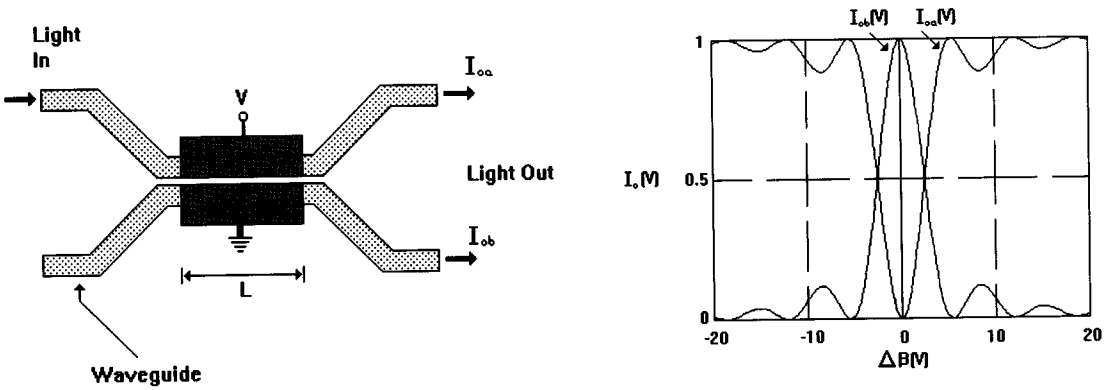

FIGURE 31.23 Directional coupler switch and transfer function.

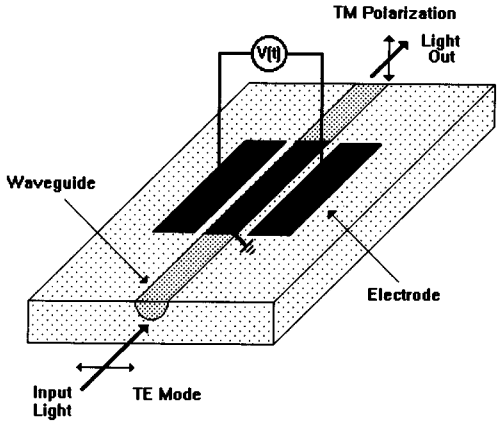

FIGURE 31.24 Guided-wave polarization controller.

with that achieved with the balanced-bridge switch. The transfer function for the Δβ directional coupler switch can be expressed as

$$I_{0a} = \sin^2 \kappa L^* \text{sqrt}(1 + (\Delta\beta/2\kappa)^2)/(1 + (\Delta\beta/2\kappa)^2) \tag{31.33}$$

$$I_{0b} = 1 - I_{0a} \tag{31.34}$$

where κ is the coupling constant and Δβ is the voltage-induced change in the propagation constant. This transfer function is depicted in Fig. 31.23.

Another type of active component that has recently become available commercially is the **polarization controller.** This component allows the incoming optical polarization to be continuously adjustable. The device functions as an electrically variable optical waveplate, where both the birefringence and axes orientation can be controlled. The controller is realized by using a three-electrode configuration as shown in Fig. 31.24 on a substrate orientation where the TE and TM optical polarizations have almost equal velocities. Typical performance values are TE/TM conversion of greater than 99% with less than 50 V.

One of the great strengths of integrated optic technology is the possibility of integrating different types or multiple copies of the same type of device on a single substrate. While this concept is routinely used in the semiconductor IC industry, its application in the optical domain is novel. The scale of integration in integrated optics is quite modest by semiconductor standards. To date the most complex component demonstrated is an

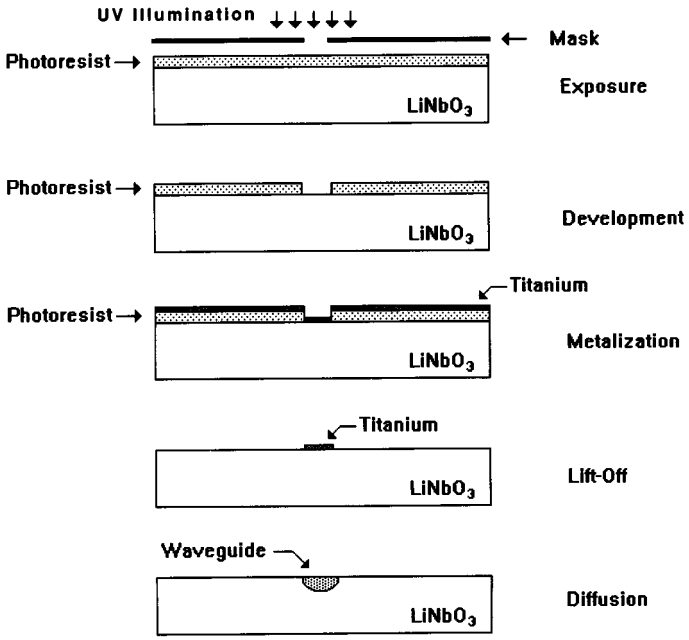

FIGURE 31.25 Ti-indiffused $LiNbO_3$ waveguide fabrication.

8×8 optical switch matrix that uses 64 identical 2×2 optical switches. The most device diversity on a given substrate is found in fiber gyro applications. Here, components incorporating six phase modulators, two electrically tunable directional couplers, and two passive directional couplers have been demonstrated.

Device Fabrication

The fabrication of an integrated optic device uses the same techniques as used in the semiconductor IC industry. Device designs are first entered into a computer-aided design (CAD) system for accurate feature placement and dimensional control. This design is then output as a digitized tape that will control a pattern generation system for fabrication of the chrome masks that are used in device fabrication. A variety of equipment such as step-and-repeat and E-beam systems has been developed for the semiconductor IC industry for the generation of chrome masks. These same systems are used today for generation of masks for integrated optic devices.

The waveguides can be fabricated by using either the Ti indiffusion method or the proton exchange method. The first step in fabricating a waveguide device using Ti indiffusion is the patterning in titanium. The bare $LiNbO_3$ surface is first cleaned and then coated with photoresist. Next, the coated substrate is exposed using the waveguide-layer chrome mask. The photoresist is then developed. The areas that have been exposed are removed in the development cycle. The patterned substrates are then coated with titanium in a vacuum evaporator. The titanium covers the exposed regions of the substrate as well as the surface of the remaining photoresist. The substrate is next soaked in a photoresist solvent. This causes all the residual photoresist (with titanium on top) to be removed, leaving only the titanium that coated the bare regions of the substrate. This process is known as *lift-off*. Finally, the substrate, which is now patterned with titanium, is placed in a diffusion system. At temperatures above 1000°C the titanium diffuses into the substrate, slightly raising the refractive index of these regions. This process typically takes less than 10 hours. This sequence of steps is depicted in Fig. 31.25. The proton exchange method is depicted in Fig. 31.26. Here a chrome masking layer is first deposited on the $LiNbO_3$ substrate. It is patterned using photoresist and etching. Next, the substrate is submerged in hot benzoic acid. Finally, the chrome mask is removed and the substrate is annealed. The regions that have been exposed to the benzoic acid will have an increased refractive index and will guide light.

If the devices being fabricated are to be active (i.e., voltage controlled), then an electrode fabrication step is also required. This sequence of steps parallels the waveguide fabrication sequence. The only differences are that

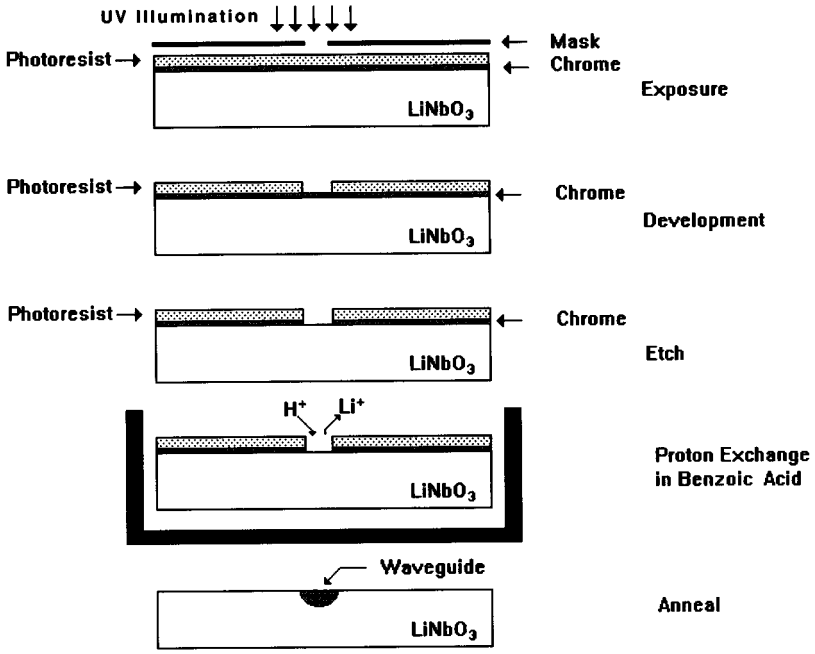

FIGURE 31.26 Proton exchange $LiNbO_3$ waveguide fabrication.

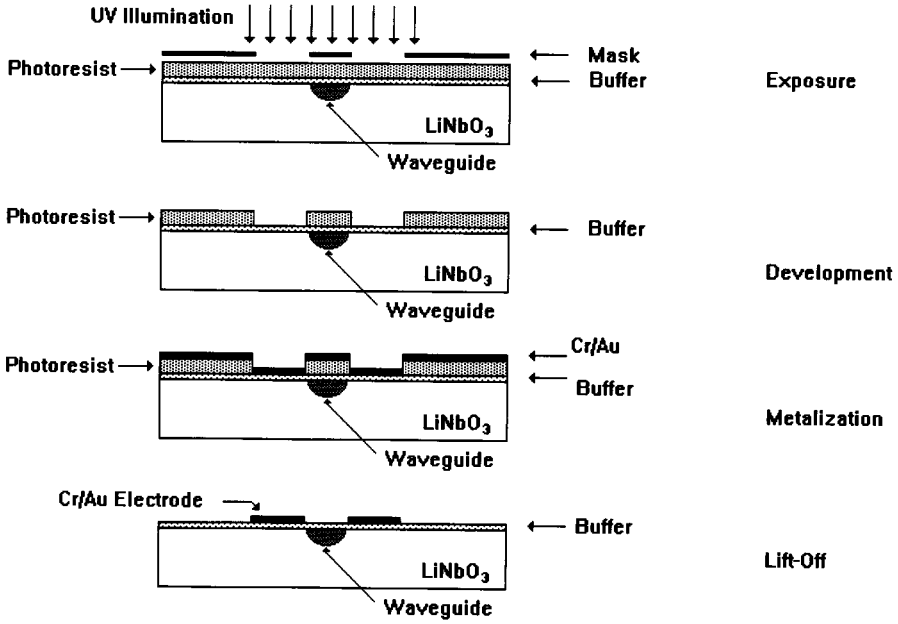

FIGURE 31.27 Electrode fabrication via lift-off.

an electrode mask is used and the vacuum-deposited metal used is chrome/gold or chrome/aluminum. This sequence of steps is shown in Fig. 31.27.

In order to get the light in and out of the waveguide, the endfaces have to be lapped and polished flat with chip-free knife edges. This is currently accomplished using standard lapping and polishing techniques. After

this step, the substrate can be diced into as many devices as were included on the substrate. Finally, the diced parts need to be electrically and optically packaged.

Packaging

To get the light in and out of an integrated optic waveguide requires a tiny optical window to be polished onto the waveguide's end. Currently, the entire endface of the substrate is polished to a sharp, nearly perfect corner, making the whole endface into an optical window. An optical fiber can then be aligned to the waveguide end and attached. Typically, centration of the fiber axis to the waveguide axis must be better than 0.2 μm. Some devices require multiple inputs and outputs. In this case the fibers are prealigned in silicon V-grooves. These V-grooves are fabricated by anisotropic etching of a photolithographically defined pattern on the silicon. The center-to-center spacing of the fiber V-groove array can be made to closely match that of the multiple waveguide inputs and outputs.

Integrated optic devices built on $LiNbO_3$ are inherently single-mode devices. This means that the light is confined in a cross-sectional area of approximately 30 μm^2. The optical mode has a near-field pattern that is 5 to 10 μm across and 3 to 6 μm deep, depending on the wavelength. These mode spot sizes set limits on how light can be coupled in and out. There are a number of methods that can be used to couple the light into $LiNbO_3$ waveguides. These include prism coupling, grating coupling, end-fire coupling with lenses, and end-fire coupling with single-mode optical fibers. In general, most of these techniques are only useful for laboratory purposes. The most practical real-world technique is end-fire coupling with an optical fiber. In this case the optical fiber is aligned to the waveguide end. This is an excellent practical method since integrated optic devices are most often used in fiber optic systems. Therefore, the coupling problem is one of aligning and fixing a single-mode fiber to the single-mode $LiNbO_3$ waveguide. The size of the single-mode radiation pattern and its angular divergence set the alignment tolerances. A low-loss connection between a fiber and a $LiNbO_3$ waveguide requires <1/20 of a mode spot diameter (0.25–0.5 μm) in transverse offset, angular tilt of <2 degrees, and a longitudinal offset of <1 mode spot diameter (5–10 μm). These are very stringent alignment requirements, especially if they have to be maintained over a wide temperature range.

Another aspect of the problem is that many integrated optic devices require a single, well-defined linearly polarized input. Ordinary single-mode fiber is not suitable in this case. The solution is to use polarization preserving fiber. This fiber is made such that it will maintain a single linearly polarized input over long distances. The use of polarization preserving fiber, however, adds another requirement to the coupling problem. This requirement is that the fiber must be rotationally aligned about its cylindrical axis so that the linearly polarized light coincides with the desired rotational axis of the $LiNbO_3$ waveguide. The rotational precision needed is <0.5 degrees.

Many $LiNbO_3$ devices, such as fiber gyro components, require multiple input and/or output optical connections. Thus, the packaging must be able to accommodate multiple inputs/outputs and maintain strict alignment for all connections.

The method of end-fire coupling optical fibers to the $LiNbO_3$ waveguide is commonly called *pigtailing*. This is the only practical packaging method now used for integrated optic devices that operate in a real system and outside the laboratory. The reasons for this are quite logical. The end user installs the device in his system by connecting to the fiber pigtails. The connection can be made with single-mode connectors or by splicing. Flexibility is one of the big advantages of using fiber pigtails.

The typical $LiNbO_3$ device is packaged in a metallic case with optical fiber pigtails connected at both ends. Electrical connections are provided by RF connectors or pins, which are common in the electronics industry. If hermetically sealed packages are desired, then the optical fiber pigtails must be hermetically sealed to the metallic package.

Applications

Many useful systems have been demonstrated using $LiNbO_3$-based integrated optic devices. These system applications can be grouped into four broad categories: telecommunications, instrumentation, signal processing, and sensors. In some cases only a single integrated optic device is used, while in other applications a multifunction component is required.

Optical switches have been shown to be quite useful in the telecommunications area. High-speed 2×2 switches for time-domain mux/demux as well as lower-speed 4×4 switch arrays have been successfully demonstrated. In both cases a major advantage of optical switching is that the switch data transmission rate is not limited by the switch itself as is the case for electronic switches. Thus, it is possible to route optical signals at data rates exceeding terabits/per second (1,000,000,000,000 bits/s).

Aside from the switching application in telecommunications, there also is the high-speed laser modulation application. Using an external $LiNbO_3$-based optic intensity modulator, both analog and digital data transmission systems have been demonstrated. Analog transmission systems using integrated optic devices are particularly attractive as remote antenna links because of their high speed and ability to be driven directly by the received signal without amplification. Recently, the use of high-power diode-pumped YAG lasers operating at 1300 nm and external intensity modulators based on $LiNbO_3$ have found wide application in the cable TV industry. In addition, the ability of the Mach–Zehnder intensity modulator to control intensity with a controlled wavelength change (i.e., chirp) has allowed its use in long-haul telecommunications systems.

Another demonstrated application of integrated optics in the telecommunications area is in coherent communication systems. These systems require both phase modulators and polarization controllers. Current optical fiber transmission systems rely on intensity modulated data transmission schemes. Coherent communication systems are attractive because of the promise of higher bit rates, wavelength division multiplexing capability, and greater noise immunity. In coherent communication systems the information is coded by varying either the phase or frequency of the optical carrier with a phase modulator. At the receiver, a polarization controller is used to ensure a good signal-to-noise ratio in the heterodyne detection system.

One promising application of integrated optic devices in instrumentation is a high-speed, polarization-independent optical switch for use in optical-time-domain reflectometers (OTDR). OTDRs are used to locate breaks or poor splices in fiber optic networks. The instruments work by sending out an optical pulse and measuring the backscattered radiation returning to the instrument as a function of time. The next generation of OTDRs will possibly employ an optical switch, which will be used to rapidly switch the optical fiber under test from the pulsed light source to the OTDR receiver. Such an instrument could detect faults closer to the OTDR than currently possible, which is important in the short-haul systems now being installed. This feature is necessary for local area network (LAN) installations.

Several types of sensors using integrated optic devices have been demonstrated. Two of the most promising are electric/magnetic field or voltage sensors and rotation sensors (fiber optic gyro). Electric field sensors typically consist of either a Mach–Zehnder intensity modulator or an optical switch that is biased midway between the on and off states. For small modulation depths about this midpoint the induced optical modulation is linear with respect to applied voltage. Linear dynamic ranges in excess of 80 dB have been accomplished. This is larger than that obtained using any other known technology.

Perhaps the most promising near-term application of integrated optic devices in the field of rotation sensing is as a key component in optical fiber gyroscopes. A typical fiber optic gyro component is shown in Fig. 31.28. The device consists of a polarizer, a Y-junction, and two phase modulators, all integrated on a single substrate. In fiber gyro systems, the integrated optic component replaces individual, fiber-based components that perform the same function. The integrated optic component offers a greatly improved performance, at a significant reduction in cost, compared to the fiber-based components. Most fiber optic gyro development teams have done away with the fiber components and have adopted $LiNbO_3$-based components as the technology of choice.

Defining Terms

Integrated optics: The monolithic integration of one or more optical guided-wave devices on a common substrate.

Intensity modulator: A modulator that alters only the intensity of the incident light.

Lithium niobate ($LiNbO_3$): A single-crystal oxide that displays electro-optic, acousto-optic, piezoelectric, and pyroelectric properties that is often the substrate of choice for surface acoustic wave devices and integrate optical devices.

Optical guided-wave device: An optical device that transmits or modifies light while it is confined in a thin-film optical waveguide.

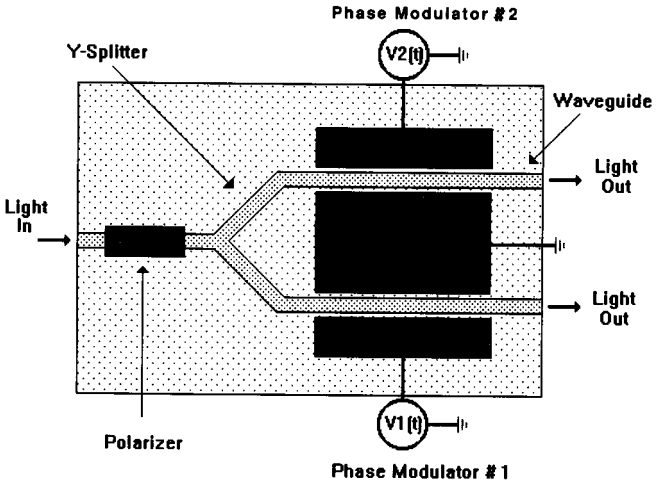

FIGURE 31.28 Fiber-optic gyro chip.

Phase modulator: A modulator that alters only the phase of the incident light.
Polarization controller: A device that alters only the polarization state of the incident light.

Digital-to-analog (D/A) conversion is the process of converting digital codes into a continuous range of analog signals. *Analog-to-digital (A/D) conversion* is the complementary process of converting a continuous range of analog signals into digital codes. Such conversion processes are necessary to interface real-world systems, which typically monitor continuously varying analog signals, with digital systems that process, store, interpret, and manipulate the analog values.

D/A and A/D applications have evolved from predominately military-driven applications to consumer-oriented applications. Up to the mid-1980s, the military applications determined the design of many D/A and A/D devices. The military applications required very high performance coupled with hermetic packaging, radiation hardening, shock and vibration testing, and military specification and record keeping. Cost was of little concern, and "low power" applications required approximately 2.8 W. The major applications up the mid-1980s included military radar warning and guidance systems, digital oscilloscopes, medical imaging, infrared systems, and professional video.

The applications requiring D/A and A/D circuits in the 1990s have different performance criteria from those of earlier years. In particular, low power and high speed applications are driving the development of D/A and A/D circuits, as the devices are used extensively in battery-operated consumer products. The predominant applications include cellular telephones, hand-held camcorders, portable computers, and set-top cable TV boxes. These applications generally have low power and long battery life requirements, and they may have high speed and high resolution requirements, as is the case with the set-top cable TV boxes.

32.1 D/A and A/D Circuits

D/A and A/D conversion circuits are available as integrated circuits (ICs) from many manufacturers. A huge array of ICs exists, consisting of not only the D/A or A/D conversion circuits, but also closely related circuits such as sample-and-hold amplifiers, analog multiplexers, voltage-to-frequency and frequency-to-voltage converters, voltage references, calibrators, operation amplifiers, isolation amplifiers, instrumentation amplifiers, active filters, dc-to-dc converters, analog interfaces to digital signal processing systems, and data acquisition subsystems. Data books from the IC manufacturers contain an enormous amount of information about these devices and their applications to assist the design engineer.

The ICs discussed in this chapter will be strictly the D/A and A/D conversion circuits. Table 32.1 lists a small sample of the variety of the D/A and A/D converters currently available. The ICs usually perform either D/A or A/D conversion. There are serial interface ICs, however, typically for high-performance audio and digital signal processing applications, that perform both A/D and D/A processes.

TABLE 32.1 D/A and A/D Integrated Circuits

D/A Converter ICs	Resolution, b	Multiplying vs. Fixed Reference	Settling Time, μs	Input Data Format
Analog Devices AD558	8	Fixed reference	3	Parallel

D/A and A/D Converter Performance Criteria

The major factors that determine the quality of performance of D/A and A/D converters are *resolution, sampling rate, speed,* and *linearity.*

The *resolution* of a D/A circuit is the smallest change in the output analog signal. In an A/D system, the resolution is the smallest change in voltage that can be detected by the system and that can produce a change in the digital code. The resolution determines the total number of digital codes, or *quantization levels*, that will be recognized or produced by the circuit.

The *resolution* of a D/A or A/D IC is usually specified in terms of the bits in the digital code or in terms of the least significant bit (LSB) of the system. An *n*-bit code allows for 2^n quantization levels, or $2^n - 1$ steps between quantization levels. As the number of bits increases, the step size between quantization levels decreases, therefore increasing the accuracy of the system when a conversion is made between an analog and digital signal. The system resolution can be specified also as the voltage step size between quantization levels. For A/D circuits, the resolution is the smallest input voltage that is detected by the system.

The *speed* of a D/A or A/D converter is determined by the time it takes to perform the conversion process. For D/A converters, the speed is specified as the *settling time.* For A/D converters, the speed is specified as the *conversion time.* The settling time for D/A converters will vary with supply voltage and transition in the digital code; thus, it is specified in the data sheet with the appropriate conditions stated.

A/D converters have a maximum *sampling rate* that limits the speed at which they can perform continuous conversions. The sampling rate is the number of times per second that the analog signal can be sampled and converted into a digital code. For proper A/D conversion, the minimum sampling rate must be at least two times the highest frequency of the analog signal being sampled to satisfy the Nyquist sampling criterion. The conversion speed and other timing factors must be taken into consideration to determine the maximum sampling rate of an A/D converter. **Nyquist A/D converters** use a sampling rate that is slightly more than twice

the highest frequency in the analog signal. **Oversampling A/D converters** use sampling rates of *N* times this rate, where *N* typically ranges from 2 to 64.

Both D/A and A/D converters require a voltage reference in order to achieve absolute conversion accuracy. Some conversion ICs have internal voltage references, while others accept external voltage references. For high-performance systems, an external precision reference is needed to ensure long-term stability, load regulation, and control over temperature fluctuations. External precision voltage reference ICs can be found in manufacturers' data books.

Measurement accuracy is specified by the converter's *linearity. Integral linearity* is a measure of linearity over the entire conversion range. It is often defined as the deviation from a straight line drawn between the endpoints and through zero (or the offset value) of the conversion range. Integral linearity is also referred to as *relative accuracy.* The *offset* value is the reference level required to establish the zero or midpoint of the conversion range. *Differential linearity* is the linearity between code transitions. Differential linearity is a measure of the *monotonicity* of the converter. A converter is said to be monotonic if increasing input values result in increasing output values.

The accuracy and linearity values of a converter are specified in the data sheet in units of the LSB of the code. The linearity can vary with temperature, so the values are often specified at +25°C as well as over the entire temperature range of the device.

D/A Conversion Processes

Digital codes are typically converted to analog voltages by assigning a voltage weight to each bit in the digital code and then summing the voltage weights of the entire code. A general D/A converter consists of a network of precision resistors, input switches, and level shifters to activate the switches to convert a digital code to an analog current or voltage. D/A ICs that produce an analog current output usually have a faster settling time and better linearity than those that produce a voltage output. When the output current is available, the designer can convert this to a voltage through the selection of an appropriate output amplifier to achieve the necessary response speed for the given application.

D/A converters commonly have a fixed or variable reference level. The reference level determines the switching threshold of the precision switches that form a controlled impedance network, which in turn controls the value of the output signal. **Fixed reference D/A converters** produce an output signal that is proportional to the digital input. **Multiplying D/A converters** produce an output signal that is proportional to the product of a varying reference level times a digital code.

D/A converters can produce bipolar, positive, or negative polarity signals. A four-quadrant multiplying D/A converter allows both the reference signal and the value of the binary code to have a positive or negative polarity. The four-quadrant multiplying D/A converter produces bipolar output signals.

D/A Converter ICs

Most D/A converters are designed for general-purpose control applications. Some D/A converters, however, are designed for special applications, such as video or graphic outputs, high-definition video displays, ultra high-speed signal processing, digital video tape recording, digital attenuators, or high-speed function generators.

D/A converter ICs often include special features that enable them to be interfaced easily to microprocessors or other systems. Microprocessor control inputs, input latches, buffers, input registers, and compatibility to standard logic families are features that are readily available in D/A ICs. In addition, the ICs usually have laser-trimmed precision resistors to eliminate the need for user trimming to achieve full-scale performance.

A/D Conversion Processes

Analog signals can be converted to digital codes by many methods, including integration, **succesive approximation,** parallel (flash) conversion, **delta modulation, pulse code modulation,** and **sigma-delta conversion.** Two of the most common A/D conversion processes are successive approximation A/D conversion and parallel or flash A/D conversion. Very high-resolution digital audio or video systems require specialized A/D techniques that often incorporate one of these general techniques as well as specialized A/D conversion processes. Examples

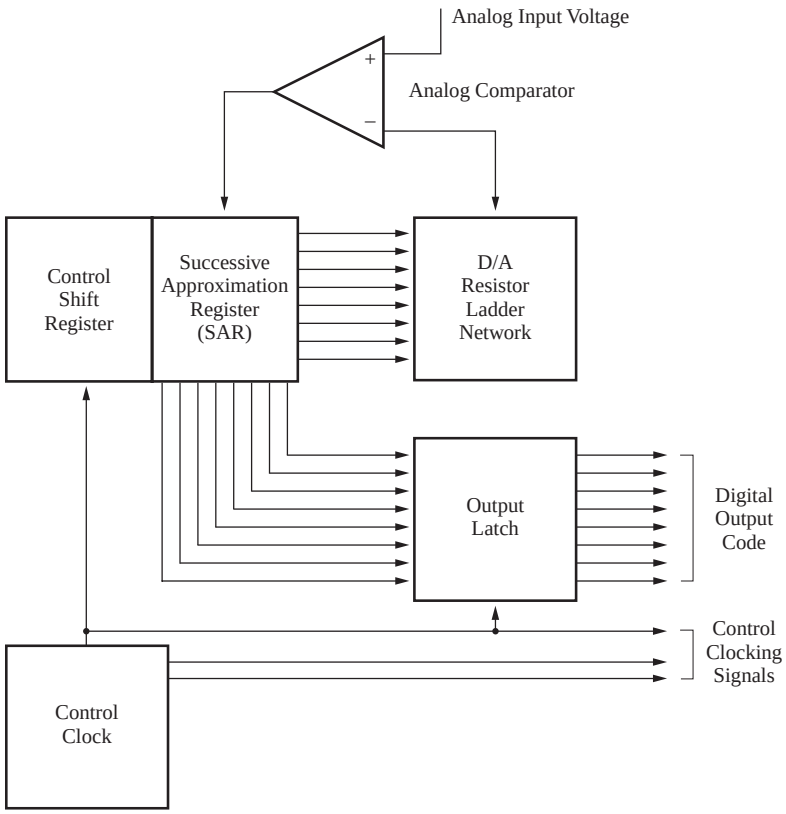

FIGURE 32.1 Successive approximation A/D converter block diagram.

of specialized A/D conversion techniques are pulse code modulation (PCM), and sigma-delta conversion. PCM is a common voice encoding scheme used not only by the audio industry in digital audio recordings but also by the telecommunications industry for voice encoding and multiplexing. Sigma-delta conversion is an oversampling A/D conversion where signals are sampled at very high frequencies. It has very high resolution and low distortion and is being used in the digital audio recording industry.

Successive approximation A/D conversion is a technique that is commonly used in medium- to high-speed data acquisition applications. It is one of the fastest A/D conversion techniques that requires a minimum amount of circuitry. The conversion times for successive approximation A/D conversion typically range from 10 to 300 μs for 8-bit systems.

The successive approximation A/D converter can approximate the analog signal to form an n-bit digital code in n steps. The successive approximation register (SAR) individually compares an analog input voltage to the midpoint of one of n ranges to determine the value of one bit. This process is repeated a total of n times, using n ranges, to determine the n bits in the code. The comparison is accomplished as follows: The SAR determines if the analog input is above or below the midpoint and sets the bit of the digital code accordingly. The SAR assigns the bits beginning with the most significant bit. The bit is set to a 1 if the analog input is greater than the midpoint voltage, or it is set to a 0 if it is less than the midpoint voltage. The SAR then moves to the next bit and sets it to a 1 or a 0 based on the results of comparing the analog input with the midpoint of the next allowed range. Because the SAR must perform one approximation for each bit in the digital code, an n-bit code requires n approximations.

A successive approximation A/D converter consists of four functional blocks, as shown in Fig. 32.1: the SAR, the analog comparator, a D/A converter, and a clock.

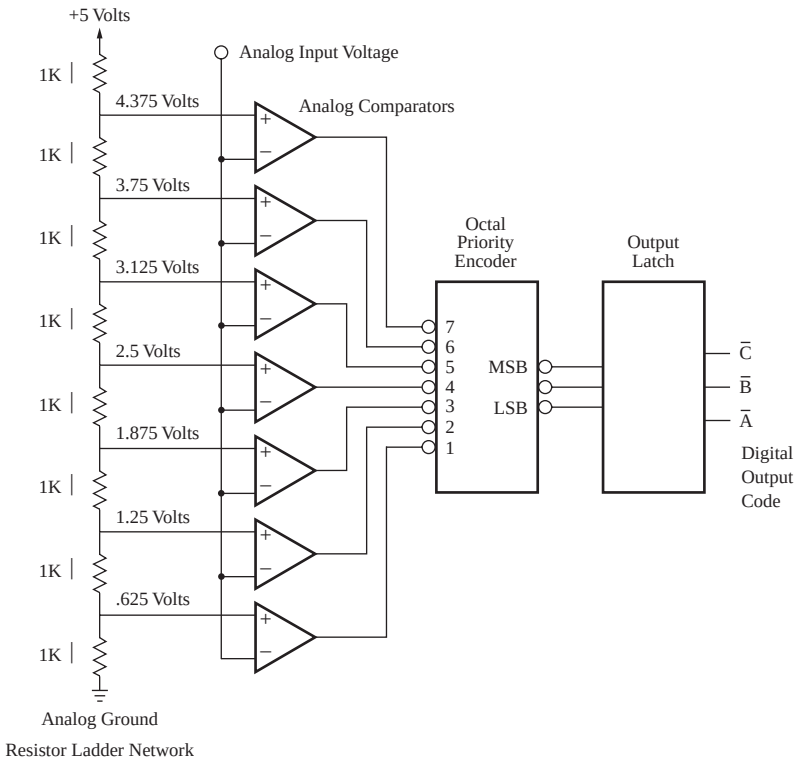

FIGURE 32.2 Flash A/D converter block diagram.

Parallel or flash A/D conversion is used in high-speed applications such as video signal processing, medical imaging, and radar detection systems. A flash A/D converter simultaneously compares the input analog voltage to $2^n - 1$ threshold voltages to produce an n-bit digital code representing the analog voltage. Typical flash A/D converters with 8-bit resolution operate at 20 to 100 MHz.

The functional blocks of a flash A/D converter are shown in Fig. 32.2. The circuitry consists of a precision resistor ladder network, $2^n - 1$ analog comparators, and a digital priority encoder. The resistor network establishes threshold voltages for each allowed quantization level. The analog comparators indicate whether or not the input analog voltage is above or below the threshold at each level. The output of the analog comparators is input to the digital priority encoder. The priority encoder produces the final digital output code that is stored in an output latch.

An 8-bit flash A/D converter requires 255 comparators. The cost of high-resolution A/D comparators escalates as the circuit complexity increases and as the number of analog converters rises by $2^n - 1$. As a low-cost alternative, some manufacturers produce modified flash A/D converters that perform the A/D conversion in two steps to reduce the amount of circuitry required. These modified flash A/D converters are also referred to as *half-flash* A/D converters, since they perform only half of the conversion simultaneously.

A/D Converter ICs

A/D converter ICs can be classified as general-purpose, high-speed, flash, and sampling A/D converters. The *general-purpose A/D converters* are typically low speed and low cost, with conversion times ranging from 2 μs to 33 ms. A/D conversion techniques used by these devices typically include successive approximation, tracking, and integrating. The general-purpose A/D converters often have control signals for simplified microprocessor interfacing. These ICs are appropriate for many process control, industrial, and instrumentation applications, as well as for environmental monitoring such as seismology, oceanography, meteorology, and pollution monitoring.

High-speed A/D converters have conversion times typically ranging from 400 ns to 3 μs. The higher speed performance of these devices is achieved by using the successive approximation technique, modified flash techniques, and statistically derived A/D conversion techniques. Applications appropriate for these A/D ICs include fast Fourier transform (FFT) analysis, radar digitization, medical instrumentation, and multiplexed data acquisition. Some ICs have been manufactured with an extremely high degree of linearity, to be appropriate for specialized applications in digital spectrum analysis, vibration analysis, geological research, sonar digitizing, and medical imaging.

Flash A/D converters have conversion times ranging typically from 10 to 50 ns. Flash A/D conversion techniques enable these ICs to be used in many specialized high-speed data acquisition applications such as TV video digitizing (encoding), radar analysis, transient analysis, high-speed digital oscilloscopes, medical ultrasound imaging, high-energy physics, and robotic vision applications.

Sampling A/D converters have a sample-and-hold amplifier circuit built into the IC. This eliminates the need for an external sample-and-hold circuit. The throughput of these A/D converter ICs ranges typically from 35 kHz to 100 MHz. The speed of the system is dependent on the A/D technique used by the sampling A/D converter.

A/D converter ICs produce digital codes in a serial or parallel format, and some ICs offer the designer both formats. The digital outputs are compatible with standard logic families to facilitate interfacing to other digital systems. In addition, some A/D converter ICs have a built-in analog multiplexer and therefore can accept more than one analog input signal.

Pulse code modulation (PCM) ICs are high-precision A/D converters. The PCM IC is often refered to as a PCM *codec* with both encoder and decoder functions. The encoder portion of the codec performs the A/D conversion, and the decoder portion of the codec performs the D/A conversion. The digital code is usually formatted as a serial data stream for ease of interfacing to digital transmission and multiplexing systems.

PCM is a technique where an analog signal is sampled, quantized, and then encoded as a digital word. The PCM IC can include successive approximation techniques or other techniques to accomplish the PCM encoding. In addition, the PCM codec may employ nonlinear data compression techniques, such as **companding**, if it is necessary to minimize the number of bits in the output digital code. Companding is a logarithmic technique used to compress a code to fewer bits before transmission. The inverse logarithmic function is then used to expand the code to its original number of bits before converting it to the analog signal. Companding is typically used in telecommunications transmission systems to minimize data transmission rates without degrading the resolution of low-amplitude signals. Two standardized companding techniques are used extensively: A-law and μ-law. The A-law companding is used in Europe, whereas the μ-law is used predominantly in the U.S. and Japan. Linear PCM conversion is used in high-fidelity audio systems to preserve the integrity of the audio signal throughout the entire analog range.

Digital signal processing (DSP) techniques provide another type of A/D conversion ICs. Specialized A/D conversion such as *adaptive differential pulse code modulation* (ADPCM), *sigma-delta modulation, speech sub-band encoding, adaptive predictive speech encoding,* and *speech recognition* can be accomplished through the use of DSP systems. Some DSP systems require analog front ends that employ traditional PCM codec ICs or DSP interface ICs. These ICs can interface to a digital signal processor for advanced A/D applications. Some manufacturers have incorporated DSP techniques on board the single-chip A/D IC, as in the case of the DSP56ACD16 sigma-delta modulation IC by Motorola.

Integrating A/D converters are used for conversions that must take place over a long period of time, such as digital voltmeter applications or sensor applications such as thermocouples. The integrating A/D converter produces a digital code that represents the average of the signal over time. Noise is reduced by means of the signal averaging, or integration. Dual-slope integration is accomplished by a counter that advances while an input voltage charges a capacitor in a specified time interval, *T.* This is compared to another count sequence that advances while a reference voltage discharges across the same capacitor in a time interval, δ *T.* The ratio of the charging count value to the discharging count value is proportional to the ration of the input voltage to the reference voltage. Hence, the integrating converter provides a digital code that is a measure of the input voltage averaged over time. The conversion accuracy is independent of the capacitor and the clock frequency since they affect both the charging and discharging operations. The charging period, T, is selected to be the

period of the fundamental frequency to be rejected. The maximum conversion rate is slightly less than 1/(2T) conversions per second. While this limits the conversion rate to be too slow for high-speed data acquisition applications, it is appropriate for long-duration applications of slowly varying input signals.

Grounding and Bypassing on D/A and A/D ICs

D/A and A/D converter ICs require correct grounding and capacitive bypassing in order to operate according to performance specifications. The digital signals can severely impair analog signals. To combat the electromagnetic interference induced by the digital signals, the analog and digital grounds should be kept separate and should have only one common point on the circuit board. If possible, this common point should be the connection to the power supply.

Bypass capacitors are required at the power connections to the IC, the reference signal inputs, and the analog inputs to minimize noise that is induced by the digital signals. Each manufacturer specifies the recommended bypass capacitor locations and values in the data sheet. The 1-μF tantalum capacitors are commonly recommended, with additional high-frequency power supply decoupling sometimes being recommended through the use of ceramic disc shunt capacitors. The manufacturers' recommendations should be followed to ensure proper performance.

Selection Criteria for D/A and A/D Converter ICs

Hundreds of D/A and A/D converter ICs are available, with prices ranging from a few dollars to several hundred dollars each. The selection of the appropriate type of converter is based on the application requirements of the system, the performance requirements, and cost. The following issues should be considered in order to select the appropriate converter.

1. What are the input and output requirements of the system? Specify all signal current and voltage ranges, logic levels, input and output impedances, digital codes, data rates, and data formats.
2. What level of accuracy is required? Determine the resolution needed throughout the analog voltage range, the dynamic response, the degree of linearity, and the number of bits encoding.
3. What speed is required? Determine the maximum analog input frequency for sampling in an A/D system, the number of bits for encoding each analog signal, and the rate of change of input digital codes in a D/A system.
4. What is the operating environment of the system? Obtain information on the temperature range and power supply to select a converter that is accurate over the operating range.

Final selection of D/A and A/D converter ICs should be made by consulting manufacturers to obtain their technical specifications of the devices. Major manufacturers of D/A and A/D converters include Analog Devices, Burr-Brown, DATEL, Maxim, National, Phillips Components, Precision Monolithics, Signetics, Sony, Texas Instruments, Ultra Analog, and Yamaha. Information on contacting these manufacturers and others can be found in an *IC Master Catalog*.

Defining Terms

Companding: A process designed to minimize the transmission bit rate of a signal by compressing it prior to transmission and expanding it upon reception. It is a rudimentary "data compression" technique that requires minimal processing.

Delta modulation: An A/D conversion process where the digital output code represents the change, or slope, of the analog input signal, rather than the absolute value of the analog input signal. A 1 indicates a rising slope of the input signal. A 0 indicates a falling slope of the input signal. The sampling rate is dependent on the derivative of the signal, since a rapidly changing signal would require a rapid sampling rate for acceptable performance.

Fixed reference D/A converter: The analog output is proportional to a fixed (nonvarying) reference signal.

Flash A/D: The fastest A/D conversion process available to date, also referred to as parallel A/D conversion. The analog signal is simultaneously evaluated by $2^n - 1$ comparators to produce an n-bit digital code in one step. Because of the large number of comparators required, the circuitry for flash A/D converters can be very expensive. This technique is commonly used in digital video systems.

Integrating A/D: The analog input signal is integrated over time to produce a digital signal that represents the area under the curve, or the integral.

Multiplying D/A: A D/A conversion process where the output signal is the product of a digital code multiplied times an analog input reference signal. This allows the analog reference signal to be scaled by a digital code.

Nyquist A/D converters: A/D converters that sample analog signals that have a maximum frequency that is less than the Nyquist frequency. The Nyquist frequency is defined as one-half of the sampling frequency. If a signal has frequencies above the Nyquist frequency, a distortion called *aliasing* occurs. To prevent aliasing, an *antialiasing filter* with a flat passband and very sharp roll-off is required.

Oversampling converters: A/D converters that sample frequencies at a rate much higher than the Nyquist frequency. Typical oversampling rates are 32 and 64 times the sampling rate that would be required with the Nyquist converters.

Pulse code modulation (PCM): An A/D conversion process requiring three steps: the analog signal is sampled, quantized, and encoded into a fixed length digital code. This technique is used in many digital voice and audio systems. The reverse process reconstructs an analog signal from the PCM code. The operation is very similar to other A/D techniques, but specific PCM circuits are optimized for the particular voice or audio application.

Sigma-delta A/D conversion: An *oversampling* A/D conversion process where the analog signal is sampled at rates much higher (typically 64 times) than the sampling rates that would be required with a Nyquist converter. Sigma-delta modulators integrate the analog signal before performing the delta modulation. The integral of the analog signal is encoded rather than the change in the analog signal, as is the case for traditional delta modulation. A digital sample rate reduction filter (also called a digital decimation filter) is used to provide an output sampling rate at twice the Nyquist frequency of the signal. The overall result of oversampling and digital sample rate reduction is greater resolution and less distortion compared to a Nyquist converter process.

Successive approximation: An A/D conversion process that systematically evaluates the analog signal in n steps to produce an n-bit digital code. The analog signal is successively compared to determine the digital code, beginning with the determination of the most significant bit of the code.

33.1 Introduction

Motivation

In the thermal control of microelectronic components, it is necessary to provide an acceptable *microclimate* for a diversity of devices and packages, which vary widely in size, power dissipation, and sensitivity to temperature. Although the **thermal management** of all electronic components is motivated by a common set of concerns, this diversity often leads to the design and development of distinct thermal control systems for different types of electronic equipment. Moreover, due to substantial variations in the performance, cost, and environmental specifications across product categories, the thermal control of similar components may require widely differing thermal management strategies.

The prevention of **catastrophic thermal failure,** defined as an immediate, thermally induced, total loss of electronic function, must be viewed as the primary and foremost aim of electronics thermal control. Catastrophic failure may result from a significant deterioration in the performance of the component/system or from a loss of structural integrity at one of the relevant packaging levels. In early microelectronic systems, catastrophic failure was primarily *functional* and thought to result from changes in the bias voltage, *thermal runaway* produced by regenerative heating, and dopant migration, all occurring at elevated transistor junction temperatures. While these failure modes may still occur during the device development process, improved silicon simulation tools and thermally compensated integrated circuits have largely quieted these concerns and substantially broadened the operating temperature range of today's silicon-based logic and memory devices. Similar concerns do still exist in the use of CMOS devices for high-performance systems. Because of the dependence of CMOS circuit speed on temperature, it may be necessary to limit the maximum chip temperature to achieve a desired cycle time and/or to maintain timing margins in the system.

More generally, however, thermal design in the 1990s is aimed at preventing thermally induced physical failures, through reduction of the temperature rise above ambient and minimization of temperature variations within the packaging structure(s). The use of many low-temperature materials and the structural complexity of chip packages and printed circuit boards has increased the risk of catastrophic failures associated with the vaporization of organic materials, the melting of solders, and thermal-stress fracture of leads, joints, and seals, as well as the fatigue-induced delamination and fracture or creep-induced deformation of encapsulants and

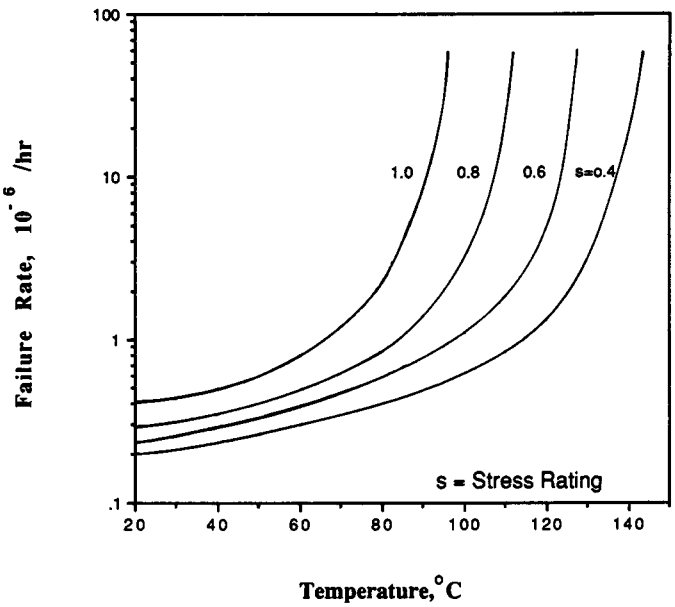

FIGURE 33.1 Exponential dependence of failure rate on component temperature.

laminates. To prevent catastrophic thermal failure, the designer must know the maximum allowable temperatures, acceptable internal temperature differences, and the power consumption/dissipation of the various components. This information can be used to select the appropriate fluid, heat transfer mode, and inlet temperature for the coolant and to thus establish the thermal control strategy early in the design process.

After the selection of an appropriate thermal control strategy, attention can be turned to meeting the desired system-level reliability and the target failure rates of each component and subassembly. Individual solid-state electronic devices are inherently reliable and can typically be expected to operate, at room temperature, for some 100,000 years, i.e., with a base failure rate of 1 FIT (failures in 10^9 h). However, since the number of devices in a typical logic component is rapidly approaching 1 million and since an electronic system may consist of many tens to several hundreds of such components, achieving a system Mean Time Between Failures of several thousand hours in military equipment and 40,000–60,000 hours in commercial electronics is a most formidable task.

Many of the failure mechanisms, which are activated by prolonged operation of electronic components, are related to the local temperature and/or temperature gradients, as well as the thermal history of the package [Pecht et al., 1992]. Device-related functional failures often exhibit a strong relationship between failure rate and operating temperature. This dependence, illustrated in Fig. 33.1, is exponential in nature and commonly represented in the form of an Arrhenius relation, with unique, empirically determined coefficients for each component type. In the normal operating range of microelectronic components, a 10–20°C increase in chip temperature is thought to double the component failure rate, and even a 1°C decrease may lower the predicted failure rate associated with such mechanisms by 2–4% [Morrison et al., 1982].

Unfortunately, it is not generally possible to characterize thermally induced structural failures, which develop as a result of differential thermal expansion among the materials constituting an electronic package, in the form of an Arrhenius relation. Although these mechanical stresses may well increase as the temperature of the component is elevated, thermal stress failures are, by their nature, dependent on the details of the local temperature fields, as well as the assembly, attachment, and local operating history of the component. Furthermore, thermal stress generation in packaging materials and structures is exacerbated by power transients, as well as by the periodically varying environmental temperatures, experienced by most electronic systems, during both qualification tests and actual operation. However, stress variations in the elastic domain or in the range below the fatigue limit may have little effect on the component failure rate. Consequently, the minimization or elimination of thermally induced failures often requires careful attention to both the temperature and stress

fields in the electronic components and necessitate the empirical validation of any proposed thermostructural design criteria.

To initiate the development of a thermal design for a specified electronic product, it is first necessary to define the relevant packaging level. The commonly accepted categorization places the chip package, which houses and protects the chip, at the bottom of the packaging hierarchy (Level 1), the printed circuit board, which provides for chip-to-chip interconnect, as Level 2, the backplane, or "motherboard," which interconnects the printed circuit boards, as Level 3, and defines the box, rack, or cabinet, which houses the entire system, as Level 4.

The primary thermal transport mechanisms and commonly used heat removal techniques vary substantially from one packaging level to the next. While Level 1 thermal packaging is primarily concerned with conducting heat from the chip to the package, at Level 2 attention must be devoted to heat spreading by conduction in the printed circuit board and convection of the heat tot he ambient air, and/or transport of the heat to the board edge. Many of today's electronic systems, as might be surmised from the frequently cited "computer-on-a-chip" or "computer-on-a-board" terminology, can be adequately packaged at Level 1 or 2. Heat sinks, or finned surfaces protruding into the air stream, are often used at Level 1 and 2 to aid in the transfer of heat into the ambient air. When Level 3 and/or 4 are present, thermal packaging generally involves the use of active thermal control measures, such as air handling systems, refrigeration systems, or water channels, heat exchangers, and pumps.

Requirements

Consideration of the Arrhenius relationship has resulted in peak allowable temperatures of 110–120°C for most military equipment [Morrison et al., 1982] and has led designers of commercial equipment to specify average chip operating temperatures in the 65–85°C range [Bar-Cohen, 1987, 1988]. Theoretical predictions of dramatic reductions in component failure rates have been used to justify the use of refrigerated avionics [Morrison, 1982] and cryogenic electronics [Jaeger, 1986; Vacca et al., 1987]. To accomodate rising power dissipation, commercial chip operating temperatures are expected to increase past 100°C in the coming decade.

The stabilization of component temperature and minimization of the temperature differences between adjacent devices, components, and various packaging levels have long been known to reduce failure rates in electronic systems [Hilbert and Kube, 1969]. In layered structures, such as chip packages and printed circuit boards, and in the joints of surface mounted components, temperature nonuniformities, in all but the most clever designs, accentuate the differences in the thermal expansion coefficients among the various materials and can frequently result in thermal stresses that threaten the integrity of these components and joints [Englemier, 1984; Suhir, 1988]. The growing integration on a single chip of functionally distinct and thermally diverse devices, as in the power-integrated chips of the late 1980s and in the microsensor, RF, and in optoelectronic chips under development today, can be expected to focus renewed attention on the minimization of transient temperature and stress fields produced by localized heat sources.

Despite the precipitous drop in transistor switching energy from more than 10^{-9} J in 1960 to nearly 10^{-13} J in devices used during the late 1980s and down to 10^{-14} J in the early 1990s, the cooling requirements of microelectronic packages have not diminished. Because of increased device densities and higher operating speeds, chip heat removal requirements have actually risen from 0.1 to 0.3 W, typical of the SSI devices used in the early 1960s, to 1 to 5 W in the LSI ECL components and VLSI CMOS devices of the mid-1980s, and to values in the range of 15 to 30 W for commercial equipment in the early 1990s. Projections of current trends suggest that by the year 2000, the thermal designer will have to contend with chip power dissipations in excess of 150 W, producing surface heat fluxes of nearly 80 W/cm^2 for the smaller chips and approximately 40 W/cm^2 for the larger (2×2 cm) chips likely to be available in that time period. It may be anticipated that, by the turn of the century, substrate heat fluxes of more than 25 W/cm^2 will be encountered in both large ($30 \times 30 \times 5$ cm) and small ($5 \times 5 \times 2$ cm) multichip modules.

The successful removal of these heat fluxes, in the presence of severe electrical, manufacturing cost, and reliability constraints, poses a formidable challenge to the packaging community. Nevertheless, it must be noted that the heat fluxes encountered in today's "cutting edge technology" chips already pose a significant challenge to the thermal packaging engineer. Chip heat fluxes in the mid-1980s typically ranged from 5 W/cm^2 to nearly

30 W/cm^2, for both single-chip packages and multichip modules [Bar-Cohen, 1987]. Recently released commercial computers often include chips dissipating 15 to 30 W/cm^2 [e.g., Kaneko et al., 1990; Pei et al., 1990], and laboratory prototypes have extended the chip heat flux range to nearly 65 W/cm^2. These heat fluxes are comparable, at the upper end, to the thermal loading experienced by reentry vehicles and even, at the lower end, to heat fluxes imposed on rocket motor cases. The anticipated peak heat flux in the year 2000 of approximately 100 W/cm^2 is in the range of thermal loadings associated with nuclear blasts.

Design Procedure

Generation of an appropriate thermal design begins with tabulation of the specified critical temperatures (source and sink) and the heat generation rate. These parameters can be used to define the target thermal resistance, as

$$R_{\text{target}} = (T_{\text{source}} - T_{\text{sink}})/q_{\text{gen}} \ [\text{K/W}]$$

The electronics thermal control literature, as well as subsequent sections of this chapter, present much of the relevant thermal packaging information in the form of thermal resistances. At its most fundamental level, the thermal packaging task involves selecting a combination of heat removal mechanisms which yield an overall thermal resistance that is not greater than the target value. The implementation of such a system will assure that the heat source, typically a microprocessor or memory chip, will operate at an acceptable temperature.

As will be discussed later in this chapter, in nearly all modes of heat transfer the geometry of the heat flow path, i.e., length and area, play an important role in determining the heat source temperature. Consequently, it is desirable to obtain the relevant geometric details (lengths, thicknesses, areas, volumes) at this early stage in the design process. Combining the geometric information with the target thermal resistance, it is often convenient to define an area-specific or volume-specific target thermal resistance in units of K/(W/cm^2) and K/(W/cm^3), respectively.

When the target thermal resistance is known, first-order (or "back-of-the-envelope") calculations are performed to evaluate the severity of the thermal management problem. Although some designs can be completed at this stage, often more precise calculations are needed to verify that the proposed approach does indeed meet the target thermal resistance value. Such calculations can be performed analytically by drawing on the wealth of knowledge in the thermal sciences, numerically using commercial general purpose software, or with commercial software specifically tailored to the thermofluid and thermostructural configurations encountered in packaging. Due to the difficulty in predicting thermal contact resistances at lightly and variably loaded mechanical interfaces and in determining the convective resistances associated with irregular package and printed circuit board geometries, some experimental data is generally needed to establish key parameters or verify system performance.

The search for an adequate thermal packaging strategy generally begins with consideration of passive transfer modes—conduction, natural convection, and radiation, which require no external motive power and no moving parts. Due to its near-universal availability, air is the most common and preferred cooling fluid. Many electronic systems can be successfully cooled by passive means and especially by natural convection in air. When such passive means are incapable of properly controlling the heat source temperature, the designer must examine the use of active thermal control techniques, including blown air, pumped water, and circulated refrigerants. Immersion of the electronic components directly in dielectric liquids, which can then be pumped or allowed to circulate naturally, provides an additional, though less common, alternative.

33.2 Heat Transfer Fundamentals

To determine the temperature differences encountered in the flow of heat within electronic systems, it is necessary to recognize several different heat transfer mechanisms and their governing relations. In a typical system, heat removal from the active regions of the chip(s) requires the use of several mechanisms, some operating in series and others in parallel, to transport the generated heat to the coolant.

Thermal transport through solids is governed by the Fourier equation, which, in one-dimensional form, is expressible as

$$q = kAdT/dx \ [\text{W}] \tag{33.1}$$

TABLE 33.1 Thermal Conductivities of Typical Packaging Materials at Room Temperature

Materials	Thermal Conductivity (W/m K)
Air	0.024
Mylar	0.19
Silicone rubber	0.19
Solder mask	0.21
Epoxy (dielectric)	0.23
Ablefilm 550 dielectric	0.24
Nylon	0.24
Polytetrafluorethylene	0.24
RTV	0.31

Copper	395
Silver	419
Diamond	2000

where q is the heat flow, k is the thermal conductivity of the medium, A is the cross-sectional area for heat flow, and dT/dx the temperature gradient.

The temperature difference resulting from the conduction of heat is thus related to the thermal conductivity of the material, the cross-sectional area, and the path length, Δx, or

$$(T_1 - T_2)_{\text{cond}} = q(\Delta x/kA) \ [\text{K}] \tag{33.2}$$

The form of this equation suggests that, by analogy to electrical current flow in a conductor, it is possible to define a conduction thermal resistance as [Kraus, 1958]

$$R_{\text{cond}} = (T_1 - T_2)/q = \Delta x/kA \ [\text{K/W}] \tag{33.3}$$

Using the thermal conductivities tabulated in Table 33.1, conduction resistance values for packaging materials with typical dimensions can be found by use of Eq. 33.3 or by inspection of Fig. 33.2. Values are seen to range from 2K/W for a 100 mm^2 by 1 mm thick layer of epoxy encapsulant to 0.0006 K/W for a 100 mm^2 by 25 micron (1 mil) thick layer of copper. Similarly, the values of the conduction resistance for typical "soft" bonding materials are found to lie in the range of 0.1 K/W for solder and 1–3K/W for epoxies and thermal pastes, for Δx/A ratios of 0.25 to 1 m^{-1}.

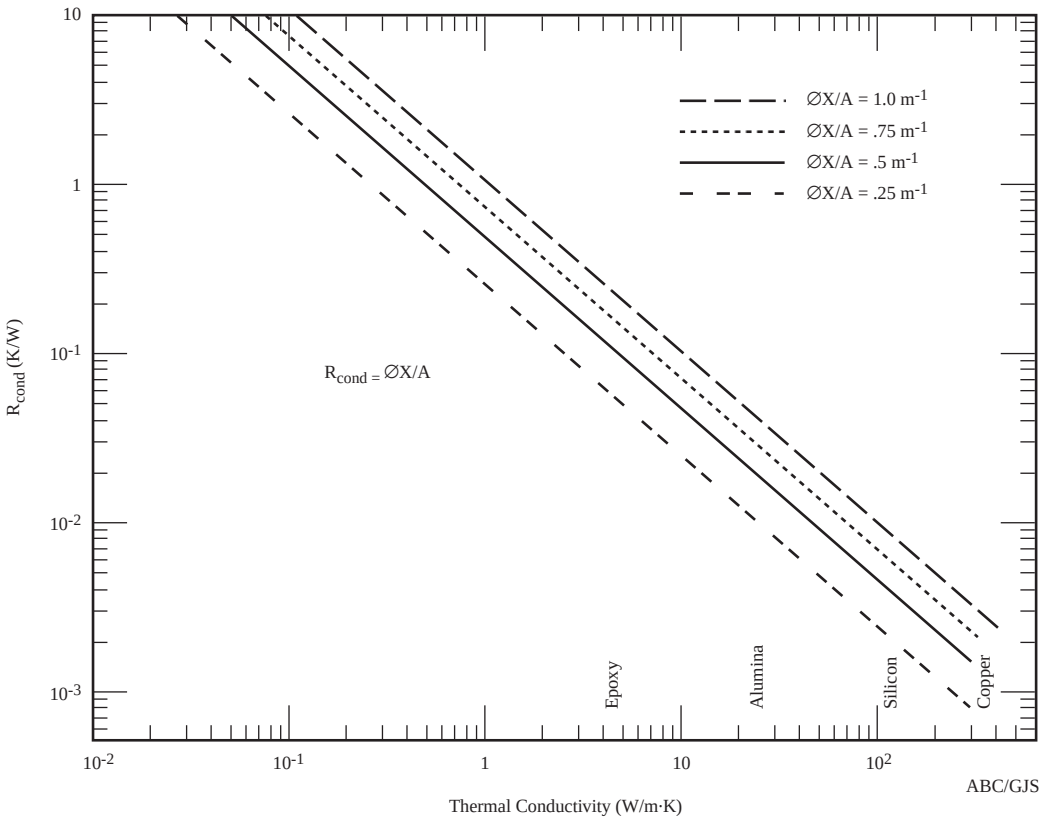

FIGURE 33.2 Conductive thermal resistances for packaging materials.

Thermal transport from a surface to a fluid in motion is called **convective heat transfer** and can be related to the **heat transfer coefficient**, h, the surface-to-fluid temperature difference, and the "wetted" area, in the form

$$q = hA(T_{surf} - T_{fluid}) \text{ [W]} \tag{33.4}$$

The differences among convection to a fast-moving fluid, a slowly flowing fluid, and a stagnant fluid, as well as variations in the convective heat transfer rate among various fluids, are reflected in the value of h. Some theoretical and many empirical correlations are available for determining this convective heat transfer coefficient (e.g., Kraus and Bar-Cohen, 1983). Using Eq. (33.4), it is possible to define the convective **thermal resistance,** as

$$R_{conv} = (hA)^{-1} \text{ [K/W]} \tag{33.5}$$

Values of this convective resistance, for a variety of coolants and heat transfer mechanisms, are shown in Fig. 33.3 for a typical heat source area of 10 cm^2 and a velocity range of 2–8 m/s. These resistances are seen to vary from 100 K/W for natural convection in air to 33 K/W for forced convection in air, to 1 K/W in fluorocarbon liquid in forced convection to less than 0.5 K/W for boiling in fluorocarbon liquids.

Unlike conduction and convection, **radiative heat transfer** between two surfaces or between a surface and its surroundings is not linearly dependent on the temperature difference and is expressed instead as

$$q = \sigma AF(T_1^4 - T_2^4) \text{ [W]} \tag{33.6}$$

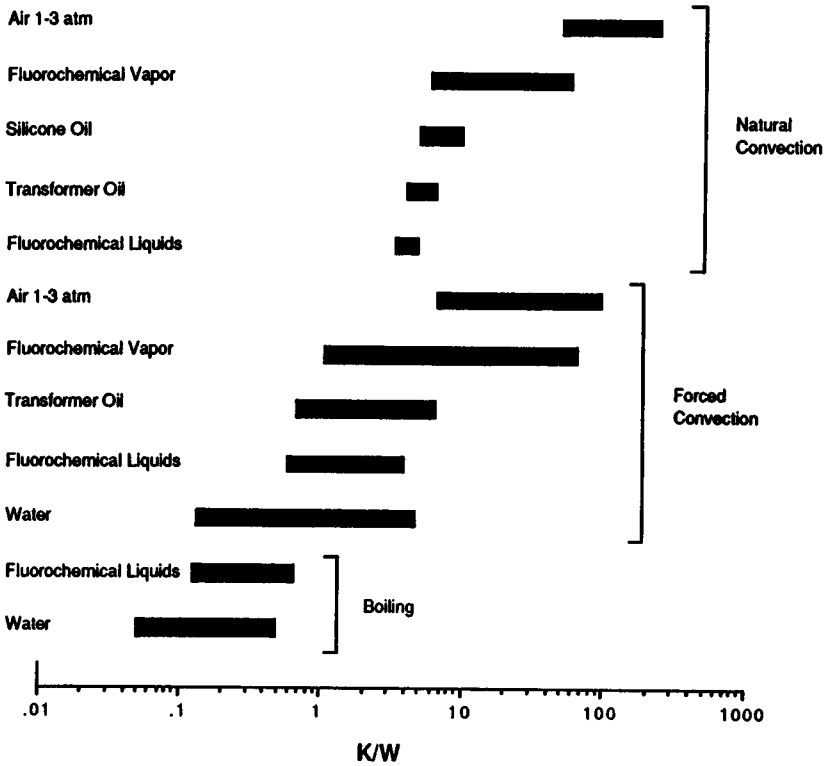

FIGURE 33.3 External thermal resistances for various fluids and cooling modes.

where F includes the effect of surface properties and geometry and σ is the Stefan-Boltzmann constant, which equals 5.67×10^{-8} W/m^{2}K^4. For an ideal, or black, radiating surface in a perfectly absorbing environment, F equals unity.

For modest temperature differences, this equation can be linearized to the form

$$q_r = h_r A(T_1 - T_2) \text{ [W]} \tag{33.7}$$

where h_r is the effective "radiation" heat transfer coefficient and is approximately equal to $4\sigma F (T_1 T_2)^{1.5}$. It is of interest to note that for temperature differences on the order of 10 K, the radiative heat transfer coefficient, h_r, for a radiationally ideal surface in an absorbing environment, is approximately equal to the heat transfer coefficient in natural convection of air. Noting the form of Eq. (33.7), the radiational thermal resistance, analogous to the convective resistance, is seen to equal $(h_r A)^{-1}$.

Ebullient thermal transport displays a complex dependence on the temperature difference between the heated surface and the saturation temperature (boiling point) of the liquid. In nucleate boiling, the primary region of interest, the **ebullient heat transfer** rate can be approximated by a relation of the form

$$q_b = C'_{sf} A(T_{\text{surf}} - T_{\text{sat}})^3 \text{ [W]} \tag{33.8}$$

where C'_{sf} is a function of the surface/fluid combination and T_{sat} is the boiling point of the liquid. For comparison purposes, it is possible to define a boiling heat transfer coefficient, h_b, equal to $C'_{sf}(T_1 - T_{\text{sat}})^2$, which, however, will vary strongly with surface temperature.

In the thermal design of electronic equipment, frequent use is made of heat sinks, involving finned or *extended* surfaces (Kraus and Bar-Cohen, 1995). While such finning can substantially increase the surface area in contact with the coolant, conduction in the **thermal fin** reduces the average temperature of the exposed surface relative

to the fin base. In the analysis of such finned surfaces, it is thus common to define a **fin efficiency**, η, equal to the ratio of the average temperature rise of the fin (above the coolant) to the temperature rise of the fin base. Using this approach, heat transfer by a fin or fin structure can be expressed in the form

$$q_f = hA\eta(T_o - T_f) \text{ [W]} \tag{33.9}$$

where T_o is the temperature of the fin base. The thermal resistance of a finned surface is given by $(\eta hA)^{-1}$ and for a properly designed surface, the fin efficiency can be expected to lie between 0.5 and 0.8.

The transfer of heat to a flowing gas or liquid, not undergoing a phase change, results in an increase in the coolant temperature, according to

$$q = \dot{m}c_p(T_{\text{out}} - T_{\text{in}}) = \rho\Theta c_p(T_{\text{out}} - T_{\text{in}}) \text{ [W]} \tag{33.10}$$

where $\dot{m}$ is the mass flow rate of the coolant, ρ is the density, and Θ is the volumetric flow rate. Based on this relation, it is possible to define an effective flow resistance, R_f, as

$$R_f = (\dot{m}c_p)^{-1} \text{ [K/W]} \tag{33.11}$$

In a first-order thermal model, it is generally appropriate to relate the heat source temperature to the average (rather than the outlet) coolant temperature. In such calculations the flow resistance should be taken to equal one-half of the value given by Eq. (33.11). These average flow resistances for the three common coolants in electronics thermal management, i.e., air, water, and FC-72 (3M Trade Name), are shown in Figure 33.4.

The expression of the governing heat transfer relations in the form of thermal resistances greatly simplifies the first-order thermal analysis of electronic systems. Following the established rules for resistance networks, thermal resistances that occur sequentially along a thermal path can be simply summed to establish the overall thermal resistance for that path. Similarly, the reciprocal of the effective overall resistance of several parallel heat transfer paths can be found by summing the reciprocals of the individual resistances. In refining the thermal design of an electronic system, prime attention should, then, be devoted to reducing the largest resistances along a specified thermal path and/or providing parallel paths for heat removal from a critical area.

While the thermal resistances associated with various paths and thermal transport mechanisms constitute the building blocks in performing a detailed thermal analysis, they have also found widespread application as figures-of-merit in evaluating and comparing the thermal efficacy of various packaging techniques and thermal management strategies. The determination of the relevant thermal resistances is, thus, the key task in the thermal design of an electronic system.

33.3 Chip Module Thermal Resistance

Definition

The thermal performance of chip packaging techniques is commonly compared on the basis of the overall (junction-to-coolant) thermal resistance, R_T. This packaging figure-of-merit is generally defined in a purely empirical fashion to equal

$$R_T = (T_j - T_f)/q_c \text{ [K/W]} \tag{33.12}$$

where T_j and T_f are the junction and coolant (fluid) temperatures, respectively, and q_c is the chip heat dissipation.

Unfortunately, however, most measurement techniques are incapable of detecting the actual junction temperature, i.e., the temperature of the small volume at the interface of *p*-type and *n*-type semiconductors, and, hence, this term generally refers to the average temperature or a representative temperature on the chip. Because

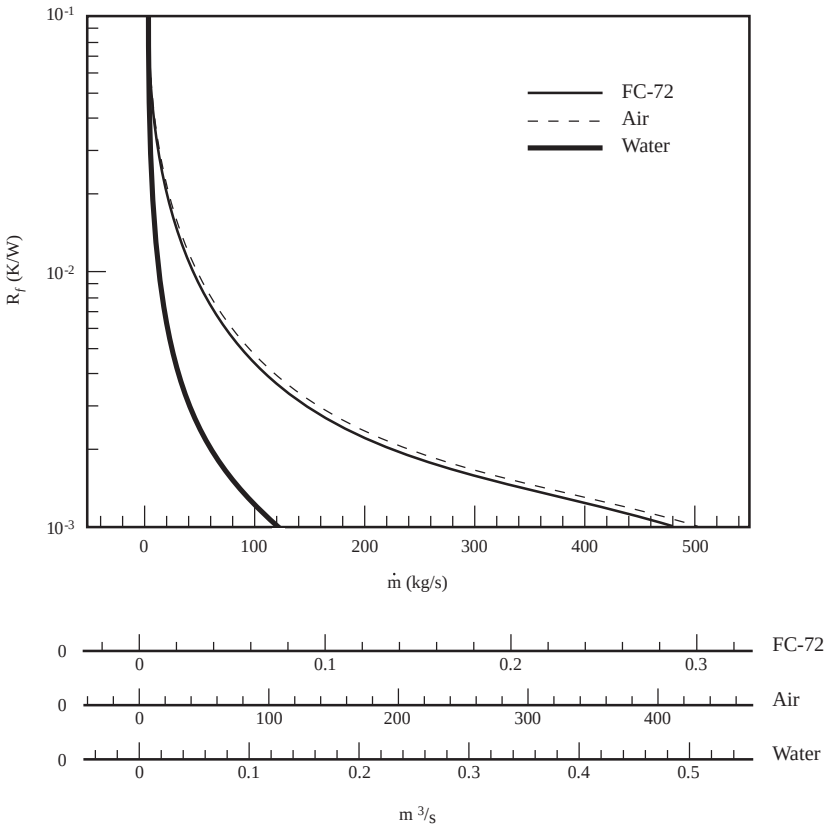

FIGURE 33.4 Flow thermal resistances for typical electronic coolants.

many of the failure mechanisms of integrated circuits are accelerated by an increase in the average chip temperature, low thermal resistances are to be preferred in nearly all categories of electronic packaging.

Single-chip packages can be characterized by their internal, or so-called junction-to-case, resistance. The convective heat removal techniques applied to the external surfaces of the package, including the effect of finned heat sinks and other thermal enhancements, can be compared on the basis of the external thermal resistance. The complexity of heat flow and coolant flow paths in a multichip module generally requires that the thermal capability of these packaging configurations be examined on the basis of overall, or chip-to-coolant, thermal resistance.

Examination of various packaging techniques reveals that the junction-to-coolant thermal resistance is, in fact, composed of an internal, largely conductive, resistance and an external, primarily convective, resistance. As shown in Fig. 33.5, the internal resistance, R_{jc}, is encountered in the flow of dissipated heat from the active chip surface, through the materials used to support and bond the chip, and on to the case of the integrated circuit package. The flow of heat from the case directly to the coolant, or indirectly through a fin structure and then to the coolant, must overcome the external resistance, R_{ex}.

Internal Resistance

As previously noted, conductive thermal transport is governed by the Fourier equation (Eq. 33.1). For composite, rectilinear structures, as encountered in many chip modules, the Fourier equation (with temperature and time invariant properties), takes the form

$$q = (T_i - T_e) \Big/ \sum_p (\Delta x/kA) \ [\mathrm{W}] \tag{33.13}$$

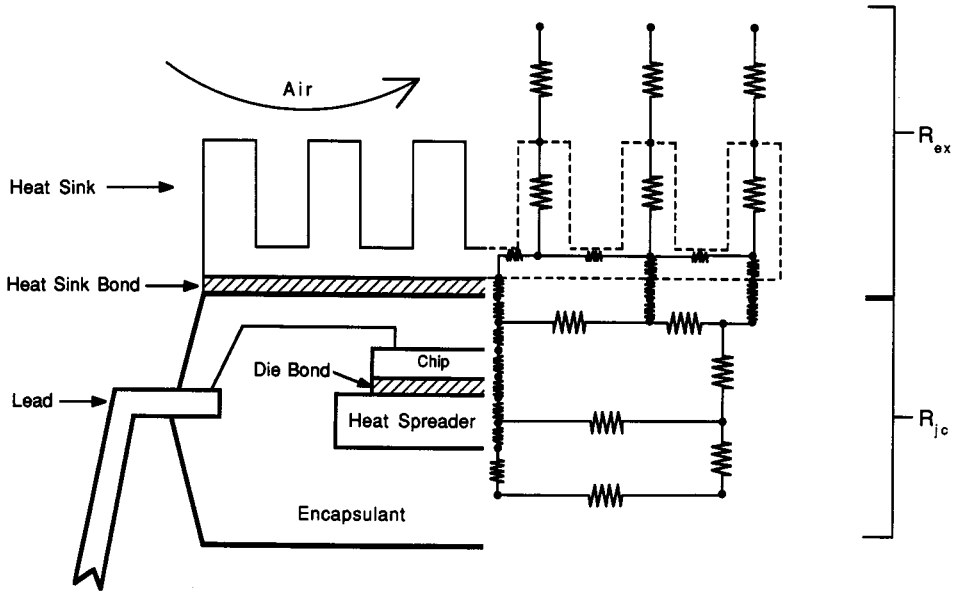

FIGURE 33.5 Thermal resistances in a single-chip package.

where T_i and T_e are the temperatures internal and external to the composite structure, respectively, Δx is the thickness of each material in the direction of heat flow, and the summation sign pertains to p distinct layers of material. The thermal conductivities of typical packaging materials are tabulated in Table 33.1.

Assuming that power is dissipated uniformly across the chip surface and that heat flow is largely one-dimensional, Eq. (33.13) can be used to provide a first-order approximation for the internal chip module resistance, as

$$R_{jc} = (T_j - T_c)/q_c = \sum_p (\Delta x/kA) \ [\text{K/W}] \tag{33.14}$$

where the summed terms represent the thermal resistances of the individual layers of silicon, solder, copper, alumina, etc. It is to be noted that the contact resistances that occur at the interfaces between pairs of materials can be added, as appropriate, to this summation. As may be seen in Fig. 32.2, decreasing the thickness of each layer and/or increasing the thermal conductivity and cross-sectional area, reduce the resistance of the individual layers.

In chip packages that provide for lateral spreading of the heat generated in the chips, the increasing cross-sectional area for heat flow at successive layers reduces the internal thermal resistance. Unfortunately, however, there is an additional resistance associated with the lateral flow of the heat, which must be taken into account in determining the chip-to-case temperature difference.

Following Yovanovich and Antonetti [1988], the spreading resistance for a small heat source on a thick substrate (typically 3–5 times thicker than the square root of the heat source area) can be expressed as

$$R_c = (0.475 - 0.62\varepsilon + 0.13\varepsilon^3)/k\,(A_c)^{0.5} \ [\text{K/W}] \tag{33.15}$$

where ε is the square root of the ratio of the heat source area to the substrate area, k the thermal conductivity of the substrate, and A_c the area of the heat source. For relatively thin layers on thicker substrates, Eq. (33.15) cannot provide an acceptable prediction of R_c. Instead, use can be made of the numerical results plotted in Fig. 33.6 to obtain the requisite value of the spreading resistance.

The internal thermal resistance of a chip package can be expected to vary from approximately 50 K/W for a plastic package with no heat spreader, to 10 to 15 K/W for a plastic package with heat spreader, and to 3 to

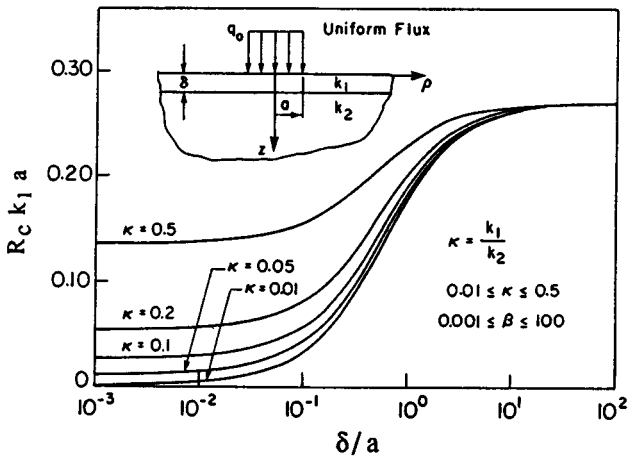

FIGURE 33.6 The thermal resistance for a circular heat source on a two-layer substrate. (*Source:* M.M. Yovanovich and V.W. Antonetti, "Application of Thermal Contact Resistance Theory toElectronic Packages," in *Advances in Thermal Modeling of Electronic Components and Systems,* vol. 1, A. Bar-Cohen and A.D. Kraus, Eds., New York: Hemisphere, 1988, pp. 79–128. With permission.)

8 K/W for a ceramic package or a specially designed plastic chip package. Carefully designed chip packages can attain even lower values of R_{jc}, but the conductive thermal resistances at the interfaces between materials, and especially along the chip surfaces where the heat fluxes are highest, can typically reach 1 K/W for epoxied interfaces and impose a lower bound on the internal package resistance.

External Resistance

To precisely determine the resistance to thermal transport from a surface to a fluid in motion, i.e., the convective resistance, it is necessary to quantify the heat transfer coefficient, *h*. For a particular geometry and flow regime, *h* may be found from available empirical correlations and/or theoretical relations. For flow along plates and in the inlet zones of parallel-plate channels, as may well be encountered in electronic cooling applications, the low velocity, or laminar flow, average convective heat transfer coefficient is given by [Kraus and Bar-Cohen, 1983]

$$h = 0.664(k/l)(\mathrm{Re})^{0.5}(\mathrm{Pr})^{0.333}\ [\mathrm{W/m^2K}] \qquad (33.16)$$

$$\text{for } \mathrm{Re} < 2 \times 10^5$$

where *k* is the fluid thermal conductivity, *l* the length (in the flow direction) of the surface, Re the **Reynolds number** (equal to the product of velocity, density, and length divided by the fluid viscosity), and Pr the **Prandtl number** (equal to the product of specific heat and viscosity divided by the thermal conductivity of the fluid).

Inserting the various parameters associated with the Re and Pr in Eq. (33.16), the laminar heat transfer coefficient is found to be directly proportional to the square root of fluid velocity and inversely proportional to the square root of the length. Furthermore, increases in the thermal conductivity of the fluid and in the Pr, as are encountered in replacing air with a liquid coolant, can be expected to result in higher heat transfer coefficients. In studies of low-velocity convective air cooling of simulated integrated circuit packages, *h* has been found to depend somewhat more strongly on Re than suggested in Eq. (33.16), and to display an Re exponent of 0.54-0.72 [Buller and Kilburn, 1981; Sparrow et al., 1982; Wirtz and Dykshoorn, 1984].

In higher velocity turbulent flow, the dependence of the convective heat transfer coefficient on the Re increases and is typically given by [Kraus and Bar-Cohen, 1983]:

$$h = 0.036(k/l)\ (\mathrm{Re})^{0.8}\ (\mathrm{Pr})^{0.333},\ \mathrm{W/m^2K} \qquad (33.17)$$

$$\text{for } \mathrm{Re} > 3 \times 10^5$$

In this flow regime, the convective heat transfer coefficient is, thus, found to vary directly with the velocity to the 0.8 power and inversely with the characteristic dimension to the 0.2 power. The dependence on fluid conductivity and Pr remains unchanged.

Applying Eq. (33.16) or (33.17) to the transfer of heat from the case of a chip module to the coolant, the external resistance, $R_{ex} = 1/hA$, is found to be inversely proportional to the wetted area and to the coolant velocity to the 0.5 to 0.8 power and directly proportional to the length in the flow direction to the 0.5 to 0.2 power. It may, thus, be observed that the external resistance can be strongly influenced by the fluid velocity and package dimensions and that these factors must be addressed in any meaningful evaluation of the external thermal resistances offered by various packaging technologies.

As previously noted, values of the external resistance, for a variety of coolants and heat transfer mechanisms, are shown in Fig. 33.3 for a typical component wetted area of 10 cm^2 and a velocity range of 2 m/s to 8 m/s. Clearly, larger chip packages will experience proportionately lower external resistances than the tabulated values, and conduction of heat through the leads and package base into the printed circuit board or substrate will serve to further reduce the effective thermal resistance.

When the direct cooling of the package surface is inadequate to maintain the desired chip temperature, it is common to attach finned heat sinks, or compact heat exchangers, to the chip package. These heat sinks can considerably increase the wetted area but may act to reduce the convective heat transfer coefficient and most definitely introduce additional conductive resistances in the adhesive used to bond the heat sink to the package and in the body of the heat sink. Typical air-cooled heat sinks for a single chip package with a base area of 3.3 × 3.3 cm on one side can reduce the external resistance to approximately 15 K/W in natural convection and as low as 5 K/W for moderate forced convection velocities.

When a heat sink or compact heat exchanger is attached to the package, the external resistance can be modified to account for the bond-layer conduction and fin efficiency as

$$R_{ex} = (T_c - T_f)/q_c = (\Delta x/kA)_b + (\eta hA)^{-1} \tag{33.18}$$

In properly designed fin structure, η can be expected to fall in the range of 0.5 to 0.8 [Kraus and Bar-Cohen, 1983]. Relatively thick fins in a low velocity flow of gas are likely to yield fin efficiencies approaching unity. This same unity value would be appropriate, as well, for an unfinned surface and, thus, serve to generalize the use of Eq. (33.18) to all package configurations.

Total Resistance

Based on the accuracy of the assumptions used in the preceding development, the overall chip module resistance, relating the chip temperature to the inlet temperature of the coolant, can be found by summing the internal, external, and flow resistances to yield:

$$R_T = R_{jc} + R_{ex} + R_f = \sum_p [R_c + (\Delta x/kA)] + (\eta hA)^{-1} + \dot{m}c_p/2 \tag{33.19}$$

In evaluating the thermal resistance by this relation, care must be taken to determine the effective cross-sectional area for heat flow at each layer in the module. For single-chip modules, the requisite areas can be readily obtained, although care must be taken to consider possible voidage in solder and adhesive layers.

As previously noted in the development of the relations for external and internal resistances, Eq. (33.19) shows R_T to be a strong function of the convective heat transfer coefficient, the flowing heat capacity of the coolant, and geometric parameters (thickness and cross-sectional area of each layer). Thus, the introduction of a superior coolant, use of thermal enhancement techniques that increase the local heat transfer coefficient, and selection of a heat transfer mode with inherently high heat transfer coefficients (e.g., boiling) will all be reflected in appropriately lower external and total thermal resistances. Similarly, improvements in the thermal conductivity of and reduction in the thickness of the relatively low conductivity bonding materials (e.g., soft solder, epoxy, silicone) would act to reduce the internal and total thermal resistances.

Frequently, however, even more dramatic reductions in the total resistance can be achieved simply by increasing the cross-sectional area for heat flow, within the chip module (e.g., chip, substrate, heat spreader) as well as along the wetted exterior surface. The implementation of such a scale-up generally results in a larger module footprint and/or lower volumetric packaging density, both of which are highly undesirable, and yet is rewarded with a lower thermal resistance. In evaluating packaging approaches, it must, therefore, be understood that the thermal resistance is a somewhat flawed figure-of-merit and that a better reflection of the efficacy of a thermal management technique can be obtained by normalizing R_T with respect to the packaging density, using the number of chips on a substrate or number of chips/packages on a printed circuit board.

Multichip Modules

The thermostructural complexity of the multichip modules in current use hampers effective thermal characterization and introduces significant uncertainty in any attempt to compare the thermal performance of these packaging configurations. Variations in heat generation patterns across the active chips (e.g., devices versus drivers), as well as nonuniformities in heat dissipation among the chips assembled in a single module, further complicate this task. To establish a common, though approximate, basis for comparison of multichip modules, it is possible to neglect these variations and consider that the heat generated by each chip flows through a unit cell of the module structure to the external coolant [Bar-Cohen, 1987, 1988]. For a given structure, increasing the area of the unit cell allows heat to spread from the chip to a larger cross section, reducing the heat flux at some of the thermally critical interfaces and at the convectively cooled surfaces. Consequently, the thermal performance of a multichip module can be best represented by the area-specific thermal resistance, i.e., the temperature difference between the chip and the coolant divided by the substrate heat flux. This figure-of-merit is equivalent to the inverse of the overall heat transfer coefficient, U, commonly used in the compact heat exchanger literature. Despite significant variation in design and fabrication, all the late-1980s water-cooled modules and one air-cooled module provide a specific thermal resistance of approximately 20°C for every watt per square centimeter at the substrate. In cutting-edge multichip modules in use in the 1990s, this value was reduced to 5–10 K/(W/cm^2).

Nomenclature

A	area, m^2
c_p	specific heat, W/kgK
C'_{sf}	boiling surface parameter, W/m^{2}K^3
F	radiational factor
h	heat transfer coefficient, W/m^{2}K
k	thermal conductivity, W/mK
l	path length, m
m	mass flow, kg/s
Pr	Prandtl Number, $\equiv c_p\mu/k$
q	heat flow, W
R	thermal resistance, K/W
Re	Reynolds Number, $\equiv \rho vl/\mu$
T	temperature, K
v	velocity, m/s
x	length, m
σ	Stefan-Boltzmann constant, $5.67 \times 10{-}8$ W/m^{2}K^4
η	fin efficiency
ρ	density, kg/m^3
$\mathcal{Q}$	volumetric flow rate, m^3/s
ε	ratio of heater to substrate size
μ	viscosity, kg/ms

Subscripts

b	bond layer
b	boiling
c	constriction or spreading
cond	conduction
conv	convection
f, fluid	fluid
i	internal
in	inlet
j	junction
jc	junction to case
o	base, external
out	outlet
r	radiation
sat	thermodynamic saturation
surf	surface
T	total

Defining Terms

Catastrophic thermal failure: An immediate, thermally induced total loss of electronic function by a component or system.

Conductive heat transfer: The process by which heat diffuses through a solid or stationary fluid.

Convective heat transfer: The process by which a moving fluid transfers heat to or from a wetted surface.

Ebullient heat transfer: The heat transfer process associated with the formation and release of vapor bubbles on a heated surface.

Fin efficiency: A thermal characteristic of an extended surface that relates the heat transfer ability of the additional area to that of the base area.

Heat transfer coefficient: A characteristic parameter of convective heat transfer that determines the heat flux that can be transported from a wetted surface with a specified temperature difference.

Prandtl number: A nondimensional characteristic of fluids, relating the rate of momentum diffusion to heat diffusion.

Radiative heat transfer: The process by which long-wave electromagnetic radiation transports heat from a surface to its surroundings.

Reynolds number: A nondimensional parameter used to determine the transition to turbulence in a fluid flowing in pipes or past surfaces.

Thermal fin: An extension of the surface area in contact with a heat transfer fluid, usually in the form of a cylinder or rectangular prism protruding from the base surface.

Thermal management or control: The process or processes by which the temperature of a specified component or system is maintained at the desired level.

Thermal resistance: A thermal characteristic of a heat flow path, establishing the temperature drop required to transport heat across the specified segment or surface; analogous to electrical resistance.

34.1 Introduction

The field of **design automation** (DA) technology, also commonly called *computer-aided design* (CAD) or *computer-aided engineering* (CAE), involves developing computer programs to conduct portions of product design and manufacturing on behalf of the designer. Competitive pressures to produce more efficiently new generations of products having improved function and performance are motivating the growing importance of DA. The increasing complexities of microelectronic technology, shown in Fig. 34.1, illustrate the importance of relegating portions of product development to computer automation [Barbe, 1980].

Advances in microelectronic technology enable over 1 million devices to be manufactured on an **integrated circuit** that is smaller than a postage stamp; yet the ability to exploit this capability remains a challenge. Manual design techniques are unable to keep pace with product design cycle demands and are being replaced by automated design techniques [Saprio, 1986; Dillinger, 1988].

Figure 34.2 summarizes the historical development of DA technology. DA computer programs are often simply called *applications* or *tools*. DA efforts started in the early 1960s as academic research projects and captive industrial programs; these efforts focused on tools for physical and logical design. Follow-on developments extended logic simulation to more-detailed *circuit* and *device* simulation and more-abstract *functional* simulation. Starting in the mid to late 1970s, new areas of test and synthesis emerged and vendors started offering commercial DA products. Today, the electronic design automation (EDA) industry is an international business with a well-established and expanding technical base [Trimberger, 1990]. EDA will be examined by presenting an overview of the following areas:

- Design entry,
- Synthesis,
- Verification,
- Physical design, and
- Test.

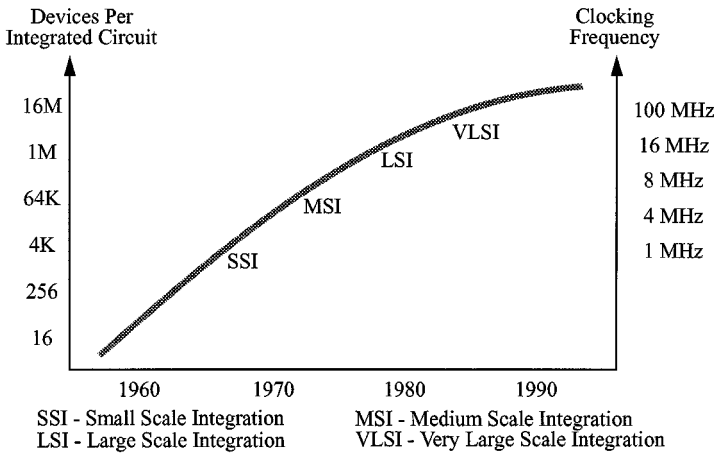

FIGURE 34.1 Microelectronic technology complexity.

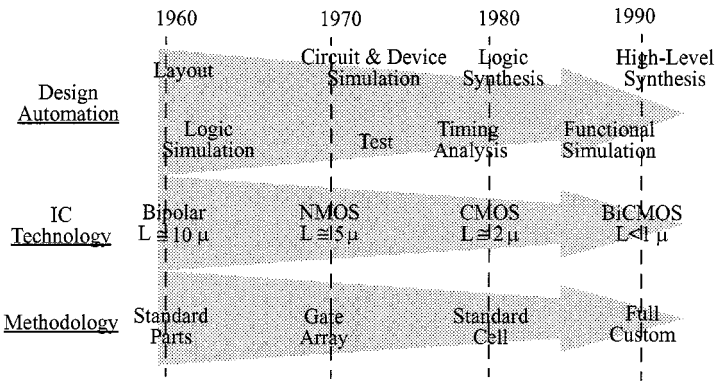

FIGURE 34.2 DA technology development.

34.2 Design Entry

Design entry, also called *design capture*, is the process of communicating with a DA system. In short, design entry is how an engineer "talks" to a DA application and/or system.

Any sort of communication is composed of two elements: language and mechanism. Language provides common semantics; mechanism provides a means by which to convey the common semantics. For example, people communicate via a language, such as English or German, and a mechanism, such as a telephone or electronic mail. For design, a digital system can be described in many ways, involving different perspectives or *abstractions*. An abstraction defines at a particular level of detail the behavior or semantics of a digital system, i.e., how the outputs respond to the inputs. Fig. 34.3 illustrates several popular levels of abstractions. Moving from the lower left to the upper right, the level of abstraction generally increases, meaning that physical models are the most detailed and specification models are the least detailed. The trend toward higher levels of design entry abstraction supports the need to address greater levels of complexity [Peterson, 1981].

The physical level of abstraction involves geometric information that defines electrical devices and their interconnection. Geometric information includes the shape of objects and how objects are placed relative to each other. For example, Fig. 34.4 shows the geometric shapes defining a simple complementary metal-oxide semiconductor (**CMOS**) inverter. The shapes denote different materials, such as aluminum and polysilicon, and connections, called *contacts* or **vias**.

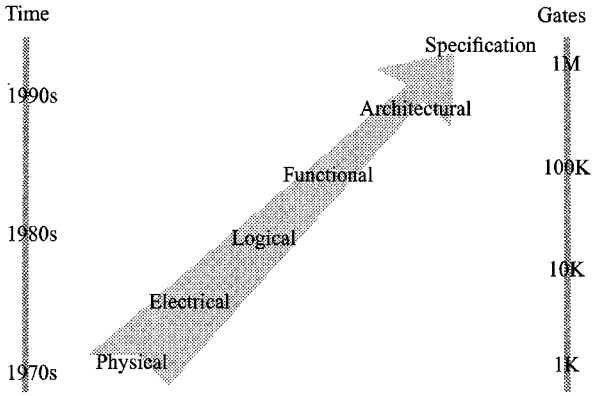

FIGURE 34.3 DA abstractions.

Design entry mechanisms for physical information involve textual and graphical techniques. With textual techniques, geometric shape and placement are described via an artwork description language, such as Caltech Intermediate Form (CIF) or Electronic Design Intermediate Form (EDIF). With graphical techniques, geometric shape and placement are described by rendering the objects on a display terminal.

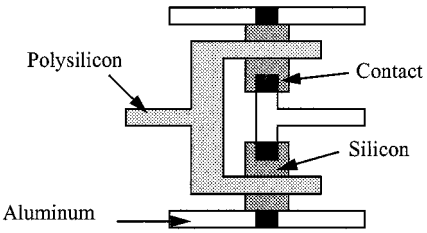

FIGURE 34.4 Physical abstraction.

The electrical level abstracts physical information into corresponding electrical devices, such as **capacitors**, **transistors**, and **resistors**. Electrical information includes device behavior in terms of terminal current and voltage relationships. Device behavior may also be defined in terms of manufacturing parameters. Fig. 34.5 shows the electrical symbols denoting a CMOS inverter.

The logical level abstracts electrical information into corresponding logical elements, such as **and** gates, **or** gates, and inverters. Logical information includes truth table and/or characteristic-switching algebra equations and active-level designations. Fig. 34.6 shows the logical symbol for a CMOS inverter. Notice how the amount of information decreases as the level of abstraction increases.

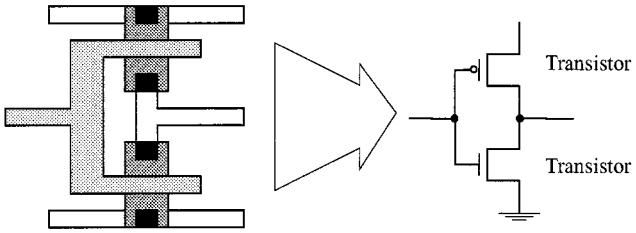

FIGURE 34.5 Electrical abstraction.

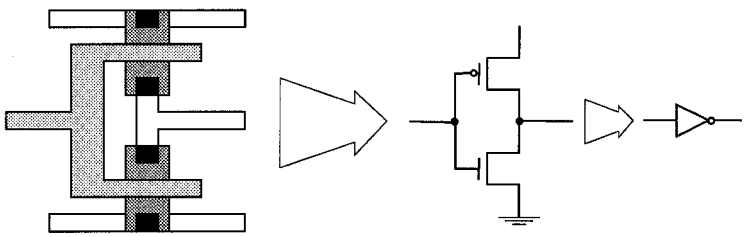

FIGURE 34.6 Logical abstraction.

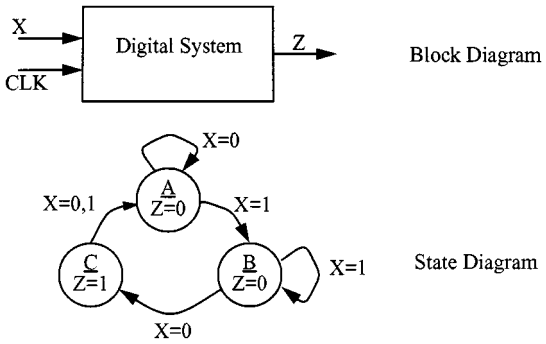

FIGURE 34.7 State diagram.

Design entry mechanisms for electrical and logical abstractions are collectively called *schematic capture* techniques. Schematic capture defines hierarchical structures, commonly called **netlists**, of components. A designer creates instances of components supplied from a library of predefined components and connects component pins or ports via wires [Douglas-Young, 1988; Pechet, 1991].

The functional level abstracts logical elements into corresponding computational units, such as registers, multiplexers, and arithmetic logic units (ALUs). The architectural level abstracts functional information into computational algorithms or paradigms. Examples of common computational paradigms are listed below:

- State diagrams,
- Petri nets,
- Control/data flow graphs,
- Function tables,
- Spreadsheets, and
- Binary decision diagrams.

These higher levels of abstraction support a more expressive, "higher-bandwidth" communication interface between engineers and DA programs. Engineers can focus their creative, cognitive skills on concept and behavior, rather than on the complexities of detailed implementation. Associated design entry mechanisms typically use hardware description languages with a combination of textual and graphic techniques [Birtwistle and Subrahmanyan, 1988].

Figure 34.7 shows an example of a simple state diagram. The state diagram defines three states, denoted by circles. State-to-state transitions are denoted by labeled arcs; state transitions depend on the present state and the input X. The output, Z, per state is given within each state. Since the output is dependent on only the present state, the digital system is classified as a Moore **finite state machine**. If the output is dependent on the present state and input, then the digital system is classified as a Mealy finite state machine.

A hardware description language model written in **VHDL** of the Moore finite state machine is given in Fig. 34.8. The VHDL model, called a *design entity*, uses a "**data flow**" description style to describe the state machine [Dewey, 1983, 1992, 1997]. The entity statement defines the interface, i.e., the ports. The ports include two input signals, X and CLK, and an output signal Z. The ports are of type BIT, which specifies that the signals may only carry the values 0 or 1. The architecture statement defines the input/output transform via two concurrent signal assignment statements. The internal signal STATE holds the finite state information and is driven by a guarded, conditional concurrent signal assignment statement that executes when the associated block expression

(CLK='1' **and not** CLK'STABLE)

is true, which is only on the rising edge of the signal CLK. STABLE is a predefined attribute of the signal CLK; CLK'STABLE is true if CLK has *not* changed value. Thus, if "**not** CLK'STABLE" is true, meaning that CLK has

```
-- entity statement
entity MOORE_MACHINE is
 port (X, CLK : in BIT;   Z : out BIT);
end MOORE_MACHINE;

-- architecture statement
architecture FSM of MOORE_MACHINE is
  type STATE_TYPE is (A, B, C);
  signal STATE : STATE_TYPE := A;
begin
 NEXT_STATE:
 block (CLK='1' and not CLK'STABLE)
 begin
    -- guarded conditional concurrent signal assignment statement
    STATE <= guarded B when (STATE=A and X='1') else
                          C when (STATE=B and X='0') else
                          A when (STATE=C) else
                          STATE;
 end block NEXT_STATE;
 -- unguarded selected concurrent signal assignment statement
 with STATE select
   Z <= '0' when A,
        '0' when B,
        '1' when C;
end FSM;
```

FIGURE 34.8 VHDL model.

just changed value, and "CLK='1'," then a rising transition has occurred on CLK. The output signal Z is driven by a nonguarded, selected concurrent signal assignment statement that executes any time STATE changes value.

34.3 Synthesis

Figure 34.9 shows that the **synthesis** task generally follows the design entry task. After describing the desired system via design entry, synthesis DA programs are invoked to assist generating the required detailed design.

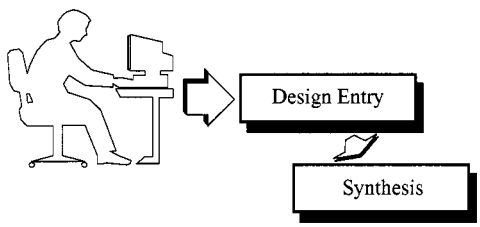

FIGURE 34.9 Design process — synthesis.

Synthesis translates or transforms a design from one level of abstraction to another, more-detailed level of abstraction. The more-detailed level of abstraction may be only an intermediate step in the entire design process, or it may be the final implementation. Synthesis programs that yield a final implementation are sometimes called **silicon compilers** because the programs generate sufficient detail to proceed directly to silicon fabrication [Ayres, 1983; Gajski, 1988].

Like design abstractions, synthesis techniques can be hierarchically categorized, as shown in Fig. 34.10. The higher levels of synthesis offer the advantage of less complexity, but also the disadvantage of less control over the final design.

Algorithmic synthesis, also called *behavioral* synthesis, addresses "multicycle" behavior, which means behavior that spans more than one *control step*. A control step equates to a clock cycle of a synchronous, sequential digital system, i.e., a state in a finite-state machine controller or a microprogram step in a microprogrammed controller.

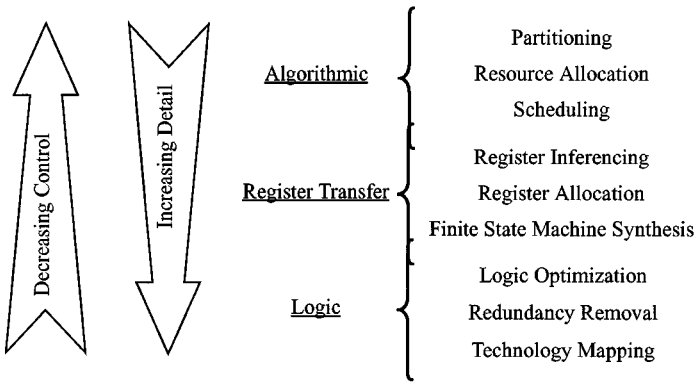

FIGURE 34.10 Taxonomy of synthesis techniques.

Algorithmic synthesis typically accepts sequential design descriptions that define an input/output transform, but provide little information about the parallelism of the final design [Camposano and Wolfe, 1991; Gajski et al., 1992].

Partitioning decomposes the design description into smaller behaviors. Partitioning is an example of a high-level transformation. High-level transformations include common software programming compiler optimizations, such as loop unrolling, subprogram in-line expansion, constant propagation, and common subexpression elimination.

Resource allocation associates behaviors with hardware computational units, and scheduling determines the order in which behaviors execute. Behaviors that are mutually exclusive can potentially share computational resources. Allocation is performed using a variety of graph clique covering or node coloring algorithms. Allocation and scheduling are interdependent, and different synthesis strategies perform allocation and scheduling different ways. Sometimes scheduling is performed first, followed by allocation; sometimes allocation is performed first, followed by scheduling; and sometimes allocation and scheduling are interleaved.

Scheduling assigns computational units to control steps, thereby determining which behaviors execute in which clock cycles. At one extreme, all computational units can be assigned to a single control step, exploiting maximum concurrency. At the other extreme, computational units can be assigned to individual control steps, exploiting maximum sequentiality. Several popular scheduling algorithms are listed below:

- As-soon-as-possible (ASAP),
- As-late-as-possible (ALAP),
- List scheduling,
- Force-directed scheduling, and
- Control step splitting/merging.

ASAP and ALAP scheduling algorithms order computational units based on data dependencies. List scheduling is based on ASAP and ALAP scheduling, but considers additional, more-global constraints, such as maximum number of control steps. Force-directed scheduling computes the probabilities of computational units being assigned to control steps and attempts to evenly distribute computation activity among all control steps. Control step splitting starts with all computational units assigned to one control step and generates a schedule by splitting the computational units into multiple control steps. Control step merging starts with all computational units assigned to individual control steps and generates a schedule by merging or combining units and steps [Paulin and Knight, 1989; Camposano and Wolfe, 1991].

Register transfer synthesis takes as input the results of algorithmic synthesis and addresses "per-cycle" behavior, which means the behavior during one clock cycle. Register transfer synthesis selects logic to realize the hardware computational units generated during algorithmic synthesis, such as realizing an addition operation with a carry–save adder or realizing addition and subtraction operations with an arithmetic logic unit.

Data that must be retained across multiple clock cycles are identified, and registers are allocated to hold the data. Finally, finite-state machine synthesis involves state minimization and state assignment. State minimization seeks to eliminate redundant or equivalent states, and state assignment assigns binary encodings for states to minimize combinational logic [Brayton et al., 1992; Sasao, 1993].

Logic synthesis optimizes the logic generated by register transfer synthesis and maps the optimized logic operations onto physical gates supported by the target fabrication technology. Technology mapping considers the foundry cell library and associated electrical restrictions, such as **fan-in/fan-out** limitations.

34.4 Verification

Figure 34.11 shows that the **verification** task generally follows the synthesis task. The verification task checks the correctness of the function and performance of a design to ensure that an intermediate or final design faithfully realizes the initial, desired specification. Three major types of verification are listed below:

- Timing analysis,
- Simulation, and
- Emulation.

Timing Analysis

Timing analysis checks that the overall design satisfies operating speed requirements and that individual signals within a design satisfy transition requirements. Common signal transition requirements, also called *timing hazards*, include *rise* and *fall times*, *propagation delays*, *clock periods*, *race conditions*, *glitch detection*, and *setup* and *hold times*. For instance, setup and hold times specify relationships between data and control signals to ensure that memory devices (level-sensitive latches or edge-sensitive flip-flops) correctly and reliably store desired data. The data signal carrying the information to be stored in the memory device must be stable for a period equal to the setup time prior to the control signal transition to ensure that the correct value is sensed by the memory device. Also, the data signal must be stable for a period equal to the hold time after the control signal transition to ensure that the memory device has enough time to store the sensed value.

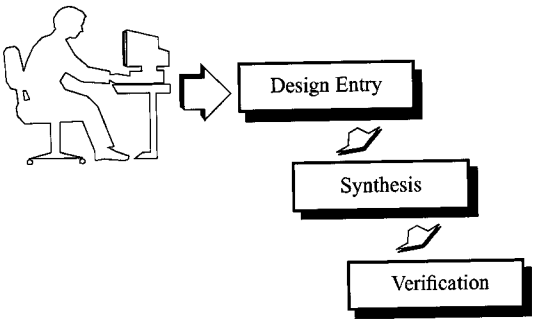

FIGURE 34.11 Design process — verification.

Another class of timing transition requirements, commonly called signal integrity checks, include *reflections*, *crosstalk*, **ground bounce**, and *electromagnetic interference*. Signal integrity checks are typically required for high-speed designs operating at clock frequencies above 75 MHz. At such high frequencies, the transmission line behavior of wires must be analyzed. A wire should be properly terminated, i.e., connected, to a port having an impedance matching the wire characteristic impedance to prevent signal reflections. Signal reflections are portions of an emanating signal that "bounce back" from the destination to the source. Signal reflections reduce the power of the emanating signal and can damage the source. Crosstalk refers to unwanted reactive coupling between physically adjacent signals, providing a connection between signals that are supposed to be electrically isolated. Ground bounce is another signal integrity problem. Since all conductive material has a finite impedance, a ground signal network does not in practice offer the exact same electrical potential throughout an entire design. These potential differences are usually negligible because the distributive impedance of the ground signal network is small compared with other finite-component impedances. However, when many signals switch value simultaneously, a substantial current can flow through the ground signal network. High intermittent currents yield proportionately high intermittent potential drops, i.e., ground bounces, which can

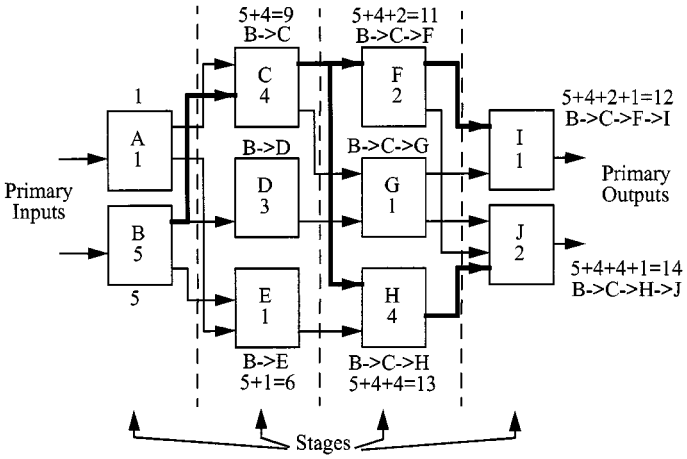

FIGURE 34.12 Block-oriented static timing analysis.

cause unwanted circuit behavior. Finally, electromagnetic interference refers to signal harmonics radiating from design components and interconnects. This harmonic radiation may interfere with other electronic equipment or may exceed applicable environmental safety regulatory limits [McHaney, 1991].

Timing analysis can be performed dynamically or statically. Dynamic timing analysis exercises the design via simulation or emulation for a period of time with a set of input stimuli and records the timing behavior. Static timing analysis does not exercise the design via simulation or emulation. Rather, static analysis records timing behavior based on the timing behavior, e.g., propagation delay, of the design components and their interconnection.

Static timing analysis techniques are primarily *block oriented* or *path oriented*. Block-oriented timing analysis generates design input (also called primary input) to design output (also called primary output), and propagation delays by analyzing the design "stage-by-stage" and by summing up the individual stage delays. All devices driven by primary inputs constitute stage 1, all devices driven by the outputs of stage 1 constitute stage 2, and so on. Starting with the first stage, all devices associated with a stage are annotated with worst-case delays. A worst-case delay is the propagation delay of the device plus the delay of the last input to arrive at the device, i.e., the signal path with the longest delay leading up to the device inputs. For example, the device labeled "H" in stage 3 in Fig. 34.12 is annotated with the worst-case delay of 13, representing the device propagation delay of 4 and the delay of the last input to arrive through devices "B" and "C" of 9 [McWilliams and Widdoes, 1978]. When the devices associated with the last stage, i.e., the devices driving the primary outputs, are processed, the accumulated worst-case delays record the longest delay from primary inputs to primary outputs, also call the critical paths. The critical path for each primary output is highlighted in Fig. 34.12.

Path-oriented timing analysis generates primary input to primary output propagation delays by traversing all possible signal paths one at a time. Thus, finding the critical path via path-oriented timing analysis is equivalent to finding the longest path through a directed acyclic graph, where devices are graph vertices and interconnections are graph edges [Sasiki et al., 1978].

To account for realistic variances in component timing due to manufacturing tolerances, aging, or environmental effects, timing analysis often provides stochastic or statistical checking capabilities. Statistical timing analysis uses random-number generators based on empirically observed probabilistic distributions to determine component timing behavior. Thus, statistical timing analysis describes design performance and the likelihood of the design performance.

Simulation

Simulation exercises a design over a period of time by applying a series of input stimuli and generating the associated output responses. The general event-driven, also called schedule-driven, simulation algorithm is diagrammed in Fig. 34.13. An event is a change in signal value. Simulation starts by initializing the design;

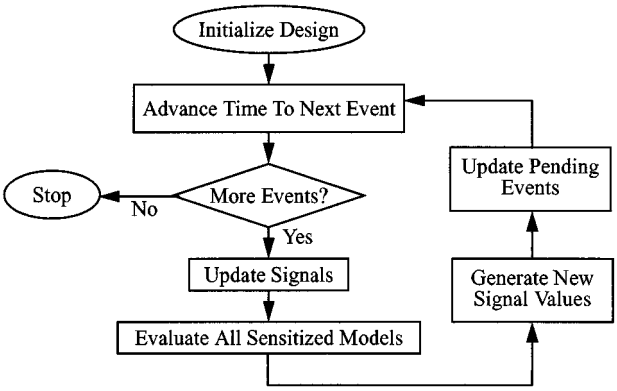

FIGURE 34.13 General event-driven simulation algorithm.

initial values are assigned to all signals. Initial values include starting values and pending values that constitute future events. Simulation time is advanced to the next pending event(s), signals are updated, and sensitized models are evaluated [Pooch, 1993]. The process of evaluating the sensitized models yields new, potentially different, values for signals, i.e., a new set of pending events. These new events are added to the list of pending events, time is advanced to the next pending event(s), and the simulation algorithm repeats. Each pass through the loop in Fig. 34.13 of evaluating sensitized models at a particular time step is called a **simulation cycle**. Simulation ends when the design yields no further activity, i.e., when there are no more pending events to process.

Logic simulation is computationally intensive for large, complex designs. As an example, consider simulating 1 s of a 200K-gate, 20-MHz processor design. By assuming that, on average, only 10% of the total 200K gates are active or sensitized on each processor clock cycle, Eq. 34.1 shows that simulating 1 s of actual processor time equates to 400 billion events.

$$\begin{aligned} 400 \text{ billion events} &= (20 \text{ million clock cycles})(200\text{K gates})(10\% \text{ activity}) \\ 140 \text{ h} &= (400 \text{ billion events})\left(\frac{50 \text{ instructions}}{\text{event}}\right)\left(\frac{50 \text{ million instructions}}{\text{s}}\right) \end{aligned} \tag{34.1}$$

Assuming that, on average, a simulation program executes 50 computer instructions per event on a computer capable of processing 50 million instructions per second (MIP), Eq. 34.1 also shows that processing 400 billion events requires 140 h or just short of 6 days. Fig. 34.14 shows how simulation computation generally scales with design complexity.

To address the growing computational demands of simulation, several simulation acceleration techniques have been introduced. Schedule-driven simulation, explained above, can be accelerated by removing layers of interpretation and running a simulation as a native executable image; such an approach is called complied, scheduled-driven simulation.

As an alternative to schedule-driven simulation, *cycle-driven* simulation avoids the overhead of event queue processing by evaluating all devices at regular intervals of time. Cycle-driven simulation is efficient when a design exhibits a high degree of concurrency, i.e., when a large percentage of the devices are active per simulation cycle. Based on the staging of devices, devices are *rank-ordered* to determine the order in which they are evaluated at each time step to ensure the correct causal behavior yielding the proper ordering of events. For functional verification, logic devices are often assigned zero-delay and memory devices are assigned unit-delay. Thus, any number of stages of logic devices may execute between system clock periods.

In another simulation acceleration technique, *message-driven* simulation, also called *parallel* or *distributed* simulation, device execution is divided among several processors and the device simulations communicate

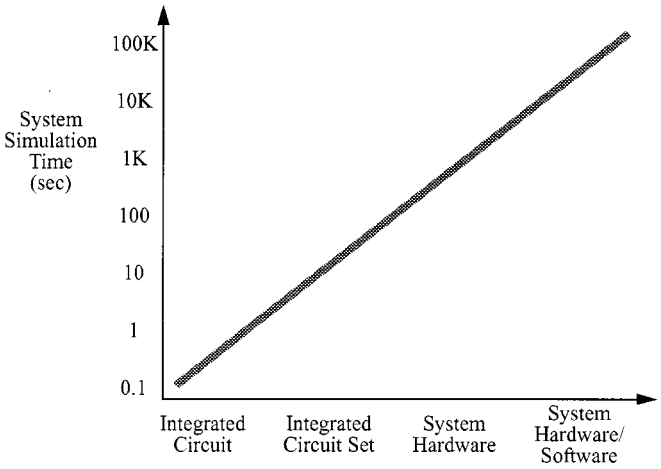

FIGURE 34.14 Simulation requirements.

event activity via messages. Messages are communicated using conservative or optimistic strategies. Optimistic message-passing strategies, such as *time warp* and *lazy cancellation,* make assumptions about future event activity to advance local device simulation. If the assumptions are correct, the processors operate more independently and better exploit parallel computation. However, if the assumptions are incorrect, then local device simulations may be forced to "roll back" to synchronize local device simulations [Bryant, 1979; Chandy and Misra, 1981].

Schedule-driven, cycle-driven, and message-driven simulations are software-based simulation acceleration techniques. Simulation can also be accelerated by relegating certain simulation activities to dedicated hardware. For example, *hardware modelers* can be attached to software simulators to accelerate the activity of device evaluation. As the name implies, hardware modeling uses actual hardware devices instead of software models to obtain stimulus/response information. Using actual hardware devices reduces the expense of generating and maintaining software models and provides an environment to support application software development. However, it is sometimes difficult for a slave hardware modeler to preserve accurate real-time device operating response characteristics within a master non-real-time software simulation environment. For example, some hardware devices may not be able to retain state information between invocations, so the hardware modeler must save the history of previous inputs and reapply them to bring the hardware device to the correct state to apply a new input.

Another technique for addressing the growing computational demands of simulation is via simulation engines. A simulation engine can be viewed as an extension of the simulation acceleration technique of hardware modeling. With a hardware modeler, the simulation algorithm executes in software and component evaluation executes in dedicated hardware. With a simulation engine, the simulation algorithm *and* component evaluation execute in dedicated hardware. Simulation engines are typically two to three orders of magnitude faster than software simulation [Takasaki et al., 1989].

Analog Simulation

Analog simulation involves time-domain analyses and frequency-domain analyses, which are generally conducted using some form of direct current (DC) simulation, diagrammed in Fig. 34.15. DC simulation determines the quiescent or steady-state operating point for a circuit, specifying **node voltages**, **branch** currents, input/output resistances, element sensitivities, and input/output gains [Chua and Lin, 1975; Nagel, 1975].

Several popular equation formulation schemes are summarized in Table 34.1. Equation formulation schemes generate a set of linear equations denoting relationships between circuit voltages and currents; these relationships are based on the physical principle of the conservation of energy expressed via **Kirchoff's current law** (KCL), **Kirchoff's voltage law** (KVL), and branch constitutive relationships (BCRs). A circuit having N nodes and B branches possesses $2B$ independent variables defining B branch voltages and B branch currents. These

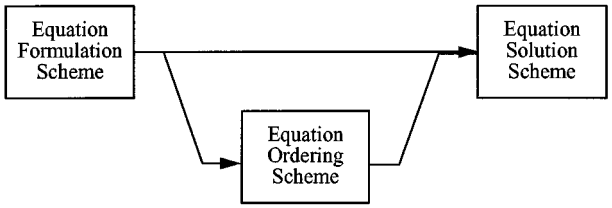

FIGURE 34.15 DC simulation.

TABLE 34.1 Common Circuit Equation Formulation Schemes

Equation Formulation Schemes	Desired Unknowns
Nodal analysis	Node voltages
Modified nodal analysis	Node voltages
	Dependent source currents
	Independent voltage source currents
Sparse tableau analysis	Node voltages
	Branch currents
	Branch voltages
Reduced tableau analysis	Node voltages
	Branch currents
Tree analysis	Tree branch voltages
Link analysis	Link branch currents

variables are governed by $2B$ linearly independent equations composed of $N-1$ KCL equations, $B-N+1$ KVL equations, and B BCR equations [Hachtel et al., 1971; Ho et al., 1975].

Equation-ordering schemes augment equation formulation schemes by reorganizing, modifying, and scaling the equations to improve the efficiency and/or accuracy of the subsequent equation solution scheme. More specifically, equation-ordering schemes seek to improve the "diagonal dominance" structure of the coefficient matrix by maximizing the number of "off-diagonal" zeros. Popular equation-ordering schemes include pivoting and row ordering (Markowitz) [Zlatev, 1980].

Finally, equation solution schemes determine the values for the independent variables that comply with the governing equations. There are basically two types of equation solution schemes: explicit and implicit. Explicit solution schemes, such as Gaussian elimination and/or LU factorization, determine independent variable values using closed-form, deterministic techniques. Implicit solution schemes, such as Gauss–Jacobi and Gauss–Seidel, determine independent variable values using iterative, nondeterministic techniques.

Emulation

Emulation, also called *computer-aided prototyping*, verifies a design by realizing the design in "preproduction" hardware and exercising the hardware. The term *preproduction* hardware means nonoptimized hardware providing the correct functional behavior, but not necessarily the correct performance. That is, emulation hardware may be slower, require more area, or dissipate more power than production hardware. At present, preproduction hardware commonly involves some form of **programmable logic devices** (PLDs), typically field-programmable **gate arrays** (FPGAs). PLDs provide generic combinational and sequential digital system logic that can be programmed to realize a wide variety of designs [Walters, 1991].

Emulation offers the advantage of providing prototype hardware early in the design cycle to check for errors or inconsistencies in initial functional specifications. Problems can be isolated and design modifications can be easily accommodated by reprogramming the logic devices. Emulation can support functional verification at computational rates much greater than conventional simulation. However, emulation does not generally support performance verification because, as explained above, prototype hardware typically does not operate at production clock rates.

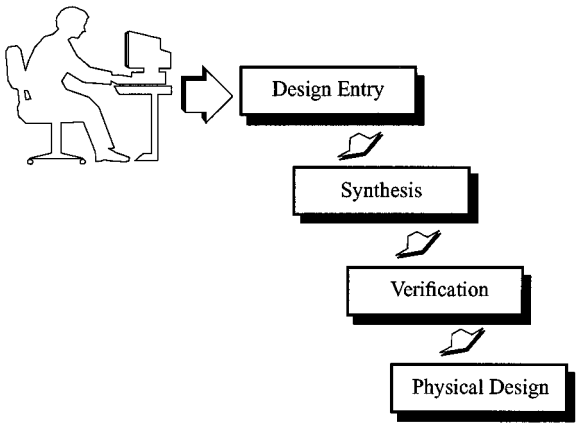

FIGURE 34.16 Design process — physical design.

34.5 Physical Design

Figure 34.16 shows that the physical design task generally follows the verification task. Having validated the function and performance of the detailed design during verification, physical design realizes the detailed design by translating logic into actual hardware. Physical design involves placement, routing, artwork generation, rules checking, and back annotation [Sait and Youseff, 1995].

Placement transforms a logical hierarchy into a physical hierarchy by defining how hardware elements are oriented and arranged relative to each other. Placement determines the overall size, i.e., area, a digital system will occupy. Two popular placement algorithms are *mincut* and *simulated annealing*. Mincut placement techniques group highly connected cells into clusters. Then, the clusters are sorted and arranged according to user-supplied priorities. Simulated annealing conducts a series of trial-and-error experiments by pseudorandomly moving cells and evaluating the resulting placements, again according to user-supplied priorities.

Routing defines the wires that establish the required port-to-port connections. Routing is often performed in two stages: global and local. Global routing assigns networks to major wiring regions, called tracks; local routing defines the actual wiring for each network within its assigned track. Two common classes of routing algorithms are *channel* and *maze*. Channel routing connects ports abutting the same track. Maze routing, also called switch-box routing, connects ports abutting different channels. Routing considers a variety of metrics, including timing skew, wire length, number of vias, and number of jogs (corners) [Spinks, 1985; Preas et al., 1988].

Rules checking verifies that the final layout of geometric shapes and their orientation complies with logical, electrical, and physical constraints. Logical rules verify that the implementation realizes the desired digital system. Electrical rules verify conformance to loading, noise margins, and fan-in/fan-out connectivity constraints. Finally, physical rules verify conformance to dimensional, spacing, and alignment constraints [Hollis, 1987].

34.6 Test

Figure 34.17 shows that **test** follows physical design. After physical design, the digital system is manufactured and test checks the resulting hardware for correct function and performance. Thus, the primary objective of test is to detect a faulty device by applying input test stimuli and observing expected results [Buckroyd, 1989; Weyerer and Goldemund, 1992].

The test task is difficult because designs are growing in complexity; more components provide more opportunity for manufacturing defects. Test is also challenged by new microelectronic fabrication processes. These new processes support higher levels of integration that provide fewer access points to probe internal electrical nodes and new failure modes that provide more opportunity for manufacturing defects.

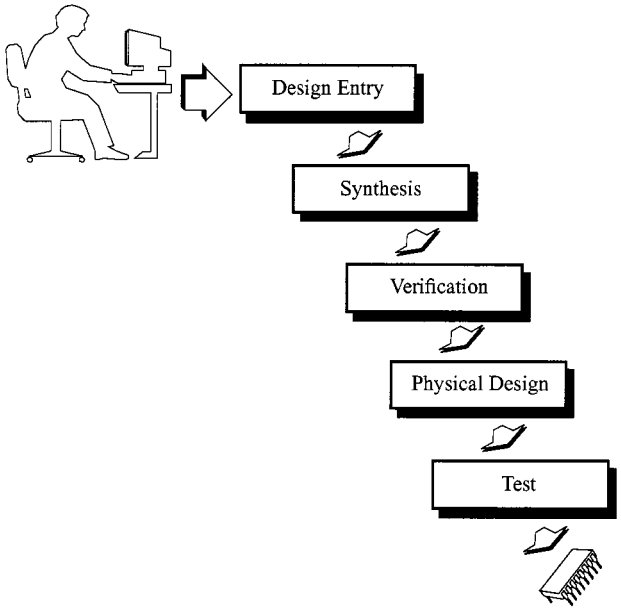

FIGURE 34.17 Design process — test.

Fault Modeling

What is a fault? A fault is a manufacturing or aging defect that causes a device to operate incorrectly or to fail. A sample listing of common integrated circuit physical faults are given below:

- Wiring faults,
- Dielectric faults,
- Threshold faults, and
- Soft faults.

Wiring faults are unwanted opens and shorts. Two wires or networks that should be electrically connected, but are not connected constitute an open. Two wires or networks that should not be electrically connected, but are connected constitute a short. Wiring faults can be caused by manufacturing defects, such as metallization and etching problems, or aging defects, such as corrosion and **electromigration**. Dielectric faults are electrical isolation defects that can be caused by **masking defects**, chemical impurities, material imperfections, or electrostatic discharge. Threshold faults occur when the turn-on and turn-off voltage potentials of electrical devices exceed allowed ranges. Soft faults occur when radiation exposure temporarily changes electrical charge distributions. Such changes can alter circuit voltage potentials, which can, in turn, change logical values, also called *dropping bits*. Radiation effects are called "soft" faults because the hardware is not permanently damaged [Zobrist, 1993].

To simplify the task of fault testing, the physical faults described above are translated into logical faults. Typically, a single logical fault covers several physical faults. A popular logical fault model is the *single stuck line* (SSL) fault model. The single stuck line fault model supports faults that denote wires permanently set to a logic 0, "stuck-at-0," or a logic 1, "stuck-at-1." Building on the single stuck line fault model, the *multiple stuck line* (MSL) fault model supports faults where multiple wires are stuck-at-0/stuck-at-1. Stuck fault models do not address all physical faults because not all physical faults result in signal lines permanently set to low or high voltages, i.e., stuck-at-0 or stuck-at-1 logic faults. Thus, other fault models have been developed to address specific failure mechanisms. For example, the *bridging* fault model addresses electrical shorts that cause unwanted coupling or spurious feedback loops.

Fault Testing

Once the physical faults that may cause device malfunction have been identified and categorized and how the physical faults relate to logical faults has been determined, the next task is to develop tests to detect these faults. When the tests are generated by a computer program, this activity is called *automatic test program generation* (ATPG). Examples of fault testing techniques are listed below:

- Stuck-at techniques,
- Scan techniques,
- Signature techniques,
- Coding techniques, and
- Electrical monitoring techniques.

Basic stuck-at fault testing techniques address combinational digital systems. Three of the most popular stuck-at fault testing techniques are the D algorithm, the Path-Oriented Decision Making (Podem) algorithm, and the Fan algorithm. These algorithms first identify a circuit fault, e.g., stuck-at-0 or stuck-at-1, and then try to generate an input stimulus that detects the fault and makes the fault visible at an output. Detecting a fault is called *fault sensitization* and making a fault visible is called *fault propagation*. To illustrate this process, consider the simple combinational design in Fig. 34.18 [Goel, 1981; Fujiwara and Shimono, 1983].

The combinational digital design is defective because a manufacturing defect has caused the output of the top **and** gate to be permanently tied to ground, i.e., stuck-at-0, using a positive logic convention. To sensitize the fault, the inputs A and B should both be set to 1, which should force the top **and** gate output to a 1 for a good circuit. To propagate the fault, the inputs C and D should both be set to 0, which should force the **xor** gate output to 1, again for a good circuit. Thus, if A = 1, B = 1, C = 0, and D = 0 in Fig. 34.18, then a good circuit would yield a 1, but the defective circuit yields a 0, which detects the stuck-at-0 fault at the top **and** gate output.

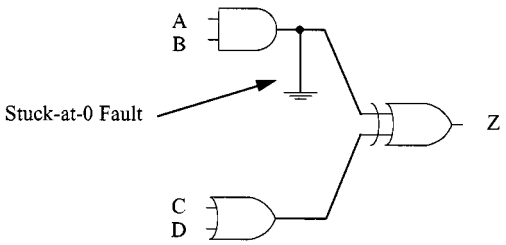

FIGURE 34.18 Combinational logic stuck-at fault testing.

Sequential ATP generation is more difficult than combinational ATPG because exercising or sensitizing a particular circuit path to detect the presence of a possible manufacturing fault may require a *sequence* of input test vectors. One technique for testing sequential digital systems is scan fault testing. Scan fault testing is an example of *design for testability* (DFT) because it modifies or constrains a design in a manner that facilitates fault testing. Scan techniques impose a logic design discipline that connects all state registers into one or more chains to form "scan rings," as shown in Fig. 34.19 [Eichelberger and Williams, 1977].

During normal device operation, the scan rings are disabled and the registers serve as conventional memory (state) storage elements. During test operation, the scan rings are enabled and stimulus test vectors are shifted into the memory elements to set the state of the digital system. The digital system is exercised for one clock cycle and then the results are shifted out of the scan ring to record the response.

A variation of scan DFT, called *boundary scan*, has been defined for testing integrated circuits on printed circuit boards (PCBs). Advancements in PCB manufacturing, such as fine-lead components, surface mount assembly, and **multichip modules**, have yielded high-density boards with fewer access points to probe individual pins. These PCBs are difficult to test. As the name implies, boundary scan imposes a design discipline for PCB components to enable the input/output pins of the components to be connected into scan chains. As an example, Fig. 34.20 shows a simple PCB containing two integrated circuits configured for boundary scan. Each integrated circuit contains scan registers between its input/output pins and its core logic to enable the PCB test bus to control and observe the behavior of individual integrated circuits [Parker, 1989].

Another DFT technique is signature analysis, also called *built-in self-test* (BIST). Signature testing techniques use additional logic, typically linear feedback shift registers, to generate automatically pseudorandom test vectors. The output responses are compressed into a single vector and compared with a known good vector. If the output response vector does not exactly match the known good vector, then the design is considered faulty.

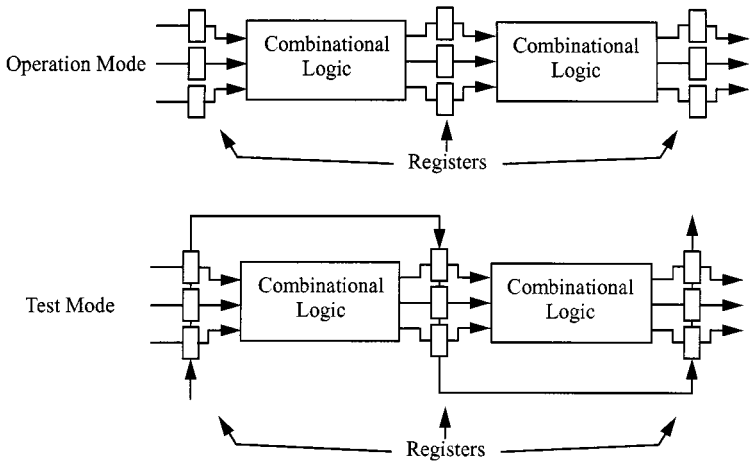

FIGURE 34.19 Scan-based DFT.

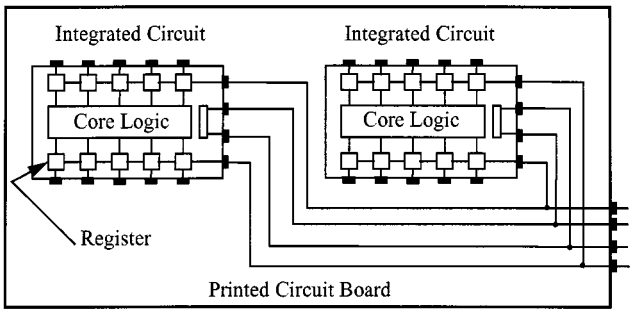

FIGURE 34.20 Boundary scan.

Matching the output response vector and a known good vector does not guarantee correct hardware; however, if enough pseudorandom test vectors are exercised, then the chances are acceptably small of obtaining a false positive result. Signature analysis is often used to test memories [Agrawal et al., 1993].

Coding test techniques encode signal information so that errors can be detected and possibly corrected. Although often implemented in software, coding techniques can also be implemented in hardware. For example, a simple coding technique called *parity checking* is often implemented in hardware. Parity checking adds an extra bit to multibit data. The parity bit is set such that the total number of logic 1s in the multibit data *and* parity bit is either an even number (even parity) or an odd number (odd parity). An error has occurred if an even-parity-encoded signal contains an odd number of logic 1s or if an odd-parity-encoded signal contains an even number of logic 1s. Coding techniques are used extensively to detect and correct transmission errors on system buses and networks, storage errors in system memory, and computational errors in processors [Peterson and Weldon, 1972].

Finally, electrical monitoring testing techniques, also called current/voltage testing, rely on the simple observation that an out-of-range current or voltage often indicates a defective or bad part. Possibly a short or open is present causing a particular input/output signal to have the wrong voltage or current. Current testing, or I_{ddq} *testing*, is particularly useful for digital systems using CMOS integrated circuit technology. Normally, CMOS circuits have very low static or quiescent currents. However, physical faults, such as **gate oxide** defects, can increase static current by several orders of magnitude. Such a substantial change in static current is straightforward to detect. The principal advantages of current testing are that the tests are simple and the fault models address detailed transistor-level defects. However, current testing requires that enough time be allotted between input stimuli to allow the circuit to reach a static state, which slows testing down and causes problems with circuits that cannot be tested at scaled clock rates.

34.7 Summary

DA technology offers the potential of serving as a powerful fulcrum in leveraging the skills of a designer against the growing demands of electronic system design and manufacturing. DA programs help to relieve the designer of the burden of tedious, repetitive tasks that can be labor-intensive and error prone.

DA technology can be broken down into several topical areas, such as design entry, synthesis, verification, physical design, and test. Each topical area has developed an extensive body of knowledge and experience.

Design entry defines a desired specification. Synthesis refines the initial design specification into a detailed design ready for implementation. Verification checks that the detailed design faithfully realizes the desired specification. Physical design defines the implementation, i.e., the actual hardware. Finally, test checks that the manufactured part is functionally and parametrically correct.

Defining Terms

Bipolar: Type of semiconductor transistor that involves both minority and majority carrier conduction mechanisms.

BiCMOS: Bipolar/complementary metal-oxide semiconductor. A logic family and form of microelectronic fabrication.

Branch: A circuit element between two nodes. Branch current is the current through the branch. Branch voltage is the potential difference between the nodes. The relationship between the branch current and voltage is defined by the branch constitutive relationship.

Capacitor: Two-terminal electronic device governed by the branch constitutive relationship, Charge = Capacitance $\times$ Voltage.

CMOS: Complementary metal-oxide semiconductor. A logic family and form of microelectronic fabrication.

Data Flow: Nonprocedural modeling style in which the textual order that statements are written has no bearing on the order in which they execute.

Design automation: Computer programs that assist engineers in performing digital system development.

Design entry: Area of DA addressing modeling analog and digital electronic systems. Design entry uses a hierarchy of models involving physical, electrical, logical, functional, and architectural abstractions.

Electromigration: Gradual erosion of metal due to excessive currents.

Fan-in/fan-out: Fan-in defines the maximum number of logic elements that may drive another logic element. Fan-out defines the maximum number of logic elements a logic element may drive.

Finite state machine: Sequential digital system. A finite state machine is classified as either Moore and Mealy.

Gate array: Application-specific integrated circuit implementation technique that realizes a digital system by programming the metal interconnect of a prefabricated array of gates.

Gate oxide: Dielectric insulating material between the gate and source/drain terminals of a MOS transistor.

Ground bounce: Transient condition when the potential of a ground network varies appreciably from its uniform static value.

Integrated circuit: Electronic circuit manufactured on a monolithic piece of semiconductor material, typically silicon.

Kirchoff's current law: The amount of current entering a circuit node equals the amount of current leaving a circuit node.

Kirchoff's voltage law: Any closed loop of circuit branch voltages sums to zero.

Masking defects: Defects in masking plate patterns used for integrated circuit lithography that result in errant material composition and/or placement.

Multichip modules: Multiple integrated circuits interconnected on a monolithic substrate.

Netlist: Collection of wires that are electrically connected to each other.

NMOS: N-type metal-oxide semiconductor. A logic family and form of microelectronic fabrication.

Node voltage: Potential of a circuit node relative to ground potential.

Programmable logic devices (PLDs): Generic logic devices that can be programmed to realize specific digital systems. PLDs include programmable logic arrays, programmable array logic, memories, and field-programmable gate arrays.

Resistor: Two-terminal electronic device governed by the branch constitutive relationship, Voltage = Resistance × Current.

Silicon compilation: Synthesis application that generates final physical design ready for silicon fabrication.

Simulation: Computer program that examines the dynamic semantics of a model of a digital system by applying a series of inputs and generating the corresponding outputs. Major types of simulation include schedule driven, cycle driven, and message driven.

Skew: Timing difference between two events that are supposed to occur simultaneously.

Standard cell: Application-specific integrated circuit implementation technique that realizes a digital system using a library of predefined (standard) logic cells.

Synthesis: Computer program that helps generate a digital/analog system design by transforming a high-level model of abstract behavior into a lower-level model of more-detailed behavior.

Test: Area of EDA that addresses detecting faulty hardware. Test involves stuck-at, scan, signature, coding, and monitoring techniques.

Timing analysis: Verifies timing behavior of electronic system including rise time, fall time, setup time, hold time, glitch detection, clock periods, race conditions, reflections, and cross talk.

Transistor: Electronic device that enables a small voltage and/or current to control a larger voltage and/or current. For analog systems, transistors serves as amplifiers. For digital systems, transistors serve as switches.

Verification: Area of EDA that addresses validating designs for correct function and expected performance. Verification involves timing analysis, simulation, emulation, and formal proofs.

VHDL: Hardware description language used as an international standard for communicating electronic systems information.

Via: Connection or contact between two materials that are otherwise electrically isolated.

High power gyrotron from CPI. The 110-GHz gyrotron is the current world record holder for high frequency power generation. This gyrotron is used in electron cyclotron resonance heating (ECRH) by producing extremely high frequencies of microwaves which heat a hydrogen gas — "plasma" — to very high levels in experimental fusion reactors.

In the photo, the lower section is the electron gun region that generates extremely high-powered electron beam. Shown in the middle section of the gyrotron is an interactive window. The produced microwave power is transformed into a microwave beam that then passes through the high power interaction window. The large upper section is a fully instrumented collector of the "spent" electron beam. (Photo courtesy of Communications & Power Industries.)

ELECTRIC AND MAGNETIC FORCES are among the five original forces in the universe. These forces are important as we are affected by them almost every instant. Electromagnetics is the combined effect of electric and magnetic fields. Today's scientific development to a great extent is based on the electromagnetic fields, their propagation, and varying effects under different boundary conditions. Very few subjects are understood as thoroughly as electromagnetics and have such wide applications. Electricity, telephones, radio, television, datalinks, medical electronics, radar, remote sensing, etc.—all have considerable impact on human life. Now that impact is being carried out further with optical fiber technology, which is also based on the concept of electromagnetic wave propagation. All of human society has been revolutionized by electromagnetics, but still our understanding is not complete. As H.G. Wells once wrote, and this is still true, "The past is but a beginning of a beginning, and all that is and has been is but the twilight of the dawn."

This section focuses on the basic electromagnetic field concepts, wave propagation, devices, circuits, and other applications. The electric fields which are produced by stationary or moving charges are described in Chapter 35. Maxwell's equations and their solutions under different boundary conditions help in determining the electric field components and resulting effects. The next chapter describes the magnetic fields and magnetic effects due to moving charges or current. These magnetic fields are also governed by Maxwell's equations and their solutions are obtained for different boundary conditions. Particular magnetic materials with an assemblage of ferromagnetic particles in a nonferromagnetic matrix are useful as audio or video tapes. This subject is investigated in Chapter 36 to provide insight into the recording mechanism of the music we hear all the time. The time-varying electromagnetic field propagation in space or in transmission lines provides the concept of radio communication as discussed in Chapter 37. Another article in the chapter analyzes the transmission of energy through waveguides and microstriplines. Microstriplines have become the basic building blocks for microwave integrated circuits (MICS). For the propagation of electromagnetic fields in space, properly matched antennas between generator and space are required, as described in Chapter 38. Wire and aperture antennas are also described.

The high-frequency or microwave-frequency electromagnetic field concepts are helpful in studying the microwave devices as discussed in Chapter 39. The electromagnetic compatibility (EMC) study in the following chapter is important for proper functioning of microwave devices and circuits. The important application of electromagnetic radiation in the form of radar, discussed in Chapter 41, is useful not only for defense but in remote sensing and weather forecasting also. The next chapter explains the propagation of light through waveguides and optical fibers/cables. Optical fiber technology is an emerging technology and is affecting every facet of human life. Microwave circuits are the practical realization of electromagnetic field concepts and are discussed in Chapter 42. With the arrival of sophisticated software packages and high-speed computers, now it is possible and worthwhile to do 3-D analysis and computer modeling of electromagnetic fields in the circuits or devices, as discussed in the last two chapters of this section. This is helpful in the accurate design of microwave components and circuits. All the topics mentioned in this introduction are discussed in detail in their respective chapters.

Nomenclature

Symbol	Quantity	Unit
A_e	actual effective aperture of antenna	m^2
A_{em}	maximum effective aperture of antenna	m^2
α	attenuation constant	neper/m
b	Doppler filter bandwidth	Hz
B	magnetic flux density	Wb/m^2
β	phase constant	rad/m
c	velocity of light in vacuum	2.998×10^8 m/s
D	electric displacement	C/m^2
D	divergent factor	
D	directivity of antenna	dB
δ	penetrating depth	m
E	electric field intensity	V/m
ϵ	permittivity	F/m
ϵ_0	8.854×10^{-12}	F/m
f_D	Doppler frequency	Hz
F	receiver noise figure	dB
g_m	transconductance	S
G	gain of antenna	dB
γ	propagation constant	m^{-1}
Γ	Fresnel reflection coefficient	
H	magnetic field intensity	A/m
η	intrinsic impedance	Ω
J	electric current density	A/m^2
J	electric charge density	C/m^2
k	wavenumber	
k	radiation efficiency factor	
L	antenna loss	dB
λ	wavelength	m
μ	permeability	H/m
μ_0	$4\pi \times 10^{-7}$	H/m
P	Poynting vector	W/m^2
P_T	average power	W
Ψ	grazing angle	degree
q	electronic charge	1.6×10^{-19} C
R	detection range of target	m
ρ_s	roughness coefficient	
$S(\theta)$	shadowing function	
U	unilateral power gain	dB

35.1 Maxwell Equations[1]

The fundamental equations of electromagnetic theory were established by James Clerk Maxwell in 1873. In three-dimensional vector notation, the Maxwell equations are

$$\nabla \times \bar{E}(\bar{r},t) + \frac{\partial}{\partial t}\bar{B}(\bar{r},t) = 0 \tag{35.1}$$

$$\nabla \times \bar{H}(\bar{r},t) - \frac{\partial}{\partial t}\bar{D}(\bar{r},t) = \bar{J}(\bar{r},t) \tag{35.2}$$

$$\nabla \cdot \bar{B}(\bar{r},t) = 0 \tag{35.3}$$

$$\nabla \cdot \bar{D}(\bar{r},t) = \rho(\bar{r},t) \tag{35.4}$$

where $\bar{E}$, $\bar{B}$, $\bar{H}$, $\bar{D}$, $\bar{J}$, and ρ are real functions of position and time.

$$\begin{aligned}
\bar{E}(\bar{r},t) &= \text{electric field strength} && (\text{volts/m}) \\
\bar{B}(\bar{r},t) &= \text{magnetic flux density} && (\text{webers/m}^2) \\
\bar{H}(\bar{r},t) &= \text{magnetic field strength} && (\text{amperes/m}) \\
\bar{D}(\bar{r},t) &= \text{electric displacement} && (\text{coulombs/m}^2) \\
\bar{J}(\bar{r},t) &= \text{electric current density} && (\text{amperes/m}^2) \\
\rho(\bar{r},t) &= \text{electric charge density} && (\text{coulombs/m}^3)
\end{aligned}$$

[1]This chapter is an abridged version of Chapter 1 in *Electromagnetic Wave Theory* (J. A. Kong), New York: Wiley-Interscience, 1990.

Equation (35.1) is Faraday's induction law. Equation (35.2) is the generalized Ampere's circuit law. Equations (35.3) and (35.4) are Gauss' laws for **magnetic and electric fields.** Taking the divergence of (35.2) and introducing (35.4), we find that

$$\nabla \cdot \bar{J}(\bar{r},t) + \frac{\partial}{\partial t}\rho(\bar{r},t) = 0 \tag{35.5}$$

This is the conservation law for electric charge and current densities. Regarding (35.5) as a fundamental equation, we can use it to derive (35.4) by taking the divergence of (35.2). Equation (35.3) can also be derived by taking the divergence of (35.1) which gives $\partial(\nabla \cdot \bar{B}(\bar{r},t))/\partial t = 0$ or that $\nabla \cdot \bar{B}(\bar{r},t)$ is a constant independent of time. Such a constant, if not zero, then implies the existence of magnetic monopoles similar to free electric charges. Since magnetic monopoles have not been found to exist, this constant must be zero and we arrive at (35.3).

35.2 Constitutive Relations

The Maxwell equations are fundamental laws governing the behavior of electromagnetic fields in free space and in media. We have so far made no reference to the various material properties that provide connections to other disciplines of physics, such as plasma physics, continuum mechanics, solid-state physics, fluid dynamics, statistical physics, thermodynamics, biophysics, etc., all of which interact in one way or another with electromagnetic fields. We did not even mention the Lorentz force law, which constitutes a direct link to mechanics. It is time to state how we are going to account for this vast "outside" world. From the electromagnetic wave point of view, we shall be interested in how electromagnetic fields behave in the presence of media, whether the wave is diffracted, refracted, or scattered. Whatever happens to a medium, whether it is moved or deformed, is of secondary interest. Thus we shall characterize material media by the so-called constitutive relations that can be classified according to the various properties of the media.

The necessity of using constitutive relations to supplement the Maxwell equations is clear from the following mathematical observations. In most problems we shall assume that sources of electromagnetic fields are given. Thus $\bar{J}$ and ρ are known and they satisfy the conservation law (35.5). Let us examine the Maxwell equations and see if there are enough equations for the number of unknown quantities. There are a total of 12 scalar unknowns for the four field vectors $\bar{E}$, $\bar{H}$, $\bar{B}$, and $\bar{D}$. As we have learned, Eqs. (35.3) and (35.4) are not independent equations; they can be derived from Eqs. (35.1), (35.2), and (35.5). The independent equations are Eqs. (35.1) and (35.2), which constitute six scalar equations. Thus we need six more scalar equations. These are the constitutive relations.

The constitutive relations for an isotropic medium can be written simply as

$$\bar{D} = \epsilon\bar{E} \qquad \text{where } \epsilon = \text{permittivity} \tag{35.6a}$$

$$\bar{B} = \mu\bar{H} \qquad \text{where } \mu = \text{permittivity} \tag{35.6b}$$

By isotropy we mean that the field vector $\bar{E}$ is parallel to $\bar{D}$ and the field vector $\bar{H}$ is parallel to $\bar{B}$. In free space void of any matter, $\mu = \mu_o$ and $\epsilon = \epsilon_o$,

$$\mu_o = 4\pi \times 10^{-7} \qquad \text{henry/meter}$$

$$\epsilon_o \approx 8.85 \times 10^{-12} \qquad \text{farad/meter}$$

Inside a material medium, the permittivity ϵ is determined by the electrical properties of the medium and the permeability μ by the magnetic properties of the medium.

A dielectric material can be described by a free-space part and a part that is due to the material alone. The material part can be characterized by a polarization vector $\bar{P}$ such that $\bar{D} = \epsilon_o \bar{E} + \bar{P}$. The polarization $\bar{P}$ symbolizes the electric dipole moment per unit volume of the dielectric material. In the presence of an external electric field, the polarization vector may be caused by induced dipole moments, alignment of the permanent dipole moments of the medium, or migration of ionic charges.

A magnetic material can also be described by a free-space part and a part characterized by a magnetization vector $\bar{M}$ such that $\bar{B} = \mu_o \bar{H} + \mu_o \bar{M}$. A medium is diamagnetic if $\mu \leq \mu_o$ and paramagnetic if $\mu \geq \mu_o$. Diamagnetism is caused by induced magnetic moments that tend to oppose the externally applied magnetic field. Paramagnetism is due to alignment of magnetic moments. When placed in an inhomogeneous magnetic field, a diamagnetic material tends to move toward regions of weaker magnetic field and a paramagnetic material toward regions of stronger magnetic field. Ferromagnetism and antiferromagnetism are highly nonlinear effects. Ferromagnetic substances are characterized by spontaneous magnetization below the Curie temperature. The medium also depends on the history of applied fields, and in many instances the magnetization curve forms a hysteresis loop. In an antiferromagnetic material, the spins form sublattices that become spontaneously magnetized in an antiparallel arrangement below the Néel temperature.

Anisotropic and Bianisotropic Media

The constitutive relations for anisotropic media are usually written as

$$\bar{D} = \bar{\bar{\epsilon}} \cdot \bar{E} \quad \text{where } \bar{\bar{\epsilon}} = \text{permittivity tensor} \tag{35.7a}$$

$$\bar{B} = \bar{\bar{\mu}} \cdot \bar{H} \quad \text{where } \bar{\bar{\mu}} = \text{permeability tensor} \tag{35.7b}$$

The field vector $\bar{E}$ is no longer parallel to $\bar{D}$, and the field vector $\bar{H}$ is no longer parallel to $\bar{B}$. A medium is *electrically anisotropic* if it is described by the permittivity tensor $\bar{\bar{\epsilon}}$ and a scalar permeability μ, and *magnetically anisotropic* if it is described by the permeability tensor $\bar{\bar{\mu}}$ and a scalar permittivity ϵ. Note that a medium can be both electrically and magnetically anisotropic as described by both $\bar{\bar{\epsilon}}$ and $\bar{\bar{\mu}}$ in Eq. (35.7).

Crystals are described in general by symmetric permittivity tensors. There always exists a coordinate transformation that transforms a symmetric matrix into a diagonal matrix. In this coordinate system, called the *principal system,*

$$\bar{\bar{\epsilon}} = \begin{bmatrix} \epsilon_x & 0 & 0 \\ 0 & \epsilon_y & 0 \\ 0 & 0 & \epsilon_z \end{bmatrix} \tag{35.8}$$

The three coordinate axes are referred to as the principal axes of the crystal. For cubic crystals, ϵ_x $\bar{\bar{\epsilon}}_y$ $\bar{\bar{\epsilon}}_z$ and they are isotropic. In tetragonal, hexagonal, and rhombohedral crystals, two of the three parameters are equal. Such crystals are *uniaxial.* Here there is a two-dimensional degeneracy; the principal axis that exhibits this anisotropy is called the optic axis. For a uniaxial crystal with

$$\bar{\bar{\epsilon}} = \begin{bmatrix} \epsilon & 0 & 0 \\ 0 & \epsilon & 0 \\ 0 & 0 & \epsilon_z \end{bmatrix} \tag{35.9}$$

the z axis is the optic axis. The crystal is *positive uniaxial* if $\epsilon_z > \epsilon$; it is *negative uniaxial* if $\epsilon_z < \epsilon$. In orthorhombic, monoclinic, and triclinic crystals, all three crystallographic axes are unequal. We have $\epsilon_x \neq \epsilon_y \neq \epsilon_z$, and the medium is *biaxial.*

For isotropic or anisotropic media, the constitutive relations relate the two electric field vectors and the two magnetic field vectors by either a scalar or a tensor. Such media become polarized when placed in an electric field and become magnetized when placed in a magnetic field. A bianisotropic medium provides the cross coupling between the electric and magnetic fields. The constitutive relations for a bianisotropic medium can be written as

$$\overline{D} = \overline{\overline{\epsilon}} \cdot \overline{E} + \overline{\overline{\xi}} \cdot \overline{H} \tag{35.10a}$$

$$\overline{B} = \overline{\overline{\zeta}} \cdot \overline{E} + \overline{\overline{\epsilon}} \cdot \overline{H} \tag{35.10b}$$

When placed in an electric or a magnetic field, a bianisotropic medium becomes both polarized and magnetized.

Magnetoelectric materials, theoretically predicted by Dzyaloshinskii and by Landau and Lifshitz, were observed experimentally in 1960 by Astrov in antiferromagnetic chromium oxide. The constitutive relations that Dzyaloshinskii proposed for chromium oxide have the following form:

$$\overline{D} = \begin{bmatrix} \epsilon & 0 & 0 \\ 0 & \epsilon & 0 \\ 0 & 0 & \epsilon_z \end{bmatrix} \cdot \overline{E} + \begin{bmatrix} \xi & 0 & 0 \\ 0 & \xi & 0 \\ 0 & 0 & \xi_z \end{bmatrix} \cdot \overline{H} \tag{35.11a}$$

$$\overline{B} = \begin{bmatrix} \xi & 0 & 0 \\ 0 & \xi & 0 \\ 0 & 0 & \xi_z \end{bmatrix} \cdot \overline{E} + \begin{bmatrix} \mu & 0 & 0 \\ 0 & \mu & 0 \\ 0 & 0 & \mu_z \end{bmatrix} \cdot \overline{H} \tag{35.11b}$$

It was then shown by Indenbom and by Birss that 58 magnetic crystal classes can exhibit the magnetoelectric effect. Rado proved that the effect is not restricted to antiferromagnetics; ferromagnetic gallium iron oxide is also magnetoelectric.

Biisotropic Media

In 1948, the gyrator was introduced by Tellegen as a new element, in addition to the resistor, the capacitor, the inductor, and the ideal transformer, for describing a network. To realize his new network element, Tellegen conceived of a medium possessing constitutive relations of the form

$$\overline{D} = \epsilon\overline{E} + \xi\overline{H} \tag{35.12a}$$

$$\overline{B} = \xi\overline{E} + \mu\overline{H} \tag{35.12b}$$

where $\xi^2/\mu\epsilon$ is nearly equal to 1. Tellegen considered that the model of the medium had elements possessing permanent electric and magnetic dipoles parallel or antiparallel to each other, so that an applied electric field that aligns the electric dipoles simultaneously aligns the magnetic dipoles, and a magnetic field that aligns the magnetic dipoles simultaneously aligns the electric dipoles. Tellegen also wrote general constitutive relations Eq. (35.10) and examined the symmetry properties by energy conservation.

Chiral media, which include many classes of sugar solutions, amino acids, DNA, and natural substances, have the following constitutive relations

$$\overline{D} = \epsilon \overline{E} - \chi \frac{\partial \overline{H}}{\partial t} \tag{35.13a}$$

$$\overline{B} = \mu \overline{H} + \chi \frac{\partial \overline{E}}{\partial t} \tag{35.13b}$$

where χ is the chiral parameter. Media characterized by the constitutive relations, Eqs. (35.12) and (35.13), are biisotropic media.

Media in motion were the first bianisotropic media to receive attention in electromagnetic theory. In 1888, Roentgen discovered that a moving dielectric becomes magnetized when it is placed in an electric field. In 1905, Wilson showed that a moving dielectric in a uniform magnetic field becomes electrically polarized. Almost any medium becomes bianisotropic when it is in motion.

The bianisotropic description of material has fundamental importance from the point of view of relativity. The principle of relativity postulates that all physical laws of nature must be characterized by mathematical equations that are form-invariant from one observer to the other. For electromagnetic theory, the Maxwell equations are form-invariant with respect to all observers, although the numerical values of the field quantities may vary from one observer to another. The constitutive relations are form-invariant when they are written in bianisotropic form.

Constitutive Matrices

Constitutive relations in the most general form can be written as

$$c\overline{D} = \overline{\overline{P}} \cdot \overline{E} + \overline{\overline{L}} \cdot c\overline{B} \tag{35.14a}$$

$$\overline{H} = \overline{\overline{M}} \cdot \overline{E} + \overline{\overline{Q}} \cdot c\overline{B} \tag{35.14b}$$

where $c = 3 \times 10^8$ m/s is the velocity of light in vacuum, and $\overline{\overline{P}}$, $\overline{\overline{Q}}$, $\overline{\overline{L}}$, and $\overline{\overline{M}}$ are all 3×3 matrices. Their elements are called *constitutive parameters*. In the definition of the constitutive relations, the constitutive matrices $\overline{\overline{L}}$ and $\overline{\overline{M}}$ relate electric and magnetic fields. When $\overline{\overline{L}}$ and $\overline{\overline{M}}$ are not identically zero, the medium is *bianisotropic*. When there is no coupling between electric and magnetic fields, $\overline{\overline{L}} = \overline{\overline{M}} = 0$ and the medium is *anisotropic*. For an anisotropic medium, if $\overline{\overline{P}} = c\epsilon \overline{\overline{I}}$ and $= Q = (1/c\mu)\ \overline{\overline{I}}$ with $\overline{\overline{I}}$ denoting the 3×3 unit matrix, the medium is *isotropic*. The reason that we write constitutive relations in the present form is based on relativistic considerations. First, the fields $\overline{E}$ and $c\,\overline{B}$ form a single tensor in four-dimensional space, and so do $c\overline{D}$ and $\overline{H}$. Second, constitutive relations written in the form Eq. (35.14) are Lorentz-covariant.

Equation (35.14) can be rewritten in the form

$$\begin{bmatrix} c\overline{D} \\ \overline{H} \end{bmatrix} = \overline{\overline{C}} \cdot \begin{bmatrix} \overline{E} \\ c\overline{B} \end{bmatrix} \tag{35.15a}$$

and $\overline{\overline{C}}$ is a 6×6 constitutive matrix:

$$\overline{\overline{C}} = \begin{bmatrix} \overline{\overline{P}} & \overline{\overline{L}} \\ \overline{\overline{M}} & \overline{\overline{Q}} \end{bmatrix} \tag{35.15b}$$

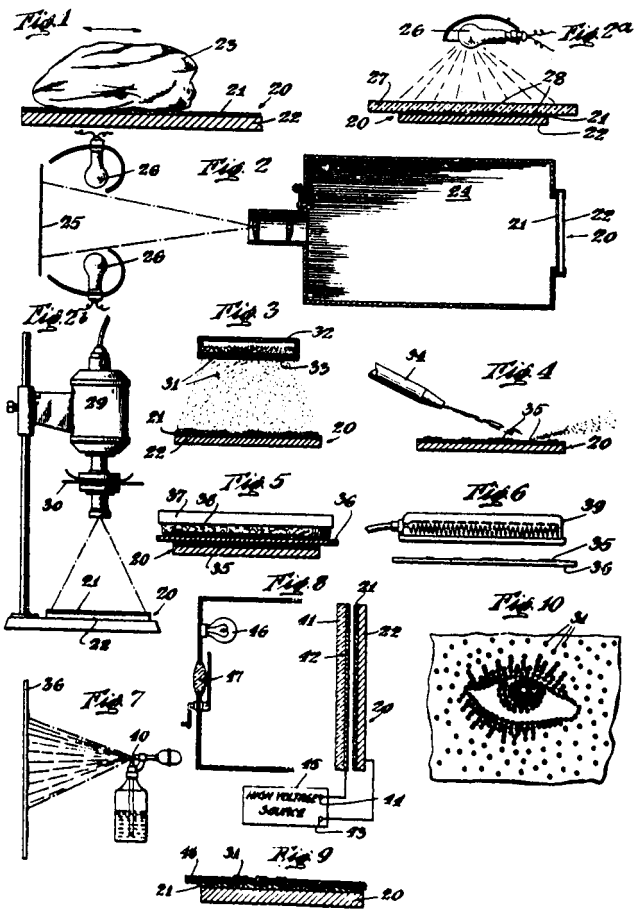
which has the dimension of admittance.

ELECTROPHOTOGRAPHY

Chester F. Carlson
Patented October 6, 1942
#2,297,691

An excerpt from Chester Carlson's patent application:

A feature of the present invention resides in the use of photoelectric or photoconductive materials for photographic purposes. In its preferred form the invention involves the use of materials which are insulators in the dark but become partial conductors when illuminated. These materials respond to light, being slightly conductive whenever they are illuminated and again becoming insulating when the light is cut off. They can be called photoconductive insulating materials.



Working in the patent department at the P.R. Mallory Company in the 1930s, Carlson became frustrated trying to obtain copies of patent drawings and specifications. Unlike others attempting chemical photographic methods, he used the principles of electrostatics to produce his first dry copy in 1938. A photoconductive plate connected to an electric charge was exposed to the desired image. The plate retained the electric charge on the dark areas of the image and lost it on the white areas. Dusting the plate with a powder reproduced the image. Xerox Corporation negotiated rights to the process in 1947 and introduced its first office copier in 1968.

The constitutive matrix $\overline{\overline{C}}$ may be functions of space–time coordinates, thermodynamical and continuum-mechanical variables, or electromagnetic field strengths. According to the functional dependence of $\overline{\overline{C}}$, we can classify the various media as (1) inhomogeneous if $\overline{\overline{C}}$ is a function of space coordinates, (2) nonstationary if $\overline{\overline{C}}$ is a function of time, (3) time-dispersive if $\overline{\overline{C}}$ is a function of time derivatives, (4) spatial-dispersive if $\overline{\overline{C}}$ is a function of spatial derivatives, (5) nonlinear if $\overline{\overline{C}}$ is a function of the electromagnetic field, and so forth. In the general case $\overline{\overline{C}}$ may be a function of integral-differential operators and coupled to fundamental equations of other physical disciplines.

35.3 Wave Equations and Wave Solutions

The Maxwell equations in differential form are valid at all times for every point in space. First we shall investigate solutions to the Maxwell equations in regions void of source, namely, in regions where $\overline{J} = \rho = 0$. This, of course, does not mean that there is no source anywhere in all space. Sources must exist outside the regions of interest in order to produce fields in these regions. From the source-free Maxwell equations, a wave equation for the electric field $\overline{E}$ can be easily derived for isotropic permittivity ϵ and permeability μ

$$\nabla^2 \overline{E} - \mu\epsilon \frac{\partial^2}{\partial t^2} \overline{E} = 0 \tag{35.16}$$

The Laplacian operator ∇^2 in a rectangular coordinate system is

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

The wave Eq. (35.16) is a second-order partial differential equation of space and time coordinates *x*, *y*, *z*, and *t*.

Wave Solution

The simplest solution to Eq. (35.16) for the electric field $\overline{E}$ is

$$\overline{E} = \hat{x} E_0 \cos(kz - \omega t) = \hat{x} E_x(z, t) \tag{35.17}$$

Substituting Eqs. (35.17) in (35.16) we find that the following equation, called the dispersion relation, which relates ω and k, must be satisfied:

$$k^2 = \omega^2 \mu\epsilon \tag{35.18}$$

There are two points of view useful in the study of a space–time varying quantity such as $E_x(z,t)$. The first is to examine the time variation at fixed points in space. The second is to examine spatial variation at fixed times, a process that amounts to taking a series of pictures.

We first fix our attention to one particular point in space, say $z = 0$. We then have the electric vector $E_x(z,t) = E_0 \cos \omega t$. Plotted as a function of time, we find that the waveform repeats itself in time as $\omega t = 2m\pi$ for any integer m. The period is defined as the time T for which $\omega T = 2\pi$. The frequency f is defined as $f = 1/T$ which gives

$$f = \frac{\omega}{2\pi}$$

Since $\omega = 2\pi f$, ω is the angular frequency of the wave.

To examine wave behavior from the other point of view, we let $\omega t = 0$ and plot $E_x(z,t)$. The waveform repeats itself in space when $kz = 2m\pi$ for integer values of m. The wavelength λ is defined as the distance for which $k\lambda = 2\pi$. Thus $\lambda = 2\pi/k$, or

$$k = \frac{2\pi}{\lambda}$$

We call k the wavenumber which is equal to the number of wavelengths in a distance of 2π and has the dimension inverse length.

Wave Vector $\bar{k}$

The solution for the electric field $\bar{E}$ in Eq. (35.17) represents an electromagnetic wave propagating in the $\hat{z}$-direction. For a wave propagating in a general direction, we define a wave vector

$$\bar{k} = \hat{x}k_x + \hat{y}k_y + \hat{z}k_z \tag{35.19}$$

It is easily verified that the electric field

$$\bar{E}(\bar{r},t) = \bar{E}_0 \cos(k_x x + k_y y + k_z z - \omega t) \tag{35.20}$$

is a solution to Eq. (35.16), where $\bar{E}_0$ is a constant vector.

The dispersion relation corresponding to Eq. (35.18) is obtained by substituting Eq. (35.20) in Eq. (35.16) which yields

$$k_x^2 + k_y^2 + k_z^2 = \omega^2\mu\epsilon$$

We may write the solution, Eq. (35.20), in the following form:

$$\bar{E}(\bar{r}, t) = \bar{E}_0 \cos(\bar{k} \cdot \bar{r} - \omega t)$$

where

$$\bar{r} = \hat{x}x + \hat{y}y + \hat{x}x$$

is a position vector. The wave vector $\bar{k}$ is often referred to simply as the $\bar{k}$ vector.

Wavenumbers k

The wavenumber k is the magnitude of the wave vector $\bar{k}$ and is of more fundamental importance in electromagnetic wave theory than both of the more popular concepts of wavelength λ and frequency f. In Fig. 35.1, we illustrate the electromagnetic wave spectrum according to the free space wavenumber $k = k_o = \omega/c$. The corresponding values of frequency and wavelength are $f = ck_o/2\pi$ and $\lambda = 2\pi/k_o$. It is useful to define a fundamental unit K_o such that for free space $k_o = 1\mathrm{K}_o = 2\pi\ \mathrm{m}^{-1}$. Thus $k_o = A\ \mathrm{K}_o$ corresponds to $\lambda = 1/A$ m and $f = 3 \times 10^8\ A$ Hz. The photon energy in electronvolts is calculated from $\hbar\omega = \hbar ck$ where $\hbar = 1.05 \times 10^{-34}$ Joule-sec is Planck's constant divided by 2π and the electron charge is $q = 1.6 \times 10^{-19}$ C. Thus $\hbar\omega = (2\pi\hbar c/q)k_o \approx 1.26 \times 10^{-6}\ k_o$ and $k_o = A\ \mathrm{K}_o$ corresponds to $1.26 \times 10^{-6}\ A$ eV.

Defining Terms

Electric field: State of a region in which charged bodies are subject to forces by virtue of their charge, the force acting on a unit positive charge.

Magnetic field: State produced by electric charge in motion and evidenced by a force exerted on a moving charge in the field.

Magnetic flux: Summation obtained by integrating flux density over an area.

Magnetic flux density: Measure of the strength and direction of a magnetic field at a point.

36.1 Magnetism

Geoffrey Bate

Static Magnetic Fields

To understand the phenomenon of magnetism we must also consider electricity and vice versa. A stationary electric charge produces, at a point a fixed distance from the charge, a static (i.e., time-invariant) electric field. A moving electric charge, i.e., a current, produces at the same point a time-dependent electric field and a magnetic field, d**H**, whose magnitude is constant if the electric current, I, represented by the moving electric charge, is constant.

Fields from Constant Currents

Figure 36.1 shows that the direction of the magnetic field is perpendicular both to the current I and to the line, **R**, from the element d**L** of the current to a point, P, where the magnetic field, d**H**, is being calculated or measured.

$$\mathrm{d}\mathbf{H} = I\,\mathrm{d}\mathbf{L} \times \mathbf{R}/4\pi R^3 \quad \text{A/m when I is in amps and d}\mathbf{L}\text{ and } R \text{ are in meters}$$

If the thumb of the right hand points in the direction of the current, then the fingers of the hand curl in the direction of the magnetic field. Thus, the stream lines of H, i.e., the lines representing at any point the direction of the H field, will be an infinite set of circles having the current as center. The magnitude of the field $H_\phi = I/2\pi R$ A/m. The line integral of H about any closed path around the current is $\oint \mathbf{H} \cdot \mathrm{d}\mathbf{L} = I$. This relationship (known as Ampère's circuital law) allows one to find formulas for the magnetic field strength for a variety of symmetrical coil geometries, e.g.,

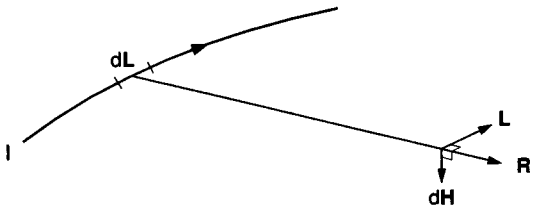

FIGURE 36.1 A current I flowing through a small segment d**L** of a wire produces at a distance **R** a magnetic field whose direction d**H** is perpendicular both to **R** and d**L**.

1. At a radius, ρ, between the conductors of a coaxial cable

$$H_\phi = I/2\pi\rho \text{ A/m}$$

2. Between two infinite current sheets in which the current, **K**, flows in opposite directions

$$\mathbf{H} = \mathbf{K} \times \mathbf{a}_n$$

   where $\mathbf{a}_n$ is the unit vector normal to the current sheets
3. Inside an infinitely long, straight solenoid of diameter d, having N turns closely wound

$$\mathbf{H} = NI/d \text{ A/m}$$

4. Well inside a toroid of radius ρ, having N closely wound turns

$$\mathbf{H} = NI/2\pi\rho \cdot \mathbf{a}_\phi \text{ A/m}$$

Applying Stokes' theorem to Ampère's circuital law we find the point form of the latter.

$$\nabla \times \mathbf{H} = \mathbf{J}$$

where **J** is the current density in amps per square meter.

Time-Dependent Electric and Magnetic Fields

A constant current I produces a constant magnetic field **H** which, in turn, polarizes the medium containing **H**. While we cannot obtain isolated magnetic poles, it is possible to separate the "poles" by a small distance to create a magnetic dipole (i.e., to *polarize* the medium), and the dipole moment (the product of the pole strength and the separation of the poles) per unit volume is defined as the *magnetization M*. The units are emu/cc in the cgs system and amps per meter in the SI system of units. Because it is usually easier to determine the mass of a sample than to determine its volume, we also have a magnetization per unit mass, σ, whose units are emu/g or Am^2/kg. The conversion factors between cgs and SI units in magnetism are shown in Table 36.1.

The effects of the static and time-varying currents may be summarized as follows:

Static	$[\mathbf{I}]_o \rightarrow [\mathbf{H}]_o \rightarrow [\mathbf{M}]_o$
	↙ motion
Time-varying	$[\mathbf{I}]_t \rightarrow [\mathbf{H}]_t \rightarrow [\mathbf{M}]_t$

where the suffixes "o" and "t" signify *static* and *time-dependent*, respectively.

TABLE 36.1 Units in Magnetism

Quality	Symbol	cgs Units	×	Factor	=	SI units
		$B = H + 4\pi M$				$B = \mu_o(H + M)$
Magnetic flux density	B	gauss (G)	×	10^{-4}	=	tesla (T), Wb/m^2
Magnetic flux	Φ	maxwell (Mx) G · cm^2	×	10^{-8}	=	webers (Wb)
Magnetic potential difference (magnetomotive force)	U	gilbert (Gb)	×	$10/4\pi$	=	ampere (A)
Magnetic field strength	H	oersted (Oe)	×	$10^3/4\pi$	=	A/m
Magnetization (per volume)	M	emu/cc	×	10^3	=	A · m
Magnetization (per mass)	σ	emu/g	×	1	=	A · m^2/kg
Magnetic moment	m	emu	×	10^{-3}	=	A · m^2
Susceptibility (volume)	χ	dimensionless	×	4π	=	dimensionless
Susceptibility (mass)	κ	dimensionless	×	4π	=	dimensionless
Permeability (vacuum)	μ_o	dimensionless	×	$4\pi.10^{-7}$	=	Wb/A · m
Permeability (material)	μ	dimensionless	×	$4\pi.10^{-7}$	=	Wb/A · m
Bohr magneton	μ_B	$= 0.927 \times 10^{-20}$ erg/Oe	×	10^{-3}	=	Am^2
Demagnetizing factor	N	dimensionless	×	$1/4\pi$	=	dimensionless

Magnetic Flux Density

In the case of electric fields there is in addition to **E** an electric flux density field **D,** the lines of which begin on positive charges and end on negative charges. D is measured in coulombs per square meter and is associated with the electric field **E** (V/m) by the relation $\mathbf{D} = \epsilon_r\epsilon_o\mathbf{E}$ where ϵ_o is the *permittivity* of free space ($\epsilon_o = 8.854 \times 10^{-12}$ F/m) and ϵ_r is the (dimensionless) dielectric constant.

For magnetic fields there is a magnetic flux density $\mathbf{B}(\text{Wb/m}^2) = \mu_r\mu_o\mathbf{H}$, where μ_o is the *permeability* of free space ($\mu_o = 4\pi \times 10^{-7}$ H/m) and μ_r is the (dimensionless) permeability. In contrast to the lines of the **D** field, lines of **B** are closed, having no beginning or ending. This is not surprising when we remember that while isolated positive and negative charges exist, no magnetic monopole has yet been discovered.

Relative Permeabilities

The range of the relative permeabilities covers about six orders of magnitude (Table 36.2) whereas the range of dielectric constants is only three orders of magnitude.

Forces on a Moving Charge

A charged particle, q, traveling with a velocity v and subjected to a magnetic field experiences a force

$$\mathbf{F} = q\mathbf{v} \times \mathbf{B}$$

This equation reveals how the Hall effect can be used to determine whether the majority current carriers in a sample of a semiconductor are (negatively charged) electrons flowing, say, in the negative direction or (positively charged) holes flowing in the positive direction. The (transverse) force (Fig. 36.2) will be in the same direction in either case, but the *sign* of the charge transported to the voltage probe will be positive for holes and negative for electrons.

In general, when both electric and magnetic fields are present, the force experienced by the carriers is given by

$$\mathbf{F} = q\,(\mathbf{E} + \mathbf{v} \times \mathbf{B})$$

The Hall effect is the basis of widely used and sensitive instruments for measuring the intensity of magnetic fields over a range of 10^{-5} to 2×10^6 A/m.

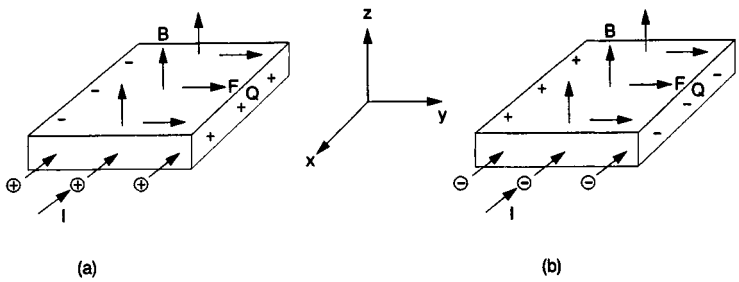

FIGURE 36.2 Hall effect. A magnetic field **B** applied to a block of semiconducting material through which a current I is flowing exerts a force $\mathbf{F} = \mathbf{V} \times \mathbf{B}$ on the current carriers (electrons or holes) and produces an electric charge on the right face of the block. The charge is positive if the carriers are holes and negative if the carriers are electrons.

Time-Varying Magnetic Fields

In 1831, 11 years after Oersted demonstrated that a current produced a magnetic field which could deflect a compass needle, Faraday succeeded in showing the converse effect—that a magnetic field could produce a current. The reason for the delay between the two discoveries was that it is only when a magnetic field is changing that an emf is produced.

$$\text{emf} = -\frac{d\Phi}{dt} \quad \text{V}$$

where $\Phi = BS$ = flux density (in gauss) × area S. The time-changing flux, $d\Phi/dt$, can happen as a result of

1. A changing magnetic field within a stationary circuit
2. A circuit moving through a steady magnetic field
3. A combination of 1 and 2

The electrical circuit may have N turns and then

$$\text{emf} = -N \frac{d\Phi}{dt}$$

We can write emf = $\mathbf{E} \cdot d\mathbf{L}$ and in the presence of changing magnetic fields or a moving electrical circuit $\mathbf{E} \cdot d\mathbf{L}$ is no longer required to be equal to 0 as it was for stationary fields and circuits.

Maxwell's Equations

Because the flux Φ can be written $\int \mathbf{B} \cdot d\mathbf{s}$ we have emf = $\mathbf{E} \cdot d\mathbf{L} = -d/dt\, \mathbf{B} \cdot d\mathbf{s}$, and by using Stokes' theorem

$$(\nabla \times \mathbf{E}) \cdot d\mathbf{s} = -d\mathbf{B}/dt\ d\mathbf{s}$$

or

$$\nabla \times \mathbf{E} = -d\mathbf{B}/dt$$

That is, a spatially changing *electric field* produces a time-changing *magnetic field*. This is one of Maxwell's equations linking electric and magnetic fields.

By a similar argument it can be shown that

$$\nabla \times \mathbf{H} = \mathbf{J} + d\mathbf{D}/dt$$

This is another of Maxwell's equations and shows a spatially changing *magnetic field* produces a time-changing *electric field*. The latter $d\mathbf{D}/dt$ can be treated as an electric current which flows through a dielectric, e.g., in a capacitor, when an alternating potential is applied across the plates. This current is called the *displacement current* to distinguish it from the conduction current which flows in conductors. The *conduction current* involves the movement of electrons from one electrode to the other through the conductor (usually a metal). The *displacement current* involves no translation of electrons or holes but rather an alternating polarization throughout the dielectric material which is between the plates of the capacitor.

From the last two equations we see a key conclusion of Maxwell: that in electromagnetic fields a time-varying magnetic field produces a spatially varying electric field and a time-varying electric field produces a spatially varying magnetic field.

Maxwell's equations in point form, then, are

$$\nabla \times \mathbf{E} = d\mathbf{B}/dt$$

$$\nabla \times \mathbf{H} = \mathbf{J} + d\mathbf{D}/dt$$

$$\nabla \cdot \mathbf{D} = \rho_v$$

$$\nabla \cdot \mathbf{B} = 0$$

These equations are supported by the following auxiliary equations:

$\mathbf{D} = \epsilon\mathbf{E}$ (displacement = permittivity × electric field intensity)

$\mathbf{B} = \mu\mathbf{H}$ (flux density = permeability × magnetic field intensity)

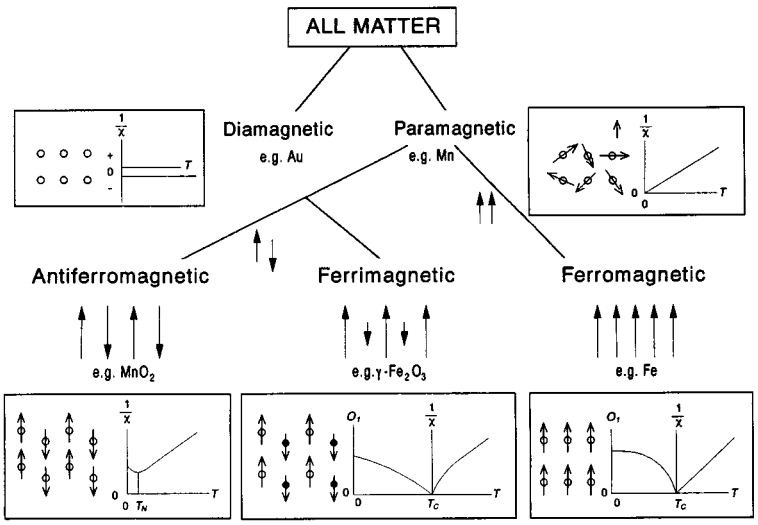

FIGURE 36.3 All matter consists of diamagnetic material (atoms having no permanent magnetic dipole moment) or paramagnetic material (atoms having magnetic dipole moment). Paramagnetic materials may be further divided into ferromagnetics, ferrimagnetics, and antiferromagnetics.

$$\mathbf{J} = \sigma\mathbf{E} \text{ (current density = conductivity } \times \text{ electric field strength)}$$

$$\mathbf{J} = \rho_v\mathbf{V} \text{ (current density = volume charge density } \times \text{ carrier velocity)}$$

$$\mathbf{D} = \boldsymbol{\epsilon}_o\mathrm{E} + \mathrm{P} \text{ (displacement as function of electric field and polarization)}$$

$$\mathbf{B} = \mu_o(\mathbf{H} + \mathbf{M}) \text{ (magnetic flux density as function of magnetic field strength and magnetization)}$$

$$\mathbf{P} = \chi_e\boldsymbol{\epsilon}_o\mathbf{E} \text{ (polarization = electric susceptibility } \times \text{ permittivity of free space } \times \text{ electrical field strength)}$$

$$\mathbf{M} = \chi_m\mu_o\mathbf{H} \text{ (magnetization = magnetic susceptibility } \times \text{ permeability of free space } \times \text{ magnetic field strength)}$$

The last two equations relate, respectively, the electric polarization **P** to the displacement $\mathbf{D} = \boldsymbol{\epsilon}_o\mathbf{E}$ and the magnetic moment **M** to the flux density $\mathbf{B} = \mu_o\mathbf{H}$. They apply only to "linear" materials, i.e., those for which **P** is linearly related to **E** and **M** to **H**. For magnetic materials we can say that nonlinear materials are usually of greater practical interest.

Dia- and Paramagnetism

The phenomenon of magnetism arises ultimately from moving electrical charges (electrons). The movement may be orbital around the nucleus or the other degree of freedom possessed by electrons which, by analogy with the motion of the planets, is referred to as *spin*. In technologically important materials, i.e., ferromagnetics and ferrimagnetics, spin is more important than orbital motion. Each arrow in Fig. 36.3 represents the *total spin* of an atom.

An atom may have a permanent magnetic moment, in which case it is referred to as belonging to a paramagnetic material, or the atom may be magnetized only when in the presence of a magnetic field, in which case it is called *diamagnetic*. Diamagnetics are magnetized in the *opposite direction* to that of the applied magnetic field, i.e., they display *negative* susceptibility (a measure of the induced magnetization per unit of applied magnetic field). Paramagnetics are magnetized in the *same* direction as the applied magnetic field, i.e., they

TABLE 36.3 The Occurrence of Ferromagnetism

	Cr	Mn	Fe	Co	Ni	Gd
Atomic number	24	25	26	27	28	64

At 0 K	—	—	221.89	162.5	57.50	250
Curie point, Θ_c K	—	—	1,043	1,400	631	289
Néel temp., Θ_n K	475	100	—	—	—	—

have *positive* susceptibility. *All* atoms are diamagnetic by virtue of their having electrons. *Some* atoms are also paramagnetic as well, but in this case they are called *paramagnetics* since paramagnetism is roughly a hundred times stronger than diamagnetism and overwhelms it. Faraday discovered that paramagnetics are attracted by a magnetic field and move toward the region of maximum field, whereas diamagnetics are repelled and move toward a field minimum.

The total magnetization of both paramagnetic and diamagnetic materials is zero in the absence of an applied field, i.e., they have zero **remanence**. Atomic paramagnetism is a necessary condition but not a sufficient condition for ferro- or ferrimagnetism, i.e., for materials having useful magnetic properties.

Ferromagnetism and Ferrimagnetism

To develop technologically useful materials, we need an additional force that ensures that the spins of the outermost (or almost outermost) electrons are mutually parallel. Slater showed that in iron, cobalt, and nickel this could happen if the distance apart of the atoms (D) was more than 1.5 times the diameter of the 3d electron shell (d). (These are the electrons, *near* the outside of atoms of iron, cobalt, and nickel, that are responsible for the strong paramagnetic moment of the atoms. Paramagnetism of the atoms is an essential prerequisite for ferro- or ferrimagnetism in a material.)

Slater's result suggested that, of these metals, iron, cobalt, nickel, and gadolinium should be ferromagnetic at room temperature, while chromium and manganese should not be ferromagnetic. This is in accordance with experiment. Gadolinium, one of the rare earth elements, is only weakly ferromagnetic in a cool room. Chromium and manganese in the elemental form narrowly miss being ferromagnetic. However, when manganese is alloyed with copper and aluminum ($Cu_{61}Mn_{24}Al_{15}$) to form what is known as a Heusler alloy [Crangle, 1962], it becomes ferromagnetic. The radius of the 3d electrons has not been changed by alloying, but the atomic spacing has been increased by a factor of 1.53/1.47. This small change is sufficient to make the difference between positive exchange, parallel spins, and ferromagnetism and negative exchange, antiparallel spins, and antiferromagnetism.

For all ferromagnetic materials there exists a temperature (the **Curie temperature**) above which the thermal disordering forces are stronger than the exchange forces that cause the atomic spins to be parallel. From Table 36.3 we see that in order of descending Curie temperature we have Co, Fe, Ni, Gd. From Fig. 36.4 we find that this is also the order of descending values of the exchange integral, suggesting that high positive values of the exchange integral are indicative of high Curie temperatures rather than high magnetic intensity in ferromagnetic materials.

Negative values of exchange result in an antiparallel arrangement of the spins of adjacent atoms and in antiferromagnetic materials (Fig. 36.3). Until 5 years ago, it was true to say that antiferromagnetism had no practical application. Thin films on antiferromagnetic materials are now used to provide the bias field which is used to linearize the response of some magnetoresistive reading heads in magnetic disk drives. Ferrimagnetism, also illustrated in Fig. 36.3, is much more widely used. It can be produced as soft, i.e., low **coercivity**, ferrites for use in magnetic recording and reading heads or in the core of transformers operating at frequencies up to tens of megahertz. High-coercivity, single-domain particles (which are discussed later) are used in very large quantities to make magnetic recording tapes and flexible disks γ-Fe_2O_3 and cobalt-impregnated iron oxides and to make barium ferrite, the most widely used material for permanent magnets.

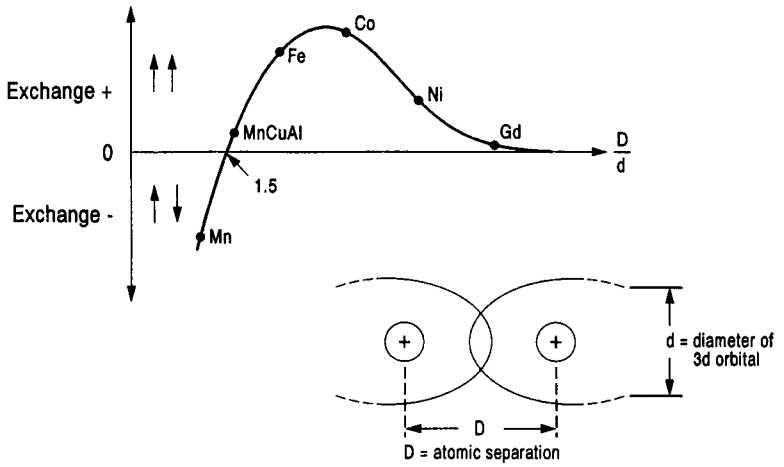

FIGURE 36.4 Quantum mechanical exchange forces cause a parallel arrangement of the spins of materials for which the ratio of atomic separation, D, is at least $1.5 \times d$, the diamter of the $3d$ orbital.

Intrinsic Magnetic Properties

Intrinsic magnetic properties are those properties that depend on the type of atoms and their composition and crystal structure, but not on the previous history of a particular sample. Examples of intrinsic magnetic properties are the *saturation* magnetization, Curie temperature, magnetocrystallic anisotropy, and magnetostriction.

Extrinsic magnetic properties depend on type, composition, and structure, but they also depend on the previous history of the sample, e.g., heat treatment. Examples of extrinsic magnetic properties include the technologically important properties of *remanent* magnetization, coercivity, and permeability. These properties can be substantially altered by heat treatment, quenching, cold-working the sample, or otherwise changing the size of the magnetic particle.

A ferromagnetic or ferrimagnetic material, on being heated, suffers a reduction of its magnetization (per unit mass, i.e., σ, and per unit volume, M). The slope of the curve of M_s vs. T increases with increasing temperature as shown in Fig. 36.5. This figure represents the conflict between the ordering tendency of the exchange interaction and the disordering effect of increasing temperature. At the Curie temperature, the order no longer exists and we have a paramagnetic material. The change from ferromagnetic or ferrimagnetic materials to paramagnetic is completely reversible on reducing the temperature to its initial value. Curie temperatures are always lower than melting points.

A single crystal of iron has the body-centered structure at room temperature. If the magnetization as a function of applied magnetic field is measured, the shape of the curve is found to depend on the direction of the field. This phenomenon is *magnetocrystalline anisotropy.* Iron has body-centered structure at room temperature, and the "easy" directions of magnetization are those directions parallel to the cube edges [100], [010], and [001] or, collectively, <100>. The hard direction of magnetization for iron is the body diagonal [111]. At higher temperatures, the anisotropy becomes smaller and disappears above 300°C.

Nickel crystals (face-centered cubic) have an easy direction of [111] and a hard direction of [100]. Cobalt has the hexagonal close-packed (HCP) structure and the hexagonal axis is the easy direction at room temperature.

Magnetocrystalline anisotropy plays a very important part in determining the coercivity of ferro- or ferrimagnetic materials, i.e., the field value at which the direction of magnetization is reversed.

Many magnetic materials change dimensions on becoming magnetized: the phenomenon is known as *magnetostriction* and can be positive, i.e., length increases, or negative. Magnetostriction plays an important role in determining the preferred direction of magnetization of *soft*, i.e., low H_c, films such as those of alloys of nickel and iron, known as *Permalloy.*

The origin of both magnetocrystalline anisotropy and magnetostriction is *spin-orbit* coupling. The magnitude of the magnetization of the film is controlled by the electron spin as usual, but the preferred direction of that

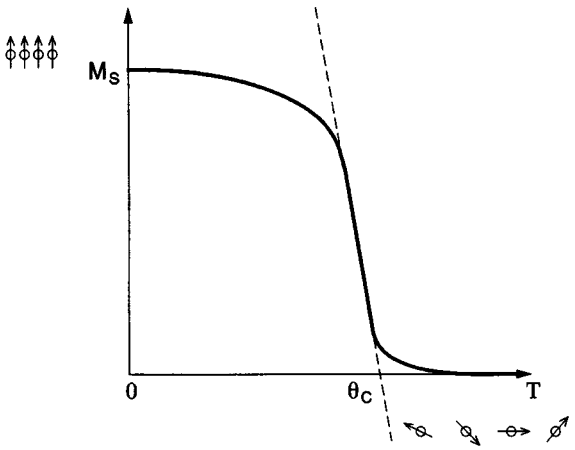

FIGURE 36.5 Ferro- and ferrimagnetic materials lose their spontaneous magnetic moment at temperatures above the Curie temperature, Θ_c.

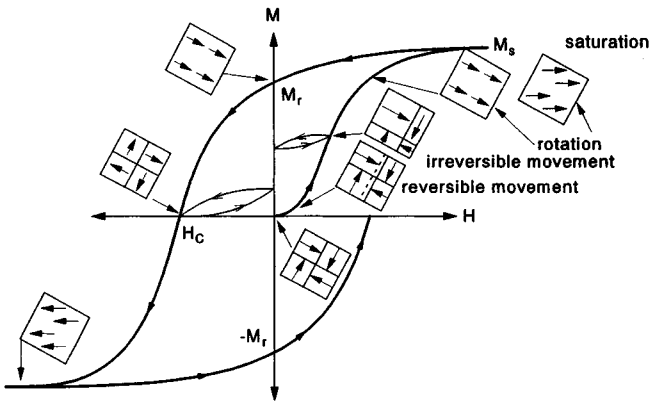

FIGURE 36.6 In soft magnetic materials domains form such that the total magnetization is zero. By applying small magnetic fields, domain walls move and the magnetization changes.

magnetization with respect to the crystal lattice is determined by the electron orbits which are large enough to interact with the atomic structure of the film.

Extrinsic Magnetic Properties

Extrinsic magnetic properties are those properties that depend not only on the shape and size of the sample, but also on the shape and size of the magnetic constituents of the sample. For example, if we measure the hysteresis loop like the one shown in Fig. 36.6 on a disk-shaped sample punched from a magnetic recording tape, the result will depend not only on the diameter and thickness of the disk coating but also on the distribution of shapes and sizes of the magnetic particles within the disk. They display hysteresis individually and collectively. For a soft magnetic material, i.e., one that might be used to make the laminations of a transformer, the dependence of magnetization, M, on the applied magnetic field, H, is also complex. Having once left a point described by the coordinates (H_1, M_1), it is not immediately clear how one might return to that point.

Alloys of nickel and iron, in which the nickel content is the greater, can be capable of a reversal of magnetization by the application of a magnetic field, H, which is weaker than the earth's magnetic field (0.5 Oe, 40 A/m) by a factor of five. (To avoid confusion caused by the geomagnetic field it would be necessary to screen the sample, for example, by surrounding it by a shield of equally soft material or by measuring the earth's field

TABLE 36.4 "Hard" and "Soft" Magnetic Materials

	High M_s	Low H_c	Low M_r	High μ

and applying a field which is equal in magnitude but opposite in direction to the earth's field in order to cancel its effects.)

The magnetization of the sample in zero field may be macroscopically zero, but locally the material may be magnetized virtually to the saturation state. As shown in Fig. 36.6, which shows a greatly simplified domain structure, the net magnetization at the center of the loop is zero because the magnetization of the four "domains" cancels in pairs. A domain is a region (not necessarily square or even of a regular shape, although the shape often is regular in Ni–Fe thin films or sheets) over which the magnetization is constant in magnitude and direction. Thus, the sample in Fig. 36.6 consists of four domains, initially separated from each other by "domain walls." If a magnetic field is applied in the direction of $+H$, that domain will grow whose direction of magnetization is closest to the field direction and the domains will shrink if their magnetization is opposed to the field. For small applied fields, the movement of the walls is reversible, i.e., on reducing the applied field to zero, the original domain configuration will be obtained. Beyond a certain field the movement of the walls is irreversible, and eventually near the knee of the magnetization curve all the domain walls have been swept away by the applied field. The sample is not yet in the saturated state since the direction of M is not quite the same as the direction of the applied field. However, a small increase in the strength of the applied field finally achieves the saturated state by rotating the magnetization of the whole sample into the field direction.

On removing the applied field, the sample does not retrace the magnetization curve, and when the applied field is zero, we can see that a considerable amount of magnetization remains, M_r. Appropriately, this is referred to as the remanent state, and M_r is the *remanent magnetization*. By reversing the original direction of the applied field, domains reappear and the magnetization is eventually reduced to zero at the *coercive field*, H_c. It should be noticed that, at H_c, although the net magnetization is clearly zero, the individual domains may be magnetized in directions that are different from those at the starting point. Figure 36.6 shows an incomplete hysteresis loop. If the field H were increased beyond $+H_c$ the loop would be completed.

The differences between ideally magnetically soft materials (used in transformers and magnetic read/write heads) and magnetically hard materials (used in permanent magnets and in recording tapes and disks) are as follows:

Magnetically soft materials:	H_c 0;	M_r 0;	M_s high value
Magnetically hard materials:	H_c high value;	M_r/M_s ("squareness");	M_s high value

Examples are given in Table 36.4.

It is noticeable that the differences between hard and soft magnetic materials are confined to the extrinsic properties, M_r, H_c, and permeability, μ. The latter is related to M and H as follows:

$$\mathbf{B}\ (\mathrm{G}) = \mathbf{H}\ (\mathrm{Oe}) + 4\pi\mathbf{M}\ (\mathrm{emu/cc})$$

$$\mu = \mathbf{B}/\mathbf{H} = 1 + 4\pi\kappa\ (\mathrm{cgs\ units})$$

or

$$\mathbf{B}\ (\mathrm{Wb/m^2}) = \mu_o\ (\mathbf{H}\ \mathrm{A/m} + \mathbf{M}\ \mathrm{A/m})$$

$$= \mu_o\mu_r\mathbf{H} = \mu\mathbf{H}\ (\mathrm{SI\ units})$$

Domain walls form in order to minimize the magnetic energy of the sample. The magnetic energy is $\mu H^2/8\pi$ cgs units or $1/2\,\mu H^2$ J/m^3 (SI units) and clearly depends on **H**, the magnetic field emanating from the sample. In the *initial* domain configuration shown in Fig. 36.6, there is no net magnetization of the sample and thus no substantial **H** exists outside the sample and the magnetostatic energy is zero. Thus, the establishment of domains *reduces* the energy associated with H but it *increases* the energy needed to establish domain walls within the sample. A compromise is reached in which domain walls are formed until the establishment of one more wall would *increase*, rather than decrease, the total magnetic energy of the sample.

The wall energy depends on the area of the wall, i.e., L^2, while the energy associated with the external magnetic field depends on L^3, the volume of the sample. Clearly, as the size of single particles becomes small, terms in L^2 are more important than terms in L^3, and so for small magnetic particles, the formation of domain walls may not be energetically feasible and a *single-domain particle* results. These are found in the particles of iron oxide, cobalt-modified iron oxide, chromium dioxide, iron, or barium ferrite, which are used to make magnetic recording tapes, and in barium ferrite, samarium cobalt, and neodymium iron boron, which are used to make powerful permanent magnets. In the latter cases, the very high coercivities are caused by domain walls being pinned at grain boundaries between the main phase grains and finely precipitated secondary phases. This is an example of *nucleation-controlled coercivity.*

The amount of available energy that can be stored in a permanent magnet is the area of the largest rectangle that can be drawn in the second quadrant of the B vs. H hysteresis loop. The *energy product* has grown remarkably by a factor of about 50 since 1900 [Strnat, 1986]. We see from the graph in Fig. 36.7 of *intrinsic* coercive force, i.e., the coercive force obtained from the graph of M vs. H (in contrast to the smaller coercive force obtained by plotting B vs. H), that increases in H_c (rather than increases in M_r) have been responsible for almost all the improvement in the energy product.

The key attributes of technologically important magnetic materials are

1. Large, spontaneous atomic magnetic moments
2. Large, positive exchange integrals
3. Magnetic anisotropy and heterogeneity which are small for soft magnetic materials and large for hard magnetic materials.

In single-domain materials, the magnetic particles are so small that reversal of the magnetization can only occur by rotation of the magnetization vector. This rotation can be resisted by combinations of three anisotropies: crystalline anisotropy, shape anisotropy, and magnetoelastic anisotropy (which depends on the magnetostrictive properties of the material).

Crystalline Anisotropy

Crystalline anisotropy arises from the existence of easy and hard directions of magnetization within the crystal structure of the material. For example, in iron the {100} directions are easy directions while the {111} directions are hard. In nickel crystals the reverse is true. In cobalt the hexagonal {00.1} directions are easy and the {10.0} directions in the basal plane are hard.

Hard and easy directions in crystalline materials come about as a result of spin-orbit coupling. The spin, as usual, determines the occurrence of ferro- or ferrimagnetization, while the orbital motion of the electrons (3*d* in the case of Fe, Co, and Ni) responds to the structure of the crystal lattice.

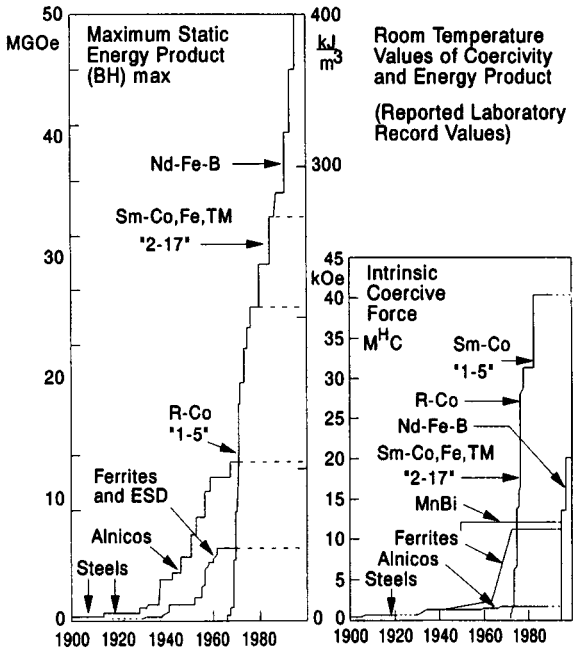

FIGURE 36.7 The development of magnetic materials for permanent magnets showing the increase in energy product and in intrinsic coercivity as a function of time.

The maximum value of coercivity resulting from crystalline anisotropy is given by $H_c = 2K_1/M_s$, where K_1 is the first magnetocrystalline anisotropy constant and M_s is the saturation magnetization.

Shape Anisotropy

A spherical particle has no shape anisotropy, i.e., all directions are equally easy (or hard). For particles (having low crystalline anisotropy) of any other shape, the longest dimension is the easy direction and the shortest dimension is the hardest direction of magnetization. Thus, a needle-shaped (acicular) particle will tend to be magnetized along the long dimension, whereas a particle in the form of a disk will have the axis of the disk as its hard direction, while any direction in the plane of the disk will be equally easy (assuming that shape is the dominant anisotropy).

For an acicular particle, the maximum value of the particle's switching field is [Stoner and Wohlfarth, 1948]

$$H_c = (N_b - N_a)\ M_s$$

where N_b is the demagnetizing factor in the shorter dimension and N_a is the factor for the long axis of the particle. When the ratio $b/a \rightarrow \infty$, then

$$\left.\begin{array}{l} N_a \rightarrow 0 \\ N_b \rightarrow 2\pi \end{array}\right\} N_a + N_b + N_c \equiv 4\pi$$

and H_c for iron > 10,000 Oe (7.95×10^5 A/m), higher than has been achieved in the laboratory for single-domain iron particles. Particles of iron having $H_c \leq 2000$ Oe are widely used in high-quality audio and video tapes.

The reason for the discrepancy is that the simplest single-domain model makes the assumption that the spins on all the atoms in a particle rotate in the same direction and at the same time, i.e., are coherent. This seems to be improbable since switching may begin at different places in the single-domain particle at the same time. Jacobs and Bean [1955] proposed an incoherent mode, *fanning*, in which different segments on a

TABLE 36.5 Maximum Coercivity (Oe) for Single-Domain Particles (Coherent Rotation)

	Iron	Cobalt	Nickel	γ-Fe2O3
Crystalline	250	3,000	70	230
Strain	300	300	2,000	<10
Shape (10:1)	5,300	4,400	1,550	2,450

longitudinal chain of atoms rotate in opposite directions. Shtrikman and Treves [1959] introduced another incoherent mode, *buckling*. These incoherent modes of magnetization reversal within single-domain particles not only predicted values of coercivity closer to the observed values, but also they could explain why the observed coercivity values for single-domain particles increased with decreasing particle size [Bate, 1980].

Shape anisotropy also plays an important role in determining the magnetization direction in thin magnetic films. It, of course, favors magnetization in the film plane.

Magnetoelastic Anisotropy

Spin-orbit coupling is also responsible for magnetostriction (the increase or decrease of the dimensions of a body on becoming magnetized or demagnetized). The magnetostriction coefficient λ_s = fractional change of a dimension of the body. It can be positive or negative, and it varies with changes in the direction and magnitude of the applied stress (or internal stress) and of the applied magnetic field. It is highly sensitive to composition, to structure, and to the previous history of the sample. The maximum coercivity is given by the formula $H_c = 3\lambda_s T/M_s$ where λ_s is the saturation magnetostriction coefficient, T is the tension, and M_s the saturation magnetization. Magnetostriction has been put to practical use in the generation of sonar waves for the detection of schools of fish or submarines.

For samples made of single-domain particles, the maximum coercivity for three ferromagnetic metals and one ferrimagnetic oxide (widely used in magnetic recording) is calculated using the preceding formula. Table 36.5 shows maximum coercivity (Oe) for single-domain particles (coherent rotation).

The assumption is made that all the spins rotate so that they remain parallel at all times. This is known as *coherent rotation*. In the case of γ-Fe_2O_3, an incoherent mode of reversal probably occurs since the maximum observed coercivity is only 350 Oe. Several incoherent modes have been proposed, e.g., chain-of-spheres fanning [Jacobs and Bean, 1955], curling [Shtrikman and Treves, 1959]. Their characteristics and differences are discussed by Bate [1980]. The coercivity of particles of γ-Fe_2O_3 is increased (in order to make recording tapes of extended frequency response) by precipitating cobalt hydroxide on the surface of the particles. After gentle warming, the cobalt is incorporated on the surface of the particles and increases the coercivity to 650 Oe (51 · 73 kA/m).

Figure 36.8 illustrates two additional extrinsic magnetic properties of importance. They are the remanence coercivity, H_r, and the switching field distribution (SFD). These are of particular importance in magnetic particles used in magnetic tapes (audio, video, or data) or magnetic disks. The coercivity, H_c, of a magnetic material is the value of the magnetic field (the major loop) at which $M = 0$. However, if the applied field is allowed to go to zero, a small magnetization remains. It is necessary to increase the applied field from $H_c > H_r$ (Fig. 36.8) to achieve $M_r = 0$. H_r is the *remanence coercivity* and is more relevant than is H_c in discussing the writing process in magnetic recording since it corresponds to the center of the remanent magnetization transition on the recording medium.

Particles, for example, in a magnetic recording do not all reverse their magnetization at the same field; there is a distribution of switching fields, which can be found by differentiating M with respect to H around the point H_c. The result is shown as the broken curve on Fig. 36.8, where the SFD = $\Delta H/H_c$, ΔH being the width at half the maximum of the curve. Typically, SFD = 0.2–0.3 for a high-quality particulate medium and smaller than this for thin-film recording media.

Figure 36.8 also shows the construction used to find the parameter S^*. The quantity $1 - S^*$ is found to be very close to $\Delta H/H_c$ and it is quicker to evaluate. Either of these parameters can be used to determine the distribution of switching fields, small values of which are required to achieve high recording densities.

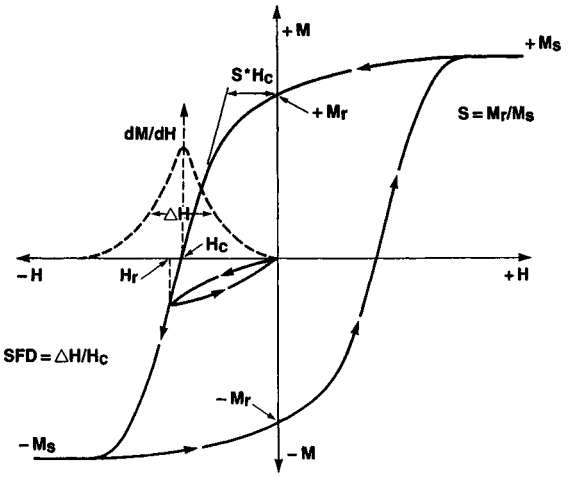

FIGURE 36.8 The switching field distribution (SFD) for a magnetic recording medium can be obtained in two ways: (1) SFD = $\Delta H/H_c$ or (2) SFD = $1 - S^*$.

Amorphous Magnetic Materials

Before 1960, all the known ferro- and ferrimagnetic materials were crystalline. Because the occurrence of these magnetic states is known to depend on short-range interaction between atoms, there is no reason why amorphous materials (which have *only* short-range order) should not have useful magnetic properties. This was found to be true in 1960, when thin, amorphous ribbons of $Au_{81}Si_{19}$ were made by rapidly cooling the molten alloy through the melting point and the lower glass transition temperature. Because there is always at least one crystalline phase more stable than the amorphous state, the problem is to invent a production method that yields the amorphous phase rather than the crystalline one.

Most methods involve cooling the molten mixture so rapidly that there is insufficient time for crystals to form. Cooling rates of 10^5–10^6 degrees per second are needed and can be achieved in several ways:

1. Pouring the molten mixture from a silica crucible onto the edge of a rapidly rotating copper wheel. This yields a ribbon of the amorphous alloy, typically 1 mm wide and 25 μm thick.
2. Depositing a thin film from a metal vapor or a solution of metal ions.
3. Irradiating a thin sample of the metal with high-energy particles.

Once an amorphous alloy is formed, it will remain indefinitely in the *glassy* state at room temperature. The problem is that only *thin* films are obtained, and large areas are required to make, for example, the core of a transformer.

There are three main groups of amorphous films:

1. Metal-metalloid alloys, e.g., $Au_{81}Si_{19}$
2. Late transition–early transition metal alloys, e.g., $Ni_{60}Nb_{40}$
3. Simple metal alloys, e.g., $Cu_{65}Al_{35}$

When normal metals freeze, crystallization begins at a fixed temperature, the *liquidus*, T_e. In amorphous alloys *configurational freezing* occurs at a lower temperature, the *glass temperature*, T_g, which is not as well defined as T_e. There is an abrupt increase in the time required for the rearrangement of the atoms, from 10^{-12} s for liquids to 10^5 s (a day) for glasses. Not surprisingly, this increase in atomic rearrangement time is associated with an abrupt increase in viscosity, from 10^{-2} poise for liquids, e.g., water or mercury, to 10^{15} poise for glasses.

The principal difference between magnetic glasses and ferromagnetic alloys is that the glasses are completely isotropic (all directions of magnetization are very easy directions), and consequently, considering only the magnetic properties, soft amorphous alloys are almost ideally suited for use in the core of power transformers

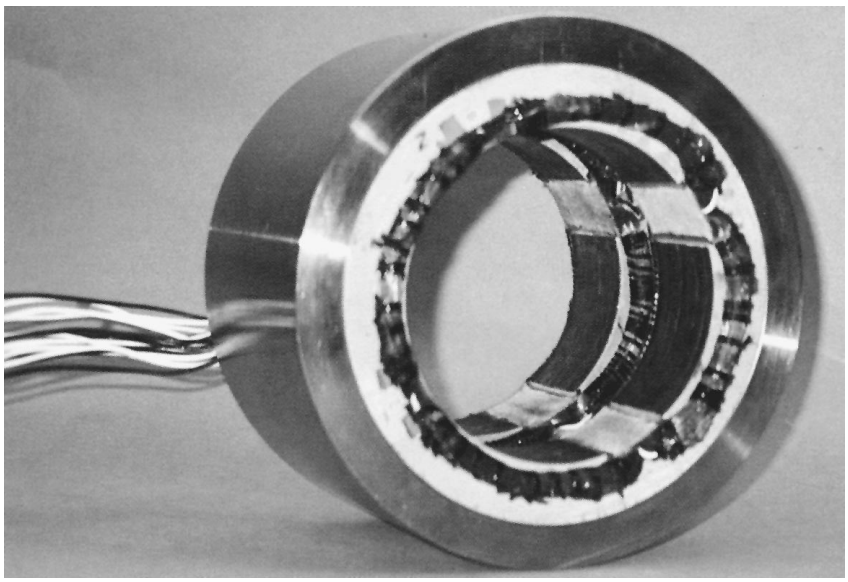
Magnetic Bearing

Magnetic bearings support moving machinery without physical contact. For example, they can levitate a rotating shaft and permit relative motion without friction or wear. Long considered a promising advancement, magnetic bearings are now in actual service in such industrial applications as electric power generation, petroleum refining, machine tool operation, and natural gas pipelines.

AVCON, Inc. worked initially with Lewis Research Center on the development of a magnetic bearing system for a cryogenic magnetic bearing test facility. The resulting AVCON development was extensively tested over a two-year span and these tests provided a wealth of data on the performance of magnetic bearings under severe conditions. In this program, AVCON developed the basic hybrid magnetic bearing approach in which both permanent magnets and electromagnets are employed to suspend a shaft; the permanent magnets provide suspension, the electromagnets provide control. Analyses of AVCON bearing tests showed that a hybrid magnetic bearing test was typically only one-third the weight, substantially smaller and dramatically less power-demanding than previous generations of magnetic bearings.

In 1993, Marshall Space Flight Center awarded AVCON a contract to fabricate a set of magnetic bearings, install them in a fixture representing a Space Shuttle main engine turbopump, and test them under simulated shuttle mission conditions.

AVCON has been able to develop a unique "homopolar" approach to permanent magnet type bearings that the company says are significantly smaller than prior designs, their control electronics are a fraction of the weight of previous systems, and power consumption is much lower than in all electromagnetic designs. Among other advantages cited are virtually zero friction and therefore no lubricant requirement, no wear, no vibration, longer service life, and very high reliability because single point failure modes are eliminated. (Courtesy of National Aeronautics and Space Administration.)



This AVCON magnetic bearing permits motion without friction or wear. (Photo courtesy of National Aeronautics and Space Administration.)

or magnetic recording heads, where almost zero remanence and coercivity are desired at frequencies up to megahertz. The limit on their performance seems to be the magnetic anisotropy which arises from strains generated during the manufacturing process.

When an amorphous material is required to store energy (as in a permanent magnet) or information (as in magnetic bubbles or thermomagneto-optic films), it must have magnetic anisotropy. This is generally produced by applying a magnetic field at high temperatures to the amorphous material. The field and temperature must be high enough to allow a local rearrangement of atoms to take place in order to create the desired degree of magnetocrystalline anisotropy.

Amorphous materials will apparently play increasingly important roles as magnetic materials. To accelerate their use, we need to have answers to the questions "What governs the formation of amorphous materials?" and "What is the origin of their anisotropy and magnetostriction?".

Defining Terms

Coercivity, H_c (Oe, A/m): The property of a magnetized body enabling it to resist reversal of its magnetization.

Compensation temperature, T_c (°C, K): The temperature at which the magnetization of a material comprising ferromagnetic atoms (e.g., Fe, Co, Ni) and rare earth atoms (e.g., Gd, Tb) becomes zero because the magnetization of the sublattice of ferromagnetic atoms is canceled by the opposing magnetization of the rare earth sublattice.

Curie temperature, Θ_c (°C, K): The temperature at which the spontaneous magnetization of a ferromagnetic or ferrimagnetic body becomes zero.

Remanence, M_r (emu/cc, A/m): The property of a magnetized body enabling it to retain its magnetization.

36.2 Magnetic Recording

Mark H. Kryder

Magnetic recording is used in a wide variety of applications and formats, ranging from relatively low-density, low-cost floppy disk drives and audio recorders to high-density videocassette recorders, digital audio tape recorders, computer tape drives, rigid disk drives, and instrumentation recorders. The storage density of this technology has been advancing at a very rapid pace. With a storage density exceeding 1 Gbit/in.^{2}, magnetic recording media today can store the equivalent of about 50,000 pages of text on one square inch. This is more than 500,000 times the storage density on the RAMAC, which was introduced in 1957 by IBM as the first disk drive for storage of digital information. The original Seagate 5.25-inch magnetic disk drive, introduced in 1980, stored just 5 Mbytes. Today, instead of storing megabytes, 5.25-inch drives store tens of gigabytes, and drives as small as 2.5 inches store over a gigabyte.

This astounding rate of progress shows no sign of slowing. Fundamental limits to magnetic recording density are still several orders of magnitude away, and recent product announcements and laboratory demonstrations indicate the industry is accelerating the rate of progress rather than approaching practical limits. Recently IBM demonstrated the feasability of storing information at a density of 3 Gbit/in.^{2} [Tsang et al., 1996]. Similar advances can also be expected in audio and video recording.

Fundamentals of Magnetic Recording

Although magnetic recording is practiced in a wide variety of formats and serves a wide variety of applications, the fundamental principles by which it operates are similar in all cases. The fundamental magnetic recording configuration is illustrated in Fig. 36.9. The recording head consists of a toroidally shaped core of soft magnetic material with a few turns of conductor around it. The magnetic medium below the head could be either tape or disk, and the substrate could be either flexible (for tape and floppy disks) or rigid (for rigid disks). To record on the medium, current is applied to the coil around the core of the head, causing the high-permeability magnetic core to magnetize. Because of the gap in the recording head, magnetic flux emanates from the head and penetrates the medium. If the field produced by the head is sufficient to overcome the **coercive force** of the medium, the medium will be magnetized by the head field. Thus, a representation of the current waveform applied to the head is stored in the magnetization pattern in the medium.

Readout of previously recorded information is typically accomplished by using the head to sense the magnetic stray fields produced by the recorded patterns in the medium. The recorded patterns in the medium cause magnetic stray fields to emanate from the medium and to flow through the core of the head. Thus, if the medium is moved with respect to the head, the flux passing through the coil around the head will change in a manner which is representative of the recorded magnetization pattern in the medium. By Faraday's law of induction, a voltage representative of the recorded information is thus induced in the coil.

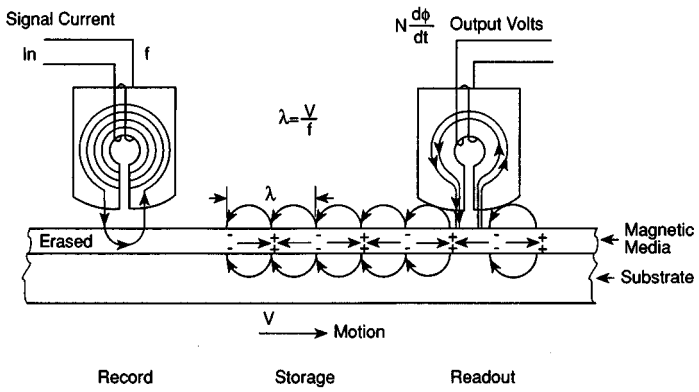

FIGURE 36.9 The fundamental magnetic recording configuration.

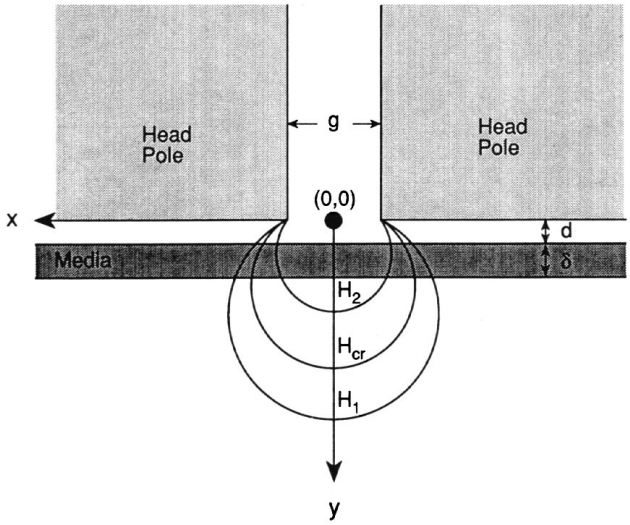

FIGURE 36.10 The constant longitudinal field contours in the gap region of a recording head.

The Recording Process

During recording the head is used to produce large magnetic fields which magnetize the medium. It was shown by Karlqvist [1954] that, in the case where the track width and length of the poles along the gap are both large compared to the gap length, the fields produced by a recording head could be described by

$$H_x = \frac{NI}{\pi g}\left[\tan^{-1}\left(\frac{x + g/2}{y}\right) - \tan^{-1}\left(\frac{x - g/2}{y}\right)\right] \tag{36.1a}$$

$$H_y = \frac{NI}{2\pi g}\ln\left[\frac{(x + g/2)^2 + y^2}{(x - g/2)^2 + y^2}\right] \tag{36.1b}$$

where H_x and H_y are the longitudinal and perpendicular components of field, as indicated by the coordinates in Fig. 36.10, N is the number of turns on the head, I is the current driving the head, and g is the gap width of the head. In this approximation, the contours of equal longitudinal field are described by circles which intersect the gap corners as shown in Fig. 36.10.

In digital or saturation recording, the recording head is driven with sufficiently large currents that a portion of the recording medium is driven into saturation. However, because of the gradient in the head fields, other portions of the medium see fields less than those required for saturation. This is illustrated in Fig. 36.10 where the contours for three different longitudinal fields are drawn. In this figure H_{cr} is the **remanence coercivity** or the field required to produce zero **remanent magnetization** in the medium after it was saturated in the opposite direction, and H_1 and H_2 are fields which would produce negative and positive remanent magnetization, respectively. Note that the head field gradient is the sharpest near the pole tips of the head. This means that smaller head-to-medium spacing and thinner medium both lead to narrower transitions being recorded.

Modeling the recording process involves convolving the head field contours with the very nonlinear and hysteretic magnetic properties of the recording medium. A typical M-H hysteresis loop for a longitudinal magnetic recording medium is shown in Fig. 36.11. Whether the medium has positive or negative magnetization depends upon not only the magnetic field applied but the past history of the magnetization. If the medium was previously saturated at $-M_s$, then when the magnetic field H is reduced to zero, the remanent magnetization will be $-M_r$; however, if it was previously saturated at $+M_s$, then the remanent magnetization would be $+M_r$.

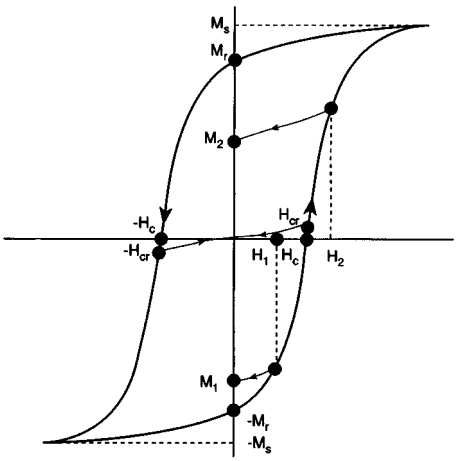

FIGURE 36.11 A remanent *M-H* hysteresis loop for a longitudinal recording medium.

Similarly, if the medium was initially saturated to $-M_s$, then magnetized by a field $+H_1$, and finally allowed to go to a remanent state, the magnetization would go to value M_1. This hysteretic behavior is the basis for the use of the medium for long-term storage of information but makes the recording process highly nonlinear.

An additional complicating factor in determining the actual recorded pattern is the **demagnetizing field** of the medium itself. As shown in Fig. 36.9, transitions in the recorded magnetization direction produce effective magnetostatic charge given by

$$\rho_M = -\nabla \cdot \vec{\mathbf{M}} \tag{36.2}$$

which in turn results in demagnetizing fields. The demagnetizing fields outside the medium are what is sensed by the head during readback, but demagnetizing fields also exist inside the medium and act to alter the total field seen by the medium during the recording process from that of the head field alone.

Taking into account the head field gradients, the nonlinear *M-H* loop characteristics of the medium and the demagnetizing fields, Williams and Comstock [1971] developed a model for the recording process. This model predicts the width of a recorded transition, in a material with a square hysteresis loop, to be

$$a = \sqrt{\frac{M_r \delta d}{\pi H_c}} \tag{36.3}$$

where δ is the medium thickness, d is the head-medium spacing, M_r is the remanent magnetization of the medium, and H_c is the coercivity of the medium. That the transition widens with the product $M_r \cdot \delta$ is a result of the fact that the demagnetizing fields increase linearly with this quantity. Similarly, the transition narrows as H_c is increased, because with high coercivity, the medium can resist the transition broadening due to the demagnetizing fields. The increase in transition width with d is due to the fact that a poorer head field gradient is obtained with larger head-medium spacing.

The nonlinearities of the recording process can be largely removed by a technique referred to as ac bias recording. This is frequently used in analog recording in audio and video recorders. In this technique, a high-frequency ac bias is added to the signal to be recorded. This ac bias signal is ramped from a value much larger than the coercivity of the medium to zero. This removes the hysteretic behavior of the medium and causes it to assume a magnetization state which represents the minimum energy state determined by the amount of field produced by the signal to be recorded.

The Readback Process

As opposed to the recording process, the readback process can usually be modeled as a linear process. This is because the changes in magnetization which occur in either the head or the medium during readback are typically small.

The most common way to model the readback process is to use the principle of reciprocity, which states that the flux produced by the head through a cross section of an element of the medium, normalized by the number of ampere turns of current driving the head, is equal to the flux produced in the head by the element of medium, normalized by the equivalent current required to produce the magnetization of that element. For a magnetic recording head, which produces the longitudinal field $H_x(x,y)$ when driven by NI ampere turns of current, this principle leads to the following expression for the voltage induced in the head by a recording medium with magnetization $M(x,y)$ and moving with velocity v relative to the head:

$$e = \frac{\mu_o W v}{I} \int_d^{d+\delta} \int_{-\infty}^{\infty} \frac{\partial M_x(x - \bar{x}, y)}{\partial \bar{x}} H_x(x, y) dx dy \tag{36.4}$$

where W is the track width of the head.

This expression shows that the readback voltage induced in the recording head is linearly dependent upon the magnitude of the magnetization in the recording medium being sensed and the relative head-to-medium velocity. The linearity of the readback process ensures that analog recordings such as those recorded on audio or video tapes are faithfully reproduced.

Magnetic Recording Media

A wide variety of magnetic recording media are available today. Different applications require different media, but furthermore, in many cases the same application will be able to utilize a variety of different competitive media.

Just a decade ago, essentially all recording media consisted of fine acicular magnetic particles embedded in a polymer and coated onto either flexible substrates such as mylar for floppy disks and tapes or onto rigid aluminum-alloy substrates for rigid disks. Today, although such particulate media are still widely used for tape and floppy disks, thin-film media have almost entirely taken over the rigid disk business, and metal-evaporated thin-film media has been introduced into the tape marketplace. Furthermore, many new particle types have been introduced.

The most common particulate recording media today are γ-Fe_2O_3, Co surface-modified γ-Fe_2O_3, CrO_2, and metal particle media. All of these particles are acicular in shape with aspect ratios on the order of 5 or 10 to 1. The particles are sufficiently small that it is energetically most favorable for them to remain in a single-domain saturated state. Because of demagnetizing effects caused by the acicular shape, the magnetization prefers to align along the long axis of the particle.

As was noted in the discussion of Eq. (36.3), to achieve higher recording densities requires media with higher coercivity. The coercivity of a particle is determined by the field required to cause the magnetization to switch by 180°. If the magnetization remained in a single-domain state during the switching process, then the coercivity should be given by

$$H_c = (N_a - N_b) M_s \tag{36.5}$$

where N_a and N_b are the demagnetizing factors in the directions transverse and parallel to the particle axis, respectively. In practice the coercivity is measured to be less than this. This has been explained as being a result of the fact the magnetization does not remain uniform during the switching process, but switches inhomogeneously [White, 1984]. In addition to the effects which the shape anisotropy of the particles has on the coercivity, crystalline anisotropy can also be used to control coercivity.

TABLE 36.6 Magnetic Material, Saturation Remanence $M_r(\infty)$, Coercivity H_c, Switching-Field Distribution Δh_r, and Number of Particles per Unit Volume, N, of Various Particulate Magnetic Recording Media

Application	Material	*Mr* (∞), kA/m (emu/cm³)	*Hc*, kA/m (4π Oe)	Δ*hr*	*N*, $10^3/\mu m^3$
Reel-to-reel audio tape	γ-Fe_2O_3	100–120	23–28	0.30–0.35	0.3
Audio tape IEC I	γ-Fe_2O_3	120–140	27–32	0.25–0.35	0.6

The coercivity of the medium which is made from the particles is determined by the distribution of coercivities of the particles from which it is made, their orientation in the medium relative to the fields from the head, and their interactions among each other. The coercivities of a variety of particulate recording media are summarized in Table 36.6.

Although coercivity is indeed an important parameter for magnetic recording media, it is by no means the only one. Particle size affects the medium noise because, at any time, the head is sensing a fixed volume of the medium. Because the particles are quantized and there are statistical variations in their switching behavior, the medium power signal-to-noise ratio varies linearly with the number of particles contained in that volume. To reduce particulate medium noise, it is therefore generally desirable to use small particles.

There is a limit, however, to how small particles may be made and still remain stable. When the thermal energy kT is comparable in magnitude to the energy required to switch a particle, $M \cdot H_c$, the particle becomes unstable and may switch because of thermal excitation. This phenomenon is known as **superparamagnetism** and can lead to decay of recorded magnetization patterns over time.

The remanent magnetization of a medium is important because it directly affects the signal level during readback as shown by Eq. (36.4). The remanent magnetizations of several particulate media are listed in Table 36.6. Obtaining high remanent magnetization in particulate media requires the use of particles with high **saturation magnetization** and a high-volume packing fraction of particles in the polymer binder. Obtaining a high-volume packing fraction of particles in the binder, however, can lead to nonuniform distributions of particles and agglomerates of many particles, which switch together, also causing noise during readback.

Generally, then, to obtain good high-density particulate recording media it is desired to have adequate coercivity (to achieve the required recording density), small particles (for low noise), with a very narrow switching field distribution (to obtain a narrow transition), to have them oriented along the direction of recording (to obtain a large remanence), and to have them uniformly dispersed (to obtain low modulation noise), with high packing density (to obtain large signals).

Thin-film recording media generally have excellent magnetic properties for high-density recording. Because they are nearly 100% dense (voids at the grain boundaries reduce the density somewhat), they can be made to have the highest possible magnetization. Because of their high magnetization, they can be made extremely thin and still provide adequate signal during readback. This helps narrow the recorded transition since the head field gradient is sharper for thinner media, as was discussed in reference to Fig. 36.10.

Thin-film media can also be made extremely smooth. To achieve the smallest possible head-to-medium spacing and therefore the sharpest head field gradient and the least spacing loss, smooth media are required.

The coercivity of thin-film media can also be made very high. In volume production today are media with coercivities of 160 kA/m; however, media with coercivities to 250 kA/m have been made and appear promising [Velu and Lambeth, 1992]. Such high coercivities are adequate to achieve more than an order of magnitude higher recording density than today.

Numerical models indicate that noise in thin-film media increases when the grains in polycrystalline films are strongly exchange coupled [Zhu and Bertram, 1988]. Exchange coupled films tend to exhibit zigzag transitions, which produce considerable jitter in the transition position relative to the location where the record current in the head goes through zero. A variety of experimental studies have indicated that the introduction of nonmagnetic elements which segregate to the grain boundaries and careful control of the sputtering conditions to achieve a porous microstructure at the grain boundaries reduce such transition jitter [Chen and Yamashita, 1988].

Magnetic Recording Heads

Early recording heads consisted of toroids of magnetically soft ferrites, such as NiZn-ferrite and MnZn-ferrite, with a few turns of wire around them. For high-density recording applications, however, ferrite can no longer be used, because the saturation magnetization of ferrite is limited to about 400 kA/m. Saturation of the pole tips of a ferrite head begins to occur when the deep gap field in the head approaches one-half the saturation magnetization of the ferrite. Because the fields seen by a medium are one-half to one-quarter the deep gap field, media with coercivities above about 80 kA/m cannot be reliably written with a ferrite head. High-density thin-film disk media, metal particle media, and metal evaporated media, therefore, cannot be written with a ferrite head.

Magnetically soft alloys of metals such as Permalloy (NiFe) and Sendust (FeAlSi) have saturation magnetizations on the order of 800 kA/m, about twice that of ferrites, but because they are metallic may suffer from eddy current losses when operated at high frequencies. To overcome the limitations imposed by eddy currents, they are used in layers thinner than a skin depth at their operating frequency. To prevent saturation of the ferrite heads, the high magnetization metals are applied to the pole faces of the ferrite, making a so-called metal-in-gap or MiG recording head, as shown in Fig. 36.12. Since the corners of the pole faces are the first parts of a ferrite head to saturate, the high magnetization metals enable these MiG heads to be operated to nearly twice the field to which a ferrite head can be operated. Because the layer of metal is thin, it can furthermore be less than a skin depth, and eddy current losses do not limit performance at high frequencies.

Yet another solution to the saturation problem of ferrite heads is to use thin-film heads. Thin-film heads are made of Permalloy and are therefore metallic, but the films are made sufficiently thin that they are thinner than the skin depth and, consequently, the heads operate well at high frequencies. A diagram of a thin-film head is shown in Fig. 36.13. It consists of a bottom yoke of Permalloy, some insulating layers, a spiral conductor, and a top yoke of Permalloy, which is joined to the bottom yoke at the back gap but separated from it by a thin insulator at the recording gap. These thin-film heads are made using photolithography and microfabrication techniques similar to those used in the manufacture of semiconductor devices. The thin pole tips of these heads actually sharpen the head field function and, consequently, the pulse shape produced by an isolated transition, although at the expense of some undershoot, as illustrated in Fig. 36.14. Because thin-film heads are made by photolithographic techniques, they can be made extremely small and to have low inductance. This, too, helps extend the frequency of operation.

A relatively new head which is now being used for readback of information in high-density recording is the magnetoresistive (MR) head. MR heads are based on the phenomenon of **magnetoresistance**, in which the electrical resistance of a magnetic material is dependent upon the direction of magnetization in the material

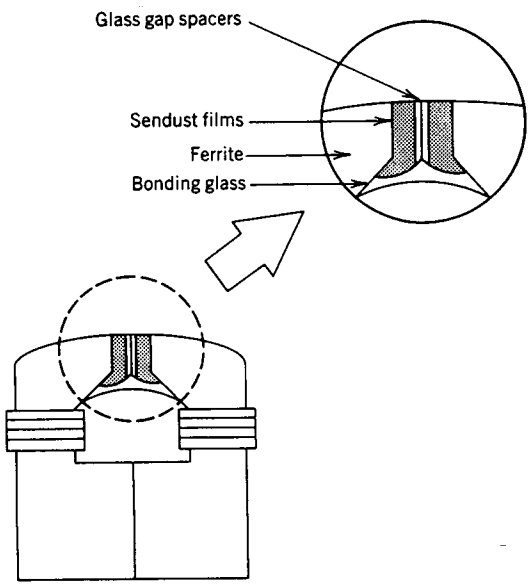

FIGURE 36.12 A diagram of a metal-in-gap or MiG recording head. (*Source:* A.S. Hoagland and J.E. Monson, *Digital Magnetic Recording*, 2nd ed., New York: Wiley-Interscience, 1991, p. 127. With permission.)

relative to the direction of current flow. An unshielded MR head is depicted in Fig. 36.15. Current flows in one end of the head and out the other. The resistivity of Permalloy from which the head is made varies as

$$\rho = \rho_o + \Delta\rho \cos^2\theta \tag{36.6}$$

where θ is the angle which the magnetization in the Permalloy makes relative to the direction of current flow, ρ_o is the isotropic resistivity, and $\Delta\rho$ is the magnetoresistivity. When the recording medium with a changing magnetization pattern moves under the MR head, the stray fields from the medium cause a change in the

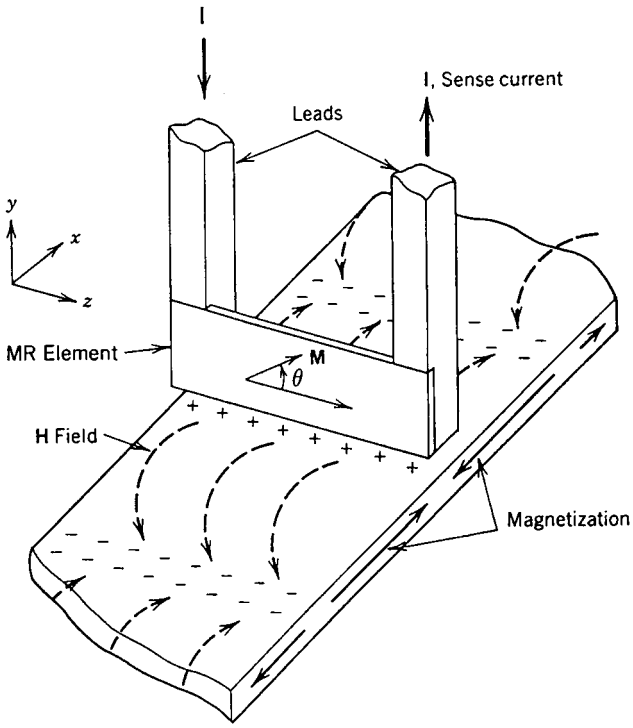

FIGURE 36.15 An unshielded magnetoresistive element. (*Source:* A.S. Hoagland and J.E. Monson, *Digital Magnetic Recording*, 2nd ed., New York: Wiley-Interscience, 1991, p. 131. With permission.)

direction of magnetization and, consequently, a change in resistance in the head. With a constant current source driving the head, the head will therefore exhibit a change in voltage across its terminals.

Magnetoresistive heads are typically more sensitive than inductive heads and therefore produce larger signal amplitudes during readback. The increased sensitivity and the fact that the read head is independent of the write head can be used to make a write/read head combination in which the write head writes a wider track than the read head senses. Thus, adjacent track interference is reduced during the readback process.

Another advantage of the MR head is that it senses magnetic flux ϕ, not the time rate of change of flux $d(\phi)/dt$ as an inductive head does. Consequently, whereas the inductive head output voltage is dependent upon the head-to-medium velocity as was shown by Eq. (36.4), the output voltage of an MR head is independent of velocity.

Conclusions

Magnetic recording today is used in a wide variety of formats for a large number of applications. Formats range from tape, which has the highest volumetric packing density and lowest cost per bit stored, to rigid disks, which provide fast access to a large volume of data. Applications include computer data storage, audio and video recording, and collecting data from scientific instruments.

The technology has increased storage density by more than a factor of 1,000,000 over the past 35 years since it was first used in a disk format for computer data storage; however, fundamental limits, set by superparamagnetism, are estimated yet to be a factor of more than 1,000 from where we are today. Furthermore, recent product announcements and developments in research labs suggest that the rate of progress is likely to accelerate. Storage densities of over 5 Gbit/in.^{2} are likely by the end of this decade and densities of 100 Gbit/in.^{2} appear likely in the early twenty-first century.

Defining Terms

Coercive force or coercivity: The magnetic field required to reduce the mean magnetization of a sample to zero after it was saturated in the opposite direction.

Demagnetizing field: The magnetic field produced by divergences in the magnetization of a magnetic sample.

Magnetoresistance: The resistance change produced in a magnetic sample when its magnetization is changed.

Remanence coercivity: The magnetic field required to produce zero remanent magnetization in a material after the material was saturated in the opposite direction.

Remanent magnetization: The magnetic moment per unit volume of a material in zero field.

Saturation magnetization: The magnetic moment per unit volume of a material when the magnetization in the sample is aligned (saturated) by a large magnetic field.

Superparamagnetism: A form of magnetism in which the spins in small particles are exchange coupled but may be collectively switched by thermal energy.

37.1 Space Propagation

Matthew N. O. Sadiku

This section summarizes the basic principles of electromagnetic (EM) **wave propagation** in space. The principles essentially state how the characteristics of the earth and the atmosphere affect the propagation of EM waves. Understanding such principles is of practical interest to communication system engineers. Engineers cannot competently apply formulas or models for communication system design without an adequate knowledge of the propagation issue.

Propagation of an EM wave may be regarded as a means of transferring energy or information from one point (a transmitter) to another (a receiver). EM wave propagation is achieved through guided structures such as transmission lines and waveguides or through space. Wave propagation through waveguides and microstrip lines will be treated in Section 37.2. In this section, our major focus is on EM wave propagation in space and the power resident in the wave.

For a clear understanding of the phenomenon of EM wave propagation, it is expedient to break the discussion of propagation effects into categories represented by four broad frequency intervals [Collin, 1985]:

- Very low frequencies (VLF), 3–30 kHz
- Low-frequency (LF) band, 30–300 kHz
- High-frequency (HF) band, 3–30 MHz
- Above 50 MHz

In the first range, wave propagates as in a waveguide, using the earth's surface and the ionosphere as boundaries. Attenuation is comparatively low, and hence VLF propagation is useful for long-distance worldwide telegraphy and submarine communication. In the second frequency range, the availability of increased bandwidth makes standard AM broadcasting possible. Propagation in this band is by means of surface wave due to the presence of the ground. The third range is useful for long-range broadcasting services via sky wave reflection and refraction by the ionosphere. Basic problems in this band include fluctuations in the ionosphere and a limited usable frequency range. Frequencies above 50 MHz allow for line-of-sight space wave propagation, FM radio and TV channels, radar and navigation systems, and so on. In this band, due consideration must be given to reflection from the ground, refraction by the troposphere, scattering by atmospheric hydrometeors, and **multipath** effects of buildings, hills, trees, etc.

EM wave propagation can be described by two complementary models. The physicist attempts a theoretical model based on universal laws, which extends the field of application more widely than currently known. The engineer prefers an empirical model based on measurements, which can be used immediately. This section presents complementary standpoints by discussing theoretical factors affecting wave propagation and the semiempirical rules allowing handy engineering calculations. First, we consider wave propagation in idealistic simple media, with no obstacles. We later consider the more realistic case of wave propagation around the earth, as influenced by its curvature and by atmospheric conditions.

Propagation in Simple Media

The conventional propagation models, on which the basic calculation of radio links is based, result directly from Maxwell's equations:

$$\nabla \cdot \mathbf{D} = \rho_v \tag{37.1}$$

$$\nabla \cdot \mathbf{B} = 0 \tag{37.2}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{37.3}$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \tag{37.4}$$

In these equations, **E** is electric field strength in volts per meter, **H** is magnetic field strength in amperes per meter, **D** is electric flux density in coulombs per square meter, **B** is magnetic flux density in webers per square meter, **J** is conduction current density in amperes per square meter, and ρ_v is electric charge density in coulombs per cubic meter. These equations go hand in hand with the constitutive equations for the medium:

$$\mathbf{D} = \epsilon \mathbf{E} \tag{37.5}$$

$$\mathbf{B} = \mu \mathbf{H} \tag{37.6}$$

$$\mathbf{J} = \sigma \mathbf{E} \tag{37.7}$$

where $\epsilon = \epsilon_o \epsilon_r$, $\mu = \mu_o \mu_r$, and σ are the permittivity, the permeability, and the conductivity of the medium, respectively.

Consider the general case of a lossy medium which is charge-free ($\rho_v = 0$). Assuming time-harmonic fields and suppressing the time factor $e^{j\omega t}$, Eqs. (37.1) to (37.7) can be manipulated to yield Helmholtz's wave equations

$$\nabla^2 \mathbf{E} - \gamma^2 \mathbf{E} = 0 \tag{37.8}$$

$$\nabla^2 \mathbf{H} - \gamma^2 \mathbf{H} = 0 \tag{37.9}$$

where $\gamma = \alpha + j\beta$ is the **propagation constant**, α is the *attenuation constant* in nepers per meter or decibels per meter, and β is the *phase constant* in radians per meter. Constants α and β are given by

$$\alpha = \omega \sqrt{\frac{\mu\epsilon}{2}\left[\sqrt{1 + \left(\frac{\sigma}{\omega\epsilon}\right)^2} - 1\right]} \tag{37.10}$$

$$\beta = \omega \sqrt{\frac{\mu\epsilon}{2}\left[\sqrt{1+\left(\frac{\sigma}{\omega\epsilon}\right)^2}+1\right]} \tag{37.11}$$

where $\omega = 2\pi f$ is the frequency of the wave. The wavelength λ and wave velocity u are given in terms of β as

$$\lambda = \frac{2\pi}{\beta} \tag{37.12}$$

$$u = \frac{\omega}{\beta} = f\lambda \tag{37.13}$$

Without loss of generality, if we assume that wave propagates in the z-direction and the wave is polarized in the x-direction, solving the wave equations (37.8) and (37.9) results in

$$\mathbf{E}(z,t) = E_o e^{-\alpha z}\cos(\omega t - \beta z)\mathbf{a}_x \tag{37.14}$$

$$\mathbf{H}(z,t) = \frac{E_o}{|\eta|} e^{-\alpha z}\cos(\omega t - \beta z - \theta_\eta)\mathbf{a}_y \tag{37.15}$$

where $\eta = |\eta|\angle\theta_\eta$ is the *intrinsic impedance* of the medium and is given by

$$|\eta| = \frac{\sqrt{\mu/\epsilon}}{\sqrt[4]{\left[1+\left(\frac{\sigma}{\omega\epsilon}\right)\right]^{1/4}}}, \qquad \tan 2\theta_\eta = \frac{\sigma}{\omega\epsilon}, \qquad 0 \le \theta_\eta \le 45^\circ \tag{37.16}$$

Equations (37.14) and (37.15) show that as the EM wave travels in the medium, its amplitude is attenuated according to $e^{-\alpha z}$, as illustrated in Fig. 37.1. The distance δ through which the wave amplitude is reduced by a factor of e^{-1} (about 37%) is called the *skin depth* or *penetration depth* of the medium, i.e.,

$$\delta = \frac{1}{\alpha} \tag{37.17}$$

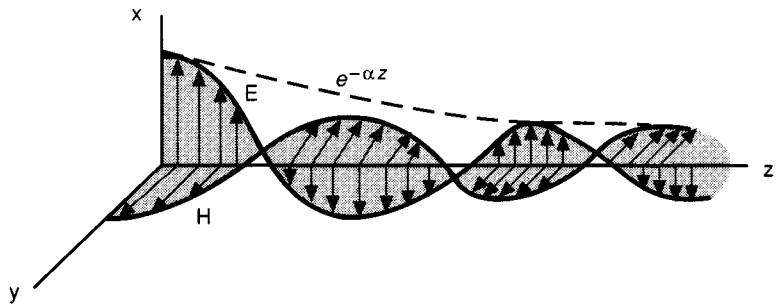

FIGURE 37.1 The magnetic and electric field components of a plane wave in a lossy medium.

The power density of the EM wave is obtained from the Poynting vector

$$\mathbf{P} = \mathbf{E} \times \mathbf{H} \tag{37.18}$$

with the time-average value of

$$\begin{aligned} P_{\text{ave}} &= \frac{1}{2}\,\text{Re}(\mathbf{E} \times \mathbf{H}^*) \\ &= \frac{E_o^2}{2\,|\eta|}\, e^{-2\alpha z} \cos\theta_\eta \mathbf{a}_z \end{aligned} \tag{37.19}$$

It should be noted from Eqs. (37.14) and (37.15) that **E** and **H** are everywhere perpendicular to each other and also to the direction of wave propagation. Thus, the wave described by Eqs. (37.14) and (37.15) is said to be *plane-polarized*, implying that the electric field is always parallel to the same plane (the *xz*-plane in this case) and is perpendicular to the direction of propagation. Also, as mentioned earlier, the wave decays as it travels in the *z*-direction because of loss. This loss is expressed in the *complex relative permittivity* of the medium

$$\epsilon_c = \epsilon_r' - j\epsilon_r'' = \epsilon_r\left(1 - j\,\frac{\sigma}{\omega\epsilon}\right) \tag{37.20}$$

and measured by the *loss tangent*, defined by

$$\tan\delta = \frac{\epsilon_r''}{\epsilon_r'} = \frac{\sigma}{\omega\epsilon} \tag{37.21}$$

The imaginary part $\epsilon_r'' = \sigma/\omega\epsilon_o$ corresponds to the losses in the medium. The refractive index of the medium *n* is given by

$$n = \sqrt{\epsilon_c} \tag{37.22}$$

Having considered the general case of wave propagation through a lossy medium, we now consider wave propagation in other types of media. A medium is said to be a good conductor if the loss tangent is large ($\sigma >> \omega\epsilon$) or a lossless or good dielectric if the loss tangent is very small ($\sigma << \omega\epsilon$). Thus, the characteristics of wave propagation through other types of media can be obtained as special cases of wave propagation in a lossy medium as follows:

1. Good conductors: $\sigma >> \omega\epsilon$, $\epsilon = \epsilon_o$, $\mu = \mu_o\mu_r$
2. Good dielectric: $\sigma << \omega\epsilon$, $\epsilon = \epsilon_o\epsilon_r$, $\mu = \mu_o\mu_r$
3. Free space: $\sigma = 0$, $\epsilon = \epsilon_o$, $\mu = \mu_o$

where $\epsilon_o = 8.854 \times 10^{-12}$ F/m is the free-space permittivity, and $\mu_o = 4\pi \times 10^{-7}$ H/m is the free-space permeability.

The conditions for each medium type are merely substituted in Eqs. (37.10) to (37.21) to obtain the wave properties for that medium. The formulas for calculating attenuation constant, phase constant, and intrinsic impedance for different media are summarized in Table 37.1.

TABLE 37.1 Attenuation Constant, Phase Constant, and Intrinsic Impedance for Different Media

	Lossy Medium	Good Conductor $\sigma/\omega\epsilon >> 1$	Good Dielectric $\sigma/\omega\epsilon << 1$	Free Space
Attenuation constant α	$\omega\sqrt{\frac{\mu\epsilon}{2}\left[\sqrt{1+\left(\frac{\sigma}{\omega\epsilon}\right)^2}-1\right]}$	$\sqrt{\frac{\omega\mu\sigma}{2}}$	$\simeq 0$	0
Phase constant β	$\omega\sqrt{\frac{\mu\epsilon}{2}\left[\sqrt{1+\left(\frac{\sigma}{\omega\epsilon}\right)^2}+1\right]}$	$\sqrt{\frac{\omega\mu\sigma}{2}}$	$\omega\sqrt{\mu\epsilon}$	$\omega\sqrt{\mu_o\epsilon_o}$
Intrinsic impedance η	$\sqrt{\frac{j\omega\mu}{\sigma+j\omega\epsilon}}$	$\sqrt{\frac{\omega\mu}{2\sigma}}(1+j)$	$\sqrt{\frac{\mu}{\epsilon}}$	377

The classical model of a wave propagation presented in this subsection helps us understand some basic concepts of EM wave propagation and the various parameters that play a part in determining the motion of a wave from the transmitter to the receiver. We now apply the ideas to the particular case of wave propagation in the atmosphere.

Propagation in the Atmosphere

Wave propagation hardly occurs under the idealized conditions assumed in the previous subsection. For most communication links, the analysis must be modified to account for the presence of the earth, the ionosphere, and atmospheric precipitates such as fog, raindrops, snow, and hail. This will be done in this subsection.

The major regions of the earth's atmosphere that are of importance in radio wave propagation are the troposphere and the ionosphere. At radar frequencies (approximately 100 MHz to 300 GHz), the troposphere is by far the most important. It is the lower atmosphere consisting of a nonionized region extending from the earth's surface up to about 15 km. The ionosphere is the earth's upper atmosphere in the altitude region from 50 km to one earth radius (6370 km). Sufficient ionization exists in this region to influence wave propagation.

Wave propagation over the surface of the earth may assume one of the following three principal modes:

- Surface wave propagation along the surface of the earth
- Space wave propagation through the lower atmosphere
- Sky wave propagation by reflection from the upper atmosphere

These modes are portrayed in Fig. 37.2. The sky wave is directed toward the ionosphere, which bends the propagation path back toward the earth under certain conditions in a limited frequency range (0–50 MHz approximately). The surface wave is directed along the surface over which the wave is propagated. The space wave consists of the direct wave and the reflected wave. The direct wave travels from the transmitter to the receiver in nearly a straight path, while the reflected wave is due to ground reflection. The space wave obeys the optical laws in that direct and reflected wave components contribute to the total wave. Although the sky and surface waves are important in many applications, we will only consider space waves in this section.

Figure 37.3 depicts the electromagnetic energy transmission between two antennas in space. As the wave radiates from the transmitting antenna and propagates in space, its power density decreases, as expressed ideally in Eq. (37.19). Assuming that the antennas are in free space, the power received by the receiving antenna is given by the *Friis transmission equation* [Liu and Fang, 1988]:

$$P_r = G_r G_t \left(\frac{\lambda}{4\pi r}\right)^2 P_t \tag{37.23}$$

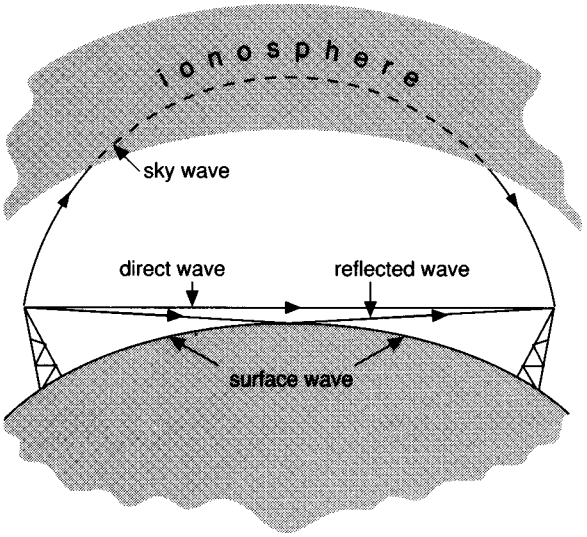

FIGURE 37.2 Modes of wave propagation.

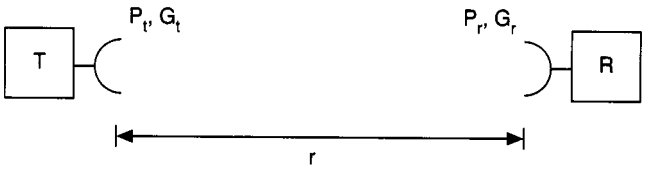

FIGURE 37.3 Transmitting and receiving antennas in free space.

where the subscripts t and r, respectively, refer to transmitting and receiving antennas. In Eq. (37.23), P is the power in watts, G is the antenna gain (dimensionless), r is the distance between the antennas in meters, and λ is the wavelength in meters. The Friis equation relates the power received by one antenna to the power transmitted by the other provided that the two antennas are separated by $r > 2d^2/\lambda$, where d is the largest dimension of either antenna. Thus, the Friis equation applies only when the two antennas are in the far-field of each other. In case the propagation path is not in free space, a correction factor F is included to account for the effect of the medium. This factor, known as the **propagation factor**, is simply the ratio of the electric field intensity E_m in the medium to the electric field intensity E_o in free space, i.e.,

$$F = \frac{E_m}{E_o} \tag{37.24}$$

The magnitude of F is always less than unity since E_m is always less than E_o. Thus, for a lossy medium, Eq. (37.23) becomes

$$P_r = G_r G_t \left(\frac{\lambda}{4\pi r}\right)^2 P_t \left|F\right|^2 \tag{37.25}$$

For practical reasons, Eqs. (37.23) and (37.25) are commonly expressed in the logarithmic form. If all terms are expressed in decibels (dB), Eq. (37.25) can be written in the logarithmic form as

$$P_r = P_t + G_r + G_t - L_o - L_m \tag{37.26}$$

where P is power in decibels referred to 1 W (or simply dBW), G is gain in decibels, L_o is free-space loss in decibels, and L_m is loss in decibels due to the medium.

The free-space loss is obtained from standard monograph or directly from

$$L_o = 20 \log \left(\frac{4\pi r}{\lambda} \right) \tag{37.27}$$

while the loss due to the medium is given by

$$L_m = -20 \log |F| \tag{37.28}$$

Our major concern in the rest of the section is to determine L_o and L_m for two important cases of space propagation that differ considerably from the free-space conditions.

Effect of the Earth

The phenomenon of multipath propagation causes significant departures from free-space conditions. The term *multipath* denotes the possibility of EM wave propagation along various paths from the transmitter to the receiver. In multipath propagation of an EM wave over the earth's surface, two such paths exist: a direct path and a path via reflection and diffractions from the interface between the atmosphere and the earth. A simplified geometry of the multipath situation is shown in Fig. 37.4. The reflected and diffracted component is commonly separated into two parts, one specular (or coherent) and the other diffuse (or incoherent), that can be separately analyzed. The specular component is well defined in terms of its amplitude, phase, and incident direction. Its main characteristic is its conformance to Snell's law for reflection, which requires that the angles of incidence and reflection be equal and coplanar. It is a plane wave and, as such, is uniquely specified by its direction. The diffuse component, however, arises out of the random nature of the scattering surface and, as such, is nondeterministic. It is not a plane wave and does not obey Snell's law for reflection. It does not come from a given direction but from a continuum.

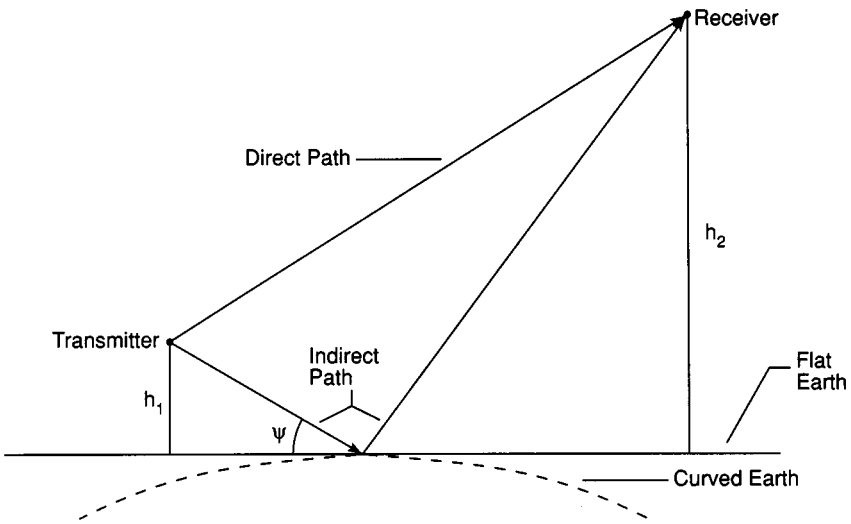

FIGURE 37.4 Multipath geometry.

The loss factor F that accounts for the departures from free-space conditions is given by

$$F = 1 + \Gamma \rho_s D\, S(\theta) e^{-j\Delta} \tag{37.29}$$

where Γ is the Fresnel reflection coefficient, ρ_s is the roughness coefficient, D is the divergence factor, $S(\theta)$ is the shadowing function, and Δ is the phase angle corresponding to the path difference. We now account for each of these terms.

The Fresnel reflection coefficient Γ accounts for the electrical properties of the earth's surface. Because the earth is a lossy medium, the value of the reflection coefficient depends on the complex relative permittivity ϵ_c of the surface, the grazing angle ψ, and the wave polarization. It is given by

$$\Gamma = \frac{\sin\psi - z}{\sin\psi + z} \tag{37.30}$$

where

$$z = \sqrt{\epsilon_c - \cos^2\psi} \qquad \text{for horizontal polarization} \tag{37.31}$$

$$z = \frac{\sqrt{\epsilon_c - \cos^2\psi}}{\epsilon_c} \qquad \text{for vertical polarization} \tag{37.32}$$

$$\epsilon_c = \epsilon_r - j\frac{\sigma}{\omega\epsilon_o} = \epsilon_r - j60\sigma\lambda \tag{37.33}$$

ϵ_r and σ are the dielectric constant and conductivity of the surface; ω and λ are the frequency and wavelength of the incident wave; and ψ is the grazing angle. It is apparent that $0 < |\Gamma| < 1$.

To account for the spreading (or divergence) of the reflected rays because of the earth's curvature, we introduce the divergence factor D. The curvature has a tendency to spread out the reflected energy more than a corresponding flat surface. The divergence factor is defined as the ratio of the reflected field from curved surface to the reflected field from flat surface [Kerr, 1951]. Using the geometry of Fig. 37.5, D is given by

$$D \simeq \left(1 + \frac{2G_1G_2}{a_eG\sin\psi}\right)^{-1/2} \tag{37.34}$$

where $G = G_1 + G_2$ is the total ground range and $a_e = 6370$ km is the effective earth radius. Given the transmitter height h_1, the receiver height h_2, and the total ground range G, we can determine G_1, G_2, and ψ. If we define

$$p = \frac{2}{\sqrt{3}}\left[a_e(h_1 + h_2) + \frac{G^2}{4}\right]^{1/2} \tag{37.35}$$

$$\alpha = \cos^{-1}\left[\frac{2a_e(h_1 - h_2)G}{p^3}\right] \tag{37.36}$$

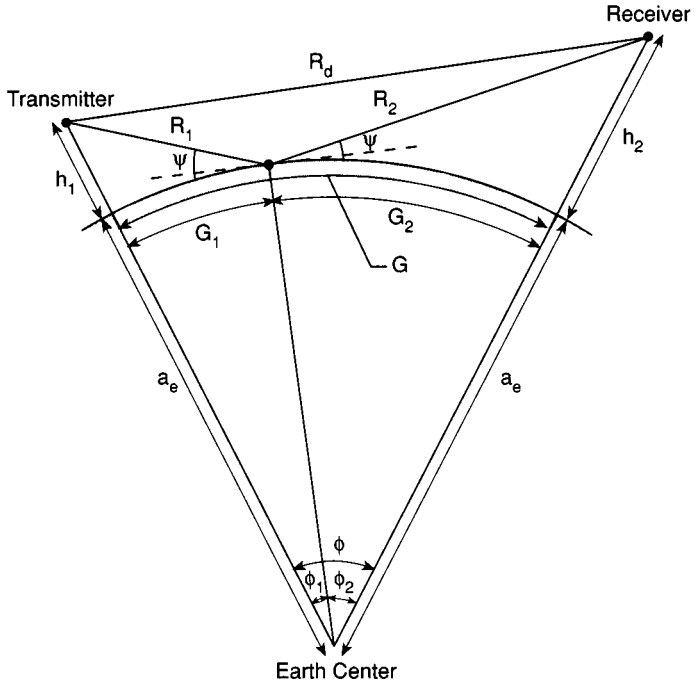

FIGURE 37.5 Geometry of spherical earth reflection.

and assume $h_1 \leq h_2$, $G_1 \leq G_2$, using small angle approximation yields [Blake, 1986]

$$G_1 = \frac{G}{2} + p \cos\left(\frac{\pi + \alpha}{3}\right) \tag{37.37}$$

$$G_2 = G - G_1 \tag{37.38}$$

$$\phi_i = \frac{G_i}{a_e}, \qquad i = 1, 2 \tag{37.39}$$

$$R_i = [h_i^2 + 4a_e(a_e + h_i)\sin^2(\phi_i/2)]^{1/2}, \qquad i = 1, 2 \tag{37.40}$$

The grazing angle is given by

$$\psi = \sin^{-1}\left[\frac{2a_e h_1 + h_1^2 - R_1^2}{2a_e R_1}\right] \tag{37.41}$$

or

$$\psi = \sin^{-1}\left[\frac{2a_e h_1 + h_1^2 + R_1^2}{2(a_e + h_1)R_1}\right] - \phi_1 \tag{37.42}$$

Although D varies from 0 to 1, in practice D is a significant factor at low grazing angle ψ.

The phase angle corresponding to the path difference between direct and reflected waves is given by

$$\Delta = \frac{2\pi}{\lambda}(R_1 + R_2 - R_d) \tag{37.43}$$

The roughness coefficient ρ_s takes care of the fact that the earth's surface is not sufficiently smooth to produce specular (mirrorlike) reflection except at a very low grazing angle. The earth's surface has a height distribution that is random in nature. The randomness arises out of the hills, structures, vegetation, and ocean waves. It is found that the distribution of the heights of the earth's surface is usually the Gaussian or normal distribution of probability theory. If σ_h is the standard deviation of the normal distribution of heights, we define the roughness parameters

$$g = \frac{\sigma_h \sin \psi}{\lambda} \tag{37.44}$$

If $g < 1/8$, specular reflection is dominant; if $g > 1/8$, diffuse scattering results. This criterion, known as *Rayleigh criterion*, should only be used as a guideline since the dividing line between a specular and diffuse reflection or between a smooth and a rough surface is not well defined [Beckman and Spizzichino, 1963]. The roughness is taken into account by the roughness coefficient ($0 < \rho_s < 1$), which is the ratio of the field strength after reflection with roughness taken into account to that which would be received if the surface were smooth. The roughness coefficient is given by

$$\rho_s = \exp[-2(2\pi g)^2] \tag{37.45}$$

The shadowing function $S(\theta)$ is important at a low grazing angle. It considers the effect of geometric shadowing—the fact that the incident wave cannot illuminate parts of the earth's surface shadowed by higher parts. In a geometric approach, where diffraction and multiple scattering effects are neglected, the reflecting surface will consist of well-defined zones of illumination and shadow. As there will be no field on a shadowed portion of the surface, the analysis should include only the illuminated portions of the surface. The phenomenon of shadowing of a stationary surface was first investigated by Beckman in 1965 and subsequently refined by Smith [1967] and others. A pictorial representation of rough surfaces illuminated at angle of incidence θ ($= 90° - \psi$) is shown in Fig. 37.6. It is evident from the figure that the shadowing function $S(\theta)$ is equal to unity when $\theta = 0$ and zero when $\theta = \pi/2$. According to Smith [1967],

$$S(\theta) \simeq \frac{\left[1 - \frac{1}{2}\operatorname{erfc}(a)\right]}{1 + 2B} \tag{37.46}$$

where $\operatorname{erfc}(x)$ is the complementary error function,

$$\operatorname{erfc}(x) = 1 - \operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-t^2} dt \tag{37.47}$$

and

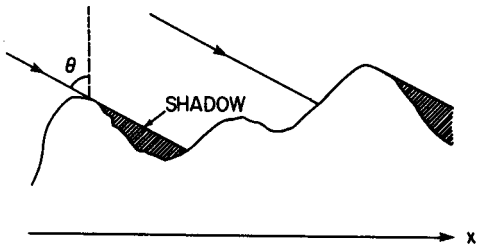

FIGURE 37.6 Rough surface illuminated at an angle of incidence θ.

$$B = \frac{1}{4a}\left[\frac{1}{\sqrt{\pi}}e^{a^2} - a\,\mathrm{erfc}(a)\right] \tag{37.48}$$

$$a = \frac{\cot\theta}{2s} \tag{37.49}$$

$$s = \frac{\sigma_h}{\sigma_l} = \text{rms surface slope} \tag{37.50}$$

In Eq. (37.50) σ_h is the rms roughness height and σ_l is the correlation length. Alternative models for $S(\theta)$ are available in the literature. Using Eqs. (37.30) to (37.50), the loss factor in Eq. (37.29) can be calculated. Thus

$$L_o = 20\log\left(\frac{4\pi R_d}{\lambda}\right) \tag{37.51}$$

$$L_m = -20\log\left[1 + \Gamma\,\rho_s D\,S(\theta)e^{-j\Delta}\right] \tag{37.52}$$

Effect of Atmospheric Hydrometeors

The effect of atmospheric hydrometeors on satellite–earth propagation is of major concern at microwave frequencies. The problem of scattering of electromagnetic waves by atmospheric hydrometeors has attracted much interest since the late 1940s. The main hydrometeors that exist for long duration and have the greatest interaction with microwaves are rain and snow. At frequencies above 10 GHz, rain has been recognized as the most fundamental obstacle on the earth–space path. Rain has been known to cause attenuation, phase difference, and depolarization of radio waves. For analog signals, the effect of rain is more significant above 10 GHz, while for digital signals, rain effects can be significant down to 3 GHz. Attenuation of microwaves because of precipitation becomes severe owing to increased scattering and beam energy absorption by raindrops, thus impairing terrestrial as well as earth–satellite communication links. Cross-polarization distortion due to rain has also engaged the attention of researchers. This is of particular interest when frequency reuse employing signals with orthogonal polarizations is used for doubling the capacity of a communication system. A thorough review on the interaction of microwaves with hydrometeors has been given by Oguchi [1983].

The loss due to a rain-filled medium is given by

$$L_m = \gamma(R)\,\ell_e(\mathrm{R})\,\mathrm{p}(\mathrm{R}) \tag{37.53}$$

where γ is attenuation per unit length at rain rate R, ℓ is the equivalent path length at rain rate R, and p(R) is the probability in percentage of rainfall rate R.

Attenuation is a function of the cumulative rain-rate distribution, drop-size distribution, refractive index of water, temperature, and other variables. A rigorous calculation of $\gamma(R)$ incorporating raindrop-size distribution, velocity of raindrops, and refractive index of water can be found in Sadiku [1992]. For practical engineering purposes, what is needed is a simple formula relating attenuation to rain parameters. Such is found in the aR^b empirical relationship, which has been used to calculate rain attenuation directly [Collin, 1985], i.e.,

$$\gamma(R) = aR^b \text{ dB/km} \tag{37.54}$$

where R is the rain rate and a and b are constants. At 0°C, the values of a and b are related to frequency f in gigahertz as follows:

$$a = G_a f^{Ea} \tag{37.55}$$

where $G_a = 6.39 \times 10^{-5}$, $E_a = 2.03$, for $f < 2.9$ GHz; $G_a = 4.21 \times 10^{-5}$, $E_a = 2.42$, for $2.9 \text{ GHz} \le f \le 54$ GHz; $G_a = 4.09 \times 10^{-2}$, $E_a = 0.699$, for $54 \text{ GHz} \le f < 100$ GHz; $G_a = 3.38$, $E_a = -0.151$, for $180 \text{ GHz} < f$; and

$$b = G_b f^{Eb} \tag{37.56}$$

where $G_b = 0.851$, $E_b = 0.158$, for $f < 8.5$ GHz; $G_b = 1.41$, $E_b = -0.0779$, for $8.5 \text{ GHz} \le f < 25$ GHz; $G_b = 2.63$, $E_b = -0.272$, for $25 \text{ GHz} \le f < 164$ GHz; $G_b = 0.616$, $E_b = 0.0126$, for $164 \text{ GHz} \le f$.

The effective length $\ell_e(R)$ through the medium is needed since rain intensity is not uniform over the path. Its actual value depends on the particular area of interest and therefore has a number of representations [Liu and Fang, 1988]. Based on data collected in western Europe and eastern North America, the effective path length has been approximated as [Hyde, 1984]

$$\ell_e(R) = [0.00741R^{0.766} + (0.232 - 0.00018R)\sin\theta]^{-1} \tag{37.57}$$

where θ is the elevation angle.

The cumulative probability in percentage of rainfall rate R is given by [Hyde, 1984]

$$p(R) = \frac{M}{87.66}[0.03\beta e^{-0.03R} + 0.2(1-\beta)(e^{-0.258R} + 1.86e^{-1.63R})] \tag{37.58}$$

where M is the mean annual rainfall accumulation in millimeters and β is the Rice–Holmberg thunderstorm ratio.

The effect of other hydrometeors such as water vapor, fog, hail, snow, and ice is governed by similar fundamental principles as the effect of rain [Collin, 1985]. In most cases, however, their effects are at least an order of magnitude less than the effect of rain.

Other Effects

Besides hydrometeors, the atmosphere has the composition given in Table 37.2. While attenuation of EM waves by hydrometeors may result from both absorption and scattering, gases act only as absorbers. Although some of these gases do not absorb microwaves, some possess permanent electric and/or magnetic dipole moment and play some part in

TABLE 37.2 Composition of Dry Atmosphere from Sea Level to about 90 km

Constituent	Percent by Volume	Percent by Weight
Nitrogen	78.088	75.527
Oxygen	20.949	23.143
Argon	0.93	1.282
Carbon dioxide	0.03	0.0456
Neon	1.8×10^{-3}	1.25×10^{-3}
Helium	5.24×10^{-4}	7.24×10^{-5}
Methane	1.4×10^{-4}	7.75×10^{-5}
Krypton	1.14×10^{-4}	3.30×10^{-4}
Nitrous oxide	5×10^{-5}	7.60×10^{-5}
Xenon	8.6×10^{-6}	3.90×10^{-5}
Hydrogen	5×10^{-5}	3.48×10^{-6}

microwave absorption. For example, nitrogen molecules do not possess permanent electric or magnetic dipole moment and therefore play no part in microwave absorption. Oxygen has a small magnetic moment, which enables it to display weak absorption lines in the centimeter and millimeter wave regions. Water vapor is a molecular gas with a permanent electric dipole moment. It is more responsive to excitation by an EM field than is oxygen.

Defining Terms

Multipath: Propagation of electromagnetic waves along various paths from the transmitter to the receiver.

Propagation constant: The negative of the partial logarithmic derivative, with respect to the distance in the direction of the wave normal, of the phasor quantity describing a traveling wave in a homogeneous medium.

Propagation factor: The ratio of the electric field intensity in a medium to its value if the propagation took place in free space.

Wave propagation: The transfer of energy by electromagnetic radiation.

Further Information

There are several sources of information dealing with the theory and practice of wave propagation in space. Some of these are in the reference section. Journals such as *Radio Science, IEE Proceedings Part H,* and *IEEE Transactions on Antennas and Propagation* are devoted to EM wave propagation. *Radio Science* is available from the American Geophysical Union, 2000 Florida Avenue NW, Washington DC 20009; *IEE Proceedings Part H* from IEE Publishing Department, Michael Faraday House, 6 Hills Way, Stevenage, Herts, SG1 2AY, U.K.; and *IEEE Transactions on Antennas and Propagation* from IEEE, 445 Hoes Lane, P.O. Box 1331, Piscataway, NJ 08855-1331.

Other mechanisms that can affect EM wave propagation in space, not discussed in this section, include clouds, dust, and the ionosphere. The effect of the ionosphere is discussed in detail in standard texts.

37.2 Waveguides

Kenneth Demarest

Waveguide Modes

Any structure that guides electromagnetic waves can be considered a **waveguide**. Most often, however, this term refers to closed metal cylinders that maintain the same cross-sectional dimensions over long distances. Such a structure is shown in Fig. 37.7, which consists of a metal cylinder filled with a dielectric. When filled with low-loss dielectrics (such as air), waveguides typically exhibit lower losses than transmission lines, which makes them useful for transporting RF energy over relatively long distances. They are most often used for frequencies ranging from 1 to 150 GHz.

Every type of waveguide has an infinite number of distinct electromagnetic field configurations that can exist inside it. Each of these configurations is called a **waveguide mode**. The characteristics of these modes depend upon the cross-sectional dimensions of the conducting cylinder, the type of dielectric material inside the waveguide, and the frequency of operation.

Waveguide modes are typically classed according to the nature of the electric and magnetic field components E_z and H_z. These components are called the longitudinal components of the fields. Several types of modes are possible in waveguides:

TE modes: Transverse-electric modes, sometimes called H modes. These modes have $E_z = 0$ at all points within the waveguide, which means that the electric field vector is always perpendicular (i.e., transverse) to the waveguide axis. These modes are always possible in waveguides with uniform dielectrics.

TM modes: Transverse-magnetic modes, sometimes called E modes. These modes have $H_z = 0$ at all points within the waveguide, which means that the magnetic field vector is perpendicular to the waveguide axis. Like TE modes, they are always possible in waveguides with uniform dielectrics.

EH modes: EH modes are hybrid modes in which neither E_z nor H_z are zero, but the characteristics of the transverse fields are controlled more by E_z than H_z. These modes are often possible in waveguides with inhomogeneous dielectrics.

HE modes: HE modes are hybrid modes in which neither E_z nor H_z are zero, but the characteristics of the transverse fields are controlled more by H_z than E_z. Like EH modes, these modes are often possible in waveguides with inhomogeneous dielectrics.

TEM modes: Transverse-electromagnetic modes, often called transmission line modes. These modes can exist only when a second conductor exists within the waveguide, such as a center conductor on a coaxial cable. Because these modes cannot exist in single, closed conductor structures, they are not waveguide modes.

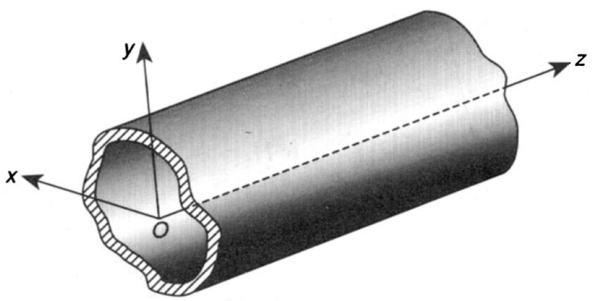

FIGURE 37.7 A uniform waveguide with arbitrary cross section.

Waveguide modes are most easily determined by first computing the longitudinal field components, E_z and H_z, that can be supported by the waveguide. From these, the transverse components (such as E_x and E_y) can easily be found simply by taking spatial derivatives of the longitudinal fields [Collin, 1992].

When the waveguide properties are constant along the z axis, E_z and H_z vary in the longitudinal direction as E_z, $H_z \propto \exp(\omega t - \gamma z)$, where $\omega = 2\pi f$ is the radian frequency of operation and γ is a complex number of the form

$$\gamma = \alpha + j\beta \tag{37.59}$$

The parameters γ, α, and β are called the propagation, attenuation, and phase constants, respectively, and $j = \sqrt{-1}$. When there are no metal or dielectric losses, γ is always either purely real or imaginary. When γ is real, E_z and H_z have constant phase and decay exponentially with increasing z. When γ is imaginary, E_z and H_z vary in phase with increasing z but do not decay in amplitude. When this occurs, the fields are said to be propagating.

When the dielectric is uniform (i.e., homogeneous), E_z and H_z satisfy the scalar wave equation at all points within the waveguide:

$$\nabla_t^2 E_z + h^2 E_z = 0 \tag{37.60}$$

and

$$\nabla_t^2 H_z + h^2 H_z = 0 \tag{37.61}$$

where

$$h^2 = (2\pi f)^2 \mu\epsilon + \gamma^2 = k^2 + \gamma^2 \tag{37.62}$$

Here, μ and ϵ are the permeability and permittivity of the dielectric media, respectively, and $k = 2\pi f\sqrt{\mu\epsilon}$ is the wavenumber of the dielectric. The operator ∇_t^2 is called the transverse Laplacian operator. In Cartesian coordinates,

$$\nabla_t^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$$

Most of the properties of the allowed modes in real waveguides can usually be found by assuming that the walls are perfectly conducting. Under this condition, $E_z = 0$ and $\partial H_z/\partial p = 0$ at the waveguide walls, where p is the direction perpendicular to the waveguide wall. When these conditions are imposed upon the general solutions of Eqs. (37.60) and (37.61), it is found that only certain values of h are allowed. These values are called the *modal eigenvalues* and are determined by the cross-sectional shape of the waveguide. Using Eq. (37.62), the propagation constant γ for each mode varies with frequency according to

$$\gamma = \alpha + j\beta = h\sqrt{1 - \left(\frac{f}{f_c}\right)^2} \tag{37.63}$$

where

$$f_c = \frac{h}{2\pi\sqrt{\mu\epsilon}} \tag{37.64}$$

The modal parameter f_c has units hertz and is called the **cut-off frequency** of the mode it is associated with. According to Eq. (37.63), when $f > f_c$, the propagation constant γ is imaginary and thus the mode is propagating. On the other hand, when $f < f_c$, γ is real, which means that the fields decay exponentially with increasing values of z. Modes operated at frequencies below their cut-off frequency are not able to propagate energy over long distances and are called evanescent modes.

The dominant mode of a waveguide is the one with the lowest cut-off frequency. Although higher-order modes are often useful for a variety of specialized uses of waveguides, signal distortion is usually minimized when a waveguide is operated in the frequency range where only the dominant mode exists. This range of frequencies is called the *dominant rang*e of the waveguide.

The distance over which the fields of propagating modes repeat themselves is called the **guide wavelength** λ_g. From Eq. (37.63), it can be shown that λ_g always varies with frequency according to

$$\lambda_g = \frac{\lambda_o}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} \tag{37.65}$$

where $\lambda_o = 1/(f\sqrt{\mu\epsilon})$ is the wavelength of a plane wave of the same frequency in an infinite sample of the waveguide dielectric. For $f >> f_c$, $\lambda_g \approx \lambda_o$. Also, $\lambda_g \to \infty$ as $f \to f_c$, which is one reason why it is usually undesirable to operate a waveguide mode near modal cut-off frequencies.

Although waveguide modes are not plane waves, the ratio of their transverse electric and magnetic field magnitudes is constant throughout the cross section of the waveguide, just as for plane waves. This ratio is called the modal **wave impedance** and has the following values for TE and TM modes:

$$Z_{TE} = \frac{E_T}{H_T} = \frac{j\omega\mu}{\gamma} \tag{37.66}$$

and

$$Z_{TM} = \frac{E_T}{H_T} = \frac{\gamma}{j\omega\epsilon} \tag{37.67}$$

where E_T and H_T are the magnitudes of the transverse electric and magnetic fields, respectively. In the limit as $f \to \infty$, both Z_{TE} and Z_{TM} approach $\sqrt{\mu\epsilon}$, which is the intrinsic impedance of the dielectric medium. On the other hand, as $f \to f_c$, $Z_{TE} \to \infty$ and $Z_{TM} \to 0$, which means that the transverse electric fields are dominant in TE modes near cut-off and vice versa for TM modes.

Rectangular Waveguides

A rectangular waveguide is shown in Fig. 37.8. The conducting walls are formed such that the inner surfaces form a rectangular cross section, with dimensions a and b along the x and y coordinate axes, respectively.

If the walls are perfectly conducting and the dielectric material is lossless, the field components for the TE_{mn} modes are given by

$$E_x = H_0 \frac{j\omega\mu}{h_{mn}^2}\left(\frac{n\pi}{b}\right)\cos\left(\frac{m\pi}{a}x\right)\sin\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.68}$$

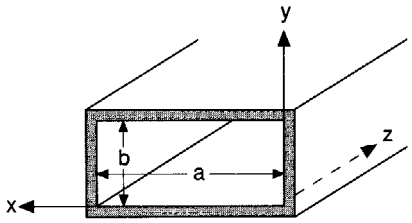

FIGURE 37.8 A rectangular waveguide.

$$E_y = -H_0 \frac{j\omega\mu}{h_{mn}^2}\left(\frac{m\pi}{a}\right)\sin\left(\frac{m\pi}{a}x\right)\cos\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.69}$$

$$E_z = 0$$

$$H_x = H_0 \frac{\gamma_{mn}}{h_{mn}^2}\left(\frac{m\pi}{a}\right)\sin\left(\frac{m\pi}{a}x\right)\cos\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.70}$$

$$H_y = H_0 \frac{\gamma_{mn}}{h_{mn}^2}\left(\frac{n\pi}{b}\right)\cos\left(\frac{m\pi}{a}x\right)\sin\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.71}$$

$$H_z = H_0 \cos\left(\frac{m\pi}{a}x\right)\cos\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.72}$$

where

$$h_{mn} = \sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2} = 2\pi f_{c_{mn}}\sqrt{\mu\epsilon} \tag{37.73}$$

For the TM_{mn} modes, m and n can be any positive integer value, including zero, as long as both are not zero.

The field components for the TM_{mn} modes are

$$E_x = -E_0 \frac{\gamma_{mn}}{h_{mn}^2}\left(\frac{m\pi}{a}\right)\cos\left(\frac{m\pi}{a}x\right)\sin\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.74}$$

$$E_y = -E_0 \frac{\gamma_{mn}}{h_{mn}^2}\left(\frac{n\pi}{b}\right)\sin\left(\frac{m\pi}{a}x\right)\cos\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.75}$$

$$E_z = E_0 \sin\left(\frac{m\pi}{a}x\right)\sin\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.76}$$

4.0	TE_{40}

$$H_x = E_0 \frac{j\omega\epsilon}{h_{mn}^2}\left(\frac{n\pi}{b}\right)\sin\left(\frac{m\pi}{a}x\right)\cos\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.77}$$

$$H_y = -E_0 \frac{j\omega\epsilon}{h_{mn}^2}\left(\frac{m\pi}{a}\right)\cos\left(\frac{m\pi}{a}x\right)\sin\left(\frac{n\pi}{b}y\right)\exp(j\omega t - \gamma_{mn}z) \tag{37.78}$$

$$H_z = 0 \tag{37.79}$$

where the values of h_{mn} and f_{cmn} are given by Eq. (37.73). For the TM_{mn} modes, m and n can be any positive integer value except zero.

The dominant mode in a rectangular waveguide is the TE_{10} mode, which has a cut-off frequency

$$f_{c_{10}} = \frac{1}{2a\sqrt{\mu\epsilon}} = \frac{c}{2a} \tag{37.80}$$

where c is the speed of light in the dielectric media. The modal field patterns for this mode are shown in Fig. 37.9.

Table 37.3 shows the cut-off frequencies of the lowest-order rectangular waveguide modes (as referenced to the cut-off frequency of the dominant mode) when $a/b = 2.1$. The modal field patterns for several lower-order modes are shown in Fig. 37.10.

Circular Waveguides

A circular waveguide with inner radius a is shown in Fig. 37.11. Here the axis of the waveguide is aligned with the z axis of a circular-cylindrical coordinate system, where ρ and ϕ are the radial and azimuthal coordinates,

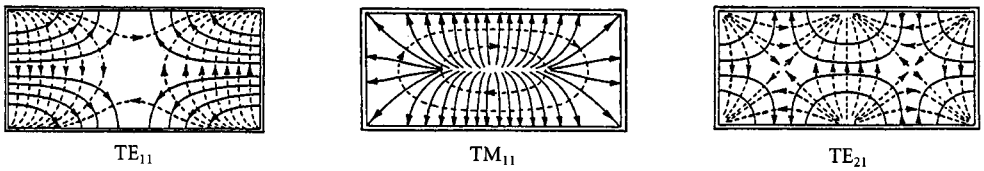

FIGURE 37.10 Field configurations for the TE_{11}, TM_{11}, and the TE_{21} modes. Solid lines, E; dashed lines, H. (*Source:* Adapted from N. Marcuvitz, *Waveguide Handbook*, 2nd. ed., London: Peter Peregrinus Ltd., and New York: McGraw-Hill, 1986, p. 59. With permission.)

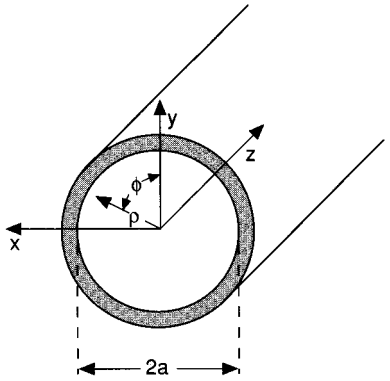

FIGURE 37.11 A circular waveguide.

respectively. If the walls are perfectly conducting and the dielectric material is lossless, the equations for the TE_{nm} modes are

$$E_\rho = H_0 \frac{j\omega\mu n}{h_{nm}^2 \rho} J_n(h_{nm}\rho) \sin(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.81}$$

$$E_\phi = H_0 \frac{j\omega\mu}{h_{nm}} J_n'(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.82}$$

$$E_z = 0 \tag{37.83}$$

$$H_\rho = -H_0 \frac{\gamma_{nm}}{h_{nm}} J_n'(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.84}$$

$$H_\phi = H_0 \frac{\gamma_{nm}}{h_{nm}^2 \rho} J_n(h_{nm}\rho) \sin(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.85}$$

$$H_z = H_0 J_n(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.86}$$

where n is any positive valued integer, including zero, and $J_n(x)$ and $J_n'(x)$ are the regular Bessel function of order n and its first derivative, respectively. The allowed values of the modal eigenvalues h_{nm} satisfy

$$J_n'(h_{nm}\, a) = 0 \tag{37.87}$$

where m signifies the root number of Eq. (37.87). By convention, $1 < m < \infty$, where $m = 1$ indicates the smallest root.

The equations that define the TM_{nm} modes in circular waveguides are

$$E_\rho = -E_0 \frac{\gamma_{nm}}{h_{nm}} J_n'(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.88}$$

$$E_\phi = E_0 \frac{\gamma_{nm}}{h_{nm}^2 \rho} J_n(h_{nm}\rho) \sin(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.89}$$

$$E_z = E_0 J_n(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.90}$$

$$H_\rho = -E_0 \frac{j\omega\epsilon n}{h_{nm}^2 \rho} J_n(h_{nm}\rho) \sin(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.91}$$

$$H_\phi = -E_0 \frac{j\omega\epsilon}{h_{nm}} J_n'(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm} z) \tag{37.92}$$

$$H_z = 0 \tag{37.93}$$

where n is any positive valued integer, including zero. For the TM_{nm} modes, the values of the modal eigenvalues are solutions of

$$J_n(h_{nm} a) = 0 \tag{37.94}$$

where m signifies the root number of Eq. (37.94). As in the case of the TE modes, $1 < m < \infty$.

The dominant mode in a circular waveguide is the TE_{11} mode, which has a cut-off frequency given by

$$f_{c_{11}} = \frac{0.293}{a\sqrt{\mu\epsilon}} \tag{37.95}$$

The configuration of the electric and magnetic fields of this mode is shown in Fig. 37.12.

Table 37.4 shows the cut-off frequencies of the lowest-order modes for circular waveguides, referenced to the cut-off frequency of the dominant mode. The modal field patterns for several lower-order modes are shown in Fig. 37.13.

Commercially Available Waveguides

The dimensions of standard rectangular waveguides are given in Table 37.5.

In addition to rectangular and circular waveguides, several other waveguide types are commonly used in microwave applications. Among these are ridge waveguides and elliptical waveguides. The modes of elliptical waveguides can be expressed in terms of Mathieu functions [Kretzschmar, 1970] and are similar to those of circular waveguides but are less perturbed by minor twists and bends of the waveguide. This property makes them attractive for coupling to antennas.

Single-ridge and double-ridge waveguides are shown in Fig. 37.14. The modes of these waveguides bear similarities to those of rectangular guides, but can only be derived numerically [Montgomery, 1971]. Ridge waveguides are useful because their dominant ranges exceed those of rectangular waveguides. However, this range increase is obtained at the expense of higher losses.

Waveguides are also available in a number of constructions, including rigid, semirigid, and flexible. In applications where it is not necessary for the waveguide to bend, rigid construction is always the best since it exhibits the lowest loss. In general, the more flexible the waveguide construction, the higher the loss.

Waveguide Losses

There are two mechanisms that cause losses in waveguides: dielectric losses and metal losses. In both cases, these losses cause the amplitudes of the propagating modes to decay as $\exp(-\alpha z)$, where α is the attenuation constant, measured in units of nepers/meter. Typically, the attenuation constant is considered as the sum of

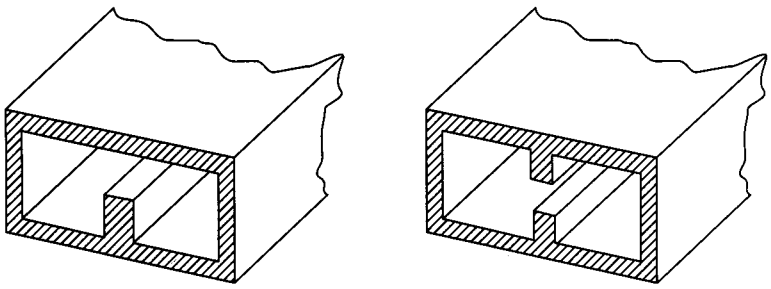

FIGURE 37.14 Single- and double-ridged waveguides.

two components: $\alpha = \alpha_{die} + \alpha_{met}$, where α_{die} and α_{met} are the dielectric and metal attenuation constants, respectively.

The attenuation constant α_{die} can be found directly from Eq. (37.63) simply by generalizing the dielectric wavenumber k to include the effect of the dielectric conductivity σ. For a lossy dielectric, the wavenumber is given by $k^2 = \omega^2\mu\epsilon[1 + (\sigma/j\omega\epsilon)]$. Thus, from Eqs. (37.62) and (37.63) the attenuation constant α_{die} due to dielectric losses is given by

$$\alpha_{die} = \text{real}\left[\sqrt{h^2 - \omega^2\mu\epsilon\left(1 + \frac{\sigma}{j\omega\epsilon}\right)}\right] \tag{37.96}$$

where the allowed values of h are given by Eq. (37.73) for rectangular modes and Eqs. (37.87) and (37.94) for circular modes.

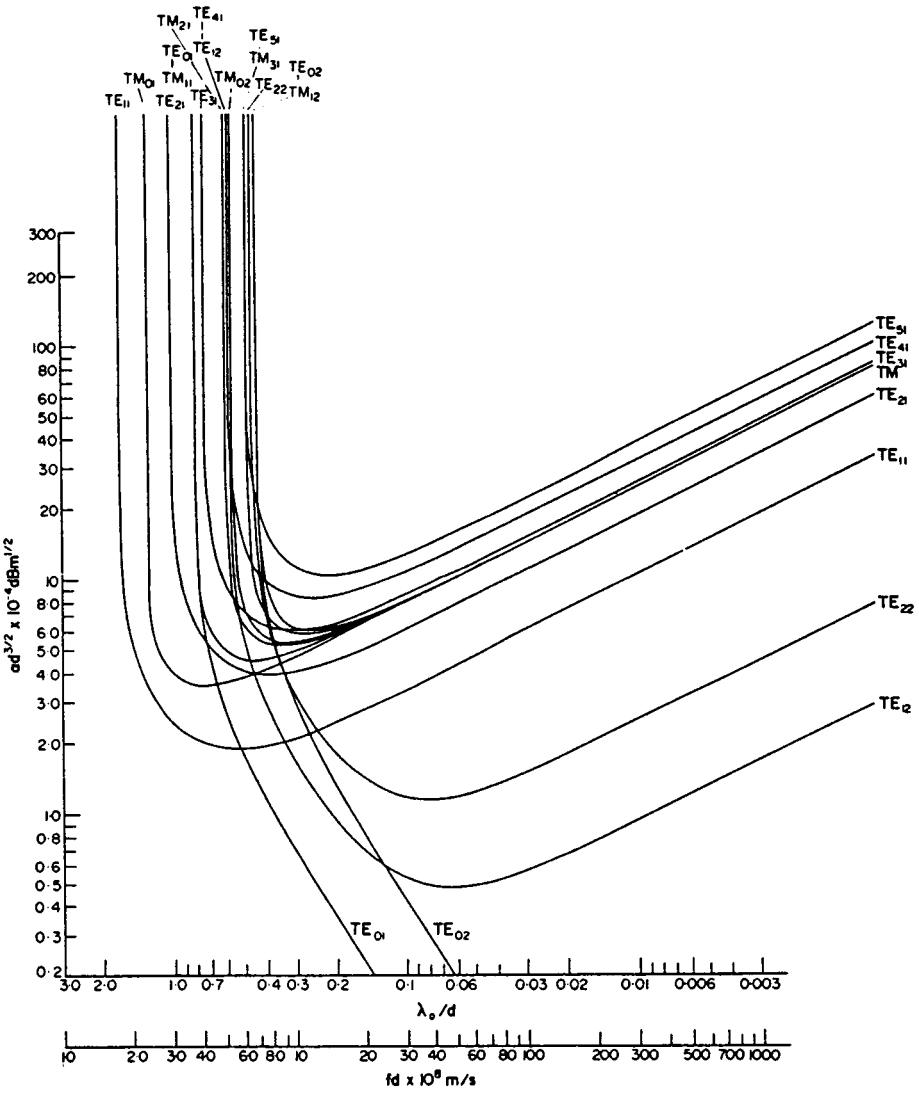

FIGURE 37.15 Values of metallic attenuation constant α for the first few waveguide modes in a circular waveguide of diameter d, plotted against normalized wavelength. (*Source:* A.J. Baden Fuller, *Microwaves,* 2nd ed., New York: Pergamon Press, 1979, p. 138. With permission.)

The metal loss constant α_{met} is usually obtained by assuming that the wall conductivity is high enough to have only a negligible effect on the transverse properties of the modal field patterns. Using this assumption, the power loss in the walls per unit distance along the waveguide can then be calculated to obtain α_{met} [Marcuvitz, 1986]. Figure 37.15 shows the metal attenuation constants for several circular waveguide modes, each normalized to the resistivity R_s of the walls, where $R_s = \sqrt{(\pi f \mu / \sigma)}$ and where μ and σ are the permeability and conductivity of the metal walls, respectively. As can be seen from this figure, the TE_{0m} modes exhibit particularly low loss at frequencies significantly above their cut-off frequencies, making them useful for transporting microwave energy over large distances.

Mode Launching

When coupling electromagnetic energy into a waveguide, it is important to ensure that the desired modes are excited and that reflections back to the source are minimized. Similar concerns must be considered when

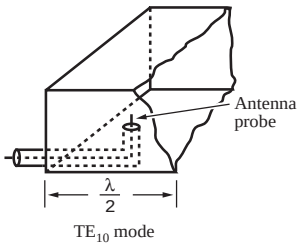

FIGURE 37.16 Coaxial to rectangular waveguide transition that couples the transmission line mode to the dominant waveguide mode

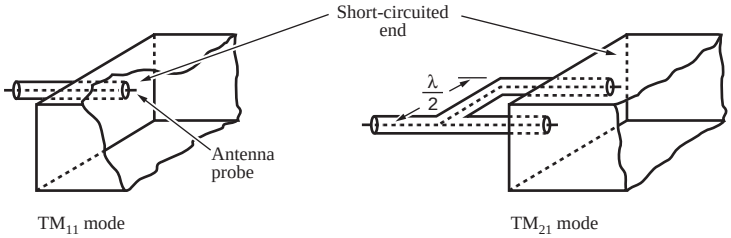

FIGURE 37.17 Coaxial to rectangular waveguide transitions that couple the transmission line mode to the TM_{11} and TM_{21} waveguide modes.

coupling energy from a waveguide to a transmission line or circuit element. This is achieved by using launching (or coupling) structures that allow strong coupling between the desired modes on both structures.

Figure 37.16 shows a mode launching structure for coaxial cable to rectangular waveguide transitions.

This structure provides good coupling between the TEM (transmission line) mode on a coaxial cable and the TE_{10} mode in the waveguide because the antenna probe excites a strong transverse electric field in the center of the waveguide, directed between the broad walls. The distance between the probe and the short circuit back wall is chosen to be approximately $\lambda/4$, which allows the TE_{10} mode launched in this direction to reflect off the short circuit and arrive in phase with the mode launched towards the right.

Launching structures can also be devised to launch higher-order modes. Mode launchers that couple the transmission line mode on a coaxial cable to the TM_{11} and TM_{21} waveguide mode are shown in Fig. 37.17.

Defining Terms

Cut-off frequency: The minimum frequency at which a waveguide mode will propagate energy with little or no attenuation.

Guide wavelength: The distance over which the fields of propagating modes repeat themselves in a waveguide.

Waveguide: A closed metal cylinder, filled with a dielectric, used to transport electromagnetic energy over short or long distances.

Waveguide modes: Unique electromagnetic field configurations supported by a waveguide that have distinct electrical characteristics.

Wave impedance: The ratio of the transverse electric and magnetic fields inside a waveguide.

38.1 Wire

N.J. Kolias and R.C. Compton

Antennas have been widely used in communication systems since the early 1900s. Over this span of time scientists and engineers have developed a vast number of different antennas. The radiative properties of each of these antennas are described by an antenna pattern. This is a plot, as a function of direction, of the power P_r per unit solid angle Ω radiated by the antenna. The antenna pattern, also called the **radiation pattern,** is usually plotted in spherical coordinates θ and φ. Often two orthogonal cross sections are plotted, one where the *E*-field lies in the plane of the slice (called the *E*-plane) and one where the *H*-field lies in the plane of the slice (called the *H*-plane).

Short Dipole

Antenna patterns for a short dipole are plotted in Fig. 38.1. In these plots the radial distance from the origin to the curve is proportional to the radiated power. Antenna plots are usually either on linear scales or decibel scales (10 log power).

The antenna pattern for a short dipole may be determined by first calculating the vector potential **A** [Collin, 1985; Balanis, 1982; Harrington, 1961; Lorrain and Corson, 1970]. Using Collin's notation, the vector potential in spherical coordinates is given by

$$\mathbf{A} = \mu_0 I\, dl\, \frac{e^{-jk_0 r}}{4\pi r} (\mathbf{a}_r \cos\theta - \mathbf{a}_\theta \sin\theta) \tag{38.1}$$

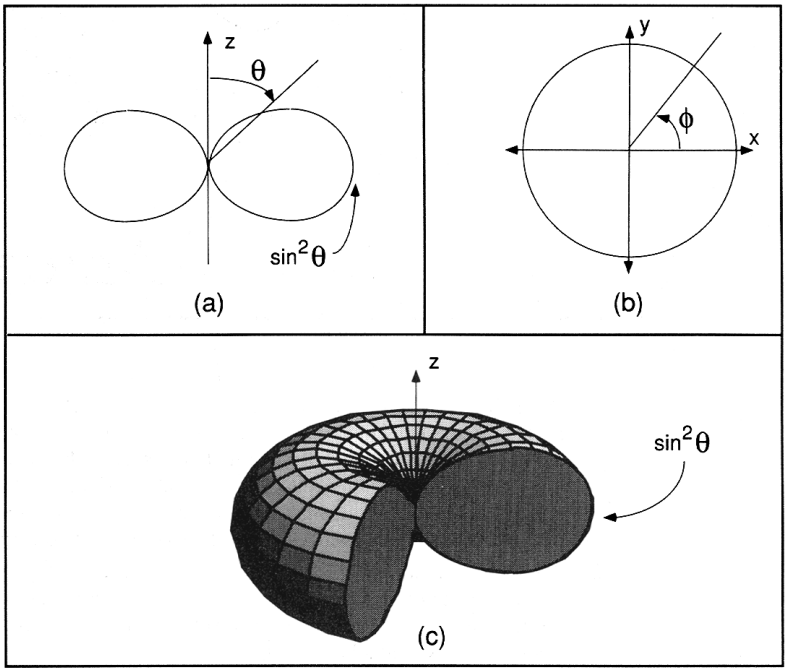

FIGURE 38.1 Radiation pattern for a short dipole of length dl ($dl << \lambda_0$). These are plots of power density on linear scales. (a) *E*-plane; (b) *H*-plane; (c) three-dimensional view with cutout.

where $k_0 = 2\pi/\lambda_0$, and I is the current, assumed uniform, in the short dipole of length dl ($dl << \lambda_0$). Here the assumed time dependence $e^{j\omega t}$ has not been explicitly shown. The electric and magnetic fields may then be determined using

$$\mathbf{E} = -j\omega\mathbf{A} + \frac{\nabla\nabla\cdot\mathbf{A}}{j\omega\mu_0\varepsilon_0} \qquad \mathbf{H} = \frac{1}{\mu_0}\nabla\times\mathbf{A} \tag{38.2}$$

The radiated fields are obtained by calculating these fields in the so-called *far-field region* where $r >> \lambda$. Doing this for the short dipole yields

$$\begin{aligned}\mathbf{E} &= jZ_0 Idlk_0 \sin\theta\,\frac{e^{-jk_0 r}}{4\pi r}\,\mathbf{a}_\theta \\ \mathbf{H} &= jIdlk_0 \sin\theta\,\frac{e^{-jk_0 r}}{4\pi r}\,\mathbf{a}_\varphi\end{aligned} \tag{38.3}$$

where $Z_0 = \sqrt{\mu_0/\varepsilon_0}$. The average radiated power per unit solid angle Ω can then be found to be

$$\frac{\Delta P_r(\theta,\varphi)}{\Delta\Omega} = \frac{1}{2}r^2\Re\mathrm{e}\{\mathbf{E}\times\mathbf{H}^*\cdot\mathbf{a}_r\} = |I|^2 Z_0(dl)^2 k_0^2\,\frac{\sin^2\theta}{32\pi^2} \tag{38.4}$$

Directivity

The **directivity** $D(\theta,\varphi)$ and **gain** $G(\theta,\varphi)$ of an antenna are defined as

$$\begin{aligned} D(\theta,\varphi) &= \frac{\text{Radiated power per solid angle}}{\text{Total radiated power}/4\pi} = \frac{\Delta P_r(\theta,\varphi)/\Delta\Omega}{P_r/4\pi} \\ G(\theta,\varphi) &= \frac{\text{Radiated power per solid angle}}{\text{Total input power}/4\pi} = \frac{\Delta P_r(\theta,\varphi)/\Delta\Omega}{P_{\text{in}}/4\pi} \end{aligned} \tag{38.5}$$

Antenna efficiency, η, is given by

$$\eta \equiv \frac{P_r}{P_{\text{in}}} = \frac{G(\theta,\varphi)}{D(\theta,\varphi)} \tag{38.6}$$

For many antennas $\eta \approx 1$ and so the words *gain* and *directivity* can be used interchangeably. For the short dipole

$$D(\theta,\varphi) = \frac{3}{2}\sin^2\theta \tag{38.7}$$

The maximum directivity of the short dipole is 3/2. This single number is often abbreviated as the antenna directivity. By comparison, for an imaginary isotropic antenna which radiates equally in all directions, $D(\theta,\varphi) = 1$. The product of the maximum directivity with the total radiated power is called the *effective isotropic radiated power* (EIRP). It is the total radiated power that would be required for an isotropic radiator to produce the same signal as the original antenna in the direction of maximum directivity.

Magnetic Dipole

A small loop of current produces a *magnetic dipole*. The far fields for the magnetic dipole are dual to those of the electric dipole. They have the same angular dependence as the fields of the electric dipole, but the polarization orientations of **E** and **H** are interchanged.

$$\begin{aligned} \mathbf{H} &= -Mk_0^2 \sin\theta \frac{e^{-jk_0 r}}{4\pi r}\mathbf{a}_\theta \\ \mathbf{E} &= MZ_0 k_0^2 \sin\theta \frac{e^{-jk_0 r}}{4\pi r}\mathbf{a}_\varphi \end{aligned} \tag{38.8}$$

where $M = \pi\ r_0^2\ I$ for a loop with radius r_0 and uniform current I.

Input Impedance

At a given frequency the impedance at the feedpoint of an antenna can be represented as $Z_a = R_a + jX_a$. The real part of Z_a (known as the input resistance) corresponds to radiated fields plus losses, while the imaginary part (known as the input reactance) arises from stored evanescent fields. The radiation resistance is obtained from $R_a = 2P_r/|I|^2$ where P_r is the total radiated power and I is the input current at the antenna terminals. For electrically small electric and magnetic dipoles with uniform currents

$$R_a = 80\pi^2\left(\frac{dl}{\lambda_0}\right)^2 \quad \text{electric dipole}$$
$$R_a = 320\pi^6\left(\frac{r_0}{\lambda_0}\right)^4 \quad \text{magnetic dipole} \tag{38.9}$$

The reactive component of Z_a can be determined from $X_a = 4\omega(W_m\text{-}W_e)/|I|^2$ where W_m is the average magnetic energy and W_e is the average electric energy stored in the near-zone evanescent fields. The reflection coefficient, Γ, of the antenna is just

$$\Gamma = \frac{Z_a - Z_0}{Z_a + Z_0} \tag{38.10}$$

where Z_0 is the characteristic impedance of the system used to measure the reflection coefficient.

Arbitrary Wire Antennas

An arbitrary wire antenna can be considered as a sum of small current dipole elements. The vector potential for each of these elements can be determined in the same way as for the short dipole. The total vector potential is then the sum over all these infinitesimal contributions and the resulting E in the far field can be found to be

$$\mathbf{E}(r) = jk_0Z_0\frac{e^{-jk_0r}}{4\pi r}\int_c[(\mathbf{a}_r\cdot\mathbf{a})\mathbf{a}_r - \mathbf{a}]I(l')e^{jk_0\mathbf{a}_r\cdot\mathbf{r}'}dl' \tag{38.11}$$

where the integral is over the contour C of the wire, $\mathbf{a}$ is a unit vector tangential to the wire, and $\mathbf{r}'$ is the radial vector to the infinitesimal current element.

Resonant Half-Wavelength Antenna

The resonant half-wavelength antenna (commonly called the half-wave dipole) is used widely in antenna systems. Factors contributing to its popularity are its well-understood radiation pattern, its simple construction, its high efficiency, and its capability for easy impedance matching.

The electric and magnetic fields for the half-wave dipole can be calculated by substituting its current distribution, $I = I_0\cos(k_0z)$, into Eq. (38.11) to obtain

$$\mathbf{E} = jZ_0I_0\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\frac{e^{-jk_0r}}{2\pi r}\mathbf{a}_\theta$$
$$\mathbf{H} = jI_0\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\frac{e^{-jk_0r}}{2\pi r}\mathbf{a}_\varphi \tag{38.12}$$

The total radiated power, P_r, can be determined from the electric and magnetic fields by integrating the expression $1/2\ \Re\mathrm{e}\{\mathbf{E}\times\mathbf{H}^*\cdot\mathbf{a}_r\}$ over a surface of radius r. Carrying out this integration yields $P_r = 36.565\ |I_0|^2$. The radiation resistance of the half-wave dipole can then be determined from

$$R_a = \frac{2P_r}{|I_0|^2} \approx 73\,\Omega \tag{38.13}$$

This radiation resistance is considerably higher than the radiation resistance of a short dipole. For example, if we have a dipole of length 0.01λ, its radiation resistance will be approximately $0.08\,\Omega$ (from Eq. 38.9). This resistance is probably comparable to the ohmic resistance of the dipole, thereby resulting in a low efficiency. The half-wave dipole, having a much higher radiation resistance, will have much higher efficiency. The higher resistance of the half-wave dipole also makes impedance matching easier.

End Loading

At many frequencies of interest, for example, the broadcast band, a half-wavelength becomes unreasonably long. Figure 38.2 shows a way of increasing the effective length of the dipole without making it longer. Here, additional wires have been added to the ends of the dipoles. These wires increase the end capacitance of the dipole, thereby increasing the effective electrical length.

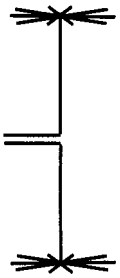

FIGURE 38.2 Using end loading to increase the effective electrical length of an electric dipole.

Arrays of Wire Antennas

Often it is advantageous to have several antennas operating together in an **array.** Arrays of antennas can be made to produce highly directional radiation patterns. Also, small antennas can be used in an array to obtain the level of performance of a large antenna at a fraction of the area.

The radiation pattern of an array depends on the number and type of antennas used, the spacing in the array, and the relative phase and magnitude of the excitation currents. The ability to control the phase of the exciting currents in each element of the array allows one to electronically scan the main radiated beam. An array that varies the phases of the exciting currents to scan the radiation pattern through space is called an electronically scanned **phased array.** Phased arrays are used extensively in radar applications.

Analysis of General Arrays

To obtain analytical expressions for the radiation fields due to an array one must first look at the fields produced by a single array element. For an isolated radiating element positioned as in Fig. 38.3, the electric field at a far-field point P is given by

$$\mathbf{E}_i = a_i \mathbf{K}_i(\theta, \varphi) e^{j[k_0(\mathbf{R}_i \cdot \mathbf{i}_p) - \alpha_i]} \tag{38.14}$$

where $\mathbf{K}_i(\theta,\varphi)$ is the electric field pattern of the individual element, $a_i\, e^{-j\alpha i}$ is the excitation of the individual element, $\mathbf{R}_i$ is the position vector from the phase reference point to the element, $\mathbf{i}_p$ is a unit vector pointing toward the far-field point P, and k_0 is the free space wave vector.

Now, for an array of N of these arbitrary radiating elements the total E-field at position P is given by the vector sum

$$\mathbf{E}_{\text{tot}} = \sum_{i=0}^{N-1} \mathbf{E}_i = \sum_{i=0}^{N-1} a_i \mathbf{K}_i(\theta, \varphi) e^{j[k_0(\mathbf{R}_i \cdot \mathbf{i}_p) - \alpha_i]} \tag{38.15}$$

This equation may be used to calculate the total field for an array of antennas where the mutual coupling between the array elements can be neglected. For most practical antennas, however, there is mutual coupling,

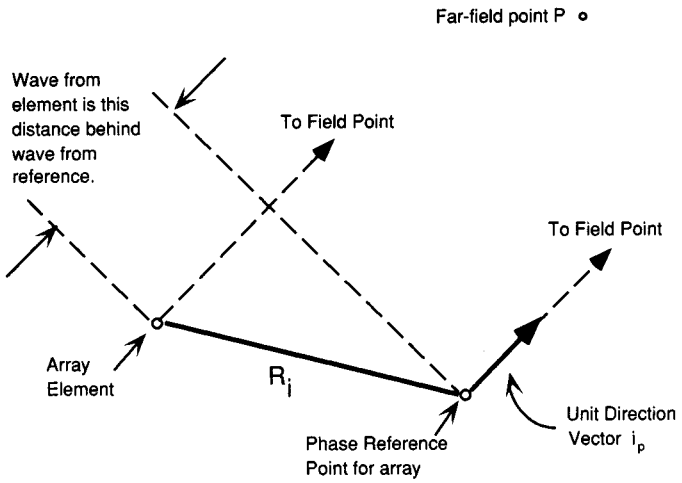

FIGURE 38.3 Diagram for determining the far field due to radiation from a single array element. (*Source: Reference Data for Radio Engineers,* Indianapolis: Howard W. Sams & Co., 1975, chap. 27–22. With permission.)

and the individual patterns will change when the element is placed in the array. Thus, Eq. (38.15) should be used with care.

Arrays of Identical Elements

If all the radiating elements of an array are identical, then $\mathbf{K}_i(\theta,\varphi)$ will be the same for each element and Eq. (38.15) can be rewritten as

$$\mathbf{E}_{\text{tot}} = \mathbf{K}(\theta,\varphi)\sum_{i=0}^{N-1} a_i e^{j[k_0(\mathbf{R}_i\cdot\mathbf{i}_p)-\alpha_i]} \tag{38.16}$$

This can also be written as

$$\mathbf{E}_{\text{tot}} = \mathbf{K}(\theta,\varphi)\, f(\theta,\varphi) \qquad \text{where} \quad f(\theta,\varphi) = \sum_{i=0}^{N-1} a_i e^{j[k_0(\mathbf{R}_i\cdot\mathbf{i}_p)-\alpha_i]} \tag{38.17}$$

The function $f(\theta,\varphi)$ is normally called the array factor or the array polynomial. Thus, one can find $\mathbf{E}_{\text{tot}}$ by just multiplying the individual element's electric field pattern, $\mathbf{K}(\theta,\varphi)$, by the array factor, $f(\theta,\varphi)$. This process is often referred to as pattern multiplication.

The average radiated power per unit solid angle is proportional to the square of $\mathbf{E}_{\text{tot}}$. Thus, for an array of identical elements

$$\frac{\Delta P_r(\theta,\varphi)}{\Delta\Omega} \sim \left|\mathbf{K}(\theta,\varphi)\right|^2 \left|f(\theta,\varphi)\right|^2 \tag{38.18}$$

Equally Spaced Linear Arrays

An important special case occurs when the array elements are identical and are arranged on a straight line with equal element spacing, *d,* as shown in Fig. 38.4. If a linear phase progression, α, is assumed for the excitation currents of the elements, then the total field at position *P* in Fig. 38.4 will be

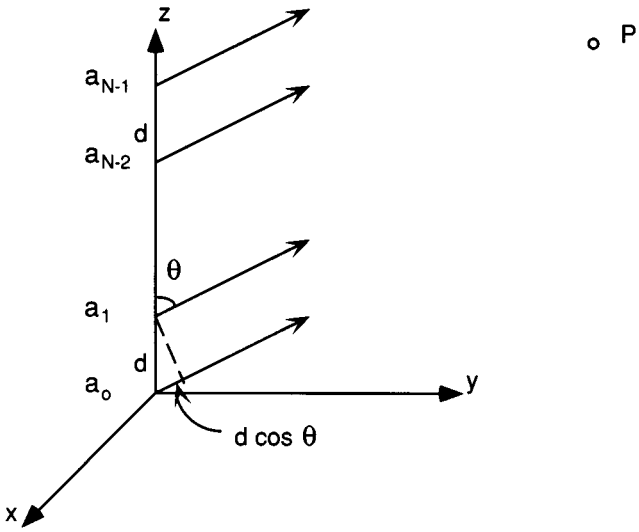

FIGURE 38.4 A linear array of equally spaced elements.

$$\begin{aligned} \mathbf{E}_{\text{tot}} &= \mathbf{K}(\theta,\varphi)\sum_{n=0}^{N-1} a_n e^{jn(k_0 d\cos\theta-\alpha)} \\ &= \mathbf{K}(\theta,\varphi)\sum_{n=0}^{N-1} a_n e^{jn\psi} = \mathbf{K}(\theta,\varphi) f(\psi) \end{aligned} \tag{38.19}$$

where $\psi = k_0 d\cos\theta - \alpha$.

Broadside Arrays

Suppose that, in the linear array of Fig. 38.4, all the excitation currents are equal in magnitude and phase ($a_0 = a_1 = \ldots = a_{N-1}$ and $\alpha = 0$). The array factor, $f(\psi)$, then becomes

$$f(\psi) = a_0\sum_{n=0}^{N-1} e^{jn\psi} = a_0\,\frac{1-e^{jN\psi}}{1-e^{j\psi}} \tag{38.20}$$

This can be simplified to obtain the normalized form

$$f'(\psi) = \left|\frac{f(\psi)}{a_0 N}\right| = \left|\frac{\sin\dfrac{N\psi}{2}}{N\sin\dfrac{\psi}{2}}\right| \tag{38.21}$$

Note that $f'(\psi)$ is maximum when $\psi = 0$. For our case, with $\alpha = 0$, we have $\psi = k_0 d\cos\theta$. Thus $f'(\psi)$ will be maximized when $\theta = \pi/2$. This direction is perpendicular to the axis of the array (see Fig. 38.4), and so the resulting array is called a broadside array.

Phased Arrays

By adjusting the phase of the elements of the array it is possible to vary the direction of the maximum of the array's radiation pattern. For arrays where all the excitation currents are equal in magnitude but not necessarily phase, the array factor is a maximum when $\psi = 0$. From the definition of ψ, one can see that at the pattern maximum

$$k_0 d \cos\theta = \alpha$$

Thus, the direction of the array factor maximum is given by

$$\theta = \cos^{-1}\left(\frac{\alpha}{k_0 d}\right) \tag{38.21b}$$

Note that if one is able to control the phase delay, α, the direction of the maximum can be scanned without physically moving the antenna.

Planar (2-D) Arrays

Suppose there are M linear arrays, all identical to the one pictured in Fig. 38.4, lying in the yz-plane with element spacing d in both the y and the z direction. Using the origin as the phase reference point, the array factor can be determined to be

$$f(\theta, \varphi) = \sum_{n=0}^{N-1} \sum_{m=0}^{M-1} a_{mn} e^{[jn(k_0\, d \cos\theta - \alpha_z) + jm(k_0\, d \sin\theta \sin\varphi - \alpha_y)]} \tag{38.22}$$

where α_y and α_z are the phase differences between the adjacent elements in the y and z directions, respectively. The formula can be derived by considering the 2-D array to be a 1-D array of subarrays, where each subarray has an antenna pattern given by Eq. (38.19).

If all the elements of the 2-D array have excitation currents equal in magnitude and phase (all the a_{mn} are equal and $\alpha_z = \alpha_y = 0$), then the array will be a broadside array and will have a normalized array factor given by

$$f'(\theta, \varphi) = \frac{\sin\left(\frac{Nk_0 d}{2}\cos\theta\right)}{N \sin\left(\frac{k_0 d}{2}\cos\theta\right)} \frac{\sin\left(\frac{Mk_0 d}{2}\sin\theta\sin\varphi\right)}{M \sin\left(\frac{k_0 d}{2}\sin\theta\sin\varphi\right)} \tag{38.23}$$

Yagi–Uda Arrays

The Yagi–Uda array can be found on rooftops all over the world—the standard TV antenna is a Yagi–Uda array. The Yagi–Uda array avoids the problem of needing to control the feeding currents to all of the array elements by driving only one element. The other elements in the Yagi–Uda array are excited by near-field coupling from the driven element.

The basic three-element Yagi–Uda array is shown in Fig. 38.5. The array consists of a driven antenna of length l_1, a reflector element of length l_2, and a director element of length l_3. Typically, the director element is shorter than the driven element by 5% or more, while the reflector element is longer than the driven element by 5% or more [Stutzman and Thiele, 1981]. The radiation pattern for the array in Fig. 38.5 will have a maximum in the $+z$ direction.

One can increase the gain of the Yagi–Uda array by adding additional director elements. Adding additional reflector elements, however, has little effect because the field behind the first reflector element is small.

Yagi–Uda arrays typically have directivities between 10 and 100, depending on the number of directors [Ramo et al., 1984]. TV antennas usually have several directors.

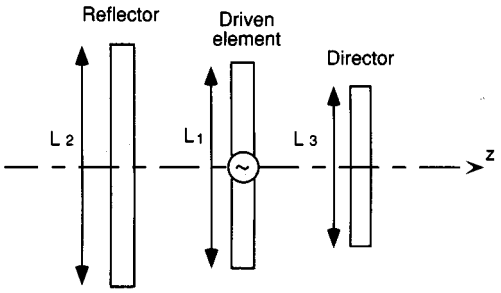

FIGURE 38.5 Three-element Yagi–Uda antenna. (*Source:* Shintaro Uda and Yasuto Mushiake, *Yagi–Uda Antenna,* Sendai, Japan: Sasaki Printing and Publishing Company, 1954, p. 100. With permission.)

Log-Periodic Dipole Arrays

Another variation of wire antenna arrays is the log-periodic dipole array. The log-periodic is popular in applications that require a broadband, frequency-independent antenna. An antenna will be independent of frequency if its dimensions, when measured in wavelengths, remain constant for all frequencies. If, however, an antenna is designed so that its characteristic dimensions are periodic with the logarithm of the frequency, and if the characteristic dimensions do not vary too much over a period of time, then the antenna will be essentially frequency independent. This is the basis for the log-periodic dipole array, shown in Fig. 38.6.

In Fig 38.6, the ratio of successive element positions equals the ratio of successive dipole lengths. This ratio is often called the scaling factor of the log-periodic array and is denoted by

$$\tau = \frac{z_{n+1}}{z_n} = \frac{L_{n+1}}{L_n} \tag{38.24}$$

Also note that there is a mechanical phase reversal between successive elements in the array caused by the crossing over of the interconnecting feed lines. This phase reversal is necessary to obtain the proper phasing between adjacent array elements.

To get an idea of the operating range of the log-periodic antenna, note that for a given frequency within the operating range of the antenna, there will be one dipole in the array that is half-wave resonant or is nearly so. This half-wave resonant dipole and its immediate neighbors are called the active region of the log-periodic array. As the operating frequency changes, the active region shifts to a different part of the log-periodic. Hence, the frequency range for the log-periodic array is roughly given by the frequencies at which the longest and shortest dipoles in the array are half-wave resonant (wavelengths such that $2L_N < \lambda < 2L_1$) [Stutzman and Thiele, 1981].

Defining Terms

Antenna gain: The ratio of the actual radiated power per solid angle to the radiated power per solid angle that would result if the total input power were radiated isotropically.

Array: Several antennas arranged together in space and interconnected to produce a desired radiation pattern.

Directivity: The ratio of the actual radiated power per solid angle to the radiated power per solid angle that would result if the radiated power was radiated isotropically. Oftentimes the word *directivity* is used to refer to the maximum directivity.

Phased array: An array in which the phases of the exciting currents are varied to scan the radiation pattern through space.

Radiation pattern: A plot as a function of direction of the power per unit solid angle radiated in a given polarization by an antenna. The terms *radiation pattern* and *antenna pattern* can be used interchangeably.

Further Information

For general-interest articles on antennas the reader is directed to the *IEEE Antennas and Propagation Magazine.* In addition to providing up-to-date articles on current issues in the antenna field, this magazine also provides easy-to-read tutorials. For the latest research advances in the antenna field the reader is referred to the *IEEE Transactions on Antennas and Propagation.* In addition, a number of very good textbooks are devoted to antennas. The books by Collin and by Stutzman and Thiele were especially useful in the preparation of this section.

38.2 Aperture

J. Patrick Fitch

The main purpose of an **antenna** is to control a wave front at the boundary between two media: a source (or receiver) and the medium of propagation. The source can be a fiber, cable, waveguide, or other transmission line. The medium of propagation may be air, vacuum, water, concrete, metal, or tissue, depending on the application. Antenna aperture design is used in acoustic, optic, and electromagnetic systems for imaging, communications, radar, and spectroscopy applications.

There are many classes of antennas: wire, horn, slot, notch, reflector, lens, and **array**, to name a few (see Fig. 38.7). Within each class is a variety of subclasses. For instance, the horn antenna can be pyramidal or conical. The horn can also have flaring in only one direction (sectoral horn), asymmetric components, shaped

High-Speed Space Data Communications

TSI/TelSys Inc., Columbia, Maryland, is a company formed to commercialize NASA high-data-rate telemetry technology originally developed at Goddard Space Flight Center's Microelectronic Systems Branch. Today, TSI/TelSys Inc. designs, manufactures, markets, and supports a broad range of commercial satellite telecommunications gateway products. These technologies and products support two-way, high-speed space data communications for telemetry, satellite remote sensing, and high-data-rate communications applications. The satellite antenna shown above is part of a system used for high-speed data transmissions. (Courtesy of National Aeronautics and Space Administration.)

edges, or a compound design of sectoral and pyramidal combined. For all antennas, the relevant design and analysis will depend on antenna aperture size and shape, the center wavelength λ, and the distance from the aperture to a point of interest (the range, R). This section covers discrete **oscillators**, arrays of oscillators, synthetic apertures, geometric design, Fourier analysis, and parameters of some typical antennas. The emphasis is on microwave-type designs.

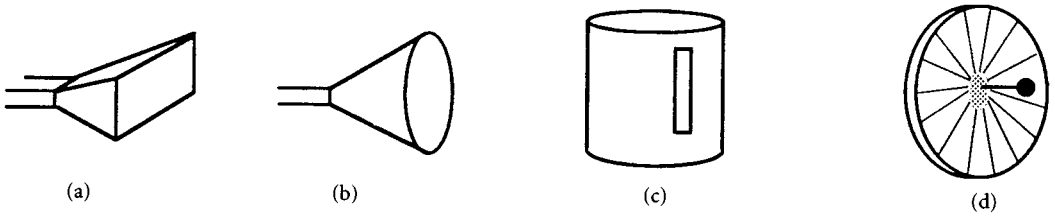

FIGURE 38.7 Examples of several types of antennas: (a) pyramidal horn, (b) conical horn, (c) axial slot on a cylinder, and (d) parabolic reflector.

The Oscillator or Discrete Radiator

The basic building block for antenna analysis is a linear conductor. Movement of electrons (current) in the conductor induces an electromagnetic field. When the electron motion is oscillatory—e.g., a dipole with periodic electron motion, the induced electric field, E, is proportional to $\cos(\omega t - kx + \phi)$, where ω is radian frequency of oscillation, t is time, k is wave number, x is distance from the oscillator, and ϕ is the phase associated with this oscillator (relative to the time and spatial coordinate origins). When the analysis is restricted to a fixed position x, the electric field can be expressed as

$$E(t) = A\cos(\omega t + \phi) \tag{38.25}$$

where the phase term ϕ now includes the kx term, and all of the constants of proportionality are included in the amplitude A. Basically, the assumption is that oscillating currents produce oscillating fields. The description of a receiving antenna is analogous: an oscillating field induces a periodic current in the conductor.

The field from a pair of oscillators separated in phase by δ radians is

$$E_\delta(t) = A_1\cos(\omega t + \phi) + A_2\cos(\omega t + \phi + \delta) \tag{38.26}$$

Using phasor notation, $\tilde{E}_\delta$, the cosines are converted to complex exponentials and the radial frequency term, ωt, is suppressed,

$$\tilde{E}_\delta(t) = A_1 e^{i\phi} + A_2 e^{i(\phi+\delta)} \tag{38.27}$$

The amplitude of the sinusoidal modulation $E_\delta(t)$ can be calculated as $|\tilde{E}_\delta|$. The intensity is

$$I = |\tilde{E}_\delta|^2 = |A_1|^2 + |A_2|^2 + 2A_1A_2\cos(\delta) \tag{38.28}$$

When the oscillators are of the same amplitude, $A = A_1 = A_2$, then

$$\begin{aligned} E_\delta(t) &= A\cos(\omega t + \phi) + A\cos(\omega t + \phi + \delta) \\ &= 2A\cos\left(\frac{\delta}{2}\right)\cos\left(\omega t + \phi + \frac{\delta}{2}\right) \end{aligned} \tag{38.29}$$

For a series of n equal amplitude oscillators with equal phase spacing

$$E_{n\delta}(t) = \sum_{j=0}^{n-1} A\cos(\omega t + \phi + j\delta) \tag{38.30}$$

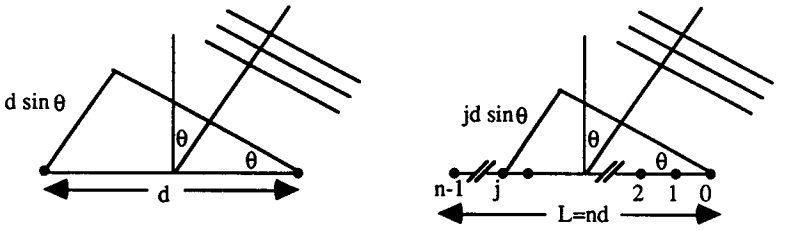

FIGURE 38.8 A two-element and an n-element array with equal spacing between elements. The propagation length difference between elements is $d\sin\theta$, which corresponds to a phase difference of $kd\sin\theta$, where k is the wave number $2\pi/\lambda$. The length L corresponds to a continuous aperture of length nd with the sample positions beginning $d/2$ from the ends.

By using phasor arithmetic the intensity is given as

$$I_{n\delta}(t) = \left|\tilde{E}_{n\delta}\right|^2 = \left|Ae^{i\phi}\sum_{j=0}^{n-1} e^{ij\delta}\right|^2 = A^2\left|\frac{1-e^{in\delta}}{1-e^{i\delta}}\right|^2 = I_0\,\frac{1-\cos(n\delta)}{1-\cos(\delta)} = I_0\,\frac{\sin^2(n\delta/2)}{\sin^2(\delta/2)} \tag{38.31}$$

where $I_0 = n^{-2}$ to normalize the intensity pattern at $\delta = 0$.

For an incoming plane wave which is tilted at an angle θ from the normal, the relative phase difference between two oscillators is $kd\sin\theta$, where d is the distance between oscillators and k is the wave number $2\pi/\lambda$ (see Fig. 38.8). For three evenly spaced oscillators, the phase difference between the end oscillators is $2kd\sin\theta$. In general, the end-to-end phase difference for n evenly spaced oscillators is $(n-1)kd\sin\theta$. This formulation is identical to the phase representation in Eq. (38.30) with $\delta = kd\sin\theta$. Therefore, the intensity as a function of incidence angle θ for an evenly spaced array of n elements is

$$I_{nL}(\theta) = I_0\,\frac{\sin^2\left(\frac{1}{2}knd\sin\theta\right)}{\sin^2\left(\frac{1}{2}kd\sin\theta\right)} = I_0\,\frac{\sin^2\left(\frac{1}{2}kL\sin\theta\right)}{\sin^2\left(\frac{1}{2n}kL\sin\theta\right)} = I_0\,\frac{\sin^2\left(\frac{\pi L}{\lambda}\sin\theta\right)}{\sin^2\left(\frac{\pi L}{n\lambda}\sin\theta\right)} \tag{38.32}$$

where $L = nd$ corresponds to the physical dimension (length) of the aperture of oscillators. The zeros of this function occur at $kL\sin\theta = 2m\pi$, for any nonzero integer m. Equivalently, the zeros occur when $\sin\theta = m\lambda/L$. When the element spacing d is less than a wavelength, the number of zeros for $0 < \theta < \pi/2$ is given by the largest integer M such that $M \le L/\lambda$. Therefore, the ratio of wavelength to largest dimension, λ/L, determines both the location (in θ space) and the number of zeros in the intensity pattern when $d \le \lambda$. The number of oscillators controls the amplitude of the side lobes.

For $n = 1$, the intensity is constant—i.e., independent of angle. For $\lambda > L$, both the numerator and denominator of Eq. (38.32) have no zeros and as the length of an array shortens (relative to a wavelength), the intensity pattern converges to a constant ($n = 1$ case). As shown in Fig. 38.9, a separation of $\lambda/4$ has an intensity rolloff less than 1 dB over $\pi/2$ radians (a $\lambda/2$ separation rolls off 3 dB). This implies that placing antenna elements closer than $\lambda/4$ does not significantly change the intensity pattern. Many microwave antennas exploit this and use a mesh or parallel wire (for polarization sensitivity) design rather than covering the entire aperture with conductor. This reduces both weight and sensitivity to wind loading. Note that the analysis has not accounted for phase variations from position errors in the element placement where the required accuracy is typically better than $\lambda/10$.

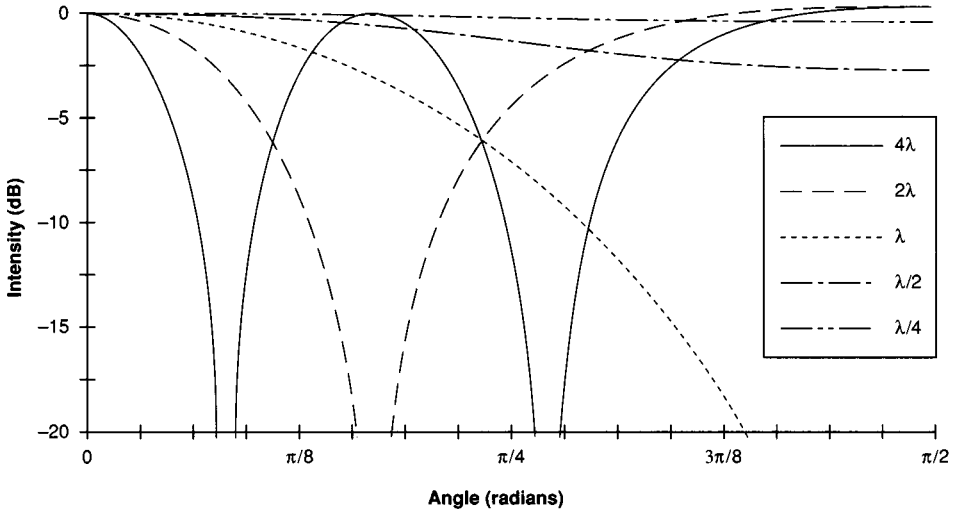

FIGURE 38.9 Normalized intensity pattern in decibels (10 log(I)) for a two-element antenna with spacing 4λ, 2λ, λ, λ/2, and λ/4 between the elements.

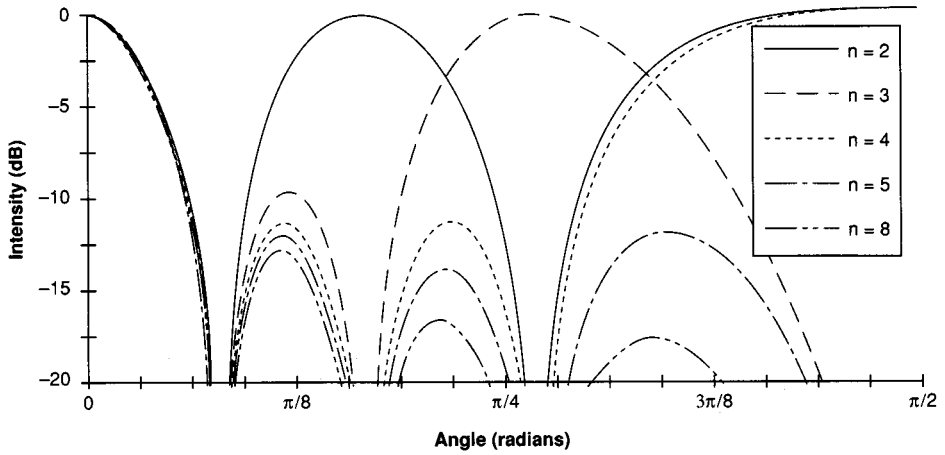

FIGURE 38.10 Normalized intensity pattern in decibels (10 log(I)) for a length 4λ array with 2, 3, 4, 5, and 8 elements.

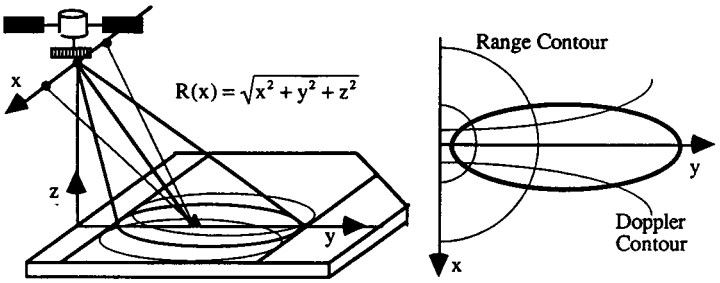
For $L >> \lambda$, $\sin\theta \approx \theta$, which implies that the first zero is at $\theta = \lambda/L$. The location of the first zero is known as the Rayleigh resolution criteria. That is, two plane waves separated by at least λ/L radians can be discriminated. For imaging applications, this corresponds roughly to the smallest detectable feature size. As shown in Fig. 38.10, the first zero occurs at approximately $\lambda/L = 0.25$ radians (the Rayleigh resolution). Note that there is no side lobe suppression until $d \leq \lambda$, when the location of the zeros becomes fixed. Having more than eight array elements (separation of less than a quarter wavelength) only moderately reduces the height of the maximum side lobe.

Synthetic Apertures

In applications such as air- and space-based radar, size and weight constraints prohibit the use of very large antennas. For instance, if the L-band (23.5-cm wavelength) radar imaging system on the Seasat satellite (800-km altitude, launched in 1978) had a minimum resolution specification of 23.5 m, then, using the Rayleigh resolution criteria, the aperture would need to be 8 km long. In order to attain the desired resolution, an aperture is "synthesized" from data collected with a physically small (10 m) antenna traversing an 8-km flight



(a) Data collection geometry (b) Coordinates in radar footprint

FIGURE 38.11 Synthetic aperture radar geometry and nearly orthogonal partitioning of the footprint by range (circular) and Doppler frequency (hyperbolic) contours.

path. Basically, by using a stable oscillator on the spacecraft, both amplitude and phase are recorded, which allows postprocessing algorithms to combine the individual echoes in a manner analogous to an antenna array. From an antenna perspective, an individual scattering element produces a different round trip propagation path based on the position of the physical antenna—a synthetic antenna array. Using the geometry described in Fig. 38.11, the phase is

$$\phi(x) = \frac{2\pi}{\lambda} 2R(x) = \frac{2\pi}{\lambda} 2\sqrt{x^2 + y^2 + z^2} \tag{38.33}$$

It is convenient to assume a straight-line flight path along the x-axis, a planar earth (x, y plane), and a constant velocity, v, with range and cross-range components $v_r(x)$ and $v_c(x)$, respectively. In many radar applications the broad side distance to the center of the footprint, R, is much larger than the size of the footprint. This allows the distance $R(x)$ to be expanded about R resulting in

$$\phi(t) = \frac{2\pi}{\lambda} 2R(vt) = 2\pi\left\{\frac{2R}{\lambda} + \frac{2v_r}{\lambda} t + \frac{v_c^2}{\lambda R} t^2\right\} \tag{38.34}$$

The first term in Eq. (38.34) is a constant phase offset corresponding to the center of beam range bin and can be ignored from a resolution viewpoint. The second term, $2v_r/\lambda$, is the Doppler frequency shift due to the relative (radial) velocity between antenna and scattering element. The third term represents a quadratic correction of the linear flight path to approximate the constant range sphere from a scattering element. It is worth noting that synthetic aperture systems do not require the assumptions used here, but accurate position and motion compensation is required.

For an antenna with cross range dimension D and a scattering element at range R, the largest synthetic aperture that can be formed is of dimension $\lambda R/D$ (the width of the footprint). Because this data collection scenario is for round trip propagation, the phase shift at each collecting location is twice the shift at the edges of a single physical antenna. Therefore at a range R, the synthetic aperture resolution is

$$\frac{\lambda R}{D_{SA}} = \frac{\lambda R}{2\lambda R/D} = \frac{D}{2} \tag{38.35}$$

The standard radar interpretation for synthetic apertures is that information coded in the Doppler frequency shift can be decoded to produce high-resolution images. It is worth noting that the synthetic aperture can be formed even with no motion (zero Doppler shift). For the no-motion case the antenna array interpretation is appropriate. This approach has been used for acoustic signal processing in nondestructive evaluation systems as

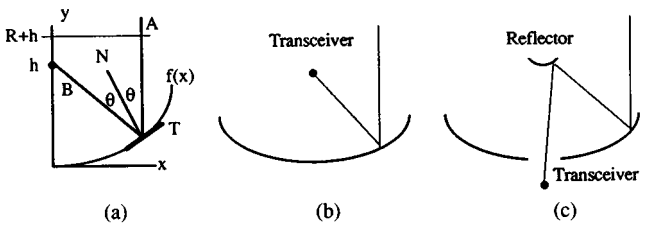


FIGURE 38.12 Parabolic reflector systems: (a) geometry for determining the function with a constant path length and specular reflection, (b) single-bounce parabolic reflector, (c) two-bounce reflector with a parabolic primary and hyperbolic secondary (Cassegrain).

well as wave migration codes for seismic signal processing. When there is motion, the Doppler term in the expansion of the range dominates the phase shift and therefore becomes the useful metric for predicting resolution.

Geometric Designs

The phase difference in a linear array was caused by the spatial separation and allowed the discrimination of plane waves arriving at different angles. Desired phase patterns can be determined by using analytic geometry to position the elements. For example, if coherent superposition across a wave front is desired, the wave front can be directed (reflected, refracted, or diffracted) to the receiver in phase. For a planar wave front, this corresponds to a constant path length from any point on the reference plane to the receiver. Using the geometry in Fig. 38.12, the sum of the two lengths $(x, R + h)$ to (x, y) and (x, y) to $(0, h)$ must be a constant independent of x—which is $R + 2h$ for this geometry. This constraint on the length is

$$R + h - y + \sqrt{x^2 + (h - y)^2} = R + 2h \quad \text{or} \quad x^2 = 4hy \tag{38.36}$$

This is the equation for a parabola. Losses would be minimized if the wave front were specularly reflected to the transceiver. Specular reflection occurs when the angles between the normal vector **N** [or equivalently the tangent vector $\mathbf{T} = (x, f'(x))] = (1, x/2h)$ and the vectors $\mathbf{A} = (0, -1)$ and $\mathbf{B} = (-x, h - y)$ are equal. This is the same as equality of the inner products of the normalized vectors, which is shown by

$$\hat{\mathbf{T}} \cdot \hat{\mathbf{A}} = \frac{(2h, x)}{\sqrt{x^2 + 4h^2}} \cdot (0, -1) = \frac{-x}{\sqrt{x^2 + 4h^2}} \tag{38.37}$$

$$\hat{\mathbf{T}} \cdot \hat{\mathbf{B}} = \frac{(2h, x)}{\sqrt{x^2 + 4h^2}} \cdot \frac{(-x, h - y)}{\sqrt{x^2 + (h - y)^2}} = \frac{-x(x^2 + 4h^2)}{(x^2 + 4h^2)^{3/2}} = \frac{-x}{\sqrt{x^2 + 4h^2}} \tag{38.38}$$

The constant path length and high gain make the parabolic antenna popular at many wavelengths including microwave and visible. More than one reflecting surface is allowed in the design. The surfaces are typically conical sections and may be designed to reduce a particular distortion or to provide better functionality. Compound designs often allow the active elements to be more accessible and eliminate long transmission lines. A two-bounce reflector with a parabolic primary and a hyperbolic secondary is known as a Cassegrain system. In all reflector systems it is important to account for the blockage ("shadow" of the feed, secondary reflector, and support structures) as well as the spillover (radiation propagating past the intended reflecting surface).

Continuous Current Distributions (Fourier Transform)

Ideally, antennas would be designed using solutions to Maxwell's equations. Unfortunately, in most cases exact analytic and numerical solutions to Maxwell's equations are difficult to obtain. Under certain conditions,

approximations can be introduced that allow solution to the wave equations. Approximating spherical wave fronts as quadratics has been shown for the synthetic aperture application and is valid when the propagation distance is greater than $(\pi L^2/4\lambda)^{1/3}$, where L is the aperture size. In general, this is known as the **Fresnel** or **near-field** approximation. When the propagation distance is at least $2L^2/\lambda$, the angular radiation pattern can be approximated as independent of distance from the aperture. This pattern is known as the normalized **far-field** or **Fraunhofer** distribution, $E(\theta)$, and is related to the normalized current distributed across an antenna aperture, $i(x)$, by a Fourier transform:

$$E(u) = \int i(x')e^{i2\pi ux'}dx' \tag{38.39}$$

where $u = \sin\theta$ and $x' = x/\lambda$.

Applying the Fraunhofer approximation to a line source of length L

$$E_L(u = \sin\theta) = \int_{-L/2\lambda}^{L/2\lambda} e^{i2\pi ux'}dx' = \frac{\sin\left(\frac{\pi L}{\lambda}u\right)}{\frac{\pi L}{\lambda}u} = \frac{\sin\left(\frac{\pi L}{\lambda}\sin\theta\right)}{\frac{\pi L}{\lambda}\sin\theta} \tag{38.40}$$

which is Eq. (38.32) when $n >> L/\lambda$. As with discrete arrays, the ratio L/λ is the important design parameter: $\sin\theta = \lambda/L$ is the first zero (no zeros for $\lambda > L$) and the number of zeros is the largest integer M such that $M \le L/\lambda$.

In two dimensions, a rectangular aperture with uniform current distribution produces

$$E_R(u_1, u_2) = \frac{\sin\left(\frac{\pi}{\lambda}u_1L_1\right)}{\frac{\pi}{\lambda}u_1L_1}\,\frac{\sin\left(\frac{\pi}{\lambda}u_2L_2\right)}{\frac{\pi}{\lambda}u_2L_2} \quad \text{and} \quad I_R(u_1, u_2) = \left|E_L(u_1)\right|^2\left|E_L(u_2)\right|^2 \tag{38.41}$$

The field and intensity given in Eq. (38.41) are normalized. In practice, the field is proportional to the aperture area and inversely proportional to the wavelength and propagation distance.

The normalized far-field intensity distribution for a uniform current on a circular aperture is a circularly symmetric function given by

$$I_C(u) = \left[\frac{2J_1\left(\frac{\pi}{\lambda}uL\right)}{\frac{\pi}{\lambda}uL}\right]^2 \tag{38.42}$$

where J_1 is the Bessel function of the first kind, order one. This far-field intensity is called the Airy pattern. As with the rectangular aperture, the far-field intensity is proportional to the square of the area and inversely proportional to the square of the wavelength and the propagation distance. The first zero (Rayleigh resolution criteria) of the Airy pattern occurs for $uL/\lambda = 1.22$ or $\sin\theta = 1.22\lambda/L$. As with linear and rectangular apertures, the resolution scales with λ/L.

Figure 38.13 shows a slice through the normalized far-field intensity of both a rectangular aperture and a circular aperture. The linearity of the Fourier transform allows apertures to be represented as the superposition of subapertures. The primary reflector, the obscurations from the support structures, and the secondary reflector

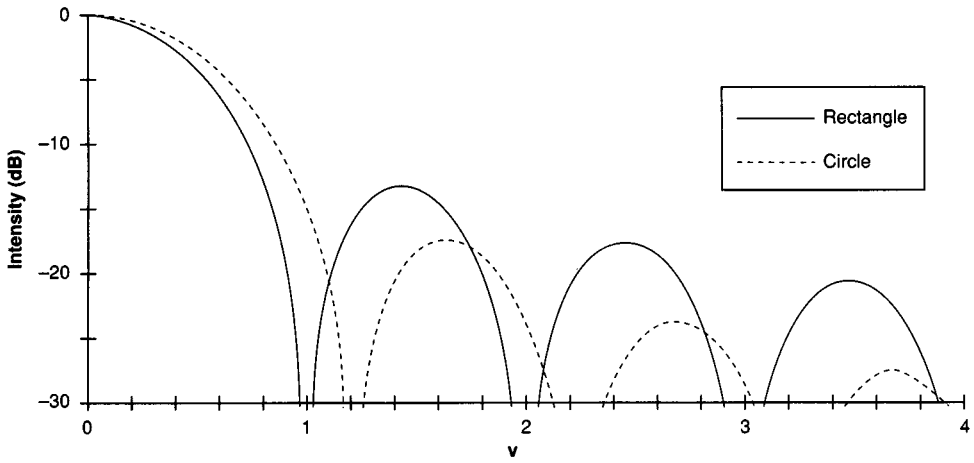

FIGURE 38.13 Normalized intensity pattern in decibels ($10 \log[I(v = uL/\lambda)]$) for a rectangular and a circular antenna aperture with uniform current distributions.

TABLE 38.1 Directivity and Gain of Some Higher Frequency Antennas

Antenna Type	Directivity[a]	Gain[a]
Uniform rectangular aperture	$\frac{4\pi}{\lambda^2} L_x L_y$	$\frac{4\pi}{\lambda^2} L_x L_y$
Large square aperture	$12.6\left(\frac{L}{\lambda}\right)^2$	$7.7\left(\frac{L}{\lambda}\right)^2$
Large circular aperture (parabolic reflector)	$9.87\left(\frac{D}{\lambda}\right)^2$	$7\left(\frac{D}{\lambda}\right)^2$
Pyramidal horn	$\left(\frac{4\pi}{\lambda^2}\right)L_x L_y$	$0.5\left(\frac{4\pi}{\lambda^2}\right)L_x L_y$

[a] Directivity and gain are relative to a half-wave dipole.

of a Cassegrain-type antenna can be modeled. Numerical evaluation of the Fourier transform permits straightforward calculation of the intensity patterns, even for nonuniform current distributions.

Antenna Parameters

Direct solutions to Maxwell's equations or solutions dependent on approximations provide the analytic tools for designing antennas. Ultimately, the analysis must be confirmed with experiment. Increasingly sensitive radar and other antenna applications have resulted in much more attention to edge effects (from the primary aperture, secondary, and/or support structures). The geometric theory of diffraction as well as direct Maxwell solvers are making important contributions.

With the diversity of possible antenna designs, a collection of design rules of thumb are useful. The **directivity** and **gain** for a few popular antenna designs are given in Table 38.1. Directivity is the ratio of the maximum to average radiation intensity. The gain is defined as the ratio of the maximum radiation intensity from the subject antenna to the maximum radiation intensity from a reference antenna with the same power input. The directivity, D, and gain, G, of an antenna can be expressed as

$$D = \left(\frac{4\pi}{\lambda^2}\right)A_{em} \qquad \text{and} \qquad G = \left(\frac{4\pi}{\lambda^2}\right)A_e \tag{38.43}$$

where A_{em} is the maximum effective aperture and A_e is the actual effective aperture of the antenna. Because of losses in the system, $A_e = kA_{em}$, where k is the radiation efficiency factor. The gain equals the directivity when there are no losses ($k = 1$), but is less than the directivity if there are any losses in the antenna ($k < 1$), that is, $G = kD$.

As an example, consider the parabolic reflector antenna where efficiency degradation includes

- Ohmic losses are small ($k = 1$)
- Aperture taper efficiency ($k = 0.975$)
- Spillover (feed) efficiency ($k = 0.8$)
- Phase errors in aperture field ($k = 0.996$ to 1)
- Antenna blockage efficiency ($k = 0.99$)
- Spar blockage efficiency ($k = 0.994$)

Each antenna system requires a customized analysis of the system losses in order to accurately model performance.

Defining Terms

Antenna: A physical device for transmitting or receiving propagating waves.

Aperture antenna: An antenna with a physical opening, hole, or slit. Contrast with a wire antenna.

Array antenna: An antenna system performing as a single aperture but composed of antenna subsystems.

Directivity: The ratio of the maximum to average radiation intensity.

Fraunhofer or far field: The propagation region where the normalized angular radiation pattern is independent of distance from the source. This typically occurs when the distance from the source is at least $2L^2/\lambda$, where L is the largest dimension of the antenna.

Fresnel or near field: The propagation region where the normalized radiation pattern can be calculated using quadratic approximations to the spherical Huygens' wavelet surfaces. The pattern can depend on distance from the source and is usually valid for distances greater than $(\pi/4\lambda)^{1/3}L^{2/3}$, where L is the largest dimension of the antenna.

Gain: The ratio of the maximum radiation intensity from the subject antenna to the maximum radiation intensity from a reference antenna with the same power input. Typical references are a lossless isotropic source and a lossless half-wave dipole.

Oscillator: A physical device that uses the periodic motion within the material to create propagating waves. In electromagnetics, an oscillator can be a conductor with a periodic current distribution.

Reactive near field: The region close to an antenna where the reactive components of the electromagnetic fields from charges on the antenna structure are very large compared to the radiating fields. Considered negligible at distances greater than a wavelength from the source (decay as the square or cube of distance). Reactive field is important at antenna edges and for electrically small antennas.

38.3 Microstrip Antennas

David M. Pozar

Introduction

Microstrip antenna technology has been the most rapidly developing topic in the antenna field in the last 15 years, receiving the creative attentions of academic, industrial, and government engineers and researchers throughout the world. As a result, microstrip antennas have quickly evolved from a research novelty to commercial reality, with applications in a wide variety of microwave systems. Rapidly developing markets in personal communications systems (PCS), mobile satellite communications, direct broadcast television (DBS), wireless local-area networks (WLANs), and intelligent vehicle highway systems (IVHS) suggest that the demand for microstrip antennas and arrays will increase even further.

Although microstrip antennas have proved to be a significant advance in the established field of antenna technology, it is interesting to note that it is usually their nonelectrical characteristics that make microstrip antennas preferred over other types of radiators. Microstrip antennas have a low profile and are light in weight, they can be made conformal, and they are well suited to integration with **microwave integrated circuits (MICs)**. If the expense of materials and fabrication is not prohibitive, they can also be low in cost. When compared with traditional antenna elements such as wire or aperture antennas, however, the electrical performance of the basic microstrip antenna or array suffers from a number of serious drawbacks, including very narrow **bandwidth**, high feed network losses, poor cross polarization, and low power-handling capacity. Intensive research and development has demonstrated that most of these drawbacks can be avoided, or at least alleviated to some extent, with innovative variations and extensions to the basic microstrip element [James and Hall, 1989; Pozar and Schaubert, 1995]. Some of the basic features of microstrip antennas are listed below:

- Low profile form factor
- Potential light weight
- Potential low cost
- Potential conformability with mounting structure
- Easy integration with planar circuitry
- Capability for linear, dual, and circular polarizations
- Versatile feed geometries

Basic Microstrip Antenna Element

The basic microstrip antenna element is derived from a $\lambda_g/2$ **microstrip** transmission **line** resonator [Pozar, 1990]. It consists of a thin metallic conducting patch etched on a grounded dielectric substrate, as shown in Fig. 38.14. This example is shown with a coaxial probe feed, but other feeds are possible, as discussed below.

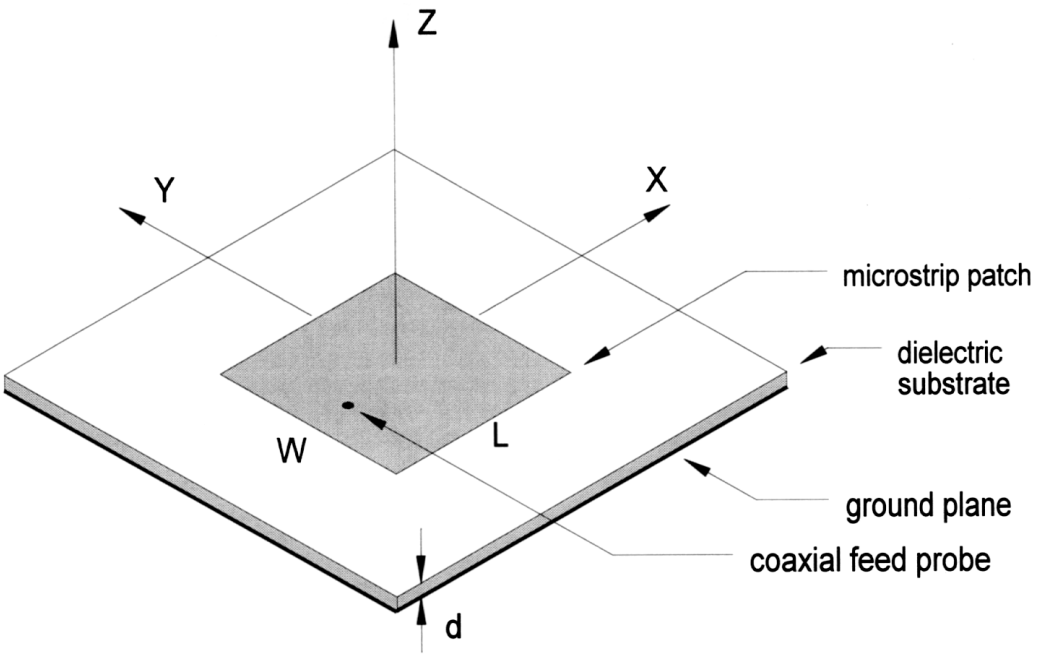

FIGURE 38.14 Geometry of rectangular coaxial probe-fed microstrip antenna.

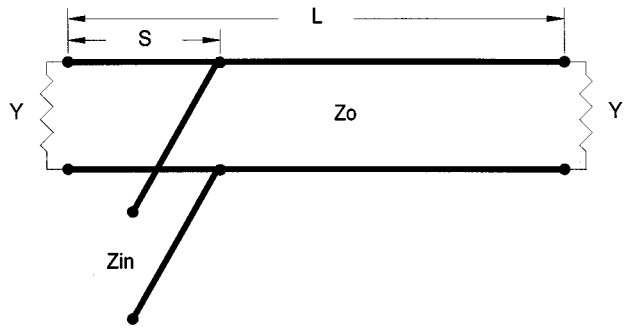

FIGURE 38.15 Transmission line circuit model for a rectangular microstrip antenna. The feed point is positioned a distance *s* from the radiating edge of the patch.

The patch has a length *L* along the *x*-axis, and width *W* along the *y*-axis. The dielectric substrate has a thickness *d* and a dielectric constant ε_r, and is backed with a conducting ground plane. With a coaxial probe feed, the outer conductor of the coaxial line is connected to the ground plane, and the inner conductor is attached to the patch element. The position of the feed point relative to the edge of the patch controls the input impedance level of the antenna. In operation, the length of the patch element is approximately $\lambda_g/2$, forming an open-circuit resonator. Because the patch is relatively wide, the patch edges at $x = -L/2$ and $L/2$ effectively form slot apertures which radiate in phase to form a broadside radiation pattern.

Many analytical models have been developed for the impedance and radiation properties of microstrip antennas [James and Hall, 1989], but most of the qualitative behavior of the element can be demonstrated using the relatively simple transmission line model. As shown in Fig. 38.15, the patch element is modeled as a length, *L*, of microstrip transmission line of characteristic impedance Z_0. The characteristic impedance of the line can be found using simple approximations [Pozar, 1990] and is a function of the width, *W*, of the line as well as the substrate thickness and dielectric constant. The ends of the transmission line are terminated in

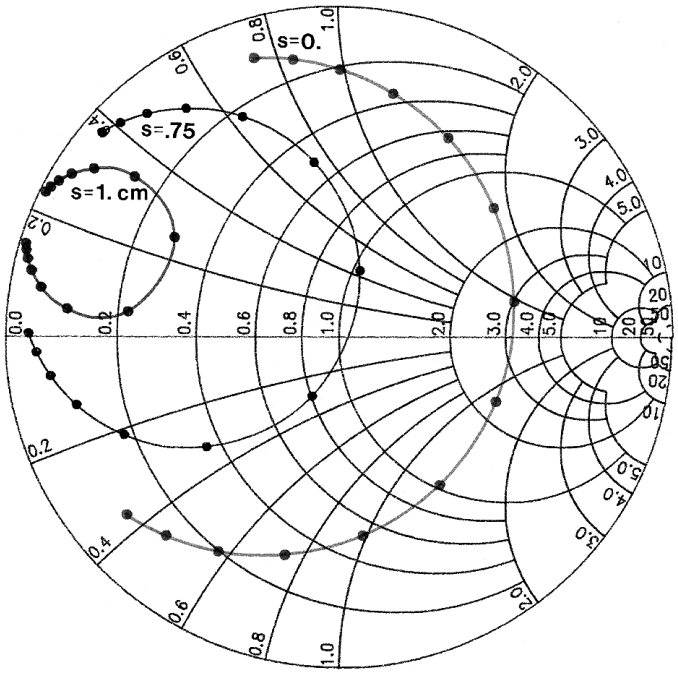

FIGURE 38.16 Smith chart plot of the input impedance of a probe-fed rectangular microstrip antenna vs. frequency, for three different feed positions. Patch parameters are $L = 2.5$ cm, $W = 3.0$ cm, $\varepsilon_r = 2.2$, $d = 0.79$ cm. Frequency sweep runs from 3.6 to 4.25 GHz, in steps of 50 MHz.

admittances, $Y = G + jB$, where the conductance serves to model the radiation from the ends of the line, and the susceptance serves to model the effective length extension of the line (due to fringing fields). Several approximations are available for calculating the end admittances [James and Hall, 1989], with a typical result for $d << \lambda_0$ given as

$$Y = G + jB = \frac{k_0 W}{2\eta_0}\left[1 + j\left(1 - 0.64 \ln k_0 d\right)\right] \tag{38.44}$$

where $k_0 = 2\pi/\lambda_0$ and $\eta = \sqrt{\frac{\mu_0}{\varepsilon_0}}$. The susceptance B is typically positive, implying a capacitive end effect. This means that the resonant length of the patch will be slightly less than $\lambda_g/2$. If the feed probe is located a distance s from the edge of the patch, the input impedance seen by the probe can be calculated using basic transmission line theory from the circuit of Fig. 38.15. Resonance is defined as the frequency at which the imaginary part of the input impedance is zero.

As a result of the symmetry of the transmission line resonator, the voltage along the transmission line will have maxima at the ends and a null at the center of the line. This implies that the input impedance will be maximum when the feed point is at the edge of the patch, and will decrease to zero as the feed is moved to the center of the patch. Fig. 38.16 shows a Smith chart plot of the input impedance of a coaxial probe-fed microstrip antenna vs. frequency, for three different probe positions. Observe that the input impedance locus decreases as the feed point moves toward the center of the patch. Also, observe that the impedance locus becomes more inductive as the feed point moves toward the center of the patch.

The far-field radiation patterns can also be derived from the transmission line model by treating the radiating edges at $x = -L/2$ and $L/2$ as equivalent slots. In the coordinate system of Fig. 38.14, the normalized far-zone fields of the rectangular patch can be expressed as

$$E_\theta = E_0 \frac{\sin \alpha}{\alpha} \cos \beta \cos \phi \tag{38.45a}$$

$$E_\phi = E_0 \frac{\sin \alpha}{\beta} \cos \beta \cos \theta \sin \phi \tag{38.45b}$$

where

$$\alpha = \frac{k_0 W}{2} \sin \theta \sin \phi$$

$$\beta = \frac{k_0 L}{2} \sin \theta \cos \phi$$

and θ and ϕ are spherical coordinates. These patterns have maxima broadside ($\theta = 0$) to the patch, with 3-dB **beamwidths** typically in the range of 90° to 120°. Typical *E*-plane ($\phi = 0$) and *H*-plane ($\phi = 90°$) microstrip antenna radiation patterns are shown in Fig. 38.17.

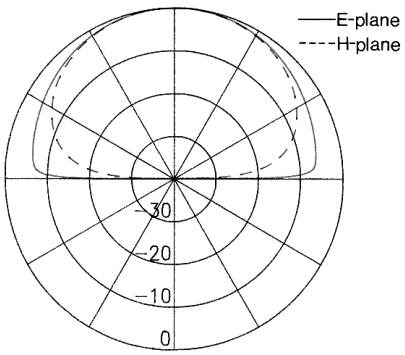

FIGURE 38.17 *E*- and H-plane far-field radiation patterns of the rectangular microstrip antenna of Fig. 38.16.

Microstrip antenna elements have a number of useful and interesting features, but probably the most serious limitation of this technology is the narrow bandwidth of the basic element. While antenna elements such as dipoles, slots, and waveguide horns have operating bandwidths ranging from 15 to 50%, the traditional microstrip patch element typically has an impedance bandwidth of only a few percent. Fig. 38.18 shows the impedance bandwidth vs. substrate thickness for a rectangular microstrip antenna with substrate permittivities of 2.2 and 10.2. Observe from the figure that bandwidth decreases as the substrate becomes thinner and as the dielectric constant increases. Both of these trends are explained as a result of the increased *Q* of the resonator, basically due to the fact that the patch current is in close proximity to its negative image in the substrate ground plane. In terms of bandwidth, it is preferable to use a thick antenna substrate, with a low dielectric constant. But because of inductive loading and possible spurious radiation from coplanar microstrip circuitry, the thickness of a microstrip antenna substrate is typically limited to 0.02λ or less. This illustrates the essential compromise associated with the microstrip antenna concept, as it is not possible to obtain optimum performance from both a microstrip antenna and microstrip circuitry on a single dielectric substrate. These two functions are distinct electromagnetically, since the bound fields associated with nonradiating circuitry obviate efficient radiation.

While the bandwidth of the basic element is limited, considerable research and development during the last 15 years has led to a number of creative and novel techniques for the enhancement of microstrip antenna bandwidth, so that impedance bandwidths ranging from 10 to 40% can now be achieved [James and Hall, 1989; Pozar and Schaubert, 1995]. While there have been dozens of proposed techniques for the enhancement of microstrip antenna bandwidth, they can all be categorized according to three canonical approaches:

- Impedance matching using matching network
- Introducing dual resonance with stacked or parasitic elements
- Reducing efficiency by adding lossy elements

The reader is referred to the literature for more details on specific techniques for bandwidth improvement.

Figure 38.18 also shows the efficiency of the antenna, defined as

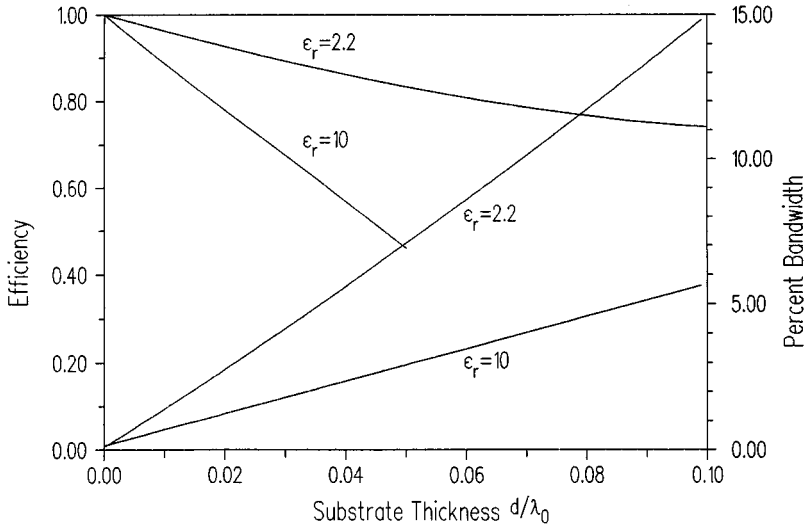

FIGURE 38.18 Impedance bandwidth and radiation efficiency of a microstrip antenna vs. substrate thickness, for two values of substrate permittivity.

$$e = \frac{P_{\text{rad}}}{P_{\text{rad}} + P_{\text{loss}}} \tag{38.46}$$

where P_{rad} is the radiated power and P_{loss} is the power lost in the antenna. Losses in a microstrip antenna occur in three ways: conductor loss, dielectric loss, and surface wave loss. Unless the substrate is extremely thin, conductor loss is generally negligible. For quality microwave substrates (loss tangent ≤ 0.002), dielectric loss is also relatively small. Surface waves, which are fields bound to the dielectric substrate that propagate along its surface, often account for the dominant loss mechanism for microstrip antennas. As can be seen in Fig. 38.18, efficiency decreases with increasing substrate thickness and dielectric constant, again suggesting the use of low-dielectric-constant substrates. The overall radiation efficiency of a microstrip antenna on a low-dielectric substrate is typically 95%, or better.

Besides rectangular patch elements, it is possible to use a variety of other patch shapes as resonant radiating elements. For purposes of polarization purity and analytical simplicity, however, it is usually preferable to use rectangular, square, or circular elements. Linear polarization is best obtained with rectangular elements, while dual linear or circular polarization can be obtained with square or circular patch elements [James and Hall, 1989; Pozar and Schaubert, 1995].

Feeding Techniques for Microstrip Antennas

While Fig. 38.14 shows a coaxial probe-fed microstrip antenna element, it is also possible to feed the patch element by several other methods. Fig. 38.19a shows a rectangular patch element fed with a microstrip transmission line coplanar with the patch element. The amount of inset of the feed line controls the input impedance level at resonance, in a manner analogous to the positioning of the coax probe feed for impedance control. The equivalent circuit of the antenna near resonance is also shown in the figure. The patch appears as a parallel RLC resonant circuit, with a series inductance that represents the near-field effect of the microstrip feed line. (The same equivalent circuit applies to the probe-fed microstrip antenna.) Both the probe feed and the line feed excite the patch element through coupling between the equivalent J_z electric current of the feed and the E_z directed field of the patch resonator, which has a maximum below the center of the patch.

The direct-contacting coax probe and inset microstrip line feeds have the advantage of simplicity, but suffer from some disadvantages. First, bandwidth is limited because of the requirement of a thin substrate, as discussed above. In addition, the inherent *E*-plane asymmetry of these feeds generates higher-order modes which lead

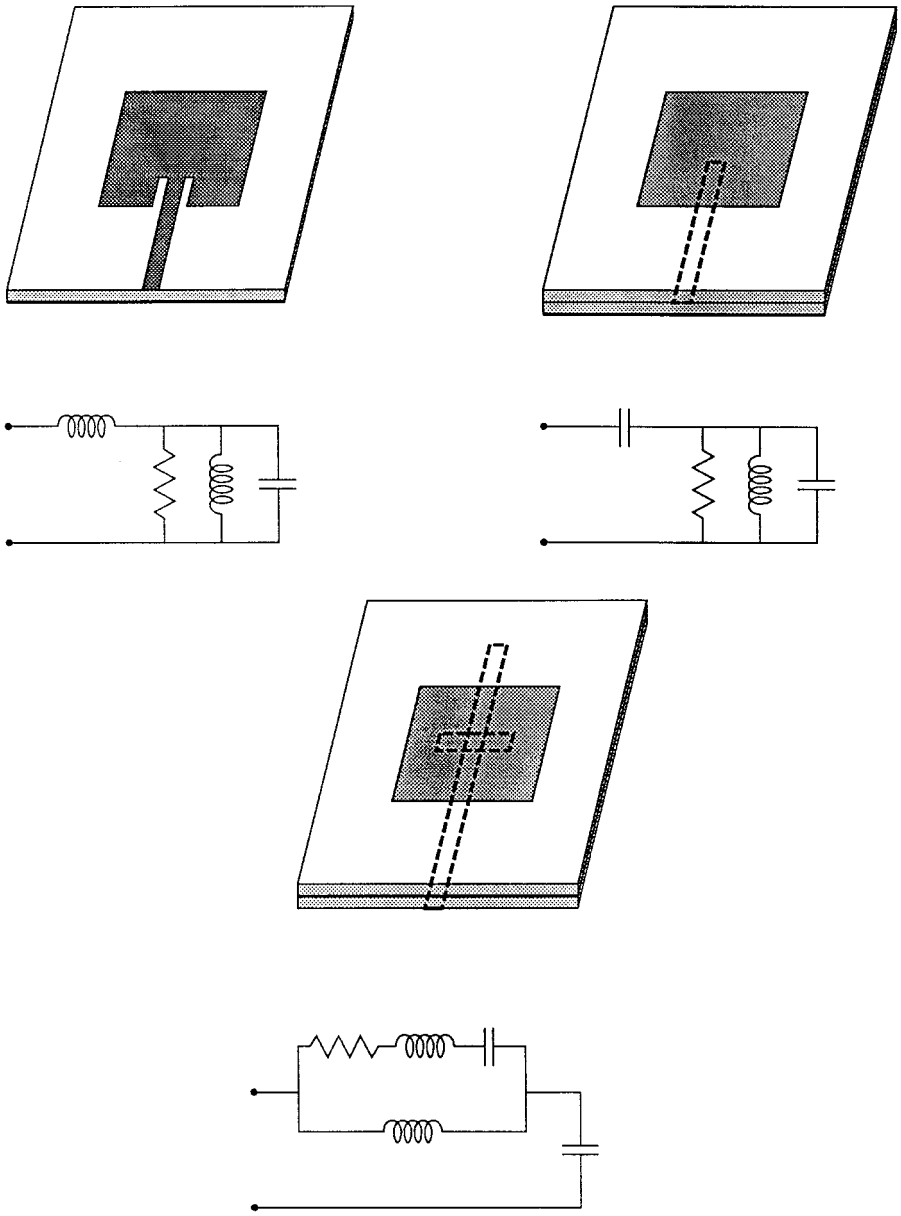

FIGURE 38.19 Three types of feeding methods for rectangular microstrip antennas, and their associated equivalent circuits: (a) patch fed with an inset microstrip transmission line, (b) patch fed by proximity coupling to a microstrip transmission line, (c) patch fed by aperture coupling to a microstrip transmission line.

to cross polarization. And, in the case of the coax feed, the need for soldering can decrease reliability and increase cost if a large number of elements are involved.

It is also possible to feed a microstrip antenna element using noncontacting feeds of various forms. Fig. 38.19b shows a proximity feed, where a two-layer substrate houses an embedded microstrip transmission feed line, with the radiating patch located on the top of a substrate layer placed over the microstrip feed line. The feed line is terminated in an open-circuited stub below the patch. Proximity coupling (often referred to in the literature by the less-descriptive term *electromagnetic coupling*) has the advantage of allowing the patch to reside on a relatively thick substrate, for enhanced bandwidth, while the feed line sees an effectively thinner substrate,

which is preferred to minimize spurious radiation and coupling. Fabrication is a bit more difficult than the single-layer coax or line feed, because of the requirement of bonding and aligning two substrates. The equivalent circuit of the proximity-coupled element is shown in Fig. 38.19b, where the series capacitor is indicative of the capacitive nature of the coupling between the open-ended microstrip line and the patch element.

Another type of noncontacting feed is the aperture-coupled microstrip antenna shown in Fig. 38.19c [James and Hall, 1989; Pozar and Schaubert, 1995]. This configuration consists of two parallel substrates separated by a ground plane. A microstrip feed line on the bottom of the bottom substrate is coupled through a small aperture (typically a thin slot) in the ground plane to a microstrip patch element on the top of the top substrate. This arrangement allows a thin, high-dielectric-constant substrate to be used for the feed line, and a thicker, low-dielectric-constant substrate to be used for the radiating element. In this way, the two-layer design of the aperture-coupled element allows the substrates to be optimized for the distinct functions of circuit components and radiating elements. In addition, the ground plane provides isolation between the radiating aperture and possible spurious radiation or coupling from the feed network. An important aspect of the aperture-coupled approach is that the coupling aperture is below resonant size, so that the backlobe radiated by the slot is typically 15 to 20 dB below the main forward beam.

The aperture-coupled geometry affords several degrees of freedom for control of the electrical properties of the antenna. The slot size (length) primarily determines the coupling level and, hence, the input impedance. Tightest coupling occurs when the slot is centered below the patch, with the input impedance decreasing as the slot size is decreased. As with any microstrip antenna, the resonant frequency is controlled primarily by the length of the patch. The feed line stub length can be used to adjust the reactance loading of the element, and the antenna substrate thickness and dielectric constant has a direct effect on the bandwidth of the element. It is also possible to use the slot to provide a double tuning effect to increase significantly impedance bandwidth. Such aperture-coupled antennas have been demonstrated with bandwidths up to 40% [Pozar and Schaubert, 1995]. Another unique feature of the aperture coupled patch is that the principal plane patterns have theoretically zero cross polarization because of the symmetry of the element.

Microstrip Antenna Arrays

One of the most useful features of microstrip antenna technology is the ease with which **array antennas** can be constructed, since the feed network can be fabricated with microstrip transmission lines and microstrip circuit components at the same time as the microstrip radiating elements. This eliminates the cumbersome and expensive coaxial or waveguide feed networks that are necessary for other types of arrays. In fact, microstrip technology offers such versatility in design that a wide variety of series-fed, corporate-fed, fixed-beam, scanning, multilayer, and polarization agile microstrip arrays have been demonstrated, many examples of which can be found in the literature [James and Hall, 1989; Pozar and Schaubert, 1995].

One of the most convenient architectures for microstrip arrays is the single-layer design where the microstrip feed lines are printed on the same substrate layer as the radiating patch elements. This results in a simple, low-profile, inexpensive, and easily fabricated antenna assembly. An example of a 2×4 microstrip array using this type of configuration is shown in Fig. 38.20. The microstrip feed network consists of a main feed line driving three levels of coplanar two-way power dividers, which in turn drive eight edge-fed patches. This is an example of a corporate feed network, in contrast to a series type of feed where array elements are tapped off of a single microstrip line. The corporate feed provides good bandwidth and allows precise control of element excitation, but requires considerable substrate area and can be lossy. A series feed can be very compact and efficient, but its bandwidth is typically limited to a few percent. Both types of feeds can be used for single and dual polarizations. More flexibility for feed network layout can be obtained by using a two-sided aperture-coupled patch geometry. This allows the feed network to be isolated from the radiating aperture by the ground plane, and the extra substrate area can be very useful for arrays that require dual polarization or dual-frequency operation. Similar features can be obtained by using feedthrough pins or vias, but the added fabricational complexity of solder connections can be formidable in a large array.

A serious limitation of microstrip array technology is that array gain is limited by the relatively high losses of microstrip transmission lines. While array directivity increases with the area of the radiating aperture, the losses of the feed network increase exponentially with array size. This is especially serious at higher frequencies,

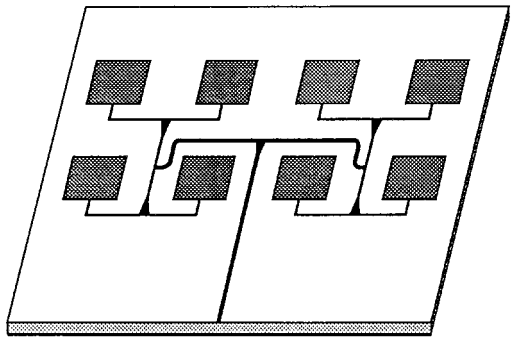

FIGURE 38.20 A corporate-fed eight-element microstrip array antenna.

where it is usually impractical to design a microstrip array with a coplanar feed network for gains in excess of 28 to 32 dB. Off-board feed networks or multilayer designs can be used to partially circumvent this problem, but at the expense of simplicity and cost.

Computer-Aided Design for Microstrip Antennas

Ideally, antenna CAD software would combine a user-friendly interface with a computationally efficient set of accurate and versatile theoretical models. While software with such features has reached a fairly high level of refinement for the analysis of low-frequency and microwave circuit analysis and optimization, the development of microstrip antenna CAD software lags far behind. One reason is the economic reality that the market for antenna software is relatively small, which perhaps explains why there is very little commercially available antenna CAD software of any type. Microstrip antenna CAD software development has also been slow because of the fact that such antennas are relatively new, receiving serious attention only during the last 15 years. Furthermore, microstrip antenna geometries are relatively difficult to model because of the presence of dielectric inhomogeneities and a wide variety of feeding techniques and other geometric features. This last consideration makes the development of a general-purpose microstrip antenna analysis package extremely difficult.

It may come as a surprise to the newcomer to practical antenna development, but it must be realized that many microstrip antenna designs have been successfully completed with little or no CAD support. There are, however, many situations where antennas and arrays can be designed more effectively, with better performance and less experimental iteration, when proper CAD software tools are available. And there are situations involving large arrays of microstrip elements which critically rely on the use of CAD software for successful design. Thus, CAD software is not absolutely necessary for all facets of microstrip antenna design work, but good software tools can be very useful for dealing with the more-complicated microstrip geometries. Another point that seems to be especially true for antenna design in general is that CAD software, no matter how versatile or accurate, cannot substitute for experience and understanding of the fundamentals of antenna operation. Further discussion of microstrip antenna CAD issues can be found in [Pozar and Schaubert, 1995].

Defining Terms

Array antenna: A repetitive grouping of basic antenna elements functioning as a single antenna with improved gain or pattern characteristics.

Bandwidth: The fractional frequency range over which the impedance match or pattern qualities of an antenna meet a required specification.

Beamwidth: The angular width of the main beam of an antenna, typically measured at either –3 or –10 dB below beam maximum.

Microstrip line: A planar transmission line consisting of a conducting strip printed (or etched) on a grounded dielectric substrate.

Microwave integrated circuit (MIC): A microwave or RF subsystem formed by the monolithic or hybrid integration of active devices, transmission lines, and related components.

39.1 Passive Microwave Devices

Michael B. Steer

Wavelengths in air at microwave and millimeter-wave frequencies range from 1 m at 300 MHz to 1 mm at 300 GHz and are comparable to the physical dimensions of fabricated electrical components. For this reason circuit components commonly used at lower frequencies, such as resistors, capacitors, and inductors, are not readily available above 10 GHz. The available microwave frequency lumped elements have dimensions of around 1 mm. The relationship between the wavelength and physical dimensions enables new classes of distributed components to be constructed that have no analogy at lower frequencies. Components are realized by disturbing the field structure on a transmission line, resulting in energy storage and thus reactive effects. Electric (E) field disturbances have a capacitive effect and the magnetic (H) field disturbances appear inductive. Microwave components are fabricated in waveguide, coaxial lines, and strip lines. The majority of circuits are constructed using strip lines as the cost is relatively low and they are highly reproducible due to the photolithographic techniques used. Fabrication of waveguide components requires precision machining but they can tolerate higher power levels and are more easily realized at millimeter-wave frequencies (30–300 GHz) than either coaxial or microstrip components.

Characterization of Passive Elements

Passive microwave elements are defined in terms of their reflection and transmission properties for an incident wave of electric field or voltage. Scattering (S) parameters are based on traveling waves and so naturally describe these properties. As well they are the only ones that can be measured directly at microwave frequencies. S parameters are defined in terms of root power waves which in turn are defined using forward and backward traveling voltage waves. Consider the N port network of Fig. 39.1 where the nth port has a reference transmission line of characteristic impedance Z_{0n} and of infinitesimal length. The transmission line at the nth port serves to separate the forward and backward traveling voltage (V_n^+ and V_n^-) and current (I_n^+ and I_n^-) waves. The reference characteristic impedance matrix, $\mathbf{Z}_0$ is a diagonal matrix, $\mathbf{Z}_0 = \text{diag}(Z_{01} \ldots Z_{0n} \ldots Z_{0N})$, and the root power waves at the nth port, a_n and b_n, are defined by

$$a_n = V_n^+ \Big/ \sqrt{Z_{0n}} \qquad \text{and} \qquad b_n = V_n^- \sqrt{Z_{0n}} \tag{39.1}$$

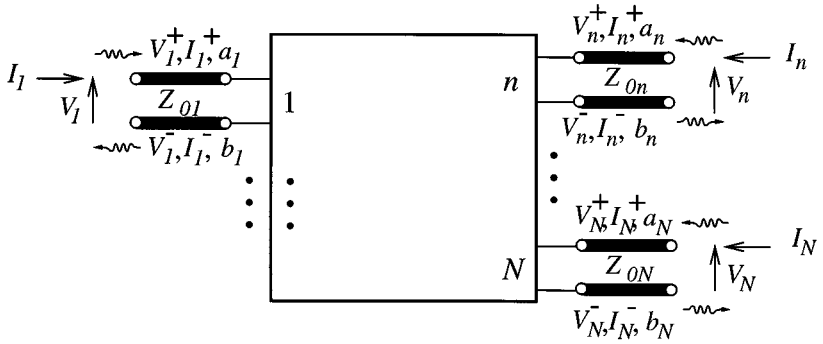

FIGURE 39.1 N port network with reference transmission lines used in defining S parameters.

In matrix form

$$\mathbf{a} = \mathbf{Z}_0^{-1/2}\mathbf{V}^+ = \mathbf{V}_0^{1/2}\mathbf{V}^+, \qquad \mathbf{b} = \mathbf{Z}_0^{-1/2}\mathbf{V}^- = \mathbf{Y}_0^{1/2}\mathbf{V}^-, \tag{39.2}$$

$$\mathbf{V}^+ = \mathbf{Z}_0^{1/2}\mathbf{a} = \mathbf{Y}_0^{-1/2}\mathbf{a} \qquad \text{and} \qquad \mathbf{V}^- = \mathbf{Z}_0^{1/2}\mathbf{b} = \mathbf{Y}_0^{-1/2}\mathbf{b} \tag{39.3}$$

where

$$\mathbf{a} = \left[a_1 \ldots a_n \ldots a_N\right]^{\mathrm{T}}, \qquad \mathbf{b} = \left[b_1 \ldots b_n \ldots b_N\right]^{\mathrm{T}}, \tag{39.4}$$

$$\mathbf{V}^+ = \left[V_1^+ \ldots V_n^+ \ldots V_N^+\right]^{\mathrm{T}}, \qquad \mathbf{V}^- = \left[V_1^- \ldots V_n^- \ldots V_N^-\right]^{\mathrm{T}}. \tag{39.5}$$

and the characteristic admittance matrix $\mathbf{Y}_0$ and $\mathbf{Z}_0^{-1}$. Now S parameters can be formally defined:

$$\mathbf{b} = \mathbf{Sa} \tag{39.6}$$

Thus, $\mathbf{Y}_0^{1/2}\mathbf{V}^- = \mathbf{S}\mathbf{Y}_0^{1/2}\mathbf{V}^+$ and so $\mathbf{V}^- = \mathbf{Y}_0^{-1/2}\mathbf{S}\mathbf{Y}_0^{1/2}\mathbf{V}^+$. This reduces to $\mathbf{V}^- = \mathbf{S}\mathbf{V}^+$ when all of the reference transmission lines have the same characteristic impedance.

S parameters can be related to other network parameters after first considering the relationship of total port voltage $\mathbf{V} = [V_1 \ldots V_n \ldots V_N]^{\mathrm{T}}$ and current $\mathbf{I} = [I_1 \ldots I_n \ldots I_N]^{\mathrm{T}}$ to forward and backward voltage and current waves:

$$\mathbf{V} = \mathbf{V}^+ + \mathbf{V}^- \qquad \text{and} \qquad \mathbf{I} = \mathbf{I}^+ + \mathbf{I}^- \tag{39.7}$$

where $\mathbf{I}^+ = \mathbf{Y}_0\mathbf{V}^+ = \mathbf{Y}_0^{1/2}\mathbf{a}$ and $\mathbf{I}^- = -\mathbf{Y}_0\mathbf{V}^- = -\mathbf{Y}_0^{1/2}\mathbf{b}$. The development of the relationship between S parameters and other network parameters is illustrated by considering Y parameters defined by

$$\mathbf{I} = \mathbf{YV} \tag{39.8}$$

Using traveling waves this becomes

$$\mathbf{I}^+ + \mathbf{I}^- = \mathbf{Y}\left(\mathbf{V}^+ + \mathbf{V}^-\right) \tag{39.9}$$

$$\mathbf{Y}_0\left(\mathbf{V}^+ - \mathbf{V}^-\right) = \mathbf{Y}\left(\mathbf{V}^+ + \mathbf{V}^-\right) \tag{39.10}$$

$$\mathbf{Y}_0\left(\mathbf{1} - \mathbf{Y}_0^{-1/2}\mathbf{S}\mathbf{Y}_0^{1/2}\right)\mathbf{V}^+ = \mathbf{Y}\left(\mathbf{1} + \mathbf{Y}_0^{-1/2}\mathbf{S}\mathbf{Y}_0^{1/2}\right)\mathbf{V}^+ \tag{39.11}$$

$$\mathbf{Y} = \mathbf{Y}_0\left(\mathbf{1} - \mathbf{Y}_0^{-1/2}\mathbf{S}\mathbf{Y}_0^{1/2}\right)\left(\mathbf{1} + \mathbf{Y}_0^{-1/2}\mathbf{S}\mathbf{Y}_0^{1/2}\right)^{-1} \tag{39.12}$$

Alternatively (39.10) can be rearranged as

$$\left(\mathbf{Y}_0 + \mathbf{Y}\right)\mathbf{V}^- = \left(\mathbf{Y}_0 - \mathbf{Y}\right)\mathbf{V}^+ \tag{39.13}$$

$$\mathbf{V}^- = \left(\mathbf{Y}_0 + \mathbf{Y}\right)^{-1}\left(\mathbf{Y}_0 - \mathbf{Y}\right)\mathbf{V}^+ \tag{39.14}$$

$$\mathbf{Y}_0^{-1/2}\mathbf{b} = \left(\mathbf{Y}_0 + \mathbf{Y}\right)^{-1}\left(\mathbf{Y}_0 - \mathbf{Y}\right)\mathbf{Y}_0^{-1/2}\mathbf{a} \tag{39.15}$$

Comparing this to the definition of S parameters, (39.6), leads to

$$\mathbf{S} = \mathbf{Y}_0^{1/2}\left(\mathbf{Y}_0 + \mathbf{Y}\right)^{-1}\left(\mathbf{Y}_0 - \mathbf{Y}\right)\mathbf{Y}_0^{-1/2} \tag{39.16}$$

For the usual case where all of the reference transmission lines have the same characteristic impedance $Z_0 = 1/Y_0$, $\mathbf{Y} = Y_0(\mathbf{1} - \mathbf{S})(\mathbf{1} + \mathbf{S})^{-1}$ and $\mathbf{S} = (\mathbf{Y}_0 + \mathbf{Y})^{-1}(\mathbf{Y}_0 - \mathbf{Y})$.

The most common situation involving conversion to and from S parameters is for a two port with both ports having a common reference characteristic impedance Z_0. Table 39.1 lists the most common conversions. S parameters require that the reference impedances be specified. If they are not it is assumed that it is 50 **Ω**. They are commonly plotted on Smith Charts — polar plots with lines of constant resistance and reactance [Vendelin *et al.*].

In Fig. 39.2(a) a travelling voltage wave with phasor $\mathbf{V}_1^+$ is incident at port 1 of a two-port passive element. A voltage $\mathbf{V}_1^-$ is reflected and $\mathbf{V}_2^-$ is transmitted. $\mathbf{V}_2^-$ is then reflected by Z_L to produce $\mathbf{V}_2^+$. $\mathbf{V}_2^+$ is zero if $Z_L = Z_0$. The input voltage reflection coefficient

$$\Gamma_1 = \mathbf{V}_1^-/\mathbf{V}_1^+ = s_{11} + s_{12}s_{21}/\left(1 - s_{22}\Gamma_L\right),$$

transmission coefficient

$$\mathrm{T} = \mathbf{V}_2^-/\mathbf{V}_1^+$$

and the load reflection coefficient

$$\Gamma_L = \left(Z_L - Z_0\right)/\left(Z_L + Z_0\right)$$

More convenient measures of reflection and transmission performance are the **return loss** and **insertion loss** as they are relative measures of power in transmitted and reflected signals. In decibels

$$\text{RETURN LOSS} = -20\log\Gamma_1\ (dB) \qquad \text{INSERTION LOSS} = -20\log\mathrm{T}\ (dB)$$

The input impedance at port 1, Z_{in}, is related to Γ by

$$Z_{\text{in}} = Z_0\left(1 + \Gamma_1/1 - \Gamma_1\right)$$

	$S_{12} = 2H'_{12}/\delta$	$H'_{12} = 2S_{12}/\delta$
	$S_{21} = -2H'_{21}/\delta$	$H'_{21} = -2S_{21}/\delta$
	$S_{22} = \left[(1+H'_{11})(1-H'_{22}) + H'_{12}H'_{21}\right]/\delta$	$H'_{22} = \left[(1-S_{11})(1-S_{22}) - S_{12}S_{21}\right]/\delta$

Note: The Z′, Y′ and H′ parameters are normalized to Z_0.

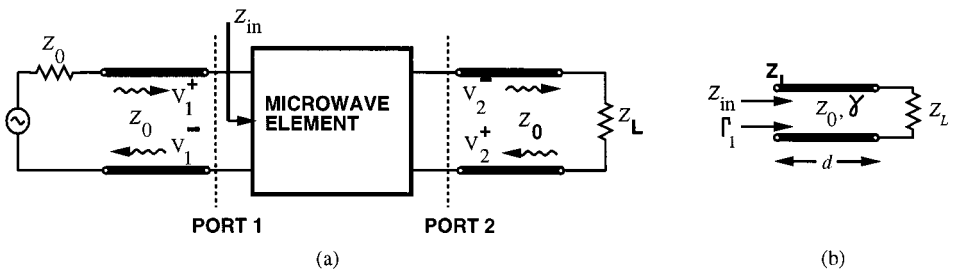

FIGURE 39.2 Incident, reflected and transmitted traveling voltage waves at (a) a passive microwave element and (b) a transmission line.

The reflection characteristics are also described by the voltage standing wave ratio (VSWR), a quantity that can be measured using relatively simple equipment. The VSWR is the ratio of the maximum voltage amplitude on the imput transmission line $\left(\left|V_1^+\right| + \left|V_1^-\right|\right)$ to the minimum voltage amplitude $\left(\left|V_1^+\right| - \left|V_1^-\right|\right)$. Thus,

$$\text{VSWR} = \left(1 + \left|\Gamma_1\right|\right)\Big/\left(1 - \left|\Gamma_1\right|\right)$$

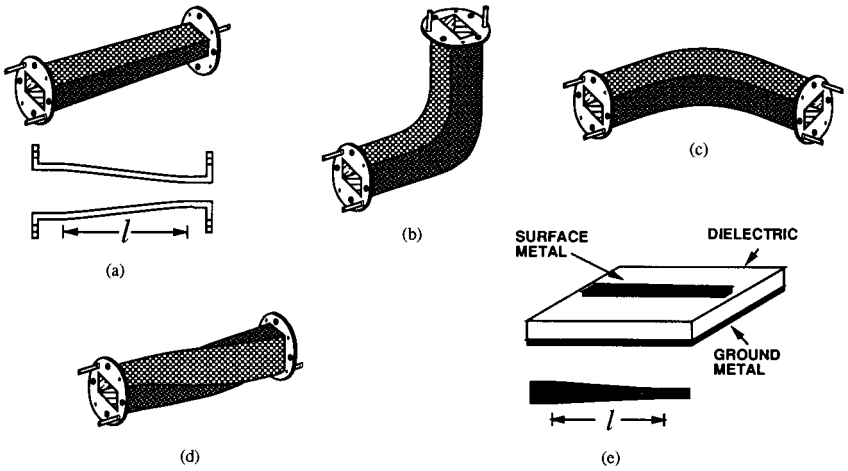

FIGURE 39.3 Sections of transmission lines used for interconnecting components: (a) waveguide tapered section, (b) waveguide E-plane bend, (c) waveguide H-plane bend, (d) waveguide twist, and (e) microstrip taper.

Most passive devices, with the notable exception of ferrite devices, are reciprocal and so $S_{pq} = S_{qp}$. A loss-less passive device also satisfies the unitary condition: $\Sigma_p |S_{pq}|^2 = 1$, which is a statement of power conservation indicating that all power is either reflected or transmitted.

Most microwave circuits are designed to minimize the reflected energy and maximize transmission at least over the frequency range of operation. Thus, the return loss is high and the VSWR ≈ 1 for well-designed circuits.

A terminated transmission line such as that in Fig. 39.2(b) has an input impedance

$$Z_{\text{in}} = Z_0 \frac{Z_L + jZ_0 \tanh \gamma d}{Z_0 + jZ_L \tanh \gamma d}$$

Thus, a short section ($\gamma_d << 1$) of a short circuited ($Z_L = 0$) transmission line looks like an inductor and a capacitor if it is open circuited ($Z_L = \infty$). When the line is a half wavelength long, an open circuit is presented at the input to the line if the other end is short circuited.

Transmission Line Sections

The simplest microwave circuit element is a uniform section of transmission line which can be used to introduce a time delay or a frequency-dependent phase shift. Other line segments for interconnections include bends, corners, twists, and transitions between lines of different dimensions (see Fig. 39.3). The dimensions and shapes are designed to minimize reflections and so maximize return loss and minimize insertion loss.

Discontinuities

The waveguide discontinuities shown in Fig. 39.4(a)–(f) illustrate most clearly the use of E and H field disturbances to realize capacitive and inductive components. An E-plane discontinuity [Fig. 39.4(a)] can be modeled approximately by a frequency-dependent capacitor. H-plane discontinuities [Figs. 39.4(b) and (c)] resemble inductors as does the circular iris of Fig. 39.4(d). The resonant waveguide iris of Fig. 39.4(e) disturbs both the E and H fields and can be modeled by a parallel LC resonant circuit near the frequency of resonance. Posts in waveguide are used both as reactive elements [Fig. 39.4(f)] and to mount active devices [Fig. 39.4(g)]. The equivalent circuits of microstrip discontinuities [Figs. 39.4(k)–(o)] are again modeled by capacitive elements if the E field is interrupted and by inductive elements if the H field (or current) is interrupted. The stub shown in Fig. 39.4(j) presents a short circuit to the through transmission line when the length of the stub is $\lambda_g/4$. When the stubs are electrically short ($<< \lambda_g/4$) they introduce shunt capacitances in the through transmission line.

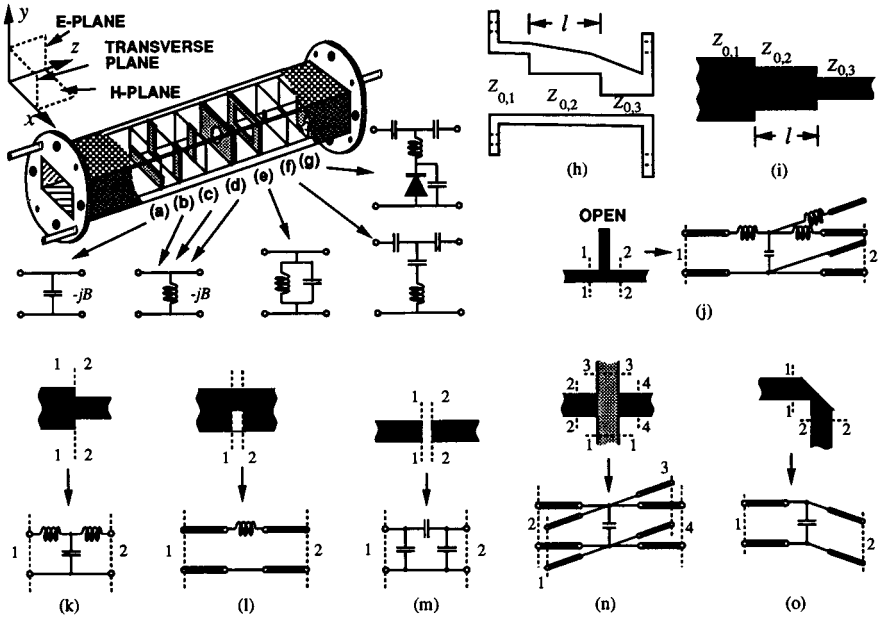

FIGURE 39.4 Discontinuities. Waveguide discontinuities: (a) capacitive E-plane discontinuity, (b) inductive H-plane discontinuity, (c) symmetrical inductive H-plane discontinuity, (d) inductive post discontinuity, (e) resonant window discontinuity, (f) capacitive post discontinuity, (g) diode post mount, and (h) quarter-wave impedance transformer. Microstrip discontinuities: (i) quarter-wave impedance transformer, (j) open microstrip stub, (k) step, (l) notch, (m) gap, (n) crossover, and (o) bend.

Impedance Transformers

Impedance transformers are used to interface two sections of line with different **characteristic impedances**. The smoothest transition and the one with the broadest bandwidth is a tapered line as shown in Fig. 39.3(a) and (e). This element tends to be very long and so step terminations called quarter-wave impedance transformers [see Fig. 39.4(h) and (i)] are sometimes used although their bandwidth is relatively small centered on the frequency at which $l = \lambda_g/4$. Ideally, $Z_{0,2} = \sqrt{Z_{0,1}Z_{0,3}}$.

Terminations

In a termination, power is absorbed by a length of lossy material at the end of a shorted piece of transmission line [Fig. 39.5 (a) and (c)]. This type of termination is called a matched load as power is absorbed and reflections are very small irrespective of the characteristic impedance of the transmission line. This is generally preferred as the characteristic impedance of transmission lines varies with frequency, particularly so for waveguides. When the characteristic impedance of a line does not vary much with frequency, as is the case with a coaxial line, a simpler smaller termination can be realized by placing a resistor to ground [Fig. 39.5(b)].

Attenuators

Attenuators reduce the level of a signal traveling along a transmission line. The basic construction is to make the line lossy but with a characteristic impedance approximating that of the connecting lines so as to reduce reflections. The line is made lossy by introducing a resistive vane in the case of a waveguide [Fig. 39.5(d)], replacing part of the outer conductor of a coaxial line by resistive material [Fig. 39.5(e)], or covering the line by resistive material in the case of a microstrip line [Fig. 39.5(f)]. If the amount of lossy material introduced into the transmission line is controlled, a variable attenuator is achieved, e.g., Fig. 39.5(d).

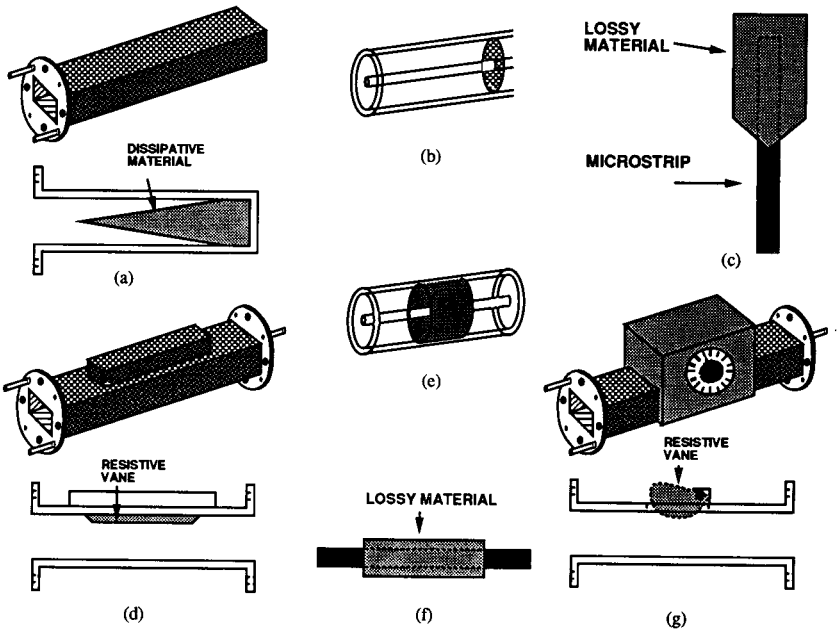

FIGURE 39.5 Terminations and attenuators: (a) waveguide matched load, (b) coaxial line resistive termination, (c) microstrip matched load, (d) waveguide fixed attenuator, (e) coaxial fixed attenuator, (f) microstrip attenuator, and (g) waveguide variable attenuator.

Microwave Resonators

In a lumped element resonant circuit, stored energy is transferred between an inductor which stores magnetic energy and a capacitor which stores electric energy, and back again every period. Microwave resonators function the same way, exchanging energy stored in electric and magnetic forms but with the energy stored spatially. Resonators are described in terms of their quality factor

$$Q = 2\pi f_0 \left(\frac{\text{Maximum energy stored in the resonator at } f_0}{\text{Power lost in the cavity}} \right) \tag{39.17}$$

where f_0 is the resonant frequency. The Q is reduced and thus the resonator bandwidth is increased by the power lost due to coupling to the external circuit so that the loaded Q

$$\begin{aligned} Q_L &= 2\pi f_0 \left(\frac{\text{Maximum energy stored in the resonator at } f_0}{\text{Power lost in the cavity and to the external circuit}} \right) \\ &= \frac{1}{1/Q + 1/Q_{\text{ext}}} \end{aligned} \tag{39.18}$$

where Q_{ext} is called the external Q. Q_L accounts for the power extracted from the resonant circuit and is typically large. For the simple response shown in Fig. 39.6(a) the half power (3 dB) bandwidth is f_0/Q_L.

Near resonance the response of a microwave resonator is very similar to the resonance response of a parallel or series R, L, C resonant circuit [Fig. 39.6(f) and (g)]. These equivalent circuits can be used over a narrow frequency range.

Several types of resonators are shown in Fig. 39.6. Figure 39.6(b) is a rectangular cavity resonator coupled to an external coaxial line by a small coupling loop. Figure 39.6(c) is a microstrip patch reflection resonator.

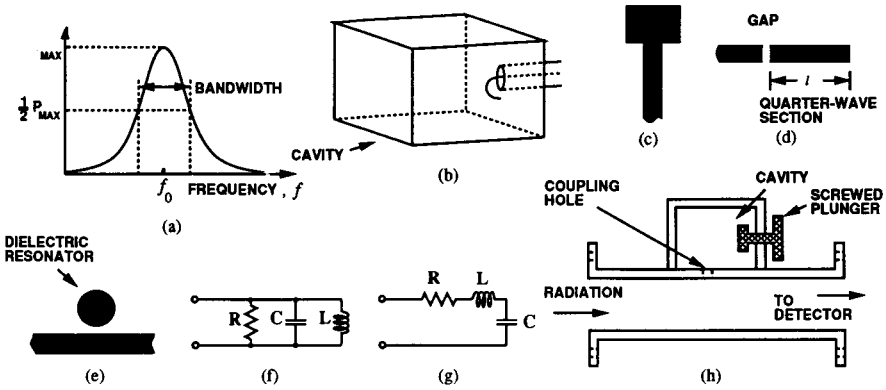

FIGURE 39.6 Microwave resonators: (a) resonator response, (b) rectangular cavity resonator, (c) microstrip patch resonator, (d) microstrip gap-coupled reflection resonator, (e) transmission dielectric transmission resonator in microstrip, (f) parallel equivalent circuits, (g) series equivalent circuits, and (h) waveguide wavemeter.

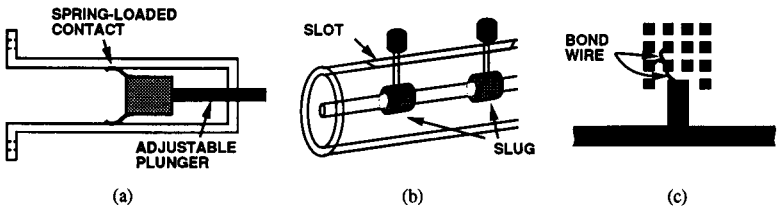

FIGURE 39.7 Tuning elements: (a) waveguide sliding short circuit, (b) coaxial line slug tuner, (c) microstrip stub with tuning pads.

This resonator has large coupling to the external circuit. The coupling can be reduced and photolithographically controlled by introducing a gap as shown in Fig. 39.6(d) for a microstrip gap-coupled transmission line reflection resonator. The Q of a resonator can be dramatically increased by using a high dielectric constant material as shown in Fig. 39.6(e) for a dielectric transmission resonator in microstrip. One simple application of a cavity resonator is the waveguide wavemeter [Fig. 39.6(h)]. Here the resonant frequency of a rectangular cavity is varied by changing the physical dimensions of the cavity with a null of the detector indicating that the frequency corresponds to the resonant cavity frequency.

Tuning Elements

In rectangular waveguide the basic adjustable tuning element is the sliding short shown in Fig. 39.7(a). Varying the position of the short will change resonance frequencies of cavities. It can be combined with hybrid tees to achieve a variety of tuning functions. The post in Fig. 39.4(f) can be replaced by a screw to obtain a screw tuner which is commonly used in waveguide filters. Sliding short circuits can be used in coaxial lines and in conjunction with branching elements to obtain stub tuners. Coaxial slug tuners are also used to provide adjustable matching at the input and output of active circuits. The slug is movable and changes the characteristic impedance of the transmission line. It is more difficult to achieve variable tuning in passive microstrip circuits. One solution is to provide a number of pads as shown in Fig. 39.7(c) which, in this case, can be bonded to the stub to obtain an adjustable stub length. Variable amounts of phase shift can be inserted by using a variable length of line called a line stretcher, or by a line with a variable propagation constant. One type of waveguide variable phase shifter is similar to the variable attenuator of Fig. 39.5(d) with the resistive material replaced by a low-loss dielectric.

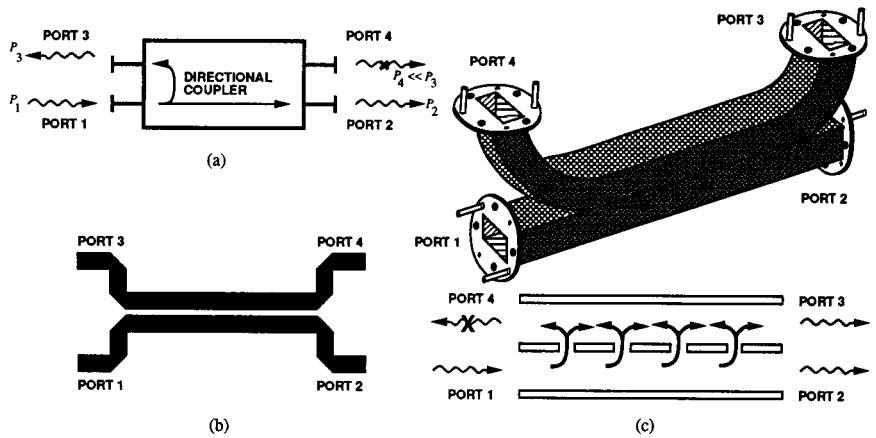

FIGURE 39.8 Directional couplers: (a) schematic, (b) backward-coupling microstrip directional coupler, (c) forward-coupling waveguide directional coupler.

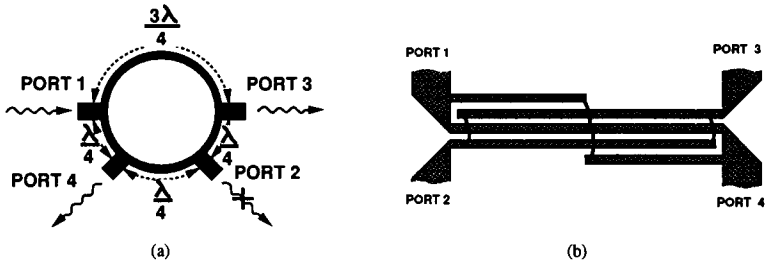

FIGURE 39.9 Microstrip hybrids: (a) rat race hybrid and (b) Lange coupler.

Hybrid Circuits and Directional Couplers

Hybrid circuits are multiport components which preferentially route a signal incident at one port to the other ports. This property is called directivity. One type of hybrid is called a directional coupler, the schematic of which is shown in Fig. 39.8(a). Here the signal incident at port 1 is coupled to ports 2 and 3 while very little is coupled to port 4. Similarly, a signal incident at port 2 is coupled to ports 1 and 4 but very little power appears at port 3. The feature that distinguishes a directional coupler from other types of hybrids is that the power at the output ports (here ports 2 and 3) is different. The performance of a directional coupler is specified by three parameters:

$$\begin{aligned} \text{Coupling factor} &= P_1/P_3 \\ \text{Directivity} &= P_3/P_4 \\ \text{Isolation} &= P_1/P_4 \end{aligned} \tag{39.19}$$

Microstrip and waveguide realizations of directional couplers are shown in Figs. 39.8(b) and (c) where the microstrip coupler couples in the backward direction and the waveguide coupler couples in the forward direction. The powers at the output ports of the hybrids shown in Fig. 39.9 are equal and so the hybrids serve to split a signal into half as well as having directional sensitivity.

Filters

Filters are combinations of microwave passive elements designed to have a specified frequency response. Typically, a topology of a filter is chosen based on established lumped element filter design theory. Then computer-aided design techniques are used to optimize the response of the circuit to the desired response.

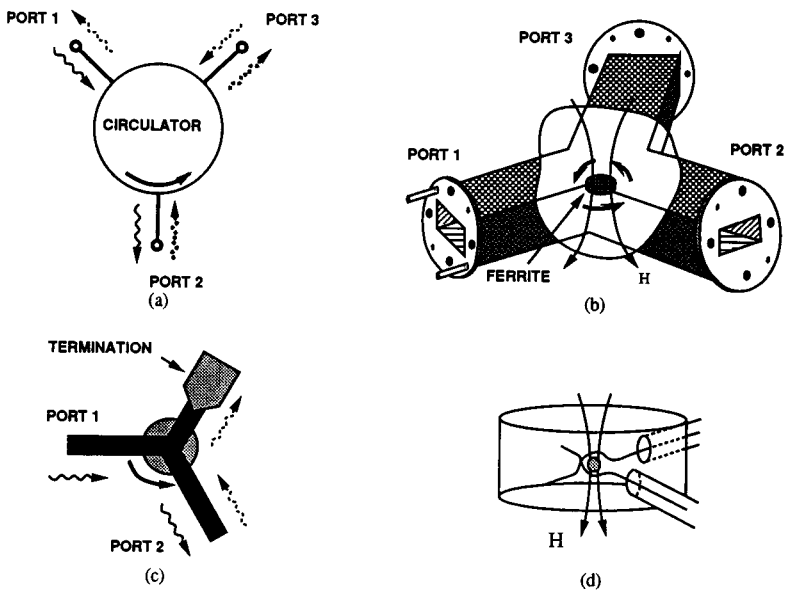

FIGURE 39.10 Ferrite components: (a) schematic of a circulator, (b) a waveguide circulator, (c) a microstrip isolator, and (d) a YIG tuned bandpass filter.

Ferrite Components

Ferrite components are nonreciprocal in that the insertion loss for a wave traveling from port A to port B is not the same as that from port B to port A.

Circulators and Isolators

The most important type of ferrite component is a circulator [Fig. 39.10(a) and (b)]. The essential element of a circulator is a piece of ferrite which when magnetized becomes nonreciprocal, preferring progression of electromagnetic fields in one circular direction. An ideal circulator has the scattering matrix

$$[S] = \begin{bmatrix} 0 & 0 & S_{13} \\ S_{21} & 0 & 0 \\ 0 & S_{32} & 0 \end{bmatrix} \tag{39.20}$$

In addition to the insertion and return losses, the performance of a circulator is described by its isolation which is its insertion loss in the undesired direction. An isolator is just a three-port circulator with one of the ports terminated in a matched load as shown in the microstrip realization of Fig. 39.10(c). It is used in a transmission line to pass power in one direction but not in the reverse direction. It is commonly used to protect the output of equipment from high reflected signals. The heart of isolators and circulators is the nonreciprocal element. Electronic versions have been developed for MMICs. A four-port version is called a duplexer and is used in radar systems and to separate the received and transmitted signals in a transceiver.

YIG Tuned Resonator

A magnetized YIG (yttrium iron garnet) sphere, shown in Fig. 39.10(d), provides coupling between two lines over a very narrow bandwidth. The center frequency of this bandpass filter can be adjusted by varying the magnetizing field.

Passive Semiconductor Devices

A semiconductor diode can be modeled by a voltage-dependent resistor and capacitor in shunt. Thus an applied dc voltage can be used to change the value of a passive circuit element. Diodes optimized to produce a voltage variable capacitor are called varactors. In detector circuits a diode's voltage variable resistance is used to achieve rectification and, through design, produce a dc voltage proportional to the power of an incident microwave signal. A controllable variable resistance is used in a PIN diode to realize an electronic switch.

Defining Terms

Characteristic impedance: Ratio of the voltage and current on a transmission line when there are no reflections.
Insertion loss: Power lost when a signal passes through a device.
Reference impedance: Impedance to which scattering parameters are referenced.
Return loss: Power lost upon reflection from a device.
Voltage standing wave ratio (VSWR): Ratio of the maximum voltage amplitude on a line to the minimum voltage ampitude.

Rohde, Wiley, New York, 1990, provides a comprehensive treatment of computer-aided design techniques for both passive and active microwave circuits. *Microwave Transistor Amplifiers: Analysis and Design,* 2nd ed., by G. Gonzalez, Prentice-Hall, Englewood Cliffs, N.J., 1996.

The monthly journals *IEEE Transactions on Microwave Theory Techniques, IEEE Microwave and Guided Wave Letters,* and *IEEE Transactions on Antennas and Propagation* publish articles on modeling and design of microwave passive circuit components. Articles in the first two journals are more circuit and component oriented while the third focuses on field theoretic analysis. These are published by The Institute of Electrical and Electronics Engineers, Inc. For subscription or ordering contact: IEEE Service Center, 445 Hoes Lane, P.O. Box 1331, Piscataway, New Jersey 08855-1331.

Articles can also be found in the biweekly magazine *Electronics Letters* and the bimonthly magazine *IEE Proceedings Part H—Microwave, Optics and Antennas.* Both are published by the Institute of Electrical Engineers and subscription inquiries should be sent to IEE Publication Sales, P.O. Box 96, Stenage, Herts. SG1 2SD, United Kingdom. Telephone number (0438) 313311.

The *International Journal of Microwave and Millimeter-Wave Computer-Aided Engineering* is a quarterly journal devoted to the computer-aided design aspects of microwave circuits and has articles on component modeling and computer-aided design techniques. It has a large number of review-type articles. For subscription information contact John Wiley & Sons, Inc., Periodicals Division, P.O. Box 7247-8491, Philadelphia, Pennsylvania 19170-8491.

39.2 Active Microwave Devices

Robert J. Trew

Active devices that can supply gain at microwave frequencies can be fabricated from a variety of semiconductor materials. The availability of such devices permits a wide variety of system components to be designed and fabricated. Systems are generally constructed from components such as filters, amplifiers, oscillators, mixers, phase shifters, switches, etc. Active devices are primarily required for the oscillator and amplifier components. For these functions, devices that can supply current, voltage, or power gain at the frequency of interest are embedded in circuits that are designed to provide the device with the proper environment to create the desired response. The operation of the component is dictated, therefore, by both the capabilities of the active device and its embedding circuit.

It is common to fabricate microwave integrated circuits using both hybrid and monolithic techniques. In the hybrid approach, discrete active devices are mounted in RF circuits that can be fabricated from waveguides or transmission lines fabricated using coaxial, microstrip, stripline, coplanar waveguide, or other such media. Monolithic circuits are fabricated with both the active device and the RF circuit fabricated in the same semiconductor chip. Interconnection lines and the embedding RF circuit are generally fabricated using microstrip or coplanar waveguide transmission lines.

Active microwave devices can be fabricated as **two-terminal devices** (diodes) or **three-terminal devices** (transistors). Generally, three-terminal devices are preferred for most applications since the third terminal provides a convenient means to control the RF performance of the device. The third terminal allows for inherent isolation between the input and output RF circuit. Amplifiers and oscillators can easily be designed by providing circuits with proper stabilization or feedback characteristics. Amplifiers and oscillators can also be designed using two-terminal devices (diodes), but input/output isolation is more difficult to achieve since only one RF port is available. In this case it is generally necessary to use RF isolators or circulators.

The most commonly used two-terminal active devices consist of Gunn, tunnel, and IMPATT diodes. These devices can be designed to provide useful gain from low gigahertz frequencies to high millimeter-wave frequencies. Three-terminal devices consist of bipolar (BJT), heterojunction bipolar (HBT), and field-effect transistors (MESFETs and HEMTs). These devices can also be operated from UHF to millimeter-wave frequencies.

Semiconductor Material Properties

Active device operation is strongly dependent upon the charge transport characteristics of the semiconductor materials from which the device is fabricated. Semiconductor materials can be grown in single crystals with very high purity. The electrical conductivity of the crystal can be precisely controlled by introduction of minute quantities of dopant impurities. When these impurities are electrically activated, they permit precise values of current flow through the crystals to be controlled by potentials applied to contacts, placed upon the crystals. By clever positioning of the metal contacts, various types of semiconductor devices are fabricated. In this section we will briefly discuss the important material characteristics.

Semiconductor material parameters of interest for device fabrication consist of those involved in charge transport through the crystal, as well as thermal and mechanical properties of the semiconductor. The charge transport properties describe the ease with which free charge can flow through the material. For example, the velocity-electric field characteristics for several commonly used semiconductors are shown in Fig. 39.11. At low values of electric field, the charge transport is ohmic and the charge velocity is directly proportional to the magnitude of the electric field. The proportionality constant is called the mobility and has units of cm^2/V-s. Above a critical value for the electric field, the charge velocity saturates and either becomes constant (e.g., Si) or decreases with increasing field (e.g., GaAs). Both of these behaviors have implications for device fabrication, especially for devices intended for high-frequency operation. Generally, a high velocity is desired since current is directly proportional to velocity. Also, a low value for the saturation electric field is desirable since this implies a high-charge mobility. High mobility implies low resistivity and, therefore, low values for parasitic and access resistances for semiconductor devices.

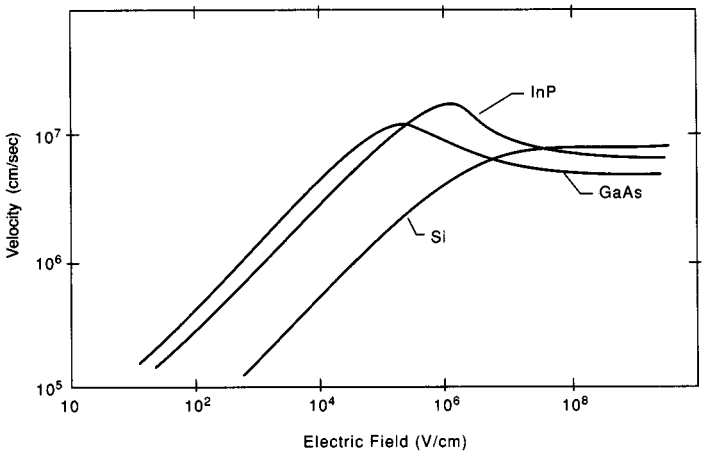

FIGURE 39.11 Electron velocity versus electric field for several semiconductors. This figure shows the electron velocity in several common semiconductors as a funcation of electric field strength. At low electric field the electron velocity is ohmic, as indicated by the linear characteristic. At higher electric field strength the electron velocity saturates and becomes nonlinear. Compound semiconductors such as GaAs and InP have highly nonlinear behavior at large electric fields.

TABLE 39.2 Material Parameters for Several Semiconductors

Semiconductor	E_g (eV)	ε_r	κ (W/cm-K) @300 K	E_c (V/cm)	$\tau_{minority}$ (s)
Si	1.12	11.9	1.5	3×10^5	2.5×10^{-3}
GaAs	1.42	12.5	0.54	4×10^5	$\sim 10^{-8}$
InP	1.34	12.4	0.67	4.5×10^5	$\sim 10^{-8}$
α-SiC	2.86	10.0	4	$(1–5) \times 10^6$	$\sim(1–10) \times 10^{-9}$
β-SiC	2.2	9.7	4	$(1–5) \times 10^6$	$\sim(1–10) \times 10^{-9}$

The decreasing electron velocity with electric field characteristic for compound semiconductors such as GaAs and InP makes possible active two-terminal devices called transferred electron devices (TEDs) or Gunn diodes. The negative slope of the velocity versus electric field characteristic implies a decreasing current with increasing voltage. That is, the device has a negative resistance. When a properly sized piece of these materials is biased and placed in a resonant cavity, the device will be unstable up to very high frequencies. By proper selection of embedding impedances oscillators or amplifiers can be constructed.

Other semiconductor materials parameters of interest include thermal, dielectric constant, energy bandgap, electric breakdown characteristics, and minority carrier lifetime. The thermal conductivity of the material is important because it describes how easily heat can be extracted from the device. The thermal conductivity has units of W/cm-K. Generally, high thermal conductivity is desirable. Compound semiconductors, such as GaAs and InP, have relatively poor thermal conductivity compared to elemental semiconductors such as Si. Materials such as SiC have excellent thermal conductivity and have uses in high-power electronic devices. The dielectric constant is important since it affects the size of the semiconductor device. The larger the dielectric constant, the smaller the device. Electric breakdown characteristics are important since breakdown limits the magnitudes of the dc and RF voltages that can be applied to the device. This is turn limits the RF power that can be handled by the device. The electric breakdown for the material is generally described by the critical value of electric field that produces avalanche ionization. Minority carrier lifetime is important for bipolar devices, such as pn junction diodes, rectifiers, and bipolar junction transistors (BJTs). A low value for minority carrier lifetime is desirable for devices such as diode temperature sensors and switches where low reverse bias leakage current is desirable. A long minority carrier lifetime is desirable for devices such as bipolar transistors. For materials such as Si and SiC, the minority carrier lifetime can be varied by controlled impurity doping. A comparison of some of the important material parameters for several common semiconductors is presented in Table 39.2.

Two-Terminal Active Microwave Devices

The IMPATT diode, transferred electron device, and tunnel diode are the most commonly used two-terminal devices. These devices can operate from the low microwave through high millimeter-wave frequencies. They were the first semiconductor devices that could provide useful RF power levels at microwave and millimeter-wave frequencies. The three devices are similar in that they are fabricated from blocks of semiconductors and require two electrodes (anode and cathode) for supplying dc bias. The same electrodes are used for the RF port, and since only two electrodes are available, the devices must be operated as a **one-port network.** This is generally accomplished by mounting the semiconductor in a pin-type package. The package can then be positioned in an RF circuit or resonant cavity and the top and bottom pins on the package used as the dc and RF electrical contacts. This arrangement works quite well and packaged devices can be operated up to about 90–100 GHz. For higher-frequency operation, the devices are generally mounted directly into circuits using microstrip or some other similar technology.

All three devices operate as negative immittance components. That is, their active characteristics can be described as either a negative resistance or a negative conductance. Which description to use is determined by the physical operating principles of the particular device.

Tunnel Diodes

Tunnel diodes [Sze, 1981] generate active characteristics by a mechanism involving the physical tunneling of electrons between energy bands in highly doped semiconductors. For example, if a pn junction diode is heavily doped, the conduction and valence bands will be located in close proximity and **charge carriers** can tunnel through the electrostatic barrier separating the p-type and n-type regions, rather than be thermionically emitted over the barrier as generally occurs in this type of diode. When the diode is biased (either forward or reverse bias) current immediately flows and junction conduction is basically ohmic. In the forward bias direction, conduction occurs until the applied bias forces the conduction and valence bands to separate. The tunnel current then decreases and normal junction conduction occurs. In the forward bias region where the tunnel current is decreasing with increasing bias voltage, a negative immittance characteristic is generated. The immittance is called "N-type" because the I-V characteristic "looks like" the letter N. This type of active element is short-circuit stable and is described by a negative conductance in shunt with a capacitance. Tunnel diodes are limited in operation frequency by the time it takes for charge carriers to tunnel through the junction. Since this time is very short (on the order of 10^{-12} s) operation frequency can be very high, approaching 1000 GHz. Tunnel diodes have been operated at hundreds of gigahertz, limited by practical packaging and parasitic impedance considerations. The RF power available from a tunnel diode is limited (hundreds of milliwatts level) since the maximum RF voltage swing that can be applied across the junction is limited by the forward turn-on characteristics of the device (typically 0.6–0.9 V). Increased RF power can only be obtained by increasing device area to increase RF current, but device area is limited by operation frequency according to an inverse scaling law. Tunnel diodes have moderate dc-to-RF conversion efficiency (<10%), very low **noise figures,** and are useful in low-noise systems applications, such as microwave and millimeter-wave receivers.

Transferred Electron Devices

Transferred electron devices (i.e., Gunn diodes) [Bosch and Engelmann, 1975] also have N-type active characteristics and can be modeled as a negative conductance in parallel with a capacitance. Device operation, however, is based upon a fundamentally different principle. The negative conductance derives from the complex conduction band structure of certain compound semiconductors, such as GaAs and InP. In these direct bandgap materials the central (or Γ) conduction band is in close energy-momentum proximity to secondary, higher-order conduction bands (i.e., the X and L valleys). The electron effective mass is determined by the shape of the conduction bands, and the effective mass is "light" in the Γ valley but "heavy" in the higher-order X and L valleys. When the crystal is biased, current flow is initially due to electrons in the light effective mass Γ valley and conduction is ohmic. However, as the bias field is increased, an increasing proportion of the free electrons are transferred into the X and L valleys where the electrons have heavier effective mass. The increased effective mass slows down the electrons, with a corresponding decrease in conduction current through the crystal. The net result is that the crystal displays a region of applied bias voltages where current decreases with increasing voltage. That is, a negative conductance is generated. The device is unstable and, when placed in an RF circuit

or resonant cavity, oscillators or amplifiers can be fabricated. The device is not actually a diode since no pn or Schottky junction is used. The phenomenon is a characteristic of the bulk material and the special structure of the conduction bands in certain compound semiconductors. Most semiconductors do not have the conduction band structure necessary for the transferred electron effect. The term *Gunn diode* is actually a misnomer since the device is not a diode. TEDs are widely used in oscillators from the microwave through high millimeter-wave frequency bands. They have good RF output power capability (milliwatts to watts level), moderate efficiency (<20%), and excellent noise and bandwidth capability. Octave band tunable oscillators are easily fabricated using devices such as YIG (yttrium iron garnet) resonators or varactors as the tuning element. Most commercially available solid-state sources for 60- to 100-GHz operation generally use InP TEDs.

IMPATT Diodes

IMPATT (impact avalanche transit time) diodes [Bhartia and Bahl, 1984] are fabricated from pn or Schottky junctions. A typical pn junction device is shown in Fig. 39.12. For optimum RF performance the diode is separated, by use of specially designed layers of controlled impurity doping, into avalanche and drift regions. In operation the diode is reverse biased into avalanche breakdown. Due to the very sensitive I-V characteristic, it is best to bias the diode using a constant current source in which the magnitude of the current is limited. When the diode is placed in a microwave resonant circuit, RF voltage fluctuations in the bias circuit grow and are forced into a narrow frequency range by the impedance characteristics of the resonant circuit. Due to the avalanche process the RF current across the avalanche region lags the RF voltage by 90 degrees. This inductive delay is not sufficient, by itself, to produce active characteristics. However, when the 90 degrees phase shift is added to that arising from an additional inductive delay caused by the transit time of the carriers drifting through the remainder of the diode external to the avalanche region, a phase shift between the RF voltage and current greater than 90 degrees is obtained. A Fourier analysis of the resulting waveforms reveals a device impedance with a negative real part. That is, the device is active and can be used to generate or amplify RF signals. The device impedance has an "S-type" active characteristic and the device equivalent circuit consists of a negative resistance in series with an inductor. The device has significant pn junction capacitance that must be considered, and a complete equivalent circuit would include the device capacitance in parallel with the series negative resistance-inductance elements. For optimum performance the drift region is designed so that the electric field throughout the RF cycle is sufficiently high to produce velocity saturation for the charge carriers. In order to achieve this, it is common to design complex structures consisting of alternating layers of highly doped and lightly doped semiconductor regions. These structures are called "high-low," "low-high-low," or "Read" diodes, after the man who first proposed their use. They can also be fabricated in a back-to-back arrangement to form double-drift structures. These devices are particularly attractive for millimeter-wave applications. IMPATT diodes can be fabricated from most semiconductors, but are generally fabricated from Si or GaAs. The devices are capable of good RF output power (mW to W) and good dc-to-RF conversion efficiency (~10–20%). They operate well into the millimeter-wave region and have been operated as high as 340 GHz. They have moderate bandwidth capability, but have relatively poor noise performance due to the impact ionization process.

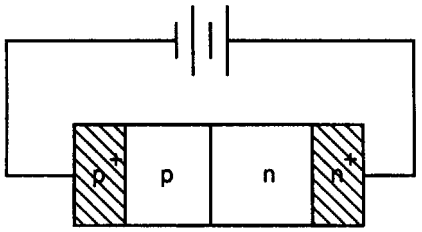

FIGURE 39.12 Diagram showing the structure for a typical pn junction IMPATT diode. This particular diode is called a double-drift device because avalanche breakdown occurs at the pn junction, which is located in the middle of the device. When operated in breakdown, electrons would travel through the n-type region towards the positive terminal of the bias source and holes would travel through the p-type region towards the negative terminal of the source. The diode, therefore, operates as two diodes connected in a back-to-back configuration. The frequency capability of the device is directly proportional to the width of the n and p regions.

Although the two-terminal active devices are used in many electronic systems, the one-port characteristic can introduce significant complexity into circuit design. Isolators and circulators are generally required, and these components are often large and bulky. They are often fabricated from magnetic materials, which can introduce thermal sensitivities. For these reasons three-terminal devices have replaced two-terminal devices in many practical applications. Generally, if two-terminal and three-terminal devices with comparable capability

are available, the three-terminal device offers a more attractive design solution and will be selected. Two-terminal devices are generally only used when a comparable three-terminal device is not available. For this reason IMPATT and TED devices are used in millimeter-wave applications, where they retain an advantage in providing good RF power. Tunnel diodes are not often used, except in a few special applications where their low-noise and wide-bandwidth performance can be used to advantage.

Three-Terminal Active Microwave Devices

The high-frequency performance of three-terminal semiconductor devices has improved dramatically during the past two decades. Twenty years ago transistors that could provide useful **gain** at frequencies above 10 GHz were a laboratory curiosity. Today, such devices are readily available, and state-of-the-art transistors operate well above 100 GHz. This dramatic improvement has been achieved by advances in semiconductor growth technology, coupled with improved device design and fabrication techniques. Semiconductor materials technology continues to improve and new device structures that offer improved high-frequency performance are continually being reported.

In this section we will discuss the two most commonly employed transistors for microwave applications, the metal-semiconductor field-effect transistor (MESFET) [Liechti, 1976] and the bipolar transistor (BJT) [Cooke, 1971]. These two transistors are commonly employed in practical microwave systems as amplifiers, oscillators, and gain blocks. The transistors have replaced many two-terminal devices due to their improved performance and ease of use. Transistors are readily integrated into both hybrid and monolithic integrated circuit environments (MICs). This, in turn, has resulted in significantly reduced size, weight, and dc power consumption, as well as increased reliability and mean time to failure for systems that use these components. Transistors are easily biased and the **two-port network** configuration leads naturally to inherent separation between input and output networks.

Field-Effect Transistors

A cross-sectional view of a microwave MESFET is shown in Fig. 39.13. The device is conceptionally very simple. The MESFET has two ohmic contacts (the source and drain) separated by some distance, usually in the range of 3 to 10 μm. A rectifying Schottky contact (the gate) is located between the two ohmic contacts. Typically, the gate length is on the order of 0.1 to 2 μm for modern microwave devices. The width of the device scales with frequency and typically ranges from about 1 to 10 μm for power microwave devices to 50 μm for millimeter-wave devices. All three contacts are located on the surface of a thin conducting layer (the channel) which is located on top of a high-resistivity, nonconductive substrate to form the device. The channel region is typically very thin (on the order of 0.1–0.3 μm) and is fabricated by epitaxial growth or ion implantation. In operation, the drain contact is biased at a specified potential (positive drain potential for an n-channel device) and the source is grounded. The flow of current through the conducting channel is controlled by negative dc and superimposed RF potentials applied to the gate, which modulate the channel current and provide RF gain. The current flow is composed of only one type of charge carrier (generally electrons) and the device is termed *unipolar*. The MESFET can be fabricated from a variety of semiconductors, but is generally fabricated from GaAs. MESFETs fabricated from Si do not work at high frequencies as well as those fabricated from GaAs due to lower electron mobility in Si (e.g., μ_n ~6000 cm²/V-s for GaAs and 1450 cm²/V-s for Si). The lower electron mobility in Si produces high source resistance, which seriously degrades the high-frequency gain possible from the device.

MESFETs can be optimized for small-signal, low-noise operation or for large-signal, RF power applications. Generally, low-noise operation requires short gate lengths, relatively narrow gate widths, and highly doped channels. Power devices generally have longer gate lengths, much wider gate widths, and lower doped channels. Low-noise devices can be fabricated that operate with good gain (~10 dB) and low noise figure (<3 dB) to above 100 GHz. Power devices can provide RF power levels on the order of watts (W) up to over 20 GHz.

The current gain of the MESFET is indicated by the f_T of the device, sometimes called the gain-bandwidth product. This parameter is defined as the frequency at which the short-circuited current gain is reduced to unity and can be expressed as

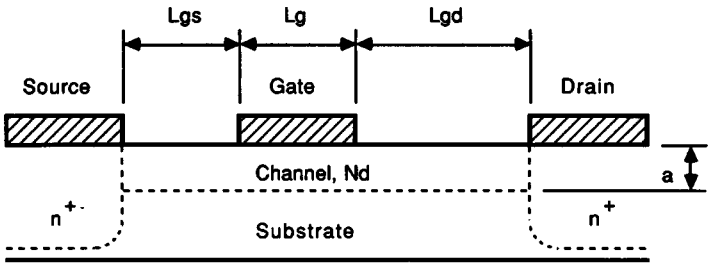

FIGURE 39.13 Cross-sectional view of a microwave MESFET. The cross-hatched areas indicate metal electrodes placed upon the semiconductor to provide for electrical connections. The areas indicated as n^+ are highly doped, highly conducting regions to reduce ohmic access resistances. The channel contains the region of current flow and the substrate is highly resistive and nonconducting so that the current flow is confined to the channel.

$$f_T = \frac{g_m}{2\pi C_{gs}} \tag{39.21}$$

where g_m is the device transconductance (a measure of gain capability) and C_{gs} is the gate source capacitance. High f_T is desirable and this is achieved with highly doped channels and low capacitance gates. The RF power gain is also of interest and this performance can be indicated by the unilateral power gain defined as

$$U = \frac{1}{4}\left(\frac{f_T}{f}\right)^2 \frac{R_{ds}}{R_g} \tag{39.22}$$

where U is the unilateral power gain, f is the operating frequency, R_{ds} is the drain-source resistance, and R_g is the gate resistance. As this expression indicates, large power gain requires a high f_T, and a large R_{ds}/R_g ratio. The highest frequency at which the device could be expected to produce power gain can be defined from the frequency, f, at which U goes to zero. This frequency is called the maximum frequency of oscillation, or $f_{\max}$, and is defined as

$$f_{\max} = \frac{f_T}{2}\sqrt{\frac{R_{ds}}{R_g}} \tag{39.23}$$

A different form of field-effect transistor can be fabricated by inserting a highly doped, wider-bandgap semiconductor between the conducting channel and the gate electrode [Drummond et al., 1986]. The conducting channel is then fabricated from undoped semiconductor. The discontinuity in energy bandgaps between the two semiconductors, if properly designed, results in free charge transfer from the highly doped, wide-bandgap semiconductor into the undoped, lower-bandgap channel semiconductor. The charge accumulates at the interface and creates a two-dimensional electron gas (2DEG). The sheet charge is essentially two-dimensional and allows current to flow between the source and drain electrodes. The amount of charge in the 2DEG can be controlled by the potential applied to the gate electrode. In this manner the current flow through the device can be modulated by the gate and gain results. Since the charge flows at the interface between the two materials, but is confined in the undoped channel semiconductor, very little impurity scattering occurs and extremely high charge carrier mobility results. The device, therefore, has very high transconductance and is capable of very high frequency operation and very low noise figure operation. This type of device is called a high electron mobility transistor (HEMT). HEMTs can be fabricated from material systems such as AlGaAs/GaAs or AlInAs/GaInAs/InP. The latter material system produces devices that have f_T's above 300 GHz and have produced noise figures of about 1 dB at 100 GHz.

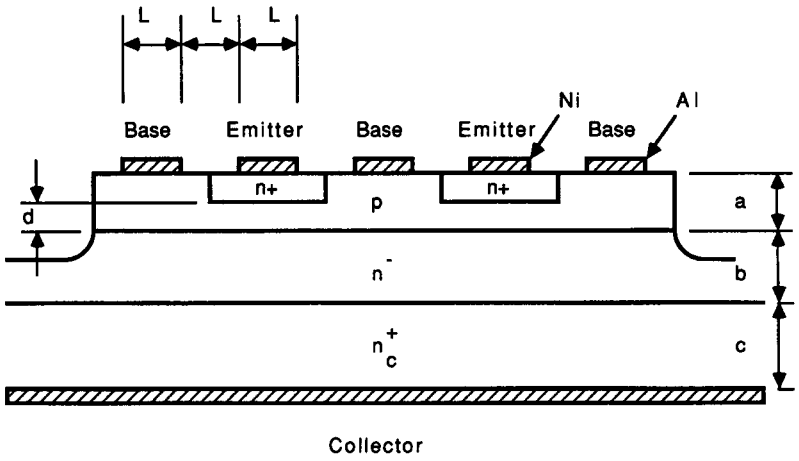

FIGURE 39.14 Cross-sectional view of a microwave bipolar transistor (BJT). The cross-hatched areas indicate metal electrodes. The electrode pattern on the surface is interdigitated with the base electrodes connected together at one end and the emitter electrodes connected together at the other end. Due to the interdigitated structure, there will always be one more base electrode than the number of emitter electrodes. The n^+, p, n^-, and n_c^+ designations indicate the impurity doping type and relative concentration level. This device has the collector electrode on the bottom of the device.

Bipolar Transistors

A cross-sectional view of a bipolar transistor is shown in Fig. 39.14. The bipolar transistor consists of back-to-back pn junctions arranged in a sandwich structure. The three regions are designated the emitter, base, and collector. This type of device differs from the field-effect transistors in that both electrons and holes are involved in the current transport process (thus the designation *bipolar*). Two structures are possible: pnp or npn, depending upon the conductivity type common to both pn junctions. Generally, for microwave applications the npn structure is used since device operation is controlled by electron flow. In general, electron transport is faster than that for holes, and npn transistors are capable of superior high-frequency performance compared to comparable pnp transistors. In operation, the base-emitter pn junction is forward biased and the collector-base pn junction is reverse biased. When an RF signal is applied to the base-emitter junction the junction allows a current to be injected into the base region. The current in the base region consists of minority charge carriers (i.e., carriers with the opposite polarity compared to the base material—electrons for an npn transistor). These charge carriers then diffuse across the base region to the base-collector junction, where they are swept across the junction by the large reverse bias electric field. The reverse bias electric field in the base-collector region is generally made sufficiently large that the carriers travel at their saturation velocity. The transit time of the charge carriers across this region is small, except for millimeter-wave transistors where the base-collector region transit time can be a significant fraction of the total time required for a charge carrier to travel from the emitter through the collector. The operation of the transistor is primarily controlled by the ability of the minority charge carriers to diffuse across the base region. For this reason microwave transistors are designed with narrow base regions in order to minimize the time required for the carriers to travel through this region. The base region transit time is generally the limiting factor in determining the high-frequency capability of the transistor. The gain of the transistor is also significantly affected by minority carrier behavior in the base region. The density of minority carriers is significantly smaller than the density of majority carriers (majority carrier density is approximately equal to the impurity doping density) for typical operating conditions and the probability that the minority charge will recombine with a majority carrier is high. If recombination occurs, the minority charge cannot reach the base-collector junction but appears as base current. This, in turn, reduces the current gain capability of the transistor. Narrow base regions reduce the semiconductor volume where recombination can occur and, therefore, result in increased gain. Modern microwave transistors typically have base regions on the order of 0.1–0.25 μm.

The frequency response of a bipolar transistor can be determined by an analysis of the total time it takes for a charge carrier to travel from the emitter through the collector. The total time can be expressed as

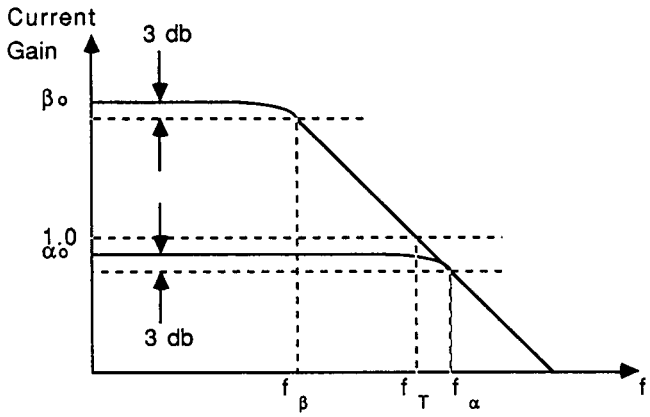

FIGURE 39.15 Current gains versus frequency for bipolar transistors. The common-emitter and common-base current gains are designated as β and α, respectively. The subscript "o" indicates the dc value. The gains decrease with frequency above a certain value. The frequencies where the gains are reduced by 3 dB from their dc values are indicated as the CE and CB cutoff frequencies, f_β and f_α, respectively. The frequency at which the CE current gain is reduced to unity is defined as the gain-bandwidth product f_T. Note that the CB current gain is restricted to values less than unity and that the CE current gain has values that significantly exceed unity.

$$\tau_{ec} = \tau_e + \tau_b + \tau_c + \tau'_c \tag{39.24}$$

where τ_{ec} is the total emitter-collector transit time, τ_e is the base-emitter junction capacitance charging time, τ_b is the base region transit time, τ_c is the base-collector junction capacitance charging time, and τ_c' is the base-collector region transit time. The total emitter-base time is related to the gain-bandwidth capability of the transistor according to the relation

$$f_T = \frac{1}{2\pi\tau_{ec}} \tag{39.25}$$

Since the bipolar transistor has three terminals, it can be operated in various configurations, depending upon the electrode selected as the common terminal. The two most commonly employed are the common emitter (CE) and the common base (CB) configurations, although the common collector (CC) configuration can also be used. Small-signal amplifiers generally use the CE configuration and power amplifiers often use the CB configuration.

The current gain for a bipolar transistor is shown in Fig. 39.15. The current gains of the transistor operated in the CE and CB configurations are called β and α, respectively. As indicated in the figure, the CE current gain β is much larger than the CB current gain α, which is limited to values less than unity. For modern microwave transistors $\alpha_o \sim 0.98$–0.99 and $\beta_o \sim 50$–60.

A measure of the RF power gain for the transistor is indicated by the unilateral power gain, which can be expressed as

$$U \cong \frac{\alpha_o}{16\pi^2 r_b C_c f^2 \left(\tau_{ec} + \dfrac{r_e C_c}{a_o}\right)} \tag{39.26}$$

where U is the power gain, α_o is the dc CB current gain, r_b is the base resistance, C_c is the collector capacitance, τ_{ec} is the total emitter-to-collector transit-time, and r_e is the emitter resistance. The frequency at which U is

Tracking a Microwave-Cavity Resonance by Use of Vibrations

A microwave heating apparatus that comprises a resonant cavity excited by a magnetron has been equipped with an automated tuning system (see figure) to maintain resonance. Resonance is a desirable condition because it maximizes the transfer of power to the material sample that one seeks to heat. Typically, the cavity becomes detuned from resonance during heating of the sample because the permittivity of the sample changes with temperature, altering the electromagnetic field in the cavity. A system like this that automatically compensates for the detuning effect can enhance efficiency and productivity in microwave processing of materials.

This tuning system, like others, is based on the old-fashioned radio tuning principle, in which one brackets a resonance by manual back-and-forth actuation of a tuning device while seeking an optimum quantitative or qualitative measure of the signal. In both traditional manual tuning and in other automated resonance-tracking systems, the tuning adjustments usually vary the frequencies, but in this case, one does not have the option of frequency tuning because the frequency of oscillation of the magnetron is not adjustable and is nominally constant.

The back-and-forth tuning action needed to locate the resonance is provided by an auxiliary tuning device, which includes a hollow metal rod that is mounted on a loudspeaker outside the cavity and that protrudes into the cavity, preferably at a position of maximum electric field. An audio oscillator drives the loudspeaker at a convenient frequency between 30 and 100 Hz, causing the rod to vibrate and thereby impose a slight modulation on the microwave field in the cavity. A diode across the cavity from the vibrating rod detects the amplitude modulation on the electric field.

Both the signal from the audio oscillator and the amplified output of the diode are fed to the mixer at saturating amplitudes, so the low-pass filtered output of the mixer depends only on the difference between the phases of these two signals. This phase difference is a measure of the deviation from resonance. Thus, the output of the mixer constitutes an error signal that indicates the adjustment needed to restore the cavity to resonance. This signal is fed to the motor that drives the plunger to obtain the required tuning adjustment.

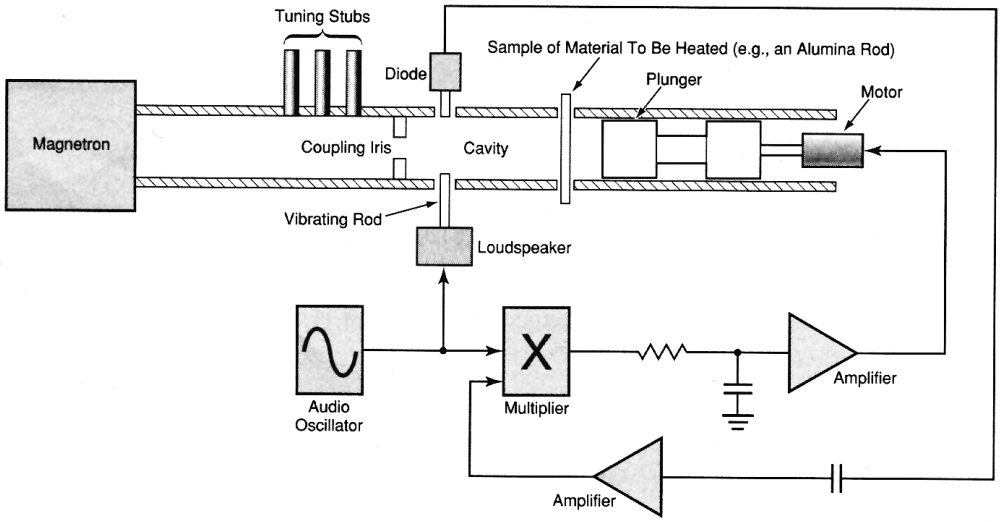
reduced to unity (f_{max}) is the maximum frequency at which the device will have active characteristics. This frequency is

$$f_{max} = \left[\frac{f_T}{8\pi r_b C_c}\right]^{1/2} \tag{39.27}$$

In order to maximize the high-frequency performance of a transistor, it is necessary to design the device so that it has high current gain (f_T), low base resistance (r_b), and low collector capacitance (C_c).

Bipolar transistors operating to about 20 GHz are generally fabricated from Si. These devices are easily fabricated and low cost. They are useful in moderate gain and low to high RF power applications. The have relatively high noise figure that varies from about 1 dB at 1 GHz to about 4–5 dB at 10 GHz.

An improved high-frequency bipolar transistor can be fabricated using heterostructures of compound semiconductors, such as AlGaAs/GaAs [Kroemer, 1982]. These devices have their emitters fabricated from a wide-bandgap semiconductor (such as AlGaAs) and the remainder of the device fabricated from the lower-bandgap semiconductor (GaAs). The wide-bandgap emitter results in improved charge injection efficiency across the base-emitter junction into the base region and much improved RF performance. While the operation of standard



The vibrating rod modulates the electric field in the cavity. The phase difference between the vibrations and the modulation provides an indication of deviation from resonance and is used to control repositioning of the plunger to maintain resonance. (Reprinted with permission from *NASA Tech Briefs,* 20(10), 54, 1996.)

The effectiveness of the automated tuning system was demonstrated in experiments in which the microwave apparatus was used to heat an alumina rod. The apparatus was operated with a forward microwave power of 200 W in two cases; one with and one without automatic tuning. Without automatic tuning, the rod attained an asymptotic temperature of about 600°C in 5 min. With automatic tuning, the temperature of the rod exceeded 900°C (and was still increasing) in less than 2 min.

This work was done by Martin Barmatz and Ofer Iny of Caltech for NASA's Jet Propulsion Laboratory. (Reprinted with permission from *NASA Tech Briefs,* 20(10), 54, 1996.)

Si bipolar transistors is limited to frequencies less than about 40 GHz, the heterojunction bipolar transistors (HBTs) can operate in excess of 100 GHz. They are useful in both low-noise and high RF power applications. The heterostructure concept has recently been applied in Si-based devices using heterostructures using SiGe/Si compounds. These devices show consider promise for high-frequency applications and the transistors have demonstrated RF performance comparable to that obtained from the AlGaAs/GaAs HBTs.

Comparison of Bipolar Transistor and MESFET Noise Figures

In low-noise applications, GaAs MESFETs are generally preferred to Si bipolar transistors. The MESFET demonstrates a lower noise figure than the bipolar transistor throughout the microwave frequency range, and the advantage increases with frequency. This advantage is demonstrated by a comparison of the expressions for the minimum noise figure for the two devices. The bipolar transistor has a minimum noise figure that can be expressed as

$$F_{\min} \cong 1 + bf^2\left[1 + \sqrt{1 + \frac{2}{bf^2}}\right] \tag{39.28}$$

where $F_{\min}$ is the noise figure and

$$b = \frac{40 I_c r_b}{f_T^2} \tag{39.29}$$

where I_c is the collector current and the other terms are as previously defined. The minimum noise figure for the MESFET is

$$F_{\min} \cong 1 + mf \tag{39.30}$$

where

$$m = \frac{2.5}{f_T} \sqrt{g_m (R_g + R_s)} \tag{39.31}$$

where g_m is the MESFET **transconductance**, R_g is the gate resistance, and R_s is the source resistance.

Comparing these expressions shows that the minimum noise figure increases with frequency quadratically for bipolar transistors and linearly for MESFETs. Therefore, as operating frequency increases, the MESFET demonstrates increasingly superior noise figure performance as compared to Si bipolar transistors.

Conclusions

Various active solid-state devices that are useful at microwave and millimeter-wave frequencies have been discussed. Both two-terminal and three-terminal devices were included. The most commonly used two-terminal devices are tunnel diodes, transferred-electron devices, and IMPATT diodes. Three-terminal devices consist of various forms of field-effect transistors and bipolar transistors. Recent advances employ heterostructures using combinations of different semiconductors to produce devices with improved RF performance, especially for high-frequency applications. Both two-terminal and three-terminal devices can provide useful gain at frequencies in excess of 100 GHz. Further improvements are likely as fabrication technology continues to improve.

Defining Terms

Active device: A device that can convert energy from a dc bias source to a signal at an RF frequency. Active devices are required in oscillators and amplifiers.

Charge carriers: Units of electrical charge that when moving produce current flow. In a semiconductor two types of charge carriers exist: electrons and holes. Electrons carry unit negative charge and have an effective mass that is determined by the shape of the conduction band in energy-momentum space. The effective mass of an electron in a semiconductor is generally significantly less than an electron in free space. Holes have unit positive charge. Holes have an effective mass that is determined by the shape of the valence band in energy-momentum space. The effective mass of a hole is generally significantly larger than that for an electron. For this reason electrons generally move much faster than holes when an electric field is applied to the semiconductor.

Gain: A measure of the ability of a network to increase the energy level of a signal. Gain is generally measured in decibels. For voltage or current gain: G (dB) = 20 log($S_{\text{out}}/S_{\text{in}}$), where S is the RF voltage or current out of and into the network. For power gain G (dB) = 10 log($P_{\text{out}}/P_{\text{in}}$). If the network has net loss, the gain will be negative.

Noise figure: A measure of the noise added by a network to an RF signal passing through it. Noise figure can be defined in terms of signal-to-noise ratios at the input and output ports of the network. Noise figure is generally measured in decibels and can be defined as F (dB) = 10 log[$(S/N)_{\text{in}}/(S/N)_{\text{out}}$].

One-port network: An electrical network that has only one RF port. This port must be used as both the input and output to the network. Two-terminal devices result in one-port networks.

Three-terminal device: An electronic device that has three contacts, such as a transistor.

Transconductance: A measure of the gain capability of a transistor. It is defined as the change in output current as a function of a change in input voltage.

Two-port network: An electrical network that has separate RF ports for the input and output. Three-terminal devices can be configured into two-port networks.

Two-terminal device: An electronic device, such as a diode, that has two contacts. The contacts are usually termed the cathode and anode.

40.1 Grounding, Shielding, and Filtering

Leland H. Hemming

Electromagnetic interference (EMI) is defined to exist when undesirable voltages or currents are present to influence adversely the performance of an electronic circuit or system. Interference can be within the system (intrasystem), or it can be between systems (intersystem). The system is the equipment or circuit over which one exercises design or management control.

The cause of an EMI problem is an unplanned coupling between a source and a receptor by means of a transmission path. Transmission paths may be conducted or radiated. Conducted interference occurs by means of metallic paths. Radiated interference occurs by means of near- and far- field coupling. These different paths are illustrated in Fig. 40.1.

The control of EMI is best achieved by applying good interference control principles during the design process. These involve the selection of signal levels, impedance levels, frequencies, and circuit configurations that minimize conducted and radiated interference. In addition, signal levels should be selected to be as low as possible, while being consistent with the required signal-to-noise ratio. Impedance levels should be chosen to minimize undesirable capacitive and inductive coupling.

The frequency spectral content should be designed for the specific needs of the circuit, minimizing interference by constraining signals to desired paths, eliminating undesired paths, and separating signals from interference. Interference control is also achieved by physically separating leads carrying currents from different sources.

For optimum control, the three major methods of EMI suppression—grounding, shielding, and filtering—should be incorporated early in the design process. The control of EMI is first achieved by proper grounding, then by good shielding design, and finally by filtering.

Grounding is the process of electrically establishing a low impedance path between two or more points in a system. An ideal ground plane is a zero potential, zero impedance body that can be used as reference for all signals in the system. Associated with grounding is *bonding*, which is the establishment of a low impedance path between two metal surfaces.

Shielding is the process of confining radiated energy to the bounds of a specific volume or preventing radiated energy from reaching a specific volume. *Filtering* is the process of eliminating conducted interference by controlling the spectral content of the conducted path. Filtering is the last step in the EMI design process.

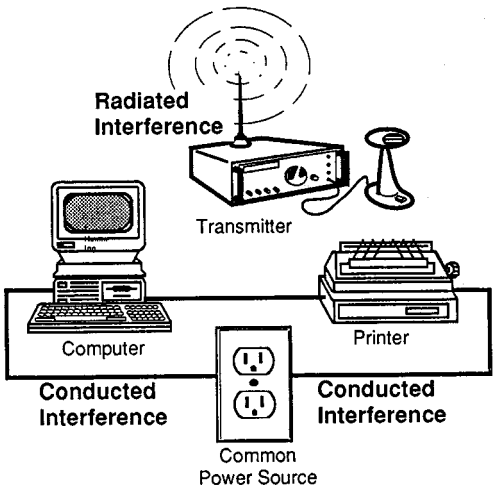

FIGURE 40.1 Electromagnetic interference is caused by uncontrolled conductive paths and radiated near/far fields.

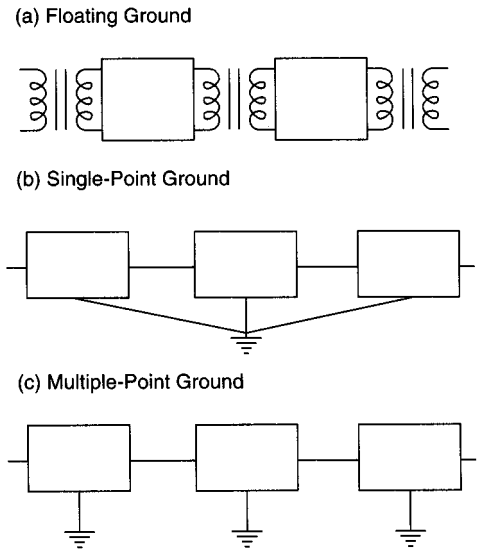

FIGURE 40.2 The type of ground system used must be selected carefully.

Grounding

Grounding Principles

The three fundamental grounding techniques—floating, single-point, and multiple-point—are illustrated in Fig. 40.2.

Floating grounds are used to isolate circuits or equipment from a common ground plane. Static charges are a hazard with this type of ground. Dangerous voltages may develop or a noise-producing discharge might occur. Generally, bleeder resistors are used to control the static problem. Floating grounds are useful only at low frequencies where capacitive coupling paths are negligible.

The single-point ground is a single physical point in a circuit. By connecting all grounds to a common point, no interference will be produced in the equipment because the configuration does not result in potential differences across the equipment. At high frequencies care must be taken to prevent capacitive coupling, which will result in interference.

A multipoint ground system exists when each ground connection is made directly to the ground plane at the closest available point on it, thus minimizing ground lead lengths. A large conductive body is chosen for the ground. Care must be taken to avoid ground loops.

Circuit grounding design is dependent on the function of each type of circuit. In unbalanced systems, care must be taken to reduce the potential of common mode noise. Differential devices are commonly used to suppress this form of noise. The use of high circuit impedances should be minimized. Where it cannot be avoided, all interconnecting leads should be shielded, with the shield well grounded. Power supply grounding must be done properly to minimize load inducted noise on a power supply bus. When electromechanical relays are used in a system, it is best that they be provided with their own power supplies.

Cable shield grounding must be designed based upon the frequency range, impedance levels, (whether balanced or unbalanced) and operating voltage and/or current. Cross talk between cables is a major problem and must be carefully considered during the design process.

Building facility grounds must be provided for electrical faults, signal, and lightning. The fault protection (green wire) subsystem is for the protection of personnel and equipment from the hazards of electrical power faults and static charge buildup. The lightning protection system consists of air terminals (lightning rods), heavy duty down-conductors, and ground rods. The **signal reference subsystem** provides a ground for signal circuits to control static charges and noise and to establish a common reference between signals and loads.

Earth grounds may consist of vertical rods, horizontal grids or radials, plates, or incidental electrodes such as utility pipes or buried tanks. The latter must be constructed and tested to meet the design requirements of the facility.

Grounding Design Guidelines

The following design guidelines represent good practice but should be applied subject to the detailed design objectives of the system.

Fundamental Concepts

- Use single-point grounding for circuit dimensions less than 0.03 λ (wavelength) and multipoint grounding for dimensions greater than 0.15 λ.
- The type of grounding for circuit dimensions between 0.03 and 0.15 λ depends on the physical arrangement of the ground leads as well as the conducted emission and conducted susceptibility limits of the circuits to be grounded. Hybrid grounds may be needed for circuits that must handle a broad portion of the frequency spectrum.
- Apply floating ground isolation techniques (i.e., transformers) if ground loop problems occur.
- Keep all ground leads as short as possible.
- Design ground reference planes so that they have high electrical conductivity and can be maintained easily to retain good conductivity.

Safety Considerations

- Connect test equipment grounds directly to the grounds of the equipment being tested.
- Make certain the ground connections can handle fault currents that might flow unexpectedly.

Circuit Grounding

- Maintain separate circuit ground systems for signal returns, signal shield returns, power system returns, and chassis or case grounds. These returns then can be tied together at a single ground reference point.
- For circuits that produce large, abrupt current variations, provide a separate grounding system, or provide a separate return lead to the ground to reduce transient coupling into other circuits.
- Isolate the grounds of low-level circuits from all other grounds.
- Where signal and power leads must cross, make the crossing so that the wires are perpendicular to each other.
- Use balanced differential circuitry to minimize the effects of ground circuit interference.
- For circuits whose maximum dimension is significantly less than λ/4, use tightly twisted wires (either shielded or unshielded, depending on the application) that are single-point grounded to minimize equipment susceptibility.

Cable Grounding

- Avoid pigtails when terminating cable shields.
- When coaxial cable is needed for signal transmission, use the shield as the signal return and ground at the generator end for low-frequency circuits. Use multipoint grounding of the shield for high-frequency circuits.
- Provide multiple shields for low-level transmission lines. Single-point grounding of each shield is recommended.

Shielding

The control of near- and far-field coupling (radiation) is accomplished using shielding techniques. The first step in the design of a shield is to determine what undesired field level may exist at a point with no shielding and what the tolerable field level is. The difference between the two then is the needed **shielding effectiveness.**

This section discusses the shielding effectiveness of various solid and nonsolid materials and their application to various shielding situations. **Penetrations** and their design are discussed so that the required shielding effectiveness is maintained. Finally, common shielding effectiveness testing methods are reviewed.

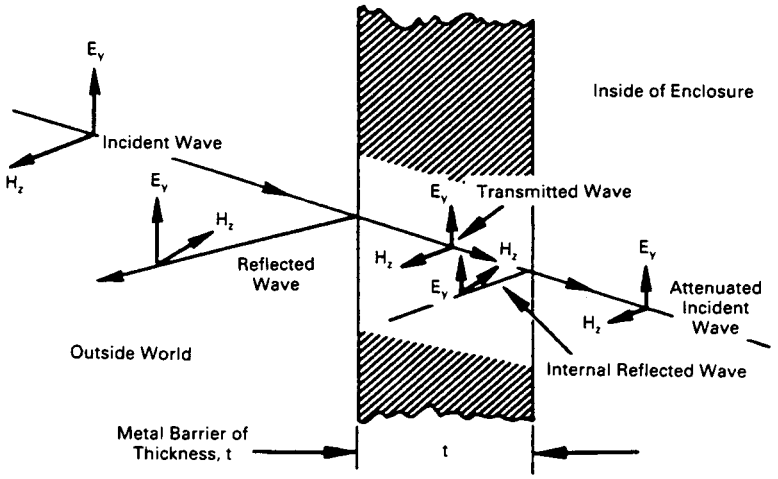

FIGURE 40.3 Shielding effectiveness is the result of three loss mechanisms.

Enclosure Theory

The attenuation provided by a shield results from three loss mechanisms as illustrated in Fig. 40.3.

1. Incident energy is reflected (R) by the surface of the shield because of the impedance discontinuity of the air–metal boundary. This mechanism does not require a particular material thickness but simply an impedance discontinuity.
2. Energy that does cross the boundary (not reflected) is attenuated (A) in passing through the shield.
3. The energy that reaches the opposite face of the shield encounters another air–metal boundary and thus some of it is reflected (B) back into the shield. This term is only significant when $A < 15$ dB and is generally neglected because the barrier thickness is generally great enough to exceed the 15-dB loss rule of thumb.

Thus:

$$S = R + A + B \text{ dB} \tag{40.1}$$

Absorption loss is independent of the type of wave (electric/magnetic) and is given by

$$A = 1.314(f\mu_r\sigma_r)^{1/2}d \text{ dB} \tag{40.2}$$

where d is shield thickness in centimeters, μ_r is relative permeability, f is frequency in Hz, and σ_r is conductivity of metal relative to that of copper. Typical absorption loss is provided in Table 40.1.

Reflection loss is a function of the intrinsic impedance of the metal boundary with respect to the wave impedance, and therefore, three conditions exist: near-field magnetic, near-field electric, and plane wave.

The relationship for low-impedance (magnetic field) source is

$$R = 20 \log_{10}\{[1.173(\mu_r/f\sigma_r)^{1/2}/D] + 0.0535\ D(f\sigma_r/\mu_r)^{1/2} + 0.354 \text{ dB}\} \tag{40.3}$$

where D is distance to source in meters. For a plane wave source the reflection loss is

$$R = 168 - 10 \log_{10}(f\mu_r/\sigma_r) \text{ dB} \tag{40.4}$$

For a high-impedance (electric field) source the reflection loss R is

$$R = 362 - 20 \log_{10}[(\mu_r f^3/\sigma_r)^{1/2} D] \text{ dB} \tag{40.5}$$

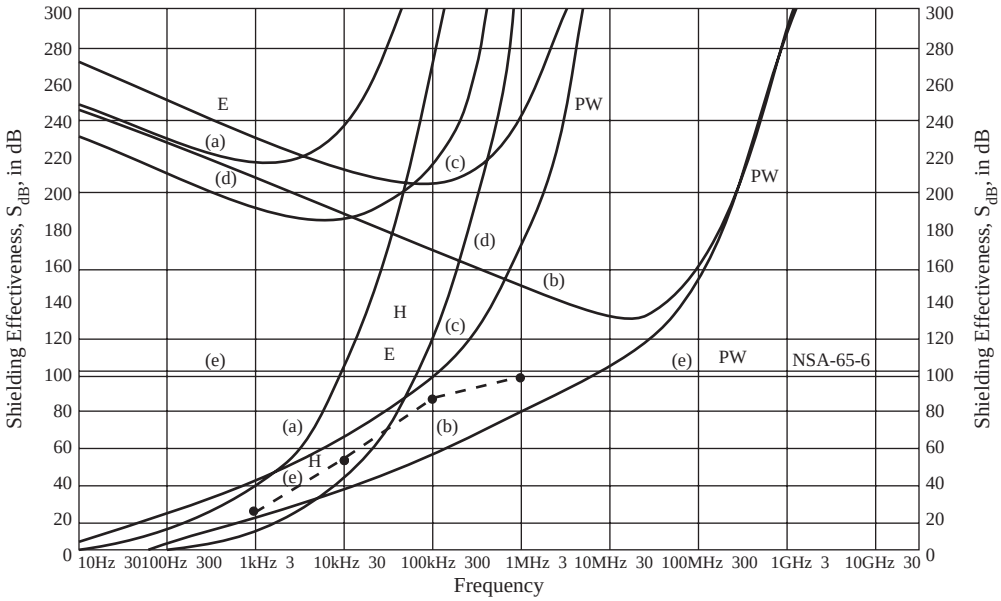

FIGURE 40.4 The shielding effectiveness of common sheet metals, 1 m separation. (a) 26-gage steel; (b) 3-oz. copper foil; (c) 0.030-in. aluminum sheet; (d) 0.003-in. Permalloy; (e) is a common specification for shielded enclosures.

Figure 40.4 illustrates the shielding effectiveness of a variety of common materials versus various thicknesses for a source distance of 1 m. This is the shielding effectiveness of a six-sided enclosure. To be useful, the enclosure must be penetrated for various services or devices. This is illustrated in Fig. 40.5(a) for small enclosures and Fig. 40.5(b) for room-sized enclosures.

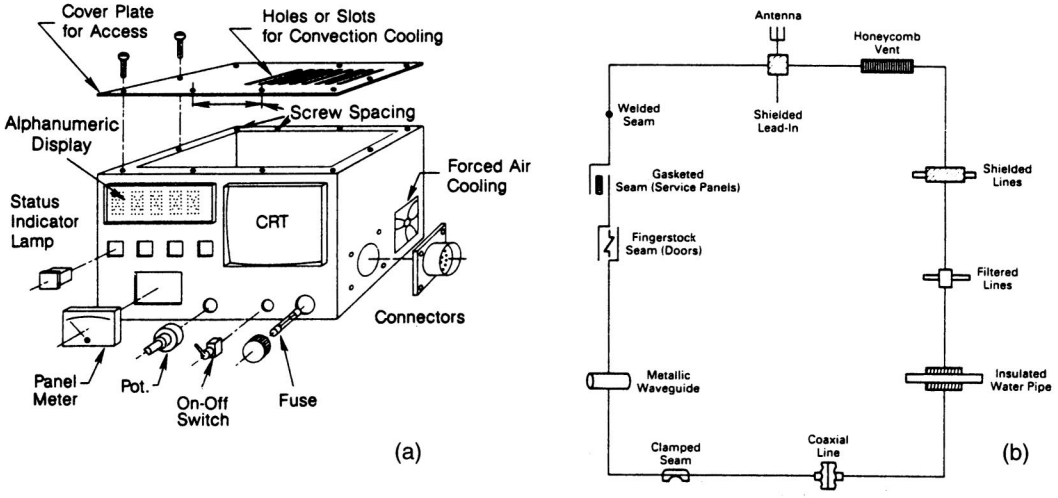

FIGURE 40.5 Penetrations in small (a) and large (b) enclosures.

Shielding Penetrations

Total shielding effectiveness of an enclosure is a function of the basic shield and all of the leakages associated with the penetrations in the enclosure. The latter includes seams, doors, vents, control shafts, piping, filters, windows, screens, and fasteners.

The design of the seams is a function of the type of enclosure and the level and nature of the shielding effectiveness required. For small instruments, computers, and similar equipment, the typical shielding required is on the order of 60 dB for electric and plane wave shielding. EMI gaskets are commonly used to seal the openings in sheet metal construction. In some high-performance applications the shielding is achieved using very tight-fitting machined housings. Examples are IF strips and large dynamic range log amplifier circuits. Various methods of sealing joints are illustrated in Fig. 40.6. EMI gasketing methods are shown in Fig. 40.7. For large room-sized enclosures, the performance requirements typically range from 60 to 120 dB. Conductive EMI shielding tape is used in the 60-dB realm, clamped seams for 80–100 dB, and continuous welded seams for 120-dB performance. These are illustrated in Fig. 40.8.

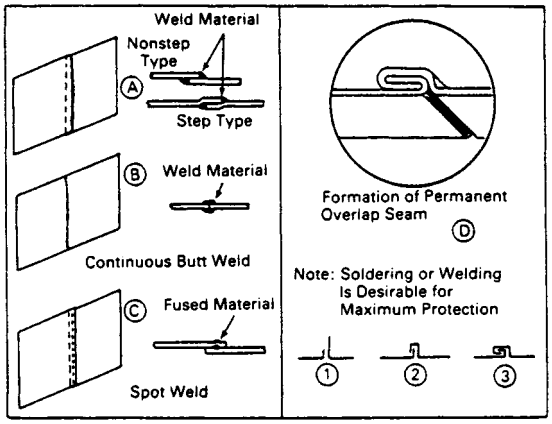

FIGURE 40.6 Methods of sealing enclosure seams.

A good electromagnetic shielded door design must meet a variety of physical and electrical requirements. Figure 40.9 illustrates a number of ways this is accomplished.

For electronic equipment, a variety of penetrations must be made to make the shielded volume functional. These include control shafts, windows, lights, filters, and displays. Careful design is required to maintain the required shielding integrity.

Shield Testing

The most common specification used for shield evaluation is the procedure given in MIL-STD-285. This consists of establishing a reference level without the shield and then enclosing the receiver within the shield and determining the difference. The ratio is the shielding effectiveness. This applies regardless of materials used in the construction of the shield. Care must be taken in evaluating the results since the measured value is a function of a variety of factors, not all of which are definable.

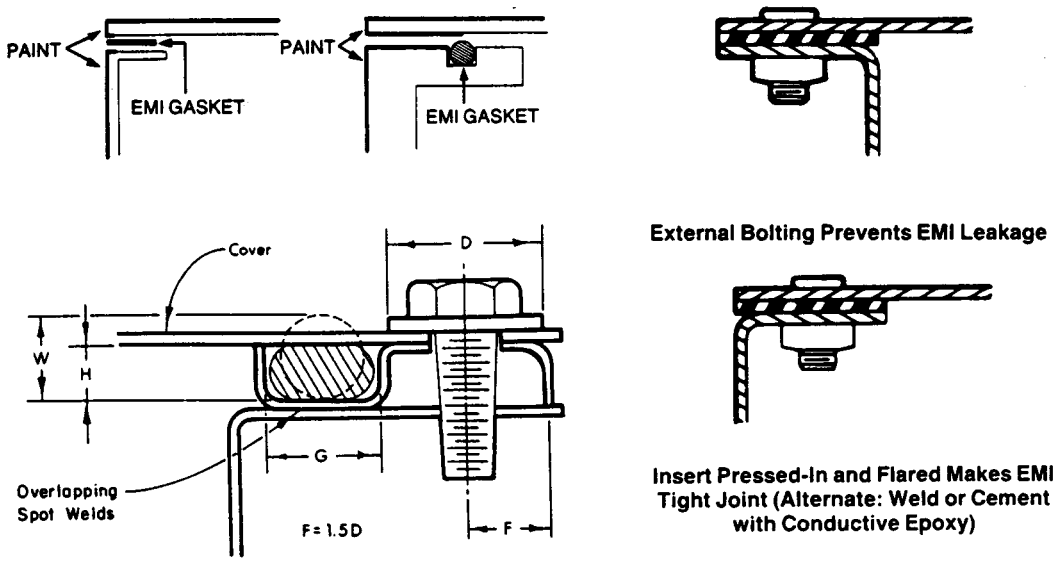

FIGURE 40.7 Methods of constructing gasketed joints.

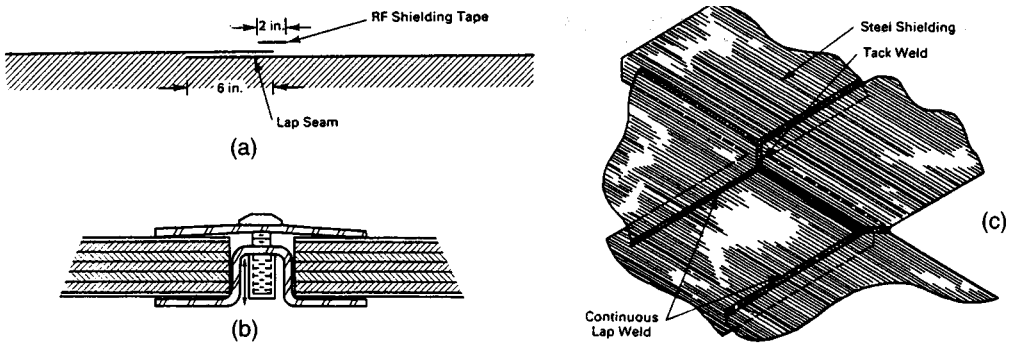

FIGURE 40.8 Most common seams in large enclosures. (a) Foil and shielding tape; (b) clamped; (c) welded.

Summary of Good Shielding Practice

Shielding Effectiveness

- Good conductors, such as copper and aluminum, should be used for electric field shields to obtain high reflection loss. A shielding material thick enough to support itself usually provides good electric shielding at all frequencies.
- Magnetic materials, such as iron and special high-permeability alloys, should be used for magnetic field shields to obtain high absorbtion loss.
- In the plane wave region, the sealing of all apertures is critical to good shielding practice.

Multiple Shields

- Multiple shields are quite useful where high degrees of shielding effectiveness are required.

Shield Seams

- All openings or discontinuities should be addressed in the design process to ensure achievement of the required shielding effectiveness. Shield material should be selected not only from a shielding requirement, but also from electrochemical corrosion and strength considerations.
- Whenever system design permits, use continuously overlapping welded seams. Obtain intimate contact between mating surfaces over as much of the seam as possible.

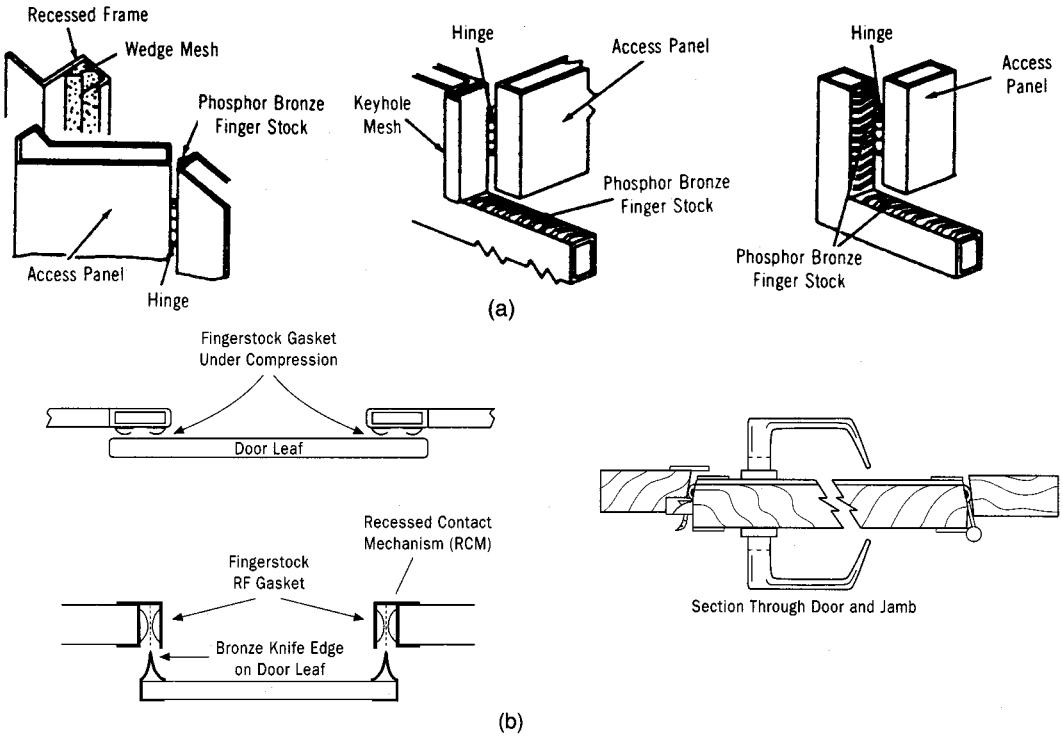

FIGURE 40.9 Methods of sealing seams in RF enclosure small (a) and large (b) doors.

- Surfaces to be mated must be clean and free from nonconducting finishes, unless the bonding process positively and effectively cuts through the finish. When electromagnetic compatibility (**EMC**) and finish specifications conflict, the finishing requirements must be modified.

Case Construction

- Case material should have good shielding properties.
- Seams should be welded or overlapped.
- Panels and cover plates should be attached using conductive gasket material with closely spaced fasteners.
- Mating surfaces should be cleaned just before assembly to ensure good electrical contact and to minimize corrosion.
- A variety of special devices are available for sealing around doors, vents, and windows.
- Internal interference generating circuits must be isolated both electrically and physically. Electrical isolation is achieved by circuit design; physical isolation may be achieved by proper shielding.
- For components external to the case, use EMI boots on toggle switches, EMI rotary shaft seals on rotary shafts, and screening and shielding on meters and other indicator faces.

Cable Shields

- Cabling that penetrates a case should be shielded and the shield should be terminated in a peripheral bond at the point of entry. This peripheral bond should be made to the connector or adaptor shell.

Filtering

An electrical filter is a combination of lumped or distributed circuit elements arranged so that it has a frequency characteristic that passes some frequencies and blocks others.

Filters provide an effective means for the reduction and suppression of electromagnetic interference as they control the spectral content of signal paths. The application of filtering requires careful consideration of an extensive list of factors including insertion loss, impedance, power handling capability, signal distortion, tunability, cost, weight, size, and rejection of undesired signals. Often they are used as stopgap measures, but if suppression techniques are used early in the design process, then the complexity and cost of interference fixes can be minimized. There are many textbooks on filtering, which should be used for specific applications.

The types of filters are classified according to the band of frequencies to be transmitted or attenuated. The basic types illustrated in Fig. 40.10 include low-pass, high-pass, bandpass, and bandstop (reject).

Filters can be composed of lumped, distributed, or dissipative elements; the type used is mainly a function of frequency.

Filtering Guidance

- It is best to filter at the interference source.
- Suppress all spurious signals.
- Design nonsusceptible circuits.
- Ensure that all filter elements interface properly with other EMC elements, i.e., proper mounting of a filter in a shielded enclosure.

Filter Design

Filters using lumped and distributive elements generally are reflective, in that the various component combinations are designed for high series impedance and low shunt impedance in the stopband while providing low series impedance and high shunt impedance in the passband.

The impedance mismatches associated with the use of reflective filters can result in an increase of interference. In such cases, the use of dissipative elements is found to be useful. A broad range of ferrite components are available in the form of beads, tubes, connector shells, and pins. A very effective method of low-pass filtering is to form the ferrite into a coaxial geometry, the properties of which are proportional to the length of the ferrite, as shown in Fig. 40.11.

Application of filtering takes many forms. A common problem is transient suppression as illustrated in Fig. 40.12. All sources of transient interference should be treated at the source.

Power line filtering is recommended to eliminate conducted interference from reaching the powerline and adjacent equipment. Active filtering is very useful in that it can be built in as part of the circuit design and can be effective in passing only the design signals. A variety of noise blankers, cancelers, and limiter circuits are available for active cancellation of interference.

Special Filter Types

A variety of special-purpose filters are used in the design of electronic equipment. Transmitters require a variety of filters to achieve a noise-free output.

Receive preselectors play a useful role in interference rejection. Both distributed (cavity) and lumped element components are used.

IF filters control the selectivity of a receiving system and use a variety of mechanical and electrical filtering components.

Testing

The general requirements for electromagnetic filters are detailed in MIL-F-15733, MIL-F-18327, and MIL-F-25880. Insertion loss is measured in accordance with MIL-STD-220.

Defining Terms

Earth electrode system: A network of electrically interconnected rods, plates, mats, or grids, installed for the purpose of establishing a low-resistance contact with earth. The design objective for resistance to earth of this subsystem should not exceed 10 Ω.

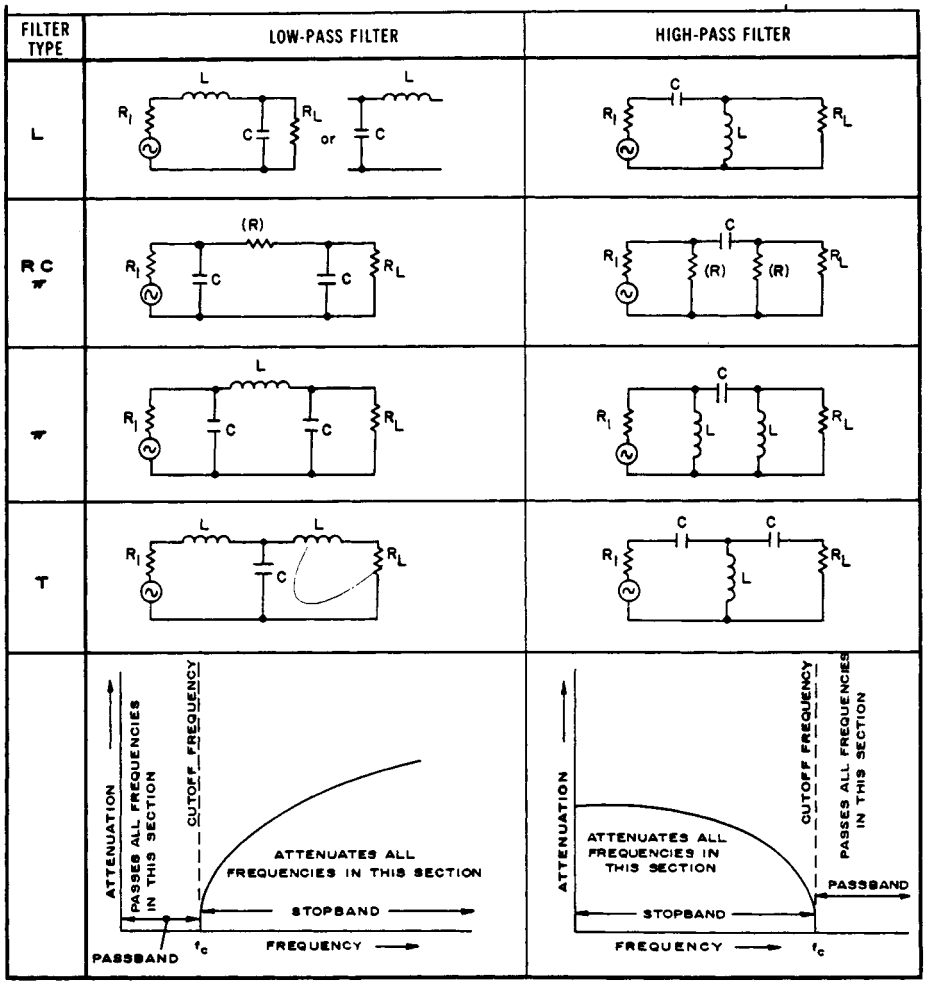

FIGURE 40.10 Filters provide a variety of frequency characteristics.

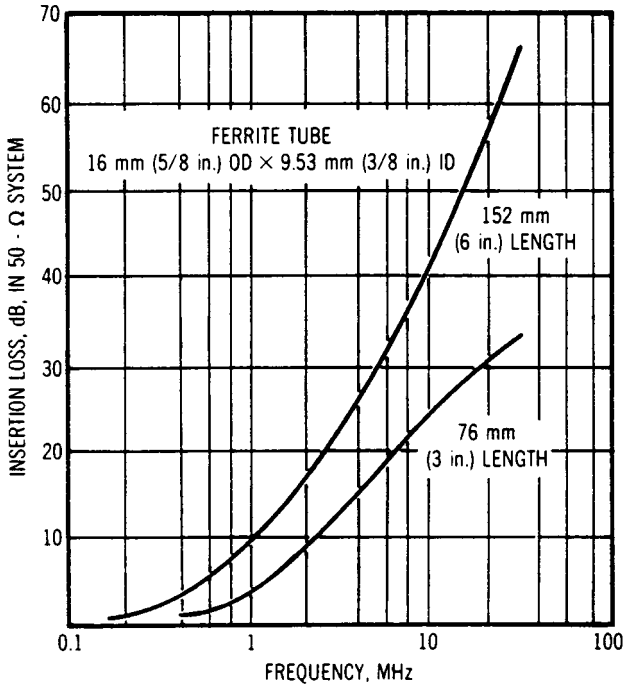

FIGURE 40.11 Ferrite provides a flexible means of achieving a low-pass filter with good high-frequency loss characteristics.

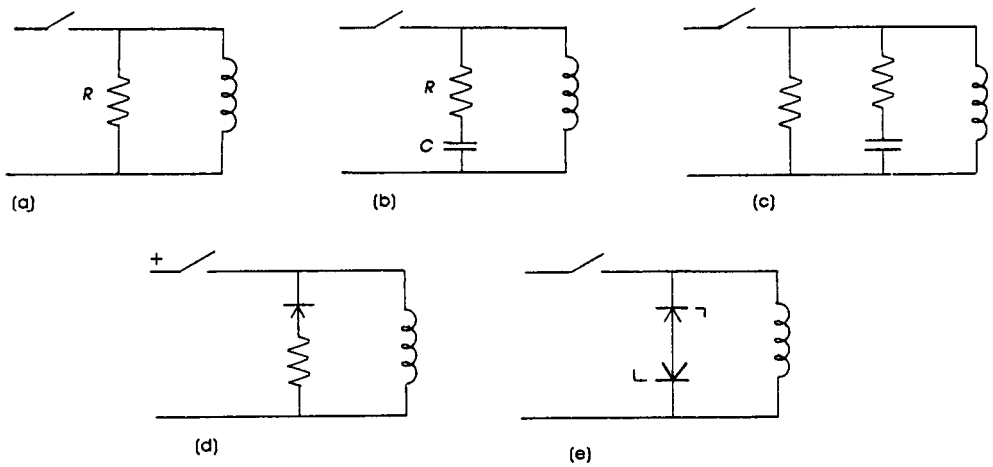

FIGURE 40.12 Transient responses are controlled using simple filters at the source. (a) Resistance damping; (b) capacitance suppression; (c) RC suppression; (d) diode suppression; (e) back-to-back diode suppression.

Electromagnetic compatibility (EMC): The capability of equipment or systems to be operated in their intended operational environment at designed levels of efficiency without causing or receiving degradation owing to unintentional electromagnetic interference. Electromagnetic compatibility is the result of an engineering planning process applied during the life cycle of the equipment. The process involves careful considerations of frequency allocation, design, procurement, production, site selection, installation, operation, and maintenance.

Electromagnetic pulse (EMP): A large impulsive-type electromagnetic wave generated by nuclear or chemical explosions.

Field strength: A general term that means the magnitude of the electric field vector (in volts per meter) or the magnitude of the magnetic field vector (in ampere-turns per meter). As used in the field of EMC/EMI, the term *field strength* shall be applied only to measurements made in the far field and shall be abbreviated as FS. For measurements made in the near field, the term *electric field strength* (EFS) or *magnetic field strength* (MFS) shall be used, according to whether the resultant electric or magnetic field, respectively, is measured.

Penetration: The passage through a partition or wall of an equipment or enclosure by a wire, cable, pipe, or other conductive object.

Radio frequency interference (RFI): Synonymous with *electromagnetic interference.*

Shielding effectiveness: A measure of the reduction or attenuation in the electromagnetic field strength at a point in space caused by the insertion of a shield between the source and that point.

Signal reference subsystem: This subsystem provides the reference points for all signal grounding to control static charges, noise, and interference. It may consist of any one or a combination of the lower frequency network, higher frequency network, or hybrid signal reference network.

TEMPEST: A code word (not an acronym) which encompasses the government/industrial program for controlling the emissions from systems processing classified data. Individual equipment may be *TEMPESTed* or commercial equipment may be placed in shielded enclosures.

Further Information

The annual publication *Interference Technology Engineers' Master (Item),* published by R&B Enterprises, West Conshohocken, Pennsylvania, covers all aspects of EMI including an extensive product directory.

The periodical *IEEE Transactions on Electromagnetic Compatibility,* which is published by The Institute of Electrical and Electronics Engineers, Inc., provides theory and practice in the EMI field.

The periodical *EMC Test & Design,* published by the Cardiff Publishing Company, is a good source for practical EMI design information.

The periodical "emf-emi control" published bimonthly by EEC Press, Gainesville, VA, is an excellent source of practical EMI information.

The periodical *Compliance Engineering*, published quarterly by Compliance Engineering, Inc., is a good source for information on EMC regulations and rules.

40.2 Spectrum, Specifications, and Measurement Techniques

Vichate Ungvichian and John M. Roman

Electromagnetic radiation is a form of energy at a particular frequency that can propagate through a medium. This intentionally or unintentionally generated electromagnetic energy is considered as **electromagnetic interference** (EMI) if it degrades the performance of electronic systems. The purposeful generation of electromagnetic energy for communications can be defined as intentionally generated EMI; unintentionally generated EMI can be created, for example, by the electrical signals in a computer and may be radiated into space by way of the interconnecting cables and/or by openings in the device enclosures.

All electrical devices create some form of electromagnetic energy that may potentially interfere with the operation of other electrical devices outside the system (inter-system) or within the system (intra-system). Due to the increasing man-made EMI generated around the globe, allowable limits as well as measurement techniques on RF noise/interference have been set at national and international levels. The Federal Communications Commission and the Military are the two governing bodies in the United States setting standards on EMI, whereas the International Electrotechnical Commission is the ruling body in Europe. These ruling bodies are concerned with only a fraction of the total electromagnetic spectrum.

Electromagnetic Spectrum

The frequency spectrum of electromagnetic energy can span from dc to gamma ray (10^{21} Hz) and beyond. Figure 40.13 shows the typical frequency spectrum chart over a fraction of hertz to 6×10^{22} Hz.

The spectrum for use in electromagnetic compatibility (EMC) purposes covers only from a few hertz (extreme low frequency, ELF) to 40 GHz (microwave bands). ELF has been in use mostly in the area of biological research and ELF communications. On the other side of the spectrum, the electronic devices must function in a hostile environment, in military applications, over the gigahertz frequency range.

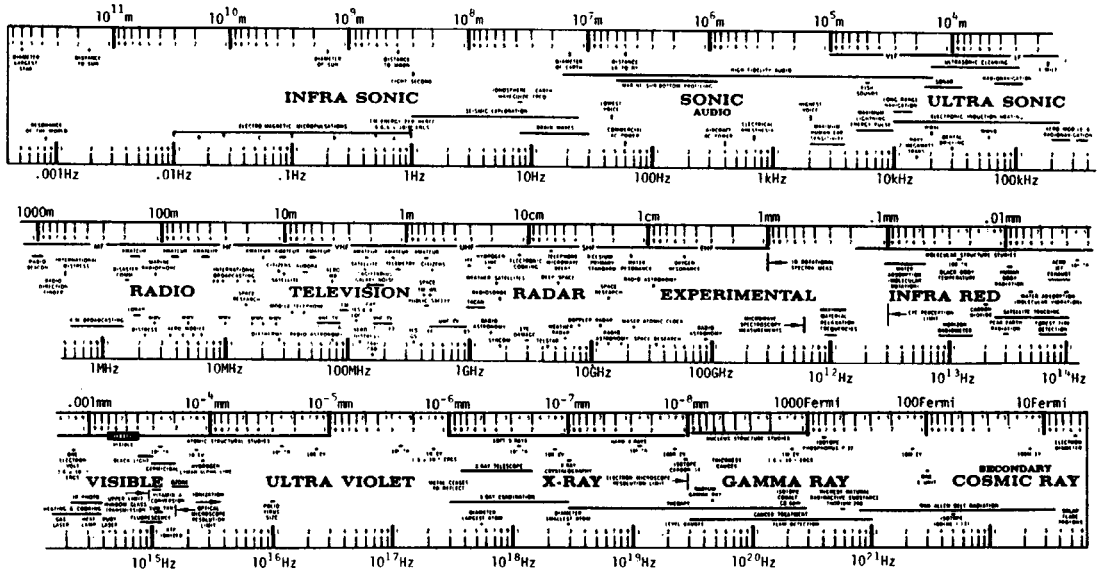

FIGURE 40.13 The frequency spectrum chart. (Contributed by Luther Monell, North America Rockwell Corp.)

Specifications

In the United States, the Federal Communications Commission (FCC) and the military (MIL) are the two regulating bodies governing the EMC standards for commercial and military-based electronic devices and systems. In Europe, each country has its own EMC governing body as well as its own standards. The Verband Deutscher Elektrotechniker (VDE), British Standards Institute (BSI), European Telecommunications Standards Institute (ETSI), and International Special Committee on Radio Interference (CISPR) standards are very few examples of the acceptable standards in European countries such as Germany and Great Britain. Not until January 1, 1996, more than 15 European countries have adopted the IEC 1000 Part 4 Sections 2 to 4 as common EMI/EMC standards with several additional sections being in the final stages of approval.

The United States of America

Federal Communications Commission. The FCC sets limits on the amount of electromagnetic radiation allowed to be emitted from commercial electronic equipment. Any electronic device capable of emitting radio frequency energy by radiation or conduction is defined by the Commission as a radio frequency device and is subject to comply with the standards. The relevant limits and some general measurement techniques, along with equipment authorization procedures, are given in the Code of Federal Regulations (CFR), Title 47 (Telecommunications).

Listed in the CFR, Title 47 are five different types of equipment authorization procedures, namely, type acceptance, type approval, notification, certification, and verification. Restrictions are placed on the marketing and sale of radio frequency devices until the appropriate equipment authorization criteria are met.

Devices and systems that require allocation of the frequency spectrum fall under either type acceptance or type approval equipment authorization procedures. These radio frequency devices usually radiate high powers as in radio or television broadcast transmitters. Radio frequency devices not within the allocated part of the RF spectrum would require either certification or verification equipment authorizations. Some receivers, such as pagers, require notification equipment authorization as well. The requirements for these types of radio frequency devices are listed in Part 15 of the CFR, Title 47.

Part 15 contains three categories of equipment. Incidental radiators (such as dc motors, mechanical light switches, etc.) are not subject to FCC Part 15 emission control requirements. Unintentional radiators are radio frequency devices that intentionally generate radio frequency energy for use within the device, but which are not intended to emit RF energy by radiation or induction. Intentional radiators are radio frequency devices that intentionally radiate radio frequency energy by radiation or by induction.

Unintentional Radiators. There are two different classifications of digital devices listed under unintentional radiators. Class A digital devices are defined as devices that are intended for use in the commercial, industrial, or business environment. Class B digital devices are defined as devices that are intended to be used in a residential

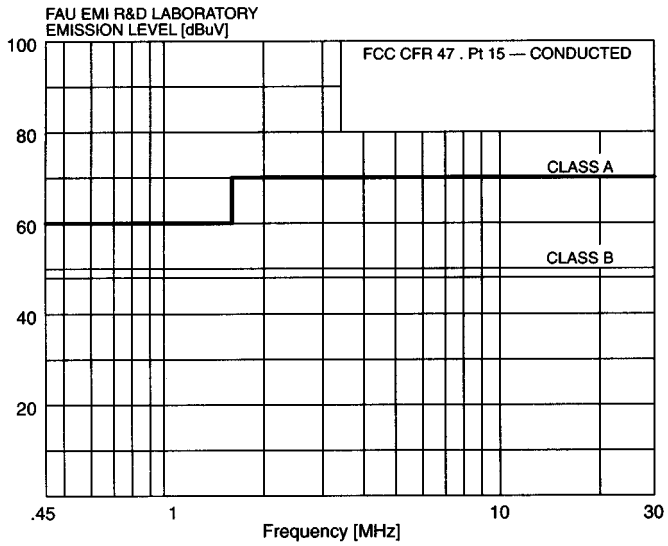

FIGURE 40.14 Class A and Class B conducted emission limits.

environment. Table 40.2 lists the different types of unintentional radiators and their corresponding equipment authorization procedures.

Unintentional Radiator Exempted Devices. There are some unintentional radiators that are listed as exempt devices. These devices are exempted from the technical requirements but are subject to the general requirements of Part 15, Sections 15.5 and 15.29, which state that if the devices cause harmful interference their operation must be ceased until such time that the interference is corrected, and that the device must be made available for inspection upon request by the Commission. It is also recommended (although not required) that these devices meet the technical specifications in Part 15. The exempted devices are as follows:

a. A digital device utilized exclusively in any transportation vehicle, including motor vehicles and aircraft.
b. A digital device used exclusively as an electronic control or power system utilized by a public utility or in an industrial plant. The term public utility includes equipment only to the extent that it is in a dedicated building or in a large room owned or leased by the utility and does not extend to equipment installed in a subscriber facility.
c. A digital device used exclusively as industrial, commercial, or medical test equipment.
d. A digital device utilized exclusively in an appliance, e.g., microwave oven, dishwasher, clothes dryer, air conditioner, etc.
e. Specialized medical digital devices (generally used at the direction of or under the supervision of a licensed health care practitioner) whether used in a patient's home or a health care facility. Nonspecialized medical devices, i.e., devices marketed through retail channels for use by the general public, are not exempted. This exemption also does not apply to digital devices used for recordkeeping or any purpose not directly connected with medical treatment.
f. Digital devices having a power consumption not exceeding 6 nW.
g. Joystick controllers, or similar devices such as a mouse, used with digital devices but which contain only nondigital circuitry or a simple circuit to convert the signal to the format required are viewed as passive add-on devices and are not directly subject to the technical standards or the equipment authorization requirements.
h. Digital devices in which the highest frequency generated and the highest frequency used are less than 1.705 MHz and which do not operate from the ac power lines or contain provisions to operate while connected to the ac power lines.
i. It should be noted that equipment containing more than one device is not exempt from the technical standards in Part 15 unless all of the devices meet the criteria for exemption.

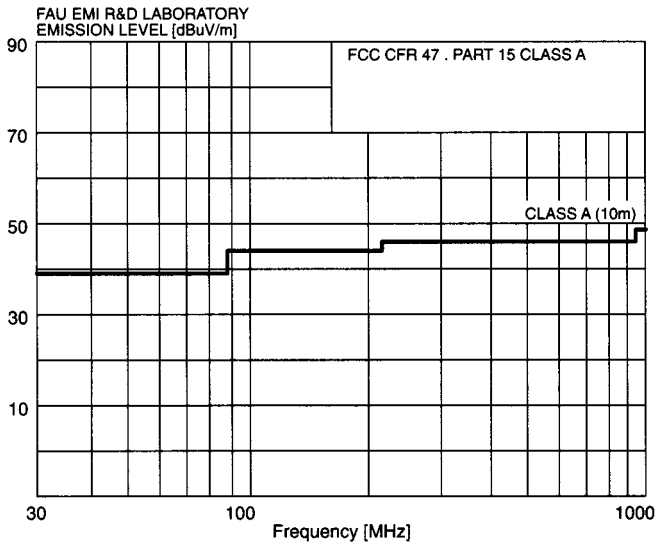

FIGURE 40.15(a) Unintentional (10 m) Class A radiated emission limit.

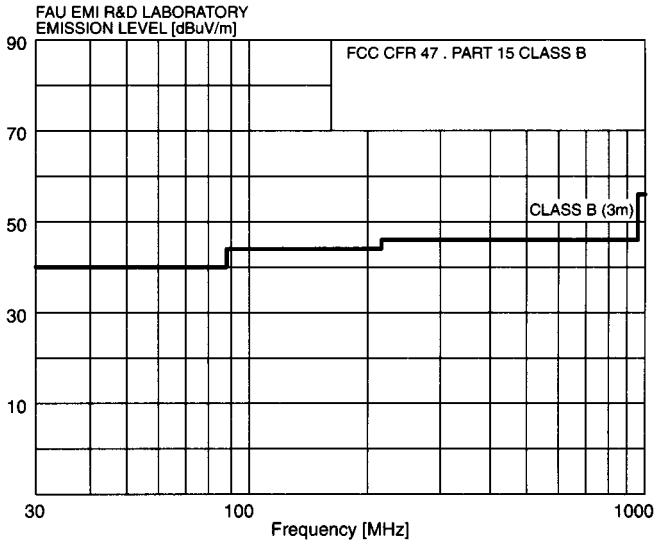

FIGURE 40.15(b) Unintentional (3 m) Class B radiated emission limits.

Unintentional Radiator Conducted Emission Limits. The limits on the interference conducted back into the ac power distribution system are given in Fig. 40.14.

Unintentional Radiator Radiated Emission Limits. Unintentional radiator radiated emission limits for Classes A and B devices are given in Figs. 40.15(a) and (b). It should be noted that a 10-m distance is required for Class A limit whereas 3 m is needed for Class B limit.

Intentional Radiators. There are different limits on devices which intentionally radiate radio frequency energy. The authorization procedure required by the Commission is the same as a certification. In addition to the radiated and conducted emission limits, there are restricted bands of operation in which the devices may not intentionally radiate (spurious emissions are permitted in these bands); these bands are given in Table 40.3.

TABLE 40.3 Restricted Bands of Operation

MHz	MHz	MHz	GHz
0.090–0.110	162.0125–167.17	2310–2390	9.3–9.5
0.49–0.51	167.72–173.2	2483.5–2500	10.6–12.7
2.1735–2.1905	240–285	2655–2900	13.25–13.4
8.362–8.366	322–335.4	3260–3267	14.47–14.5
13.36–13.41	399.9–410	3332–3339	15.35–16.2
25.5–25.67	608–614	3345.8–3358	17.7–21.4
37.5–38.25	960–1240	3600–4400	22.01–23.12
73–75.4	1300–1427	4500–5250	23.6–24.0
108–121.94	1435–1626.5	5350–5460	31.2–31.8
123–138	1660–1710	7250–7750	36.43–36.5
149.9–150.05	1718.8–1722.2	8025–8500	Above 38.6
156.7–156.9	2200–2300	9000–9200	

TABLE 40.4 General Requirement Radiated Emission Limits

Frequency (MHz)	Field Strength (μV/m)	Measurement Distance (m)
0.009–0.490	2400/F (kHz)	300
0.490–1.705	24000/F (kHz)	30
1.705–30.0	30	30
30–88	100*	3
88–216	150*	3
216–960	200*	3
Above 960	500	3

*Except as provided in paragraph (g), fundamental emissions from intentional radiators operating under this Section shall not be located in the frequency bands 54–72 MHz, 76–88 MHz, 174–216 MHz, or 470–806 MHz. However, operation within these frequency bands is permitted under other sections of this part, e.g., §§ 15.231 and 15.241.

Note: All of the limits specified above are measured using a CISPR Quasi-Peak adapter except for the frequency bands 9–90 kHz, 110–490 kHz, and above 1000 MHz; these are specified for an average measurement.

There is also a requirement that the antenna on the device be attached such that it may not be replaced by a different antenna.

Intentional Radiator Conducted Emissions. The conducted emission limits on intentional radiators are the same as for a Class B digital device (see Fig. 40.14).

Intentional Radiator Radiated Emissions. There are general provisions for the amount of radio frequency energy the intentional radiators are allowed to emit. Table 40.4 shows the general requirements for the radiated emission limits.

There are also some additional provisions for operation in specific frequency bands. Listed below are the frequency bands (and their corresponding part in the CFR) that contain additional provisions on the limits of radiated emissions. It is recommended that the CFR, Title 47 be consulted for the limits if the device in question intentionally radiates in the listed bands.

1. Part 15.217: Operation in the band 160–190 kHz.
2. Part 15.219: Operation in the band 510–1705 kHz.
3. Part 15.221: Operation in the band 525–1705 kHz (carrier current systems, am broadcast stations on a college or university).

TABLE 40.5 Appropriated Requirements for Different Platforms and Installations

Requirement	Description
CE101	Conducted emissions, power leads, 30 Hz to 10 kHz
CE102	Conducted emissions, power leads, 10 kHz to 10 MHz
CE106	Conducted emissions, antenna terminal, 10 kHz to 40 GHz
CS101	Conducted susceptibility, power leads, 30 Hz to 50 kHz
CS103	Conducted susceptibility, antenna port, intermodulation, 15 kHz to 10 GHz
CS104	Conducted susceptibility, antenna port, rejection of undesired signals, 30 Hz to 20 GHz
CS105	Conducted susceptibility, antenna port, cross-modulation, 30 Hz to 20 GHz
CS109	Conducted susceptibility, structure current, 60 Hz to 100 kHz
CS114	Conducted susceptibility, bulk cable injection, 10 kHz to 400 MHz
CS115	Conducted susceptibility, bulk cable injection, impulse excitation
CS116	Conducted susceptibility, damped sinusoidal transients, cables and power leads, 10 kHz to 100 MHz
RE101	Radiated emissions, magnetic field, 30 Hz to 100 kHz
RE102	Radiated emissions, electric field, 10 kHz to 18 GHz
RE103	Radiated emissions, antenna spurious and harmonic outputs, 10 kHz to 40 GHz
RS101	Radiated susceptibility, magnetic field, 30 Hz to 100 kHz
RS103	Radiated susceptibility, electric field, 10 kHz to 40 GHz
RS105	Radiated susceptibility, transient electromagnetic field

4. Part 15.223: Operation in the band 1.705–10 MHz.
5. Part 15.225: Operation in the band 13.553–13.567 MHz.
6. Part 15.227: Operation in the band 26.96–27.28 MHz.
7. Part 15.229: Operation in the band 40.66–40.70 MHz.
8. Part 15.231: Periodic operation in the band 40.55–40.70 MHz and above 70 MHz (alarm systems, door openers, remote switches, etc.).
9. Part 15.233: Operations within the bands 43.71–44.49 MHz, 46.60–46.98 MHz, 48.75–49.51 MHz, and 49.66–50.0 MHz (cordless telephones).
10. Part 15.235: Operation within the band 49.82–49.90 MHz.
11. Part 15.237: Operation within the bands 72.0–73.0 MHz, 74.6–74.8 MHz, and 75.2–76.0 MHz.
12. Part 15.239: Operation in the band 88–108 MHz.
13. Part 15.241: Operation in the band 174–216 MHz (biomedical telemetry devices only).
14. Part 15.243: Operation in the band 890–940 MHz (devices that use radio frequency energy to measure the characteristics of materials only).
15. Part 15.245: Operation in the bands 902–928 MHz, 2435–2465 MHz, 5785–5815 MHz, 10500–10550 MHz, and 24075–24175 MHz (field disturbance sensors only, excluding perimeter protection systems).
16. Part 15.247: Operation in the bands 902–928 MHz, 2400–2483.5 MHz, and 5725–5850 MHz (certain frequency hopping and direct sequence spread spectrum intentional radiators).
17. Part 15.249: Operation within the bands 902–928 MHz, 2400–2483.5 MHz, 5725–5875 MHZ, and 24.0–24.25 GHz.
18. Part 15.251: Operation within the bands 2.9–3.26 GHz, 3.267–3.332 GHz, 3.339–3.3458 GHz, and 3.358–3.6 GHz.

Military Standards. The standards and requirements related to the electromagnetic interference and susceptibility for the Military in the United States are described in the MIL-STD-461C document. Electromagnetic interference is defined as the radiated and conducted energy emitted from the device. Electromagnetic susceptibility is defined as the amount of radiated or conducted energy that the device can withstand without degrading its performance.

The standards are broken down into 17 segments defined by the two-letter suffix code and followed by three numbers ranging from 101–999 in the requirement name. The letter codes are conducted emissions (CE), conducted susceptibility (CS), radiated emissions (RE), radiated susceptibility (RS). Table 40.5 is a list and descriptions of the different emission and susceptibility requirements for a particular branch or type of application.

TABLE 40.6 MIL-STD-461D Emission and Susceptibility Requirements

Equipment and Subsystems Installed In, On, or Launched From the Following Platforms or Installations	Requirement Applicability																
	CE101	CE102	CE106	CS101	CS103	CS104	CS105	CS109	CS114	CS115	CS116	RE101	RE102	RE103	RS101	RS103	RS105

TABLE 40.7 RE102 Applicability and Frequency Band of Testing

Applied for:	Frequency Band
Ground	2 MHz to 18 GHz[a]
Ships, surface	10 kHz to 18 GHz[a]
Submarines	10 kHz to 1 GHz
Aircraft (Army)	10 kHz to 18 GHz[a]
Aircraft (Air Force and Navy)	2 MHz to 18 GHz[a]

[a]If the highest clock frequency of the device is less than 1.8 GHz, replace the upper frequency limit to 1 GHz or 10 times the clock frequency, whichever is greater.

There are different equipment and subsystem classes defined for the various environments in which they are to be installed into. Table 40.6 gives the descriptions of the different classes and applicapability in MIL-STD-461D. If the requirement is applicable, three letters (A, L, S) are assigned in the matrix entry. The letter A means the equipment must meet the particular requirement. An L means consulting more detail of the requirement which may have different limits due to type of equipment and installation environment. An S means depending on the procurement requirement. From Table 40.6 RE102, RS103, CE102, CS101, and CS114, segments are required for all types of equipment and platforms. In this Handbook only RE102 and CE102 limits will be described.

The RE102 encompasses electric field limits as shown in Figure 40.16 a, b, and c. The frequency bands of the testing requirements typically cover from 10 kHz to 18 GHz depending on the clock frequency of the device or types of platforms which is described in Table 40.7. Up to 30 MHz, only the vertical polarization of the electric field will be measured and compared with the limits. Above 30 MHz, both horizontal and vertical field components must be measured and again compared with the limits. The device is in conformance with the RE102 if the electric field intensity in the appropriated frequency band is less than the prescribed limit.

The CE102 requirement is applicable to all power cords (either AC or DC source) including returns utilizing five nominal voltage levels. The limit based on a nominal 28 V or less and the limit for 200 V are depicted in Fig. 40.16 d. For the other operating voltage levels (115, 270, and 440 V), the limit is modified by adding a relaxation factor corresponding to the intended line voltage to the 28-V limit. The 220-V limit is 9 dB less stringent than the 28-V limit.

The European Union (EU)

During the early 1980s, a plan to harmonize the electromagnetic compatibility (EMC) requirements for the European Nations into one sovereign community was introduced. This effort, still growing today, attempts to align commercial, judicial, and financial objectives. There are currently more than 15 countries that participate

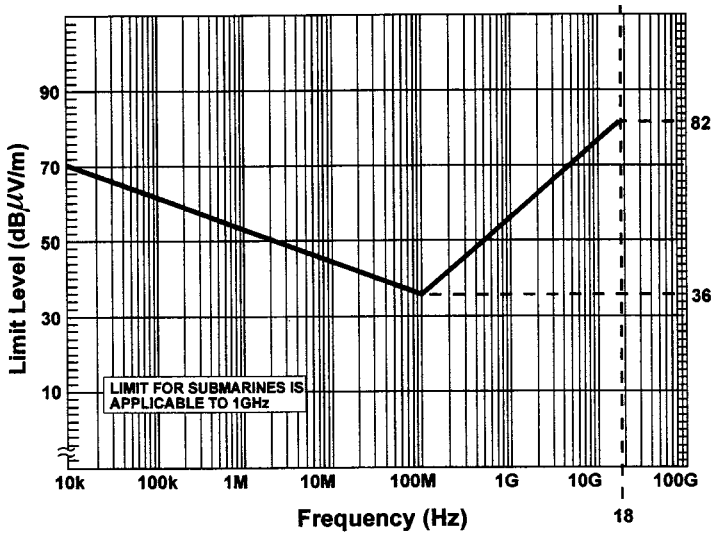

FIGURE 40.16(a) RE102 electric field limit for surface ship and submarine.

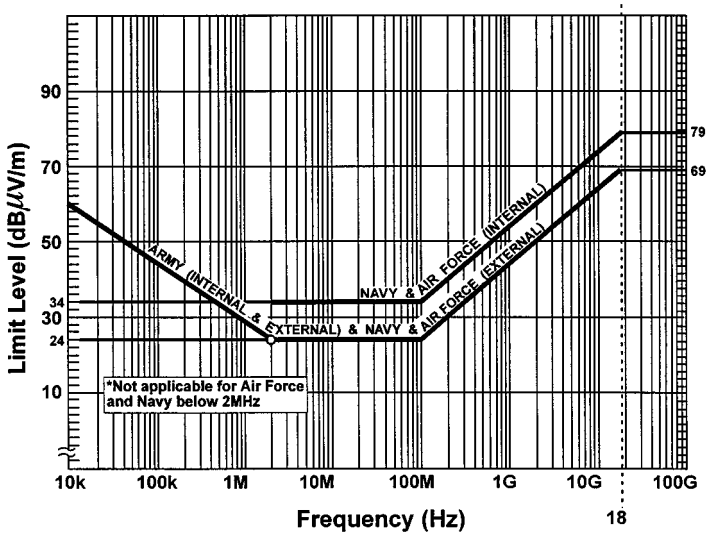

FIGURE 40.16(b) RE102 electric field limit for aircraft and space system.

in the EU requirement for EMI/EMC. Those countries have agreed to the common regulatory requirements placed on commercial products. The agreements, called directives, are listed in the Official Journal of the European Council (OJEC). Different directives for each type of equipment (Telecommunications, Information Technology Equipment [ITE], etc.) spell out the regulatory rules (EMC, Low Voltage, Telecommunications, etc.) required for approval to ship the product into the member countries, which is signified by the application of the conformity mark (CE).

The EU has approved a set of standards called the European Norms (EN). One of the EMC directives contains the International Electrotechnical Commission (IEC) test requirements for individual equipment approval. The IEC series of standards currently called upon by the EMC directive for generic equipment are EN 50081-1 (Generic Emission Standard; Part 1, residential, commercial and light industry) and EN 50082-1 (Generic Immunity Standard; Part 1, residential, commercial, and light industry equipment). These standards reference the IEC documents which list the requirements for measurement of emission and immunity characteristics.

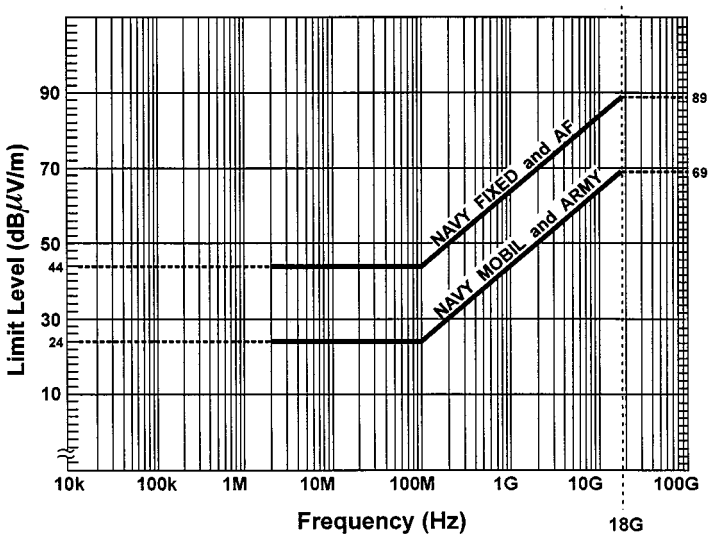

FIGURE 40.16(c) RE102 electric field limit for ground application.

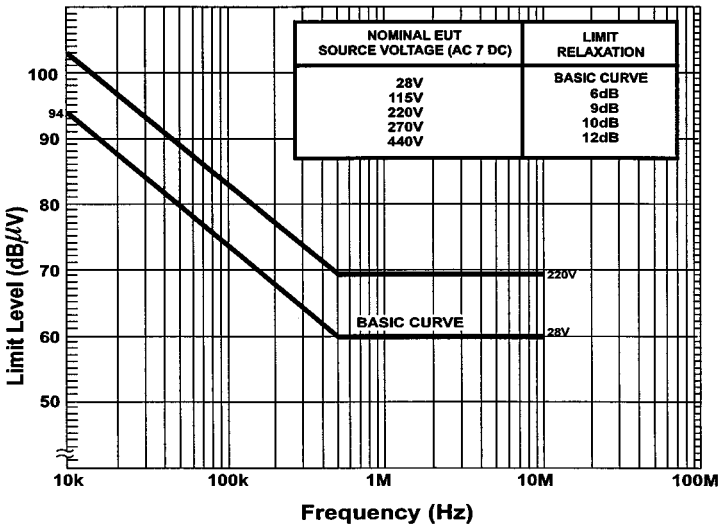

FIGURE 40.16(d) The CE102 limits for 28 V and 220 V nominal operating voltages.

The 1000-4-2 is the Electrostatic Discharge (ESD) test standard; 100-4-3 is the immunity standard; and 100-4-4 is the Electric Fast Transient (EFT) standard. The EN 55022 document contains the limits and test methods for both radiated and conducted emissions of ITE.

EN 55022 and IEC 1000 Series (Part 4)

EN 55022, also known as CISPR Publication 22, involves the limits and methods of measurement of radio interference characteristics of ITE. Currently, the ITE must meet three Parts (standards) of the IEC 1000-4 series. However, the future revision of the IEC 1000-4 series may mandate an additional eight requirements (presently int he process of review). Consult the latest versions of the applicable generic standard for the current requirements.

EN 55022 Document. The EN 55022 procedure describes for measurement of spurious signal strength, in the frequency range 0.15 MHz to 1 GHz, generated by pulsed electrical waveforms either through the power

TABLE 40.8 Limits of Mains Terminal Interference Voltage in the Frequency Range 0.15 to 30 MHz for Class A Equipment

Frequency Range (MHz)	Limits [dB (μV)]	
	Quasi-peak	Average
0.15 to 0.50	79	66
0.50 to 30	73	60

TABLE 40.9 Limits of Mains Terminal Interference Voltage in the Frequency Range 0.15 to 30 MHz for Class B Equipment

Frequency Range (MHz)	Limits [dB (μV)]	
	Quasi-peak	Average
0.15 to 0.50	66 to 56	56 to 46
0.50 to 5	56	46
5 to 30	60	50

The lower limit shall apply at the transition frequencies.
Note: In Table 40.9 the limit decreases linearly with the logarithm of the frequency in the range 0.15 to 0.50 MHz.

TABLE 40.10 Limits of Radiated Interference Field Strength in the Frequency Range 30 MHz to 1 GHz at a Test Distance of 30 m for Class A Equipment

Frequency Range (MHz)	Quasi-peak Limits [dB (μV/m)]
30 to 230	30
230 to 1000	37

[1] *x* is an open level. The level is subject to negotiations and has to be specified in the dedicated equipment specification. If higher voltages than those shown are specified, special test equipment may be needed.

main cable or through direct radiation. There are two classes of ITE: Class A and Class B. Class A equipment is usually intended for use in commercial establishments whereas Class B equipment is for domestic use. In order to conform with EN 55022, the measured voltages or field strengths shall meet the following limits.

Tables 40.8 and 40.9 are the limits of mains terminal interference voltage in the frequency range 0.15 to 30 MHz for Class A and Class B, respectively.

Tables 40.10 and 40.11 are the limits of radiated interference field strength in the frequency range 30 MHz to 1 GHz for Class A and Class B equipment.

IEC 1000-4 Section 2. The IEC 1000-4-2 document describes the static electricity discharge (ESD) requirements. At the time of publication, the current limits tabulated herein are utilized; however, the limits are subject for a revision.

Since contact discharge method and air discharge method are acceptable for ESD tests, two limits have been specified and tabulated in Table 40.12(a) and (b).

IEC 1000-4 Section 3. The IEC 1000-4-3 document involves the susceptibility requirements for equipment under test (EUT). The primary concern is the degradation of EUT under the influence of the hand-held transceiver or other sources of radiation in the frequency range 80 to 1000 MHz. Table 40.13 gives the tabulated limits of the susceptibility requirements.

TABLE 40.13 Severity Levels for Susceptibility Requirements

Level	Test Field Strength, (V/m)

1	0.5	0.25
2	1	0.5
3	2	1
4	4	2
x[1]	Special	Special

[1] *x* is an open level. The level is subject to negotiation between the user and the manufacturer or is specified by the manufacturer.

There are four classes of severity levels. Class 1 is for low-level electromagnetic radiation environments, such as those typical of local radio/television stations located more than 1 km away and levels typical of low-power transceivers. Class 2 is for moderate electromagnetic radiation environments, such as portable transceivers that are close to the EUT but not closer than 1 m. Class 3 is for severe electromagnetic radiation environments, such as levels typical of high-power transceivers in close proximity to the EUT. Class 4 is an open class for situations involving very severe electromagnetic radiation environments. The manufacturer sets the level relative to the environmental conditions into which the EUT would be installed.

IEC 1000-4 Section 4. The IEC 1000-4-4 document involves electrical fast transient/burst requirements. The purpose of this requirement is to evaluate the performance of the EUT when exposed to switching transients with high repetition frequency which may couple into the power main supply and external communication lines. Table 40.14 gives the test severity levels recommended at the time of publication. The repetition rate of the impulses is 5 kHz with a tolerance of ±20% for Levels 1 through 4, with an exception of 2.5 kHz for Level-4 power supply port.

Measurement Procedures

To determine the emission or susceptibility levels, measurement procedures were established. There are many protocols existing around the world. Each country may adopt its own measurement guidelines. In this section, only the FCC procedure will be described in detail. A list of some other procedures is given below.

FCC

The procedures used by the Commission to determine compliance are as follows:

1. FCC/OET MP-l: FCC Measurements for Determining Compliance of Radio Control and Security Alarm Devices and Associated Receivers.
2. FCC/OET MP-2: Measurement of UHF Noise Figures of TV Receivers.
3. FCC/OET MP-3: FCC Methods of Measurement of Output Signal Level, Output Terminal Conducted Spurious Emissions, Transfer Switch Characteristics, and Radio Noise Emissions from TV Interface Devices.
4. ANSI C63.4, 1992: FCC Procedure for Measuring RF Emissions from Computing Devices.
5. FCC/OET MP-9: FCC Procedure for Measuring Cable Television Switch Isolation.

In addition to the documents listed above, the FCC has outlined some generic measurement characteristics in the CFR, Title 47, Part 15, Sections 15.31 through 15.35.

Listed in the American National Standards Institute (ANSI) Specification C63.4-1992 measurement procedure document are the configuration setups for Class A and B computing devices and peripheral equipment. Some of the pertinent highlights for Class B computing devices are as follows:

- The equipment must be set up in a system configuration which includes the computer controller, a monitor, keyboard, serial device, parallel device, and any other device which may typically be connected to the system.

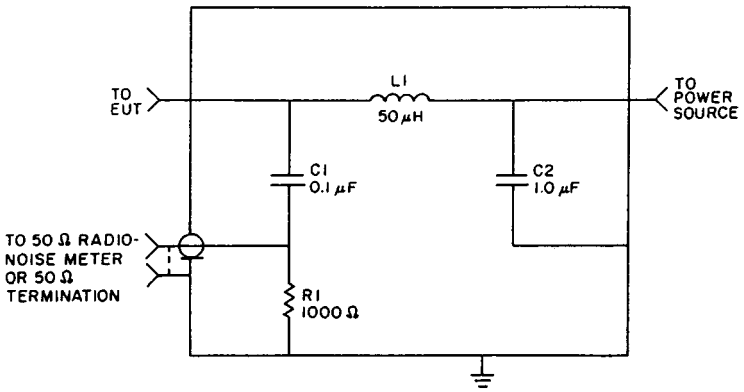

FIGURE 40.17 LISN circuit diagram.

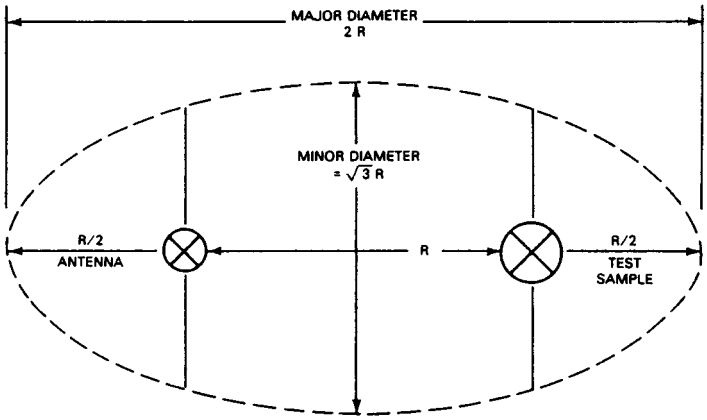

FIGURE 40.18 Minimum obstruction-free area for open field test site.

- The computer controller must be configured with the peripheral cards needed for typical operation (serial card, parallel card, video card, disk controller, memory), along with any other specialized cards defined in the typical setup to be marketed.
- A program to display, print, store, and/or send capital H characters to all of the pertinent devices (inclusive of the drives, CRT, printer, and any other data receiving devices) must be run for the duration of the evaluation.
- Typical cables and power cords are required for the test; the cables are bundled serpentine fashion at the center of the cable in 30- to 40-cm bundle lengths, to an overall length of 1 meter.

Conducted Emission Testing. Measurements are recommended to be performed inside of an RF shielded room in order to eliminate interference from ambient electromagnetic fields. The system units are placed on a nonconducting table 0.8 m high and 10 cm from the rear wall of the RF shielded enclosure. The measurements are performed with a line impedance stabilization network (LISN). This type of network is specifically designed to present a known impedance to the device under test, filter the noise present on the power line, and to match impedances with the measurement receiver. Figure 40.17 shows the typical FCC LISN circuit, applicable for monitoring the conducted noise present on either the phase or neutral line. Data is collected across phase and neutral to ground over the 450-kHz to 30-MHz frequency range and is compared with the aforementioned limits.

Radiated Emission Testing. The radiated emissions are measured at an FCC listed site (either semi-anechoic or open field), which requires a metal ground plane over the floor (typically hardware cloth). The site must satisfy a certain minimum size criteria, depending on the prescribed measurement distance. The accepted criteria is based on the Fresnel ellipse, which is presented in Fig. 40.18. The procedure for listing a site with the FCC includes the submittal of the site attenuation measurements, the site description, and a list of measurement equipment. The qualified site should meet the ±4-dB variation from theoretical values.

The EUT is placed on a nonconducting table 0.8 m above the ground plane floor. The receiving antenna is placed at the prescribed measurement distance (R) from the system (3 m for Class B and 10 m for Class A) and is scanned from 1 to 4 m in height while the EUT is rotated 360 degrees. The maximum emission data (per azimuth, elevation, and antenna orientation) is collected over the appropriate frequency range.

Defining Terms

Conducted emission: An RF current propagated through an electrical conductor.
Electromagnetic interference: An unwanted electromagnetic signal which may degrade the performance of an electronic device.
Far field: The region where the ratio of the electric to magnetic field is approximately equal to 377 Ω.
Field strength: An amount of electric or magnetic field measured in far-field region and expressed in volts/meter or amps/meter.
Line impedance stabilization network (LISN): A network designed to present a defined impedance at high frequency to a device under test, to filter any existing noise on the power mains, and to provide a 50-Ω impedance to the noise receiver.
Radiated emission: An electromagnetic field propagated through space.

40.3 Lightning

Martin A. Uman and Marcos Rubinstein

An understanding of lightning and of the electric and magnetic fields produced by lightning is critical to an understanding of lightning-induced effects on electronic and electric power systems. This section begins with an overview of the terminology and physics of lightning. Then, statistics on lightning occurrence are given. Next the characteristics of the electric and the magnetic fields resulting from lightning charges and currents are examined, and the models used to describe that relationship are discussed. The section ends with a discussion of the coupling of the electric and magnetic fields from lightning to overhead wires.

Terminology and Physics

Lightning is a transient, high-current electric spark whose length is measured in kilometers. Lightning discharges can occur within a cloud, between clouds, from cloud to air, and from cloud to ground. All discharges except the latter are known as cloud discharges. The usual cloud-to-ground lightning is initiated in the cloud, lasts about half a second, and lowers to ground some 20 to 30 Coulombs of negative cloud charge. A less frequent type of cloud-to-ground discharge, accounting for less than 10% of all cloud-to-ground lightning, also begins

in the cloud but lowers positive cloud charge. An even less frequent type of cloud-to-ground lightning is initiated in an upward direction from tall man-made structures such as TV towers or tall geographical features such as mountaintops. A complete lightning discharge of any type is called a **flash**. The usual negative cloud-to-ground lightning flash starts in the cloud when a so-called **preliminary breakdown**, a particular type of electric discharge in the cloud, occurs. This process is followed by a discharge, termed the **stepped leader**, that propagates towards the ground in a series of luminous steps tens of meters in length. In progressing toward the ground, the negatively charged stepped leader branches in a downward direction. When one or more leader branches approach within a hundred meters or so of the ground, after 10 to 20 ms of stepped leader travel at an average speed of 10^5 to 10^6 m/s, the electric field at the ground (or at objects on the ground) increases above the critical breakdown field of the surrounding air and one or more upward-going discharges is initiated, starting the **attachment process.** After traveling a few tens of meters, one of the upward-going discharges, which is essentially at ground potential, contacts the tip of one branch of the stepped leader, which is at a high negative potential, probably some tens of megavolts. From that point, ground potential propagates upward, discharging to ground some or all of the negative charge previously deposited along the channel by the stepped leader. This upward propagating potential discontinuity is called the **return stroke**. Its front is a region of high electric field that causes increased ionization, current, temperature, and pressure as it travels the 5-km or more length of the leader channel. That trip is made in about 100 μs at an initial speed of the order of one third to one half the speed of light, the speed decreasing with height. The current at ground associated with the negative first return stroke has a peak of typically 35 kA achieved in a few microseconds, has a maximum current derivative of about 10^{11} A/s and falls to half of peak value in some tens of microseconds. The cessation of the first return stroke current may or may not end the flash. If more cloud charge is made available to the first stroke channel by in-cloud discharges, another leader-return stroke sequence may ensue, typically after tens of milliseconds. Preceding and initiating a subsequent return stroke is a continuous leader lowering negative charge, called a **dart leader**. The dart leader typically propagates down the residual channel of the previous stroke, generally ignoring the first stroke branches, although in about 50% of cloud-to-ground flashes there is at least one dart leader which transforms to a stepped leader on the downward trip, creating a new path to ground. There are typically three or four leader-return stroke sequences per negative cloud-to-ground flash, but ten or more is not uncommon.

Of the many different processes that occur during the various phases of a negative cloud-to-ground lightning (e.g., the in-cloud K processes, in-cloud J processes, and cloud to ground M components that occur between strokes and after the final stroke and are not discussed here), the electric and magnetic fields associated with the return stroke described above generally are the largest and hence the most significant in inducing unwanted voltages in electronic and electric power systems. This is the case because the currents in all other lightning processes are generally smaller than return stroke currents and the ground strike point of the return stroke can be much closer to objects on the ground than are in-cloud discharges. Cloud discharges exhibit currents similar to those of the in-cloud processes occurring in ground discharges and hence produce similar relatively small fields at or near ground level.

Positive flashes to ground, those initiated in the cloud and lowering positive charge to earth, generally contain only one return stroke, which is preceded by a "pulsating" leader rather than the stepped leader characteristically preceding negative first strokes and is generally followed by a period of continuous current flow. Positive flashes contain a greater percentage of very large return stroke currents, in the 100- to 300-kA range, than do negative flashes. Positive flashes may represent half of all flashes to ground in winter storms, which produce few total flashes, and typically represent 1 to 20% of the overall flashes in summer storms, that percentage increasing with increasing latitude.

Lightning Occurrence Statistics

Lightning flash density is defined as the number of lightning flashes per unit time per unit area and is usually measured in units of lightning flashes, either cloud or cloud-to-ground or both, per square kilometer per year. The two most common techniques for directly measuring flash density are (1) the use of so-called flash counters, relatively crude devices which trigger on electric fields above a value of the order of 1 kV/m in a frequency band centered in the hundreds of hertz to kilohertz range, of which two models are extensively used, the CIGRE

10-kHz and the CIGRE 500-Hz and (2) the use of networks of wideband magnetic direction finders, networks of wideband time-of-arrival detectors, and networks combining the two technologies, such networks now covering the U.S., Canada, Japan, Korea, Taiwan, most of Europe, and parts of many other countries. The average flash density varies considerably with geographical location, generally increasing with decreasing latitude. Typical ground flash densities are 1 to 5 $km^{-2}\ yr^{-1}$, with the world's highest being 30 to 50 $km^{-2}\ yr^{-1}$. Significant variations in flash density are observed with changes in local meteorological conditions within distances of the order of 10 km, for example, perpendicular to and inland from the Florida coastline. A ground flash density map of the U.S. for 1989, obtained from the U.S. National Lightning Detection Network of 114 wideband magnetic direction finders, is given by Orville [1991]. Flash densities in the U.S. are maximum in Florida with 10 to 15 $km^{-2}\ yr^{-1}$ and minimum along portions of the Pacific coast which has essentially no lightning.

An extensively measured parameter used to describe lightning activity worldwide is the thunderday or isokeraunic level, $T_{D,}$ the number of days per year that thunder is heard at a given location. This parameter has been recorded by weather station observers worldwide for many decades, whereas the accurate direct measurement of flash density has been possible only recently. Commonly used relations to convert thunderday level to ground flash density N_g are of the form

$$N_g = aT_D^b \quad \text{km}^{-2}\ \text{yr}^{-1} \tag{40.6}$$

where the value of a is near, and usually less than, 0.1 and the value of b is near, and usually greater than, 1. It should be noted that Eq. (40.6) is relatively inaccurate in that the data to which it is a fit is highly variable. The literature contains more than ten different values of a and b determined by different investigators.

Finally, from both worldwide thunderday and earth-orbiting satellite measurements, it has been estimated that there are about 100 total flashes, cloud and cloud-to-ground, per second over the whole earth. This number corresponds to an average global total flash density of 6 $km^{-2}\ yr^{-1}$.

Electric and Magnetic Fields

For the usual negative return stroke, measurements of the vertical component of the electric field and the two horizontal components of the magnetic field at ground level using wideband systems with upper frequency 3-dB points in the 1- to 20-MHz range are well documented in the literature. Measured vertical electric field and horizontal magnetic field waveshapes are shown in Fig. 40.19. Sketches of typical electric and magnetic fields are given in Fig. 40.20 for lightning in the 1- to 5-km range and in Fig. 40.21 for lightning at 10, 15, 50, and 200 km. Measured vertical and measured horizontal electric fields near ground are shown in Fig. 40.22. The mean value of the initial peak vertical electric field, normalized to 100 km by assuming an inverse distance dependence, is about 7 V/m for negative first strokes and about 4 V/m for negative subsequent strokes.

The return stroke vertical electric field rise to peak is comprised of two distinguishable parts, evident in Fig. 40.19: a slow front immediately followed by a fast transition to peak. For first strokes the slow front has a duration of a few microseconds and rises to typically half the peak amplitude, while for subsequent strokes the same slow front lasts less than 1 μs and rises only to typically 20% of the peak. The mean 10–90% fast transition time is about 200 ns regardless of

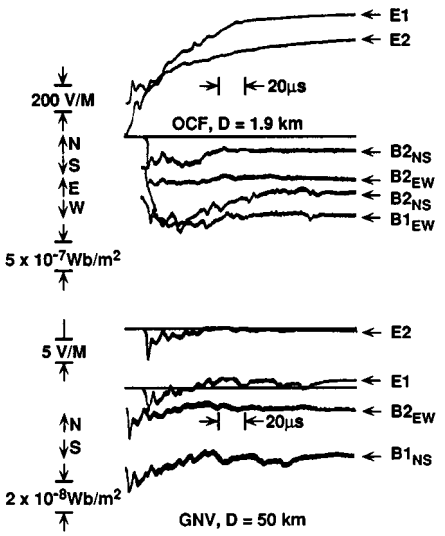

FIGURE 40.19 Simultaneously measured return stroke vertical electric field (E) and two horizontal magnetic flux densities (B_{EW} and B_{NS}) as observed about 2 and 50 km from a two-stroke flash, the first stroke being designated "1", the second "2". stroke order for strokes observed over saltwater where there is minimal distortion of the waveform due to propagation. The waveforms in Fig. 40.19 have suffered distortion in propagating over land.

After the initial field peak, the waveshapes of the vertical electric field and the horizontal magnetic field for close lightning exhibit a valley followed by a hump in the case of the magnetic field and by a ramp in the case of the electric field, as is evident from Figs. 40.19 through 40.22. Relative to the amplitude of the initial peak, the hump and the ramp decrease with increasing distance of the return stroke. For distances of 25 km or greater, the ramp in the electric field is no longer significant, and for distances of 50 km or more and for times of the

order of 100 μs, the waveshapes of the electric and magnetic fields are nearly identical, exhibiting a zero crossing and polarity reversal at some tens of microseconds.

For positive return strokes, there are more very large peak currents at the channel base, in the 100-kA range, than for return strokes lowering negative charge to ground, although the median value for both positives and negatives is not much different [Berger et al., 1975]. This observation is supported by measurements of the initial peak magnetic field from positive and negative return strokes made with magnetic direction-finding networks worldwide, where various investigations have found the mean peak positive field to be about twice the mean peak negative.

The horizontal component of the electric field has not been as well studied or characterized as the vertical. For the case of a finite-conducting earth and lightning beyond a few kilometers, Thomson et al. [1988] give wideband measurements of the three perpendicular components of the electric field about 1 m above ground level. An example is shown in Fig. 40.22. The horizontal field waveshapes are more impulsive and vary on a faster time scale than their associated vertical electric field waveshapes. In fact, the horizontal field appears to be a crude derivative of the vertical. The peak amplitudes of the horizontal electric fields are on the order of 30 times smaller than those of the vertical fields for ground conductivities of the order of 10^{-2} mho/m, this ratio being roughly proportional to the square root of the ground conductivity. The horizontal field, although considerably smaller for distant lightning, can be as important as the vertical electric field in inducing voltages on an overhead horizontal wire because of the greater horizontal extent of the wire relative to its height above ground, a fact well established by recent research, whereas in the earlier literature on power line coupling, for example, only the vertical field was considered to be important.

The so-called wavetilt formula, given in Eq. (40.7), models the ratio, in the frequency domain, of the horizontal to vertical electric field of a plane wave at the surface of an earth of conductivity σ and permittivity $\epsilon_r\epsilon_0$ for the case of grazing incidence and is certainly applicable to lightning return strokes occurring beyond a few kilometers, probably beyond a few hundred meters.

$$\frac{E_H(\omega)}{E_V(\omega)} = \frac{1}{\sqrt{\epsilon_r + \left(\dfrac{\sigma}{j\omega\epsilon_0}\right)}} \tag{40.7}$$

To the best of our knowledge, no horizontal or vertical electric fields very close to natural lightning, at distances from tens to hundreds of meters, necessary to the understanding of the voltages induced by very close lightning, have been published, although such close fields have been calculated by Diendorfer [1990] and by Rubinstein et al. [1990] using different return stroke models. These two sets of calculated fields are to be considered model-dependent estimates. Although there is disagreement between the two studies as to the waveshape of fields and in how appreciable is the influence of a finite ground conductivity at small distances, both studies yield horizontal field amplitudes at the height of a typical power distribution line comparable to the amplitude of the vertical field. Note that no return stroke model used to date (see next section) takes proper account of the attachment process referred to earlier and hence probably none accurately models the fields at very early times. Further, the leader fields preceding the return stroke field change are not taken into account in the existing models, although such fields at very close range are clearly important since it is the leader charge near ground that the return stroke discharges to ground, and hence the leader and return stroke electrostatic field changes should be of equivalent magnitude very close to the ground strike point (Rubinstein et al., 1995).

Modeling of the Return Stroke

General

A number of return stroke current models are found in the literature from which, if the current at the channel base is specified (e.g., from measurement) along with the model parameters, the channel current can be calculated as a function of height and time: the Bruce–Golde (BG) model, the transmission line (TL) model, the modified transmission line (MTL) model, the traveling current source (TCS) model, the Lin–Uman–Standler (LUS) model, the Diendorfer–Uman (DU) model, and the modified DU model. Two assumptions are

common to all of these models: that the lightning channel is perfectly straight and vertical and that the ground is a perfect conductor. Once the channel currents are determined as a function of height and time, the remote electric and magnetic fields can be calculated from Eqs. (40.8) through (40.14)

$$\overline{E} = \overline{E}_{\text{ele}} + \overline{E}_{\text{ind}} + \overline{E}_{\text{rad}} \tag{40.8}$$

$$\overline{E}_{\text{ele}} = \frac{1}{4\pi\epsilon_0}\int_{-h}^{h}\left\{\frac{2\cos\theta'\hat{a}_R + \sin\theta'\hat{a}_{\theta'}}{R^3}\int_0^t i\left(|z'|, \tau - \frac{R}{c}\right)dt\right\}dz \tag{40.9}$$

$$\overline{E}_{\text{ind}} = \frac{1}{4\pi\epsilon_0}\int_{-h}^{h}\frac{2\cos\theta'\hat{a}_R + \sin\theta'\hat{a}_{\theta'}}{cR^2} i\left(|z'|, t - \frac{R}{c}\right)dz' \tag{40.10}$$

$$\overline{E}_{\text{rad}} = \frac{1}{4\pi\epsilon_0}\int_{-h}^{h}\frac{1}{c^2R}\frac{\partial i\left(|z'|, t - \frac{R}{c}\right)}{\partial t}\hat{a}_{\theta'}dz' \tag{40.11}$$

$$\overline{B} = \overline{B}_{\text{ind}} + \overline{B}_{\text{rad}} \tag{40.12}$$

$$\overline{B}_{\text{ind}} = \frac{\mu_0}{4\pi}\int_{-h}^{h}\frac{\sin\theta'}{R^2} i\left(|z'|, t - \frac{R}{c}\right)\hat{a}_{\phi'}dz' \tag{40.13}$$

$$\overline{B}_{\text{rad}} = \frac{\mu_0}{4\pi}\int_{-h}^{h}\frac{\sin\theta'}{cR}\frac{\partial i\left(|z'|, t - \frac{R}{c}\right)}{\partial t}\hat{a}_{\phi'}dz' \tag{40.14}$$

where $i(z',t)$ is the current along the channel obtained from one of the return stroke current models mentioned above, and the geometry by which the above equations are to be interpreted is shown in Fig. 40.23. Note that the spatial integral includes the image current below the perfectly conducting ground plane so as to take account of reflections from the earth's surface. The three terms on the right-hand side of Eq. (40.8) [expanded in Eqs. (40.9) through (40.11)] are called, from left to right, the electrostatic, induction, and radiation terms. Similarly, the two terms on the right-hand side of Eq. (40.12) [expanded in Eqs. (40.13) and (40.14)] are termed the induction and radiation terms.

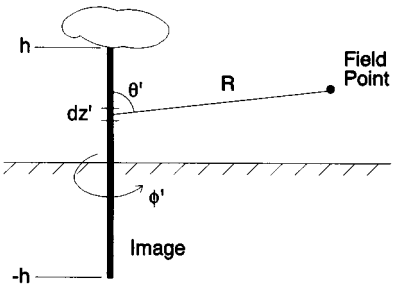

FIGURE 40.23 The geometry for the calculation of the fields using Eqs. (40.8) through (40.14).

For large distances to the lightning channel, the radiation part of the electric and magnetic fields is dominant due to its $1/R$ dependence (as compared to the $1/R^2$ and $1/R^3$ dependencies of the induction and electrostatic terms, respectively). By a similar argument, for close distances, the dominant terms will be the electrostatic term in the case of the electric field and the induction term for the magnetic field. It can be readily shown from Eqs. (40.8) through (40.14) and the preceding discussion that for any individual lightning return stroke model, the waveshapes of the vertical electric field and the horizontal magnetic field are almost identical for great distances, and this fact is also evident in the experimental data (see Fig. 40.21). Moreover, it can be shown that for great distances, the ratio of the electric field intensity E to the magnetic flux density B is the speed of light c.

A brief examination of return stroke current models follows. We discuss here only the transmission line (TL) model and the model of Diendorfer and Uman [1990] along with its modified version. More details of all models are found in Nucci et al. [1990], Diendorfer and Uman [1990], and Thottappillil et al. [1991], including fields calculated from the various models.

The Transmission Line Model

In the transmission line model it is assumed that the current waveform at the ground travels undistorted up the lightning channel at a constant speed v. Mathematically, this current is represented by

$$i(z',t) = i(0,t - z'/v) \qquad z' < vt \tag{40.15}$$

$$i(z',t) = 0 \qquad z' > vt$$

No charge is removed by the transmission line return stroke current along the channel since the charge entering the bottom of any section of the channel leaves the top when the current reaches it. All the charge is therefore transferred from the bottom to the top of the channel, an unrealistic situation given our knowledge of lightning physics.

Willett et al. [1989] have presented return stroke current, field, and speed data from artificially initiated (by firing small rockets trailing grounded wires) lightning in an attempt to validate the TL model. Using these data, Rakov et al. [1992] have shown, at least for subsequent strokes in artifically initiated lightning, that return stroke peak current can be derived from return stroke peak field by the expression $I = 1.5 - 0.037DE$ where the peak current I is in kA and is negative, the distance D is in km, and the peak electric field E is in V/m and is positive. Several investigators have published lightning peak current statistics derived from the magnetic radiation fields recorded by networks of magnetic direction finders by making use of the transmission line model. These studies are discussed by Rakov et al. [1992].

The Diendorfer–Uman (DU) Model and a Modification of It

The DU model [Diendorfer and Uman, 1990] is a physically reasonable model that can predict the salient features of the measured lightning electric and magnetic fields. Given the return stroke current at ground level, the channel current above ground is assumed to discharge the leader by way of two independent processes: (1) the discharge of the highly ionized core of the leader channel, termed the breakdown discharge process, with a time constant of 1 μs or less, and (2) the discharge of the corona envelope with a larger time constant. In both cases, the discharge at a height z' starts when the return stroke front, assumed to travel up at a constant speed v, arrives at z'. The liberated currents are assumed to flow to the ground at the speed of light.

For a current at ground $i(0,t)$, Diendorfer and Uman [1990] show that the current as a function of height and time is

$$i(z',t) = i(0,t_m) - i(0,z'/v*)\ \exp(-t_e/\tau) \tag{40.16}$$

where $t_m = (t + z'/v)$, $t_e = (t - z'/v)$, $v* = v\,(1 + v/c)$ and τ is the discharge time constant.

The Diendorfer–Uman model described above assumes that the return stroke propagates up the lightning channel at a constant speed and that the current from activated sections of the channel travels to ground at the speed of light. An analytical generalization of the DU model which allows for the return stroke speed and the downward current speed to be arbitrary functions of height has been presented by Thottappillil et al.[1991].

Lightning-Overhead Wire Interactions

General

Lightning interactions with overhead wires such as power distribution lines are a major source of electromagnetic compatibility problems, resulting in inferior power quality, power outages, and damaged electronics. Only a small fraction of all the cloud-to-ground lightning flashes directly strike overhead lines, making induced overvoltages a significant source of power disturbances. This section begins with a discussion of the appropriate transmission line equations. Then, examples of measured lightning-induced voltages on overhead lines as well as calculated voltages are presented.

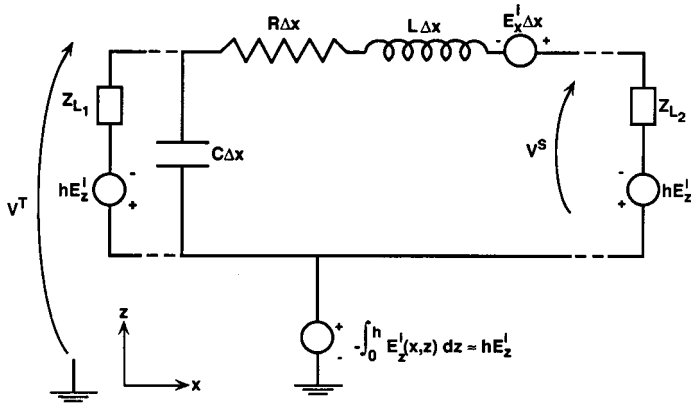

FIGURE 40.24 Equivalent circuit model obtained from Eqs. (40.17) through (40.19).

Transmission Line Equations

The transmission line equations for a nonuniform electromagnetic field impinging on a system of horizontal wires have been derived in the time domain by Agrawal et al. [1980], who adapted the theory to the case of wires above an imperfectly conducting ground. The main advantage of a time domain model over an equivalent frequency domain model is its applicability to cases of time varying and nonlinear loads and its ability to account for multiple reflections on a line with two or more discontinuities. On the other hand, with a frequency domain model it is intrinsically easier to handle frequency-dependent parameters such as the ground impedance.

The derivation of the time domain coupling equations is conceptually simple: Maxwell's equations are first integrated over closed cylindrical surfaces and along closed rectangular paths. The resulting integral equations, which are in terms of electric and magnetic fields, are then recast in terms of voltages and currents. One version of the transmission line equations, due to Agrawal et al. [1980], follows:

$$\frac{\partial V^s(x,t)}{\partial t} + Z_g * I(x,t) + L\frac{\partial I(x,t)}{\partial t} = E^i_x(x, z = h, t) \tag{40.17}$$

$$\frac{\partial I(x,t)}{\partial x} + C\frac{\partial V^s(x,t)}{\partial t} = 0 \tag{40.18}$$

$$V^t = V^i + V^s = -\int_0^h E^i_z(x,z,t)\,dz + V^s \tag{40.19}$$

where the superscript *s* identifies the "scattered" quantities, the superscript *i* identifies the "incident" quantities, the superscript *t* identifies the total, measurable quantities, and the asterisk is the convolution operator.

In these equations, the only source along the horizontal portion of the line is the horizontal component of the incident electric field. At the line terminations, the boundary condition and the termination current, *I*, are used to determine the end voltage. At those vertically oriented terminations, the vertical electric fields drive currents through the terminations into the line. The total voltage, $V^t(x,t)$, at the line terminations must equal $I_T * Z_T$ at all times, where Z_T is the termination impedance. Equations (40.17) through (40.19) can be represented by the circuit model in Fig. 40.24.

Two basic assumptions are used to arrive at Eqs. (40.17) through (40.19): (1) The response of the power line (scattered voltages and currents) to the impinging EM wave (incident field) is quasi-TEM (i.e., the scattered fields can be approximated as transverse electromagnetic). This allows us to define a "static" voltage along the line and to relate the line current and the scattered magnetic flux by an inductance, as well as the line scattered voltage and charge by a capacitance. (2) The transverse dimensions of the line system are small compared to the minimum wavelength, λ_{min}, of the excitation wave, and the height of the line is much larger than the diameter of the wire.

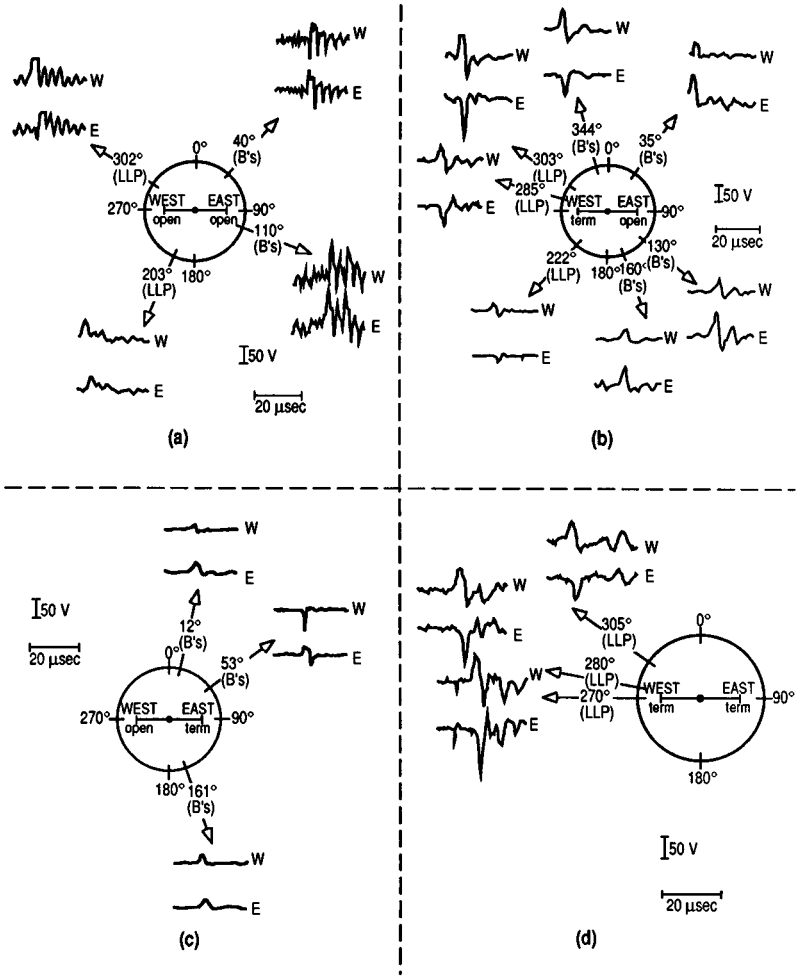

FIGURE 40.25 Examples of simultaneously measured lightning-induced voltages at the east end (E) and west end (W) of a 450-m line. Each line end is either open or terminated in its characteristic impedance, as noted. Directions to the lightning are determined from the ratio of the horizontal magnetic flux densities (*B*'s) or from a commercial lightning location system (LLP). (*Source:* Adapted from N. Georgiadis et al., "Lightning-induced voltages at both ends of a 450-meter distribution line," *IEEE Trans. EMC*, vol. 34, pp. 451–460, 1992. ©1992 IEEE. With permission.)

For other formulations of the overhead wire coupling equations, written in terms of field variables different from those used by Agrawal et al. [1980], see Rachidi [1993], Cooray [1994], and Nucci and Rachidi [1995].

Measured and Calculated Lightning-Induced Voltages on Overhead Wires

Several experiments have been carried out to test the coupling theory [e.g., Georgiadis et al., 1992; Rubinstein et al., 1994; Barker et al. 1996]. The basic strategy is the same in each experiment: to measure the lightning electric and magnetic fields in the vicinity of an instrumented overhead line while simultaneously measuring the voltages induced on the line, the measured fields then being used as inputs to a computer program written to solve Eqs. (40.17) through (40.19) and the computer-calculated voltage waveforms being compared with the measured voltage waveforms. The following discussion illustrates the types of voltage waveforms induced on overhead wires by lightning beyond a few kilometers and the degree of agreement that has been obtained in the coupling-model calculations. Examples of voltages induced on a 450-m overhead line about 10 m above the ground are shown in Fig. 40.25. Each line end was either terminated in its characteristic impedance or

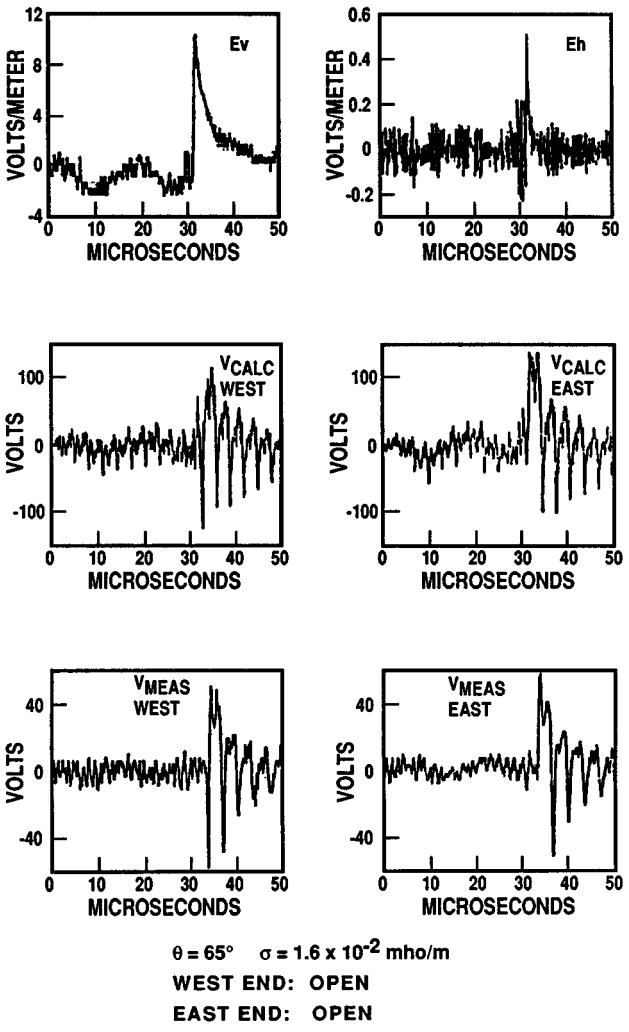

FIGURE 40.26 Measured and calculated voltages at the east and west ends of a 450-m line for both line ends open. Although the direction to the lightning as determined from the ratio of the two magnetic flux density (B) components was 40°, as shown in Fig. 40.29(a), the best calculated fit to the data was found for 65° as shown, the angular error apparently being caused by variation in the magnitudes of the magnetic flux density components due to nearby conductors as determined from comparing azimuths computed from the B's and from a commercial lightning location system (LLP). (*Source:* Adapted from N. Georgiadis et al., "Lightning-induced voltages at both ends of a 450-meter distribution line," *IEEE Trans. EMC*, vol. 34, pp. 451–460, 1992. ©1992 IEEE. With permission.)

open-circuited (four different cases), and voltages were measured simultaneously at each end. Figures 40.26 and 40.27 contain specific examples of measured and calculated voltage waveforms at each line end as well as the measured vertical electric field and calculated horizontal electric field via Eq. (40.7). It is clear from Figs. 40.25 through 40.27 that the induced voltage polarities and waveshapes are strongly dependent on the angle to the lightning and on the line end terminations. It is apparent also from Georgiadis et al. [1992] that while measured and calculated voltage waveshapes are in good agreement, the measured voltage amplitudes are, on average, a factor of three smaller than calculated voltages. This amplitude discrepancy remains unexplained but is probably due to the fact that the fields reaching the power line were shielded by trees along the line whereas the fields measured were in an open area and hence were unshielded.

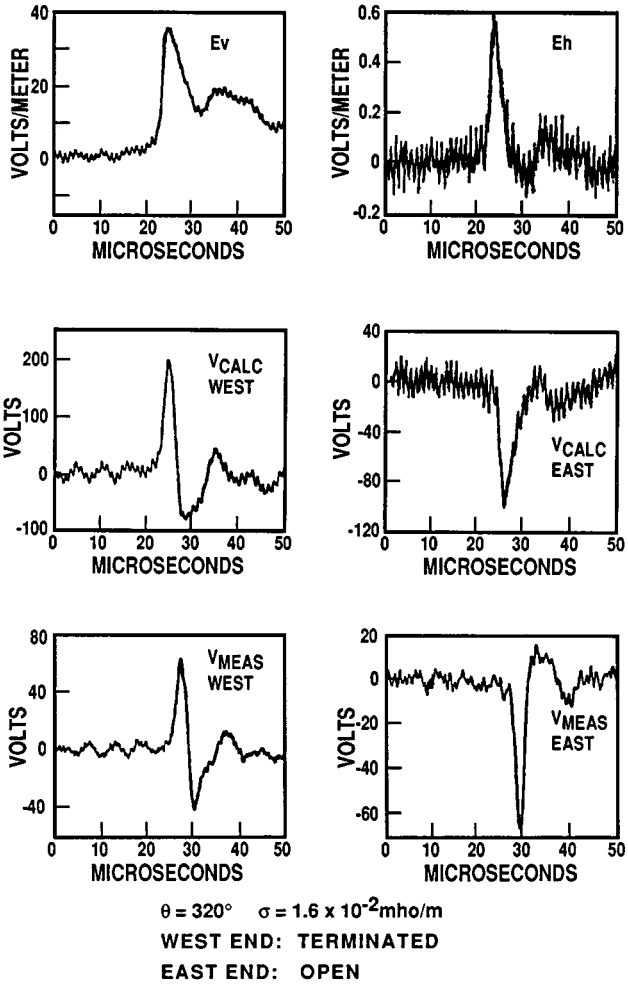

FIGURE 40.27 Measured and calculated voltages at the east and west ends of a 450-m line with the west end terminated and the east end open. The azimuth was determined from LLP data and is shown in Fig. 40.29(b). (*Source:* Adapted from N. Georgiadis et al., "Lightning-induced voltages at both ends of a 450-meter distribution line," *IEEE Trans. EMC*, vol. 34, pp. 451–460, 1992. ©1992 IEEE. With permission.)

Defining Terms

Attachment process: A process that occurs when one or more stepped leader branches approach within a hundred meters or so of the ground and the electric field at the ground increases above the critical breakdown field of the surrounding air. At that time one or more upward-going discharges is initiated. After traveling a few tens of meters, one of the upward discharges, which is essentially at ground potential, contracts the tip of one branch of the stepped leader, which is at a high potential, completing the leader path to ground.

Dart leader: A continuously moving leader lowering charge preceding a return stroke subsequent to the first. A dart leader typically propagates down the residual channel of the previous stroke.

Flash: A complete lightning discharge of any type.

Preliminary breakdown: An electrical discharge in the cloud that initiates a cloud-to-ground flash.

Return stroke: The upward propagating high-current, bright, potential discontinuity following the leader that discharges to the ground some or all of the charge previously deposited along the channel by the leader.

Stepped leader: A discharge following the preliminary breakdown that propagates from cloud towards the ground in a series of intermittant luminous steps with an average speed of 10^5 to 10^6 m/s. Negatively charged leaders clearly step, while positively charged leaders are more pulsating than stepped.

41.1 Pulse Radar

Melvin L. Belcher and Josh T. Nessmith

Overview of Pulsed Radars

Basic Concept of Pulse Radar Operation

The basic operation of a pulse radar is depicted in Fig. 41.1. The radar transmits a pulse of RF energy and then receives returns (reflections) from desired and undesired targets. Desired targets may include space, airborne, and sea- and/or surface-based vehicles. They can also include the earth's surface and the atmosphere, depending on the application. Undesired targets are termed *clutter*. Clutter sources include the ground, natural and man-made objects, sea, atmospheric phenomena, and birds. Short-range/low-altitude radar operation is often constrained by clutter since the multitude of undesired returns masks returns from targets of interest such as aircraft.

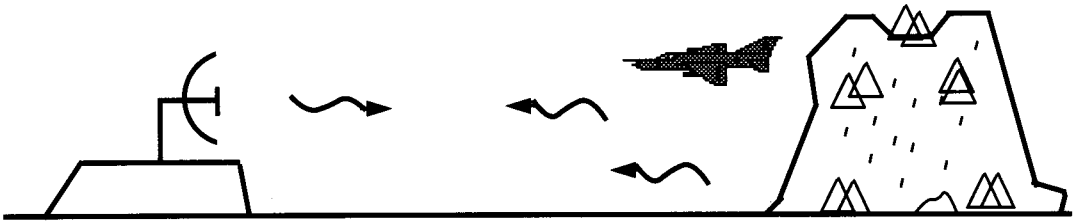
The range, azimuth angle, elevation angle, and range rate can be directly measured from a return to estimate target position and velocity. Signature data can be extracted by measuring the amplitude, phase, and polarization of the return.

Pulse radar affords a great deal of design and operational flexibility. Pulse duration and pulse rate can be tailored to specific applications to provide optimal performance. Modern computer-controlled multiple-function radars exploit this capability by choosing the best waveform from a repertoire for a given operational mode and interference environment automatically.

Radar Applications

The breadth of pulse radar applications is summarized in Table 41.1. Radar applications can be grouped into search, track, and signature measurement applications. Search radars are used for tracking but have relatively large range and angle errors. The search functions favor broad beam-widths and low bandwidths in order to efficiently search over a large spatial volume. As indicated in Table 41.1, search is preferably performed in the lower frequency bands. The antenna pattern is narrow in azimuth and has a cosecant pattern in elevation to provide acceptable coverage from the horizon to the zenith.

Tracking radars are typically characterized by a narrow beamwidth and moderate bandwidth in order to provide accurate range and angle measurements on a given target. The antenna pattern is a pencil beam with approximately the same dimensions in azimuth and elevation. Track is usually conducted at the higher frequency bands in order to minimize the beamwidth for a given antenna aperture area. After each return from a target



$$\text{Target Range} = \frac{\text{Two-Way-Time-Delay} \cdot \text{Speed-of-Light}}{}$$

FIGURE 41.1 Pulse radar.

TABLE 41.1 Radar Bands

Band	Frequency Range	Principal Applications
HF	3–30 MHz	Over-the-horizon radar
VHF	30–300 MHz	Long-range search
UHF	300–1000 MHz	Long-range surveillance
L	1000–2000 MHz	Long-range surveillance
S	2000–4000 MHz	Surveillance
		Long-range weather characterization
		Terminal air traffic control
C	4000–8000 MHz	Fire control
		Instrumentation tracking
X	8–12 GHz	Fire control
		Air-to-air missile seeker
		Marine radar
		Airborne weather characterization
Ku	12–18 GHz	Short-range fire control
		Remote sensing
Ka	27–40 GHz	Remote sensing
		Weapon guidance
V	40–75 GHz	Remote sensing
		Weapon guidance
W	75–110 GHz	Remote sensing
		Weapon guidance

is received, the range and angle are measured and input into a track filter. Track filtering smooths the data to refine the estimate of target position and velocity. It also predicts the target's flight path to provide range gating and antenna pointing control to the radar system.

Signature measurement applications include remote sensing of the environment as well as the measurement of target characteristics. In some applications, synthetic aperture radar (SAR) imaging is conducted from aircraft or satellites to characterize land usage over broad areas. Moving targets that present changing aspect to the radar can be imaged from airborne or ground-based radars via inverse synthetic aperture radar (ISAR) techniques. As defined in the subsection "Resolution and Accuracy," cross-range resolution improves with increasing antenna extent. SAR/ISAR effectively substitutes an extended observation interval over which coherent returns are collected from different target aspect angles for a large antenna structure that would not be physically realizable in many instances.

In general, characterization performance improves with increasing frequency because of the associated improvement in range, range rate, and cross-range resolution. However, phenomenological characterization to support environmental remote sensing may require data collected across a broad swath of frequencies.

A multiple-function **phased array** radar generally integrates these functions to some degree. Its design is usually driven by the track function. Its operational frequency is generally a compromise between the lower

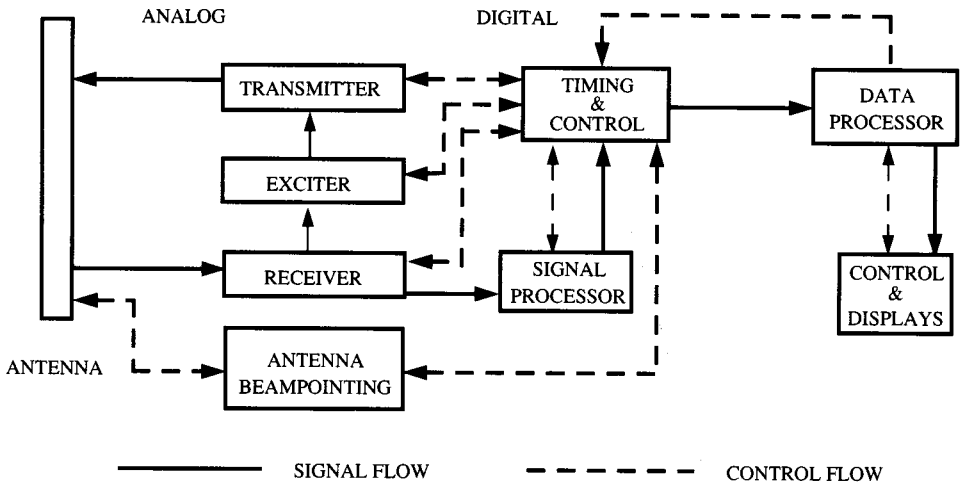


FIGURE 41.2 Radar system architecture.

frequency of the search radar and the higher frequency desired for the tracking radar. The degree of signature measurement implemented to support such functions as noncooperative target identification depends on the resolution capability of the radar as well as the operational user requirements. Multiple-function radar design represents a compromise among these different requirements. However, implementation constraints, multiple-target handling requirements, and reaction time requirements often dictate the use of phased array radar systems integrating search, track, and characterization functions.

Critical Subsystem Design and Technology

The major subsystems making up a pulse radar system are depicted in Fig. 41.2. The associated interaction between function and technology is summarized in this subsection.

Antenna

The radar antenna function is to first provide spatial directivity to the transmitted EM wave and then to intercept the scattering of that wave from a target. Most radar antennas may be categorized as mechanically scanning or electronically scanning. Mechanically scanned reflector antennas are used in applications where rapid beam scanning is not required. Electronic scanning antennas include phased arrays and frequency scanned antennas. Phased array beams can be steered to any point in their field-of-view, typically within 10 to 100 μs, depending on the latency of the beam steering subsystem and the switching time of the phase shifters. Phased arrays are desirable in multiple function radars since they can interleave search operations with multiple target tracks.

There is a Fourier transform relationship between the antenna illumination function and the far-field antenna pattern. Hence, tapering the illumination to concentrate power near the center of the antenna suppresses sidelobes while reducing the effective antenna aperture area. The phase and amplitude control of the antenna illumination determines the achievable sidelobe suppression and angle measurement accuracy.

Perturbations in the illumination due to the mechanical and electrical sources distort the illumination function and constrain performance in these areas. Mechanical illumination error sources include antenna shape deformation due to sag and thermal effects as well as manufacturing defects. Electrical illumination error is of particular concern in phased arrays where sources include beam steering computational error and phase shifter quantization. Control of both the mechanical and electrical perturbation errors is the key to both low sidelobes and highly accurate angle measurements. Control denotes that either tolerances are closely held and maintained or that there must be some means for monitoring and correction. Phased arrays are attractive for low sidelobe applications since they can provide element-level phase and amplitude control.

TABLE 41.2 Pulse Radar Transmitter Technology

Technology	Mode of Operation	Maximum Frequency (GHz)	Demonstrated Peak/ Average Power (kW)	Typical Gain	Typical Bandwidth
Thermionic					
Magnetron	Oscillator	95	1 MW/500 W @ X-band	n/a	Fixed–10%
Helix traveling wave tube (TWT)	Amplifier	95	4 kW/400 W @ X-band	40–60 dB	Octave/multioctave
Ring-loop TWT	Amplifier	18	8 kW/200 W @ X-band	40–60 dB	5–15%
Coupled-cavity TWT	Amplifier	95	100 kW/25 kW @ X-band	40–60 dB	5–15%
Extended interaction oscillator (EIO)	Oscillator	220	1 kW/10 W @ 95 GHz	n/a	0.2% (elec.) 4% (mech.)
Extended interaction Klystron (EIK)	Amplifier	140	1 kW/10 W @ 95 GHz	40–50 dB	0.5–1%
Klystron	Amplifier	35	50 kW/5 kW @ X-band	30–60 dB	0.1–2% (inst.) 1–10% (mech.)
Crossed-field amplifier (CFA)	Amplifier	18	500 kW/1 kW @ X-band	10–20 dB	5–15%
Solid state					
Silicon BJT	Amplifier	5	300 W/30 W @1 GHz	5–10 dB	10–25%
GaAs FET	Amplifier	30	15 W/5 W @ X-band	5–10 dB	5–20%
Impatt diode	Oscillator	140	30 W/10 W @ X-band	n/a	Fixed–5%

Transmitter

The transmitter function is to amplify waveforms to a power level sufficient for target detection and estimation. There is a general trend away from tube-based transmitters toward solid-state transmitters. In particular, solid-state transmit/receive modules appear attractive for constructing phased array radar systems. In this case, each radiating element is driven by a module that contains a solid-state transmitter, phase shifter, low-noise amplifier, and associated control components. Active arrays built from such modules appear to offer significant reliability advantages over radar systems driven from a single transmitter. However, microwave tube technology continues to offer substantial advantages in power output over solid-state technology. Transmitter technologies are summarized in Table 41.2.

Receiver and Exciter

This subsystem contains the precision timing and frequency reference source or sources used to derive the master oscillator and local oscillator reference frequencies. These reference frequencies are used to downconvert received signals in a multiple-stage superheterodyne architecture to accommodate signal amplification and interference rejection. The receiver front end is typically protected from overload during transmission through the combination of a circulator and a transmit/receive switch.

The exciter generates the waveforms for subsequent transmission. As in signal processing, the trend is toward programmable digital signal synthesis because of the associated flexibility and performance stability.

Signal and Data Processing

Digital processing is generally divided between two processing subsystems, i.e., signals and data, according to the algorithm structure and throughput demands. Signal processing includes pulse compression, Doppler filtering, and detection threshold estimation and testing. Data processing includes track filtering, user interface support, and such specialized functions as electronic counter-counter measures (ECCM) and built-in test (BIT), as well as the resource management process required to control the radar system.

The signal processor is often optimized to perform the repetitive complex multiply-and-add operations associated with the fast Fourier transform (FFT). FFT processing is used for implementing **pulse compression** via fast convolution and for Doppler filtering. Fast convolution consists of taking the FFT of the digitized receiver output, multiplying it by the stored FFT of the desired filter function, and then taking the inverse FFT

of the resulting product. Fast convolution results in significant computational saving over performing the time-domain convolution of returns with the filter function corresponding to the matched filter. The signal processor output can be characterized in terms of range gates and Doppler filters corresponding approximately to the range and Doppler resolution, respectively.

In contrast, the radar data processor typically consists of a general-purpose computer with a real-time operating system. Fielded radar data processors range from microcomputers to mainframe computers, depending on the requirements of the radar system. Data processor software and hardware requirements are significantly mitigated by off loading timing and control functions to specialized hardware. This timing and control subsystem typically functions as the two-way interface between the data processor and the other radar subsystems. The increasing inclusion of BIT (built-in-test) and built-in calibration capability in timing and control subsystem designs promises to result in significant improvement in fielded system performance.

Radar Performance Prediction

Radar Line-of-Sight

With the exception of over-the-horizon (OTH) radar systems, which exploit either sky-wave bounce or ground-wave propagation modes and sporadic ducting effects at higher frequencies, surface and airborne platform radar operation is limited to the refraction-constrained line of sight. Atmospheric refraction effects can be closely approximated by setting the earth's radius to 4/3 its nominal value in estimating horizon-limited range. The resulting line-of-sight range is depicted in Fig. 41.3 for a surface-based radar, an airborne surveillance radar, and a space-based radar.

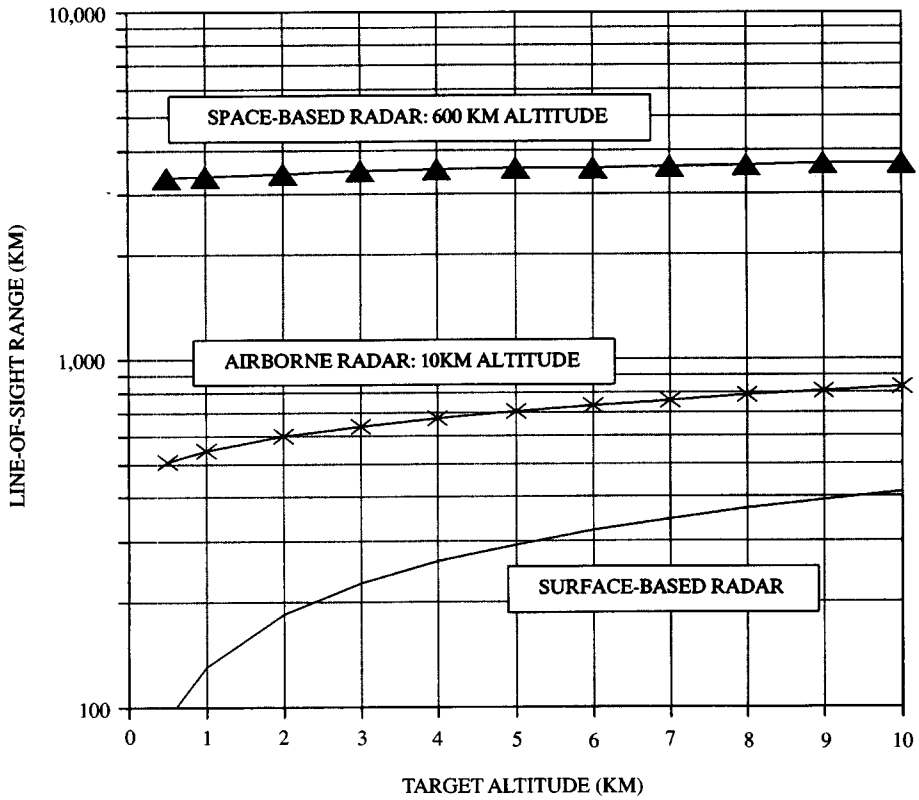

FIGURE 41.3 Maximum line-of-sight range for surface-based radar, an airborne surveillance radar, and a space-based radar.

As evident in the plot, airborne and space-based surveillance radar systems offer significant advantages in the detection of low-altitude targets that would otherwise be masked by earth curvature and terrain features from surface-based radars. However, efficient clutter rejection techniques must be used in order to detect targets since surface clutter returns will be present at almost all ranges of interest.

Radar Range Equation

The radar range equation is commonly used to estimate radar system performance, given that line-of-sight conditions are satisfied. This formulation essentially computes the signal-to-noise ratio (S/N) at the output of the radar signal processor. In turn, S/N is used to provide estimates of radar detection and position measurement performance as described in the subsections "Detection and Search" and "Estimation and Tracking." S/N can be calculated in terms of the number of pulses coherently integrated over a single coherent processing interval (CPI) using the radar range equation such that

$$S/N = \frac{PDAT_p N_p \sigma}{(4\pi)^2 R^4 L_t L_{rn} L_{sp} k T_s} \tag{41.1}$$

where P is peak transmitter power output, D is directivity of the transmit antenna, A is effective aperture area of the receive antenna in meters squared, T_p is pulse duration, σ is **radar cross section** in square meters, N_p is the number of coherently integrated pulses within the coherent processing interval, R is range to target in meters, L_t is system ohmic and nonohmic transmit losses, L_{rn} is system nonohmic receive losses, L_{sp} is signal processing losses, k is Boltzmann's constant (1.38×10^{-23} K), and T_s is system noise temperature, including receive ohmic losses (kelvin).

At X-band and above it may also be necessary to include propagation loss due to atmospheric absorption [Blake, 1986]. This form of the radar range equation is applicable to radar systems using pulse compression or pulse Doppler waveforms as well as the unmodulated single-pulse case. In many applications, average power is a better measure of system performance than peak power since it indicates the S/N improvement achievable with pulse integration over a given interval of time. Hence, the radar range equation can be modified such that

$$S/N = \frac{P_a DAT_c \sigma}{(4\pi)^2 R^4 L_t L_{rn} L_{sp} k T_s} \tag{41.2}$$

where P_a is average transmitter power and T_c is coherent processing interval (CPI).

The portion of time over which the transmitter is in operation is referred to as the radar duty cycle. The average transmitter power is the product of duty cycle and peak transmitter power. Duty cycle ranges from less than 1% for typical **noncoherent** pulse radars to somewhat less than 50% for high pulse repetition frequency (PRF) pulse Doppler radar systems. High PRF systems are sometimes referred to as interrupted continuous wave (ICW) systems because they operate essentially as a CW radar system with transmitter and receiver alternately turned on and off.

The CPI is the period over which returns are collected for **coherent** processing functions such as integration and Doppler filtering. The CPI can be estimated as the product of the number of coherently integrated pulses and the interval between pulses. Noncoherent integration is less efficient and alters the statistical character of the signal and interference.

Antenna Directivity and Aperture Area

The directivity of the antenna is

$$D = \frac{4\pi A \eta}{\lambda^2} \tag{41.3}$$

Slash marks indicate different set.

where η is aperture efficiency and λ is radar carrier wavelength. Aperture inefficiency is due to the antenna illumination factor.

The common form of the radar range equation uses power gain rather than directivity. Antenna gain is equal to the directivity divided by the antenna losses. In the design and analysis of modern radars, directivity is a more convenient measure of performance because it permits designs with distributed active elements, such as solid-state phased arrays, to be assessed to permit direct comparison with passive antenna systems. Beamwidth and directivity are inversely related; a highly directive antenna will have a narrow beamwidth. For typical design parameters,

$$D = \frac{10^7}{\theta_{az}\theta_{el}} \tag{41.4}$$

where θ_{az} and θ_{el} are the radar azimuth and elevation beamwidths, respectively, in milliradians.

Radar Cross Section

In practice, the *radar cross section* (RCS) of a realistic target must be considered a random variable with an associated correlation interval. Targets are composed of multiple interacting scatters so that the composite return varies in magnitude with the constructive and destructive interference of the contributing returns. The target RCS is typically estimated as the mean or median of the target RCS distribution. The associated correlation interval indicates the rate at which the target RCS varies over time. RCS fluctuation degrades target detection performance at moderate to high probability of detection.

The median RCS of typical targets is given in Table 41.3. The composite RCS measured by a radar system may be composed of multiple individual targets in the case of closely spaced targets such as a bird flock.

Loss and System Temperature Estimation

Sources of S/N loss include ohmic and nonohmic (mismatch) loss in the antenna and other radio frequency components, propagation effects, signal processing deviations from matched filter operation, detection thresholding, and search losses. Scan loss in phased array radars is due to the combined effects of the decrease in projected antenna area and element mismatch with increasing scan angle.

TABLE 41.4 Typical Microwave Loss and System Temperature Budgets

	Mechanically Scanned Reflector Antenna	Electronically Scanned Slotted Array	Solid-State Phased Array
Nominal losses			
Transmit loss, L_t (dB)	1	1.5	0.5
Nonohmic receiver loss, L_r (dB)	0.5	0.5	0.1
Signal processing loss, L_{sp} (dB)	1.4	1.4	1.4
Scan loss (dB)	N/A	N/A	30 log [cos (scan angle)]
Search losses, L_{DS}			
Beam shape (dB)	3	3	3
Range gate straddle (dB)	0.5	0.5	0.5
Doppler filter straddle (dB)	0.5	0.5	0.5
Detection thresholding (dB)	1	1	1
System noise temperature (kelvin)	500	600	400

Search operations impose additional losses due to target position uncertainty. Because the target position is unknown before detection, the beam, range gate, and Doppler filter will not be centered on the target return. Hence, straddling loss will occur as the target effectively straddles adjacent resolution cells in range and Doppler. Beamshape loss is a consequence of the radar beam not being pointed directly at the target so that there is a loss in both transmit and receive antenna gain. In addition, detection threshold loss associated with radar system adaptation to interference must be included [Nathanson, 1991]).

System noise temperature estimation corresponds to assessing the system thermal noise floor referenced to the antenna output. Assuming the receiver hardware is at ambient temperature, the system noise temperature can be estimated as

$$T_s = T_a + 290\ (L_{ro}\ F - 1) \tag{41.5}$$

where T_a is the antenna noise temperature, L_{ro} is receive ohmic losses, and F is the receiver noise figure.

In phased array radars, the thermodynamic temperature of the antenna receive beam-former may be significantly higher than ambient, so a more complete analysis is required. The antenna noise temperature is determined by the external noise received by the antenna from solar, atmospheric, earth surface, and other sources.

Table 41.4 provides typical loss and noise temperature budgets for several major radar classes. In general, loss increases with the complexity of the radar hardware between the transmitter/receiver and the antenna radiator. Reflector antennas and active phased arrays impose relatively low loss, while passive array antennas impose relatively high loss.

Resolution and Accuracy

The fundamental resolution capabilities of a radar system are summarized in Table 41.5. In general, there is a trade-off between mainlobe resolution corresponding to the nominal range, Doppler, and angle resolution, and effective dynamic range corresponding to suppression of sidelobe components. This is evident in the use of weighting to suppress Doppler sidebands and angle sidelobes at the expense of broadening the mainlobe and S/N loss.

Cross range denotes either of the two dimensions orthogonal to the radar line of sight. Cross-range resolution in real-aperture antenna systems is closely approximated by the product of target range and radar beamwidth in radians. Attainment of the nominal ISAR/SAR cross-range resolution generally requires complex signal processing to generate a focused image, including correction for scatterer change in range over the CPI.

The best accuracy performance occurs for the case of thermal noise-limited error. The resulting accuracy is the resolution of the radar divided by the square root of the S/N and an appropriate monopulse or interpolation factor. In this formulation, the single-pulse S/N has been multiplied by the number of pulses integrated within the CPI as indicated in Eqs. (41.1) and (41.2).

TABLE 41.5 Resolution and Accuracy

Dimension	Nominal Resolution	Noise-Limited Accuracy
Angle	$\frac{\alpha\lambda}{d}$	$\frac{\alpha\lambda}{dK_m\sqrt{2S/N}}$
Range	$\frac{\alpha C}{2B}$	$\frac{\alpha C}{2BK_i\sqrt{2S/N}}$
Doppler	$\frac{\alpha}{\text{CPI}}$	$\frac{\alpha}{\text{CPI}K_i\sqrt{2S/N}}$
SAR/ISAR	$\frac{\alpha\lambda}{2\Delta\theta}$	$\frac{\alpha\lambda}{2\Delta\theta K_i\sqrt{2S/N}}$

α, taper broadening factor, typically ranging from 0.89 (unweighted) to 1.3 (Hamming); d, antenna extent in azimuth/elevation; B, waveform bandwidth; K_m, monopulse slope factor, typically on the order of 1.5; K_i, interpolation factor, typically on the order of 1.8; $\Delta\theta$, line-of-sight rotation of target relative to radar over CPI.

In practice, accuracy is also constrained by environmental effects, target characteristics, and instrumentation error as well as the available S/N. Environmental effects include multipath and refraction. Target glint is characterized by an apparent wandering of the target position because of coherent interference effects associated with the composite return from the individual scattering centers on the target. Instrumentation error is minimized with alignment and calibration but may significantly constrain track filter performance as a result of the relatively long correlation interval of some error sources.

Radar Range Equation for Search and Track

The radar range equation can be modified to directly address performance in the two primary radar missions: search and track.

Search performance is basically determined by the capability of the radar system to detect a target of specific RCS at a given maximum detection range while scanning a given solid angle extent within a specified period of time. S/N can be set equal to the minimum value required for a given detection performance, $S/N|r$, while R can be set to the maximum required target detection range, $R_{\max}$. Manipulation of the radar range equation results in the following expression:

$$\frac{P_a A}{L_t L_r L_{sp} L_{os} T_s} \geq \left(\frac{S}{N}\right)_r \frac{R_{\max}^4 \Omega}{\sigma\ T_{fs}} \cdot 16\text{k} \tag{41.6}$$

where Ω is the solid angle over which search must be performed (steradians), T_{fs} is the time allowed to search Ω by operational requirements, and L_{os} is the composite incremental loss associated with search.

The left-hand side of the equation contains radar design parameters, while the right-hand side is determined by target characteristics and operational requirements. The right-hand side of the equation is evaluated to determine radar requirements. The left-hand side of the equation is evaluated to determine if the radar design meets the requirements.

The track radar range equation is conditioned on noise-limited angle accuracy as this measure stresses radar capabilities significantly more than range accuracy in almost all cases of interest. The operational requirement is to maintain a given data rate track providing a specified single-measurement angle accuracy for a given number of targets with specified RCS and range. Antenna beamwidth, which is proportional to the radar carrier wavelength divided by antenna extent, impacts track performance since the degree of S/N required for a given measurement accuracy decreases as the beamwidth decreases. Track performance requirements can be bounded as

TABLE 41.6 Selected Waveform Characteristics

	Comments	Time Bandwidth Product	Range Sidelobes (dB)	*S/N* Loss (dB)	Range/Doppler Coupling	ECM/EMI Robustness
Unmodulated	No pulse compression	~1	Not applicable	0	No	Poor
Linear frequency modulation	Linearly swept over bandwidth	>10	Unweighted: –13.5 Weighted: >–40[a]	0 0.7–1.4	Yes	Poor

[a]Constraint due to typical technology limitations rather than fundamental waveform characteristics.

$$\frac{P_a A^3}{\lambda^4 L_t L_r L_{sp} T_s} k_m^2 \eta^2 \geq 5k \frac{rN_t R^4}{\sigma \sigma_\theta^2} \tag{41.7}$$

where r is the single-target track rate, N_t is the number of targets under track in different beams, σ_θ is the required angle accuracy standard deviation (radians), and σ is the RCS. In general, a phased array radar antenna is required to support multiple target tracking when $N_t > 1$.

Incremental search losses are suppressed during single-target-per-beam tracking. The beam is pointed as closely as possible to the target to suppress beamshape loss. The tracking loop centers the range gate and Doppler filter on the return. Detection thresholding loss is minimal since the track range window is small.

Radar Waveforms

Pulse Compression

Typical pulse radar waveforms are summarized in Table 41.6. In most cases, the signal processor is designed to closely approximate a matched filter. As indicated in Table 41.5, the range and Doppler resolution of any match-filtered waveform are inversely proportional to the waveform bandwidth and duration, respectively. Pulse compression, using modulated waveforms, is attractive since *S/N* is proportional to pulse duration rather than bandwidth in matched filter implementations. Ideally, the intrapulse modulation is chosen to attain adequate range resolution and range sidelobe suppression performance while the pulse duration is chosen to provide the required sensitivity. Pulse compression waveforms are characterized as having a time bandwidth product (TBP) significantly greater than unity, in contrast to an unmodulated pulse, which has a TBP of approximately unity.

Pulse Repetition Frequency

The radar system pulse repetition frequency (PRF) determines its ability to unambiguously measure target range and range rate in a single CPI as well as determining the inherent clutter rejection capabilities of the radar system. In order to obtain an unambiguous measurement of target range, the interval between radar pulses (1/PRF) must be greater than the time required for a single pulse to propagate to a target at a given range and back. The maximum unambiguous range is then given by $C/(2 \cdot \text{PRF})$ where C is the velocity of electromagnetic propagation.

Returns from moving targets and clutter sources are offset from the radar carrier frequency by the associated Doppler frequency. As a function of range rate, $R\cdot$, the Doppler frequency, f_D, is given by $2R\cdot/\lambda$. A coherent pulse train samples the returns' Doppler modulation at the PRF. Most radar systems employ parallel sampling in the in-phase and quadrature baseband channels so that the effective sampling rate is twice the PRF. The target's return is folded in frequency if the PRF is less than the target Doppler.

Clutter returns are primarily from stationary or near-stationary surfaces such as terrain. In contrast, targets of interest often have a significant range rate relative to the radar clutter. Doppler filtering can suppress returns from clutter. With the exception of frequency ambiguity, the Doppler filtering techniques used to implement pulse Doppler filtering are quite similar to those described for CW radar in Section 41.2. Ambiguous measurements can be resolved over multiple CPIs by using a sequence of slightly different PRFs and correlating detections among the CPIs [Morris, 1988].

Detection and Search

Detection processing consists of comparing the amplitude of each range gate/Doppler filter output with a threshold. A detection is reported if the amplitude exceeds that threshold. A false alarm occurs when noise or other interference produces an output of sufficient magnitude to exceed the detection threshold. As the detection threshold is decreased, both the detection probability and the false alarm probability increase. S/N must be increased to enhance detection probability while maintaining a constant false alarm probability.

As noted in the subsection "Radar Cross Section," RCS fluctuation effects must be considered in assessing detection performance. The Swerling models which use chi-square probability density functions (PDFs) of 2 and 4 degrees of freedom (DOF) are commonly used for this purpose [Nathanson, 1991]. The Swerling 1 and 2 models are based on the 2 DOF PDF and can be derived by modeling the target as an ensemble of independent scatterers of comparable magnitude. This model is considered representative of complex targets such as aircraft. The Swerling 3 and 4 models use the 4 DOF PDF and correspond to a target with a single dominant scatterer and an ensemble of lesser scatterers. Missiles are sometimes represented by Swerling 2 and 4 models. The Swerling 1 and 3 models presuppose slow fluctuation such that the target RCS is constant from pulse to pulse within a scan. In contrast, the RCS of Swerling 2 and 4 targets is modeled as independent on a pulse to pulse basis.

Single-pulse detection probabilities for nonfluctuating, Swerling 1/2, and Swerling 3/4 targets are depicted in Fig. 41.4. This curve is based on a typical false alarm number corresponding approximately to a false alarm probability of 10^{-6}. The difference in S/N required for a given detection probability for a fluctuating target relative to the nonfluctuating case is termed the fluctuation loss.

The detection curves presented here and in most other references presuppose noise-limited operation. In many cases, the composite interference present at the radar system output will be dominated by clutter returns or electromagnetic interference such as that imposed by hostile electronic countermeasures. The standard textbook detection curves cannot be applied in these situations unless the composite interference is statistically similar to thermal noise with a Gaussian PDF and a white power spectral density. The presence of non-Gaussian interference is generally characterized by an elevated false alarm probability. Adaptive detection threshold estimation techniques are often required to search for targets in environments characterized by such interference.

Estimation and Tracking

Measurement Error Sources

Radars measure target range and angle position and, potentially, Doppler frequency. Angle measurement performance is emphasized here since the corresponding cross-range error dominates range error for most practical applications. Target returns are generally smoothed in a tracking filter, but tracking performance is largely determined by the measurement accuracy of the subject radar system. Radar measurement error can be characterized as indicated in Table 41.7.

The radar design and the alignment and calibration process development must consider the characteristics and interaction of these error components. Integration of automated techniques to support alignment and

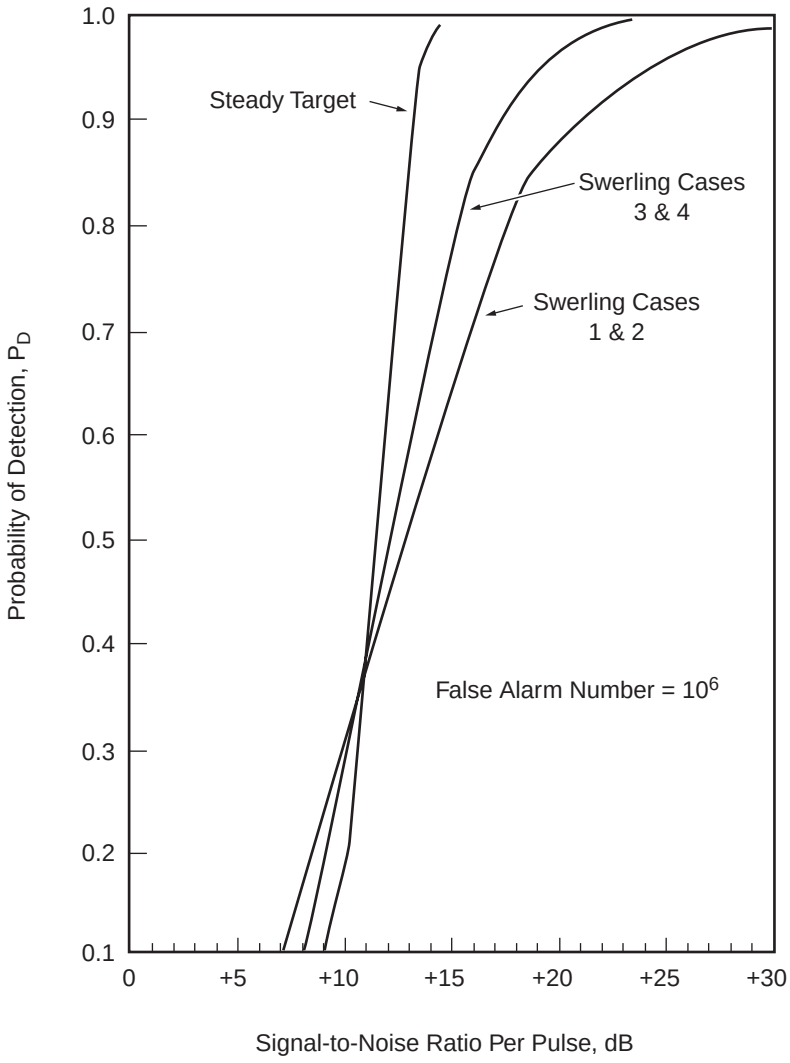

FIGURE 41.4 Detection probabilities for various target fluctuation models.

TABLE 41.7 Radar Measurement Error

Random errors	Those errors that cannot be predicted except on a statistical basis. The magnitude of the random error can be termed the *precision* and is an indication of the repeatability of a measurement.
Bias errors	A systematic error whether due to instrumentation or propagation conditions. A nonzero mean value of a random error.
Systematic error	An error whose quantity can be measured and reduced by calibration.
Residual systematic error	Those errors remaining after measurement and calibration. A function of the systematic and random errors in the calibration process.
Accuracy	The magnitude of the rms value of the residual systematic and random errors.

calibration is an area of strong effort in modern radar design that can lead to significant performance improvement in fielded systems.

As indicated previously, angle measurement generally is the limiting factor in measurement accuracy. Target azimuth and elevation position is primarily measured by a monopulse technique in modern radars though early systems used sequential lobing and conical scanning. Specialized monopulse tracking radars utilizing

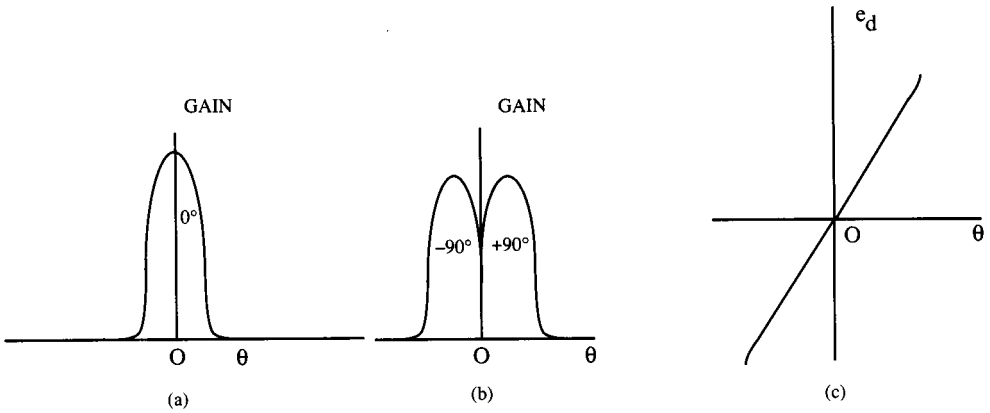

FIGURE 41.5 Monopulse beam patterns and difference voltage: (a) sum (Σ); (b) difference (Δ); (c) difference voltage.

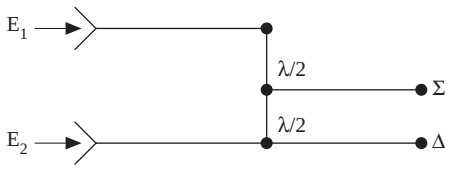

FIGURE 41.6 Monopulse comparator.

reflectors have achieved instrumentation and *S/N* angle residual systematic error as low as 50 μrad. Phased array antennas have achieved a random error of less than 60 μrad, but the composite systematic residual errors remain to be measured. The limitations are primarily in the tolerance on the phase and amplitude of the antenna illumination function.

Figure 41.5 shows the monopulse beam patterns. The first is the received sum pattern that is generated by a feed that provides the energy from the reflector or phased array antenna through two ports in equal amounts and summed in phase in a monopulse comparator shown in Fig. 41.6. The second is the difference pattern generated by providing the energy through the same two ports in equal amounts but taken out with a phase difference of π radians, giving a null at the center. A target located at the center of the same beam would receive a strong signal from the sum pattern with which the target could be detected and ranged. The received difference pattern would produce a null return, indicating the target was at the center of the beam. If the target were off the null, the signal output or difference voltage would be almost linear proportional to the distance off the center (off-axis), as shown in the figure. This output of the monopulse processor is the real part of the dot product of the complex sums and the difference signals divided by the absolute magnitude of the sum signal squared, i.e.,

$$e_d = \mathrm{Re}\left[\frac{\Sigma \cdot \Delta}{|\Sigma|^2}\right] \tag{41.8}$$

The random instrumentation measurement errors in the angle estimator are caused by phase and amplitude errors of the antenna illumination function. In reflector systems, such errors occur because of the position of the feedhorn, differences in electrical length between the feed and the monopulse comparator, mechanical precision of the reflector, and its mechanical rotation. In phased array radars, these errors are a function of the phase shifters, time delay units, and combiners between the antenna elements and the monopulse comparator as well as the precision of the array. Although these errors are random, they may have correlation intervals considerably longer than the white noise considered in the thermal-noise random error and may depend upon

the flight path of the target. For a target headed radially from or toward the radar, the correlation period of angle-measurement instrumental errors is essentially the tracking period. For crossing targets, the correlation interval may be pulse to pulse.

As in the estimate of range, the propagation effects of refraction and multipath also enter into the tracking error. The bias error in range and elevation angle by refraction can be estimated as

$$\Delta R = 0.007\ N_s \text{ cosecant } E_o \text{ (meters)} \tag{41.9}$$

$$\Delta E_o = N_s \cot E_o \text{ (μrad)}$$

where N_s is the surface refractivity and E_o is the elevation angle [Barton and Ward, 1984].

One can calculate the average error in multipath. However, one cannot correct for it as in refraction since the direction of the error cannot be known in advance unless there are controlled conditions such as in a carefully controlled experiment. Hence, the general approach is to design the antenna sidelobes to be as low as feasible and accept the multipath error that occurs when tracking close to the horizon. There has been considerable research to find means to reduce the impact, including using very wide bandwidths to separate the direct path from the multipath return.

Tracking Filter Performance

Target tracking based on processing returns from multiple CPIs generally provides a target position and velocity estimate of greater accuracy than the single-CPI measurement accuracy delineated in Table 41.5. In principle, the error variance of the estimated target position with the target moving at a constant velocity is approximately $4/n \cdot \sigma_m^2$ where n is the number of independent measurements processed by the track filter and σ_m is the single measurement accuracy. In practice, the variance reduction factor afforded by a track filter is often limited to about an order of magnitude because of the reasons summarized in the following paragraphs.

Track filtering generally provides smoothing and prediction of target position and velocity via a recursive prediction-correction process. The filter predicts the target's position at the time of the next measurement based on the current smoothed estimates of position, velocity, and possibly acceleration. The subsequent difference between the measured position at this time and the predicted position is used to update the smoothed estimates. The update process incorporates a weighting vector that determines the relative significance given the track filter prediction versus the new measurement in updating the smoothed estimate.

Target model fidelity and adaptivity are fundamental issues in track filter mechanization. Independent one-dimensional tracking loops may be implemented to control pulse-to-pulse range gate positioning and antenna pointing. The performance of one-dimensional polynomial algorithms, such as the alpha-beta filter, to track targets from one pulse to the next and provide modest smoothing is generally adequate. However, one-dimensional closed-loop tracking ignores knowledge of the equations of motion governing the target so that their smoothing and long-term prediction performance is relatively poor for targets with known equations of motion. In addition, simple one-dimensional tracking-loop filters do not incorporate any adaptivity or measure of estimation quality.

Kalman filtering addresses these shortcomings at the cost of significantly greater computational complexity. Target equations of motion are modeled explicitly such that the position, velocity, and potentially higher-order derivatives of each measurement dimension are estimated by the track filter as a state vector. The error associated with the estimated state vector is modeled via a covariance matrix that is also updated with each iteration of the track filter. The covariance matrix determines the weight vector used to update the smoothed state vector in order to incorporate such factors as measurement S/N and dynamic target maneuvering.

Smoothing performance is constrained by the degree of *a priori* knowledge of the target's kinematic motion characteristics. For example, Kalman filtering can achieve significantly better error reduction against ballistic or orbital targets than against maneuvering aircraft. In the former case the equations of motion are explicitly known, while the latter case imposes motion model error because of the presence of unpredictable pilot or guidance system commands. Similar considerations apply to the fidelity of the track filter's model of radar measurement error. Failure to consider the impact of correlated measurement errors may result in underestimating track error when designing the system.

Defining Terms

Coherent: Integration where magnitude and phase of received signals are preserved in summation.

Noncoherent: Integration where only the magnitude of received signals is summed.

Phased array: Antenna composed of an aperture of individual radiating elements. Beam scanning is implemented by imposing a phase taper across the aperture to collimate signals received from a given angle of arrival.

Pulse compression: The processing of a wideband, coded signal pulse, of initially long time duration and low-range resolution, to result in an output pulse of time duration corresponding to the reciprocal of the bandwidth.

Radar cross section (RCS): A measure of the reflective strength of a radar target; usually represented by the symbol σ, measured in square meters, and defined as 4π times the ratio of the power per unit solid angle scattered in a specified direction of the power unit area in a plane wave incident on the scatterer from a specified direction.

41.2 Continuous Wave Radar

James C. Wiltse

Continuous wave (CW) radar employs a transmitter which is on all or most of the time. Unmodulated CW radar is very simple and is able to detect the **Doppler-frequency shift** in the return signal from a target which has a component of motion toward or away from the transmitter. While such a radar cannot measure range, it is used widely in applications such as police radars, motion detectors, burglar alarms, proximity fuzes for projectiles or missiles, illuminators for semiactive missile guidance systems (such as the Hawk surface-to-air missile), and scatterometers (used to measure the scattering properties of targets or clutter such as terrain surfaces) [Nathanson, 1991; Saunders, 1990; Ulaby and Elachi, 1990].

Modulated versions include frequency-modulated (FM/CW), interrupted frequency-modulated (IFM/CW), and phase-modulated. Typical waveforms are indicated in Fig. 41.7. Such systems are used in altimeters, Doppler navigators, proximity fuzes, over-the-horizon radar, and active seekers for terminal guidance of air-to-surface missiles. The term *continuous* is often used to indicate a relatively long waveform (as contrasted to pulse radar using short pulses) or a radar with a high duty cycle (for instance, 50% or greater, as contrasted with the typical duty cycle of less than 1% for the usual pulse radar). As an example of a long waveform, planetary radars may transmit for up to 10 hours and are thus considered to be CW [Freiley et al., 1992]. Another example is interrupted CW (or **pulse-Doppler**) radar, where the transmitter is pulsed at a high rate for 10 to 60% of the total time [Nathanson, 1991]. All of these modulated CW radars are able to measure range.

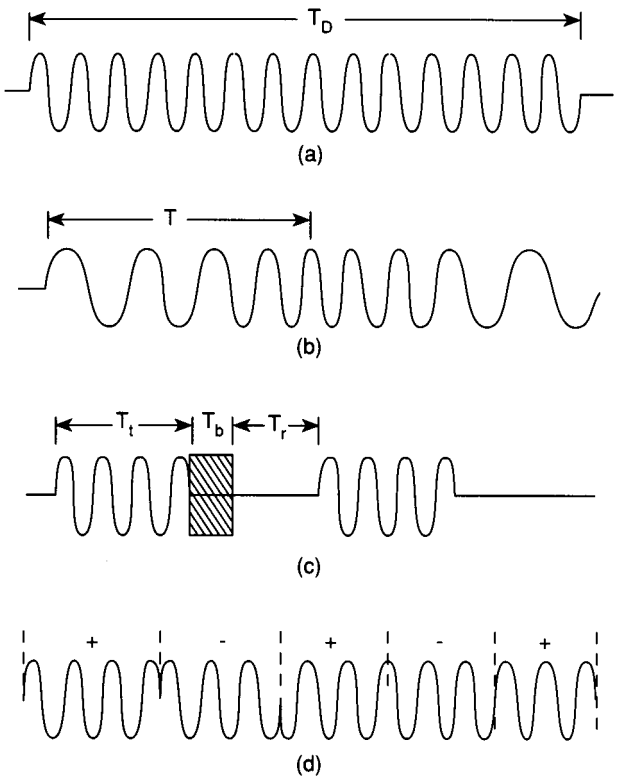

FIGURE 41.7 Waveforms for the general class of CW radar: (a) continuous sine wave CW; (b) frequency modulated CW; (c) interrupted CW; (d) binary phase-coded CW.

The first portion of this section discusses concepts, principles of operation, and limitations. The latter portion describes various applications. In general, CW radars have several potential advantages over pulse radars. Advantages include simplicity and the facts that the transmitter leakage is used as the local oscillator, transmitter spectral spread is minimal (not true for wide-deviation FM/CW), and peak power is the same as (or only a little greater than) the average power. This latter situation means that the radar is less detectable by intercepting equipment.

The largest disadvantage for CW radars is the need to provide antenna isolation (reduce spillover) so that the transmitted signal does not interfere with the receiver. In a pulse radar, the transmitter is off before the receiver is enabled (by means of a duplexer and/or receiver-protector switch). Isolation is frequently obtained in the CW case by employing two antennas, one for transmit and one for reception. When this is done, there is also a reduction of close-in clutter return from rain or terrain. A second disadvantage is the existence of noise sidebands on the transmitter signal which reduce sensitivity because the Doppler frequencies are relatively close to the carrier. This is considered in more detail below.

CW Doppler Radar

If a sine wave signal were transmitted, the return from a moving target would be Doppler-shifted in frequency by an amount given by the following equation:

$$f_d = \frac{2v_r f_T}{c} = \text{Doppler frequency} \tag{41.10}$$

where f_T = transmitted frequency; c = velocity of propagation, 3×10^8 m/s; and v_r = radial component of velocity between radar and target.

Radio Engineering during World War II

No single event had a greater effect on electrical engineering than the Second World War. The years from 1939 to 1945 saw a radical change in the field of electrical engineering as it was transformed from a specialty with well-defined applications, primarily in power and communications, into the source for the most powerful and pervasive technologies of the 20th century.

In the heat of war, radio engineering was transformed into electronics. Electronics became a technology to harness the most advanced and subtle knowledge of the very parts of matter itself, manipulating electrons and electromagnetic waves in an effort not simply to communicate, but to detect, control, and even as some saw it, think. The tremendous pressures of wartime development forged a new relationship between engineers and physical scientists. More and more the realms and tasks of both overlapped and advances in electronics made use of the latest findings, theories, and techniques of physicists and chemists, while scientific discovery came to rely progressively more on the instrumentation created by engineers. This merging of science and technology was one of the war's greatest legacies and has continued to shape our times.

The enormous demands that the war put on the world also marked the indispensable and strategic place of electric power. Electric power rose to the status of necessity, not only increasing the general industrial consumption of power, but also highlighting specialized uses of electricity, such as the production of aluminum and explosives, that were critical to the pursuit of the war. In Europe, the targeting of power plants and dams by both allied and axis bombers provided proof of electricity's central place in modern warfare.

The postwar years were ones of growth and change, accompanied by tensions and conflicts both within the engineering community and in society at large. The war was, again, followed by unprecedented prosperity, but at this time it was in a world where the dangers and possible consequences of international conflict were distressingly obvious. The efforts of engineers were, therefore, divided between the creation of a consumer society, powered by electricity and tuned by electronics, and the demands of national and international security. Alongside this division was another division of the engineering community. The split between the AIEE and the IRE became less and less justifiable and in the coming decades, this problem was solved, as engineers everywhere recognized their common interests. (Courtesy of the IEEE Center for the History of Electrical Engineering.)

TABLE 41.8 Doppler Frequencies for Several Transmitted Frequencies and Various Relative Speeds

Microwave Frequency—f_T	Relative Speed			
	1 m/s	300 m/s	1 mph	600 mph
3 GHz	20 Hz	6 kHz	8.9 Hz	5.4 kHz
10 GHz	67 Hz	20 kHz	30 Hz	17.9 kHz
35 GHz	233 Hz	70 kHz	104 Hz	63 kHz
95 GHz	633 Hz	190 kHz	283 Hz	170 kHz

Using Eq. (41.10) the Doppler frequencies have been calculated for several speeds and are given in Table 41.8.

As may be seen, the Doppler frequencies at 10 GHz (X-band) range from 30 Hz to about 18 kHz for a speed range between 1 and 600 mph. The spectral width of these Doppler frequencies will depend on target fluctuation and acceleration, antenna scanning effects, frequency variation in oscillators or components (for example, due

to microphonism from vibrations), but most significantly, by the spectrum of the transmitter, which inevitably will have noise sidebands that extend much higher than these Doppler frequencies, probably by orders of magnitude. At higher microwave frequencies the Doppler frequencies are also higher and more widely spread. In addition, the spectra of higher frequency transmitters are also wider, and, in fact, the transmitter noise-sideband problem is usually worse at higher frequencies, particularly at millimeter wavelengths (i.e., above 30 GHz). These characteristics may necessitate frequency stabilization or phase locking of transmitters to improve the spectra.

Simplified block diagrams for CW Doppler radars are shown in Fig. 41.8. The transmitter is a single-frequency source, and leakage (or coupling) of a small amount of transmitter power serves as a local oscillator signal in the mixer. The transmitted signal will produce a Doppler-shifted return from a moving target. In the case of scatterometer measurements, where, for example, terrain reflectivity is to be measured, the relative motion may be produced by moving the radar (perhaps on a vehicle) with respect to the stationary target [Wiltse et al., 1957]. The return signal is collected by the antenna and then also fed to the mixer. After mixing with the transmitter leakage, a difference frequency will be produced which is the Doppler shift. As indicated in Table 41.8, this difference is apt to range from low audio to over 100 kHz, depending on relative speeds and choice of microwave frequency. The Doppler amplifier and filters are chosen based on the information to be obtained, and this determines the amplifier bandwidth and gain, as well as the filter bandwidth and spacing. The transmitter leakage may include reflections from the antenna and/or nearby clutter in front of the antenna, as well as mutual coupling between antennas in the two-antenna case.

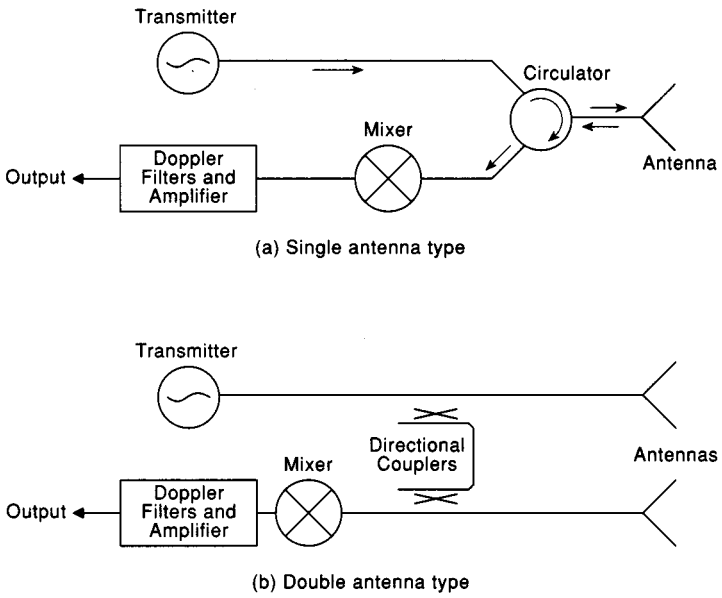

FIGURE 41.8 Block diagrams of CW-Doppler radar systems: (a) single antenna type; (b) double antenna type.

The detection range for such a radar can be obtained from the following [Nathanson, 1991]:

$$R^4 = \frac{\overline{P}_T G_T L_T A_e L_R L_p L_a L_s \delta_T}{(4\pi)^2 k T_s b (S/N)} \tag{41.11}$$

where R = the detection range of the desired target.
$-P_T$ = the average power during the pulse.
G_T = the transmit power gain of the antenna with respect to an omnidirectional radiator.

L_T = the losses between the transmitter output and free space including power dividers, waveguide or coax, radomes, and any other losses not included in A_e.

A_e = the effective aperture of the antenna, which is equal to the projected area in the direction of the target times the efficiency.

L_R = the receive antenna losses defined in a manner similar to the transmit losses.

L_p = the beam shape and scanning and pattern factor losses.

L_a = the two-way-pattern propagation losses of the medium; often expressed as $\exp(-2\propto R)$, where $\propto$ is the attenuation constant of the medium and the factor 2 is for a two-way path.

L_s = signal-processing losses that occur for virtually every waveform and implementation.

δ_T = the radar cross-sectional area of the object that is being detected.

k = Boltzmann's constant (1.38×10^{-23} W-s/K).

T_s = system noise temperature.

b = Doppler filter or *speedgate* bandwidth.

S/N = signal-to-noise ratio.

$S_{\min}$ = the minimum detectable target-signal power that, with a given probability of success, the radar can be said to *detect*, *acquire*, or *track* in the presence of its own thermal noise or some external interference. Since all these factors (including the target return itself) are generally noiselike, the criterion for a detection can be described only by some form of probability distribution with an associated probability of detection P_D and a probability that, in the absence of a target signal, one or more noise or interference samples will be mistaken for the target of interest.

While the Doppler filter should be a matched filter, it usually is wider because it must include the target spectral width. There is usually some compensation for the loss in detectability by the use of postdetection filtering or integration. The S/N ratio for a CW radar must be at least 6 dB, compared with the value of 13 dB required with pulse radars when detecting steady targets [Nathanson, 1991, p. 449].

The Doppler system discussed above has a maximum detection range based on signal strength and other factors, but it cannot measure range. The rate of change in signal strength as a function of range has sometimes been used in fuzes to estimate range closure and firing point, but this is a relative measure.

FM/CW Radar

The most common technique for determining target range is the use of frequency modulation. Typical modulation waveforms include sinusoidal, linear sawtooth, or triangular, as illustrated in Fig. 41.9. For a linear sawtooth, a frequency increasing with time may be transmitted. Upon being reflected from a stationary point target, the same linear frequency change is reflected back to the receiver, except it has a time delay which is related to the range to the target. The time is $T = (2R)/c$, where R is the range. The received signal is mixed with the transmit signal, and the difference or beat frequency (F_b) is obtained. (The sum frequency is much higher and is rejected by filtering.) For a stationary target this is given by

$$F_b = \frac{4R}{c} \cdot \Delta F \cdot F_m \tag{41.12}$$

where ΔF = frequency deviation and F_m = modulation rate.

The beat frequency is constant except near the turn-around region of the sawtooth, but, of course, it is different for targets at different ranges. (If it is desired to have a constant intermediate frequency for different ranges, which is a convenience in receiver design, then the modulation rate or the frequency deviation must be adjusted.) Multiple targets at a variety of ranges will produce multiple-frequency outputs from the mixer and frequently are handled in the receiver by using multiple range-bin filters.

If the target is moving with a component of velocity toward (or away) from the radar, then there will be a Doppler frequency component added to (or subtracted from) the difference frequency (F_b), and the Doppler will be slightly higher at the upper end of the sweep range than at the lower end. This will introduce an

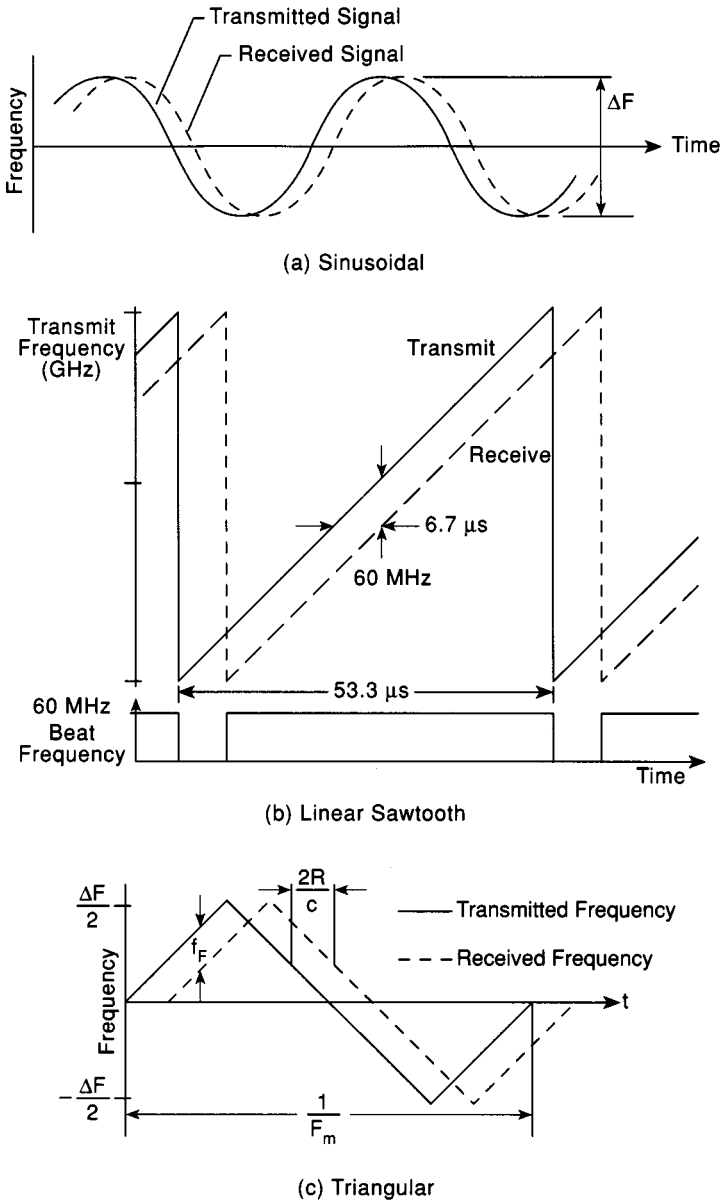

FIGURE 41.9 Frequency vs. time waveforms for FM/CW radar: (a) sinusoidal, (b) linear sawtooth, (c) triangular modulations.

uncertainty or ambiguity in the measurement of range, which may or may not be significant, depending on the parameters chosen and the application. For example, if the Doppler frequency is low (as in an altimeter) and/or the difference frequency is high, the error in range measurement may be tolerable. For the symmetrical triangular waveform, a Doppler less than F_b averages out, since it is higher on one-half of a cycle and lower on the other half. With a sawtooth modulation, only a decrease or increase is noted, since the frequencies produced in the transient during a rapid flyback are out of the receiver passband. Exact analyses of triangular, sawtooth, dual triangular, dual sawtooth, and combinations of these with noise have been carried out by Tozzi [1972]. Specific design parameters are given later in this chapter for an application utilizing sawtooth modulation in a **missile terminal guidance seeker**.

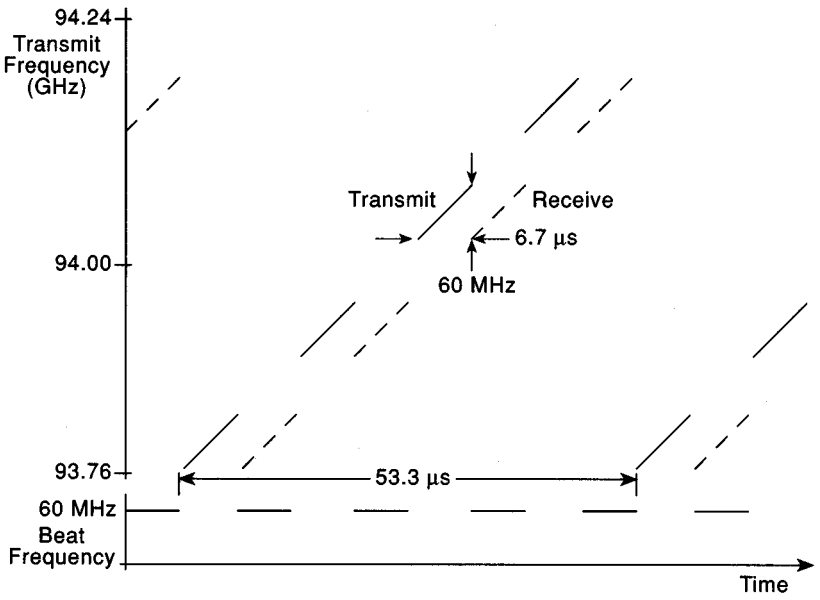

FIGURE 41.10 Interrupted FM/CW waveform. (*Source:* S.O. Piper, "MMW seekers," in *Principles and Applications of Millimeter Wave Radar*, N. Currie and C. E. Brown, Eds., Norwood, Mass.: Artech House, 1987, p. 683. With permission.)

For the case of sinusoidal frequency modulation the spectrum consists of a series of lines spaced away from the carrier by the modulating frequency or its harmonics. The amplitudes of the carrier and these sidebands are proportional to the values of the Bessel functions of the first kind (J_n, $n = 0, \ldots 1, \ldots 2, \ldots 3, \ldots$), whose argument is a function of the modulating frequency and range. By choosing a particular modulating frequency, the values of the Bessel functions and thus the characteristics of the spectral components can be influenced. For instance, the signal variation with range at selected ranges can be optimized, which is important in fuzes. A short-range dependence that produces a rapid increase in signal, greater than that corresponding to the normal range variation, is beneficial in producing well-defined firing signals. This can be accomplished by proper choice of modulating frequency and filtering to obtain the signal spectral components corresponding to the appropriate order of the Bessel function. In a similar fashion, spillover and/or reflections from close-in objects can be reduced by filtering to pass only certain harmonics of the modulating frequency (F_m). Receiving only frequencies near $3F_m$ results in considerable spillover rejection, but at a penalty of 4 to 10 dB in signal-to-noise [Nathanson, 1991].

For the sinusoidal modulation case, Doppler frequency contributions complicate the analysis considerably. For details of this analysis the reader is referred to Saunders [1990] or Nathanson [1991].

Interrupted Frequency-Modulated CW (IFM/CW)

To improve isolation during reception, the IFM/CW format involves preventing transmission for a portion of the time during the frequency change. Thus, there are frequency gaps, or interruptions, as illustrated in Fig. 41.10. This shows a case where the transmit time equals the round-trip propagation time, followed by an equal time for reception. This duty factor of 0.5 for the waveform reduces the average transmitted power by 3 dB relative to using an interrupted transmitter. However, the improvement in the isolation should reduce the system noise by more than 3 dB, thus improving the signal-to-noise ratio [Piper, 1987]. For operation at short range, Piper points out that a high-speed switch is required [1987]. He also points out that the ratio of frequency deviation to beat frequency should be an even integer and that the minimum ratio is typically 6, which produces an out-of-band loss of 0.8 dB.

IFM/CW may be compared with pulse compression radar if both use a wide bandwidth. Pulse compression employs a "long" pulse (i.e., relatively long for a pulse radar) with a large frequency deviation or "chirp." A long pulse is often used when a transmitter is peak-power limited, because the longer pulse produces more

energy and gives more range to targets. The frequency deviation is controlled in a predetermined way (frequently a linear sweep) so that a matched filter can be used in the receiver. The large time-bandwidth product permits the received pulse to be compressed in time to a short pulse in order to make an accurate range measurement. A linear-sawtooth IFM/CW having similar pulse length, frequency deviation, and pulse repetition rate would thus appear similar, although arrived at from different points of view.

Applications

Space does not permit giving a full description of the many applications mentioned at the beginning of this chapter, but several will be discussed.

Radar Proximity Fuzes

Projectiles or missiles designed to be aimed at ships or surface land targets often need a height-of-burst (HOB) sensor (or target detection device) to fire or fuze the warhead at a height of a few meters. There are two primary generic methods of sensing or measuring height to generate the warhead fire signal. The most obvious, and potentially the most accurate, is to measure target round trip propagation delay employing conventional radar ranging techniques. The second method employs a simple CW Doppler radar or variation thereof, with loop gain calibrated in a manner that permits sensing the desired burst height by measurement of target return signal amplitude and/or rate of change. Often the mission requirements do not justify the complexity and cost of the radar ranging approach. Viable candidates are thus narrowed down to variations on the CW doppler fuze.

In its simplest form, the CW Doppler fuze consists of a fractional watt RF oscillator, homodyne detector, Doppler amplifier, Doppler envelope detector, and threshold circuit. When the Doppler envelope amplitude derived from the returned signal reaches the preset threshold, a fire signal is generated. The height at which the fire signal occurs depends on the radar loop gain, threshold level, and target reflectivity. Fuze gain is designed to produce the desired height of burst under nominal trajectory angle and target reflectivity conditions, which may have large fluctuations due to glint effects, and deviations from the desired height due to antenna gain variations with angle, target reflectivity, and fuze gain tolerances are accepted. A loop gain change of 6 dB (2 to 1 in voltage), whether due to a change in target reflection coefficient, antenna gain, or whatever, will result in a 2 to 1 HOB change.

HOB sensitivity to loop gain factors can be reduced by utilizing the slope of the increasing return signal, or so-called rate-of-rise. Deriving HOB solely from the rate-of-rise has the disadvantage of rendering the fuze sensitive to fluctuating signal levels such as might result from a scintillating target. The use of logarithmic amplifiers decreases the HOB sensitivity to the reflectivity range. An early (excessively high) fire signal can occur if the slope of the signal fluctuations equals the rate-of-rise threshold of the fuze. In practice a compromise is generally made in which Doppler envelope amplitude and rate-of-rise contribute in some proportion of HOB.

Another method sometimes employed to reduce HOB sensitivity to fuze loop gain factors and angle of fall is the use of FM sinusoidal modulation of suitable deviation to produce a range correlation function comprising the zero order of a Bessel function of the first kind. The subject of sinusoidal modulation is quite complex, but has been treated in detail by Saunders [1990, pp. 1422–1446 and 144.41]. The most important aspects of fuze design have to do with practical problems such as low cost, small size, ability to stand very high-g accelerations, long life in storage, and countermeasures susceptibility.

Police Radars

Down-the-road police radars, which are of the CW Doppler type, operate at 10.525, 24.150, or in the 33.4 to 36.0 GHz range, frequencies approved in the United States by the Federal Communications Commission. Half-power beamwidths are typically in the 0.21 to 0.31 radian range. The sensitivity is usually good enough to provide a range exceeding 800 meters. Target size has a dynamic range of 30 dB (from smallest cars or motorcycles to large trucks). This means that a large target can be seen well outside the antenna 3-dB point at a range exceeding the range of a smaller target near the center of the beam. Thus there can be uncertainty about which vehicle is the target. Fisher [1992] has given a discussion of a number of the limitations of these systems, but in spite of these factors probably a hundred thousand have been built.

The designs typically have three amplifier gains for detection of short, medium, or maximum range targets, plus a squelch circuit so that sudden spurious signals will not be counted. The Doppler signal is integrated and this direct current provides a speed readout. Provision is made for calibration to assure the accuracy of the readings.

TABLE 41.9 Parameters for Two Commercial Altimeters

Modulation Frequency	Frequency Deviation	Prime Power	Weight (pounds)	Radiated Power
Bendix ALA-52A	150 Hz	130 MHz	30 W	11*
Collins ALT-55	100 kHz	100 MHz	8	350 mW

*Not including antenna and indicator.

Altimeters

A very detailed discussion of FM/CW altimeters has been given by Saunders [1990, pp. 14.34–14.36], in which he has described modern commercial products built by Bendix and Collins. The parameters will be summarized below and if more information is needed, the reader may want to turn to other references [Saunders, 1990; Bendix Corp., 1982; and Maoz et al., 1991]. In his material, Saunders gives a general overview of modern altimeters, all of which use wide-deviation FM at a low modulation frequency. He discusses the limitations on narrowing the antenna pattern, which must be wide enough to accommodate attitude changes of the aircraft. Triangular modulation is used, since for this waveform the Doppler averages out, and dual antennas are employed. There may be a step error or quantization in height (which could be a problem at low altitudes), due to the limitation of counting zero crossings. A difference of one zero crossing (i.e., 1/2 Hz) corresponds to 3/4 meter for a frequency deviation of 100 MHz. Irregularities are not often seen, however, since meter response is slow. Also, if terrain is rough, there will be actual physical altitude fluctuations. Table 41.9 shows some of the altimeters' parameters. These altimeters are not acceptable for military aircraft, because their relatively wide-open front ends make them potentially vulnerable to electronic countermeasures. A French design has some advantages in this respect by using a variable frequency deviation, a difference frequency that is essentially constant with altitude, and a narrowband front-end amplifier [Saunders, 1990].

Doppler Navigators

These systems are mainly sinusoidally modulated FM/CW radars employing four separate downward looking beams aimed at about 15 degrees off the vertical. Because commercial airlines have shifted to nonradar forms of navigation, these units are designed principally for helicopters. Saunders [1990] cites a particular example of a commercial unit operating at 13.3 GHz, employing a Gunn oscillator as the transmitter, with an output power of 50 mW, and utilizing a 30-kHz modulation frequency. A single microstrip antenna is used. A low-altitude equipment (below 15,000 feet), the unit weighs less than 12 pounds. A second unit cited has an output power of 300 mW, dual antennas, dual modulating frequencies, and an altitude capability of 40,000 feet.

Millimeter-Wave Seeker for Terminal Guidance Missile

Terminal guidance for short-range (less than 2 km) air-to-surface missiles has seen extensive development in the last decade. Targets such as tanks are frequently immersed in a clutter background which may give a radar return that is comparable to that of the target. To reduce the clutter return in the antenna footprint, the antenna beamwidth is reduced by going to millimeter wavelengths. For a variety of reasons the choice is usually a frequency near 35 or 90 GHz. Antenna beamwidth is inversely proportional to frequency, so in order to get a reduced beamwidth we would normally choose 90 GHz; however, more deleterious effects at 90 GHz due to atmospheric absorption and scattering can modify that choice. In spite of small beamwidths, the clutter is a significant problem, and in most cases signal-to-clutter is a more limiting condition than signal-to-noise in determining range performance. Piper [1987] has done an excellent job of analyzing the situation for 35- and 90-GHz pulse radar seekers and comparing those with a 90-GHz FM/CW seeker. His FM/CW results will be summarized below.

In his approach to the problem, Piper gives a summary of the advantages and disadvantages of a pulse system compared to the FM/CW approach. Most of these have already been covered in earlier sections, but one difficulty for the FM/CW can be emphasized again. That is the need for a highly linear sweep, and, because of the desire for the wide bandwidth, this requirement is accentuated. The wide bandwidth is desired in order to average the clutter return and to smooth the glint effects. In particular, glint occurs from a complex target because of

the vector addition of coherent signals scattered back to the receiver from various reflecting surfaces. At some angles the vectors may add in phase (constructively) and at others they may cancel, and the effect is specifically dependent on wavelength. For a narrowband system, glint may provide a very large signal change over a small variation of angle, but, of course, at another wavelength it would be different. Thus, very wide bandwidth is desirable from this smoothing point of view, and typical numbers used in millimeter-wave radars are in the 450- to 650-MHz range. Piper chose 480 MHz.

Another tradeoff involves the choice of FM waveform. Here the use of a triangular waveform is undesirable because the Doppler frequency averages out and Doppler compensation is then required. Thus the sawtooth version is chosen, but because of the large frequency deviation desired, the difficulty of linearizing the frequency sweep is made greater. In fact many components must be extremely wideband, and this generally increases cost and may adversely affect performance. On the other hand, the difference frequency (F_b) and/or the intermediate frequency (F_{IF}) will be higher and thus further from the carrier, so the phase noise will be lower. After discussing the other tradeoffs, Piper chose 60 MHz for the beat frequency.

With a linear FM/CW waveform, the inverse of the frequency deviation provides the theoretical time resolution, which is 2.1 ns for 480 MHz (or range resolution of 0.3 meter). For an RF sweep linearity of 300 kHz, the range resolution is actually 5 meters at the 1000-meter nominal search range. (The system has a mechanically scanned antenna.) An average transmitting power of 25 mW was chosen, which was equal to the average power of the 5-W peak IMPATT assumed for the pulse system. The antenna diameter was 15 cm. For a target radar cross section of 20 m^2 and assumed weather conditions, the signal-to-clutter and signal-to-noise ratios were calculated and plotted for ranges out to 2 km and for clear weather or 4 mm per hour rainfall. The results show that for 1 km range the target-to-clutter ratios are higher for the FM/CW case than the pulse system in clear weather or in rain, and target-to-clutter is the determining factor.

Summary Comments

From this brief review it is clear that there are many uses for CW radars, and various types (such as fuzes) have been produced in large quantities. Because of their relative simplicity, today there are continuing trends toward the use of digital processing and integrated circuits. In fact, this is exemplified in articles describing FM/CW radars built on single microwave integrated circuit chips [Maoz et al., 1991; Chang et al., 1995].

Defining Terms

Doppler-frequency shift: The observed frequency change between the transmitted and received signal produced by motion along a line between the transmitter/receiver and the target. The frequency increases if the two are closing and decreases if they are receding.

Missile terminal guidance seeker: Located in the nose of a missile, a small radar with short-range capability which scans the area ahead of the missile and guides it during the terminal phase toward a target such as a tank.

Pulse Doppler: A coherent radar, usually having high pulse repetition rate and duty cycle and capable of measuring the Doppler frequency from a moving target. Has good clutter suppression and thus can see a moving target in spite of background reflections.

Further Information

For a general treatment, including analysis of clutter effects, Nathanson's [1991] book is very good and generally easy to read. For extensive detail and specific numbers in various actual cases, Saunders [1990] gives good coverage. The treatment of millimeter-wave seekers by Piper [1987] is excellent, both comprehensive and easy to read.

42.1 Lightwave Waveguides

Samuel O. Agbo

Lightwave waveguides fall into two broad categories: dielectric slab waveguides and optical fibers. As illustrated in Fig. 42.1, slab waveguides generally consist of a middle layer (the film) of **refractive index** n_1 and lower and upper layers of refractive indices n_2 and n_3, respectively.

Optical fibers are slender glass or plastic cylinders with annular cross sections. The core has a refractive index, n_1, which is greater than the refractive index, n_2, of the annular region (the cladding). Light propagation is confined to the core by total internal reflection, even when the fiber is bent into curves and loops. Optical fibers fall into two main categories: step-index and graded-index (GRIN) fibers. For step-index fibers, the refractive index is constant within the core. For GRIN fibers, the refractive index is a function of radius r given by

$$n(r) = \begin{cases} n_1\left[1 - 2\Delta\left(\dfrac{r}{a}\right)^{\alpha}\right]^{1/2} & ; r < a \\ n_1(1-2\Delta)^{1/2} = n_2 ; & a < r \end{cases} \tag{42.1}$$

In Eq. (42.1), Δ is the **relative refractive index difference**, a is the core radius, and α defines the type of graded-index profile. For triangular, parabolic, and step-index profiles, α is, respectively, 1, 2, and ∞. Figure 42.2 shows the raypaths in step-index and graded-index fibers and the cylindrical coordinate system used in the analysis of lightwave propagation through fibers. Because rays propagating within the core in a GRIN fiber undergo progressive refraction, the raypaths are curved (sinusoidal in the case of parabolic profile).

Ray Theory

Consider Fig 42.3, which shows possible raypaths for light coupled from air (refractive index n_0) into the film of a slab waveguide or the core of a step-index fiber. At each interface, the transmitted raypath is governed by Snell's law. As θ_0 (the acceptance angle from air into the waveguide) decreases, the angle of incidence θ_i increases

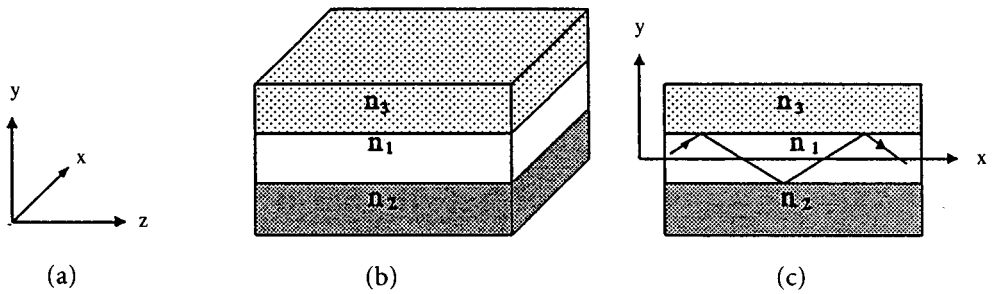

FIGURE 42.1 Dielectric slab waveguide: (a) the Cartesian coordinates used in analysis of slab waveguides; (b) the slab waveguide; (c) light guiding in a slab waveguide.

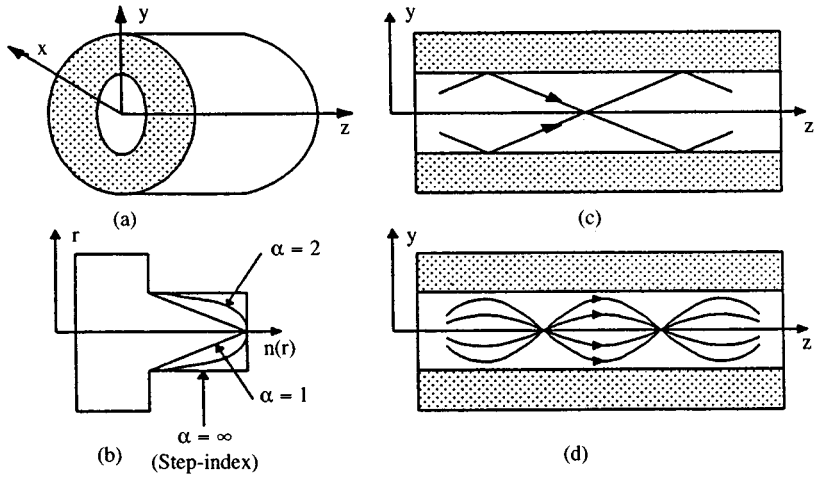

FIGURE 42.2 The optical fiber: (a) the cylindrical coordinate system used in analysis of optical fibers; (b) some graded-index profiles; (c) raypaths in step-index fiber; (d) raypaths in graded-index fiber.

until it equals the critical angle, θ_c, making θ_0 equal to the maximum acceptance angle, θ_a. According to ray theory, all rays with acceptance angles less than θ_a propagate in the waveguide by total internal reflections. Hence, the numerical aperture (NA) for the waveguide, a measure of its light-gathering ability, is given by

$$NA = n_0 \sin \theta a = n_1 \sin\left(\frac{\pi}{2} - \theta_c\right) \tag{42.2}$$

By Snell's law, $\sin \theta_c = n_2/n_1$. Hence,

$$NA = \left[n_1^2 - n_2^2\right]^{1/2} \tag{42.3}$$

For step-index fibers, the preceding analysis applies to **meridional rays**. Skew (nonmeridional) rays have larger maximum acceptance angles, θ_{as}, given by

$$\sin \theta_{as} = \frac{NA}{\cos \gamma} \tag{42.4}$$

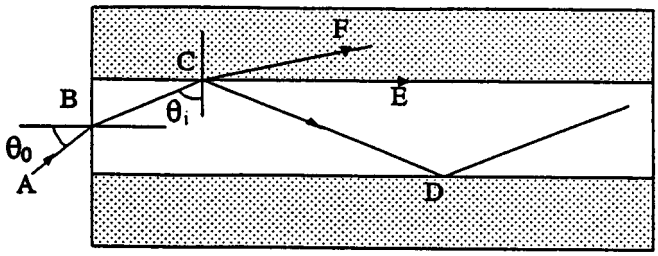

FIGURE 42.3 Possible raypaths for light coupled from air into a slab waveguide or a step-index fiber.

where NA is the numerical aperture for meridional rays and γ is the angle between the core radius and the projection of the ray onto a plane normal to the fiber axis.

Wave Equation for Dielectric Materials

Only certain discrete angles, instead of all acceptance angles less than the maximum acceptance angle, lead to guided propagation in lightwave waveguides. Hence, ray theory is inadequate, and wave theory is necessary, for analysis of light propagation in optical waveguides.

For lightwave propagation in an unbounded dielectric medium, the assumption of a linear, homogeneous, charge-free, and nonconducting medium is appropriate. Assuming also sinusoidal time dependence of the fields, the applicable Maxwell's equations are

$$\nabla \times \mathbf{E} = -j\omega\mu\mathbf{H} \tag{42.5a}$$

$$\nabla \times \mathbf{H} = j\omega\epsilon\mathbf{E} \tag{42.5b}$$

$$\nabla \times \mathbf{E} = 0 \tag{42.5c}$$

$$\nabla \times \mathbf{H} = 0 \tag{42.5d}$$

The resulting wave equations are

$$\nabla^2\mathbf{E} - \gamma^2\mathbf{E} = 0 \tag{42.6a}$$

$$\nabla^2\mathbf{H} - \gamma^2\mathbf{H} = 0 \tag{42.6b}$$

where

$$\gamma^2 = \omega^2\mu\epsilon = (j\kappa)^2 \tag{42.7}$$

and

$$\kappa = n\kappa_0 = \omega\sqrt{\mu\epsilon} = \frac{\omega}{\nu} \tag{42.8}$$

In Eq. (42.8) κ is the phase propagation constant and n is the refractive index for the medium, while κ_0 is the phase propagation constant for free space. The velocity of propagation in the medium is $\nu = 1/\sqrt{\mu\epsilon}$.

Modes in Slab Waveguides

Consider a plane wave polarized in the y direction and propagating in z direction in an unbounded dielectric medium in the Cartesian coordinates. The vector wave equations (42.6) lead to the scalar equations:

$$\frac{\partial^2 E_y}{\partial z} - \partial^2 E_y = 0 \tag{42.9a}$$

$$\frac{\partial^2 H_x}{\partial z} - \partial^2 H_x = 0 \tag{42.9b}$$

The solutions are

$$E_y = A e^{j(\omega t - \kappa z)} \tag{42.10a}$$

$$H_x = \frac{-E_y}{\eta} = \frac{A}{\eta} e^{j(\omega t - \kappa z)} \tag{42.10b}$$

where A is a constant and $\eta = \sqrt{\mu\epsilon}$ is the intrinsic impedance of the medium.

Because the film is bounded by the upper and lower layers, the rays follow the zigzag paths as shown in Fig. 42.3. The upward and downward traveling waves interfere to create a standing wave pattern. Within the film, the fields transverse to the z axis, which have even and odd symmetry about the x axis, are given, respectively, by

$$E_y = A \cos(hy) e^{j(\omega t - \beta z)} \tag{42.11a}$$

$$E_y = A \sin(hy) e^{j(\omega t - \beta z)} \tag{42.11b}$$

where β and h are the components of κ parallel to and normal to the z axis, respectively. The fields in the upper and lower layers are evanescent fields decaying rapidly with attenuation factors α_3 and α_2, respectively, and are given by

$$E_y = A_3 e^{-\alpha_3\left(y - \frac{d}{2}\right)} e^{j(\omega t - \beta z)} \tag{42.12a}$$

$$E_y = A_2 e^{-\alpha_2\left(y + \frac{d}{2}\right)} e^{j(\omega t - \beta z)} \tag{42.12b}$$

Only waves with raypaths for which the total phase change for a complete (up and down) zigzag path is an integral multiple of 2π undergo constructive interference, resulting in guided modes. Waves with raypaths not satisfying this mode condition interfere destructively and die out rapidly. In terms of a raypath with an angle of incidence $\theta_i = \theta$ in Fig. 42.3, the mode conditions [Haus, 1984] for fields transverse to the z axis and with even and odd symmetry about the x axis are given, respectively, by

$$\tan\left(\frac{hd}{2}\right) = \frac{1}{n_1 \cos\theta}\left[n_1^2 \sin^2\theta - n_2^2\right]^{1/2} \tag{42.13a}$$

$$\tan\left(\frac{hd}{2} - \frac{\pi}{2}\right) = \frac{1}{n_1 \cos\theta}\left[n_1^2 \sin^2\theta - n_2^2\right]^{1/2} \tag{42.13b}$$

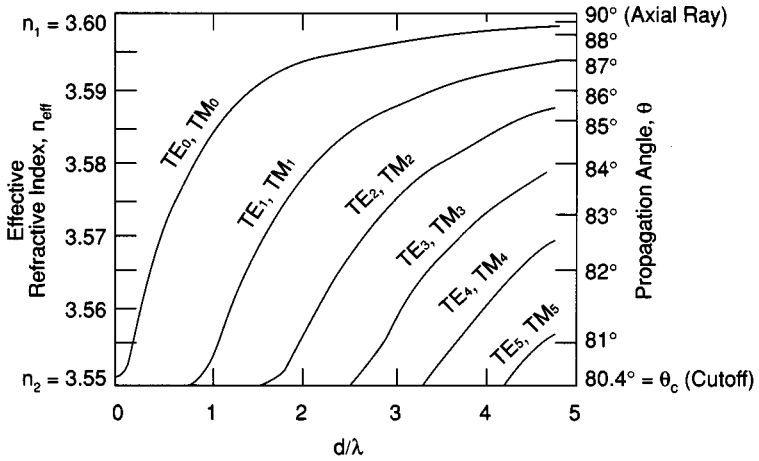

FIGURE 42.4 Mode chart for the symmetric slab waveguide with $n_1 = 3.6$, $n_2 = 3.55$.

where $h = \kappa \cos\theta = (2\pi n_1/\lambda)\cos\theta$ and λ is the free space wavelength.

Equations (42.13a) and (42.13b) are transcendental, have multiple solutions, and are better solved graphically. Let $(d/\lambda)_0$ denote the smallest value of d/λ, the film thickness normalized with respect to the wavelength, satisfying Eqs. (42.13a) and (42.13b). Other solutions for both even and odd modes are given by

$$\left(\frac{d}{\lambda}\right)_m = \left(\frac{d}{\lambda}\right)_0 + \frac{m}{2n_1 \cos\theta} \tag{42.14}$$

where m is a nonnegative integer denoting the order of the mode.

Figure 42.4 [Palais, 1992] shows a **mode chart** for a symmetrical slab waveguide obtained by solving Eqs. (42.13a) and (42.13b). For the TE_m modes, the E field is transverse to the direction (z) of propagation, while the H field lies in a plane parallel to the z axis. For the TM_m modes, the reverse is the case. The highest-order mode that can propagate has a value m given by the integer part of

$$m = \frac{2d}{\lambda}\left[n_1^2 - n_2^2\right]^{1/2} \tag{42.15}$$

To obtain a single-mode waveguide, d/λ should be smaller than the value required for $m = 1$, so that only the $m = 0$ mode is supported. To obtain a multimode waveguide, d/λ should be large enough to support many modes.

Shown in Fig. 42.5 are transverse mode patterns for the electric field in a symmetrical slab waveguide. These are graphical illustrations of the fields given by Eqs. (42.11) and (42.12). Note that, for TE_m, the field has m zeros in the film, and the evanescent field penetrates more deeply into the upper and lower layers for high-order modes.

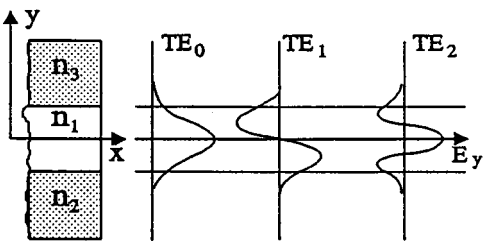

FIGURE 42.5 Transverse mode field patterns in the symmetric slab waveguide.

For asymmetric slab waveguides, the equations and their solutions are more complex than those for symmetric slab waveguides. Shown in Fig. 42.6 [Palais, 1992] is the mode chart for the asymmetric slab waveguide. Note that the TE_m and TM_m modes in this case have different

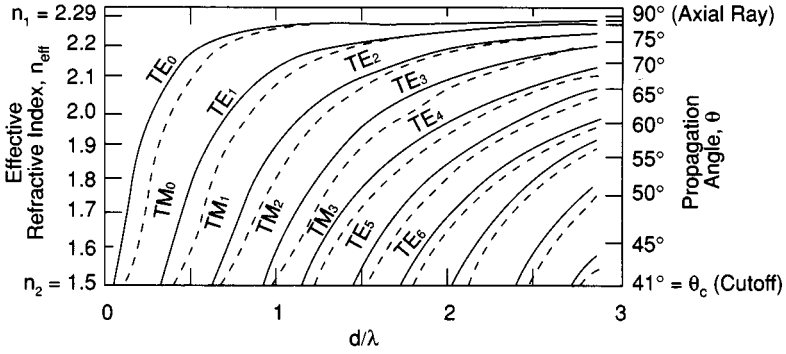

FIGURE 42.6 Mode chart for the asymmetric slab waveguide with $n_1 = 2.29$, $n_2 = 1.5$, and $n_3 = 1.0$.

propagation constants and do not overlap. By contrast, for the symmetric case, TE_m and TM_m modes are degenerate, having the same propagation constant and forming effectively one mode for each value of m.

Figure 42.7 shows typical mode patterns in the asymmetric slab waveguide. Note that the asymmetry causes the evanescent fields to have unequal amplitudes at the two boundaries and to decay at different rates in the two outer layers.

The preceding analysis of slab waveguides is in many ways similar to, and constitutes a good introduction to, the more complex analysis of cylindrical (optical) fibers. Unlike slab waveguides, cylindrical waveguides are bounded in two dimensions rather than one. Consequently, skew rays exist in optical fibers, in addition to the meridional rays found in slab waveguides. In addition to transverse modes similar to those found in slab waveguides, the skew rays give rise to hybrid modes in optical fibers.

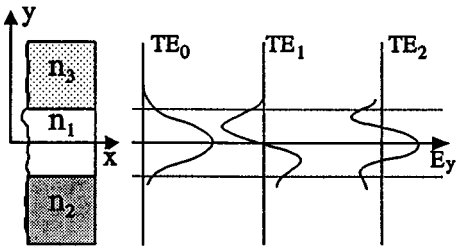

FIGURE 42.7 Transverse mode field patterns in the asymmetric slab waveguide.

Fields in Cylindrical Fibers

Let ψ represent E_z or H_z and β be the component of κ in z direction. In the cylindrical coordinates of Fig. 42.2, with wave propagation along the z axis, the wave equations (42.6) correspond to the scalar equation

$$\frac{\partial^2\psi}{\partial r^2} + \frac{1}{r}\frac{\partial\psi}{\partial r} + \frac{1}{r^2}\frac{\partial^2\psi}{\partial\Phi^2} + (\kappa^2 - \beta^2)\psi = 0 \tag{42.16}$$

The general solution to the preceding equation is

$$\psi(r) = C_1 J_\ell(\mathrm{hr}) + C_2 Y_\ell(\mathrm{hr}); \quad \kappa^2 > \beta^2 \tag{42.17a}$$

$$\psi(r) = C_1 I_\ell(\mathrm{qr}) + C_2 K_\ell(\mathrm{qr}); \quad \kappa^2 < \beta^2 \tag{42.17b}$$

In Eqs. (42.17) and (42.17b), J_ℓ and Y_ℓ are Bessel functions of the first kind and second kind, respectively, of order ℓ; I_ℓ and K_ℓ are modified Bessel functions of the first kind and second kind, respectively, of order ℓ; C_1 and C_2 are constants; $h^2 = \kappa^2 - \beta^2$ and $q^2 = \beta^2 - \kappa^2$.

E_z and H_z in a fiber core are given by Eq. (42.17a) or (42.17b), depending on the sign of $\kappa^2 - \beta^2$. For guided propagation in the core, this sign is negative to ensure that the field is evanescent in the cladding. One of the

coefficients vanishes because of asymptotic behavior of the respective Bessel functions in the core or cladding. Thus, with A_1 and A_2 as arbitrary constants, the fields in the core and cladding are given, respectively, by

$$\psi(r) = A_1 J_\ell(\mathrm{h}r) \tag{42.18a}$$

$$\psi(r) = A_2 \kappa_\ell(\mathrm{h}r) \tag{42.18b}$$

Because of the cylindrical symmetry,

$$\psi(r,t) = \psi(r,\phi)\, e^{j(\omega t - \beta z)} \tag{42.19}$$

Thus, the usual approach is to solve for E_z and H_z and then express E_r, E_ϕ, H_r, and H_ϕ in terms of E_z and H_z.

Modes in Step-Index Fibers

Derivation of the exact modal field relations for optical fibers is complex. Fortunately, fibers used in optical communication satisfy the weekly guiding approximation in which the relative index difference, ∇, is much less than unity. In this approximation, application of the requirement for continuity of transverse and tangential electric field components at the core-cladding interface (at $r = a$) to Eqs. (42.18a) and (42.18b) results in the following eigenvalue equation [Snyder, 1969]:

$$haJ_{\ell\pm1}\frac{(ha)}{J_\ell(ha)} = \pm\frac{qa\kappa_{\ell\pm1}(qa)}{\kappa_\ell(qa)} \tag{42.20}$$

Let the normalized frequency V be defined as

$$V = a(q^2 + h^2)^{1/2} = a\kappa_0\left(n_1^2 - n_2^2\right)^{1/2} = \frac{2\pi}{\lambda}a(NA) \tag{42.21}$$

Solving Eq. (42.20) allows β to be calculated as a function of V. Guided modes propagating within the core correspond to $n_2\kappa_0 \le \beta \le n_1\kappa$. The normalized frequency V corresponding to $\beta = n_1\kappa$ is the cut-off frequency for the mode.

As with planar waveguides, *TE* ($E_z = 0$) and *TM* ($H_z = 0$) modes corresponding to meridional rays exist in the fiber. They are denoted by *EH* or *HE* modes, depending on which component, *E* or *H*, is stronger in the plane transverse to the direction or propagation. Because the cylindrical fiber is bounded in two dimensions rather than one, two integers, ℓ and m, are needed to specify the modes, unlike one integer, m, required for planar waveguides. The exact modes, $\mathrm{TE}_{\ell\mathrm{m}}$, $\mathrm{TM}_{\ell\mathrm{m}}$, $\mathrm{EH}_{\ell\mathrm{m}}$, and $\mathrm{HE}_{\ell\mathrm{m}}$, may be given by two linearly polarized modes, $\mathrm{LP}_{\ell\mathrm{m}}$. The subscript ℓ is now such that $\mathrm{LP}_{\ell\mathrm{m}}$ corresponds to $\mathrm{HE}_{\ell+1,\mathrm{m}}$, $\mathrm{EH}_{\ell-1,\mathrm{m}}$, $\mathrm{TE}_{\ell-1,\mathrm{m}}$, and $\mathrm{TM}_{\ell-1,\mathrm{m}}$. In general, there are 2ℓ field maxima around the fiber core circumference and m field maxima along a radius vector. Figure 42.8 illustrates the correspondence between the exact modes and the LP modes and their field configurations for the three lowest LP modes.

Figure 42.9 gives the mode chart for step-index fiber on a plot of the refractive index, β/κ_0, against the normalized frequency. Note that for a single-mode (LP_{01} or HE_{11}) fiber, $V < 2.405$. The number of modes supported as a function of V is given by

$$N = \frac{V^2}{2} \tag{42.22}$$

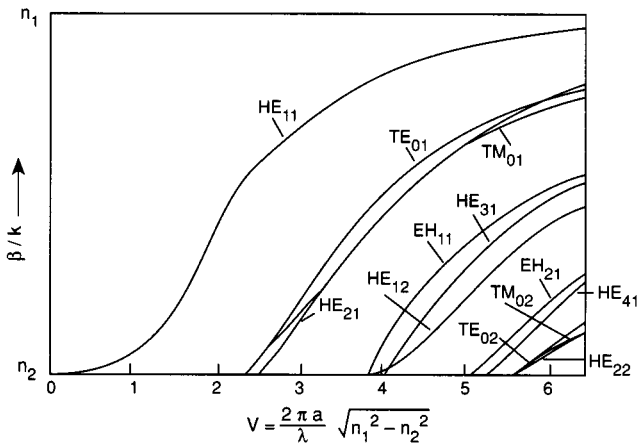

FIGURE 42.9 Mode chart for step-index fibers: $b = (\beta/\kappa_0 - n_2)/(n_1 - n_2)$ is the normalized propagation constant. (*Source:* D. B. Keck, *Fundamentals of Optical Fiber Communications,* M. K. Barnoski, Ed., New York: Academic Press, 1981, p. 13. With permission.)

Modes in Graded-Index Fibers

A rigorous modal analysis for optical fibers based on the solution of Maxwell's equations is possible only for step-index fiber. For graded-index fibers, approximate methods are used. The most widely used approximation is the WKB (Wenzel, Kramers, and Brillouin) method [Marcuse, 1982]. This method gives good modal solutions

Miniature Radar

An inexpensive miniaturized radar system developed at Lawrence Livermore National Labs (LLNL) may become the most successful technology ever privatized by a federal lab, with a potential market for the product estimated at between $100 million and $150 million.

The micropower impulse radar was developed by engineer Tom McEwan as part of a device designed to measure the one billion pulses of light emitted from LLNL's Nova laser in a single second. The system he developed is the size of a cigarette box and consists of about $10 worth of parts. The same measurement had been made previously using $40,000 worth of equipment.

Titan Technologies of Edmonton, AL, Canada, was the first to bring to market a product using the technology when they introduced storage-tank fluid sensors incorporating the system. The new radar allowed Titan to reduce its devices from the size of an apple crate to the size of a softball, and to sell them for one-third the cost of a comparable device. The Federal Highway Administration is preparing to use the radar for highway inspections and the Army Corps of Engineers has contracted with LLNL to use the system for search and rescue radar. Other applications include a monitoring device to check the heartbeats of infants to guard against Sudden Infant Death Syndrome (SIDS), robot guide sensors, automatic on/off switches for bathroom hand dryers, hand-held tools, automobile back-up warning systems, and home security.

AERES, a San Jose-based company, has developed a new approach to ground-penetrating radar using impulse radar. The first application of the technology was an airborne system for detecting underground bunkers. The design can be altered to provide high depth capability for large targets, or high resolution for smaller targets near the surface. This supports requirements in land mine searches and explosive ordinance disposal for the military. AERAS has developed both aircraft and ground-based systems designed for civilian applications as well as military. Underground utility mapping, such as locating pipes and cables; highway and bridge under-surface inspection; and geological and archeological surveying are examples of the possible civilian applications. (Reprinted with permission from *NASA Tech Briefs,* 20(10), 24, 1996.)

for graded-index fiber with arbitrary profiles, when the refractive index does not change appreciably over distances comparable to the guided wavelength [Yariv, 1991]. In this method, the transverse components of the fields are expressed as

$$E_t = \psi(r)\, e^{j\ell\phi}\ \ e^{j(\omega t - \beta z)} \tag{42.23}$$

$$H_t = \frac{\beta}{\omega\mu} E_t \tag{42.24}$$

In Eq. (42.23), ℓ is an integer. Equation (42.16), the scalar wave equation in cylindrical coordinates can now be written with $\kappa = n(r)\,\kappa_0$ as

$$\left[\frac{d^2}{dr^2} + \frac{1}{2}\frac{d}{dr} + p^2(r)\right]\psi(r) = 0 \tag{42.25}$$

where

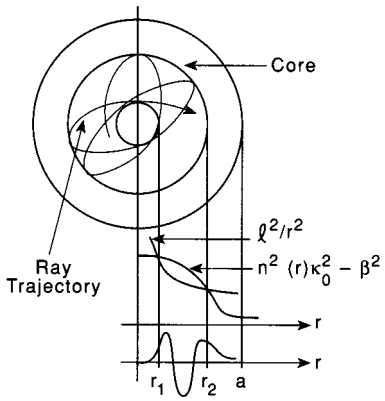

FIGURE 42.10 End view of a skew ray in a graded-index fiber, its graphical solution in the WKB method, and the resulting field that is oscillatory between r_1 and r_2 and evanescent outside that region.

$$p^2(r) = n^2(r)\kappa_0^2 - \frac{\ell^2}{r^2} - \beta^2 \tag{42.26}$$

Let r_1 and r_2 be roots of $p^2(r) = 0$ such that $r_1 < r_2$. A ray propagating in the core does not necessarily reach the core-cladding interface or the fiber axis. In general, it is confined to an annular cylinder bounded by the two caustic surfaces defined by r_1 and r_2. As illustrated in Fig. 42.10, the field is oscillatory within this annular cylinder and evanescent outside it. The fields obtained as solutions to Eq. (42.25) are

$$\psi(r) = \frac{A}{[rp(r)]^{1/2}} \exp\left[-\int_r^{r_1} |p(r)|\, dr\right]; r < r_1 \tag{42.27a}$$

$$\psi(r) = \frac{B}{[rp(r)]^{1/2}} \sin\left[\int_{r_1}^{r} p(r)dr + \frac{\pi}{4}\right]; r_1 < r \tag{42.27b}$$

$$\psi(r) = \frac{C}{[rp(r)]^{1/2}} \sin\left[\int_{r}^{r_2} p(r)dr + \frac{\pi}{4}\right]; r < r_2 \tag{42.27c}$$

$$\psi(r) = \frac{D}{[rp(r)]^{1/2}} \exp\left[-\int_{r_2}^{r} |p(r)|\, dr\right]; r_2 < r \tag{42.27d}$$

Equations (42.27b) and (42.27c) represent fields in the same region. Equating them leads to the mode condition:

$$\int_{r_1}^{r_2} \left[n^2(r)\kappa_0^2 - \frac{\ell^2}{r^2} - \beta^2\right]^{1/2} dr = (2m + 1)\frac{\pi}{2} \tag{42.28}$$

In Eq. (42.28) ℓ and m are the integers denoting the modes. A closed analytical solution of this equation for β is possible only for a few simple graded-index profiles. For other cases, numerical or approximate methods

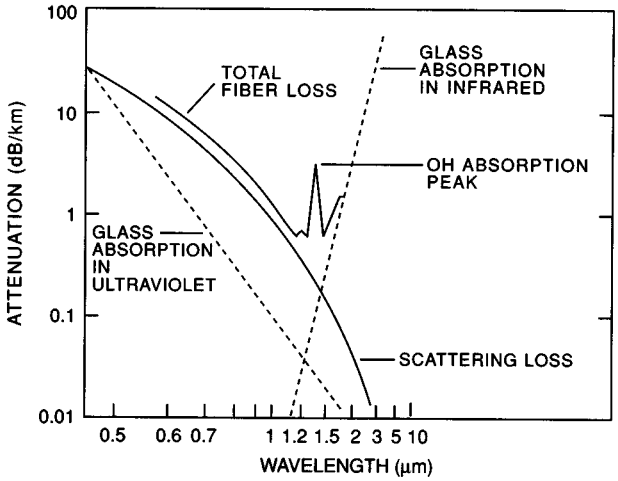

FIGURE 42.11 Attenuation of a germanium-doped low-loss silica glass fiber. (*Source:* H. Osanai et al., "Effects of dopants on transmission loss of low-OH content optical fibers," *Electronic Letters*, vol. 12, no. 21, p. 550, 1976. With permission.)

are used. It can be shown [Marcuse, 1982] that for fiber of graded index profile α, the number of modes supported N_g, and the normalized frequency V, (and hence the core radius) for single mode operations are given, respectively, by

$$N_g = \left(\frac{\alpha}{2+\alpha}\right)\left(\frac{V^2}{2}\right) \tag{42.29}$$

$$V = 2.405\left(\frac{2+\alpha}{\alpha}\right)^{\frac{1}{2}} \tag{42.30}$$

For parabolic (a = 2) index profile Eq. (40.29) give $N_g = \frac{V^2}{4}$, which is half the corresponding number of modes for step index fiber, and Eq. (40.30) gives $V \leq 2.405\sqrt{2}$. Thus, compared with step index fiber, graded index fiber will have larger core radios for single mode operation, and for the same core radius, will support a fewer number of modes.

Attenuation

The assumption of a nonconducting medium for dielectric waveguides led to solutions to the wave equation with no attenuation component. In practice, various mechanisms give rise to losses in lightwave waveguides. These mechanisms contribute a loss factor of $e^{-\alpha z}$ to Eq. (42.10) and comparable field expressions, where α is the attenuation coefficient. The attenuation due to these mechanisms and the resulting total attenuation as a function of wavelength is shown in Fig. 42.11 [Osanai et al., 1976]. Note that the range of wavelengths (0.8 to 1.6 μm) in which communication fibers are usually operated corresponds to a region of low overall attenuation. Brief discussions follow of the mechanisms responsible for the various types of attenuation shown in Fig. 42.11.

Intrinsic Absorption

Intrinsic absorption is a natural property of glass. In the ultraviolet region, it is due to strong electronic and molecular transition bands. In the infrared region, it is caused by thermal vibration of chemical bonds.

Extrinsic Absorption

Extrinsic absorption is caused by metal (Cu, Fe, Ni, Mn, Co, V, Cr) ion impurities and hydroxyl (OH) ion impurity. Metal ion absorption involves electron transition from lower to higher energy states. OH absorption

is caused by thermal vibration of the hydroxyl ion. Extrinsic absorption is strong in the range of normal fiber operation. Thus, it is important that impurity level be limited.

Rayleigh Scattering

Rayleigh scattering is caused by localized variations in refractive index in the dielectric medium, which are small relative to the optic wavelength. It is strong in the ultraviolet region. It increases with decreasing wavelength, being proportional to λ^{-4}. It contributes a loss factor of $\exp(-\alpha_R z)$. The Rayleigh scattering coefficient, α_R, is given by

$$\alpha_R = \left(\frac{8\pi^3}{3\lambda^4}\right)(\delta n^2)^2 \delta V \tag{42.31}$$

where δn^2 is the mean-square fluctuation in refractive index and V is the volume associated with this index difference.

Mie Scattering

Mie scattering is caused by inhomogeneities in the medium, with dimensions comparable to the guided wavelength. It is independent of wavelength.

Dispersion and Pulse Spreading

Dispersion refers to the variation of velocity with frequency or wavelength. Dispersion causes pulse spreading, but other nonwavelength-dependent mechanisms also contribute to pulse spreading in optical waveguides. The mechanisms responsible for pulse spreading in optical waveguides include material dispersion, waveguide dispersion, and multimode pulse spreading.

Material Dispersion

In material dispersion, the velocity variation is caused by some property of the medium. In glass, it is caused by the wavelength dependence of refractive index. For a given pulse, the resulting pulse spread per unit length is the difference between the travel times of the slowest and fastest wavelengths in the pulse. It is given by

$$\Delta\tau = \frac{-\lambda}{c} n''\Delta\lambda = -M\Delta\lambda \tag{42.32}$$

In Eq. 42.32, n'' is the second derivative of the refractive index with respect to λ, $M = (\lambda/c)n''$ is the material dispersion, and $\Delta\lambda$ is the **linewidth** of the pulse. Figure 42.12 shows the wavelength dependence of material dispersion [Wemple, 1979]. Note that for silica, zero dispersion occurs around 1.3 μm, and material dispersion is small in the wavelength range of small fiber attenuation.

Waveguide Dispersion

The effective refractive index for any mode varies with wavelength for a fixed film thickness, for a slab waveguide, or a fixed core radius, for an optical fiber. This variation causes pulse spreading, which is termed waveguide dispersion. The resulting pulse spread is given by

$$\Delta\tau = \frac{-\lambda}{c} n''_{\text{eff}}\Delta\lambda = -M_G\Delta\lambda \tag{42.33}$$

where $M_G = (\lambda/c)n''_{\text{eff}}$ is the waveguide dispersion.

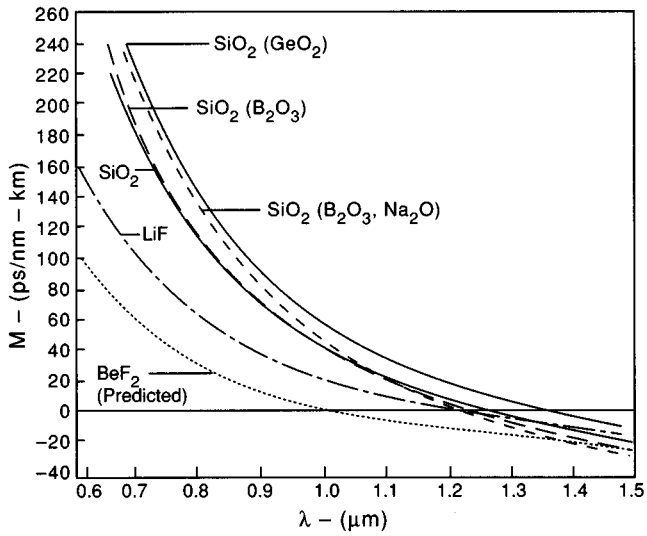

FIGURE 42.12 Material dispersion as a function of wavelength for silica and several solids. (*Source:* S.H. Wemple, "Material dispersion in optical fibers," *Applied Optics*, vol. 18, no. 1, p. 33, 1979. With permission.)

Polarization Mode Dispersion

The HE_{11} propagating in a single mode fiber actually consists of two orthogonally polarized modes, but the two modes have the same effective refractive index and propagation velocity except in birefringent fibers. Birefringent fibers have asymmetric cores or asymmetric refractive index distribution in the core, which result in different refractive indices and group velocities for the orthogonally polarized modes. The different group velocities result in a group delay of one mode relative to the other, known as polarization mode dispersion. Birefringent fibers are polarization preserving and are required for several applications, including coherent optical detection and fiber optic gyroscopes. In high birefringence fibers, polarization dispersion can exceed 1 ns/km. However, in low birefringence fibers, polarization mode dispersion is negligible relative to other pulse spreading mechanisms [Payne et al., 1982].

Multimode Pulse Spreading

In a multimode waveguide, different modes travel different path lengths. This results in different travel times and, hence, in pulse spreading. Because this pulse spreading is not wavelength dependent, it is not usually referred to as dispersion. Multimode pulse spreads are given, respectively, for a slab waveguide, a step-index fiber, and a parabolic graded-index fiber by the following equations:

$$\Delta\tau_{\text{mod}} = \frac{n_1(n_1 - n_2)}{cn_2} \quad \text{(slab waveguide)} \tag{42.34}$$

$$\Delta\tau_{\text{mod}} = \frac{n_1\Delta}{c} \quad \text{(step-index fiber)} \tag{42.35}$$

$$\Delta\tau_{\text{mod}} = \frac{n_1\Delta^2}{8c} \quad \text{(GRIN fiber)} \tag{42.36}$$

Total Pulse Spread

Total pulse spread is the overall effect of material dispersion, waveguide dispersion, and multimode pulse spread. It is given by

$$\Delta\tau_T^2 = \Delta\tau_{\text{mod}}^2 + \Delta\tau_{\text{dis}}^2 \tag{42.37}$$

where

$$\Delta\tau_{\text{dis}} = \text{total dispersion} = -(M + M_G)\Delta\lambda$$

In a multimode waveguide, multimode pulse spread dominates, and dispersion can often be ignored. In a single-mode waveguide, only material and waveguide dispersion exist; material dispersion dominates, and waveguide dispersion can often be ignored.

Total pulse spread imposes an upper limit on the bandwidth of an optical fiber. This upper limit is equal to $1/(2\Delta\tau_T)Hz$.

Defining Terms

Linewidth: The range of wavelengths emitted by a source or present in a pulse.

Meridional ray: A ray that is contained in a plane passing through the fiber axis.

Mode chart: A graphical illustration of the variation of effective refractive index (or, equivalently, propagation angle θ) with normalized thickness d/λ for a slab waveguide or normalized frequency V for an optical fiber.

Refractive index: The ratio of the velocity of light in free space to the velocity of light in a given medium.

Relative refractive index difference: The ratio $(n_1^2 - n_2^2)/2n_1^2 \approx (n_1 - n_2)/n_1$, where $n_1 > n_2$ and n_1 and n_2 are refractive indices.

42.2 Optical Fibers and Cables[1]

Allen H. Cherin and Basant K. Tariyal

Communications using light as a signal carrier and optical fibers as transmission media are termed optical fiber communications. The applications of optical fiber communications have increased at a rapid rate, since the first commercial installation of a fiber-optic system in 1977. Today every major telecommunication company is spending millions of dollars on optical fiber communication systems. In an optical fiber communication system voice, video, or data are converted to a coded pulse stream of light using a suitable light source. This pulse stream is carried by optical fibers to a regenerating or receiving station. At the final receiving station the light pulses are converted to electric signals, decoded, and converted into the form of the original information. Optical fiber communications arc currently used for telecommunications, data communications, military applications, industrial controls, medical applications, and CATV.

Introduction

Since ancient times humans have used light as a vehicle to carry information. Lanterns on ships and smoke signals or flashing mirrors on land are early examples of uses of how humans used light to communicate. It was just over a hundred years ago that Alexander Graham Bell (1880) transmitted a telephone signal a distance greater than 200 m using light as the signal carrier. Bell called his invention a "photophone" and obtained a patent for it. Bell, however, wisely gave up the photophone in favor of the electric telephone. Photophone at the time of its invention could not be exploited commercially because of two basic drawbacks: (1) the lack of a reliable light source and (2) the lack of a dependable transmission medium.

The invention of the laser in 1960 gave a new impetus to the idea of lightwave communications (as scientists realized the potential of the dazzling information-carrying capacity of these lasers). Much research was undertaken by different laboratories around the world during the early 1960s on optical devices and transmission media. The transmission media, however, remained the main problem, until K.C. Kao and G.A. Hockham in 1966 proposed that glass fibers with a sufficiently high-purity **core** surrounded by a lower refractive index **cladding** could be used for transmitting light over long distances. At the time, available glasses had losses of several thousand decibels per kilometer. In 1970, Robert Maurer of Corning Glass Works was able to produce a fiber with a loss of 20 dB/km. Tremendous progress in the production of low-loss optical fibers has been made since then in the various laboratories in the United States, Japan, and Europe, and today optical fiber communication is one of the fastest growing industries. Optical fiber communication is being used to transmit voice, video, and data over long distance as well as within a local network.

Fiber optics appears to be the future method of choice for many communications applications. The biggest advantage of a lightwave system is its tremendous information-carrying capacity. There are already systems that can carry several thousand simultaneous conversations over a pair of optical fibers thinner than human hair. In addition to this extremely high capacity, the lightguide cables are light weight, they are immune to electromagnetic interference, and they are potentially very inexpensive.

A lightwave communication system (Fig. 42.13) consists of a transmitter, a transmission medium, and a receiver. The transmitter takes the coded electronic signal (voice, video, or data) and converts it to the light signal, which is then carried by the transmission medium (an optical fiber cable) to either a **repeater** or the receiver. At the receiving end the signal is detected, converted to electrical pulses, and decoded to the proper output. This article provides a brief overview of the different components used in an optical fiber system, along with examples of various applications of optical fiber systems.

Classification of Optical Fibers and Attractive Features

Fibers that are used for optical communication are waveguides made of transparent dielectrics whose function is to guide light over long distances. An optical fiber consists of an inner cylinder of glass called the core,

[1]This section, including all illustrations, is modified from A. H. Cherin and B. K. Tariyal, "Optical fiber communication," in *Encyclopedia of Telecommunications*, R. A. Meyers, Ed., San Diego: Academic Press, 1988. With permission.

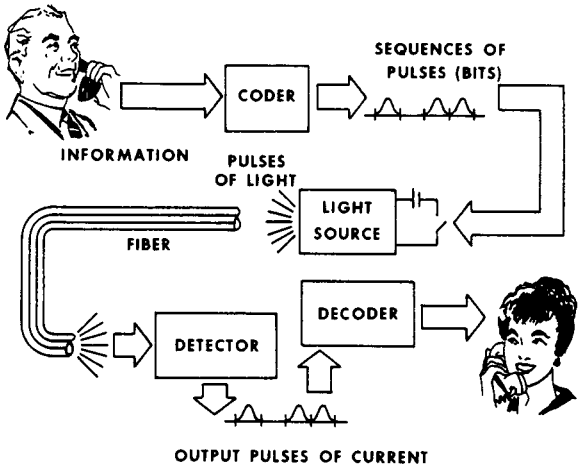

FIGURE 42.13 Schematic diagram of a lightwave communications system.

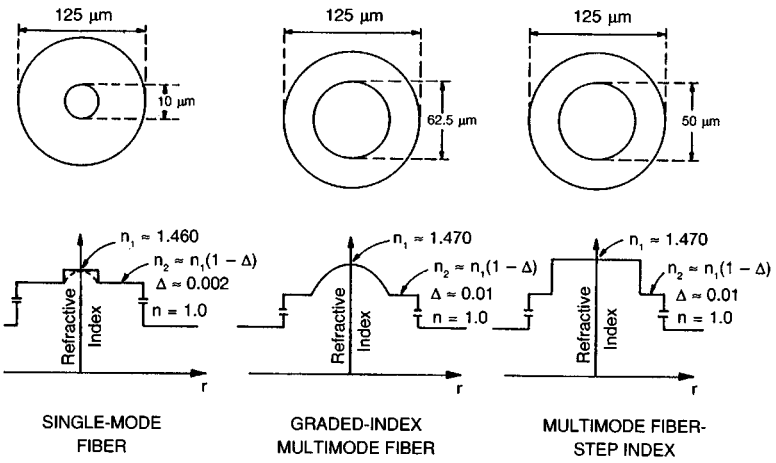

FIGURE 42.14 Geometry of single-mode and multimode fibers.

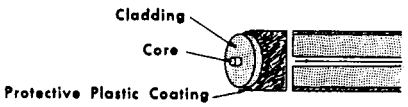
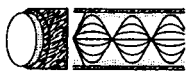
surrounded by a cylindrical shell of glass of lower refractive index, called the cladding. Optical fibers (lightguides) may be classified in terms of the refractive index profile of the core and whether one **mode** (single-mode fiber) or many modes (multimode fiber) are propagating in the guide (Fig. 42.14). If the core, which is typically made of a high-silica-content glass or a multicomponent glass, has a uniform refractive index n_1, it is called a *step-index fiber.* If the core has a nonuniform refractive index that gradually decreases from the center toward the core-cladding interface, the fiber is called a *graded-index fiber.* The cladding surrounding the core has a uniform refractive index n_2 that is slightly lower than the refractive index of the core region. The cladding of the fiber is made of a high-silica-content glass or a multicomponent glass. Figure 42.14 shows the dimensions and refractive indexes for commonly used telecommunication fibers. Figure 42.15 enumerates some of the advantages, constraints, and applications of the different types of fibers. In general, when the transmission medium must have a very high **bandwidth**—for example, in an undersea or long-distance terrestrial system—a single-mode fiber is used. For intermediate system bandwidth requirements between 200 MHz-km and 2 GHz-km, such as found in local-area networks, either a single-mode or graded-index multimode fiber would be the choice. For applications such as short data links where lower bandwidth requirements are placed on the transmission medium, either a graded-index or a step-index multimode fiber may be used.

	Single-mode Fiber	Graded-index Multimode Fiber	Step-index Multimode Fiber
			




Source	Laser preferred	Laser or LED	Laser or LED
Bandwidth	Very very large >2 GHz-km	Very large 150 MHz to 2 GHz-km	Large <200 MHz-km
Example of application	Submarine cable system	LANS	Data links

FIGURE 42.15 Applications and characteristics of fiber types.

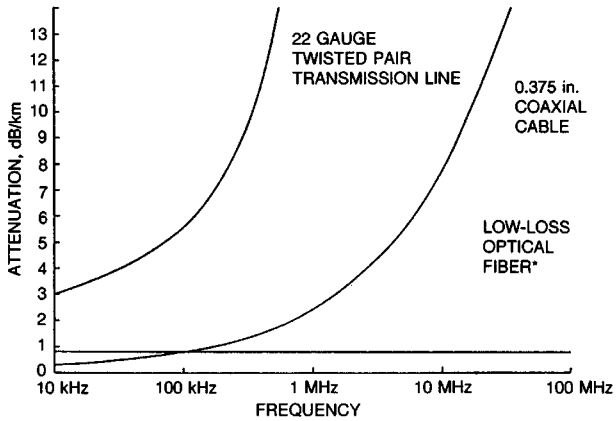


FIGURE 42.16 Attenuation versus frequency for three different transmission media. Asterisk indicates fiber loss at a carrier wavelength of 1.3 μm.

Because or their low loss and wide bandwidth capabilities, optical fibers have the potential for being used wherever twisted wire pairs or coaxial cables are used as the transmission medium in a communication system. If an engineer were interested in choosing a transmission medium for a given transmission objective, he or she would tabulate the required and desired features of alternate technologies that may be available for use in the applications. With that process in mind, a summary of the attractive features and the advantages of optical fiber transmission will be given. Some of these advantages include (a) low loss and high bandwidth; (b) small size and bending radius; (c) nonconductive, nonradiative, and noninductive; (d) light weight; and (e) providing natural growth capability.

To appreciate the low loss and wide bandwidth capabilities of optical fibers, consider the curves of signal **attenuation** versus frequency for three different transmission media shown in Fig. 42.16. Optical fibers have a "flat" transfer function well beyond 100 MHz. When compared with wire pairs of coaxial cables, optical fibers have far less loss for signal frequencies above a few megahertz. This is an important characteristic that strongly influences system economics, since it allows the system designer to increase the distance between regenerators (amplifiers) in a communication system.

The small size, small bending radius (a few centimeters), and light weight of optical fibers and cables are very important where space is at a premium, such as in aircraft, on ships, and in crowded ducts under city streets.

Because optical fibers are dielectric waveguides, they avoid many problems such as radiative interference, ground loops, and, when installed in a cable without metal, lightning-induced damage that exists in other transmission media.

Finally, the engineer using optical fibers has a great deal of flexibility. He or she can install an optical fiber cable and use it initially in a low-capacity (low-bit-rate) system. As the system needs grow, the engineer can take advantage of the broadband capabilities of optical fibers and convert to a high-capacity (high-bit-rate) system by simply changing the terminal electronics.

Fiber Transmission Characteristics

The proper design and operation of an optical communication system using optical fibers as the transmission medium requires a knowledge of the transmission characteristics of the optical sources, fibers, and interconnection devices (connectors, couplers, and splices) used to join lengths of fibers together. The transmission criteria that affect the choice of the fiber type used in a system are signal attenuation, information transmission capacity (bandwidth), and source coupling and interconnection efficiency. Signal attenuation is due to a number of loss mechanisms within the fiber, as shown in Table 42.1, and due to the losses occurring in splices and connectors. The information transmission capacity of a fiber is limited by **dispersion**, a phenomenon that causes light that is originally concentrated into a short pulse to spread out into a broader pulse as it travels along an optical fiber. Source and interconnection efficiency depends on the fiber's core diameter and its **numerical aperture**, a measure of the angle over which light is accepted in the fiber. Absorption and scattering of light traveling through a fiber leads to signal attenuation, the rate of which is measured in decibels per kilometer (dB/km). As can be seen in Fig. 42.17, for both multimode and single-mode fibers, attenuation depends strongly on wavelength. The decrease in scattering losses with increasing wavelength is offset by an increase in material absorption such that attenuation is lowest near 1.55 μm (1550 nm).

TABLE 42.1 Loss Mechanisms

Intrinsic material absorption loss
Ultraviolet absorption tail
Infrared absorption tail
Absorption loss due to impurity ions
Rayleigh scattering loss
Waveguide scattering loss
Microbending loss

The measured values given in Table 42.2 are probably close to the lower bounds for the attenuation of optical fibers. In addition to intrinsic fiber losses, extrinsic loss mechanisms, such as absorption due to impurity ions, and **microbending** loss due to jacketing and cabling can add loss to a fiber.

The bandwidth or information-carrying capacity of a fiber is inversely related to its total dispersion. The total dispersion in a fiber is a combination of three components: intermodal dispersion (modal delay distortion), material dispersion, and waveguide dispersion.

Intermodal dispersion occurs in multimode fibers because rays associated with different modes travel different effective distances through the optical fiber. This causes light in the different modes to spread out temporally as it travels along the fiber. Modal delay distortion can severely limit the bandwidth of a step-index multimode fiber to the order of 20 MHz-km. To reduce modal delay distortion in multimode fibers, the core is carefully doped to create a graded (approximately parabolic shaped) refractive index profile. By carefully designing this index profile, the group velocities of the propagating modes are nearly equalized. Bandwidths of 1.0 GHz-km are readily attainable in commercially available graded-index multimode fibers. The most effective way of eliminating intermodal dispersion is to use a single-mode fiber. Since only one mode propagates in a single-mode fiber, modal delay distortion between modes does not exist and very high bandwidths are possible. The bandwidth of a single-mode fiber, as mentioned previously, is limited by the combination of material and waveguide dispersion. As shown in Fig. 42.18, both material and waveguide dispersion are dependent on wavelength.

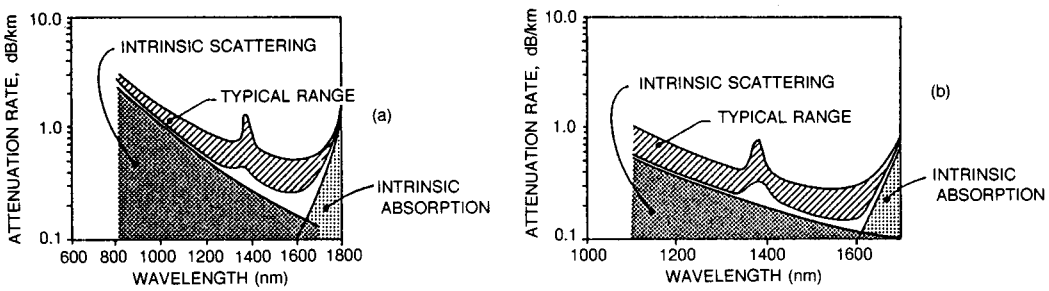

FIGURE 42.17 Spectral attenuation rate. (a) Graded-index multimode fibers. (b) Single-mode fibers.

TABLE 42.2 Best Attenuation Results (dB/km) in Ge-P-SiO_2 Core Fibers

Wavelength (nm)	$\Delta \approx 0.2\%$ (Single-mode Fibers)	$\Delta \approx 1.0\%$ (Graded-index Multimode Fibers)
850	2.1	2.20
1300	0.27	0.44
1500	0.16	0.23

Material dispersion is caused by the variation of the refractive index of the glass with wavelength and the spectral width of the system source. Waveguide dispersion occurs because light travels in both the core and cladding of a single-mode fiber at an effective velocity between that of the core and cladding materials. The waveguide dispersion arises because the effective velocity, the waveguide dispersion, changes with wavelength. The amount of waveguide dispersion depends on the design of the waveguide structure as well as on the fiber material. Both material and waveguide dispersion are measured in picoseconds (of pulse spreading) per nanometer (of source spectral width) per kilometer (of fiber length), reflecting both the increases in magnitude in source linewidth and the increase in dispersion with fiber length.

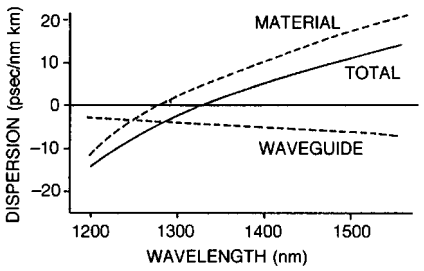

FIGURE 42.18 Single-mode step-index dispersion curve.

Material and waveguide dispersion can have different signs and effectively cancel each other's dispersive effect on the total dispersion in a single-mode fiber. In conventional germanium-doped silica fibers, the "zero-dispersion" wavelength at which the waveguide and material dispersion effects cancel each other out occurs near 1.30 μm. The zero-dispersion wavelength can be shifted to 1.55 μm, or the low-dispersion characteristics of a fiber can be broadened by modifying the refractive index profile shape of a single-mode fiber. This profile shape modification alters the waveguide dispersion characteristics of the fiber and changes the wavelength region in which waveguide and material dispersion effects cancel each other. Figure 42.19 illustrates the profile shapes of "conventional," "dispersion-shifted," and "dispersion-flattened" single-mode fibers. Single-mode fibers operating in their zero-dispersion region with system sources of finite spectral width do not have infinite bandwidth but have bandwidths that are high enough to satisfy all current high-capacity system requirements.

Optical Fiber Cable Manufacturing

Optical fiber cables should have low loss and high bandwidth and should maintain these characteristics while in service in extreme environments. In addition, they should be strong enough to survive the stresses encountered during manufacture, installation, and service in a hostile environment. The manufacturing process used

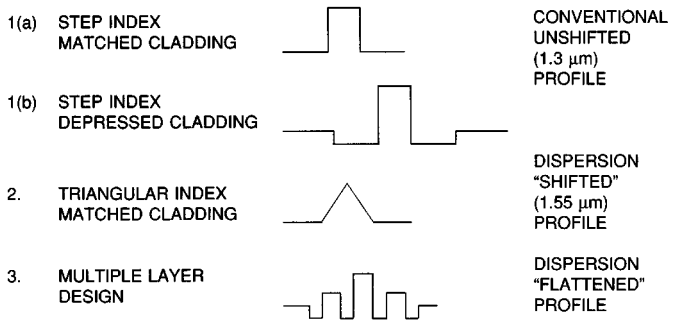

FIGURE 42.19 Single-mode refractive index profiles.

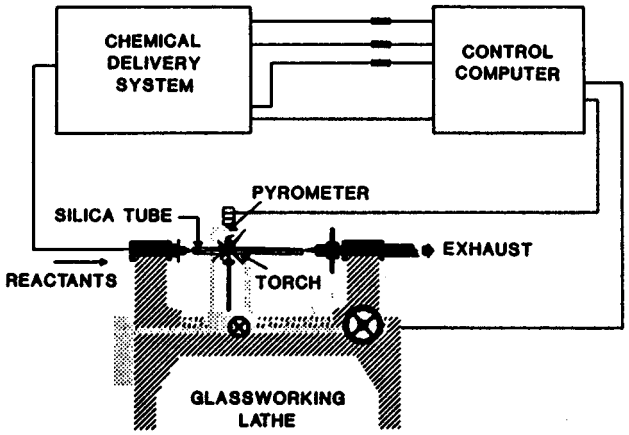

FIGURE 42.20 Schematic diagram of the MCVD process.

to fabricate the optical fiber cables can be divided into four steps: (1) preform fabrication, (2) fiber drawing and coating, (3) fiber measurement, and (4) fiber packaging.

Preform Fabrication

The first step in the fabrication of optical fiber is the creation of a glass preform. A preform is a large blank of glass several millimeters in diameter and several centimeters in length. The preform has all the desired properties (e.g., geometrical ratios and chemical composition) necessary to yield a high-quality fiber. The preform is subsequently drawn into a multi-kilometer-long hair-thin fiber. Four different preform manufacturing processes are currently in commercial use.

The most widely used process is the modified **chemical vapor deposition** (MCVD) process invented at the AT&T Bell Laboratories. Outside vapor deposition process (OVD) is used by Corning Glass Works and some of its joint ventures in Europe. Vapor axial deposition (VAD) process is the process used most widely in Japan. Philips, in Eindhoven, Netherlands, uses a low-temperature plasma chemical vapor deposition (PCVD) process.

In addition to the above four major processes, other processes are under development in different laboratories. Plasma MCVD is under development at Bell Laboratories, hybrid OVD-VAD processes are being developed in Japan, and Sol-Gel processes are being developed in several laboratories. The first four processes are the established commercial processes and are producing fiber economically. The new processes are aimed at greatly increasing the manufacturing productivity of preforms, and thereby reducing their cost.

All the above processes produce high-silica fibers using different dopants, such as germanium, phosphorus, and fluorine. These dopants modify the refractive index of silica, enabling the production of the proper core refractive index profile. Purity of the reactants and the control of the refractive index profile are crucial to the low loss and high bandwidth of the fiber.

MCVD Process. In the MCVD process (Fig. 42.20), a fused-silica tube of extremely high purity and dimensional uniformity is cleaned in an acid solution and degreased. The clean tube is mounted on a glass working lathe. A mixture of reactants is passed from one end of the tube and exhaust gases are taken out at the other end while the tube is being rotated. A torch travels along the length of the tube in the direction of the reactant flow. The reactants include ultra-high-purity oxygen and a combination of one or more of the halides and oxyhalides ($SiCl_4$, $GeCl_4$, $POCl_3$, BCl_3, BBr_3, SiF_4, CCl_4, CCl_2F_2, Cl_2, SF_6, and $SOCl_2$).

The halides react with the oxygen in the temperature range of 1300–1600°C to form oxide particles, which are driven to the wall of the tube and subsequently consolidated into a glassy layer as the hottest part of the flame passes over. After the completion of one pass, the torch travels back and the next pass is begun. Depending on the type of fiber (i.e., multimode or single-mode), a **barrier layer** or a cladding consisting of many thin layers is first deposited on the inside surface of the tube. The compositions may include B_2O_3-P_2O_5-SiO_2 or F-P_2O_5-SiO_2 for barrier layers and SiO_2, F-SiO_2, F-P_2O_5-SiO_2, or F-GeO_2-SiO_2-P_2O_5 for cladding layers. After the required number of barrier or cladding layers has been deposited the core is deposited. The core compositions

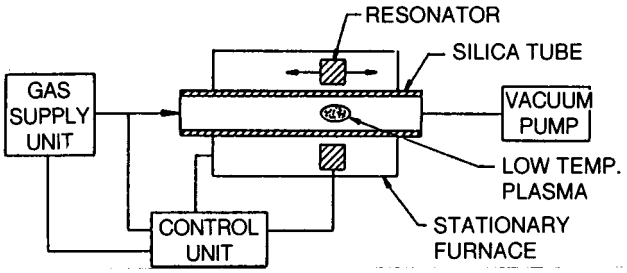

FIGURE 42.21 Schematic diagram of the PCVD process.

depend on whether the fiber is single-mode, multimode, step-index, or multimode graded-index. In the case of graded-index multimode fibers, the dopant level changes with every layer, to provide a refractive index profile that yields the maximum bandwidth.

After the deposition is complete, the reactant flow is stopped except for a small flow of oxygen, and the temperature is raised by reducing the torch speed and increasing the flows of oxygen and hydrogen through the torch. Usually the exhaust end of the tube is closed first and a small positive pressure is maintained inside the deposited tube while the torch travels backward. The higher temperatures cause the glass viscosity to decrease, and the surface tension causes the tube to contract inward. The complete collapse of the tube into a solid preform is achieved in several passes. The speed of the collapse, the rotation of the tube, the temperature of collapse, and the positive pressure of oxygen inside the tube are all accurately controlled to predetermined values in order to produce a straight and bubble-free preform with minimum ovality. The complete preform is then taken off the lathe. After an inspection to assure that the preform is free of defects, the preform is ready to be drawn into a thin fiber.

The control of the refractive index profile along the cross section of the deposited portion of the preform is achieved through a vapor delivery system. In this system, liquids are vaporized by passing a carrier gas (pure O_2) through the bubblers, made of fused silica. Accurate flows are achieved with precision flow controllers that maintain accurate carrier gas flows and extremely accurate temperatures within the bubblers. Microprocessors are used to automate the complete deposition process, including the torch travel and composition changes throughout the process. Impurities are reduced to very low levels by starting with pure chemicals, and there is further reducing of the impurities with in-house purification of these chemicals. Ultra-pure oxygen and a completely sealed vapor-delivery system are used to avoid chemical contamination. Transition-metal ion impurities of well below 1 ppb and OH^- ion impurities of less than 1 ppm are typically maintained to produce high-quality fiber.

The PCVD Process. The PCVD process (Fig. 42.21) also uses a starting tube, and the deposition takes place inside the tube. Here, however, the tube is either stationary or oscillating and the pressure is kept at 10–15 torr. Reactants are fed inside the tube, and the reaction is accomplished by a traveling microwave plasma inside the tube. The entire tube is maintained at approximately 1200°C. The plasma causes the heterogeneous depositions of glass on the tube wall, and the deposition efficiency is very high. After the required depositions of the cladding and core are complete, the tube is taken out and collapsed on a separate equipment. Extreme care is required to prevent impurities from getting into the tube during the transport and collapse procedure. The PCVD process has the advantages of high efficiency, no tube distortion because of the lower temperature, and very accurate profile control because of the large number of layers deposited in a short time. However, going to higher rates of flow presents some difficulties, because of a need to maintain the low pressure.

The PMCVD Process. The PMCVD is an enhancement of the MCVD process. Very high rates of deposition (up to 10 g/min, compared to 2 g/min for MCVD) are achieved by using larger diameter tubes and an RF plasma for reaction (Fig. 42.22). Because of the very high temperature of the plasma, water cooling is essential. An oxyhydrogen torch follows the plasma and sinters the deposition. The high rates of deposition are achieved because of very high thermal gradients from the center of the tube to the wall and the resulting high thermophoretic driving force. The PMCVD process is still in the development stage and has not been commercialized.

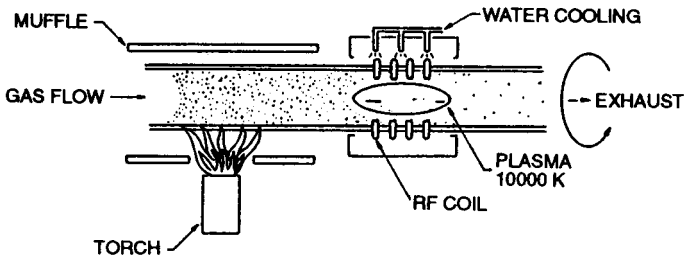

FIGURE 42.22 Schematic diagram of the PMCVD process.

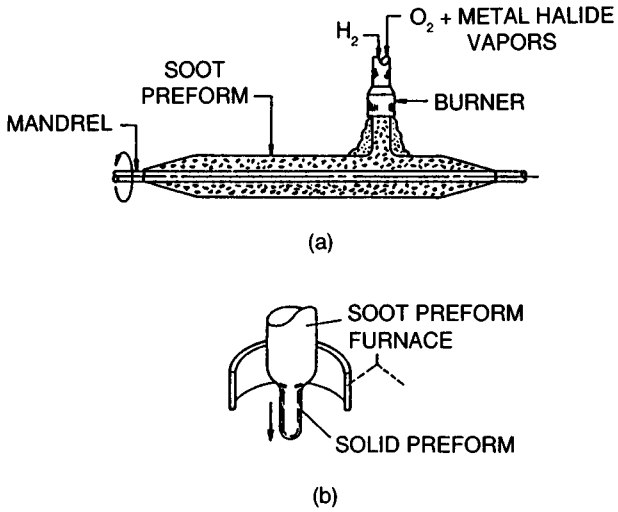

FIGURE 42.23 Schematic diagram of the outside vapor deposition. (a) Soot deposition. (b) Consolidation.

The OVD Process. The OVD process does not use a starting tube; instead, a stream of soot particles of desired composition is deposited on a bait rod (Fig. 42.23). The soot particles are produced by the reaction of reactants in a fuel gas-oxygen flame. A cylindrical porous soot preform is built layer by layer. After the deposition of the core and cladding is complete, the bait rod is removed. The porous preform is then sintered and dried in a furnace at 1400–1600°C to form a clear bubble-free preform under a controlled environment. The central hold left by the blank may or may not be closed, depending on the type of preform. The preform is now ready for inspection and drawing.

The VAD Process. The process is very similar to the OVD process. However, the soot deposition is done axially instead of radially. The soot is deposited at the end of a starting silica-glass rod (Fig. 42.24). A special torch using several annular holes is used to direct a stream of soot at the deposition surface. The reactant vapors, hydrogen gas, argon gas, and oxygen gas flow through different annular openings. Normally the core is deposited and the rotating speed is gradually withdrawn as the deposition proceeds at the end. The index profile is controlled by the composition of the gases flowing through the torch and the temperature distribution at the deposition surface. The porous preform is consolidated and dehydrated as it passes through a carbon-ring furnace in a

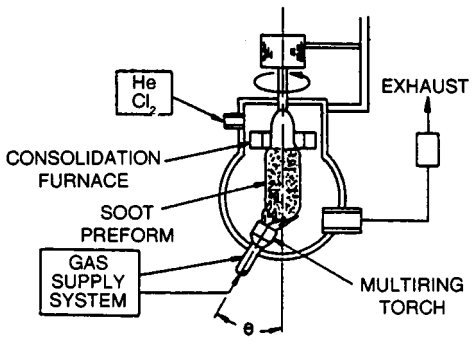

FIGURE 42.24 Schematic diagram of the vapor axial deposition.

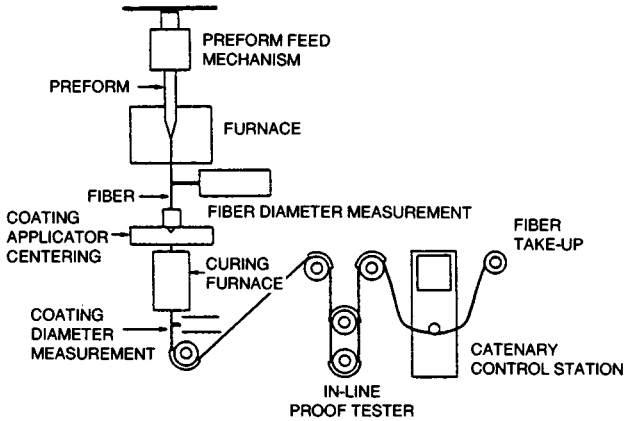

FIGURE 42.25 The fiber drawing process.

controlled environment. $SOCl_2$ and Cl are used to dehydrate the preform. Because of the axial deposition, this process is semicontinuous and is capable of producing very large preforms.

Fiber Drawing

After a preform has been inspected for various defects such as bubbles, ovality, and straightness, it is taken to a fiber drawing station. A large-scale fiber drawing process must repeatedly maintain the optical quality of the preform and produce a dimensionally uniform fiber with high strength.

Draw Process. During fiber drawing, the inspected preform is lowered into a hot zone at a certain feed rate V_p, and the fiber is pulled from the softened neck-down region (Fig. 42.25) at a rate V_f. At steady state,

$$\pi D_p^2 V_p/4 = \pi D_f^2 V_f/4 \qquad (42.38)$$

where D_p and D_f are the preform and fiber diameters, respectively. Therefore,

$$V_f = (D_p^2/D_f^2) V_p \qquad (42.39)$$

A draw machine, therefore, consists of a preform feed mechanism, a heat source, a pulling device, a coating device, and a control system to accurately maintain the fiber diameter and the furnace temperature.

Heat Source. The heat source should provide sufficient energy to soften the glass for pulling the fiber without causing excessive tension and without creating turbulence in the neck-down region. A proper heat source will yield a fiber with uniform diameter and high strength. Oxyhydrogen torches, CO_2 lasers, resistance furnaces, and induction furnaces have been used to draw fibers. An oxyhydrogen torch, although a clean source of heat, suffers from turbulence due to flame. A CO_2 laser is too expensive a heat source to be considered for the large-scale manufacture of fibers. Graphite resistance furnaces and zirconia induction furnaces are the most widely used heat sources for fiber drawing. In the graphite resistance furnace, a graphite resistive element produces the required heat. Because graphite reacts with oxygen at high temperatures, an inert environment (e.g., carbon) is maintained inside the furnace. The zirconia induction furnace does not require inert environment. It is extremely important that the furnace environment be clean in order to produce high-strength fibers. A zirconia induction furnace, when properly designed and used, has produced very-high-strength long-length fibers (over 2.0 GPa) in lengths of several kilometers.

Mechanical Systems. An accurate preform feed mechanism and drive capstan form the basis of fiber speed control. The mechanism allows the preform to be fed at a constant speed into the hot zone, while maintaining the preform at the center of the furnace opening at the top. A centering device is used to position preforms that are not perfectly straight. The preform is usually held with a collet-type chuck mounted in a vertically movable carriage, which is driven by a lead screw. A precision stainless-steel drive capstan is mounted on the

shaft of a high-performance dc servomotor. The fiber is taken up on a proper-diameter spool. The fiber is wound on the spool at close to zero tension with the help of a catenary control. In some cases fiber is proof-tested in-line before it is wound on a spool. The proof stress can be set at different levels depending on the application for which the fiber is being manufactured.

Fiber Coating System. The glass fiber coming out of the furnace has a highly polished pristine surface and the theoretical strength of such a fiber is in the range of 15–20 GPa. Strengths in the range of 4.5–5.5 GPa are routinely measured on short fiber lengths. To preserve this high strength, polymeric coatings are applied immediately after the drawing. The coating must be applied without damaging the fiber, it must solidify before reaching the capstan, and it should not cause microbending loss. To satisfy all these requirements, usually two layers of coatings are applied: a soft inner coating adjacent to the fiber to avoid microbending loss and a hard outer coating to resist abrasion. The coatings are a combination of ultraviolet- (UV) curable acrylates, UV-curable silicones, hot melts, heat-curable silicones, and nylons. When dual coatings are applied, the coated fiber diameter is typically 235–250 μm. The nylon-jacketed fiber typically used in Japan has an outside diameter of 900 μm. All coating materials are usually filtered to remove particles that may damage the fiber. Coatings are usually applied by passing the fiber through a coating cup and then curing the coating before the fiber is taken up by the capstan. The method of application, the coating material, the temperature, and the draw speed affect the proper application or a well-centered, bubble-free coating.

Fiber drawing facilities are usually located in a clean room where the air is maintained at class 10,000. The region of the preform and fiber from the coating cup to the top of the preform is maintained at class 100 or better. A class 100 environment means that there are no more than 100 particles of size greater than 0.5 μm in 1 ft^3 of air. A clean environment, proper centering of the preform in the furnace and fiber in the coating cup, and proper alignment of the whole draw tower ensure a scratch-free fiber of a very high tensile strength. A control unit regulates the draw speed, preform feed speed, preform centering, fiber diameter, furnace temperature, and draw tension.

The coated fiber wound on a spool is next taken to the fiber measurement area to assure proper quality control.

Proof Testing of Fibers. Mechanical failure is one of the major concerns in the reliability of optical fibers. Fiber drawn in kilometer lengths must be strong enough to survive all of the short- and long-term stresses that it will encounter during the manufacture, installation, and long service life. Glass is an ideal elastic isotropic solid and does not contain dislocations. Hence, the strength is determined mainly by inclusions and surface flaws. Although extreme care is taken to avoid inhomogeneities and surface flaws during fiber manufacture, they cannot be completely eliminated. Since surface flaws can result from various causes, they are statistical in nature and it is very difficult to predict the long-length strength of glass fibers. To guarantee a minimum fiber strength, proof testing has been adopted as a manufacturing step. Proof testing can be done in-line immediately after the drawing and coating or off-line before the fiber is stored.

In proof testing, the entire length of the fiber is subjected to a properly controlled proof stress. The proof stress is based on the stresses likely to be encountered by the fiber during manufacture, storage, installation, and service. The fibers that survive the proof test are stored for further packaging into cables.

Proof testing not only guarantees that the fiber will survive short-term stresses but also guarantees that the fiber will survive a lower residual stress that it may be subjected to during its long service life. It is well known that glass, when used in a humid environment, can fail under a long-term stress well below its instantaneous strength. This phenomenon is called static fatigue. Several models have been proposed to quantitatively describe the relationship between residual stress and the life of optical fibers. Use is made of the most conservative of these models, and the proof stress is determined by a consideration of the maximum possible residual stress in service and the required service life.

Fiber Packaging

In order to efficiently use one or more fibers, they need to be packaged so that they can be handled, transported, and installed without damage. Optical fibers can be used in a variety of applications, and hence the way they are packaged or cabled will also vary. There are numerous cable designs that are used by different cable manufacturers. All these designs, however, must meet certain criteria. A primary consideration in a cable design

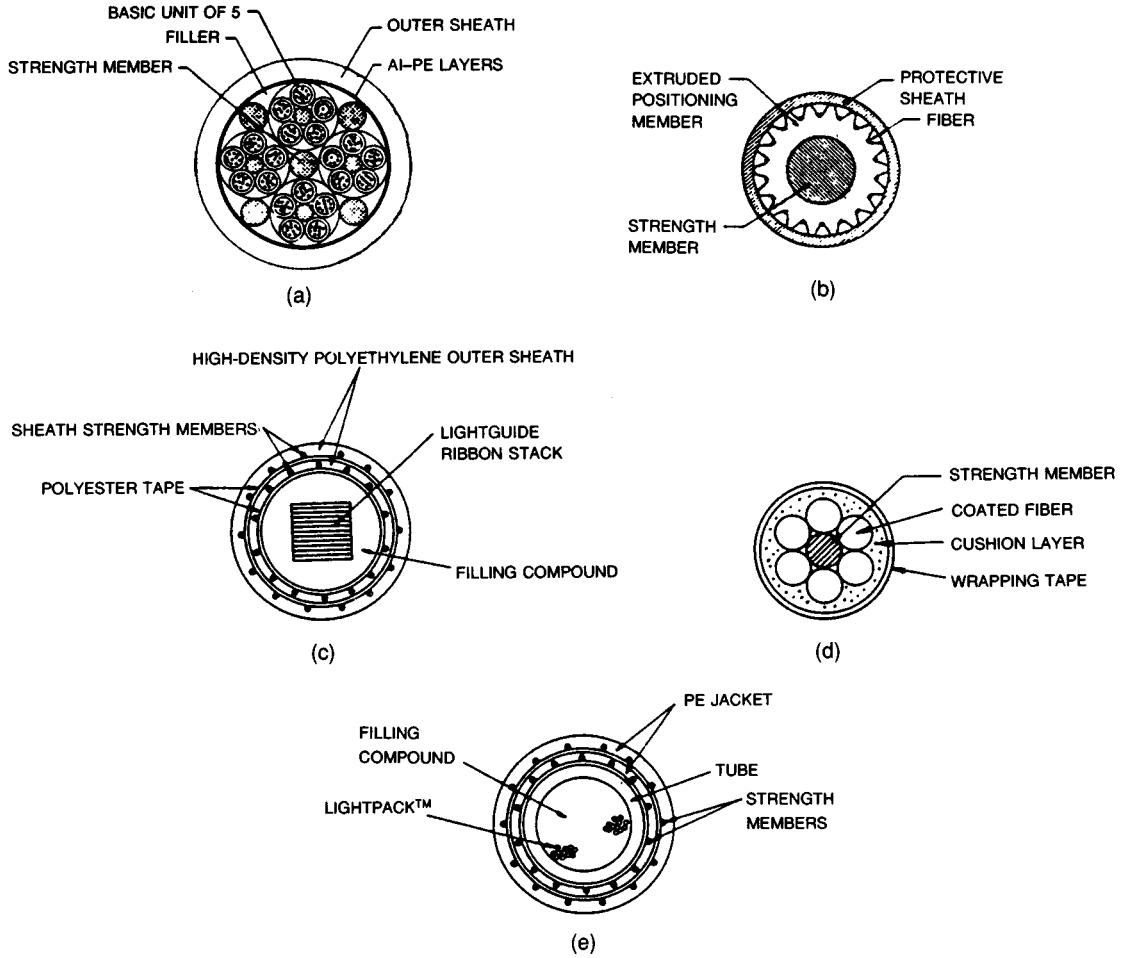

FIGURE 42.26 Fiber cable designs. (a) Loose tube design. (b) Slotted design. (c) Ribbon design. (d) Stranded unit. (e) Lightpack™ Cable design.

is to assure that the fibers in the cables maintain their optical properties (attenuation and dispersion) during their service life under different environmental conditions. The design, therefore, must minimize microbending effects. This usually means letting the fiber take a minimum energy position at all times in the cable structure. Proper selection of cabling materials so as to minimize differential thermal expansion or contraction during temperature extremes is important in minimizing microbending loss. The cable structure must be such that the fibers carry a load well below the proof-test level at all times, and especially while using conventional installation equipment. The cables must provide adequate protection to the fibers under all adverse environmental conditions during their entire service life, which may be as long as 40 years. Finally, the cable designs should be cost effective and easily connectorized or spliced.

Five different types (Fig. 42.26) of basic cable designs are currently in use: (a) loose tube, (b) fluted, (c) ribbon, (d) stranded, and (e) Lightpack Cable. The loose tube design was pioneered by Siemens in Germany. Up to 10 fibers are enclosed in a loose tube, which is filled with a soft filling compound. Since the fibers are relatively free to take the minimum energy configuration, the microbending losses are avoided. Several of these buffered loose tube units are stranded around a central glass-resin support member. Aramid yarns are stranded on the cable core to provide strength members (for pulling through ducts), with a final polyethylene sheath on the outside. The stranding lay length and pitch radius are calculated to permit tensile strain on the cable up to the rated force and to permit cooling down to the rated low temperature without affecting the fiber attenuation.

In the fluted designs, fibers are laid in the grooves of plastic central members and are relatively free to move. The shape and size of the grooves vary with the design. The grooved core may also contain a central strength member. A sheath is formed over the grooved core, and this essentially forms a unit. Several units may then be stranded around a central strength member to form a cable core of desired size, over which different types of sheaths are formed. Fluted designs have been pioneered in France and Canada.

The ribbon design was invented at AT&T Bell Laboratories and consists of a linear array of 12 fibers sandwiched between two polyester tapes with pressure-sensitive adhesive on the fiber side. The spacing and the back tension on the fibers is accurately maintained. The ribbons are typically 2.5 mm in width. Up to 12 ribbons can be stacked to give a cable core consisting of 144 fibers. The core is twisted to some lay length and enclosed in a polyethylene tube. Several combinations of protective plastic and metallic layers along with metallic or nonmetallic strength members are then applied around the core to give the final cable its required mechanical and environmental characteristics needed for use in specified conditions. The ribbon design offers the most efficient and economic packaging of fibers for high-fiber-count cables. It also lends the cable to preconnectorization and makes it extremely convenient for installation and splicing.

The tight-bound stranded designs were pioneered by Japanese and are used in the United States for several applications. In this design, several coated fibers are stranded around a central support member. The central support member may also serve as a strength member, and it may be metallic or nonmetallic. The stranded unit can have up to 18 fibers. The unit is contained within a plastic tube filled with a water-blocking compound. The final cable consists of several of these units stranded around a central member and protected on the outside with various sheath combinations.

The Lightpack Cable design, pioneered by AT&T, is one of the simplest designs. Several fibers are held together with a binder to form a unit. One or more units are laid inside a large tube, which is filled with a water-blocking compound. This design has the advantage of the loose tube design in that the fibers are free of strain, but is more compact. The tube-containing units can then be projected with various sheath options and strength members to provide the final cable.

The final step in cabling is the sheathing operation. After the fibers have been made into identifiable units, one or more of the units (as discussed earlier) form a core which is then covered with a combination of sheathing layers. The number and combination of the sheathing layers depend on the intended use. Typically, a polyethylene sheath is extruded over the filled cable core. In a typical cross-ply design, metallic or nonmetallic strength members are applied over the first sheath layer, followed by another polyethylene sheath, over which another layer of strength members is applied. The direction of lay of the two layers of the strength members is opposite to each other. A final sheath is applied and the cable is ready for the final inspection, preconnectorization, and shipment. Metallic vapor barriers and lightning- and rodent-protection sheath options are also available. Further armoring is applied to cables made for submarine application.

In addition to the above cable designs, there are numerous other cable designs used for specific applications, such as fire-resistant cables, military tactical cables, cables for missile guidance systems, cables for field communications established by air-drop operations, air deployment cables, and cables for industrial controls. All these applications have unique requirements, such as ruggedness, low loss, and repeaterless spans, and the cable designs are accordingly selected. However, all these cable designs still rely on the basic unit designs discussed above.

Defining Terms

Attenuation: Decrease of average optical power as light travels along the length or an optical fiber.

Bandwidth: Measure of the information-carrying capacity of the fiber. The greater the bandwidth, the greater the information-carrying capacity.

Barrier layer: Layer of deposited glass adjacent to the inner tube surface to create a barrier against OH diffusion.

Chemical vapor deposition: Process in which products of a heterogeneous gas-liquid or gas-solid reaction are deposited on the surface of a substrate.

Cladding: Low refractive index material that surrounds the fiber core.

Core: Central portion of a fiber through which light is transmitted.

Cut-off wavelength: Wavelength greater than which a particular mode ceases to be a bound mode.

Dispersion: Cause of distortion of the signal due to different propagation characteristics of different modes, leading to bandwidth limitations.

Graded-index profile: Any refractive index profile that varies with radius in the core.

Microbending: Sharp curvatures involving local fiber axis displacements of a few micrometers and spatial wavelengths of a few millimeters. Microbending causes significant losses.

Mode: Permitted electromagnetic field pattern within an optical fiber.

Numerical aperture: Acceptance angle of the fiber.

Optical repeater: Optoelectric device that receives a signal and amplifies it and retransmits it. In digital systems the signal is regenerated.

43.1 Introduction

Over the past two decades, microwave active circuits have evolved from individual solid state transistors and passive elements housed in conventional waveguides and/or coaxial lines to fully integrated planar assemblies, including active and passive components and interconnections, generically referred to as a microwave integrated circuit (MIC). The **hybrid microwave integrated circuit** (HMIC) consists of an interconnect pattern and distributed circuit components printed on a suitable substrate, with active and lumped circuit components (in packaged or chip form) attached individually to the printed interconnect circuit by the use of soldering and wire bonding techniques. The solid state active elements are either silicon or gallium arsenide (or other III–V compound) devices. More recently, the solid state **monolithic microwave integrated circuit** (MMIC) approach has become commonplace. In MMICs, all interconnections and components, both active and passive, are fabricated simultaneously on a semi-insulating semiconductor substrate (usually gallium arsenide, GaAs) using deposition and etching processes, thereby eliminating discrete components and wire bond interconnects. The term MMIC is used for circuits operating in the millimeter wave (30–300 GHz) region of the frequency spectrum as well as the microwave (1–30 GHz) region. Major advantages of MMICs include low cost, small size, low weight, circuit design flexibility, broadband performance, elimination of circuit tweaking, high-volume manufacturing capability, package simplification, improved reproducibility, improved reliability, and multifunction performance on a single chip.

Microwave circuits use two types of active devices: two-terminal devices, referred to as diodes, such as Schottky, Gunn, tunnel, impact avalanche and transit time (IMPATT), varactor, and **PIN**, and three-terminal devices, referred to as transistors, such as bipolar junction transistor (BJT), metal semiconductor field effect transistor (MESFET), high electron mobility transistor (HEMT), heterostructure FET (HFET), and heterojunction bipolar transistor (HBT). Microwave circuits using these devices include **amplifiers**, **oscillators**, **multipliers**, **mixers**, **switches**, **phase shifters**, **attenuators**, modulators, and many others used for receiver or transmitter applications covering microwave and millimeter wave frequency bands. New devices, microwave **computer-aided design (CAD)** tools, and automated testing have played a significant role in the advancement of these circuits during the past decade. The theory and performance of most of these circuits have been well documented [Kollberg, 1984; Bhartia and Bahl, 1984; Pucel, 1985; Maas, 1986; Bahl and Bhartia, 1988; Goyal, 1989; Ali et al., 1989; Chang, 1990; Vendelin et al., 1990; Ali and Gupta, 1991; Chang, 1994]. Solid state circuits are extensively used in such applications as radar, communication, navigation, electronic warfare (EW), smart weapons,

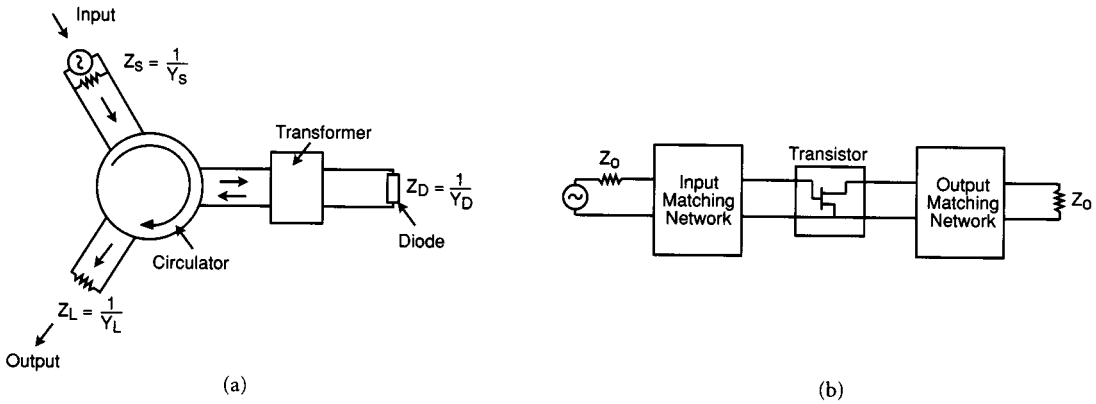

FIGURE 43.1 Amplifier circuits configurations. (a) Two-terminal negative resistance type requires a circulator to isolate the input and output ports. (b) Three-terminal transistor type requires input and output matching networks.

consumer electronics, and microwave instruments and equipment. This section will briefly describe the performance status of amplifiers, oscillators, multipliers, mixers, and microwave control circuits.

43.2 Amplifiers

Amplifier circuits have received maximum attention in solid state circuits development. The two-terminal device amplifiers, such as parametric, tunnel, Gunn, and IMPATT, are normally called *reflection-type circuits,* or *negative resistance amplifiers.* A diagram for these amplifiers is shown in Fig. 43.1(a). Parametric amplifiers are narrowband (<10%) and have very good noise figure. Tunnel-diode amplifiers are high-gain, low-noise figure, and low-power circuits. Octave **bandwidth** of such amplifiers is possible. The performance of Gunn-diode amplifiers is quite similar to tunnel-diode amplifiers. IMPATT-diode amplifiers are high power and high efficiency. They are moderately noisy, and bandwidths up to an octave are possible.

The basic circuit configuration for three-terminal device amplifiers is shown in Fig. 43.1(b). Several different types of amplifiers developed using transistors are low noise, power, high linearity, broadband, high efficiency, logarithmic, limiting, transimpedance, and variable gain. The silicon bipolar transistor performs very well up to about 4 GHz, with reliable performance, high power, high gain, and low cost. The GaAs MESFETs perform better than the bipolar transistors above 4 GHz. They are broadband, have a wide dynamic range, are highly reliable, and are low cost. Both low-noise and medium-power MESFET amplifiers are available. They compete with uncooled parametric amplifiers as well as moderate-power IMPATTs. HEMTs find a niche in low-noise and high-frequency applications. The **noise figure** of HEMT amplifiers is better than that of uncooled parametric amplifiers up to 100 GHz, as shown in Fig. 43.2.

Various techniques are used to realize small signal or low-power broadband amplifiers. Five of them are shown in Fig. 43.3. The distributed approach provides the unique capability of excellent gain-bandwidth product, low **VSWR (voltage standing wave ratio)**, and moderately low noise figure. This technique has been successfully used in monolithic ultrabroadband amplifiers. The performance of such amplifiers using various transistor devices is given in Table 43.1.

The performance of solid state power amplifiers is shown in Fig. 43.4. Currently, IMPATT and Gunn diodes provide maximum power above 10 GHz, whereas bipolar junction transistor and MESFET technologies offer the most promise to generate higher power levels below 10 GHz. In particular, IMPATT devices have been operated over the complete millimeter wave band and have shown good continuous wave (CW) and pulsed power efficiency and reliability.

During the past decade significant progress has been made in monolithic power amplifiers operating over both the narrowband and broadband [Williams and Bahl, 1992; Tserng and Saunier, 1991]. Power levels as high as 12 W from a single MMIC chip at C-band with 60% power-added efficiency (PAE) have been demonstrated. A 6-W MMIC chip has been developed at X-band. A 2-W power output has been obtained at 30 GHz.

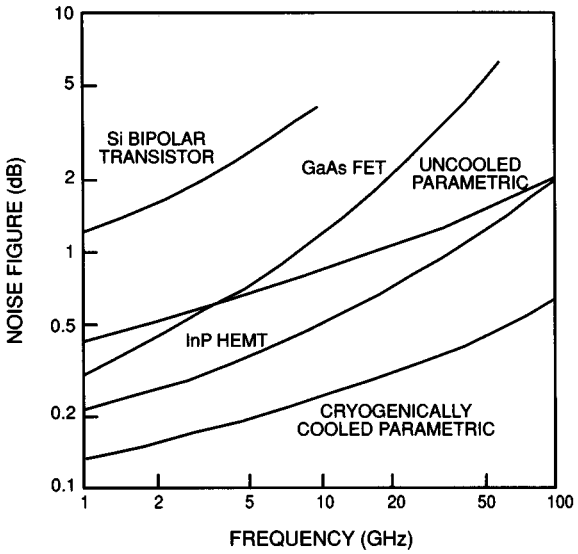

FIGURE 43.2 Comparison of noise performance of various solid state amplifiers; the InP HEMT LNA, which is also compatible with MMIC technology, is a clear choice for receiver applications where cryogenic cooling is precluded. (*Source:* D. Willems and I. Bahl, "Advances in Monolithic Microwave and Millimeter Wave Integrated Circuits," *IEEE Int. Circuits and Systems Symp. Digest,* pp. 783–786. © 1992 IEEE. With permission.)

In the high- efficiency area, a C-band MMIC amplifier with 70% PAE, 8-dB gain, and 1.7-W power output has been demonstrated. For broadband amplifiers having an octave or more bandwidth, MMIC technology has been exclusively used and is quite promising. Figure 43.5 depicts power performance for single-chip MMIC amplifiers spanning microwave and millimeter wave frequencies. The state of the art in high efficiency and broadband power MMIC amplifiers is summarized in Tables 43.2 and 43.3, respectively. Note that the high-efficiency examples included in Table 43.2 all exceed 40% PAE.

43.3 Oscillators

Solid state oscillators represent the basic microwave energy source and have the advantages of light weight and small size compared with microwave tubes. As shown in Fig. 43.6, a typical microwave oscillator consists of a MESFET as an active device (a diode can also be used) and a passive frequency-determining resonant element, such as a microstrip, surface acoustic wave (SAW), cavity resonator, or dielectric resonator for fixed tuned oscillators and a varactor or a yttrium iron garnet (YIG) sphere for tunable oscillators. These oscillators have the capability of temperature stabilization and phase locking. Dielectric resonator oscillators provide stable operation from 1 to 100 GHz as fixed frequency sources. In addition to their good frequency stability, they are simple in design, have high efficiency, and are compatible with MMIC technology. Gunn and IMPATT oscillators provide higher power levels and cover microwave and millimeter wave bands. The transistor oscillators using MESFETs, HEMTS, and HBTs provide highly cost-effective, miniature, reliable, and low-noise sources for use up to the millimeter wave frequency range, while BJT oscillators reach only 20 GHz. Compared to a GaAs MESFET oscillator, a BJT or a HBT oscillator typically has 6 to 10 dB lower phase noise very close to the carrier. Figure 43.7 shows the performance of various solid state oscillators. Higher power levels for oscillators are obtained by connecting high-power amplifiers at the output of medium-power oscillators.

43.4 Multipliers

Microwave frequency multipliers are used to generate microwave power at levels above those obtainable with fundamental frequency oscillators. Several different nonlinear phenomena can be used to achieve frequency

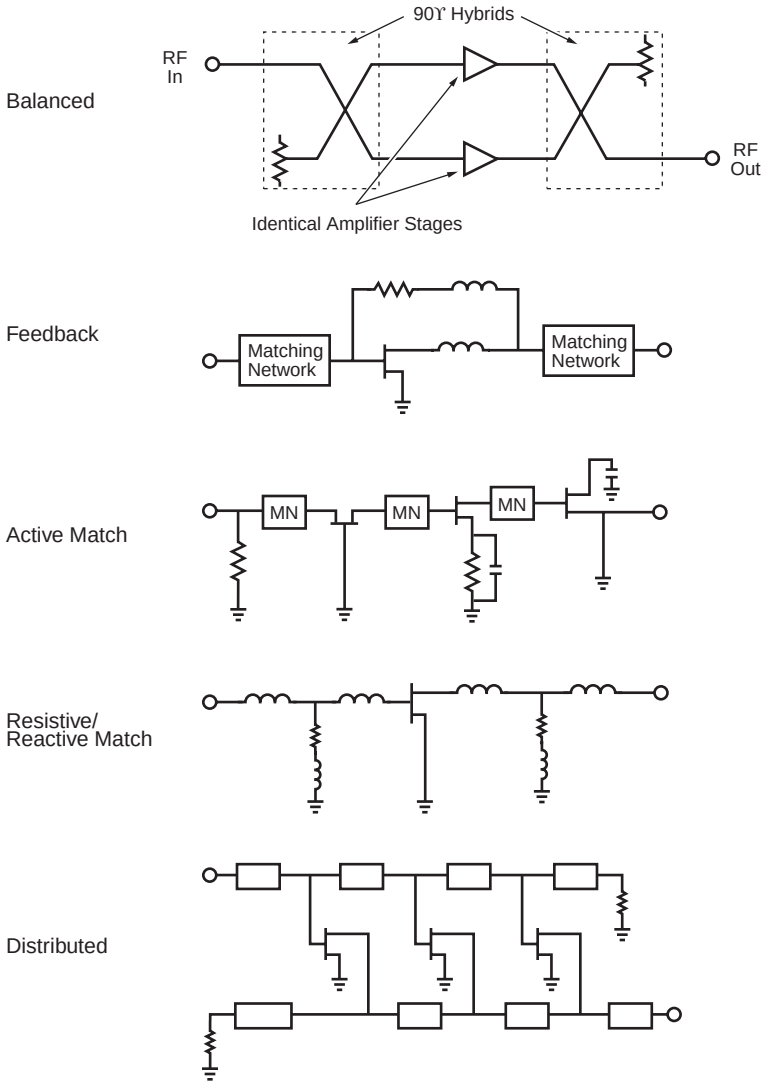

FIGURE 43.3 Broadband amplifier configurations. *Balanced* has low noise figure and better cascadability, *feedback* has small size, *active match* is more suitable for monolithic approach, and *distributed* is good for multioctave bandwidths.

multiplication, e.g., nonlinear reactance in varactors and step-recovery diodes and nonlinear resistance in Schottky barrier diodes and three-terminal devices (BJT, MESFET, HEMT, HBT).

Varactor multipliers offer the best frequency multiplier performance. Varactor multipliers (pulsed) have achieved power output in excess of 100 and 10 W at 4 and 10 GHz, respectively [Bahl and Bhartia, 1988]. Table 43.4 shows the best performance measured in the millimeter wave range and above.

43.5 Mixers

Mixers convert (heterodyne) the input frequency to a new frequency, where filtering and/or gain is easier to implement, in contrast to detectors, which are used to provide an output signal that contains the amplitude or amplitude variation information of the input signal. A mixer is basically a multiplier, which requires two

signals and uses any solid state device that exhibits nonlinear properties. Mixing is achieved by applying an RF and a high-power local oscillator signal to a nonlinear element, which can be a diode or a transistor.

As illustrated in Fig. 43.8, there are many types of mixers: one diode (single ended), two diodes (balanced or antiparallel), four diodes (double balanced), and eight diodes (double-double balanced). Mixers can also be realized using the nonlinearities associated with transistors that provide conversion gain. The most commonly used mixer configuration in the microwave frequency band is the double-balanced mixer, which has better isolation between the ports and better spurious response. However, the single and balanced mixers place lower power requirements on the local oscillator and have lower conversion loss.

Subharmonic mixing (where the local oscillator frequency is approximately half that needed in conventional mixers) has been extensively used at millimeter wave frequencies. This technique is quite useful when reliable stable local oscillators are either unavailable or prohibitively expensive at high frequencies. Figure 43.9 gives the performance of millimeter wave mixers.

43.6 Control Circuits

Control components are widely used in communication, radar, EW, instrument, and other systems for controlling the signal flow or to adjust the phase and amplitude of the signal [Bahl and Bhartia, 1988; Chang, 1990; Sharma, 1989; Sokolov, 1991]. PIN diodes and MESFETs are extensively used in HMICs and MMICs, respectively, for microwave control circuits, such as switches, phase shifters, attenuators, and limiters. PIN diode circuits have low loss and can handle higher power levels than do MESFET components; conversely, the latter have great flexibility in the design of integrated subsystems, consume negligible power, and are low cost.

Figure 43.10 shows various control configurations being developed using PIN and MESFET devices. Either device can be used in these circuits.

The most commonly used configuration for microwave switches is the single-pole double throw (SPDT) as shown in Fig. 43.10(a), which requires a minimum of two switching devices (diodes or transistors). Table 43.5 provides typical performance for broadband SPDT switches developed using GaAs MESFET monolithic technology. Table 43.5 also summarizes performance for phase shifters and attenuators, which are described briefly below.

There are four main types of solid state digitally controlled phase shifters: switched line, reflection, loaded line, and low-pass/high-pass, as shown in Fig. 43.10(b). The switched-line and low-pass/high-pass configurations, which are most suitable for broadband applications and compact size, are not suitable for analog operation. Reflection and loaded-line phase shifters are inherently narrowband; however, the loaded-line small bit phase shifters, 22.5 degrees or less, can be designed to have up to an octave bandwidth. Phase shifters using the vector-modulator concept have also been developed in monolithic form.

Voltage-controlled variable attenuators are important control elements and are widely used for automatic gain control circuits. They are indispensable for temperature compensation of gain variation in broadband

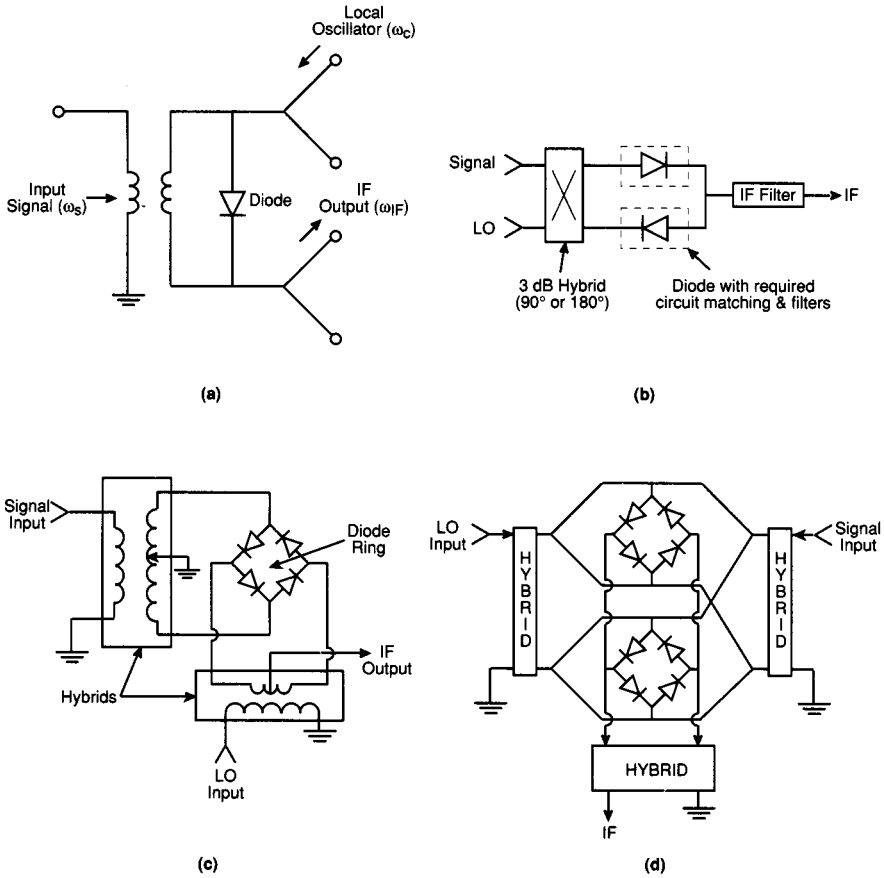

FIGURE 43.8 Basic mixer configurations: (a) single ended, (b) balanced, (c) double balanced, and (d) double-double balanced.

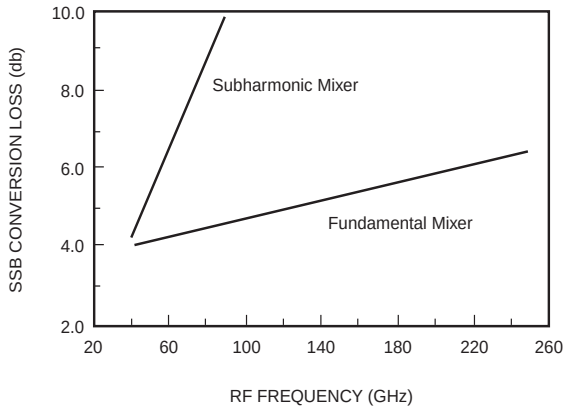

FIGURE 43.9 Single-sideband (SSB) conversion loss of millimeter wave mixers. Subharmonic type mixers have higher conversion loss but are generally less expensive.

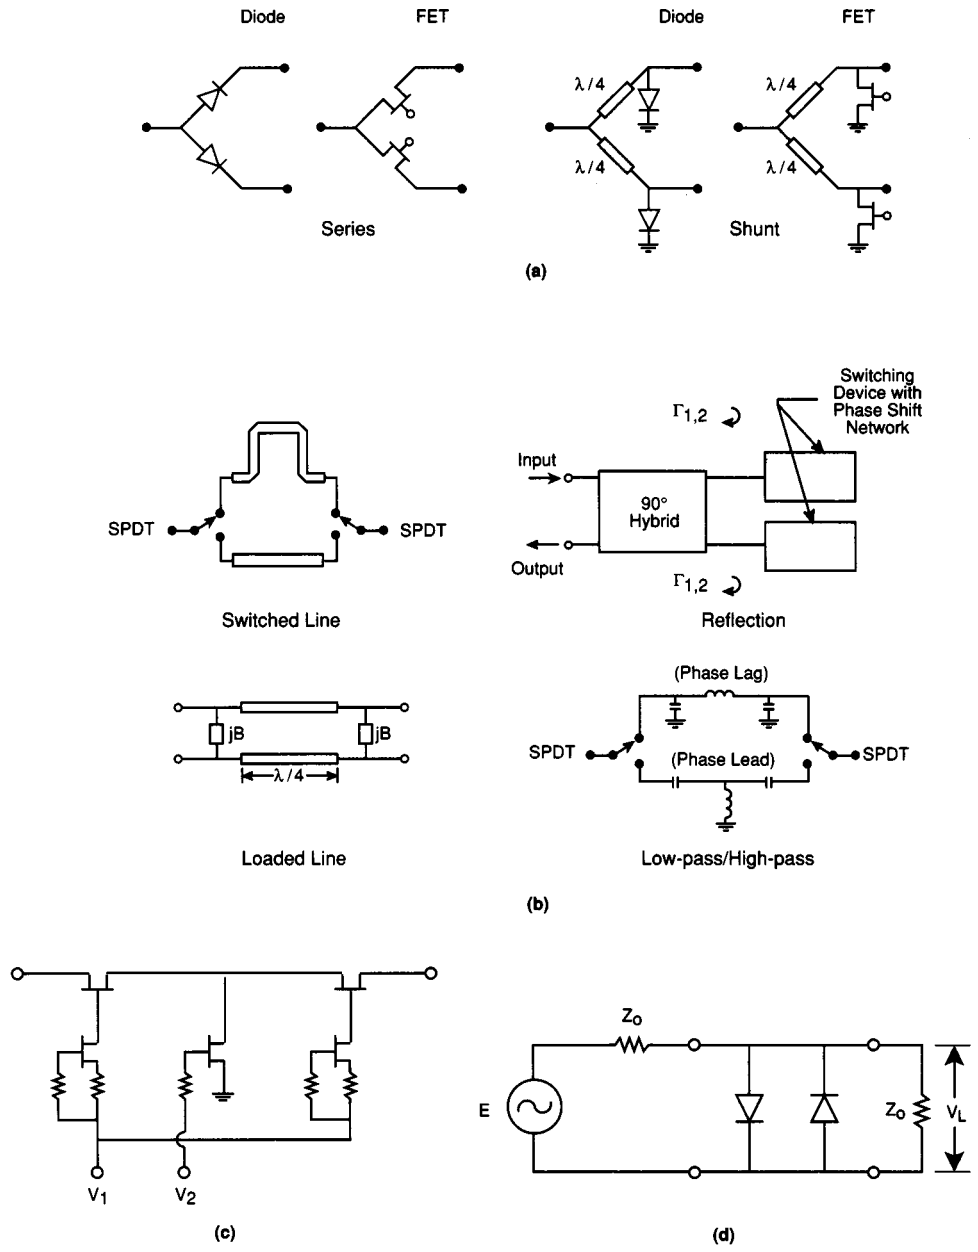

FIGURE 43.10 Microwave control circuits: (a) SPDT switch configurations, (b) basic phase shifter types, (c) schematic of a MESFET attenuator, and (d) basic limiter circuit using two rectifying diodes.

amplifiers. Both PIN diodes and GaAs MESFET devices are used for variable attenuators. Figure 43.10(c) shows a variable attenuator configuration using MESFETs in the passive mode. Apart from the use of MESFETs in the passive mode, active MESFET amplifier circuits may also be used for variable attenuation circuits. **Dual-gate MESFET** amplifiers with controlled voltage applied to the second gate are ideal for this purpose and provide a lower noise figure than the passive attenuators.

A ***limiter***, whose basic configuration is shown in Fig. 43.10(d), is an important control component used at microwave frequencies. An ideal limiter has no attenuation when low power is incident upon it but has an attenuation that increases with increasing power (above a threshold level) to maintain constant output power. Limiters are also used to protect the receivers from other nearby radar transmitters. Schottky and PIN diodes

TABLE 43.5 Performance of GaAs FET Control Monolithic ICs

Circuit Function	Frequency (GHz)	Maximum Insertion Loss (dB)	Minimum Return Loss (dB)	RMS Error (deg.)	Minimum Isolation (dB)	Minimum Dynamic Range (dB)	Maximum Power (dBm)	Minimum Switching Speed (ns)	Size (mm2)
Broadband SPDT switch	DC-20	12.0	17	—	24	—	25	0.4	1.27 × 1.27
	DC-40	13.0	17	—	23	—	25	0.8	0.84 × 1.27
2 × 2 Switch matrix	DC-20	13.5	10	—	30	—	—	—	2.03 × 1.78
6-Bit phase shifter	5–6	16.0	10	±2.0	—	—	—	5.0	9.43 × 4.20
3-Bit phase shifter	6–18	11.5	13	±8.5	—	—	—	—	2.2 × 1.25
Variable attenuator	DC-50	14.2	19	—	—	30	—	1.0	1.52 × 0.65
Multibit attenuator	DC-20	15.0	12	—	—	75	26	—	2.55 × 1.57

are commonly used to realize these components. Because they are used at the front ends of receivers, low loss is one of the basic requirements.

43.7 Summary and Future Trends

In this section we have briefly described the performance of microwave and millimeter wave solid state circuits. Currently the discrete silicon bipolar transistors, IMPATT diodes, and GaAs MESFETs are most widely used in solid state circuits and bipolar transistors, and IMPATT diodes are still the most powerful solid state sources below S-band and 10 to 300 GHz, respectively. The MESFET is the workhorse for microwave circuits up to 40 GHz. The HEMT applications are similar to the MESFET, including amplifiers, oscillators, frequency multipliers, mixers, and control circuits, and above 50 GHz, this device is exclusively used for power and low-noise amplifiers. The HBTs applications include high-efficiency amplifiers, ultrabroadband dc amplifiers, low-noise oscillators, frequency multipliers, and mixers.

During the past decade, GaAs monolithic technology has made tremendous progress in producing single and multifunction microwave and millimeter wave circuits using MESFETs, HEMTs, and HBTs. This technology is exerting a profound impact in producing low-cost and high-volume solid state circuits. Since monolithic circuits have the advantage of bandwidth and reproducibility over discrete devices because of wire bond elimination, the growth in millimeter wave solid state circuits will be based on this technology, and a cost reduction by a factor greater than 10 is expected in the near future. Wherever possible, the two-terminal devices such as IMPATT and Gunn diodes will be replaced by the transistors. Future trends in solid state circuits also include their optical control, tuning, and stabilization.

Defining Terms

Amplifier: Active two-port device with signal of higher amplitude than the input signal while retaining the essential signal characteristics of the input signal.

Attenuator: Two-port device with output signal of lower amplitude than the input signal while retaining the essential signal characteristics of the input signal.

Bandwidth (BW): A measure of the frequency range over which the circuit performs to specified parameters such as gain, noise figure, power output, etc.

Computer Aided Design (CAD): A design tool that constitutes circuit simulators and optimization programs/algorithms to aid the design of microwave circuits to meet the specified performance goals.

Dual-Gate MESFET: This device is similar in operation to MESFET but possesses two gates: an RF gate and a control gate, instead of a single RF gate.

Gain: The ratio of the output signal to the input signal of an amplifier.

Hybrid microwave integrated circuit (HMIC): A planar assembly that combines different circuit functions formed by strip or microstrip transmission lines printed onto a dielectric substrate and incorporating discrete semiconductor solid state devices and passive distributed or lumped circuit elements, interconnected with wire bonds.

Limiter: A circuit in which the output power is prevented from exceeding a predetermined value.

Mixer: A three-port device in which the output signal is a harmonic of the add mixture of an input signal and a local oscillator signal. An up converter is a mixer in which the output signal frequency is above the input signal. A down converter is a mixer in which the output signal frequency is below the input signal.

Monolithic microwave integrated circuit (MMIC): An MMIC is formed by fabricating all active and passive circuit elements or components and interconnections onto or into the surface of a semi-insulating semiconducting substrate by deposition and etching schemes such as epitaxy, ion implantation, sputtering, evaporation, and/or diffusion, and utilizing photolithographic processes for pattern definition, thus eliminating the need for internal wire bond interconnects.

Multiplier: A two-port device in which the output signal is a harmonic of the input signal.

Noise Figure: The noise figure of any linear two-port circuit is defined as the signal-to-room temperature thermal noise ratio at the input divided by the signal-to-noise ratio at the output.

Oscillator: An active one-port device which produces a nominally frequency stable constant amplitude signal.

PIN Diode: A two-port semiconductor device in which a p doped contact is isolated from an *n*-doped contact by an intrinsic region forming an anisotropic junction.

Phase Shifter: A circuit that provides a shift in the phase of the output signal with respect to a reference value.

Return Loss: Ratio of reflected power to input power of a signal port.

Switch: A circuit designed to close or open one or more transmission paths for the microwave signals.

Voltage Standing Wave Ratio (VSWR): Ratio of maximum voltage amplitude to the minimum voltage amplitude at the specified port.

Further Information

The monthly journal *IEEE Transactions on Microwave Theory and Techniques* routinely publishes articles on the design and performance of solid state circuits. Special issues published in July 1982, January and February 1983, March 1984, and September 1989 exclusively deal with this topic.

IEEEMicrowave and Millimeter-Wave Monolith Circuits Symposium Digests, published every year since 1982, include comprehensive information on the design and performance of monolithic microwave and millimeter-wave solid state circuits.

Books included in the references of this chapter discuss thoroughly the design, circuit implementation, and performance of solid state circuits.

44.1 Introduction

The three-dimensional analysis of electromagnetic fields requires the use of numerical techniques exploiting the best available computer systems. The well-found laboratory will have at its disposal a range of machines that allow interactive data processing with access to software that provides geometric modeling tools and has sufficient central processing unit (CPU) power to solve the large (>10,000) set of algebraic equations involved, see Section 44.4.

44.2 The Field Equations

The classical equations governing the physical behavior of electromagnetic fields over the frequency range dc to light are **Maxwell's equations**. These equations relate the magnetic flux density (**B**), the electric field intensity (**E**), the magnetic field intensity (**H**), and the electric field displacement (**D**) with the electric charge density (ρ) and electric current density (J). The field vectors are not independent since they are further related by the material constitutive properties: $B = \mu H$, $D = \epsilon E$, and $J = \sigma E$ where μ, ϵ, and σ are the material permeability, permittivity, and conductivity, respectively. In practice these quantities may often be field dependent, and furthermore, some materials will exhibit both anisotropic and hysteretic effects. It should be strongly stated that accurate knowledge of the material properties is one of the most important factors in obtaining reliable simulations.

Because the flux density vector satisfies a zero divergence condition (*div* $\mathbf{B} = 0$), it can be expressed in terms of a magnetic vector potential **A**, i.e., $\mathbf{B} = curl\ \mathbf{A}$, and it follows from Faraday's law that $\mathbf{E} = -(\partial A/\partial t + \nabla V)$, where V is the electric scalar potential. Neither A nor V is completely defined since the gradient of an arbitrary scalar function can be added to A and the time derivative of the same function can be subtracted from V without affecting the physical quantities E and B. These changes to A and V are the gauge transformations, and uniqueness is usually ensured by specifying the divergence of A and sufficient boundary conditions. If $\nabla \cdot A = -(\mu\sigma V + \mu\epsilon\partial V/\partial t)$ (Lorentz gauge) is selected, then the field equations in terms of A and V are:

$$\nabla \times \frac{1}{\mu} \nabla \times \mathbf{A} + \sigma \frac{\partial \mathbf{A}}{\partial t} + \epsilon \frac{\partial^2 \mathbf{A}}{\partial t^2} = \nabla \left[\frac{1}{\mu} \nabla \cdot \mathbf{A} \right]$$
$$\mu\epsilon \frac{\partial^2 V}{\partial t^2} + \mu\sigma \frac{\partial V}{\partial t} = \nabla \cdot \nabla V \tag{44.1}$$

where σ has been assumed piecewise constant. This choice of gauge decouples the vector potential from the scalar potential. For the important class of two-dimensional problems there will be only one component of A parallel to the excitation current density. For fields involving time, at least two types can be distinguished: the time harmonic (ac) case in which the fields are periodic at a given frequency ω, i.e., $A = A_o \exp(j\omega t)$, and the transient case in which the time dependence is arbitrary.

Low Frequency Fields

In the important class of problems belonging to the low frequency limit, i.e., eddy current effects at power frequencies, the second derivative terms with respect to time (wave terms) in Eq. (44.1) vanish. This approximation is valid if the dimensions of the material regions are small compared with the wavelength of the prescribed fields. In such circumstances the displacement current term in Maxwell's equations is small compared to the free current density and there will be no radiation [Stratton, 1941]. In this case, while a full vector field solution is necessary in the conducting regions, in free space regions, where $\sigma = 0$ and curl $H = J_s$ Eqs. (44.1) can be replaced by $\nabla^2\psi = 0$, where ψ is a scalar potential defined by $H = -\nabla\psi$. The scalar and vector field regions are coupled together by the standard interface conditions of continuity of normal flux (B) and tangential field (H).

Statics Limit

In the statics limit (dc) the time-dependent terms in Eq. (44.1) vanish, and the field can be described entirely by the Poisson equation in terms of a single component scalar potential, which will be economic from the numerical point of view. In this case the defining equation is

$$\nabla \cdot \mu\nabla\phi = \nabla \cdot \mu H_s \tag{44.2}$$

where ϕ is known as the reduced magnetic scalar potential with $H = H_s - \nabla\phi$, and H_s the source field given by the Biot Savart law. Some care is needed in solving Eq. (44.2) numerically, in practice, as H_s will often be calculated to a higher accuracy than ϕ. For instance, in regions with high permeability (e.g., ferromagnetic materials), the total field intensity H tends to a small quantity which can lead to significant errors due to cancellation between grad ϕ and H_s, depending upon how the computations are carried out. One approach that avoids this difficulty is to use the total scalar potential ψ in regions that have zero current density [Simkin and Trowbridge, 1979], i.e., where $H = -\nabla\psi$ and H_c is the coercive field for the material ψ satisfies

$$\nabla \cdot \mu\nabla\psi = \nabla \cdot \mu H_c \tag{44.3}$$

Again, the two regions are coupled together by the standard interface condition that results, in this case, in a potential "jump" obtained by integrating the tangential continuity condition, i.e.,

$$\phi = \psi + \int_0^\Gamma \mathbf{H}_s d\Gamma \tag{44.4}$$

where Γ is the contour delineating the two regions that must not intersect a current-carrying region; otherwise the definition of ψ will be violated.

44.3 Numerical Methods

Numerical solutions for the field equations are now routine for a large number of problems encountered in magnet design; these include, for example, two-dimensional models taking into account nonlinear, anisotropic, and even hysteretic effects. Their use for complete three-dimensional models is not so widespread because of the escalating computer resources needed as the problem size increases. Nevertheless, 3-D solutions for nonlinear statics devices are regularly obtained in industry, and time-dependent solutions are rapidly becoming more cost effective as computer hardware architectures develop.

Finite Elements

This increasing use of computer-based solutions has come about largely because of the generality of the finite element method (FEM). In this method, the problem space is subdivided (discretized) into finite regions (elements) over which the solution is assumed to follow a simple local approximating trial function (shape functions). In the simplest situation, a particular element could be a plane hexahedra defined by its eight vertices or nodes and a solution of Eq. (44.3) may be approximated by

$$\psi \approx u = \alpha_1 + \alpha_2 x + \alpha_3 y + \alpha_4 z + \alpha_5 xy + \alpha_6 yz + \alpha_7 zx + \alpha_8 xyz = \sum N_i U_i \quad (44.5)$$

Because a hexahedra has eight nodes it is natural to select a bilinear trial function with eight parameters; see Fig. 44.1 for other examples. The functions N_i are called the local shape functions and the parameters U_i are the solution values at the nodes. The finite elements can be integrated into a numerical model for the whole problem space either by (a) the variational method in which the total energy of the system is expressed in terms of the finite element trial functions and then minimized to determine the best solution or (b) the weighted residual method in which the formal error (residual), arising by substituting the trial functions into the defining equation, is weighted by a suitably chosen function and then integrated over the problem domain. The best fit for the trial function parameters can then be obtained by equating the integral to zero. Both methods lead to a set of algebraic equations and are equivalent if the weighting functions are chosen to be the trial functions (Galerkin's method [Zienkiewicz, 1990]). At the element level, the residual R_i is given by

$$R_i = \left[\int_{\text{elem}} \nabla N_i \mu \nabla N_j d\Omega \right] U_j + \int_{\text{elem}} N_i Q d\Omega \quad (44.6)$$

where Q (RHS) denotes the sources of Eqs. (44.2) or (44.3). The integrals can be readily evaluated and assembled for the whole problem by superposition, taking account of the boundary conditions and removing the redundancy at shared nodes. At interelement boundaries in a region of particular potential [reduced Eq. (44.2) or total Eq. (44.3)] the solution is forced to be continuous, but the normal flux (i.e., $\mu \partial U/\partial n$) will only be continuous in a weak sense, that is to say the discontinuity will depend upon the mesh refinement.

The FEM provides a systematic technique for replacing the continuum field equations with a set of discrete algebraic equations that can be solved by standard procedures. In Fig. 44.2 a typical field map is shown for a permanent magnet machine modeled by a computer simulator that can take into account nonlinearity and permanently magnetized materials. Although hysteresis effects can be included, the computational resources required can be prohibitive because of the vector nature of magnetization. The magnetic material must be characterized by a large number of measurements to take account of the minor loops, and from these the convolution integrals necessary to obtain the constitutive relationships can be evaluated [Mayergoyz, 1990]. These characteristics must then be followed through time; this can be implemented by solving at a discrete set of time points, given the initial conditions in the material.

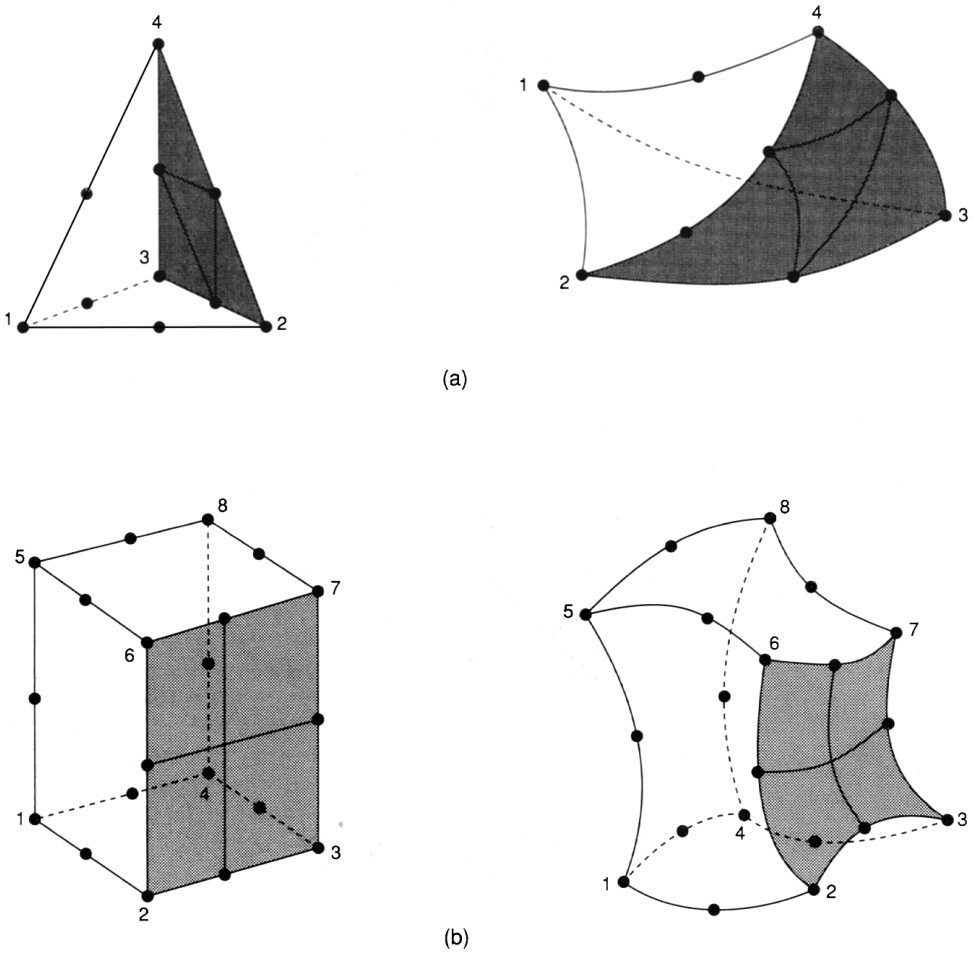

FIGURE 44.1 Three-dimensional second-order Isoparametric finite elements. (a) *Left*, master tetrahedron, 10 nodes in local space (ξ, η, ζ); right, actual tetrahedron, 10 nodes in global space (x, y, z). (b) Left, master hexahedron, 20 nodes in local space (ξ, η, ζ); right, actual hexahedron, 10 nodes in global space (x, y, z).

Although the FEM is widely used by industry for electromagnetic problems covering the entire frequency range, there are many situations where special methods are more effective. This is particularly the case for high-frequency problems, e.g., millimeter and microwave integrated circuit structures where integral equation techniques and such procedures as transmission line modeling (TLM), spectral domain approach, method of lines, and wire grid methods are often preferred [Itoh, 1989] (see Chapter 43).

Edge Elements

Using potentials and nodal finite elements (see Fig. 44.1) rather than field components directly has the advantage that difficulties arising from field discontinuities at material interfaces can be avoided. However, if the element basis functions [see Eq. (44.5)] are expressed in terms of the field (**H**, say) constrained along an element edge, then tangential field continuity is enforced [Bossavit, 1988]. The field equations [Eq. (44.1)] in terms of the field intensity for the low frequency limit reduce to

$$\nabla \times \nabla \times \mathbf{H} + \sigma \frac{\partial(\mu \mathbf{H})}{\partial t} = 0 \tag{44.7}$$

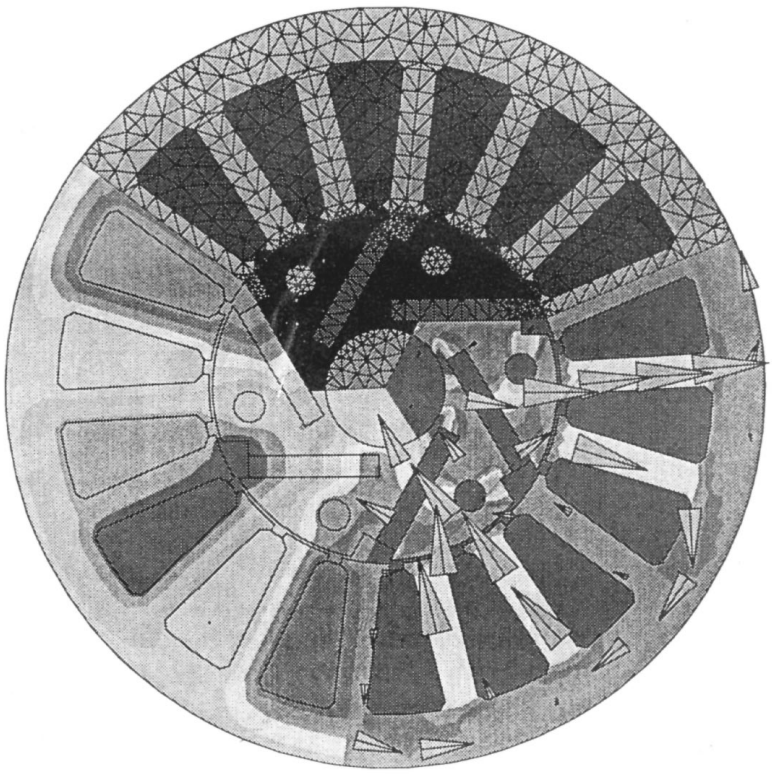

FIGURE 44.2 Permanent magnet motor.

and a suitable edge variable basis function form for solving this equation by finite elements using tetrahedral elements is

$$\mathbf{h}(\mathbf{r}) = \mathbf{a} + \mathbf{b} \times \mathbf{r} \tag{44.8}$$

where **r** is the position vector and **a** and **b**, respectively, are vectors dependent on the geometry of the element. The basis function expansion is given by

$$\mathbf{H} = \sum \mathrm{h_e(r)H_e} \tag{44.9}$$

where $\mathbf{h}_e$ is the vector basis function for edge **e**, and $\mathbf{H}_e$ is the value of the field along an element edge (see Fig. 44.3). The functions, Eqs. (44.8) and (44.9), have the property of being divergence free, and most important they ensure that the tangential component of **H** is continuous while allowing for the possibility of a discontinuity in the normal component. In nonconducting regions where the field can be economically modeled by a scalar potential, standard nodal elements can be used. At the interface the edge elements couple exactly with the nodal elements.

Integral Methods

An alternative procedure is to solve the field equations in their integral form, see also Chapter 43. For example, in magnetostatics, the magnetization vector **M** given by $\mathbf{M} = (\mu - 1)\mathrm{H}$ can be used instead of H to derive an integral equation over all ferromagnetic domains of the problem, i.e.,

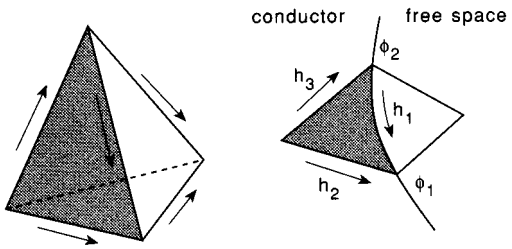

FIGURE 44.3 Edge variables for a tetrahedron element, $\mathbf{h}_1 = (\Phi_2 - \Phi_1)/l$.

$$\mathbf{M}(\mathbf{r}) = (\mu - 1)\left[\mathbf{H}_s(\mathbf{r}') - \frac{1}{4\pi}\nabla\int_{\Omega}\mathbf{M}\cdot\nabla\left(\frac{1}{R}\right)d\Omega\right] \tag{44.10}$$

where R is the distance between the source and field point, respectively. For problems with linear materials Eq. (44.10) reduces to integrations over the bounding surfaces of materials in terms of the magnetic scalar potential, i.e.,

$$4\pi\phi = -\int_{\Gamma}\left(\frac{1}{R}\frac{\partial\phi}{\partial n} - \phi\frac{\partial 1/R}{\partial n}\right)d\Gamma \tag{44.11}$$

Equation (44.11) can be solved numerically by the boundary element method (BEM) in which the active surfaces are discretized into elements. The advantages of integral formulations compared to the standard differential approach using finite elements are (a) only active regions need to be discretized, (b) the far field boundary condition is automatically taken into account, and (c) the fields recovered from the solution are usually very smooth. Unfortunately, the computational costs rapidly escalate as the problem size increases because of the complexity of the system coefficients and because the resulting matrix is fully populated, whereas in the differential approach the coefficients are simple and the matrix is sparse, allowing the exploitation of fast equation solution methods.

44.4 Modern Design Environment

The most common system used in software packages is one in which the pre-processor includes data input, model building, and mesh (element) generation. Although fully automated meshing is now a practical possibility it needs to be combined with error estimation in order to allow the generation of optimal meshes. This approach is now common for 2-D systems and is available in many 3-D systems. Figure 44.4 illustrates a field simulation environment in which the solution processor includes an adaptive mesh generator controlled by *a posteriori* error estimation. This avoids the costly and essentially heuristic task of mesh generation which, in the past, had to be performed by the designer. Furthermore a modern system should have solid modeling capabilities driven by parametric data allowing the user to specify the appropriate engineering quantities, e.g., in the case of a solid cylinder the radius and length are all that is needed to specify the geometry at some predefined location. The system should also be supported by a database which is compliant with evolving standards such as STEP (Standard for the Exchange of Product data-ISO 10303 [Owen, 1993]) thus allowing data communication between other systems.

The environment illustrated in Fig. 44.4 also shows tools for automatic optimization that are now becoming feasible in industrial design applications. Both deterministic and stochastic methods for minimizing constrained objective functions of the design space have been developed for electromagnetic applications (For a review see Russenschuck, 1996). It must be emphasized, however, that the use of optimizing methods is only part of the total problem of design. For example, the process of automatic synthesis based on design rules and engineering

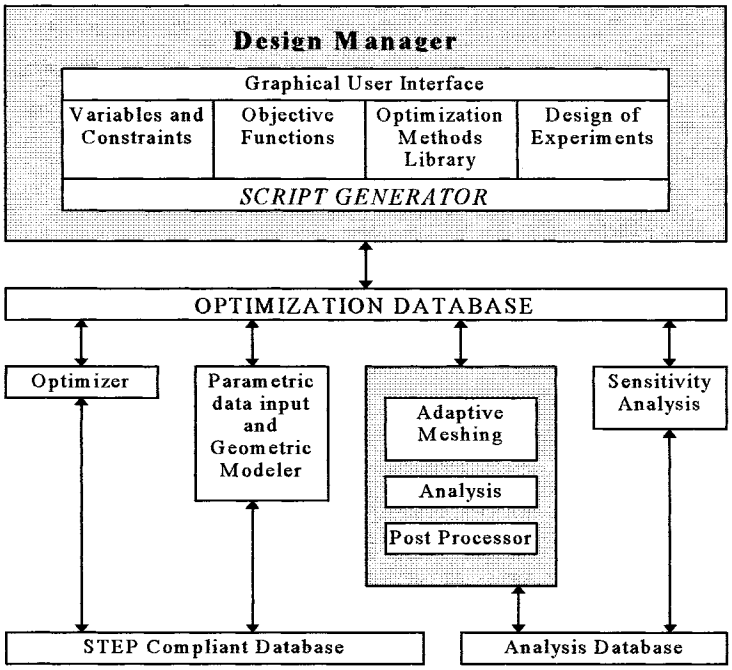

FIGURE 44.4 Electromagnetic design environment.

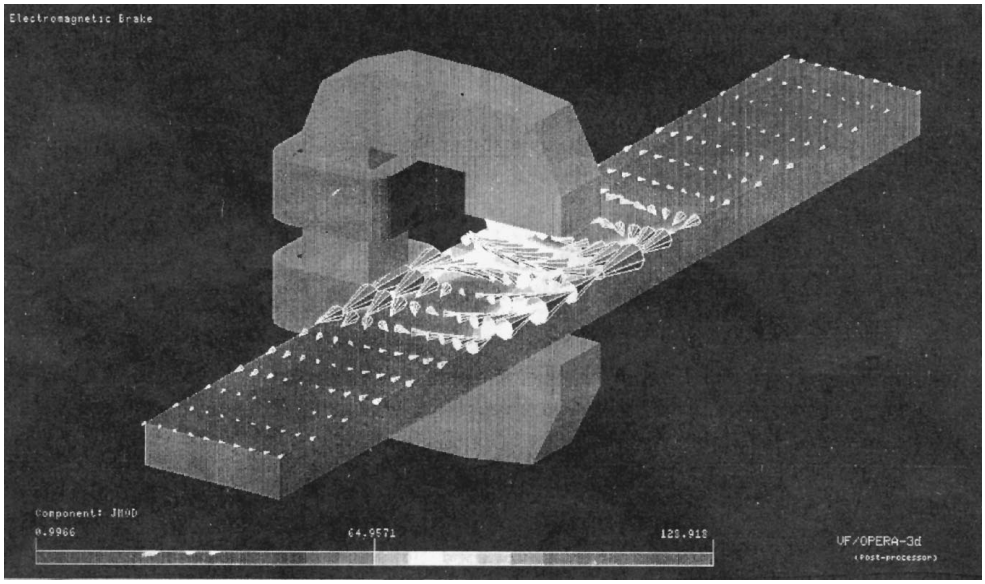

FIGURE 44.5 Moving copper strip, retarded by an electromagnet.

knowledge may provide engineers with a complementary methodology to assist in the creativity that is the essence of design (see Lowther, 1996). An example of a finite element solution displayed on a modern workstation for a three-dimensional eddy current problem with a moving conductor retarded by a *c-core* electromagnet is shown in Fig. 44.5. The post-processor indicates the magnitude and direction of the induced eddy

currents in the moving copper strip by the solid *cones* and the magnetic field by the gray scaled contours. This modest problem was modeled with 5,664 degrees of freedom (No. of equations) and needed 198 cp seconds running on a workstation rated at SPECfp92 96.5. However most industrial problems will require many more degrees of freedom, and typically a non-linear magnetostatic problem with 200,000 equations needed 75 mintues and 25 Mbytes of RAM on the same machine. The resources needed for transient non-linear problems will be far greater.

Defining Terms

Biot Savart law: $$\mathrm{H}_s = \frac{1}{4\pi}\int_{\Omega} \mathrm{J}_s \times \nabla \frac{1}{R} d\Omega$$

where **R** is the distance from the source point to the field point.

Interface conditions:
$$(\mathbf{B}_2 - \mathbf{B}_1) \cdot \mathbf{n} = \mathbf{0}$$
$$(\mathbf{D}_2 - \mathbf{D}_1) \cdot \mathbf{n} = \omega$$
$$(\mathbf{H}_2 - \mathbf{H}_1) \times \mathbf{n} = \mathbf{K}$$
$$(\mathbf{E}_2 - \mathbf{E}_1) \times \mathbf{n} = \mathbf{0}$$

where **K** and ω are the surface current and charge densities, respectively.

Maxwell's equations:
$$\nabla \cdot \mathrm{D} = \rho \quad \text{(Gauss's law)}$$
$$\nabla \cdot \mathrm{B} = 0$$
$$\nabla \times \mathrm{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad \text{(Faraday's law)}$$
$$\nabla \times \mathrm{H} = \mathrm{J} + \frac{\partial \mathbf{D}}{\partial t} \quad \text{(Ampere's law + displacement current)}$$

45.1 Introduction

The continuing growth of computing resources is changing how we think about, formulate, solve, and interpret problems. In electromagnetics as elsewhere, computational techniques are complementing the more traditional approaches of measurement and analysis to vastly broaden the breadth and depth of problems that are now quantifiable. Computational electromagnetics (CEM) may be broadly defined as that branch of electromagnetics that intrinsically and routinely involves using a digital computer to obtain numerical results. With the evolutionary development of CEM during the past 20-plus years, the third tool of computational methods has been added to the two classical tools of experimental observation and mathematical analysis.

This discussion reviews some of the basic issues involved in CEM and includes only the detail needed to illustrate the central ideas involved. The underlying principles that unify the various modeling approaches used in electromagnetics are emphasized while avoiding most of the specifics that make them different. Listed throughout are representative, but not exhaustive, numbers of references that deal with various specialty aspects of CEM. For readers interested in broader, more general expositions, the well-known book on the moment method by Harrington [1968]; the books edited by Mittra [1973, 1975], Uslenghi [1978], and Strait [1980]; the monographs by Stutzman and Thiele [1981], Popovic, et al. [1982], Moore and Pizer [1984], and Wang [1991]; and an IEEE Press reprint volume on the topic edited by Miller et al. [1991] are recommended, as is the article by Miller [1988] from which this material is excerpted.

This chapter is excerpted from E. K. Miller, "A selective survey of computational electromagnetics," *IEEE Trans. Antennas Propagat.*, vol. AP-36, pp. 1281–1305, ©1988 IEEE.

45.2 Background Discussion

Electromagnetics is the scientific discipline that deals with electric and magnetic sources and the fields these sources produce in specified environments. Maxwell's equations provide the starting point for the study of electromagnetic problems, together with certain principles and theorems such as superposition, reciprocity, equivalence, induction, duality, linearity, and uniqueness, derived therefrom [Stratton, 1941; Harrington, 1961]. While a variety of specialized problems can be identified, a common ingredient of essentially all of them is that of establishing a quantitative relationship between a cause (forcing function or input) and its effect (the response or output), a relationship which we refer to as a **field propagator**, the computational characteristics of which are determined by the mathematical form used to describe it.

Modeling as a Transfer Function

The foregoing relationship may be viewed as a generalized transfer function (see Fig. 45.1) in which two basic problem types become apparent. For the analysis or the direct problem, the input is known and the transfer function is derivable from the problem specification, with the output or response to be determined. For the case of the synthesis or inverse problem, two problem classes may be identified. The easier synthesis problem involves finding the input, given the output and transfer function, an example of which is that of determining the source voltages that produce an observed pattern for a known antenna array. The more difficult synthesis problem itself separates into two problems. One is that of finding the transfer function, given the input and output, an example of which is that of finding a source distribution that produces a given far field. The other and still more difficult is that of finding the object geometry that produces an observed scattered field from a known exciting field. The latter problem is the most difficult of the three synthesis problems to solve because it is intrinsically transcendental and nonlinear.

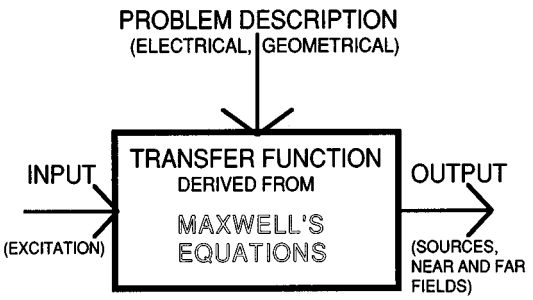

FIGURE 45.1 The electromagnetic transfer function relates the input, output, and problem.

Electromagnetic propagators are derived from a particular solution of Maxwell's equations, as the cause mentioned above normally involves some specified or known excitation whose effect is to induce some to-be-determined response (e.g., a radar cross section, antenna radiation pattern). It therefore follows that the essence of electromagnetics is the study and determination of field propagators to thereby obtain an input–output transfer function for the problem of interest, and it follows that this is also the goal of CEM.

Some Issues Involved in Developing a Computer Model

We briefly consider here a classification of model types, the steps involved in developing a **computer model**, the desirable attributes of a computer model, and finally the role of approximation throughout the modeling process.

Classification of Model Types

It is convenient to classify solution techniques for electromagnetic modeling in terms of the field propagator that might be used, the anticipated application, and the problem type for which the model is intended to be used, as is outlined in Table 45.1. Selection of a field propagator in the form, for example, of the Maxwell curl equations, a Green's function, modal or spectral expansions, or an optical description is a necessary first step in developing a solution to any electromagnetic problem.

Development of a Computer Model

Development of a computer model in electromagnetics or literally any other disciplinary activity can be decomposed into a small number of basic, generic steps. These steps might be described by different names but

TABLE 45.1 Classification of Model Types in CEM

Field Propagator	Description Based on
Integral operator	Green's function for infinite medium or special boundaries
Differential operator	Maxwell curl equations or their integral counterparts
Modal expansions	Solutions of Maxwell's equations in a particular coordinate system and expansion
Optical description	Rays and diffraction coefficients
Application	**Requires**
Radiation	Determining the originating sources of a field and patterns they produce
Propagation	Obtaining the fields distant from a known source
Scattering	Determining the perturbing effects of medium inhomogeneities
Problem type	**Characterized by**
Solution domain	Time or frequency
Solution space	Configuration or wave number
Dimensionality	1D, 2D, 3D
Electrical properties of medium and/or boundary	Dielectric, lossy, perfectly conducting, anisotropic, inhomogeneous, nonlinear, bianisotropic
Boundary geometry	Linear, curved, segmented, compound, arbitrary

TABLE 45.2 Steps in Developing a Computer Model

Step	Activity
Conceptualization	Encapsulating observation and analysis in terms of elementary physical principles and their mathematical descriptions
Formulation	Fleshing out of the elementary description into a more complete, formally solved, mathematical representation
Numerical implementation	Transforming into a computer algorithm using various numerical techniques
Computation	Obtaining quantitative results
Validation	Determining the numerical and physical credibility of the computed results

would include at a minimum those outlined in Table 45.2. Note that by its nature, validation is an open-ended process that cumulatively can absorb more effort than all the other steps together. The primary focus of the following discussion is on the issue of numerical implementation.

Desirable Attributes of a Computer Model

A computer model must have some minimum set of basic properties to be useful. From the long list of attributes that might be desired, we consider: (1) accuracy, (2) efficiency, and (3) utility the three most important as summarized in Table 45.3. Accuracy is put foremost because results of insufficient or unknown accuracy have uncertain value and may even be harmful. On the other hand, a code that produces accurate results but at unacceptable cost will have hardly any more value. Finally, a code's applicability in terms of the depth and breadth of the problems for which it can be used determines its utility.

The Role of Approximation

As approximation is an intrinsic part of each step involved in developing a computer model, we summarize some of the more commonly used approximations in Table 45.4. We note that the distinction between an approximation at the conceptualization step and during the formulation is somewhat arbitrary, but choose to use the former category for those approximations that occur before the formulation itself.

TABLE 45.3 Desirable Attributes in a Computer Model

Attribute	Description
Accuracy	The quantitative degree to which the computed results conform to the mathematical and physical reality being modeled. Accuracy, preferably of known and, better yet, selectable value, is the single most important model attribute. It is determined by the physical modeling error (ε_p) and numerical modeling error (ε_N).
Efficiency	The relative cost of obtaining the *needed* results. It is determined by the *human* effort required to develop the computer input and interpret the output and by the associated *computer* cost of running the model.
Utility	The applicability of the computer model in terms of problem size and complexity. Utility also relates to ease of use, reliability of results obtained, etc.

TABLE 45.4 Representative Approximations that Arise in Model Development

Approximation	Implementation/Implications
Conceptualization	
Physical optics	Surface sources given by tangential components of incident field, with fields subsequently propagated via a Green's function. Best for backscatter and main-lobe region of reflector antennas, from resonance region ($ka > 1$) and up in frequency.
Physical theory of diffraction	Combines aspects of physical optics and geometrical theory of diffraction, primarily via use of edge-current corrections to utilize best features of each.
Geometrical theory diffraction	Fields propagated via a divergence factor with amplitude obtained from diffraction coefficient. Generally applicable for $ka > 2$–5. Can involve complicated ray tracing.
Geometrical optics	Ray tracing without diffraction. Improves with increasing frequency.
Compensation theorem	Solution obtained in terms of perturbation from a reference, known solution.
Born–Rytov	Approach used for low-contrast, penetrable objects where sources are estimated from incident field.
Rayleigh	Fields at surface of object represented in terms of only outward propagating components in a modal expansion.
Formulation	
Surface impedance	Reduces number of field quantities by assuming an impedance relation between tangential E and H at surface of penetrable object. May be used in connection with physical optics.
Thin-wire	Reduces surface integral on thin, wirelike object to a line integral by ignoring circumferential current and circumferential variation of longitudinal current, which is represented as a filament. Generally limited to $ka < 1$ where a is the wire radius.
Numerical Implementation	
$\partial f/\partial x \rightarrow (f_+ - f_-)/(x_+ - x_-)$ $\int f(x)dx \rightarrow \sum f(x_i)\Delta x_i$	Differentiation and integration of continuous functions represented in terms of analytic operations on sampled approximations, for which polynomial or trigonometric functions are often used. Inherently a discretizing operation, for which typically $\Delta x < \lambda/2\pi$ for acceptable accuracy.
Computation	
Deviation of numerical model from physical reality	Affects solution accuracy and relatability to physical problem in ways that are difficult to predict and quantify.
Nonconverged solution	Discretized solutions usually converge globally in proportion to $\exp(-AN_x)$ with A determined by the problem. At least two solutions using different numbers of unknowns N_x are needed to estimate A.

45.3 Analytical Issues in Developing a Computer Model

Attention here is limited primarily to propagators that use either the Maxwell curl equations or source integrals which employ a Green's function, although for completeness we briefly discuss modal and optical techniques as well.

Selection of Solution Domain

Either the **integral equation** (IE) or differential equation (DE) propagator can be formulated in the time domain, where time is treated as an independent variable, or in the frequency domain, where the harmonic

time variation $\exp(j\omega t)$ is assumed. Whatever propagator and domain are chosen, the analytically formal solution can be numerically quantified via the **method of moments** (MoM) [Harrington, 1968], leading ultimately to a linear system of equations as a result of developing a discretized and sampled approximation to the continuous (generally) physical reality being modeled. Developing the approach that may be best suited to a particular problem involves making trade-offs among a variety of choices throughout the analytical formulation and numerical implementation, some aspects of which are now considered.

Selection of Field Propagator

We briefly discuss and compare the characteristics of the various propagator-based models in terms of their development and applicability.

Integral Equation Model

The basic starting point for developing an IE model in electromagnetics is selection of a Green's function appropriate for the problem class of interest. While there are a variety of Green's functions from which to choose, a typical starting point for most IE MoM models is that for an infinite medium. One of the more straightforward is based on the scalar Green's function and Green's theorem. This leads to the Kirchhoff integrals [Stratton, 1941, p. 464 *et seq.*], from which the fields in a given contiguous volume of space can be written in terms of integrals over the surfaces that bound it and volume integrals over those sources located within it.

Analytical manipulation of a source integral that incorporates the selected Green's function as part of its kernel function then follows, with the specific details depending on the particular formulation being used. Perhaps the simplest is that of boundary-condition matching wherein the behavior required of the electric and/or magnetic fields at specified surfaces that define the problem geometry is explicitly imposed. Alternative formulations, for example, the Rayleigh–Ritz variational method and Rumsey's reaction concept, might be used instead, but as pointed out by Harrington [in Miller et al., 1991], from the viewpoint of a numerical implementation any of these approaches lead to formally equivalent models.

This analytical formulation leads to an integral operator, whose kernel can include differential operators as well, which acts on the unknown source or field. Although it would be more accurate to refer to this as an integrodifferential equation, it is usually called simply an integral equation. Two general kinds of integral equations are obtained. In the frequency domain, representative forms for a perfect electric conductor are

$$\mathbf{n} \times \mathbf{E}^{\text{inc}}(\mathbf{r}) = \frac{1}{4\pi}\mathbf{n} \times \int_S \{j\omega\mu[\mathbf{n}' \times \mathbf{H}(\mathbf{r}')]\varphi(\mathbf{r}, \mathbf{r}') - [\mathbf{n}' \cdot \mathbf{E}(\mathbf{r}, \mathbf{r}')\nabla'\varphi(\mathbf{r}, \mathbf{r}')\}ds'; \quad \mathbf{r} \in S \tag{45.1a}$$

$$\mathbf{n} \times \mathbf{H}(\mathbf{r}) = 2\mathbf{n} \times \mathbf{H}^{\text{inc}}(\mathbf{r}) + \frac{1}{2\pi}\mathbf{n} \times \int_S [\mathbf{n}' \times \mathbf{H}(\mathbf{r}')] \times \nabla'\varphi(\mathbf{r}, \mathbf{r}')\}\text{ds}'; \; \mathbf{r} \in S \tag{45.1b}$$

where **E** and **H** are the electric and magnetic fields, respectively, $\mathbf{r}, \mathbf{r}'$ are the spatial coordinate of the observation and source points, the superscript inc denotes incident-field quantities, and $\varphi(\mathbf{r},\mathbf{r}') = \exp[-jk|\mathrm{r} - \mathrm{r}'|]/|\mathrm{r} - \mathrm{r}'|$ is the free-space Green's function. These equations are known respectively as Fredholm integral equations of the first and second kinds, differing by whether the unknown appears only under the integral or outside it as well [Poggio and Miller in Mittra, 1973].

Differential-Equation Model

A DE MoM model, being based on the defining Maxwell's equations, requires intrinsically less analytical manipulation than does derivation of an IE model. Numerical implementation of a DE model, however, can differ significantly from that used for an IE formulation in a number of ways for several reasons:

TABLE 45.5 Comparison of IE- and DE-Field Propagators and Their Numerical Treatment

	Differential Form	Integral Form
Field propagator	Maxwell curl equations	Green's function
Boundary treatment		
At infinity (radiation condition)	Local or global "lookback" to approximate outward propagating wave	Green's function
On object	Appropriate field values specified on mesh boundaries to obtain stairstep, piecewise linear, or other approximation to the boundary	Appropriate field values specified on object contour which can in principle be a general, curvilinear surface, although this possibility seems to be seldom used
Sampling requirements		
No. of space samples	$N_x \propto (L/\Delta L)^D$	$N_x \propto (L/\Delta L)^{D-1}$
No. of time steps	$N_t \propto (L/\Delta L) \approx cT/\delta t$	$N_t \propto (L/\Delta L) \approx cT/\delta t$
No. of excitations (right-hand sides)	$N_{\text{rhs}} \propto (L/\Delta L)$	$N_{\text{rhs}} \propto (L/\Delta L)$
Linear system L is problem size D is no. of problem dimensions (1, 2, 3) T is observation time ΔL is spatial resolution δt is time resolution	Sparse, but larger	Dense, but smaller. In this comparison, note that we assume the IE permits a sampling of order one less than the problem dimension, i.e., inhomogeneous problems are excluded.
Dependence of solution time on highest-order term in ($L/\Delta L$)		
Frequency domain	$T_\omega \propto N_x^{2(D-1)/D+1} = (L/\Delta L)^{3D-2}$	$T_\omega \propto N_x^3 = (L/\Delta L)^{3(D-1)}$
Time domain		
Explicit	$T_t \propto N_x N_t N_{\text{rhs}} = (L/\Delta L)^{D+1+r}$	$T_t \propto N_x^2 N_t N_{\text{rhs}} = (L/\Delta L)^{2D-1+r}$; $0 \le r \le 1$
Implicit	$T_t \propto N_x^{2(D-1)/D+1} = (L/\Delta L)^{3D-2}$, $D = 2, 3$; $\propto N_x N_t N_{\text{rhs}} = (L/\Delta L)^{2+r}$, $D = 1$; $0 \le r \le 1$	$T_t \propto N_x^3 = (L/\Delta L)^{3(D-1)}$

Note that D is the number of *spatial* dimensions in the problem and is not necessarily the *sampling* dimensionality d. The distinction is important because when an appropriate Green's function is available, the source integrals are usually one dimension less than the problem dimension, i.e., $d = D - 1$. An exception is an inhomogeneous, penetrable body where $d = D$ when using an IE. We also assume for simplicity that matrix solution is achieved via factorization rather than iteration but that banded matrices are exploited for the DE approach where feasible. The solution-time dependencies given can thus be regarded as upper-bound estimates. See Table 45.10 for further discussion of linear-system solutions.

1. The differential operator is a local rather than global one in contrast to the Green's function upon which the integral operator is based. This means that the spatial variation of the fields must be developed from sampling in as many dimensions as possessed by the problem, rather than one less as the IE model permits if an appropriate Green's function is available.
2. The integral operator includes an explicit radiation condition, whereas the DE does not.
3. The differential operator includes a capability to treat medium inhomogeneities, non-linearities, and time variations in a more straightforward manner than does the integral operator, for which an appropriate Green's function may not be available.

These and other differences between development of IE and DE models are summarized in Table 45.5, with their modeling applicability compared in Table 45.6.

Modal-Expansion Model

Modal expansions are useful for propagating electromagnetic fields because the source-field relationship can be expressed in terms of well-known analytical functions as an alternate way of writing a Green's function for special distributions of point sources. In two dimensions, for example, the propagator can be written in terms of circular harmonics and cylindrical Hankel functions. Corresponding expressions in three dimensions might involve spherical harmonics, spherical Hankel functions, and Legendre polynomials. Expansion in terms of analytical solutions to the wave equation in other coordinate systems can also be used but requires computation

x signifies unsuited or least advantageous.

of special functions that are generally less easily evaluated, such as Mathieu functions for the two-dimensional solution in elliptical coordinates and spheroidal functions for the three-dimensional solution in oblate or prolate spheroidal coordinates.

One implementation of modal propagators for numerical modeling is that due to Waterman [in Mittra, 1973], whose approach uses the extended boundary condition (EBC) whereby the required field behavior is satisfied away from the boundary surface on which the sources are located. This procedure, widely known as the *T-matrix* approach, has evidently been more widely used in optics and acoustics than in electromagnetics. In what amounts to a reciprocal application of EBC, the sources can be removed from the boundary surface on which the field-boundary conditions are applied. These modal techniques seem to offer some computational advantages for certain kinds of problems and might be regarded as using entire-domain basis and testing functions but nevertheless lead to linear systems of equations whose numerical solution is required. Fourier transform solution techniques might also be included in this category since they do involve modal expansions, but that is a specialized area that we do not pursue further here.

Modal expansions are receiving increasing attention under the general name "fast multipole method," which is motivated by the goal of systematically exploiting the reduced complexity of the source-field interactions as their separation increases. The objective is to reduce the significant interactions of a Green's-function based matrix from being proportional to $(N_x)^2$ to of order $N_x \log (N_x)$, thus offering the possibility of decreasing the operation count of iterative solutions.

Geometrical-Optics Model

Geometrical optics and the geometrical theory of diffraction (GTD) are high-frequency asymptotic techniques wherein the fields are propagated using such optical concepts as shadowing, ray tubes, and refraction and diffraction. Although conceptually straightforward, optical techniques are limited analytically by the unavailability of diffraction coefficients for various geometries and material bodies and numerically by the need to trace rays over complex surfaces. There is a vast literature on geometrical optics and GTD, as may be ascertained by examining the yearly and cumulative indexes of such publications as the *Transactions of the IEEE Antennas and Propagation Society.*

45.4 Numerical Issues in Developing a Computer Model

Sampling Functions

At the core of numerical analysis is the idea of polynomial approximation, an observation made by Arden and Astill [1970] in facetiously using the subtitle "Numerical Analysis or 1001 Applications of Taylor's Series." The basic idea is to approximate quantities of interest in terms of sampling functions, often polynomials, that are then substituted for these quantities in various analytical operations. Thus, integral operators are replaced by finite sums, and differential operators are similarly replaced by generalized finite differences. For example, use of a first-order difference to approximate a derivative of the function $F(x)$ in terms of samples $F(x_+)$ and $F(x_-)$ leads to

$$\frac{dF(x)}{dx} \approx \frac{F(x_+) - F(x_-)}{h}; \quad x_- \le x \le x_+ \tag{45.2a}$$

and implies a linear variation for $F(x)$ between x_+ and x_- as does use of the trapezoidal rule

$$\int_{x_-}^{x_+} F(x)dx \approx \frac{h}{2}\,[F(x_+) + F(x_-)] \tag{45.2b}$$

to approximate the integral of $F(x)$, where $h = x_+ - x_-$. The central-difference approximation for the second derivative,

$$\frac{d^2F(x)}{dx^2} \approx \frac{[F(x_+) - 2F(x_0) + F(x_-)}{h^2} \tag{45.2c}$$

similarly implies a quadratic variation for $F(x)$ around $x_0 = x_+ - h/2 = x_- + h/2$, as does use of Simpson's rule

$$\int_{x_-}^{x_+} F(x)dx \approx \frac{h}{6}\,[F(x_+) + 4F(x_0) + F(x_-)] \tag{45.2d}$$

to approximate the integral. Other kinds of polynomials and function sampling can be used, as discussed in a large volume of literature, some examples of which are Abramowitz and Stegun [1964], Acton [1970], and Press et al. [1986]. It is interesting to see that numerical differentiation and integration can be accomplished using the same set of function samples and spacings, differing only in the signs and values of some of the associated weights. Note also that the added degrees of freedom that arise when the function samples can be unevenly spaced, as in Gaussian quadrature, produce a generally more accurate result (for well-behaved functions) for

TABLE 45.7 Sampling Operations Involved in MoM Modeling

Equation	DE Model $L(s')f(s') = g(s')$	IE Model $L(s,s')f(s') = g(s)$
Sampling of:		
Unknown via basis-functions $b_j(s')$ using $f(s') \approx \sum a_j b_j(s')$	Subdomain bases usually of low order are used. Known as FD procedure when pulse basis is used, and as FE approach when bases are linear.	Can use either subdomain or entire-domain bases. Use of latter is generally confined to bodies of rotation. Former is usually of low order, with piecewise linear or sinusoidal being the maximum variation used.
Equation via weight functions $w_i(s)$ $<w_i(s),L(s,s')\sum a_j b_j(s')> = <w_i(s),g(s)>$ to get $Z_{ij}a_j = g_i$	Pointwise matching is commonly employed, using a delta function. Pulse and linear matching are also used.	Pointwise matching is commonly employed, using a delta function. For wires, pulse, linear, and sinusoidal testing is also used. Linear and sinusoidal testing is also used for surfaces.
Operator	Operator sampling for DE models is entwined with sampling the unknown in terms of the difference operators used.	Sampling needed depends on the nature of the integral operator $L(s,s')$. An important consideration whenever the field integrals cannot be evaluated in closed form.
Solution of:		
$Z_{ij}a_j = g_i$ for the a_j	Interaction matrix is sparse. Time-domain approach may be explicit or implicit. In frequency domain, banded-matrix technique usually used.	Interaction matrix is full. Solution via factorization or iteration.

a given number of samples. This suggests the benefits that might be derived from using unequal sample sizes in MoM modeling should a systematic way of determining the best nonuniform sampling scheme be developed.

The Method of Moments

Numerical implementation of the moment method is a relatively straightforward, and an intuitively logical, extension of these basic elements of numerical analysis, as described in the book by Harrington [1968] and discussed and used extensively in CEM [see, for example, Mittra, 1973, 1975; Strait, 1980; Poggio and Miller, 1988]. Whether it is an integral equation, a differential equation, or another approach that is being used for the numerical model, three essential sampling operations are involved in reducing the analytical formulation via the moment method to a computer algorithm as outlined in Table 45.7. We note that operator sampling can ultimately determine the sampling density needed to achieve a desired accuracy in the source–field relationships involving integral operators, especially at and near the "self term," where the observation and source points become coincident or nearly so and the integral becomes nearly singular. Whatever the method used for these sampling operations, they lead to a linear system of equations or matrix approximation of the original integral or differential operators. Because the operations and choices involved in developing this matrix description are common to all moment-method models, we shall discuss them in somewhat more detail.

When using IE techniques, the coefficient matrix in the linear system of equations that results is most often referred to as an impedance matrix because in the case of the E-field form, its multiplication of the vector of unknown currents equals a vector of electric fields or voltages. The inverse matrix similarly is often called an admittance matrix because its multiplication of the electric-field or voltage vector yields the unknown-current vector. In this discussion we instead use the terms *direct matrix* and *solution matrix* because they are more generic descriptions whatever the forms of the originating integral or differential equations. As illustrated in the following, development of the direct matrix and solution matrix dominates both the computer time and storage requirements of numerical modeling.

In the particular case of an IE model, the coefficients of the direct or original matrix are the mutual impedances of the multiport representation which approximates the problem being modeled, and the coefficients of its solution matrix (or equivalent thereof) are the mutual admittances. Depending on whether a subdomain or entire-domain basis has been used (see Basic Function Selection), these impedances and admittances represent either spatial or modal interactions among the N ports of the numerical model. In either case, these

TABLE 45.8 Examples of Generic Basis/Weight-Function Combinations

Method	jth Term of Basis	ith Term of Weight
Galerkin	$a_j b_j(\mathbf{r}')$	$w_i(\mathbf{r}) = b_j(\mathbf{r})$
Least square	$a_j b_j(\mathbf{r}')$	$Q(\mathbf{r})\partial\varepsilon(\mathbf{r})/\partial a_i$
Point matching	$a_j\delta(\mathbf{r} - \mathbf{r}_j)$	$\delta(\mathbf{r} - \mathbf{r}_i)$
General collocation	$a_j b_j(\mathbf{r}')$	$\delta(\mathbf{r} - \mathbf{r}_i)$
Subsectional collocation	$U(\mathbf{r}_j)\sum a_{jk} b_k(\mathbf{r}')$	$\delta(\mathbf{r} - \mathbf{r}_i)$
Subsectional Galerkin	$U(\mathbf{r}_j)\sum a_{jk} b_k(\mathbf{r}')$	$U(\mathbf{r}_i)\sum b_i(\mathbf{r})$

$\mathbf{r}'$ and $\mathbf{r}$ denote source and observation points respectively; a_j, a_{jk} are unknown constants associated with the jth basis function (entire domain) or the kth basis function of the jth subsection (subdomain); $U(\mathbf{r}_k)$ is the unit sampling function which equals 1 on the kth subdomain and is 0 elsewhere; $b_j(\mathbf{r}')$ is the jth basis function; $w_i(\mathbf{r})$ is the ith testing function; $\delta(\mathbf{r} - \mathbf{r}_i)$ is the Dirac delta function; $Q(\mathbf{r})$ is a positive-definite function of position; and $\varepsilon(\mathbf{r})$ is the residual or equation error [from Poggio and Miller in Mitra (1973)].

coefficients possess a physical relatability to the problem being modeled and ultimately provide all the information available concerning any electromagnetic observables that are subsequently obtained.

Similar observations might also be made regarding the coefficients of the DE models but whose multiport representations describe local rather than global interactions. Because the DE model almost always leads to a larger, albeit less dense, direct matrix, its inverse (or equivalent) is rarely computed. It is worth noting that there are two widely used approaches for DE modeling, finite-difference (FD) and finite-element (FE) methods. They differ primarily in how the differential operators are approximated and the differential equations are satisfied, i.e., in the order of the basis and weight functions, although the FE method commonly starts from a variational viewpoint, while the FD approach begins from the defining differential equations. The FE method is generally better suited for modeling problems with complicated boundaries to which it provides a piecewise linear or higher order approximation as opposed to the cruder stairstep approximation of FD.

Factors Involved in Choosing Basis and Weight Functions

Basis and weight function selection plays a critical role in determining the accuracy and efficiency of the resulting computer model. One goal of the basis and weight function selection is to minimize computer time while maximizing accuracy for the problem set to which the model is to be applied. Another, possibly conflicting, goal might be that of maximizing the collection of problem sets to which the model is applicable. A third might be to replicate the problem's physical behavior with as few samples as possible. Some of the generic combinations of bases and weights that are used for MoM models are listed in Table 45.8 [Poggio and Miller from Mittra, 1973].

Basis Function Selection. We note that there are two classes of bases used in MoM modeling, subdomain and entire-domain functions. The former involves the use of bases that are applied in a repetitive fashion over subdomains or sections (segments for wires, patches for surfaces, cells for volumes) of the object being modeled. The simplest example of a subdomain basis is the single-term basis given by the pulse or stairstep function, which leads to a single, unknown constant for each subdomain. Multiterm bases involving two or more functions on each subdomain and an equivalent number of unknowns are more often used for subdomain expansions.

The entire-domain basis, on the other hand, uses multiterm expansions extending over the entire object, for example, a circular harmonic expansion in azimuth for a body of revolution. As for subdomain expansions, an unknown is associated with each term in the expansion. Examples of hybrid bases can also be found, where subdomain and entire-domain bases are used on different parts of an object.

Although subdomain bases are probably more flexible in terms of their applicability, they have a disadvantage generally not exhibited by the entire-domain form, which is the discontinuity that occurs at the domain boundaries. This discontinuity arises because an n_s-term subdomain function can provide at most $n_s - 1$ degrees of continuity to an adjacent basis of the unknown it represents, assuming one of the n_s constants is reserved for the unknown itself. For example, the three-term or sinusoidal subdomain basis $a_i + b_i \sin(ks) + c_i \cos(ks)$ used for wire modeling can represent a current continuous at most up to its first derivative. This provides continuous charge density but produces a discontinuous first derivative in charge equivalent to a tripole charge at each junction.

TABLE 45.9 Examples of Specific Basis/Weight-Function Combinations

Application	*j*th Term of Basis	*i*th Term of Weight
1D/wires	Constant—$a_j U_j(s)$	Delta function—$\delta(s - s_i)$
1D/wires	Piecewise linear—$a_{j1}(s - s_j - \delta_j/2) + a_{j2}(s - s_j + \delta_j/2)$	Piecewise linear—$(s - s_i - \delta_i/2) + (s - s_i + \delta_i/2)$
1D/wires	3-term sinusoidal—$a_{j1} + a_{j2}\sin[k(s - s_j)] + a_{j3}\cos[k(s - s_j)]$	Delta function—$\delta(s - s_i)$
1D/wires	Piecewise sinusoidal—$a_{j1}\sin[k(s - s_j - \delta_j/2)] + a_{j2}\sin[k(s - s_j + \delta_j/2)]$	Piecewise sinusoidal—$\sin[k(s - s_i - \delta_i/2)] + \sin[k(s - s_i + \delta_i/2)]$
2D/surfaces	Weighted delta function—$a_j\delta(s - s_j)\Delta_j$	Delta function—$\delta(s - s_i)$
2D/rotational surfaces	Piecewise linear axially, and $\exp(in\phi)$ azimuthally	Same (Galerkin's method)
2D/surfaces	Piecewise linear	Same (Galerkin's method)
2D/surfaces	Piecewise linear subdomain/Fourier series entire domain	Same (Galerkin's method)
3D/volumes	Piecewise linear	Same (Galerkin's method)

δ_k is the length of wire segment k; Δ_k is the area of surface patch k.

As additional terms are used to develop a subdomain basis, higher-order continuity can be achieved in the unknown that the basis represents, assuming still that one unknown is reserved for the amplitude of the multiterm basis function. In the general case of the n_s-term subdomain basis, up to $n_s - 1$ constants can be determined from continuity conditions, with the remainder reserved for the unknown. The kind of basis function employed ultimately determines the degree of fit that the numerical result can provide to the true behavior of the unknown for a given order of matrix. An important factor that should influence basis-function selection, then, is how closely a candidate function might resemble the physical behavior of the unknown it represents. Another consideration is whether a system of equations that is numerically easier to solve might result from a particular choice of basis and weight function, for example, by increasing its diagonal dominance so that an iterative technique will converge more rapidly and/or reduce the number of significant interactions. Various evolving approaches having names such as "impedance-matrix localization." "fast multipole method," "spatial decomposition," and "multilevel matrix-decomposition" are being developed with these goals.

Weight Function Selection. The simplest weight that might be used is a delta function which leads to a point-sampled system of equations, but point sampling of the field operators can be sensitive to any numerical anomalies that might arise as a result of basis function discontinuities. Distributed, multiterm weight functions can also be used on either a subdomain or an entire-domain basis to provide a further smoothing of the final equations to be solved. One example of this is the special case where the same functions are used for both the bases and weights, a procedure known as Galerkin's method. The kind of testing function used ultimately determines the degree to which the equations can be matched for a given basis function and number of unknowns. Some specific examples of basis and weight function combinations used in electromagnetics are summarized in Table 45.9.

Computing the Direct Matrix

We observe that obtaining the coefficients of the direct matrix in IE modeling is generally a two-step process. The first step is that of evaluating the defining integral operator in which the unknown is replaced by the basis functions selected. The second step involves integration of this result multiplied by the weight function selected. When using delta-function weights, this second step is numerically trivial, but when using nondelta weights, such as the case in a Galerkin approach, this second step can be analytically and numerically challenging.

Among the factors affecting the choice of the basis and weight functions, therefore, one of the most important is that of reducing the computational effort needed to obtain the coefficients of the direct matrix. This is one of the reasons, aside from their physical appeal, why sinusoidal bases are often used for wire problems. In this case, where piecewise linear, filamentary current sources are most often used in connection with the thin-wire approximation, field expressions are available in easily evaluated, analytical expressions. This is the case as well where Galerkin's method is used.

TABLE 45.10 Summary of Operation Count for Solution of General Direct Matrix Having N_x Unknowns

Method	To Obtain Solution Matrix	To Obtain Solution	Comments
Cramer's rule	Expand in co-factors leading to →	$\sim N_x!$	Not an advisable procedure but useful to illustrate just how bad the problem could be
Inversion	N_x^3	N_x^2	Provides RHS-independent solution matrix
Factorization	$N_x^3/3$	N_x^2	RHS-independent solution matrix
Iteration			
General	—	$N_x^2 - N_x^3$	Each RHS requires separate solution
With FFT	—	$N_x - N_x^2$	Same, plus applicability to arbitrary problems uncertain
Symmetry			
Reflection	$(1 \text{ to } 2^p) \times (N_x/2^p)^3$	$N_x^2/2^p$	For $p = 1$ to 3 reflection planes
Translation (Toeplitz)	$n_x^3[t(\log_2 t)^2]$	N_x^2	For n_x unknowns per t sections of translation
Rotation (circulant)	$\log_2(N_x)N_x^3/n^2$	N_x	For n rotation sectors and a complete solution
	$m \log_2(N_x)(N_x/n)^3$	m	For $m = 1$ to n modes
Banded			
General	$N_x W^2$	$N_x W$	For a bandwidth of W coefficients
Toeplitz	$N_x \log_2 N_x$	W^2	For a bandwidth of W coefficients

Aside from such special cases, however, numerical evaluation of the direct-matrix coefficients will involve the equivalent of point sampling of whatever order is needed to achieve the desired accuracy as illustrated below. Using a wirelike one-dimensional problem to illustrate this point, we observe that at its most elementary level evaluation of the ijth matrix coefficient then involves evaluating integrals of the form

$$\begin{aligned} Z_{i,j} &= \int_{C(\mathbf{r})} w_i(s) \int_{C(\mathbf{r})} [b_j(s')K(s, s')ds']ds \\ &\approx \sum_{m=1}^{M(i,j)} \sum_{n=1}^{N(i,j)} p_m q_n w_i(s_n) b_j(s'_m) K(s_n, s'_m) \\ &= \sum_{m=1}^{M(i,j)} \sum_{n=1}^{N(i,j)} p_m q_n z(i, j, m, n); \quad i, j = 1, \ldots, N \end{aligned} \tag{45.03}$$

where $K(s,s')$ is the IE kernel function, and s_n and s'_m are the nth and mth locations of the observation and source integration samples. Thus, the final, direct-matrix coefficients can be seen to be constructed from sums of the more elementary coefficients $z(i,j,m,n)$ weighted by the quadrature coefficients p_m and q_n used in the numerical integration, which will be the case whenever analytical expressions are not available for the $Z_{i,j}$. These elementary coefficients, given by $w_i(s_n)b_j(s'_m)K(s_n,s'_m)$, can in turn be seen to be simply products of samples of the IE kernel or operator and sampled basis and testing functions. It should be apparent from this expanded expression for the direct-matrix coefficients that interchanging the basis and weight functions leaves the final problem description unchanged, although the added observation that two different IEs can yield identical matrices when using equivalent numerical treatments is less obvious.

Computing the Solution Matrix

Once the direct matrix has been computed, the solution can be obtained numerically using various approaches, ranging from inversion of the direct matrix to developing a solution via iteration as summarized in Table 45.10. A precautionary comment is in order with respect to the accuracy with which the solution matrix might be obtained. As computer speed and storage have increased, the number of unknowns used in modeling has also increased, from a few tens in earlier years to hundreds of thousands now when using IE models and millions of unknowns when using DE models. The increasing number of operations involved in solving these larger

matrices increases sensitivity of the results to roundoff errors. This is especially the case when the direct matrix is not well conditioned. It is therefore advisable to perform some sensitivity analyses to determine the direct-matrix condition number and to ascertain the possible need for performing some of the computations in double precision.

Obtaining the Solution

When a solution matrix has been developed using inversion or factorization, subsequently obtaining the solution (most often a current) is computationally straightforward, involving multiplication of the right-hand side (RHS) source vector by the solution matrix. When an iterative approach is used, a solution matrix is not computed, but the solution is instead developed from RHS-dependent manipulation of the direct matrix. Motivation for the latter comes from the possibility of reducing the N_x^3 dependency of the direct procedure. As problem size increases, the computation cost will be increasingly dominated by the solution time.

45.5 Some Practical Considerations

Although the overall solution effort has various cost components, perhaps the one most considered is the computer time and storage required to obtain the numerical results desired. With the increasing computer memories becoming available, where even microcomputers and workstations can directly address gigabytes, the memory costs of modeling are becoming generally less important than the time cost, with which we are primarily concerned here. For each model class considered, the computer-time dependence on the number of unknowns is presented in a generic formula followed by the highest-order $(L/\Delta L)$ term in that formula to demonstrate how computer time grows with increasing problem size.

Integral Equation Modeling

Frequency Domain

If we consider an IE model specifically, we can show that, in general, the computer time associated with its application is dependent on the number of unknowns N_x in the frequency domain as

$$T_{\mathrm{IE},\omega} \approx A_{\mathrm{fill}} N_x^2 + A_{\mathrm{solve}} N_x^3 + A_{\mathrm{source}} N_x^2 N_{\mathrm{rhs}} + A_{\mathrm{field}} N_x N_{\mathrm{rhs}} N_{\mathrm{fields}}$$
$$\sim (L/\Delta L)^{3(D-1)} \tag{45.4a}$$

where the A's are computer- and algorithm-dependent coefficients that account for computation of A_{fill}, the direct (impedance) matrix; A_{solve}, the solution (admittance) matrix (assuming inversion or factorization); A_{source}, the source response (currents and charges) for one of N_{rhs} different excitations or right-hand sides (the g term of Table 45.7); and A_{field}, one of N_{field} fields, where $A_{\mathrm{field}} \leq A_{\mathrm{fill}}$, depending on whether a near-field (=) or far-field (<) value is obtained. D is the problem dimensionality (for a wire IE model, $D = 2$ except when used for wire-mesh approximations of surfaces in which case $D = 3$); L is a characteristic length of the object being modeled; and ΔL is the spatial resolution required, being proportional to the wavelength.

Time Domain

A similar relationship holds for a time-domain IE model which uses N_t time steps,

$$T_{\mathrm{IE},t} \approx A_{\mathrm{fill}} N_x^2 + A_{\mathrm{solve}} N_x^3 + A_{\mathrm{source}} N_x^2 N_t N_{\mathrm{rhs}} + A_{\mathrm{field}} N_x N_t N_{\mathrm{rhs}} N_{\mathrm{fields}}$$
$$\sim (L/\Delta L)^{2(D-1)+1+r}, \text{ explicit approach, } 0 \leq r \leq 1$$
$$\sim (L/\Delta L)^{3(D-1)}, \quad \text{implicit approach} \tag{45.4b}$$

with the A's accounting for computation of the time-domain terms equivalent to their frequency-domain counterparts (with different numerical values), and r accounting for the RHS dependency. Although a direct matrix may require solution initially before time-stepping the model, that is normally avoided by using $\delta t \leq$

$\Delta x/c$, which yields an explicit solution, in which case $A_{\text{solve}} = 0$. As can be appreciated from these expressions, the number of unknowns that is required for these computations to be acceptably accurate has a strong influence on the computer time eventually needed.

Differential Equation Modeling

Frequency Domain

DE modeling is less commonly used in the frequency domain primarily because the order of the matrix that results depends on $(L/\Delta L)^D$ rather than the usual $(L/\Delta L)^{D-1}$ dependency of an IE model. On the other hand, the matrix coefficients require less computation whether the DE model is based on a finite-difference or finite-element treatment. Furthermore, the matrix is very sparse because a differential operator is a local rather than a global one, as is the integral operator. Matrix fill time is therefore generally not of concern, and the overall computer time is given approximately by

$$T_{\text{DE},\omega} \approx A_{\text{solve}} N_x W^2 + A_{\text{source}} N_x W N_{\text{rhs}} + A_{\text{field}} N_x^{(D-1)/D} N_{\text{rhs}} N_{\text{fields}}$$
$$\sim (L/\Delta L)^{3D-2} \tag{45.4c}$$

which exhibits a dominance by the matrix-solution term. Note that the banded nature of the DE direct matrix has been taken into account where the bandwidth W varies as N_x^0, $N_x^{1/2}$, and $N_x^{2/3}$ respectively ($N_x^{[(D-1)/D]}$), in one, two, and three dimensions.

Time Domain

Time-domain DE modeling can use either implicit or explicit solution methods for developing the time variation of the solution. An explicit technique is one whereby the update at each time step is given in terms of solved-for past values of the unknowns and the present excitation, with no interaction permitted between unknowns within the same time step, and is the approach used in a technique known as finite-difference time domain (FDTD). An implicit technique, on the other hand, does allow for interaction of unknowns within the same time step but can therefore require the solution of a matrix equation. In spite of this disadvantage, implicit techniques are important because they are not subject to Courant instability when $c\delta t > \Delta\chi$ as is an explicit approach. Books entirely devoted to FDTD and its applications are now becoming available, one of which is by Kunz and Luebbers (1993).

The solution time for the explicit case is approximated by

$$T_{\text{DE},t} \approx A_{\text{source}} N_x N_t N_{\text{rhs}} + A_{\text{field}} N_x^{(D-1)/D} N_{\text{rhs}} N_{\text{fields}}$$
$$\sim (L/\Delta L)^{D+1+r}, \text{ explicit approach; } 0 \le r \le 1 \tag{45.4d}$$
$$\approx A_{\text{solve}} N_x W^2 + A_{\text{source}} N_x W N_t N_{\text{rhs}} + A_{\text{field}} N_x^{(D-1)/D} N_{\text{rhs}} N_{\text{fields}}$$
$$\sim (L/\Delta L)^{3D-2}, \text{ for } D = 2, 3$$

and

$$\sim (L/\Delta L)^{2+r}, \text{ for } D = 1, \text{ implicit approach; } 0 \le r \le 1$$

assuming a banded matrix is used to solve the implicit direct matrix.

Discussion

It should be recognized that the above computer-time estimates assume solutions are obtained via matrix factorization, an N^3 process, and that iterative techniques when applicable should be expected to reduce the

TABLE 45.11 Nominal Sampling Requirements for Various Field Quantities

Quantity	Value
N_x, total number of spatial samples (per scalar unknown)	$\sim(L/\Delta L)^d = (2\pi L/\lambda)^d$
N_t, number of time steps for time-domain model	$\sim (L/\Delta L) = (2\pi L/\lambda)$
N_f, number of frequency steps to characterize spectral response from frequency-domain model	$\sim (L/2\Delta L) = N_t/2$
N_{rhs}, number of excitation sources for monostatic radar cross section in one plane[a]	$\sim (4L/\Delta L) = 8\pi L/\lambda$
N_{fields}, number of far fields needed for bistatic pattern in one observation plane[a]	$\sim N_{\text{rhs}} = (4L/\Delta L)$

λ is the wavelength at the highest frequency of interest; ΔL is the spatial resolution being sought; L is object maximum object dimension or dimension in observation plane; d is the number of *spatial* dimensions being sampled and is not necessarily the *problem* dimensionality D. The distinction is important because when an appropriate Green's function is available, the source integrals are usually one dimension less than the problem dimension, i.e., $d = D - 1$. An exception is an inhomogeneous, penetrable body where $d = D$ when using an integral equation.

[a]Assuming ~6 samples per lobe of the scattering pattern are needed.

maximum order of the $(L/\Delta L)$ dependency but at the cost, however, of requiring the computation to be repeated for each RHS. We also emphasize that these comparisons consider only problems involving homogeneous objects, thereby providing a more favorable situation for IE models because their sampling dimensionality $d = D - 1$ for a problem dimensionality of D but which increases to $d = D$ when an inhomogeneous object is modeled. Because of these and other factors that can lead to many different combinations of formulation and numerical treatment, the foregoing results should be viewed as only generic guidelines, with the computational characteristics of each specific model requiring individual analysis to obtain numerical values for the various A_x coefficients and their $(L/\Delta L)$ dependency. It is relevant to observe that the lowest-order size dependency for three-dimensional problems is exhibited by the DE explicit time-domain model which is on the order of $(L/\Delta L)^4$.

An additional factor that should be considered when choosing among computer models is the information needed for a particular application relative to the information provided by the model. A time-domain model, for example, can intrinsically provide a frequency response over a band of frequencies from a single calculation, whereas a frequency-domain model requires repeated evaluation at each of the frequencies required to define the wideband response. Iterative solution of the direct matrix may be preferable for problems involving only one, or a few, excitations such as is the case for antenna modeling, to avoid computing all N_x^2 admittances of the solution matrix when only a single column of that matrix is needed. A DE-based model necessarily provides the "near" fields throughout the region being modeled, while an IE-based model requires additional computations essentially the same as those done in filling the impedance matrix once the sources have been obtained to evaluate the near fields. For applications that require modest computer time and storage, these considerations may be relatively less important than those that strain available computer resources. Clearly, the overall objective from an applications viewpoint is to obtain the needed information at the required level of accuracy for the minimum overall cost.

Sampling Requirements

We may estimate the number of samples needed to adequately model the spatial, temporal, and angular variation of the various quantities of interest in terms of an object characteristic length L and sampling dimension d. This may be done from knowledge of the typical spatial and temporal densities determined from computer experiments and/or from invocation of Nyquist-like sampling rates for field variations in angle as a function of aperture size. The resulting estimates are summarized in Table 45.11 and apply to both IE and DE models.

These may be regarded as *wavelength-driven* sampling rates, in contrast with the *geometry-driven* sampling rates that can arise because of problem variations that are small in scale compared with λ. Geometry-driven sampling would affect primarily N_x, resulting in larger values than those indicated above.

We note that the computer time is eventually dominated by computation of the solution matrix and can grow as $(L/\Delta L)^3$, $(L/\Delta L)^6$, and $(L/\Delta L)^9$ (or f^3, f^6, and f^9), respectively, for wire, surface, and volume objects modeled using integral equations and matrix factorization or inversion. Thus, in spite of the fact that mainframe computer power has grown by a factor of about 10^6 from the UNIVAC-1 to the CRAY2, a growth that is anticipated to continue during the near future as shown in Fig. 45.2, the growth in problem size is much less

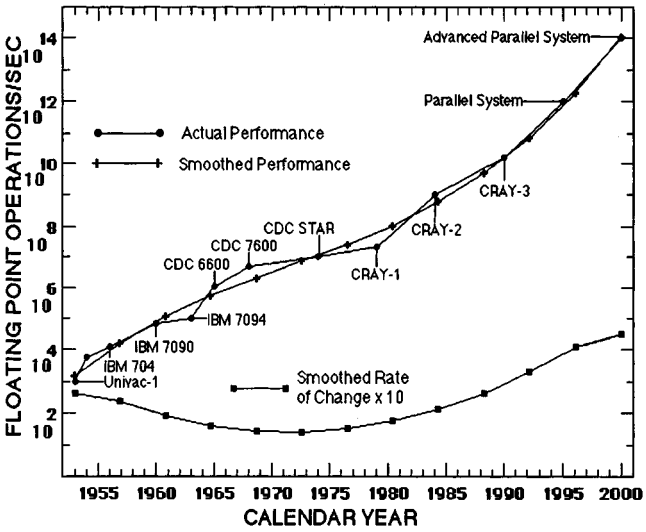

FIGURE 45.2 Raw and smoothed FLOP (floating-point operation) rates of mainframe computers and smoothed rate-of-change in speed, at year of introduction from the UNIVAC-1 to the projected performance of an advanced parallel system at year 2000. Future growth is increasingly dependent on computer architecture, requiring increasing parallelism as improvements due to component performance reach physical speed limits.

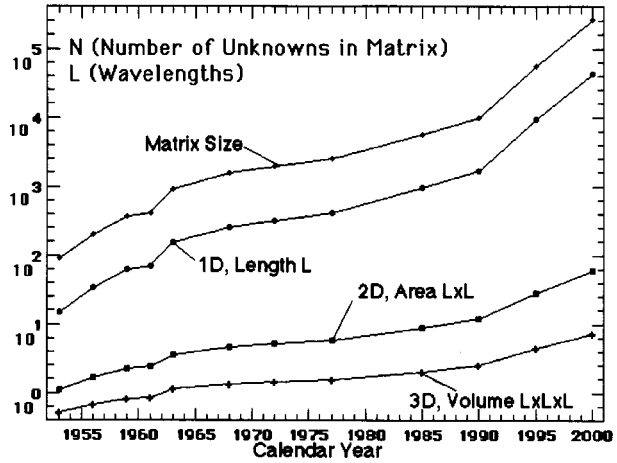

FIGURE 45.3 Time development of IE-based modeling capability for one-dimensional (e.g., a wire), two-dimensional (e.g., a plate), and three-dimensional (e.g., a penetrable, inhomogeneous cube) sampling of a problem of characteristic dimension L in wavelengths and matrix order N solvable in 1 h of computer time using mainframe computers introduced in the years indicated. Linear-systems solution using LU decomposition (an N^3 dependency) is assumed with number of unknowns proportional to L, L^2 and L^3, respectively, without any problem symmetry being exploited. These results should be viewed as upper bounds on solution time and might be substantially reduced by advances in linear-system solution procedures.

impressive, as illustrated by Fig. 45.3. The curves on this graph demonstrate emphatically the need for finding faster ways of performing the model computations, a point further emphasized by the results shown in Fig. 45.4 where the computer time required to solve a reference problem using various standard models is plotted as a function of frequency.

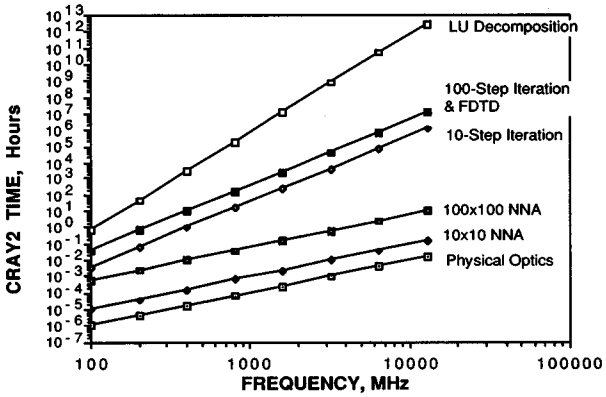

FIGURE 45.4 An illustration of the frequency dependence of the CRAY2 computer time required for some standard computer models applied to the reference problem of a perfectly conducting, space-shuttle-sized object having a surface area of 540 m^2 [Miller, 1988]. At a sampling density of $100/\lambda^2$, a total of 6,000 surface samples is assumed for an IE model at 100 MHz for which LU decomposition of the direct (impedance) matrix requires about 1 h of CRAY2 time. The top, LU, curve has a slope of f^6 as discussed in the text. The next two curves have slopes of f^4, the upper corresponding to use of a TD DE model (FDTD) as well as an iterative solution of the direct IE matrix, assuming acceptable convergence occurs in 100 iteration steps. The third curve is for a 10-step iterative solution of the IE matrix. The bottom three curves have f^2 slopes. The upper two of these are for 100- and 10-step iterative solutions used in connection with a near-neighbor approximation (NNA), wherein only the 100 and 10 largest interaction coefficients are retained in the matrix, respectively. The bottom curve is for the physical-optics approximation, in which the induced current is computed from the incident magnetic field. The effects of these different frequency slopes on the computer time can be seen to be extreme, emphasizing the need for developing more efficient solution procedures.

45.6 Ways of Decreasing Computer Time

The obvious drawback of direct moment-method models as N_x increases with increasing problem size and/or complexity suggests the need for less computationally intensive alternatives. There are various alternatives for decreasing the computer cost associated with solving electromagnetic problems using the method of moments. The basic intent in any case is either to reduce the direct cost of performing a given modeling computation or to reduce the number of modeling computations needed to obtain a desired result. An example for achieving the latter is to employ lower-order models that can accurately enough represent the behavior of observables as a function of space, angle, frequency, or time so that the sampling density of the first-principles model can be reduced. A specific example is used of the rational functions to approximate frequency-domain transfer functions. These might include analytical, computational, and experimental approaches or combinations thereof, about which further discussion and references may be found in Miller [1988].

45.7 Validation, Error Checking, and Error Analysis

Modeling Uncertainties

The process of proceeding from an original physical problem to computed results is one that is subject to numerous uncertainties caused by a variety of factors. Perhaps foremost among these factors is the degree of arbitrariness associated with many of the choices that are made by the code developer and/or modeler in the course of eventually obtaining numerical results. Whereas the numerical evaluation of classical boundary-value problems such as scattering from a sphere is numerically robust in the sense that different workers using different

TABLE 45.12 Error Types that Occur in Computational Electromagnetics

Category	Definition
Physical modeling error, ε_P	Arises because the numerical model used is normally an idealized mathematical representation of the actual physical reality
Numerical modeling error, ε_N	Arises because the numerical results obtained are only approximate solutions to that idealized representation and consists of two components: (1) Solution error—The difference that can exist between the computed results and an exact solution even were the linear system of equations to be solved exactly, due to using a finite number of unknowns (2) Equation error—The equation mismatch that can occur in the numerical solution because of roundoff due to finite-precision computations or when using an iterative technique because of limited solution convergence

computers and different software can obtain results in agreement to essentially as many significant figures as they wish, the same observation cannot be made for moment-method modeling.

Modeling uncertainties can be assigned to two basic error categories, a physical **modeling error** ε_P and a numerical modeling error ε_N as outlined in Table 45.12. The former is due to the fact that for most problems of practical interest varying degrees of approximation are needed in developing a simplified or idealized problem representation that will be compatible with the computer code to be used for the modeling computations. The latter is due to the fact that the numerical results obtained are almost invariably only approximate solutions to that idealized representation. We note that although an analytical expression may in principle represent a formally exact solution, the process of obtaining numerical results in that case is still one that inevitably involves finite-precision evaluation of the formal solution.

By its very nature, the physical modeling error requires some kind of measurement for its determination, except for those few problems whose analytical solution in principle involves no physical idealization or subsequent numerical approximation. One example of such problems is that of determining the scattering or radiating properties of the perfectly conducting or dielectric sphere.

The numerical modeling error is itself composed of two components in general, the determination of which would normally involve one or more kinds of computation. The first and generally more important of these components is the solution error that arises because the computer model used, even if solved exactly, would not provide an exact solution for the idealized problem representation. The solution error arises essentially because the computer model is solved using a finite number of unknowns. The other, generally less important contributor to the numerical modeling error is the equation error that arises because the numerical results obtained from the computer model used may not numerically satisfy the modeling equations. The equation error may be caused both by roundoff due to the computer word size as well as the solution algorithm used, as in the case of iteration, for example. The impact of equation error can be expected to increase with increasing condition number of the direct matrix.

Validation and Error Checking

One of the most time consuming and long lasting of the tasks associated with any model development is that of validation. Long after work on the model has been completed, questions will continue to arise about whether a given result is valid or whether the model can be applied to a given problem. There are essentially two kinds of validation procedures that can be considered to answer such questions: (1) internal validation, a check that can be made concerning solution validity within the model itself; and (2) external validation, a check that utilizes information from other sources which could be analytical, experimental, or numerical.

Existing computer models often do not perform internal checks on the results they produce but instead leave that as an exercise for the user. It would be of extremely great potential value if a variety of such checks could be built into the code and exercised as desired by the modeler. The topic of error checking and validation is an active one in CEM and receives a great deal of ongoing attention, for which the technical literature provides a good point of departure for the reader interested in more detail.

45.8 Concluding Remarks

In the preceding discussion we have presented a selective survey of computational electromagnetics. Attention has been directed to radiation and scattering problems solved using the method of moments, a general procedure applicable to differential- and integral-equation formulations developed by either the frequency domain or the time domain. Beginning from the viewpoint of electromagnetics as a transfer-function process, we concluded that the basic problem is one of developing source-field relationships or field propagators. Of the various ways by which these propagators might be expressed, we briefly discussed the Maxwell curl equations and Green's-function source integrals as providing the analytical basis for moment-method computer models. We then considered at more length some of the numerical issues involved in developing a computer model, including the idea of sampling functions used both to represent the unknowns to be solved for and to approximate the equations that they must satisfy. Some of the factors involved in choosing these sampling functions and their influence on the computational requirements were examined. Next, we discussed some ways of decreasing the needed computer time based on either analytical or numerical approaches. Some closing comments were directed to the important problems of validation, error checking, and error analysis. Throughout our discussion, emphasis has been given to implementation issues involved in developing and using computer models as opposed to exploring analytical details.

Defining Terms

Computer model: Based on a numerical solution of some appropriate analytical formulation that describes a physical phenomenon of interest. The model is realized in an *algorithm* or computer *code* that reduces the formulation to a series of operations suitable for computer solution.

Field propagator: The analytical description of how electromagnetic fields are related to the sources that cause them. Common field propagators in electromagnetics are the defining Maxwell equations that lead to differential equation models, Green's functions that produce integral equation models, optical propagators that lead to optics models, and multipole expansions that lead to modal models.

Integral equation: An analytical relationship in which the quantity whose solution is sought (the unknown) appears under an integral sign. When this is the only place that the unknown appears, the integral equation is commonly called a first-kind equation, while if the unknown also appears outside the integral, it is a second-kind integral equation.

Method of moments: A general technique for reducing integral, differential (including partial), and integrodifferential equations to a linear system of equations or matrix. The moment method involves discretizing, sampling, and approximating the defining equations using *basis* or *expansion* functions to replace the unknown and *testing* or *weighting* functions to satisfy the defining equations. The matrix that results may be full (all coefficients nonzero) or sparse (only a few per row are nonzero), depending on whether the model is an integral or differential equation.

Modeling errors: In essentially all computer modeling, there are two basic kinds of errors. One, the *physical modeling error*, arises from replacing some real-world physical problems with some idealized mathematical representation. The other, the *numerical modeling error*, comes from obtaining only an approximate solution to that idealized representation. Usually, the numerical modeling error can be reduced below the physical modeling error if enough unknowns, i.e., a large enough matrix, are used to model the problem of interest.

Sampling: The process of replacing a continuous physical quantity by some sequence of sampled values. These values are associated with the analytical function used to approximate the behavior of the physical quantity whose solution is sought and are the unknowns of the moment-method matrix. Sampling is also involved in determining how well the defining equations are to be satisfied. A common approach for equation sampling is *point* sampling, where the equations are explicitly satisfied at a series of discrete points in some prescribed region of space. Unknown sampling can involve localized basis functions, an approach called *subdomain* sampling, while if the basis functions reside over the entire region occupied by the unknown, the approach is called *entire-domain* sampling.

Solution domain: Electromagnetic fields can be represented as a function of time, or a *time-domain* description, or as a function of frequency using a (usually) Fourier transform, which produces a *frequency-domain* description.

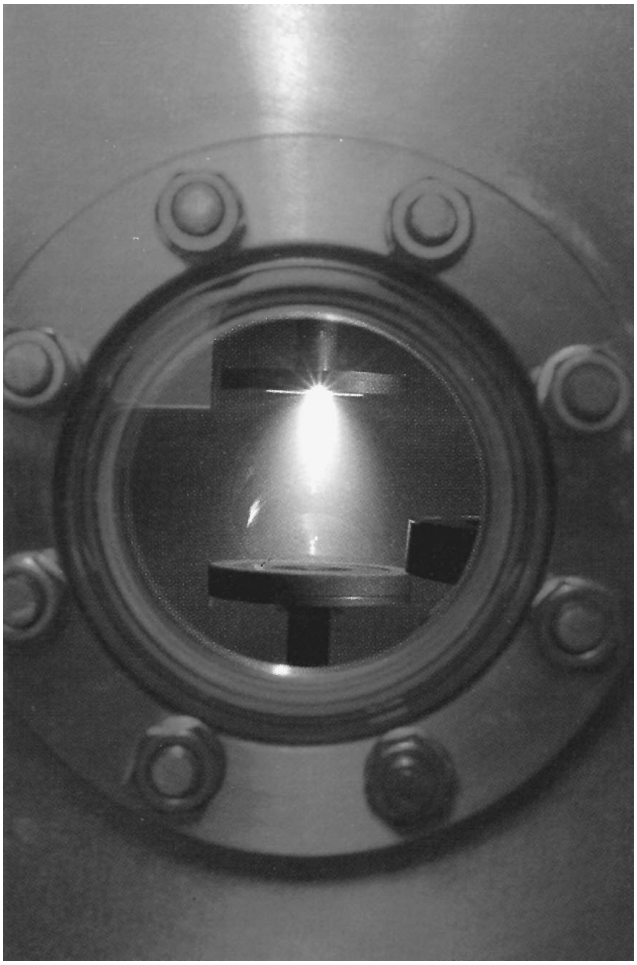
Feisel, L.D. "Section V – Electrical Effect s and Devices"
The Electrical Engineering Handbook
Ed. Richard C. Dorf
Boca Raton: CRC Press LLC, 2000



Ever since the discovery of superconductivity in 1911, researchers have sought to raise the temperature at which superconductivity occurs. With the advent of high temperature superconducting (HTS) materials in 1986, superconductors have begun to emerge from the laboratory and appear in practical applications. A pioneer in this explosively advancing technology is Superconducting Technologies, Inc., Santa Barbara, California. This company uses thallium, the highest temperature material for making high temperature superconductors. Thallium remains conductive at temperatures above 77°K and can be cooled to working temperature by a liquid nitrogen system instead of the more difficult and more expensive helium method. Shown above is a high temperature superconductor being produced by a laser ablation system. (Photo courtesy of National Aeronautics and Space Administration.)

Lyle D. Feisel
State University of New York, Binghamton

Every high school student who takes a course in physics or even general science is—or at least should be—familiar with the first-order, linear electrical effects such as resistance, inductance, capacitance, etc. The more esoteric effects, however, are often neglected, even in otherwise comprehensive undergraduate electrical engineering curricula. These effects, though, are not only fascinating in their manifestations but are also potentially—and in some cases, currently—exceedingly useful in application. This section will describe many of these higher-order electrical and magnetic effects and some of the devices that are based upon them. Readers are invited not only to study the current applications but to let their imaginations extrapolate to other uses as yet unproposed.

A number of phenomena are related to the interaction of mechanical energy with electrical energy. The field of *acoustics* deals with those situations where that mechanical energy takes the form of sound waves. Acoustic applications have been particularly fruitful, especially during the last two decades. Surface acoustic wave (SAW) filters are among the more useful applications. These elegant devices are a marriage of sophisticated signal theory and piezoelectricity, consummated on the bed of thin-film technology. Unlike some elegant devices, they have been commercially successful as well.

A special class of acoustoelectric devices deals with acoustic frequencies beyond the range of human hearing. The field of *ultrasonics* and its related devices and systems are finding broad application in the area of nondestructive testing. Of course, one of the testing applications where the nondestructive property is especially important is in investigating the human body. Medical imaging has provided considerable impetus for advances in ultrasonics in the last few years.

Most people know that if a sample of certain types of material (e.g., iron) is subjected to a magnetic field, it will exhibit a retained magnetic behavior. Few, however, realize that some materials exhibit a similar retention effect when an electric field is applied. *Ferroelectricity* is the phenomenon in which certain crystalline or polycrystalline materials retain electric polarization after an external electric field has been applied and removed. Since the direction of the polarization depends upon the direction of the applied field and since the polarization is quite persistent, memory devices can be based on this effect. Other applications have also been suggested.

For decades, the frequencies of radio transmitters have been stabilized with "crystals." In recent years, the effect called *piezoelectricity*—in which a mechanical strain induces an electric field and vice versa—has found many other applications. Like ferroelectrics, piezoelectric materials can be either crystalline or polycrystalline and can be fabricated in a variety of shapes.

If an electric charge is moved with a velocity at some angle to a magnetic field, the charge will experience a force at right angles to both the charge velocity and the magnetic field. If the charge is inside a solid material, a charge inhomogeneity is created and an electric field results. This is the well-known *Hall effect*, which finds practical application in such devices as magnetic field meters and in more basic uses as measuring and understanding the properties of semiconductors.

Probably the second electrical phenomenon observed by humans (lightning was probably the first), *ferromagnetism* deals with the interaction of molecular magnetic dipoles with external and internal magnetic fields. Ferromagnetic materials retain some polarization after an external field is removed—a desirable property if the application is a permanent magnet or a recording device—but one which causes losses in a transformer. These materials have improved as the demands of magnetic recording have increased.

If certain materials get cold enough, their resistivity goes to zero—not to some very small value but, as nearly as we can tell, zero. *Superconductivity* has been known as an interesting phenomenon for many years, but applications have been limited because the phenomenon only occurred at temperatures within a few degrees of absolute zero. Recent advances, however, have produced materials which exhibit superconductive behavior at substantially higher temperatures, and there is renewed interest in developing applications. This is certainly an area to watch in the next few years.

Some very elegant devices have been developed to exploit the interactions between electric fields and photons or optical waves. *Electrooptics* is the key to many of the recent and, indeed, future advances in optical communication. The phenomena are generally higher-order, nonintuitive, and exceedingly interesting, and the devices are generally quite elegant but simple.

We have come a long way since the first Atlantic Cable was fabricated using gutta-percha, tarred hemp, and pitch for insulation. *Dielectrics and insulators* are now better understood and controlled for a wide variety of applications. At one time the only property of real interest was dielectric strength, the insulator's ability to stand up to high voltage. Today, many other properties, as well as ease and economy of fabrication, are at least as important.

The word *application* appears many times in the preceding paragraphs. What are these applications? Many of the practical uses of the phenomena described in this section are in measuring the variables that define the phenomena. Thus, *sensors* constitute a primary application. For instance, the Hall effect can be used to measure magnetic fields, and mechanical strain can be measured using the phenomenon of piezoelectricity.

Just as photons will interact with electric fields, so, too, will they affect and be affected by magnetic fields. *Magnetooptics* is the study and application of these interactions. As with electrooptics, the increased activity in optical communications has provided renewed interest in this field.

The use of *smart materials* may solve a variety of engineering problems. In general, these are materials which change their properties to adapt to their environments, thereby doing their jobs better. This promises to be an area of increased activity in the future.

Again, the reader is admonished not only to understand the applications presented in the following chapters but to understand, at least at the phenomenological level, the phenomena upon which the applications are based. Such understanding is likely to lead to even broader applications in the future.

Nomenclature

Symbol	Quantity	Unit
α	attenuation constant	Np/m
χ_o	magnetic susceptibility of free space	
D	diffraction constant	
E	transducer efficiency	
ε	dielectric constant	
ϵ	complex permittivity	F/m
G_T	thermal conductance	W/K
η	viscosity	Poise
η	emissivity	
k	quantum mechanical wave factor	m^{-1}
k^2	SAW coupling factor	
K	thermal conductivity of pyroelectric	$W/m^2/K$
m	molar mass	kg
R	Hall coefficient	m^3/C
S	strain	
σ	conductivity	S/m
T	stress	N/m^2
τ_T	thermal time constant of element	s
θ_f	Faraday rotation coefficient	
V	phase velocity	m/s
V	Verdet constant	
W	electromagnetic energy density	W/m^2
Z_R	radiation impedance	Ω

46.1 Introduction

Electroacoustics is concerned with the transduction of acoustical to electrical energy and vice versa. Devices which convert acoustical signals into electrical signals are referred to as "**microphones**" or "hydrophones" depending on whether the acoustic medium is air or water. Devices which convert electrical signals into acoustical waves are referred to as "loudspeakers" (or earphones) in air and "projectors" in water.

46.2 Transduction Mechanisms

Piezoelectricity

Certain crystals produce charge on their surfaces when strained or conversely become strained when placed in an electric field. Important piezoelectric crystals include quartz, ADP, lithium sulphate, rochelle salt, and tourmaline. Lithium sulphate and tourmaline are "volume expanders," that is, their volume changes when subjected to an electric field in the proper direction. Such crystals can detect hydrostatic pressure directly. Crystals which are not volume expanders must have one or more surfaces shielded from the pressure field in order to convert the pressure to a uniaxial strain which can be detected. Tourmaline is relatively insensitive and used primarily in blast gauges, while quartz is used principally in high Q ultrasonic transducers.

Certain ceramics such as lead zirconate titanate (PZT), barium titanate, and lead metaniobate become piezoelectric when polarized. They exhibit relatively high electromechanical coupling, are capable of producing very large forces, and are used extensively as sources and receivers for underwater sound. PZT and barium titanate have only a small volume sensitivity; hence they must have one or more surfaces shielded in order to detect sound efficiently. Piezoelectric ceramics have extraordinarily high dielectric coefficients and hence high capacitance, and they are thus capable of driving long cables without preamplifiers.

[1]This chapter is adapted from R. M. Besançon, *Encyclopedia of Physics*, 3rd ed., New York: Chapman & Hall, 1985, pp. 337–341. With permission.

Recently, it has been discovered that certain polymers, notably polyvinylidene fluoride, are piezoelectric when stretched. Such piezoelectric polymers are finding use in directional microphones and ultrasonic hydrophones.

Magnetostriction

Some ferromagnetic materials become strained when subjected to a magnetic field. The effect is quadratic in the field, so a bias field or dc current is required for linear operation. Important magnetostrictive metals and alloys include nickel and permendur. At one time, magnetostrictive transducers were used extensively in active sonars but have now been largely replaced by ceramic transducers. Magnetostrictive transducers are rugged and reliable but inefficient and configurationally awkward. Recently, it has been discovered that certain rare earth iron alloys such as terbium-dysprosium-iron possess extremely large magnetostrictions (as much as 100 times that of nickel). They have relatively low eddy current losses but require large bias fields, are fragile, and have yet to find significant applications. Metallic glasses have also recently been considered for magnetostrictive transducers.

Electrodynamic

Electrodynamic transducers exploit the forces produced on a current-carrying conductor in a magnetic field and, conversely, the currents produced by a conductor moving in a magnetic field. Direct radiation moving coil transducers dominate the loudspeaker field. Prototypes of high-power underwater projectors have been constructed using superconducting magnets. Electrodynamic microphones, particularly the directional ribbon microphones, are also common.

Electrostatic

Electrostatic sources utilize the force of attraction between charged capacitor plates. The force is independent of the sign of the voltage, so a bias voltage is necessary for linear operation. Because the forces are relatively weak, a large area is needed to obtain significant acoustic output. The effect is reciprocal, with the change in the separation of the plates (i.e., the capacitance) produced by an incident acoustic pressure generating a voltage. The impedance of a condenser microphone, however, is high, so a preamplifier located close to the sensor is required. Condenser microphones are very flat and extremely sensitive. The change in capacitance induced by an acoustic field can also be detected by making the capacitor a part of a bridge circuit or, alternatively, a part of an oscillator circuit. The acoustic signal will then appear as either an amplitude or frequency modulation of some ac carrier. The charge storage properties of electrets have been exploited to produce electrostatic microphones which do not require a bias voltage.

Magnetic

Magnetic transducers utilize the force of attraction between magnetic poles and, reciprocally, the voltages produced when the reluctance of a magnetic circuit is changed. Magnetic speakers are used extensively in telephone receivers.

Hydraulic

Nonreversible, low-frequency, high-power underwater projectors can be constructed utilizing hydraulic forces acting to move large pistons. Electroacoustic transduction is achieved by modulating the hydraulic pressure with a spool valve actuated by an electrostrictive (PZT) stack.

Fiber Optic

An acoustic field acting on an optical fiber will change the optical path length by changing the length and index of refraction of the fiber. Extremely sensitive hydrophones and microphones can be made by using a fiber exposed to an acoustic field as one leg of an optical interferometer. Path length changes of the order of 10^{-6} optical wavelengths can be detected. The principal advantages of such sensors are their configurational flexibility,

their sensitivity, and their suitability for use with fiber optic cables. Fiber optic sensors which utilize amplitude modulation of the light (microbend transducers) are also being developed.

Parametric Transducers

The nonlinear interaction of sound waves can be used to produce highly directional sound sources with no side lobes and small physical apertures. In spite of their inherent inefficiency, substantial source levels can be achieved and such "parametric sonars" have found a number of underwater applications. Parametric receivers have also been investigated but practical applications have yet to be found.

Carbon Microphones

Carbon microphones utilize a change in electrical resistance with pressure and are used extensively in telephones.

46.3 Sensitivity and Source Level

A microphone or hydrophone is characterized by its free-field voltage sensitivity, M, which is defined as the ratio of the output voltage, E, to the free-field amplitude of an incident plane acoustic wave. That is, for an incident wave which *in the absence of the transducer* is given by

$$P = P_0 \cos(\mathbf{k} \cdot \mathbf{R} - \omega t) \tag{46.1}$$

M is defined by

$$M = E/P_0 \tag{46.2}$$

In general, M will be a function of frequency and the orientation of the transducer with respect to the wave vector $\mathbf{k}$ (i.e., the direction of incidence of the wave). Thus, for a given frequency, M is proportional to the directivity of the transducer. It is usually desirable for a microphone or hydrophone to have a flat (i.e., frequency independent) free-field voltage sensitivity over the broadest possible range of frequencies to assure fidelity of the output electrical signal.

A loudspeaker or projector is characterized in a similar manner by its transmitting current response, S, which is defined as the ratio of the acoustic source level to the driving current, I. In the farfield of a transducer the acoustic pressure is a spherical wave which can be expressed as

$$P(R) = P_s(\theta, \phi)(R_0/R) \cos(kR - \omega t) \tag{46.3}$$

where θ and ϕ are elevation and azimuth angles and R_0 an arbitrary reference distance (usually 1 meter). $P_s(\theta, \phi)$ is defined as the source level. Thus S is given by

$$S = P_s(\theta, \phi)/I \tag{46.4}$$

which is a function of θ and ϕ and the frequency ω. For high-fidelity sound reproduction S should be as flat as possible over the broadest possible bandwidth. For some purposes, however, such as ultrasonic cleaning or long-range underwater acoustic propagation, fidelity is unnecessary and high Q resonant transducers are employed to produce high-intensity sound over a narrow bandwidth.

46.4 Reciprocity

Most conventional transducers are *reversible*, that is, they can be used as either sources or receivers of sound (a carbon microphone and a fiber optic hydrophone are examples of transducers which are *not* reversible). A transducer is said to be *linear* if the input and output variables are linearly proportional (hot-wire microphones

and unbiased magnetostrictive transducers are examples of *nonlinear* transducers). A transducer is said to be *passive* if the only source of energy is the input electrical or acoustical signal (a microphone with a built-in preamplifier and a parametric projector are examples of *nonpassive* transducers). Most transducers which are linear, passive, and reversible exhibit a remarkable property called *reciprocity*. For a *reciprocal* transducer of any kind (moving coil, piezoelectric, magnetostrictive, electrostatic, magnetic, etc.) the ratio of the free-field voltage sensitivity to the transmitting current response is equal to the reciprocity factor J which is independent of the geometry and construction of the transducer. That is:

$$\frac{M(\omega, \theta, \phi)}{S(\omega, \theta, \phi)} = J(\omega) = \frac{4\pi R_0}{\rho_0 \omega} \tag{46.5}$$

where ρ_0 is the density of the medium and R_0 is the reference distance used in defining the source level. Equation (46.5) has a number of useful consequences: (1) the receiving and transmitting beam patterns of a reciprocal transducer are identical, (2) a transducer cannot be simultaneously flat as a receiver and transmitter since S has an additional factor of ω, and (3) Eq. (46.5) provides the basis for the three-transducer reciprocity calibration technique whereby an absolute calibration of a hydrophone or microphone can be obtained from purely electrical measurements.

46.5 Canonical Equations and Electroacoustic Coupling

Simple acoustic transducers can be characterized by the following canonical equations:

$$E = Z_e I + T_{em} V \tag{46.6}$$

$$F = T_{me} I + Z_m V \tag{46.7}$$

where V is the velocity of the radiating or receiving surface, F is the total force acting on the surface (including acoustic reaction forces), Z_e is the blocked ($V = 0$) electrical impedance, Z_m is the open-circuit mechanical impedance, and T_{em} and T_{me} are the electromechanical coupling coefficients. For reciprocal transducers $T_{em} = \pm T_{me}$. For example, for a moving coil transducer where the "motor" is coil in a radial magnetic field, B,

$$T_{em} = -T_{me} = BL \tag{46.8}$$

where L is the length of the wire in the coil and the electrical impedance Z_e is largely inductive. For a piston transducer with a piezoelectric "motor"

$$T_{me} = T_{em} = -id_{33}/(\epsilon^{\mathrm{T}} s \omega) \tag{46.9}$$

where d_{33} is the piezoelectric strain coefficient, s is the compliance, ϵ^{T} is the permittivity at constant stress, and the electrical impedance Z_e is largely capacitive.

If a piston transducer is placed in an acoustic field such that the average pressure over the surface of the piston is P_B, then $F = P_B A$, where A is the area of the piston, and for a receiver $I = 0$, so

$$E = (T_{em} A / Z_m) P_B \tag{46.10}$$

If the transducer is small compared with an acoustic wavelength $P_E \approx P_0$ (in general $P_B = DP_0$ where D is the diffraction constant) and the free-field voltage sensitivity is given by

$$mM = T_{em} A / Z_m \tag{46.11}$$

From Eq. (46.5) the transmitting current response is

$$S = \frac{\rho_0 \omega T_{em} A}{4\pi R_0 Z_m} \tag{46.12}$$

From these simple considerations a number of principles of practical transducer design can be deduced. The mechanical impedance Z_m is in general given by

$$Z_m = \frac{K_m}{i\omega} + i\omega M + R_m \tag{46.13}$$

where K_m is an effective spring constant, M the mass, and R_m the mechanical resistance. For a piezoelectric transducer [Eq. (46.9)] T_{em} is inversely proportional to frequency; hence from Eqs. (46.10) and (46.11) we see that a piezoelectric transducer will have a flat receiving sensitivity below resonance (i.e., where its behavior is controlled by stiffness). On the other hand, a moving coil microphone must have a resistive mechanical impedance to have a flat response. From Eq. (46.12) we derive the fundamental tenet of loudspeaker design, that a moving coil loudspeaker will have a flat transmitting current response above resonance (i.e., where it is mass controlled). Accordingly, moving coil loudspeakers are designed to have the lowest possible resonant frequency (by means of a high compliance since the output is inversely proportional to the mass) and piezoelectric hydrophones are designed to have the highest possible resonant frequency.

An interesting and important consequence of electromechanical coupling is the effect of the motion of the transducer on the electrical impedance. In the absence of external forces (including radiation reactance) from Eqs. (46.6) and (46.7)

$$E = \left(Z_e - \frac{T_{em} T_{me}}{Z_m} \right) I \tag{46.14}$$

That is, the electrical impedance has a "motional" component given by $T_{em}T_{me}/Z_m$. The motional component can be quite significant near resonance where Z_m is small. This effect is the basis of crystal-controlled oscillators.

46.6 Radiation Impedance

An oscillating surface produces a reaction force F_R on its surface given by

$$F_R = -Z_R V \tag{46.15}$$

where Z_R is the radiation impedance. We can thus rewrite Eq. (46.7) as

$$F_{ext} = T_{em} I + (Z_R + Z_m) V \tag{46.16}$$

where F_{ext} now includes only external forces. For an acoustically small baffled circular piston of radius a,

$$Z_R = \pi a^4 \rho_0 \omega^2 / 2c - i(8/3)\omega \rho_0 a^3 \tag{46.17}$$

The radiation impedance thus has a mass-like reactance with an equivalent "radiation mass" of $(8/3)\rho_0 a^3$ and a small resistive component proportional to ω^2 responsible for the radiated power. A transducer will thus have a lower resonant frequency when operated underwater than when operated in air or vacuum. The total radiated power of the piston transducer is given by

$$\pi = \mathrm{Re}Z_r|V|^2 = (\pi a^4 \rho_0 \omega^2/2c)V^2 \tag{46.18}$$

Most transducers are displacement limited, so for a direct-radiating transducer V in Eq. (46.18) is limited. To obtain the most output power the piston should have the largest possible surface area consistent with keeping the transducer omnidirectional (the transducer will become directional when $a \geq \lambda$). This is easy to do in air but difficult in water since it is hard to make pistons which are both lightweight and stiff enough to hold their shape in water. Alternatively, the driver can be placed at the apex of a horn. For a conical horn, the fluid velocity at the end of the horn (where the radius is a_e) will be reduced to $V(a/a_e)$ but the radiating piston will now have an effective radius of a_e so the radiated power will increase by a factor of $(a_e/a)^2$. For high-power operation at a single frequency, the driver can be placed at the end of a quarter wave resonator.

46.7 Directivity

It is often desirable for transducers to be directional. Directional sound sources are needed in diagnostic and therapeutic medical ultrasonics, for acoustic depth sounders; and to reduce the power requirements and reverberation in active sonars, etc. Directional microphones are useful to reduce unwanted noise (e.g., to pick up the voice of a speaker and not the audience); directional hydrophones or hydrophone arrays increase signal-to-noise and aid in target localization. One way to achieve directionality is to make the radiating surface large. A baffled circular piston has a directivity given by

$$D_e = 2J_1(ka \sin\theta)/ka \sin\theta \tag{46.19}$$

D_e equals unity for $\theta = 0$ and 1/2 when $ka \sin\theta = 2.2$. For small values of ka, D_e is near unity for all angles.

Some transducers respond to the gradient of the acoustic pressure rather than pressure, for example, the ribbon microphone which works by detecting the motion of a thin conducting strip orthogonal to a magnetic field. Such transducers have a directivity which is dipole in nature, i.e.,

$$D_e = \cos\theta \tag{46.20}$$

Note that since the force in this case is proportional not to P_0 but to kP_0, a ribbon microphone (which like a moving coil microphone is electrodynamic) will have flat receiving sensitivity when its impedance is mass controlled. By combining a dipole receiver with a monopole receiver one obtains a unidirectional cardioid receiver with

$$D_e = (1 + \cos\theta) \tag{46.21}$$

Defining Terms

Electroacoustics: Concerned with the transduction of acoustical to electrical energy and vice versa.
Microphones: Devices which convert acoustical signals into electrical signals.

47.1 Introduction

A **surface acoustic wave (SAW),** also called a Rayleigh wave, is composed of a coupled compressional and shear wave in which the SAW energy is confined near the surface. There is also an associated electrostatic wave for a SAW on a piezoelectric substrate which allows electroacoustic coupling via a transducer. SAW technology's two key advantages are its ability to electroacoustically access and tap the wave at the crystal surface and that the wave velocity is approximately 100,000 times slower than an electromagnetic wave. Assuming an electromagnetic wave velocity of 3×10^8 m/s and an acoustic wave velocity of 3×10^3 m/s, Table 47.1 compares relative dimensions versus frequency and delay. The SAW wavelength is on the same order of magnitude as line dimensions which can be photolithographically produced and the lengths for both small and long delays are achievable on reasonable size substrates. The corresponding E&M transmission lines or waveguides would be impractical at these frequencies.

Because of SAWs' relatively high operating frequency, linear delay, and tap weight (or sampling) control, they are able to provide a broad range of signal processing capabilities. Some of these include linear and dispersive filtering, coding, frequency selection, convolution, delay line, time impulse response shaping, and others. There are a very broad range of commercial and military system applications which include components for radars, front-end and IF filters, CATV and VCR components, cellular radio and pagers, synthesizers and analyzers, navigation, computer clocks, tags, and many, many others [Campbell, 1989; Matthews, 1977].

There are four principal SAW properties: transduction, reflection, regeneration and nonlinearities. Nonlinear elastic properties are principally used for convolvers and will not be discussed. The other three properties are present, to some degree, in all SAW devices, and these properties must be understood and controlled to meet device specifications.

TABLE 47.1 Comparison of SAW and E&M Dimensions versus Frequency and Delay, Where Assumed Velocities are v_{SAW} = 3000 m/s and $v_{EM} = 3 \times 10^8$ m/s

Parameter	SAW	E&M
F_0 = 10 MHz	λ_{SAW} = 300 μm	λ_{EM} = 30 m
F_0 = 2 GHz	λ_{SAW} = 1.5 μm	λ_{EM} = 0.15 m
Delay = 1 ns	L_{SAW} = 3 μm	L_{EM} = 0.3 m
Delay = 10 μs	L_{SAW} = 30 mm	L_{EM} = 3000 m

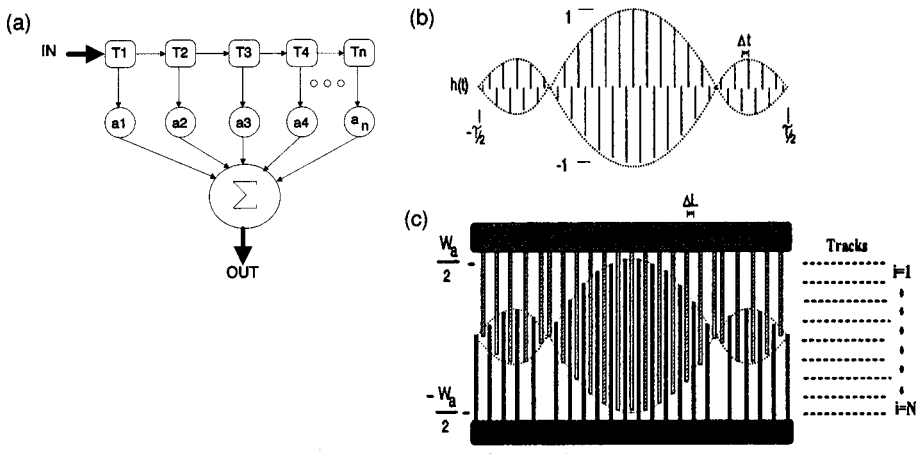

FIGURE 47.1 (a) Schematic of a finite-impulse response (FIR) filter. (b) An example of a sampled time function; the envelope is shown in the dotted lines. (c) A SAW transducer implementation of the time function $h(t)$.

A finite-impulse response (FIR) or transversal filter is composed of a series of cascaded time delay elements which are sampled or "tapped" along the delay line path. The sampled and delayed signal is summed at a junction which yields the output signal. The output time signal is finite in length and has no feedback. A schematic of an FIR filter is shown in Fig. 47.1.

A SAW transducer is able to implement an FIR filter. The electrodes or fingers provide the ability to sample or "tap" the SAW and the distance between electrodes provides the relative delay. For a uniformly sampled SAW transducer, the delay between samples, Δt, is given by $\Delta t = \Delta L / v_a$, where ΔL is the electrode period and v_a is the acoustic velocity. The typical means for providing attenuation or weighting is to vary the overlap between adjacent electrodes which provides a spatially weighted sampling of a uniform wave. Figure 47.1 shows a typical FIR time response and its equivalent SAW transducer implementation. A SAW filter is composed of a minimum of two transducers and possibly other SAW components. A schematic of a simple SAW bidirectional filter is shown in Fig. 47.2. A **bidirectional transducer** radiates energy equally from each side of the transducer (or port). Energy not being received is absorbed to eliminate spurious reflections.

47.2 SAW Material Properties

There are a large number of materials which are currently being used for SAW devices. The most popular single-crystal piezoelectric materials are quartz, lithium niobate ($LiNbO_3$), and lithium tantalate ($LiTa_2O_5$). The materials are anisotropic, which will yield different material properties versus the cut of the material and the direction of propagation. There are many parameters which must be considered when choosing a given material for a given device application. Table 47.2 shows some important material parameters for consideration for four of the most popular SAW materials [Datta, 1986; Morgan, 1985].

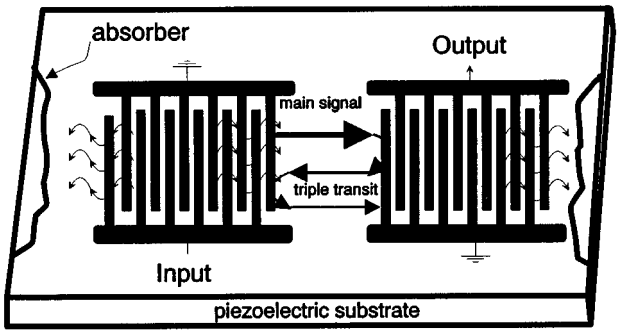

FIGURE 47.2 Schematic diagram of a typical SAW bidirectional filter consisting of two interdigital transducers. The transducers need not be identical. The input transducer launches waves in either direction and the output transducer converts the acoustic energy back to an electrical signal. The device exhibits a minimum 6-dB insertion loss. Acoustic absorber damps unwanted SAW energy to eliminate spurious reflections which could cause distortions.

TABLE 47.2 Common SAW Material Properties

Parameter/Material	ST-Quartz	YZ $LiNbO_3$	128° YX $LiNbO_3$	YZ $LiTa_2O_3$
k^2 (%)	0.16	4.8	5.6	0.72
C_s (pf/cm-pair)	0.05	4.6	5.4	4.5
v_0 (m/s)	3,159	3,488	3,992	3,230
Temp. coeff. of delay (ppm/°C)	0	94	76	35

The coupling coefficient, k^2, determines the electroacoustic coupling efficiency. This determines the fractional bandwidth versus minimum insertion loss for a given material and filter. The static capacitance is a function of the transducer electrode structure and the dielectric properties of the substrate. The values given in the table correspond to the capacitance per pair of electrodes having quarter wavelength width and one-half wavelength period. The free surface velocity, v_0, is a function of the material, cut angle, and propagation direction. The temperature coefficient of delay (TCD) is an indication of the frequency shift expected for a transducer due to a change of temperature and is also a function of cut angle and propagation direction.

The substrate is chosen based on the device design specifications and includes consideration of operating temperature, fractional bandwidth, and insertion loss. Second-order effects such as diffraction and beam steering are considered important on high-performance devices [Morgan, 1985]. Cost and manufacturing tolerances may also influence the choice of the substrate material.

47.3 Basic Filter Specifications

Figure 47.3 shows a typical time domain and frequency domain device performance specification. The basic frequency domain specification describes frequency bands and their desired level with respect to a given reference. Time domain specifications normally define the desired impulse response shape and any spurious time responses. The overall desired specification may be defined by combinations of both time and frequency domain specifications. Since time, $h(t)$, and frequency, $H(\omega)$, domain responses form unique Fourier transform pairs, given by

$$h(t) = 1/2\pi \int_{-\infty}^{\infty} H(\omega) e^{j\omega t} d\omega \tag{47.1}$$

$$H(\omega) = \int_{-\infty}^{\infty} h(t) e^{-j\omega t} dt \tag{47.2}$$

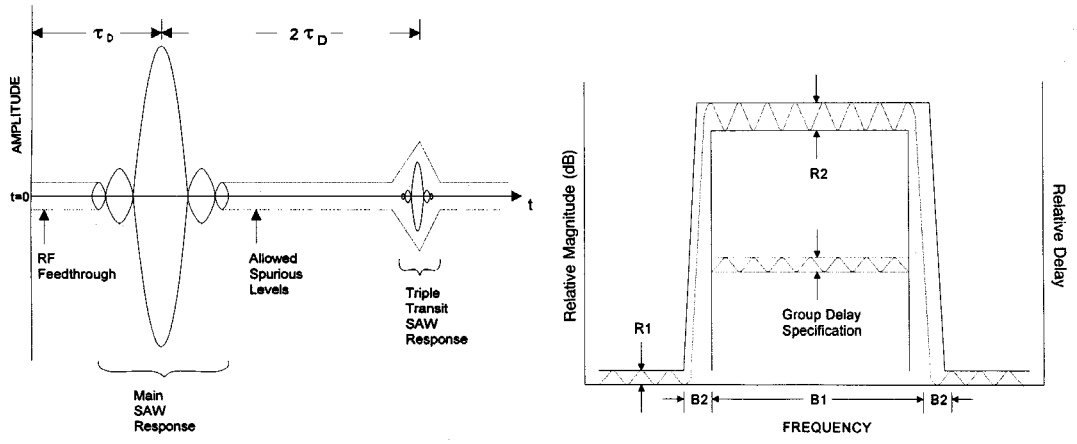

FIGURE 47.3 Typical time and frequency domain specification for a SAW filter.The filter bandwidth is B_1, the transition bandwidth is B_2, the inband ripple is R_2 and the out-of-band sidelobe level is R_1.

it is important that combinations of time and frequency domain specifications be self-consistent.

The electrodes of a SAW transducer act as sampling points for both transduction and reception. Given the desired modulated time response, it is necessary to sample the time waveform. For symmetrical frequency responses, sampling at twice the center frequency, $f_s = 2f_0$, is sufficient, while nonsymmetric frequency responses require sampling at twice the highest frequency of interest. A very popular approach is to sample at $f_s = 4f_0$. The SAW frequency response obtained is the convolution of the desired frequency response with a series of impulses, separated by f_s, in the frequency domain. The net effect of sampling is to produce a continuous set of harmonics in the frequency domain in addition to the desired response at f_0. This periodic, time-sampled function can be written as

$$g(t_n) = \sum_{-N/2}^{N/2} a_n \cdot \delta(t - t_n) \tag{47.3}$$

where a_n represents the sample values, $t_n = n\Delta t$, $n = n$th sample, and Δt = time sample separation. The corresponding frequency response is given by

$$G(f) = \sum_{-N/2}^{N/2} g(t_n) e^{-j2\pi f t_n} = \sum_{-N/2}^{N/2} g(t_n) e^{-j2\pi n f / f_s} \tag{47.4}$$

where $f_s = 1/\Delta t$. The effect of sampling in the time domain can be seen by letting $f = f + mf_s$, where m is an integer, which yields $G(f + mf_s) = G(f)$ which verifies the periodic harmonic frequency response.

Before leaving filter design, it is worth noting that a SAW filter is composed of two transducers which may have different center frequencies, bandwidth, and other filter specifications. This provides a great deal of flexibility in designing a filter by allowing the product of two frequency responses to achieve the total filter specification.

47.4 SAW Transducer Modeling

The four most popular and widely used models include the transmission line model, the coupling of modes model, the impulse response model, and the superposition model. The superposition model is an extension of the impulse response model and is the principal model used for the majority of SAW bidirectional and

multiphase filter synthesis which do not have inband, interelectrode reflections. As is the case for most technologies, many models may be used in conjunction with each other for predicting device performance based on ease of synthesis, confidence in predicted parameters, and correlation with experimental device data.

The SAW Superposition Impulse Response Transducer Model

The impulse response model was first presented by Hartmann et al. [1973] to describe SAW filter design and synthesis. For a linear causal system, the Fourier transform of the device's frequency response is the device impulse time response. Hartmann showed that the time response of a SAW transducer is given by

$$h(t) = 4k\sqrt{C_s}\, f_i^{3/2}(t)\sin[\theta(t)] \quad \text{where } \theta(t) = 2\pi\int_0^t f_i(\tau)d\tau \tag{47.5}$$

and where the following definitions are k^2 = SAW coupling coefficient, C_s = electrode pair capacitance per unit length (pf/cm-pair), and $f_i(t)$ = instantaneous frequency at a time, t. This is the general form for a uniform beam transducer with arbitrary electrode spacing. For a uniform beam transducer with periodic electrode spacing, $f_i(t) = f_0$ and $\sin\theta(t) = \sin\omega t$. This expression relates a time response to the physical device parameters of the material coupling coefficient and the electrode capacitance.

Given the form of the time response, energy arguments are used to determine the device equivalent circuit parameters. Assume a delta function voltage input, $v_{in}(t) = \delta(t)$, then $V_{in}(\omega) = 1$. Given $h(t)$, $H(\omega)$ is known and the energy launched as a function of frequency is given by $E(\omega) = 2\cdot|H(\omega)|^2$. Then

$$E(\omega) = V_{in}^2(\omega)\cdot G_a(\omega) = 1\cdot G_a(\omega) \tag{47.6}$$

or

$$G_a(\omega) = 2\cdot|H(\omega)|^2 \tag{47.7}$$

There is a direct relationship between the transducer frequency transfer function and the transducer conductance. Consider an **interdigital transducer (IDT)** with uniform overlap electrodes having N_p interaction pairs. Each gap between alternating polarity electrodes is considered a localized SAW source. The SAW impulse response at the fundamental frequency will be continuous and of duration τ, where $\tau = N\cdot\Delta t$, and $h(t)$ is given by

$$h(t) = \kappa\cdot\cos(\omega_0 t)\cdot rect(t/\tau) \tag{47.8}$$

where $\kappa = 4k\sqrt{C_s}\, f_0^{3/2}$ and f_0 is the carrier frequency. The corresponding frequency response is given by

$$H(\omega) = \frac{\kappa\tau}{2}\left\{\frac{\sin(x_1)}{x_1} + \frac{\sin(x_2)}{x_2}\right\} \tag{47.9}$$

where $x_1 = (\omega - \omega_0)\cdot\tau/2$ and $x_2 = (\omega + \omega_0)\cdot\tau/2$.

This represents the ideal SAW continuous response in both time and frequency. This can be related to the sampled response by a few substitutions of variables. Let

$$\Delta t = \frac{1}{2\cdot f_0}, \qquad t_n = n\cdot\Delta t, \qquad N\cdot\Delta t = \tau, \qquad N_p\cdot\Delta t = \tau/2 \tag{47.10}$$

Assuming a frequency bandlimited response, the negative frequency component centered around $-f_0$ can be ignored. Then the frequency response, using Eq. (47.9), is given by

$$H(\omega) = \kappa\left\{\frac{\pi N_p}{\omega_0}\right\} \cdot \frac{\sin(x_n)}{x_n} \tag{47.11}$$

where

$$x_n = \frac{(\omega - \omega_0)}{\omega_0}\pi N_p = \frac{(f - f_0)}{f_0}\pi N_p$$

The conductance, given using Eqs. (47.6) and (47.10), is

$$G_a(f) = 2\kappa^2\left\{\frac{\pi N_p}{2\pi f_0}\right\}^2 \frac{\sin^2(x_n)}{x_n^2} = 8k^2 f_0 C_s N_p^2 \cdot \frac{\sin^2(x_n)}{x_n^2} \tag{47.12}$$

This yields the frequency-dependent conductance per unit width of the transducer. Given a uniform transducer of width, W_a, the total transducer conductance is obtained by multiplying Eq. (47.12) by W_a. Defining the center frequency conductance as

$$G_a(f_0) = G_0 = 8k^2 f_0 C_s W_a N_p^2 \tag{47.13}$$

the transducer conductance is

$$G_a(f_0) = G_0 \cdot \frac{\sin^2(x_n)}{x_n^2} \tag{47.14}$$

The transducer electrode capacitance is given as

$$C_e = C_s W_a N_p \tag{47.15}$$

Finally, the last term of the SAW transducer's equivalent circuit is the frequency-dependent susceptance. Given any system where the frequency-dependent real part is known, there is an associated imaginary part which must exist for the system to be real and causal. This is given by the Hilbert transform susceptance, defined as B_a, where [Datta, 1986]

$$B_a(\omega) = \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{G_a(u)}{(u - \omega)}\,du = G_a(\omega) * 1/\omega \tag{47.16}$$

where "*" indicates convolution.

These three elements compose a SAW transducer equivalent circuit. The equivalent circuit, shown in Fig. 47.4, is composed of one lumped element and two frequency-dependent terms which are related to the substrate material parameters, transducer electrode number, and the transducer configuration. Figure 47.5 shows the

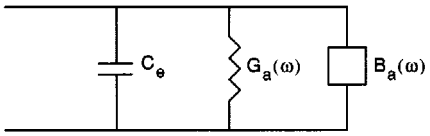

FIGURE 47.4 Electrical equivalent circuit model.

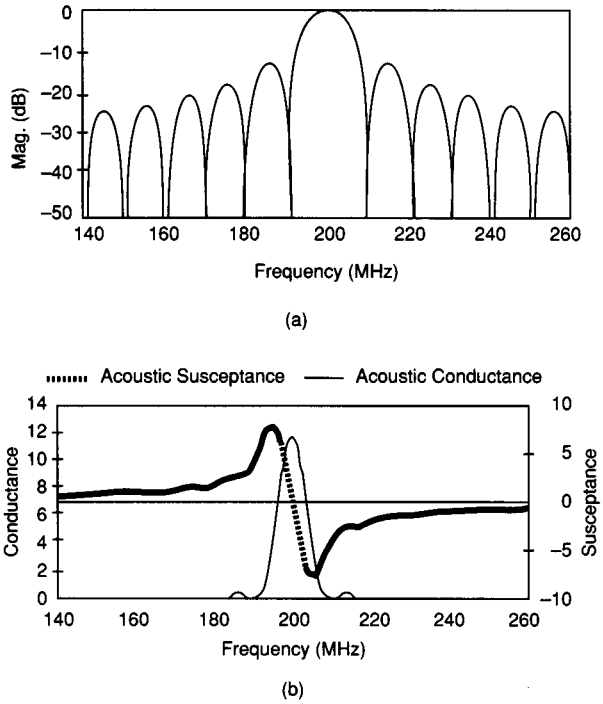

FIGURE 47.5 (a) Theoretical frequency response of a $rect(t/\tau)$ time function having a time length of 0.1 μs and a 200-MHz carrier frequency. (b) Theoretical conductance and susceptance for a SAW transducer implementing the frequency response. The conductance and susceptance are relative and are given in millisiemens.

time and frequency response for a uniform transducer and the associated frequency-dependent conductance and Hilbert transform susceptance. The simple impulse model treats each electrode as an ideal impulse; however, the electrodes have a finite width which distorts the ideal impulse response. The actual SAW potential has been shown to be closely related to the electrostatic charge induced on the transducer by the input voltage. The problem is solved assuming a quasi-static and electrostatic charge distribution, assuming a semi-infinite array of electrodes, solving for a single element, and then using superposition and convolution. The charge distribution solution for a single electrode with all others grounded is defined as the basic charge distribution function (BCDF). The result of a series of arbitrary voltages placed on a series of electrodes is the summation of scaled, time-shifted BCDFs. The identical result is obtained if an array factor, $a(x)$, defined as the ideal impulses localized at the center of the electrode or gap, is convolved with the BCDF, often called the element factor. This is very similar to the analysis of antenna arrays. Therefore, the ideal frequency transfer function and conductance given by the impulse response model need only be modified by multiplying the frequency-dependent element factor. The analytic solution to the BCDF is given in Datta [1986] and Morgan [1985], and is shown to place a small perturbation in the form of a slope or dip over the normal bandwidths of interest. The BCDF also predicts the expected harmonic frequency responses.

Apodized SAW Transducers

Apodization is the most widely used method for weighting a SAW transducer. The desired time-sampled impulse response is implemented by assigning the overlap of opposite polarity electrodes at a given position to a normalized sample weight at a given time. A tap having a weight of unity has an overlap across the entire beamwidth while a small tap will have a small overlap of adjacent electrodes. The time impulse response can be broken into tracks which have uniform height but whose time length and impulse response may vary. Each of these time tracks is implemented spatially across the transducer's beamwidth by overlapped electrode sections at the proper positions. This is shown in Fig. 47.1. The smaller the width of the tracks, the more exact the approximation of uniform time samples. There are many different ways to implement the time-to-spatial transformation; Fig. 47.1 shows just one such implementation.

The impulse response can be represented, to any required accuracy, as the summation of uniform samples located at the proper positions in time in a given track. Mathematically this is given by

$$h(t) = \sum_{i=1}^{I} h_i(t) \tag{47.17}$$

and

$$H(\omega) = \sum_{i=1}^{I} H_i(\omega) = \sum_{i=1}^{I} \left\{ \int_{-\tau/2}^{\tau/2} h_i(t) e^{-j\omega t} dt \right\} \tag{47.18}$$

The frequency response is the summation of the individual frequency responses in each track, which may be widely varying depending on the required impulse response. This spatial weighting complicates the calculations of the equivalent circuit for the transducer. Each track must be evaluated separately for its acoustic conductance, acoustic capacitance, and acoustic susceptance. The transducer elements are then obtained by summing the individual track values yielding the final transducer equivalent circuit parameters. These parameters can be solved analytically for simple impulse response shapes (such as the rect, triangle, cosine, etc.) but are usually solved numerically on a computer [Richie et al., 1988].

There is also a secondary effect of apodization when attempting to extract energy. Not all of the power of a nonuniform SAW beam can be extracted by an a uniform transducer, and reciprocally, not all of the energy of a uniform SAW beam can be extracted by an apodized transducer. The transducer efficiency is calculated at center frequency as

$$E = \frac{\left| \sum_{i=1}^{I} H(\omega_0) \right|^2}{I \cdot \sum_{i=1}^{I} H^2(\omega_0)} \tag{47.19}$$

The apodization loss is defined as

$$\text{apodization loss} = 10 \cdot \log(E) \tag{47.20}$$

Typical apodization loss for common SAW transducers is 1 dB or less.

Finally, because an apodized transducer radiates a nonuniform beam profile, the response of two cascaded apodized transducers is not the product of each transducer's individual frequency responses, but rather is given by

$$H_{12}(\omega) = \sum_{i=1}^{I} H_{1i}(\omega) \cdot H_{2i}(\omega) \neq \sum_{i=1}^{I} H_{1i}(\omega) \cdot \sum_{i=1}^{I} H_{2i}(\omega) \tag{47.21}$$

In general, filters are normally designed with one apodized and one uniform transducer or with two apodized transducers coupled with a spatial-to-amplitude acoustic conversion component, such as a multistrip coupler [Datta, 1986].

47.5 Distortion and Second-Order Effects

In SAW devices there are a number of effects which can distort the desired response from the ideal response. The most significant distortion in SAW transducers is called the **triple transit echo (TTE)** which causes a delayed signal in time and an inband ripple in the amplitude and delay of the filter. The TTE is primarily due to an electrically regenerated SAW at the output transducer which travels back to the input transducer, where it induces a voltage across the electrodes which in turn regenerates another SAW which arrives back at the output transducer. This is illustrated schematically in Fig. 47.2. Properly designed and matched **unidirectional transducers** have acceptably low levels of TTE due to their design. Bidirectional transducers, however, must be mismatched in order to achieve acceptable TTE levels. To first order, the TTE for a bidirectional two-transducer filter is given as

$$\text{TTE} \approx 2 \cdot IL + 6 \text{ dB} \tag{47.22}$$

where IL = filter insertion loss, in dB [Matthews, 1977]. As examples, the result of TTE is to cause a ghost in a video response and intersymbol interference in data transmission.

Another distortion effect is electromagnetic feedthrough which is due to direct coupling between the input and output ports of the device, bypassing any acoustic response. This effect is minimized by proper device design, mounting, bonding, and packaging.

In addition to generating a SAW, other spurious acoustic modes may be generated. Bulk acoustic waves (BAW) may be both generated and received, which causes passband distortion and loss of out-of-band rejection. BAW generation is minimized by proper choice of material, roughening of the crystal backside to scatter BAWs, and use of a SAW track changer, such as a multistrip coupler.

Any plane wave which is generated from a finite aperture will begin to diffract. This is exactly analogous to light diffracting through a slit. Diffraction's principal effect is to cause effective shifts in the filter's tap weights and phase which results in increased sidelobe levels in the measured frequency response. Diffraction is minimized by proper choice of substrate and filter design.

Transducer electrodes are fabricated from thin film metal, usually aluminum, and are finite in width. This metal can cause discontinuities to the surface wave which cause velocity shifts and frequency-dependent reflections. In addition, the films have a given sheet resistance which gives rise to a parasitic electrode resistance loss. The electrodes are designed to minimize these distortions in the device.

47.6 Bidirectional Filter Response

A SAW filter is composed of two cascaded transducers. In addition, the overall filter function is the product of two acoustic transfer functions, two electrical transfer functions, and a delay line function, as illustrated in Fig. 47.6. The acoustic filter functions are as designed by each SAW transducer. The delay line function is dependent on several parameters, the most important being frequency and transducer separation. The propagation path transfer function, $D(\omega)$, is normally assumed unity, although this may not be true for high frequencies ($f >$ 500 MHz) or if there are films in the propagation path. The electrical networks may cause distortion of the acoustic response and are typically compensated in the initial SAW transducer's design.

The SAW electrical network is analyzed using the SAW equivalent circuit model plus the addition of packaging parasitics and any tuning or matching networks. Figure 47.7 shows a typical electrical network which is computer analyzed to yield the overall transfer function for one port of the two-port SAW filter [Morgan, 1985]. The second port is analyzed in a similar manner and the overall transfer function is obtained as the product of the electrical, acoustic, and propagation delay line effects.

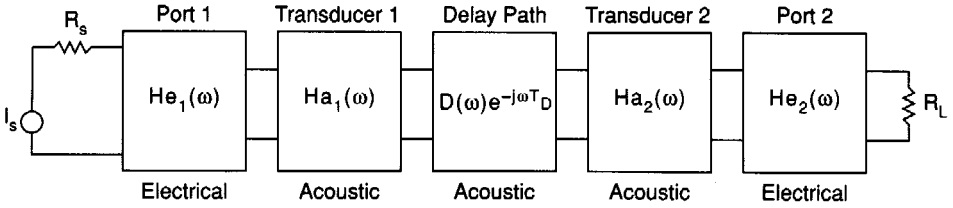

FIGURE 47.6 Complete transfer function of a SAW filter including the acoustic, electrical, and delay line transfer functions. The current generator is I_s, and R_s and R_L are the source and generator resistances, respectively.

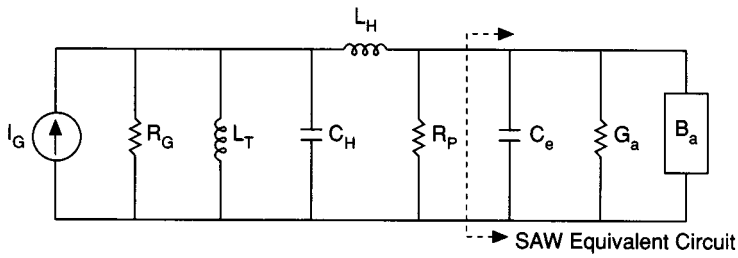

FIGURE 47.7 Electrical network analysis for a SAW transducer. I_G and R_G represent the generator source and impedance, L_T is a tuning inductor, C_H and L_H are due to the package capacitance and bond wire, respectively, and R_P represents a parasitic resistance due to the electrode transducer resistance. The entire network, including the frequency-dependent SAW network, is solved to yield the single-port transfer function.

47.7 Multiphase Unidirectional Transducers

The simplest SAW transducers are single-phase bidirectional transducers. Because of their symmetrical nature, SAW energy is launched equally in both directions from the transducer. In a two- transducer configuration, half the energy (3 dB) is lost at the transmitter, and reciprocally, only half the energy can be received at the receiver. This yields a net 6-dB loss in a filter. However, by adding nonsymmetry into the transducer, either by electrical multiphases or nonsymmetry in reflection and regeneration, energy can be unidirectionally directed yielding a theoretical minimum 0-dB loss.

The most common SAW UDTs are called the three-phase UDT (3PUDT) and the group type UDT (GUDT). The 3PUDT has the broadest bandwidth and requires multilevel metal structures with crossovers. The GUDT uses a single-level metal but has a narrower unidirectional bandwidth due to its structure. In addition, there are other UDT or equivalent embodiments which can be implemented but will not be discussed [Morgan, 1985]. The basic structure of a 3PUDT is shown in Fig. 47.8. A unit cell consists of three electrodes, each connected to a separate bus bar, where the electrode period is $\lambda_0/3$. One bus bar is grounded and the other two bus bars will be driven by an electrical network where $V_1 = V_2 \angle 60°$. The transducer analysis can be accomplished similar to a simple IDT by considering the 3PUDT as three collinear IDTs with a spatial phase shift, as shown in Fig. 47.8. The electrical phasing network, typically consisting of one or two reactive elements, in conjunction with the spatial offset results in energy being launched in only one direction from the SAW transducer. The transducer can then be matched to the required load impedance with one or two additional reactive elements. The effective unidirectional bandwidth of the 3PUDT is typically 20% or less, beyond which the transducer behaves as a normal bidirectional transducer. Figure 47.9 shows a 3PUDT filter schematic consisting of two transducers and their associated matching and phasing networks. The overall filter must be analyzed with all external electrical components in place for accurate prediction of performance. The external components can be miniaturized and may be fabricated using only printed circuit board material and area. This type of device has demonstrated as low as 2 dB insertion loss.

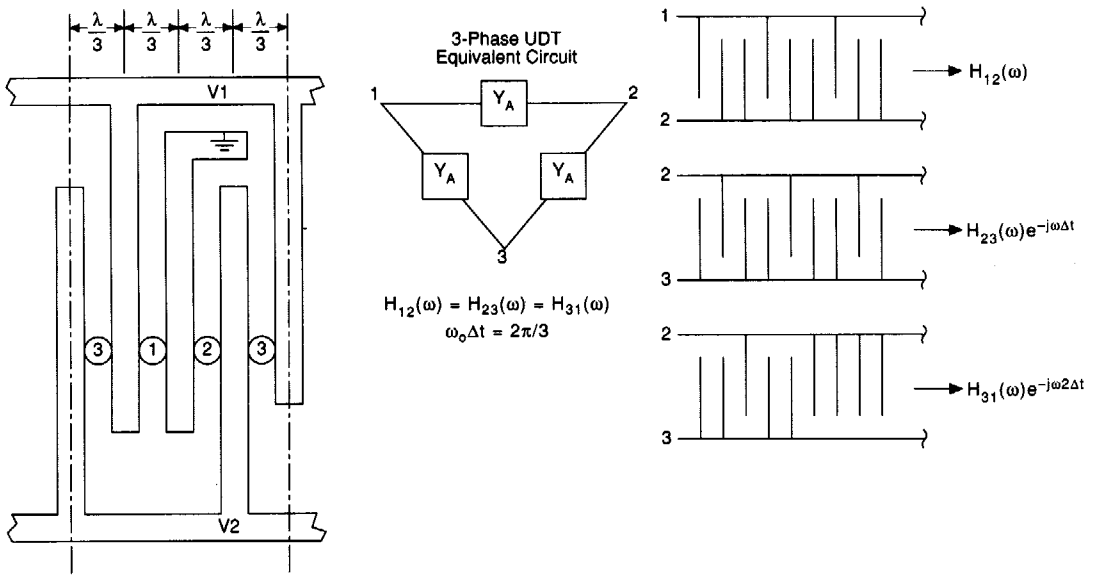

FIGURE 47.8 Schematic of a unit cell of a 3PUDT and the basic equivalent circuit. The 3PUDT can be analyzed as three collinear transducers with a spatial offset.

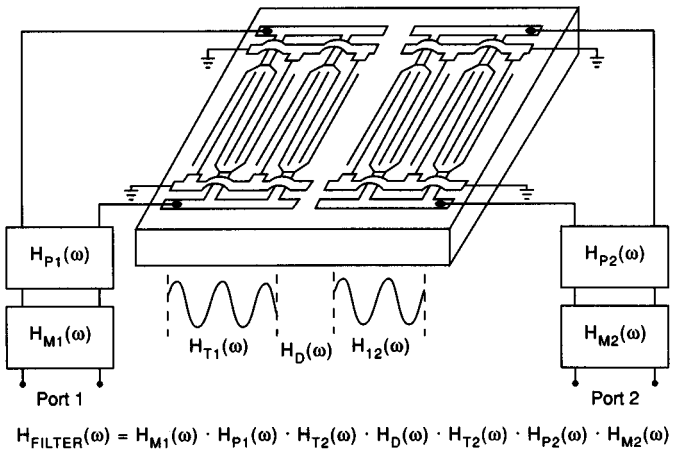

FIGURE 47.9 Schematic diagram of a 3PUDT which requires the analysis of both the acoustic transducer responses as well as electrical phasing and matching networks.

47.8 Single-Phase Unidirectional Transducers

Single-phase unidirectional transducers (SPUDT) use spatial offsets between mechanical electrode reflections and electrical regeneration to launch a SAW in one direction. A reflecting structure may be made of metal electrodes, dielectric strips, or grooved reflectors which are properly placed within a transduction structure. Under proper design and electrical matching conditions, the mechanical reflections can exactly cancel the electrical regeneration in one direction of the wave over a moderate band of frequencies. This is schematically illustrated in Fig. 47.10 which shows a reflector structure and a transduction structure merged to form a SPUDT. The transducer needs to be properly matched to the load for optimum operation. The mechanical reflections can be controlled by modifying the width, position, or height of the individual reflector. The regenerated SAW is primarily controlled by the electrical matching to the load of the transduction structure. SPUDT filters have

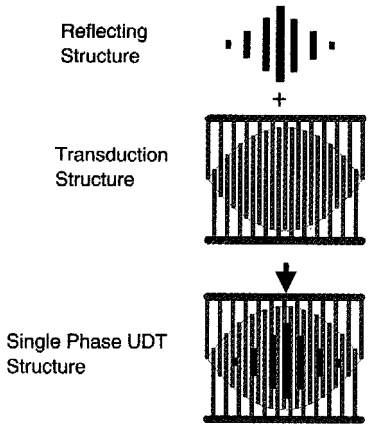

FIGURE 47.10 Schematic representation of a SPUDT which is a combination of transduction and reflecting structures to launch a SAW in one direction over moderate bandwidths.

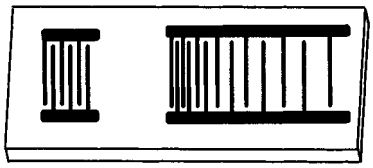

FIGURE 47.11 A SAW dispersive filter consisting of a uniform transducer and a "down chirp" dispersive transducer. The high frequencies have a shorter delay than the low frequencies in this example.

exhibited as low as 3 dB loss over fractional bandwidths of 5% or less and have the advantage of not needing phasing networks when compared to the multiphase UDTs.

47.9 Dispersive Filters

SAW filters can also be designed and fabricated using nonuniformly spaced electrodes in the transducer. The distance between adjacent electrodes determines the "local" generated frequency. As the spacing between the electrodes changes, the frequency is slowly changed either up (decreasing electrode spacing) or down (increasing electrode spacing) as the position progresses along the transducer. This slow frequency change with time is often called a "chirp." Figure 47.11 shows a typical dispersive filter consisting of a chirped transducer in cascade with a uniform transducer. Filters can be designed with either one or two chirped transducers and the rate of the chirp is variable within the design. These devices have found wide application in radar systems due to their small size, reproducibility, and large time bandwidth product.

47.10 Coded SAW Filters

Because of the ability to control the amplitude and phase of the individual electrodes or taps, it is easy to implement coding in a SAW filter. Figure 47.12 shows an example of a coded SAW filter implementation. By changing the phase of the taps, it is possible to generate an arbitrary code sequence. These types of filters are used in secure communication systems, spread spectrum communications, and tagging, to name a few [Matthews, 1977].

SAW devices can also be used to produce time impulse response shapes for use in modulators, equalizers, and other applications. An example of a SAW modulator used for generating a cosine envelope for a minimum shift keyed (MSK) modulator is shown in Fig. 47.13 [Morgan, 1985].

47.11 Resonators

Another very important class of devices is SAW resonators. Resonators can be used as frequency control elements in oscillators, as notch filters, and as narrowband filters, to name a few. Resonators are typically fabricated on piezoelectric quartz substrates due to its low TCD which yields temperature-stable devices. A resonator uses one or two transducers for coupling energy in/out of the device and one or more distributed reflector arrays to store energy in the device. This is analogous to an optical cavity with the distributed reflector arrays acting

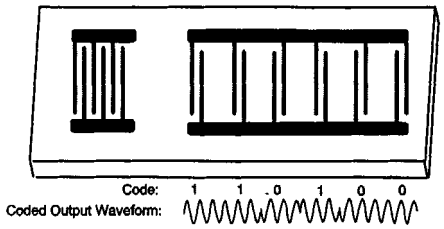

FIGURE 47.12 Example of a coded SAW tapped delay line.

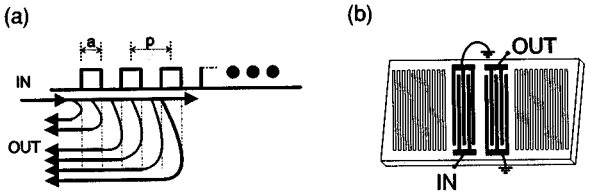

FIGURE 47.14 (a) SAW reflector array illustrating synchronous distributed reflections at center frequency. Individual electrode width (a) is 1/4 wavelength and the array period is 1/2 wavelength at center frequency. (b) A schematic of a simple single-pole, single-cavity two-port SAW resonator.

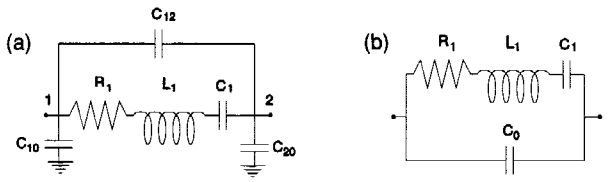

FIGURE 47.15 (a) Two-port resonator equivalent circuit and (b) one-port resonator equivalent circuit.

as the mirrors. A localized acoustic mirror, such as a cleaved edge, is not practical for SAW because of spurious mode coupling at edge discontinuities which causes significant losses.

A distributive reflective array is typically composed of a series of shorted metal electrodes, etched grooves in the substrate, or dielectric strips. There is a physical discontinuity on the substrate surface due to the individual reflectors. Each reflector is one-quarter wavelength wide and the periodicity of the array is one-half wavelength. This is shown schematically in Fig. 47.14. The net reflections from all the individual array elements add synchronously at center frequency, resulting in a very efficient reflector. The reflection from each array element is small and very little spurious mode coupling results.

Figure 47.14 shows a typical single-pole, single-cavity, two-port SAW resonator. Resonators can be made multipole by addition of multiple cavities, which can be accomplished by inline acoustic coupling, transverse acoustic coupling, and by electrical coupling. The equivalent circuit for SAW two-port and one-port resonators is shown in Fig. 47.15. SAW resonators have low insertion loss and high electrical Q's of several thousand [Campbell, 1989; Datta, 1986; Morgan, 1985].

Defining Terms

Bidirectional transducer: A SAW transducer which launches energy from both acoustic ports which are located at either end of the transducer structure.

Interdigital transducer: A series of collinear electrodes placed on a piezoelectric substrate for the purpose of launching a surface acoustic wave.

Surface acoustic wave (SAW): A surface acoustic wave (also known as a Rayleigh wave) is composed of a coupled compressional and shear wave. On a piezoelectric substrate there is also an electrostatic wave which allows electroacoustic coupling. The wave is confined at or near the surface and decays away rapidly from the surface.

Triple transit echo (TTE): A multiple transit echo received at three times the main SAW signal delay time. This echo is caused due to the bidirectional nature of SAW transducers and the electrical and/or acoustic mismatch at the respective ports. This is a primary delayed signal distortion which can cause filter distortion, especially in bidirectional transducers and filters.

Unidirectional transducer (UDT): A transducer which is capable of launching energy from primarily one acoustic port over a desired bandwidth of interest.

48.1 Introduction

In electrical engineering, the term *ultrasonics* usually refers to the study and use of waves of mechanical vibrations propagating in solids or liquids with frequencies in the megahertz or low gigahertz ranges. Such waves in these frequency ranges have wavelengths on the order of micrometers and thus can be electrically generated, directed, and detected with transducers of reasonable size. These ultrasonic devices are used for signal processing directly in such applications as filtering and pulse compression and indirectly in acousto-optic processors; for flaw detection in optically opaque materials; for resonant circuits in frequency control applications; and for medical imaging of human organs, tissue, and blood flow.

48.2 Propagation in Solids

If the solid under consideration is elastic (linear), homogeneous, and nonpiezoelectric, the components, u_i, of the displacement of an infinitesimal region of the material measured along a set of Cartesian axes, x_i, are interrelated by an equation of motion:

$$\rho \frac{\partial^2 u_i}{\partial t^2} = \sum_j \sum_k \sum_l c_{ijkl} \frac{\partial^2 u_j}{\partial x_k \partial x_l}, \qquad \text{Form: } \rho \frac{\partial^2 u}{\partial t^2} = c \frac{\partial^2 u}{\partial x^2} \tag{48.1}$$

where ρ is the mass density of the material and c_{ijkl} $(i, j, k, l = 1, 2, 3)$ is called the stiffness tensor. It is the set of proportionality constants between the components of the stress tensor T and the strain tensor S in a three-dimensional Hooke's law (form: $T = cS$ with $S = \partial u/\partial x$). In Eq. (48.1) and in the subsequent equations the form of the equation is shown without the clutter of the many subscripts. The form is useful for discussion purposes; moreover, it gives the complete equation for cases in which the propagation can be treated as one dimensional, i.e., with variations in only one direction, one component of displacement, and one relevant c.

In an infinite medium, the simplest solutions of Eq. (48.1) are plane waves given by the real part of

$$u_i = U_i e^{-jk\left(\sum_j L_j x_j - Vt\right)} \qquad \text{Form: } u = U e^{j(\omega t - kx)} \tag{48.2}$$

where the polarization vector has components U_i along the axes. The **phase velocity** of the wave V is measured along the propagation vector **k** whose direction cosines with respect to these axes are given by L_i. Substituting

the assumed solutions of Eq. (48.2) into Eq. (48.1) gives the third-order eigenvalue equations, usually known as the Christoffel equations:

$$\sum_j \sum_k \sum_l L_k L_l c_{ijkl} U_j = \rho V^2 U_i, \qquad \text{Form: } (c - \rho V^2)U = 0 \tag{48.3}$$

The three eigenvalues in Eq. (48.3) give three values of ρV^2 and hence the phase velocities of three waves propagating in the direction of positive k and three propagating in the negative k direction. The eigenvectors of the three forward solutions give the polarization vector for each, and they form a mutually perpendicular triad. The polarization vector of one of the plane waves will be parallel, or almost parallel, to the k vector, and it is called the longitudinal wave, or quasi-longitudinal if the displacement is not exactly parallel to k. The other two waves will have mutually perpendicular polarization vectors, which will each be perpendicular, or almost perpendicular, to the k vector. If the polarization is perpendicular, the wave is called a transverse or shear wave; if almost perpendicular, it is called quasi-shear. The three waves propagate independently through the solid, and their respective amplitudes depend on the exciting source.

In an isotropic medium where there are only two independent values of c_{ijkl} in Eq. (48.1), there are one longitudinal wave and two degenerate shear waves. The phase velocities of these waves are independent of the direction of propagation and are given by

$$V_l = \sqrt{\frac{c_{1111}}{\rho}} \quad \text{and} \quad V_s = \sqrt{\frac{c_{1212}}{\rho}} \tag{48.4}$$

The phase velocities in isotropic solids are often expressed in terms of the so-called Lame constants defined by $\mu = c_{1212}$ and $\lambda = c_{1111} - 2c_{1212}$. The longitudinal velocity is larger than the shear velocity. Exact velocity values depend on fabrication procedures and purity, but Table 48.1 gives typical values for some materials important in ultrasonics.

In signal processing applications of ultrasonics, the propagating medium is often a single crystal, and thus a larger number of independent stiffness constants is required to describe the mechanical properties of the medium, e.g., three in a cubic crystal, five in a hexagonal, and six in a trigonal. Note that while the number of independent constants is relatively small, a large number of the c_{ijkl} are nonzero but are related to each other by the symmetry characteristics of the crystal. The phase velocities of each of the three independent plane waves in an anisotropic medium depend on the direction of propagation. Rather than plotting V as a function of angle of propagation, it is more common to use a **slowness surface** giving the reciprocal of V (or $\mathbf{k} = \omega/V$ for a given ω) as a function of the direction of k. Usually planar cuts of such slowness surfaces are plotted as shown in Figs. 48.1(a) and (b).

In anisotropic materials the direction of energy flow (the ultrasonic equivalent of the electromagnetic Poynting vector) in a plane wave is not parallel to **k.** Thus the direction of **k** is set by the transducer but the energy flow or beam direction is normal to the tangent to the slowness surface at the point corresponding to **k.** The direction of propagation (of **k**) in Fig. 48.1 lies in the basal plane of a cubic crystal, here silicon. At each angle there are three waves—one is pure shear polarized perpendicular to this plane, one is quasilongitudinal for most angles, while the third is quasi-shear. For the latter two, the tangent to the slowness curves at an arbitrary angle is not normal to the radius vector, and thus there is an appreciable angle between the direction of energy flow and the direction of **k**. This angle is shown on the diagram by the typical **k** and **P** vectors, the latter being the direction of energy flow in an acoustic beam with this **k.** Along the cubic axes in a cubic crystal, the two shear waves are degenerate, and for all three waves the energy flow is parallel to **k.** When the particle displacement of a mode is either parallel to the propagation vector or perpendicular to it and the energy flow is parallel to **k,** the mode is called a **pure mode.** The propagation vector in Fig. 48.1(b) lies in the basal plane of a trigonal crystal, quartz.

When ultrasonic waves propagate in a solid, there are various losses that attenuate the wave. Usually the attenuation per wavelength is small enough that one can neglect the losses in the initial calculation of the

propagation characteristics of the material and the excitation, and then multiply the resulting propagating wave by a factor of the form $\exp[-\alpha x]$ where x is in the direction of k and α is called the *attenuation constant*. One loss mechanism is the viscosity of the material and due to it the attenuation constant is

$$\alpha = \eta \frac{\omega^2}{2V^3\rho} \tag{48.5}$$

in which η is the coefficient of viscosity. It should be noted that the attenuation constant for viscous loss increases as the square of the frequency. In polycrystalline solids there is also loss due to scattering from dislocation and grain structure; thus, for the same material the loss at high frequencies is much higher in a polycrystalline form than in a crystalline one. As a result, in high-frequency applications of ultrasound, such as for signal processing, the propagation material is usually in single-crystal form.

48.3 Piezoelectric Excitation

When a piezoelectric material is stressed, an electric field is generated in the stressed region; similarly, if an electric field is applied, there will be an induced stress on the material in the region of the field. Thus, there is a coupling between mechanical motion and time-varying electric fields. Analysis of wave propagation in piezoelectric solids should thus include the coupling of the mechanical equations such as Eq. (48.1) with Maxwell's equations. In most ultrasonic problems, however, the velocity of the mechanical wave solutions is slow enough that the electric fields can be described by a scalar potential ϕ. This is called the *quasi-static approximation*. Within this approximation, the equations of motion in a piezoelectric solid become

$$\rho\frac{\partial^2 u_i}{\partial t^2} - \sum_j\sum_k\sum_l c_{ijkl}\frac{\partial^2 u_j}{\partial x_k \partial x_l} = \sum_j\sum_k e_{ijk}\frac{\partial^2 \phi}{\partial x_j \partial x_k} \qquad \text{Form: } \rho\frac{\partial^2 u}{\partial t^2} - c\frac{\partial^2 u}{\partial x^2} = e\frac{\partial^2 \phi}{\partial x^2}$$
$$\sum_i\sum_j \epsilon_{ij}\frac{\partial^2 \phi}{\partial x_i \partial x_j} = \sum_i\sum_j\sum_k e_{ijk}\frac{\partial^2 u_j}{\partial x_i \partial x_k} \qquad \epsilon\nabla^2\phi = e\frac{\partial^2 u}{\partial x^2} \tag{48.6}$$

The piezoelectric coupling constants e_{ijk} form a third-rank tensor property of the solid and are the proportionality constants between the components of the electric field and the components of the stress. Similarly ϵ_{ij} is the second-rank permittivity tensor, giving the proportionality constants between the components of the electric field E and of the electric displacement D. If the material is nonpiezoelectric $e_{ijk} = 0$, then the first three equations of Eq. (48.6) reduce to the corresponding three of Eq. (48.1), whereas the fourth equation becomes the anisotropic Laplace equation. In a piezoelectric, these mechanical and electrical components are coupled.

The plane wave solution of Eq. (48.6) then has the three mechanical components of Eq. (48.2) and in addition has a potential given by

$$\phi = \Phi e^{-jk\left(\sum_j L_j x_j - Vt\right)} \qquad \text{Form: } \phi = \Phi e^{j(\omega t - kx)} \tag{48.7}$$

Thus, for the quasi-static approximation there is a wave of potential that propagates with an acoustic phase velocity V in synchronism with the mechanical variations. As will be seen in Section 48.5, it is possible to use the corresponding electric field, $-\nabla\phi$, to couple to electrode configurations and thus excite or detect the ultrasonic wave from external electric circuits.

Rather than substituting Eq. (48.7) and Eq. (48.2) into Eq. (48.6) to obtain a set of four equations similar to Eq. (48.3), it is frequently more convenient to substitute Eq. (48.7) into the fourth equation in the set of Eq. (48.6). Because there are no time derivatives involved, this substitution gives the potential as a linear combination of the components of the mechanical displacement:

$$\Phi = \frac{\sum_i \sum_j \sum_k e_{ijk} L_i L_k U_j}{\sum_i \sum_j \epsilon_{ij} L_i L_j} \qquad \text{Form:} \quad \Phi = \frac{e}{\epsilon} U \tag{48.8}$$

When this combination is substituted into the first three equations of Eq. (48.6) and terms gathered, they become identical to Eq. (48.1) but with each c_{ijkl} replaced by

$$\bar{c}_{ijkl} = c_{ijkl} + \frac{\sum_m \sum_n e_{mij} e_{nkl} L_m L_n}{\sum_m \sum_n \epsilon_{mn} L_m L_n} \qquad \text{Form:} \quad \bar{c} = c\,(1 + K^2) \text{ with } K^2 = \frac{e^2}{c\epsilon} \tag{48.9}$$

Using these so-called stiffened elastic constants, we obtain the same third-order eigenvalue equation, Eq. (48.3), and hence the velocities of each of the three modes and the corresponding mechanical displacement components. The potential is obtained from Eq. (48.8). The velocities obtained for the piezoelectric material are usually at most a few percent higher than would be obtained with the piezoelectricity ignored. The parameter K in Eq. (48.9) is called the electromechanical coupling constant.

48.4 One-Dimensional Propagation

If an acoustic plane wave as in Eq. (48.2) propagating within one medium strikes an interface with another medium, there will be reflection and transmission, much as in the corresponding case in optics. To satisfy the boundary conditions at the interface, it will be necessary in general to generate three transmitted modes and three reflected modes. Thus, the concepts of reflection and transmission coefficients for planar interfaces between anisotropic media are complicated. In many propagation and excitation geometries, however, one can consider only one independent pure mode with energy flow parallel to **k** and particle displacement polarized along **k** or perpendicular to it. This mode (plane wave) then propagates along the axis or its negative in Eq. (48.2). Discussion of the generation, propagation, and reflection of this wave is greatly assisted by considering analogies to the one-dimensional electrical transmission line.

With the transmission line model operating in the sinusoidal steady state, the particle displacement u_i of Eq. (48.2) is represented by a phasor, u. The time derivative of the particle displacement is the particle velocity and is represented by a phasor, $v = j\omega u$, which is taken as analogous to the current on the one-dimensional electrical transmission line. The negative of the stress, or the force per unit area, caused by the particle displacement is represented by a phasor, $(-T) = jkcu$, which is taken as analogous to the voltage on the transmission line. Here c is the appropriate stiffened elastic constant for the mode in question in Eq. (48.3). With these definitions, the general impedance, the characteristic impedance, the phase velocity, and the wave vector, respectively, of the equivalent line are given by

$$Z = \frac{(-T)}{v} \qquad Z_0 = \sqrt{\rho c} \qquad V = \sqrt{\frac{c}{\rho}} \qquad k = \frac{\omega}{V} \tag{48.10}$$

Some typical values of the characteristic impedance of acoustic media are given in Table 48.1. The characteristic impedance corresponding to a mode is given by the product of the density and the phase velocity, ρV, even in the anisotropic case where the effective stiffness c in Eq. (48.10) is difficult to determine.

As an example of the use of the transmission line model, consider a pure longitudinal wave propagating in an isotropic solid and incident normally on the interface with a second isotropic solid. There would be one reflected wave and one transmitted wave, both longitudinally polarized. The relative amplitudes of the stresses in these waves would be given, with direct use transmission line concepts, by the voltage reflection and transmission coefficients

$$\Gamma_R = \frac{Z_{02} - Z_{01}}{Z_{02} + Z_{01}} \quad \text{and} \quad \Gamma_T = \frac{2Z_{02}}{Z_{02} + Z_{01}} \tag{48.11}$$

When an acoustic wave meets a discontinuity or a mismatch, part of the wave is reflected. For an incident mode, an interface represents a lumped impedance. If the medium on the other side of the interface is infinitely deep, that lumped impedance is the characteristic impedance of the second medium. However, if the second medium is of finite depth h in the direction of propagation and it in turn is terminated by a lumped impedance Z_{L2} the impedance seen by the incident wave at the interface is given, as in transmission line theory, by

$$Z_{in} = Z_{02} \frac{Z_{L2} \cos k_2 h + jZ_{02} \sin k_2 h}{Z_{02} \cos k_2 h + jZ_{L2} \sin k_2 h} \tag{48.12}$$

Thus, as with transmission lines, an intervening layer can be used to match from one transmitting medium to another. For example, if the medium following the layer is infinite and of characteristic impedance Z_{03}, i.e., $Z_{L2} = Z_{03}$, the interface will look like Z_{01} to the incident wave if $kh = \pi/2$, quarter-wave thickness, and the layer characteristic impedance is $Z^2_{02} = Z_{01}Z_{03}$. This matching, which provides complete power transfer from medium 1 to medium 3, is valid only at the frequency for which $kh = \pi/2$. For matching over a band of frequencies, multiple matching layers are required.

48.5 Transducers

Electrical energy is converted to acoustic waves in ultrasonic applications by means of electro-acoustic transducers. Most transducers are reciprocal in that they will also convert the mechanical energy in acoustic waves into electrical energy. The form of the transducer is very application dependent. Categories of applications include imaging, wherein one transducer is used to create an acoustic beam, discontinuities in the propagating medium scatter this beam, and the scattered energy is captured by the same or another transducer [see Fig. 48.4(b)]. From the changes of the scattered energy as the beam is moved, characteristics of the scatterer are determined. This is the process in the use of ultrasonics for nondestructive evaluation (NDE), flaw detection, for example, and in ultrasonic images for medical diagnosis. These are radar-like applications and are practical at reasonable frequencies because most solids and liquids support acoustic waves with tolerable losses and the wavelength is short enough that the resolution is adequate for practical targets. By recording both the amplitude and phase of the scattered signal as the transmitter-receiver combination is rotated about a target, one can generate tomographic-type images of the target.

A second category of transducer provides large acoustic standing waves at a particular frequency and, as a result, has a resonant electrical input impedance at this frequency and can be used as a narrowband filter in electrical circuits. In a third category of transducer, the object is to provide an acoustic beam that distorts the medium, as it passes through, in a manner periodic in space and time, and thus provides a dynamic diffraction grating that will deflect or modulate an optical beam that is passed through it [see Fig. 48.4(c)]. Such acousto-optic devices are used in broadband signal processing.

Another category of transducer uses variation of the shape of the electrodes and the geometry of the electroacoustic coupling region so that the transfer function between a transmitting and a receiving transducer is made to have a prescribed frequency response. Such geometries find wide application in filtering and pulse compression applications in the frequency range up to a few gigahertz. Because of the ease of fabrication of complicated electrode geometries, special forms of the solution of the wave equation, Eq. (48.1), called surface acoustic waves (SAW) are dominant in such applications. Because surface acoustic waves are discussed in another section of this handbook, here we will confine the discussion to transducers that generate or detect acoustic waves that are almost plane and usually single mode, the so-called bulk modes.

The prototype geometry for a bulk-mode transducer is shown in Fig. 48.2. The active region is the portion of the piezoelectric slab between the thin metal electrodes, which can be assumed to be circular or rectangular

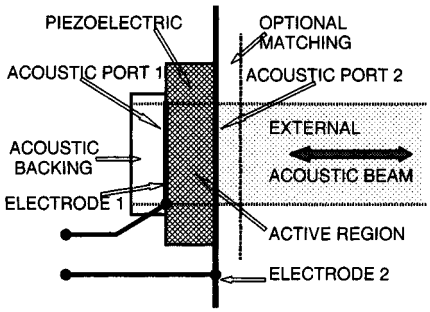

FIGURE 48.2 Prototype transducer geometry.

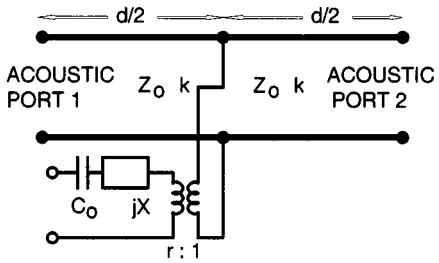

FIGURE 48.3 Model of active region.

in shape. Connections to these electrodes form the electrical port for the transducer and the voltage between them creates a spatially uniform electric field in the active region, and this time-varying electric field couples to the acoustic waves propagating between the electrodes. If the planar electrodes are many wavelengths in transverse dimensions and the active region is much thinner, and if the axial direction is a pure mode direction for the piezoelectric, the waves in the active region can be considered as plane waves. We then have the one-dimensional geometry considered earlier. The transducer may be in contact with another elastic medium on either side, as indicated in Fig. 48.2, so that the plane waves propagate in and out of the active regions in the cross-sectional region shown. Thus, the transducer has in general two acoustic ports for coupling to the outside world as well as the electrical port.

In the absence of piezoelectric coupling, the active region could be represented by a one-dimensional transmission line as discussed in the previous section and as indicated by the heavy lines in Fig. 48.3. With piezoelectricity there will be the stiffening of the appropriate stiffness constants as discussed in Eq. (48.9) with the concomitant perturbation of the characteristic impedance Z_{0p} and the phase velocity V_p, but more important there will also be coupling to the electrical port. One model including the latter coupling is shown in Fig. 48.3 in which the parameters are defined by

$$C_0 = \frac{\epsilon A}{d}; \quad jX = \frac{j}{\omega C_0} K^2 \frac{\sin(\pi\omega/\omega_0)}{\pi\omega/\omega_0} \quad r = \frac{2e/\epsilon}{\omega A Z_0} \sin(\pi\omega/2\omega_0) \tag{48.13}$$

Here C_0 is the capacity that would be measured between the electrodes if there were no mechanical strain on the piezoelectric, A is the cross-sectional area of the active region, and X is an effective reactance. The quantity r is the transformer ratio (with dimensions) of an ideal transformer coupling the electrical port to the center of the acoustic transmission line. K is the electromechanical coupling constant for the material as defined in Eq. (48.9). The so-called resonant frequency ω_0 is that angular frequency at which the length d of the active region is one-half of the stiffened wavelength, $\omega_0 = \pi V/d$. In the physical configuration of Fig. 48.4(a), the transducer has zero stress on the surfaces of the active region and hence both acoustic ports of Fig. 48.3 are terminated in short circuits and the line is mechanically resonant at the angular frequency ω_0. At this frequency the secondary of the transformer of Fig. 48.3 is open circuited if there are no losses, and thus the electrical input impedance is infinite at this frequency and behaves like a parallel resonant circuit for neighboring frequencies. This configuration can be used as a high-Q resonant circuit if the mechanical losses can be kept low, as they are in single crystals of such piezoelectric materials as quartz. It should be noted, however, that the behavior is not as simple as that of a simple L-C parallel resonant circuit, primarily because of the frequency dependence of the effective reactance X and of the transformer ratio in the equivalent circuit. The electrical input impedance is given by

$$Z_{in} = \frac{1}{j\omega C_0}\left(1 - K^2 \frac{\tan kd/2}{kd/2}\right) \tag{48.14}$$

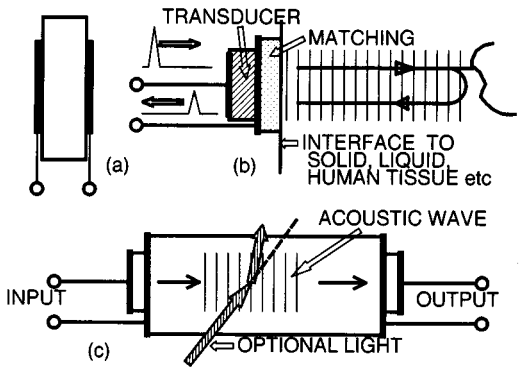

FIGURE 48.4 (a) Resonator structure; (b) acoustic probe; (c) acoustic delay line or optical modulator.

Thus, while the input impedance is infinite as in a parallel resonant circuit at ω_o, it is zero as in a series resonant circuit at a slightly lower frequency where the bracketed term in Eq. (48.14) is zero. When losses are present or there is radiation out of an acoustic port, a resistive term is included in the reactive expression of Eq. (48.14).

Behavior analogous to that of coupled tuned electrical circuits for multipole filters can be achieved by subdividing the electrodes of Fig. 48.4(a) into different areas, each of which will act separately as a tuned circuit, but if they are close enough together there will be acoustic coupling between the different radiators. By controlling this coupling, narrowband filters of very high Q and of somewhat tailored frequency response can be built in the megahertz and low gigahertz range.

The basic geometry of Fig. 48.4(c) gives an electric-to-electric delay line whose delay is given by the length of the medium between the transducers divided by the phase velocity of the acoustic wave and would be on the order of 2 μs/cm. Since the solid has little dispersion, the bandwidth of the delay line is determined by that of the transducers. Here it is necessary to choose the characteristic impedances and thicknesses of the backing and matching layers in Fig. 48.2 in such a manner that the conversion of the electrical energy incident on the electrical port to the acoustic energy out of acoustic port 2 of Fig. 48.3 is independent of frequency over a large range about the resonant frequency of the **piezoelectric transducer** itself. Varying the matching and backing layers is equivalent to varying the terminating impedances on the acoustic line of Fig. 48.3. The matching is often assisted by lumped elements in the external electrical circuit.

The geometry of Fig. 48.4(c) is also the prototype form for acousto-optic interactions. Here the second transducer is not relevant and can be replaced by an acoustic absorber so that there is no reflected wave present in the active region. An optical wave coming into the crystal as shown in Fig. 48.4(c) sees a propagating periodic perturbation of the medium, and if the photoelastic coefficients of the solid are large, the wave sees appreciable variations in the refractive index and hence a moving diffraction grating. The angle of deflection of the output optical beam and its frequency as produced by the grating depend on the amplitude of the various frequency components in the acoustic beam when the optical beam traversed it. Thus, for example, the intensity versus angular position of the emerging optical beam is a measure of the frequency spectrum of any information modulated on the acoustic beam.

As noted previously, ultrasonic waves are often used as probes when the wavelength and attenuation are appropriate. For these radar-like applications, the acoustic beam is generated by a transducer and propagates in the medium containing the scatterer to be investigated as shown in Fig. 48.4(b). The acoustic wave is scattered by any discontinuity in the medium, and energy is returned to the same or to another transducer. If the outgoing signal is pulsed, then the delay for the received pulse is a measure of the distance to the scatterer. If the transducer is displaced or rotated, the change in delay of the echo gives a measure of the shape of the scatterer. Any movement of the scatterer, for example, flowing blood in an artery, causes a Doppler shift of the echo, and this shift, along with the known direction of the returned beam, gives a map of the flow pattern. Phasing techniques with multiple transducers or multiple areas of one transducer can be used to produce focused beams or beams electrically swept in space by differential variation of the phases of the excitation of the component areas of the transducer.

Defining Terms

Characteristic impedance: Ratio of the negative of the stress to the particle velocity in an ultrasonic plane wave.

Form: Term used to indicate the structure and dimensions of a multiterm equation without details within component terms.

Phase velocity: Velocity of propagation of planes of constant phase.

Piezoelectric transducers: Devices that convert electric signals to ultrasonic waves, and vice versa, by means of the piezoelectric effect in solids.

Pure longitudinal and shear waves (modes): Ultrasonic plane waves in which the particle motion is parallel or perpendicular, respectively, to the wave vector and for which energy flow is parallel to the wave vector.

Slowness surface: A plot of the reciprocal of the phase velocity as a function of direction in an anisotropic crystal.

49.1 Introduction

Piezoelectric materials have been used extensively in actuator and ultrasonic receiver applications, while **ferroelectric** materials have recently received much attention for their potential use in nonvolatile (NV) memory applications. We will discuss the basic concepts in the use of these materials, highlight their applications, and describe the constraints limiting their uses. This chapter emphasizes properties which need to be understood for the effective use of these materials but are often very difficult to research. Among the properties which are discussed are **hysteresis** and **domains**.

Ferroelectric and piezoelectric materials derive their properties from a combination of structural and electrical properties. As the name implies, both types of materials have electric attributes. A large number of materials which are ferroelectric are also piezoelectric. However, the converse is not true. Pyroelectricity is closely related to ferroelectric and piezoelectric properties via the symmetry properties of the crystals.

Examples of the classes of materials that are technologically important are given in Table 49.1. It is apparent that many materials exhibit electric phenomena which can be attributed to ferroelectric, piezoelectric, and **electret** materials. It is also clear that vastly different materials (organic and inorganic) can exhibit ferroelectricity or piezoelectricity, and many have actually been commercially exploited for these properties.

As shown in Table 49.1, there are two dominant classes of ferroelectric materials, ceramics and organics. Both classes have important applications of their piezoelectric properties. To exploit the ferroelectric property, recently a large effort has been devoted to producing thin films of **PZT** (lead [Pb] zirconate titanate) on various substrates for silicon-based memory chips for nonvolatile storage. In these devices, data is retained in the absence of external power as positive and negative **polarization**. Organic materials have not been used for their ferroelectric properties. Liquid crystals in display applications are used for their ability to rotate the plane of polarization of light and not their ferroelectric attribute.

It should be noted that the prefix *ferro* refers to the permanent nature of the electric polarization in analogy with the magnetization in the magnetic case. It does not imply the presence of iron, even though the root of the word means iron. The root of the word piezo means pressure; hence the original meaning of the word piezoelectric implied "pressure electricity"—the generation of electric field from applied pressure. This definition ignores the fact that these materials are reversible, allowing the generation of mechanical motion by applying a field.

TABLE 49.1 Ferroelectric, Piezoelectric, and Electrostrictive Materials

Type	Material Class	Example	Applications
Electret	Organic	Waxes	No recent
Electret	Organic	Fluorine based	Microphones
Ferroelectric	Organic	PVF2	No known
Ferroelectric	Organic	Liquid crystals	Displays
Ferroelectric	Ceramic	PZT thin film	NV-memory
Piezoelectric	Organic	PVF2	Transducer
Piezoelectric	Ceramic	PZT	Transducer
Piezoelectric	Ceramic	PLZT	Optical
Piezoelectric	Single crystal	Quartz	Freq. control
Piezoelectric	Single crystal	$LiNbO_3$	SAW devices
Electrostrictive	Ceramic	PMN	Actuators

49.2 Mechanical Characteristics

Materials are acted on by forces (stresses) and the resulting deformations are called strains. An example of a strain due to a force to the material is the change of dimension parallel and perpendicular to the applied force. It is useful to introduce the coordinate system and the numbering conventions which are used when discussing these materials. Subscripts 1, 2, and 3 refer to the *x*, *y*, and *z* directions, respectively. Displacements have single indices associated with their direction. If the material has a preferred axis, such as the poling direction in PZT, the axis is designated the *z* or 3 axis. Stresses and strains require double indices such as *xx* or *xy*. To make the notation less cluttered and confusing, contracted notation has been defined. The following mnemonic rule is used to reduce the double index to a single index:

1	6	5
xx	*xy*	*xz*
	2	4
	yy	*yz*
		3
		zz

This rule can be thought of as a matrix with the diagonal elements having repeated indices in the expected order, then continuing the count in a counterclockwise direction. Note that *xy* = *yx*, etc. so that subscript 6 applies equally to *xy* and *yx*.

Any mechanical object is governed by the well-known relationship between stress and strain,

$$\mathbf{S} = \mathbf{sT} \tag{49.1}$$

where **S** is the strain (relative elongation), **T** is the stress (force per unit area), and **s** contains the coefficients connecting the two. All quantities are tensors; **S** and **T** are second rank, and **s** is fourth rank. Note, however, that usually contracted notation is used so that the full complement of subscripts is not visible. PZT converts electrical fields into mechanical displacements and vice versa. The connection between the two is via the *d* and *g* coefficients. The *d* coefficients give the displacement when a field is applied (transmitter), while the *g* coefficients give the field across the device when a stress is applied (receiver). The electrical effects are added to the basic Eq. (49.1) such that

$$\mathbf{S} = \mathbf{sT} + \mathbf{dE} \tag{49.2}$$

where **E** is the electric field and **d** is the tensor which contains the coupling coefficients. The latter parameters are reported in Table 49.2 for representative materials. One can write the matrix equation [Eq. (49.2)],

$$\begin{bmatrix} S_1 \\ S_2 \\ S_3 \\ S_4 \\ S_5 \\ S_6 \end{bmatrix} = \begin{bmatrix} s_{11} & s_{12} & s_{13} & & & \\ s_{12} & s_{11} & s_{13} & & 0 & \\ s_{13} & s_{13} & s_{33} & & & \\ & & & s_{44} & & \\ & 0 & & & s_{44} & \\ & & & & & 2(s_{11} - s_{12}) \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ T_6 \end{bmatrix} + \begin{bmatrix} 0 & 0 & d_{13} \\ 0 & 0 & d_{13} \\ 0 & 0 & d_{33} \\ 0 & d_{15} & 0 \\ d_{15} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} E_1 \\ E_2 \\ E_3 \end{bmatrix} \tag{49.3}$$

Note that **T** and **E** are shown as column vectors for typographical reasons; they are in fact row vectors. This equation shows explicitly the stress-strain relation and the effect of the electromechanical conversion.

A similar equation applies when the material is used as a receiver:

$$\mathbf{E} = -\mathbf{gT} + (\varepsilon^{\mathrm{T}})^{-1}\mathbf{D} \tag{49.4}$$

where T is the transpose and **D** the electric displacement. For all materials the matrices are not fully populated. Whether a coefficient is nonzero depends on the symmetry. For PZT, a ceramic which is given a preferred direction by the poling operation (the z-axis), only d_{33}, d_{13}, and d_{15} are nonzero. Also, again by symmetry, $d_{13} = d_{23}$ and $d_{15} = d_{25}$.

Applications

Historically the material which was used earliest for its piezoelectric properties was single-crystal quartz. Crude sonar devices were built by Langevin using quartz transducers, but the most important application was, and still is, frequency control. Crystal oscillators are today at the heart of every clock that does not derive its frequency reference from the ac power line. They are also used in every color television set and personal computer. In these applications at least one (or more) "quartz crystal" controls frequency or time. This explains the label "quartz" which appears on many clocks and watches. The use of quartz resonators for frequency control relies on another unique property. Not only is the material piezoelectric (which allows one to excite mechanical vibrations), but the material has also a very high mechanical "Q" or quality factor (Q >100,000). The actual value depends on the mounting details, whether the crystal is in a vacuum, and other details. Compare this value to a Q for PZT between 75 and 1000. The Q factor is a measure of the rate of decay and thus the mechanical losses of an excitation with no external drive. A high Q leads to a very sharp resonance and thus tight frequency control. For frequency control it has been possible to find orientations of cuts of quartz which reduce the influence of temperature on the vibration frequency.

Ceramic materials of the PZT family have also found increasingly important applications. The piezoelectric but not the ferroelectric property of these materials is made use of in transducer applications. PZT has a very high efficiency (electric energy to mechanical energy coupling factor k) and can generate high-amplitude ultrasonic waves in water or solids. The coupling factor is defined by

$$k^2 = \frac{\text{energy stored mechanically}}{\text{total energy stored electrically}} \tag{49.5}$$

Typical values of k_{33} are 0.7 for PZT 4 and 0.09 for quartz, showing that PZT is a much more efficient transducer material than quartz. Note that the energy is a scalar; the subscripts are assigned by finding the energy conversion coefficient for a specific vibrational mode and field direction and selecting the subscripts accordingly. Thus k_{33} refers to the coupling factor for a longitudinal mode driven by a longitudinal field.

Probably the most important applications of PZT today are based on ultrasonic echo ranging. Sonar uses the conversion of electrical signals to mechanical displacement as well as the reverse transducer property, which is to generate electrical signals in response to a stress wave. Medical diagnostic ultrasound and nondestructive testing systems devices rely on the same properties. Actuators have also been built but a major obstacle is the small displacement which can conveniently be generated. Even then, the required voltages are typically hundreds of volts and the displacements are only a few hundred angstroms. For PZT the strain in the z-direction due to an applied field in the z-direction is (no stress, $\mathbf{T} = 0$)

$$s_3 = d_{33}E_3 \tag{49.6}$$

or

$$s_3 = \frac{\Delta d}{d} = d_{33}\frac{V}{d} \tag{49.7}$$

where s is the strain, E the electric field, and V the potential; d_{33} is the coupling coefficient which connects the two. Thus

$$\Delta d = d_{33}V \tag{49.8}$$

Note that this expression is independent of the thickness d of the material but this is true only when the applied field is parallel to the displacement. Let the applied voltage be 100 V and let us use PZT8 for which d_{33} is 225 (from Table 49.2). Hence $\Delta d = 225$ Å or 2.25 Å/V, a small displacement indeed. We also note that Eq. (49.6) is a special case of Eq. (49.2) with the stress equal to zero. This is the situation when an actuator is used in a force-free environment, for example, as a mirror driver. This arrangement results in the maximum displacement. Any forces which tend to oppose the free motion of the PZT will subtract from the available displacement with the reduction given by the normal stress-strain relation, Eq. (49.1).

It is possible to obtain larger displacements with mechanisms which exhibit mechanical gain, such as laminated strips (similar to bimetallic strips). The motion then is typically up to about 1 millimeter but at a cost of a reduced available force. An example of such an application is the video head translating device to provide tracking in VCRs.

There is another class of ceramic materials which recently has become important. **PMN** (lead [Pb], magnesium niobate), typically doped with ≈10% lead titanate) is an **electrostrictive** material which has seen applications where the absence of hysteresis is important. For example, deformable mirrors require repositioning of the reflecting surface to a defined location regardless of whether the old position was above or below the original position.

Electrostrictive materials exhibit a strain which is quadratic as a function of the applied field. Producing a displacement requires an internal polarization. Because the latter polarization is induced by the applied field

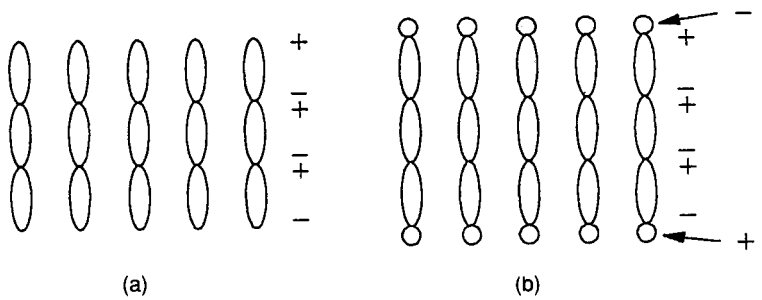

FIGURE 49.1 Charge configurations in ferroelectric model materials: (a) uncompensated and (b) compensated dipole arrays.

and is not permanent, as it is in the ferroelectric materials, electrostrictive materials have essentially no hysteresis. Unlike PZT, electrostrictive materials are not reversible; PZT will change shape on application of a field and generate a field when a strain is induced. Electrostrictive materials only change shape on application of a field and, therefore, cannot be used as receivers. PZT has inherently large hysteresis because of the domain nature of the polarization.

Organic electrets have important applications in self-polarized condenser (or capacitor) microphones where the required electric bias field in the gap is generated by the diaphragm material rather than by an external power supply.

Structure of Ferroelectric and Piezoelectric Materials

Ferroelectric materials have, as their basic building block, atomic groups which have an associated electric field, either as a result of their structure or as result of distortion of the charge clouds which make up the groups. In the first case, the field arises from an asymmetric placement of the individual ions in the group (these groupings are called unit cells). In the second case, the electronic cloud is moved with respect to the ionic core. If the group is distorted permanently, then a permanent electric field can be associated with each group. We can think of these distorted groups as represented by electric dipoles, defined as two equal but opposite charges which are separated by a small distance. Electric dipoles are similar to magnetic dipoles which have the familiar north and south poles. The external manifestation of a magnetic dipole is a magnetic field and that of an electric dipole an electric field.

Figure 49.1(a) represents a hypothetical slab of material in which the dipoles are perfectly arranged. In actual materials the atoms are not as uniformly arranged, but, nevertheless, from this model there would be a very strong field emanating from the surface of the crystal. The common observation, however, is that the fields are either absent or weak. This effective charge neutrality arises from the fact that there are free, mobile charges available which can be attracted to the surfaces. The polarity of the mobile charges is opposite to the charge of the free dipole end. The added charges on the two surfaces generate their own field, equal and opposite to the field due to the internal dipoles. Thus the effect of the internal field is canceled and the external field is zero, as if no charges were present at all [Fig. 49.1(b)].

In ferroelectric materials a crystalline asymmetry exists which allows electric dipoles to form. In their absence the dipoles are absent and the internal field disappears. Consider an imaginary horizontal line drawn through the middle of a dipole. We can see readily that the dipole is not symmetric about that line. The asymmetry thus requires that there be no center of inversion when the material is in the ferroelectric state.

All ferroelectric and piezoelectric materials have phase transitions at which the material changes crystalline symmetry. For example, in PZT there is a change from tetragonal or rhombohedral symmetry to cubic as the temperature is increased. The temperature at which the material changes **crystalline phases** is called the **Curie temperature**, T_Θ. For typical PZT compositions the Curie temperature is between 250 and 450°C.

A consequence of a phase transition is that a rearrangement of the lattice takes place when the material is cooled through the transition. Intuitively we would expect that the entire crystal assumes the same orientation throughout as we pass through the transition. By orientation we mean the direction of the preferred axis (say

the tetragonal axis). Experimentally it is found, however, that the material breaks up into smaller regions in which the preferred direction and thus the polarization is uniform. Note that cubic materials have no preferred direction. In tetragonal crystals the polarization points along the *c*-axis (the longer axis) whereas in rhombohedral lattices the polarization is along the body diagonal. The volume in which the preferred axis is pointing in the same direction is called a domain and the border between the regions is called a domain wall. The energy of the multidomain state is slightly lower than the single-domain state and is thus the preferred configuration. The direction of the polarization changes by either 90° or 180° as we pass from one uniform region to another. Thus the domains are called 90° and 180° domains. Whether an individual crystallite or grain consists of a single domain depends on the size of the crystallite and external parameters such as strain gradients, impurities, etc. It is also possible that the domain extend beyond the grain boundary and encompasses two or more grains of the crystal.

Real materials consist of large numbers of unit cells, and the manifestation of the individual charged groups is an internal and an external electric field when the material is stressed. Internal and external refer to inside and outside of the material. The interaction of an external electric field with a charged group causes a displacement of certain atoms in the group. The macroscopic manifestation of this is a displacement of the surfaces of the material. This motion is called the piezoelectric effect, the conversion of an applied field into a corresponding displacement.

49.3 Ferroelectric Materials

PZT ($PbZr_xTi_{(1-x)}O_3$) is an example of a ceramic material which is ferroelectric. We will use PZT as a prototype system for many of the ferroelectric attributes to be discussed. The concepts, of course, have general validity. The structure of this material is ABO_3 where A is lead and B is one or the other atoms, Ti or Zr. This material consists of many randomly oriented crystallites which vary in size between approximately 10 nm and several microns. The crystalline symmetry of the material is determined by the magnitude of the parameter x. The material changes from rhombohedral to tetragonal symmetry when $x > 0.48$. This transition is almost independent of temperature. The line which divides the two phases is called a **morphotropic phase boundary** (change of symmetry as a function of composition only). Commercial materials are made with $x \approx 0.48$, where the d and g sensitivity of the material is maximum. It is clear from Table 49.2 that there are other parameters which can be influenced as well. Doping the material with donors or acceptors often changes the properties dramatically. Thus niobium is important to obtain higher sensitivity and resistivity and to lower the Curie temperature. PZT typically is a *p*-type conductor and niobium will significantly decrease the conductivity because of the electron which Nb^{5+} contributes to the lattice. The Nb ion substitutes for the **B-site** ion Ti^{4+} or Zr^{4+}. The resistance to depolarization (the hardness of the material) is affected by iron doping. Hardness is a definition giving the relative resistance to depolarization. It should not be confused with mechanical hardness. Many other dopants and admixtures have been used, often in very exotic combinations to affect aging, sensitivity, etc.

The designations used in Table 49.2 reflect very few of the many combinations which have been developed. The PZT designation types were originally designed by the U.S. Navy to reflect certain property combinations. These can be obtained with different combinations of compositions and dopants. The examples given in the table are representative of typical PZT materials, but today essentially all applications have their own custom formulation. The name PZT has become generic for the lead zirconate titanates and does not reflect Navy or proprietary designations.

When PZT ceramic material is prepared, the crystallites and domains are randomly oriented, and therefore the material does not exhibit any piezoelectric behavior [Fig. 49.2(a)]. The random nature of the displacements for the individual crystallites causes the net displacement to average to zero when an external field is applied. The tetragonal axis has three equivalent directions 90° apart and the material can be poled by reorienting the polarization of the domains into a direction nearest the applied field. When a sufficiently high field is applied, some but not all of the domains will be rotated toward the electric field through the allowed angle 90° or 180°. If the field is raised further, eventually all domains will be oriented as close as possible to the direction of the field. Note however, that the polarization will not point exactly in the direction of the field [Fig. 49.2(b)]. At this point, no further domain motion is possible and the material is saturated. As the field is reduced, the majority of domains retain the orientation they had with the field on leaving the material in an oriented state which now has a net polarization. Poling is accomplished for commercial PZT by raising the temperature to

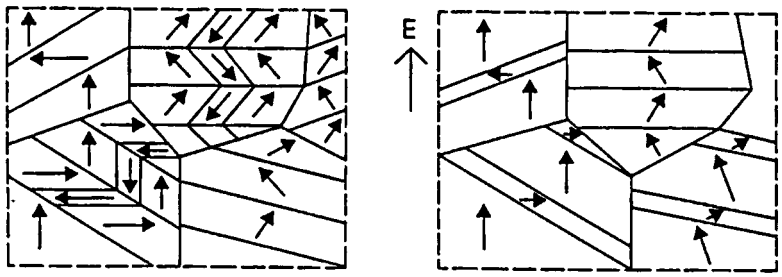

FIGURE 49.2 Domains in PZT, as prepared (a) and poled (b).

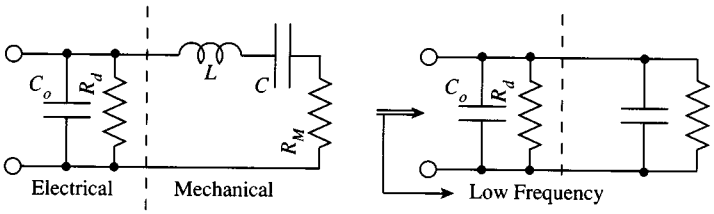

FIGURE 49.3 Equivalent circuit for a piezoelectric resonator. The reduction of the equivalent circuit at low frequencies is shown on the right.

about 150°C (to lower the **coercive field**, E_c) and applying a field of about 30–60 kV/cm for several minutes. The temperature is then lowered but it is not necessary to keep the field on during cooling because the domains will not spontaneously rerandomize.

Electrical Characteristics

Before considering the dielectric properties, we will consider the equivalent circuit for a slab of ferroelectric material. In Fig. 49.3 the circuit shows a mechanical (acoustic) component and the static or clamped capacity C_o (and the dielectric loss R_d) which are connected in parallel. The acoustic components are due to their motional or mechanical equivalents, the compliance (capacity, C) and the mass (inductance, L). There will be mechanical losses, which are indicated in the mechanical branch by R. The electrical branch has the clamped capacity C_o and a dielectric loss (R_d), distinct from the mechanical losses. This configuration will have a resonance which is usually assumed to correspond to the mechanical thickness mode but can represent other modes as well. This simple model does not show the many other modes a slab (or rod) of material will have. Thus transverse, plate, and flexural modes are present. Each can be represented by its own combination of L, C, and R. The presence of a large number of modes often causes difficulties in characterizing the material since some parameters must be measured either away from the resonances or from clean, nonoverlapping resonances. For instance, the clamped capacity (or clamped dielectric constant) of a material is measured at high frequencies where there are usually a large number of modes present. For an accurate measurement these must be avoided and often a low-frequency measurement is made in which the material is physically clamped to prevent motion. This yields the static, nonmechanical capacity, C_o. The circuit can be approximated at low frequencies by ignoring the inductor and redefining R and C. Thus, the coupling constant can be extracted from the value of C and C_o. From the previous definition of k we find

$$k^2 = \frac{\text{energy stored mechanically}}{\text{total energy stored electrically}} = \frac{CV^2/2}{(C + C_o)V^2/2} = \frac{1}{\dfrac{C_o}{C}} + 1 \qquad (49.9)$$

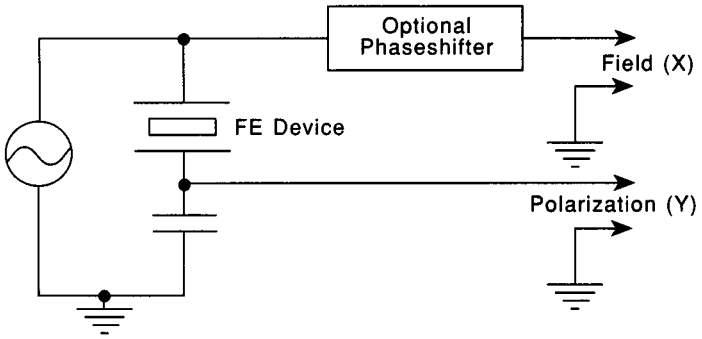

FIGURE 49.4 Sawyer Tower circuit.

It requires charge to rotate or flip a domain. Thus, there is charge flow associated with the rearrangement of the polarization in the ferroelectric material. If a bipolar, repetitive signal is applied to a ferroelectric material, its hysteresis loop is traced out and the charge in the circuit can be measured using the Sawyer Tower circuit (Fig. 49.4). In some cases the drive signal to the material is not repetitive and only a single cycle is used. In that case the starting point and the end point do not have the same polarization value and the hysteresis curve will not close on itself.

The charge flow through the sample is due to the rearrangement of the polarization vectors in the domains (the polarization) and contributions from the static capacity and losses (C_o and R_d in Fig. 49.3). The charge is integrated by the measuring capacitor which is in series with the sample. The measuring capacitor is sufficiently large to avoid a significant voltage loss. The polarization is plotted on a X-Y scope or plotter against the applied voltage and therefore the applied field.

Ferroelectric and piezoelectric materials are lossy. This will distort the shape of the hysteresis loop and can even lead to incorrect identification of materials as ferroelectric when they merely have nonlinear conduction characteristics. A resistive component (from R_d in Fig. 49.3) will introduce a phase shift in the polarization signal. Thus the display has an elliptical component, which looks like the beginnings of the opening of a hysteresis loop. However, if the horizontal signal has the same phase shift, the influence of this lossy component is eliminated, because it is in effect subtracted. Obtaining the exact match is the function of the optional phase shifter, and in the original circuits a bridge was constructed which had a second measuring capacitor in the comparison arm (identical to the one in series with the sample). The phase was then matched with adjustable high-voltage components which match C_o and R_d.

This design is inconvenient to implement and modern Sawyer Tower circuits have the capability to shift the reference phase either electronically or digitally to compensate for the loss and static components. A contemporary version, which has compensation and no voltage loss across the integrating capacitor, is shown in Fig. 49.5. The op-amp integrator provides a virtual ground at the input, reducing the voltage loss to negligible values. The output from this circuit is the sum of the polarization and the capacitive and loss components. These contributions can be canceled using a purely real (resistive) and a purely imaginary (capacitive, 90° phaseshift) compensation component proportional to the drive across the sample. Both need to be scaled (magnitude adjustments) to match them to the device being measured and then have to be subtracted (adding negatively) from the output of the op amp. The remainder is the polarization. The hysteresis for typical ferroelectrics is frequency dependent and traditionally the reported values of the polarization are measured at 50 or 60 Hz.

The improved version of the Sawyer Tower (Fig. 49.6) circuit allows us to cancel C_o and R_d and the losses, thus determining the active component. This is important in the development of materials for ferroelectric memory applications. It is far easier to judge the squareness of the loop when the inactive components are canceled. Also, by calibrating the "magnitude controls" the value of the inactive components can be read off directly. In typical measurements the resonance is far above the frequencies used, so ignoring the inductance in the equivalent circuit is justified.

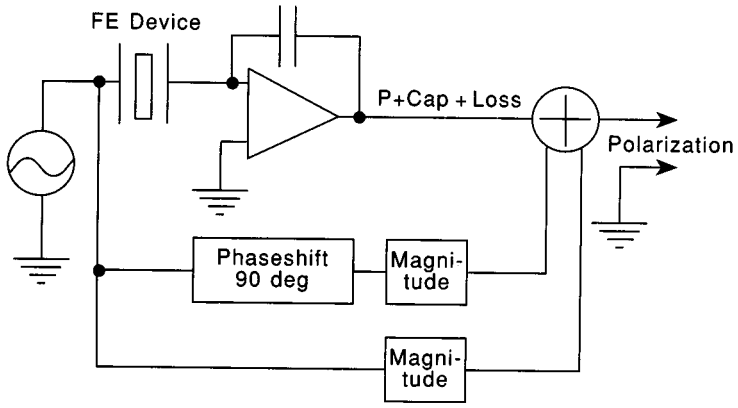

FIGURE 49.5 Modern hysteresis circuit. An op amp is used to integrate the charge; loss and static capacitance compensation are included.

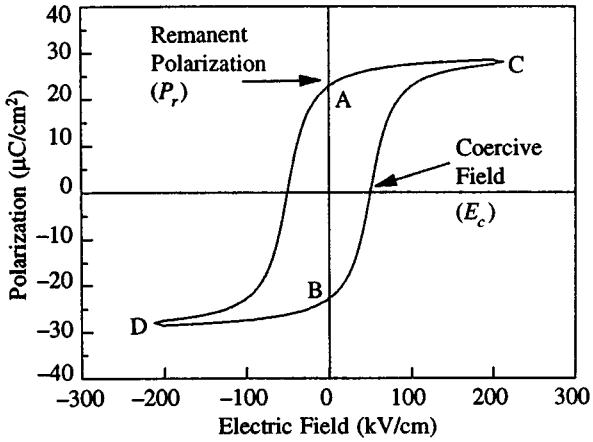

FIGURE 49.6 Idealized hysteresis curve for typical PZT materials. Many PZT materials display offsets from the origin and have asymmetries with respect to the origin. The curve shows how the remanent polarization ($\bar{P}_r$) and the coercive field ($\bar{E}_c$) are defined. While the loop is idealized, the values given for the polarization and field are realistic for typical PZT materials.

The measurement of the dielectric constant and the losses is usually very straightforward. A slab with a circular or other well-defined cross section is prepared, electrodes are applied, and the capacity and loss are measured (usually as a function of frequency). The dielectric constant is found from

$$C = \varepsilon_o \varepsilon \frac{A}{t} \tag{49.10}$$

where A is the area of the device and t the thickness. In this definition (also used in Table 49.2) ε is the relative dielectric constant and ε_o is the permittivity of vacuum. Until recently, the dielectric constant, like the polarization, was measured at 50 or 60 Hz (typical powerline frequencies). Today the dielectric parameters are typically specified at 1 kHz, which is possible because impedance analyzers with high-frequency capability are readily available. To avoid low-frequency anomalies, even higher frequencies such as 1 MHz are often selected. This is especially the case when evaluating PZT thin films. Low frequency anomalies are not included in the equivalent circuit (Fig. 49.3) and are due to interface layers. These layers will cause both the resistive and reactive components to rise at low frequencies producing readings which are not representative of the dielectric properties.

TABLE 49.3 Material Properties and Applications Areas

	Ferroelectric	Epsilon	Polarization	Coercive Field	Leakage	Aging	Electro-Optical	Electro-Mechanical
NV RAM	X		X	X	X	X		
DRAM		X			X	X		
Actuator				X				X
Display	X				X	X	X	
Optical Modulator	X				X	X	X	

A piezoelectric component often has a very simple geometric shape, especially when it is prepared for measurement purposes. There will be mechanical resonances associated with the major dimensions of a sample piece. The resonance spectrum will be more or less complicated, depending on the shape of a sample piece. If the object has a simple shape, then some of the resonances will be well separated from each other and can be associated with specific vibrations and dimensions (modes). Each of these resonances has an electrical equivalent, and inspection of the equivalent circuit shows that there will be a resonance (minimum impedance) and an antiresonance (maximum impedance). Thus an impedance plot can be used to determine the frequencies and also the coupling constants and mechanical parameters for the various modes.

49.4 Ferroelectric and High Epsilon Thin Films

While PZT and other ferroelectric (FE) bulk materials have had major commercial importance, thin films prepared from these materials have only recently been the focus of significant research efforts. In this section the material properties and process issues will be discussed. Because of the potentially large payoff, major efforts have been directed at developing the technologies for depositing thin films of ferroelectric and non-ferroelectric but high epsilon (high dielectric constant) thin films.

A recent trend has been the ever increasing density of dynamic random access memory (DRAM). The storage capacitor in these devices is becoming a major limiting factor because the dielectric has to be very thin in order to achieve the desired capacitance values to yield, in turn, a sufficient signal for the storage cell. It is often also desirable to have nonvolatile operation (no data loss on power loss). These two desires have, probably more than anything else, driven the development of high epsilon and FE thin films. Of course, these are not the only applications of FE films. Table 49.3 lists the applications of FE (nonvolatile, NV) and high epsilon films (volatile) and highlights which of the properties are important for their use. It is seen that the memory application is very demanding. Satisfying all these requirements simultaneously has produced significant challenges in the manufacture of these films.

Perhaps the least understood and to some extent still unsolved problem is that of fatigue. In nonvolatile memory applications the polarization represents the memory state of the material (up ≡ bit 1; down ≡ bit 0). In use the device can be switched at the clock rate, say 100 MHz. Thus for a lifetime of 5 years the material must withstand $\simeq 10^{16}$ polarization reversals or large field reversals. Typical materials for ferroelectric applications are PZTs with the ratio of zirconium to titanium adjusted to yield the maximum dielectric constant and polarization. This maximum will be near the morphotropic phase boundary for PZT. Small quantities of other materials can be added, such as lanthanum or niobium to modify optical or switching characteristics. The Sol-Gel method discussed below is particularly suitable for incorporating these additives. Devices made from materials at the current state of the art loose a significant portion of their polarization after 10^{10} to 10^{12} cycles, rendering them useless for their intended memory use because of the associated signal loss. This is a topic of intensive investigation and only one proprietary material has emerged which might be suitable for memory use (Symetric Corporation). High epsilon nonferroelectric materials are of great interest for DRAM applications. As an example, major efforts are extant to produce thin films of mixtures of barium and strontium titanate (BST). Dielectric constants of 600 and above have been achieved (compared to 4–6 for silicon oxides and nitrides).

In applications for FE films, significant opportunities also exist for electro-optical modulators for fiber-optic devices and light valves for displays. Another large scale application is actuators and sensors. For the latter the

TABLE 49.4 Deposition Methods for PZT and Perovskites

	Process Type	Rate nm/min	Substrate Temperature	Anneal Temperature	Target/Source
Wet	Sol-Gel	100 nm/coat	RT	450–750	Metal organic

electro-mechanical conversion property is used and large values of d_{33} (the conversion coefficient) are desirable. However, economically the importance of all other applications are, and probably will be in the foreseeable future, less significant than that of memory devices.

Integration of ferroelectric or nonferroelectric materials with silicon devices and substrates has proved to be very challenging. Contacts and control of the crystallinity and crystal size and the stack structure of the capacitor device are the principal issues. In both volatile and nonvolatile memory cells the dielectric material tends to interact with the silicon substrate. Thus an appropriate barrier layer must be incorporated while at the same time obtaining a suitable substrate on which to grow the dielectric films. A typical device structure starts with an oxide layer (SiO_x) on the silicon substrate followed by a thin titanium layer which prevents diffusion of the final substrate layer, platinum (the actual growth substrate).

Significant differences have been observed in the quality of the films depending on the nature of the substrate. The quality can be described by intrinsic parameters such as the crystallinity (i.e., the degree to which non-crystalline phases are present). The uniformity of the orientation of the crystallites also seems to play a role in determining the electrical properties of the films. In the extreme case of perfect alignment of the crystallites of the film with the substrate and the formation of large single crystal areas, an epitaxial film is obtained. These films tend to have the best electrical properties. In addition to amorphous material, other crystalline but nonferroelectric phases can be present. An example is the pyrochlore phase in PZT. These phases often form incidentally to the growth process of the desired film and usually degrade one or more of the desired properties of the film (for instance the dielectric constant). The pyrochlore and other oxide materials can accumulate between the Pt electrode and the desired PZT or BST layer. The interface layer is then electrically in series with the desired dielectric layer and degrades its properties. The apparent reduction of the dielectric constant which is often observed in these films as the thickness is reduced can be attributed to the presence of these low dielectric constant layers.

There are many growth methods for these films. Table 49.4 lists the most important techniques along with some of the critical parameters. Wet methods use metal organic compounds in liquid form. In the Sol-Gel process the liquid is spun onto the substrate. The wafer is then heated, typically to a lower, intermediate temperature (around 300°C). This spin-on and heat process is repeated until the desired thickness is reached. At this temperature only an amorphous film forms. The wafer is then heated to between 500 and 700°C usually in oxygen and the actual crystal growth takes place. Instead of simple long term heating (order of hours), rapid thermal annealing (RTA) is often used. In this process the sample is only briefly exposed to the elevated temperature, usually by a scanning infrared beam. It is in the transition between the low decomposition temperature and the firing temperature that the pyrochlore tends to form. At the higher temperatures the more volatile components have a tendency to evaporate, thus producing a chemically unbalanced compound which also has a great propensity to form one or more of the pyrochlore phases. In the case of PZT, 5 to 10% excess lead is usually incorporated which helps to form the desired perovskite material and compensates for the loss. In preparing Sol-Gel films it is generally easy to prepare the compatible liquid compounds of the major constituents and the dopants. The composition is then readily adjusted by appropriately changing the ratio of the constituents. Very fine quality films have been prepared by this method, including epitaxial films.

The current semiconductor technology is tending toward dry processing. Thus, in spite of the advantages of the Sol-Gel method, other methods using physical vapor deposition (PVD) are being investigated. These methods use energetic beams or plasma to move the constituent materials from the target to the heated substrate.

The compound then forms *in situ* on the heated wafer (≃500°C). Even then, however, a subsequent anneal is often required. With PVD methods it is much more difficult to change the composition since now the oxide or metal ratios of the target have to be changed or dopants have to be added. This involves the fabrication of a new target for each composition ratio. MOCVD is an exception here; the ratio is adjusted by regulating the carrier gas flow. However, the equipment is very expensive and the substrate temperatures tend to be high (up to 800°, uncomfortably high for semiconductor device processing). The laser sputtering method is very attractive and it has produced very fine films. The disadvantage is that the films are defined by the plume which forms when the laser beam is directed at the source. This produces only small areas of good films and scanning methods need to be developed to cover full size silicon wafers. Debris is also a significant issue in laser deposition. However, it is a convenient method to produce films quickly and with a small investment. In the long run MOCVD or Sol-Gel will probably evolve as the method of choice for realistic DRAM devices with state of the art densities.

Defining Terms

A-site: Many ferroelectric materials are oxides with a chemical formula ABO_3. The A-site is the crystalline location of the A atom.

B-site: Analogous to the definition of the A-site.

Coercive field: When a ferroelectric material is cycled through the hysteresis loop the coercive field is the electric field value at which the polarization is zero. A material has a negative and a positive coercive field and these are usually, but not always, equal in magnitude to each other.

Crystalline phase: In crystalline materials the constituent atoms are arranged in regular geometric ways; for instance in the cubic phase the atoms occupy the corners of a cube (edge dimensions ≈2–15 Å for typical oxides).

Curie temperature: The temperature at which a material spontaneously changes its crystalline phase or symmetry. Ferroelectric materials are often cubic above the Curie temperature and tetragonal or rhombohedral below.

Domain: Domains are portions of a material in which the polarization is uniform in magnitude and direction. A domain can be smaller, larger, or equal in size to a crystalline grain.

Electret: A material which is similar to ferroelectrics but charges are macroscopically separated and thus are not structural. In some cases the net charge in the electrets is not zero, for instance when an implantation process was used to embed the charge.

Electrostriction: The change in size of a nonpolarized, dielectric material when it is placed in an electric field.

Ferroelectric: A material with permanent charge dipoles which arise from asymmetries in the crystal structure. The electric field due to these dipoles can be observed external to the material when certain conditions are satisfied (ordered material and no charge on the surfaces).

Hysteresis: When the electric field is raised across a ferroelectric material the polarization lags behind. When the field is cycled across the material the hysteresis loop is traced out by the polarization.

Morphotropic phase boundary (MPB): Materials which have a MPB assume a different crystalline phase depending on the composition of the material. The MPB is sharp (a few percent in composition) and separates the phases of a material. It is approximately independent of temperature in PZT.

Piezoelectric: A material which exhibits an external electric field when a stress is applied to the material and a charge flow proportional to the strain is observed when a closed circuit is attached to electrodes on the surface of the material.

PLZT: A PZT material with a lanthanum doping or admixture (up to approximately 15% concentration). The lanthanum occupies the A-site.

PMN: Generic name for electrostrictive materials of the lead (Pb) magnesium niobate family.

Polarization: The polarization is the amount of charge associated with the dipolar or free charge in a ferroelectric or an electret, respectively. For dipoles the direction of the polarization is the direction of the dipole. The polarization is equal to the external charge which must be supplied to the material to produce a polarized state from a random state (twice that amount is necessary to reverse the polarization). The statement is rigorously true if all movable charges in the material are reoriented (i.e., saturation can be achieved).

PVF2: An organic polymer which can be ferroelectric. The name is an abbreviation for polyvinyledene difluoride.

PZT: Generic name for piezoelectric materials of the lead (Pb) zirconate titanate family.

Remanent polarization: The residual or remanent polarization of a material after an applied field is reduced to zero. If the material was saturated, the remanent value is usually referred to as the polarization, although even at smaller fields a (smaller) polarization remains.

50.5 Summary

50.1 Introduction

Electrostriction is the basic electromechanical coupling mechanism in centric crystals and amorphous solids. It has been recognized as the primary electromechanical coupling in centric materials since early in the 20th century [Cady, 1929]. Electrostriction is the quadratic coupling between the strain developed in a material and the electric field applied, and it exists in all insulating materials. **Piezoelectricity** is a better-known linear coupling mechanism that exists only in materials without a center of symmetry.

Electrostriction is a second-order property that is tunable and nonlinear. Electrostrictive materials exhibit a reproducible, nonhysteretic, and tunable strain response to electric fields, which gives them an advantage over piezoelectrics in micropositioning applications. While most electrostrictive actuator materials are **perovskite** ceramics, there has been much interest in large electrostriction effects in such polymer materials as polyvinylidene fluoride (PVDF) copolymers recently.

This chapter discusses the three electrostrictive effects and their applications. A discussion of the sizes of these effects and typical electrostrictive coefficients is followed by an examination of lead magnesium niobate (PMN) as a prototype electrostrictive material. The electromechanical properties of some common electrostrictive materials are also compared. A few common criteria used to select relaxor ferroelectrics for electrostrictive applications are also outlined.

50.2 Defining Equations

Electrostriction is defined as the quadratic coupling between strain (**x**) and electric field (**E**), or between strain and polarization (**P**). It is a fourth-rank tensor defined by the following relationship:

$$x_{ij} = M_{ijmn} E_m E_n \tag{50.1}$$

where x_{ij} is the strain tensor, E_m and E_n components of the electric field vector, and M_{ijmn} the fourth-rank field-related electrostriction tensor. The M coefficients are defined in units of m^2/V^2.

Ferroelectrics and related materials often exhibit nonlinear dielectric properties with changing electric fields. To better express the quadratic nature of electrostriction, it is useful to define a polarization-related electrostriction coefficient Q_{ijmn}, as

$$x_{ij} = Q_{ijmn} P_m P_n \tag{50.2}$$

Q coefficients are defined in units of m^4/C^2. The M and Q coefficients are equivalent. Conversions between the two coefficients are carried out using the field-polarization relationships:

$$P_m = \eta_{mn} E_n, \quad \text{and} \quad E_n = \chi_{mn} P_m \tag{50.3}$$

where η_{mn} is the dielectric susceptibility tensor and χ_{mn} is the inverse dielectric susceptibility tensor.

Electrostriction is not a simple phenomenon but manifests itself as three thermodynamically related effects [Sundar and Newnham, 1992]. The first is the well-known variation of strain with polarization, called the direct effect ($d^2x_{ij}/dE_k\, dE_l = M_{ijkl}$). The second is the stress (X_{kl}) dependence of the dielectric stiffness χ_{mn}, or the reciprocal dielectric susceptibility, called the first converse effect ($d\chi_{mn}/dX_{kl} = M_{mnkl}$). The third effect is the polarization dependence of the piezoelectric voltage coefficient g_{jkl}, called the second converse effect ($dg_{jkl}/dP_i = \chi_{mk}\chi_{nl}M_{ijmn}$).

Piezoelectricity and Electrostriction

Piezoelectricity is a third-rank tensor property found only in acentric materials and is absent in most materials. The noncentrosymmetric point groups generally exhibit piezoelectric effects that are larger than the electrostrictive effects and obscure them. The electrostriction coefficients M_{ijkl} or Q_{ijkl} constitute fourth-rank tensors which, like the elastic constants, are found in all insulating materials, regardless of symmetry.

Electrostriction is the origin of piezoelectricity in ferroelectric materials, in both conventional ceramic ferroelectrics such as $BaTiO_3$ as well as in organic polymer ferroelectrics such as PVDF copolymers [Furukawa and Seo, 1990]. In a ferroelectric material, that exhibits both spontaneous and induced polarizations, P_i^s and P_i', the strains arising from spontaneous polarizations, piezoelectricity, and electrostriction may be formulated as

$$x_{ij} = Q_{ijkl} P_k^s P_l^s + 2Q_{ijkl} P_k^s P_l' + Q_{ijkl} P_k' P_l' \tag{50.4}$$

In the paraelectric state, we may express the strain as $x_{ij} = Q_{ijkl}P_kP_l$, so that $dx_{ij}/dP_k = g_{ijk} = 2Q_{ijkl}P_l$. Converting to the commonly used d_{ijk} coefficients,

$$d_{ijk} = \chi_{mk} g_{ijm} = 2\chi_{mk} Q_{ijmn} P_n \tag{50.5}$$

This origin of piezoelectricity in electrostriction provides us an avenue into nonlinearity. In this case, it is the ability to tune the piezoelectric coefficient and the dielectric behavior of a transducer. The piezoelectric coefficient varies with the polarization induced in the material, and may be controlled by an applied electric field. The electrostrictive element may be tuned from an inactive to a highly active state. The electrical impedance of the element may be tuned by exploiting the dependence of permittivity on the biasing field for these materials, and the saturation of polarization under high fields [Newnham, 1990].

Electrostriction and Compliance Matrices

The fourth-rank electrostriction tensor is similar to the **elastic compliance** tensor, but is not identical. Compliance is a more symmetric fourth-rank tensor than is electrostriction. For compliance, in the most general case,

$$s_{ijkl} = s_{jikl} = s_{ijlk} = s_{jilk} = s_{klij} = s_{lkij} = s_{klji} = s_{lkij} \tag{50.6}$$

but for electrostriction:

$$M_{ijkl} = M_{jikl} = M_{ijlk} = M_{jilk} \neq M_{klij} = M_{lkij} = M_{klji} = M_{lkij} \tag{50.7}$$

This means that for most point groups the number of independent electrostriction coefficients exceeds those for elasticity. M and Q coefficients may also be defined in a matrix (Voigt) notation. The electrostriction and elastic compliance matrices for point groups $6/mmm$ and ∞/mm are compared below.

$$\begin{bmatrix} S_{11} & S_{12} & S_{13} & 0 & 0 & 0 \\ S_{12} & S_{11} & S_{13} & 0 & 0 & 0 \\ S_{13} & S_{13} & S_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & S_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & S_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\left(S_{44} - S_{12}\right) \end{bmatrix} \begin{bmatrix} M_{11} & M_{12} & M_{13} & 0 & 0 & 0 \\ M_{12} & M_{11} & M_{13} & 0 & 0 & 0 \\ M_{31} & M_{31} & M_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & M_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & M_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & \left(M_{11} - M_{12}\right) \end{bmatrix}$$

Compliance coefficients s_{13} and s_{31} are equal, but M_{13} and M_{31} are not. The difference arises from an energy argument which requires the elastic constant matrix to be symmetric.

It is possible to define sixth-rank and higher-order electrostriction coupling coefficients. The electrostriction tensor can also be treated as a complex quantity, similar to the dielectric and the piezoelectric tensors. The imaginary part of the electrostriction is also a fourth-rank tensor. Our discussion is confined to the real part of the quadratic electrostriction tensor.

Magnitudes and Signs of Electrostrictive Coefficients

The values of M coefficients range from about 10^{-24} m^2/V^2 in low-permittivity materials to 10^{-16} m^2/V^2 in high-permittivity actuator materials made from **relaxor ferroelectrics** such as PMN–lead titanate (PMN–PT) compositions. Large strains of the order of strains in ferroelectric piezoelectric materials such as lead zirconate titanate (PZT) may be induced in these materials. Q values vary in an opposite way to M values. Q ranges from 10^{-3} m^4/C^2 in relaxor ferroelectrics to greater than 1 m^4/C^2 in low-permittivity materials. Since the strain is directly proportional to the square of the induced polarization, it is also proportional to the square of the dielectric permittivity. This implies that materials with large dielectric permittivities, like relaxor ferroelectrics, can produce large strains despite having small Q coefficients.

As a consequence of the quadratic nature of the electrostriction effect, the sign of the strain produced in the material is independent of the polarity of the field. This is in contrast with linear piezoelectricity where reversing the direction of the field causes a change in the sign of the strain. The sign of the electrostrictive strain depends only on the sign of the electrostriction coefficient. In most oxide ceramics, the longitudinal electrostriction coefficients are positive. The transverse coefficients are negative as expected from Poisson ratio effects. Another consequence is that electrostrictive strain occurs at twice the frequency of an applied ac field. In acentric materials, where both piezoelectric and electrostrictive strains may be observed, this fact is very useful in separating the strains arising from piezoelectricity and from electrostriction.

50.3 PMN–PT — A Prototype Electrostrictive Material

Most commercial applications of electrostriction involve high-permittivity materials such as relaxor ferroelectrics. PMN ($Pb(Mg_{1/3}Nb_{2/3})O_3$) relaxor ferroelectric compounds were first synthesized more than 30 years ago. Since then, the PMN system has been well characterized in both single-crystal and ceramic forms, and may be considered the prototype ferroelectric electrostrictor [Jang et al., 1980]. Lead titanate ($PbTiO_3$, PT) and other materials are commonly added to PMN to shift T_{max} or increase the maximum dielectric constant. The addition of PT to PMN gives rise to a range of compositions, the PMN–PT system, that have a higher Curie range and superior electromechanical coupling coefficients. The addition of other oxide compounds, mostly other ferroelectrics, is a widely used method to tailor the electromechanical properties of electrostrictors [Voss et al., 1983]. Some properties of the PMN–PT system are listed here.

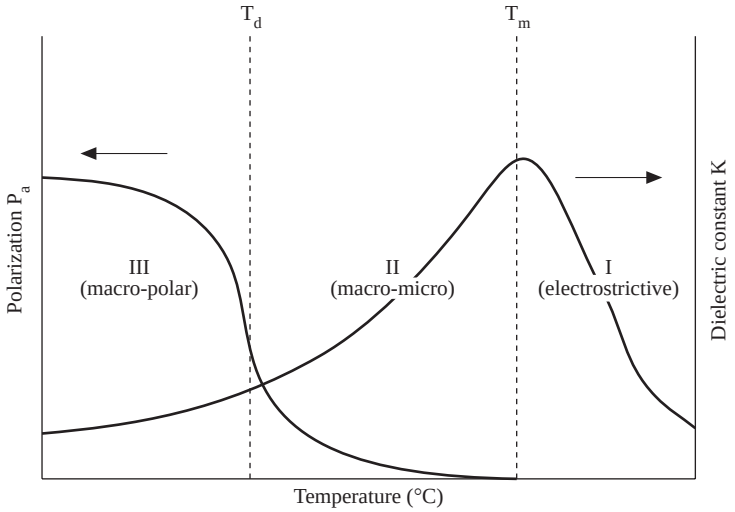

FIGURE 50.1 Polarization and dielectric behavior of a relaxor ferroelectric as a function of temperature, showing the three temperature regimes.

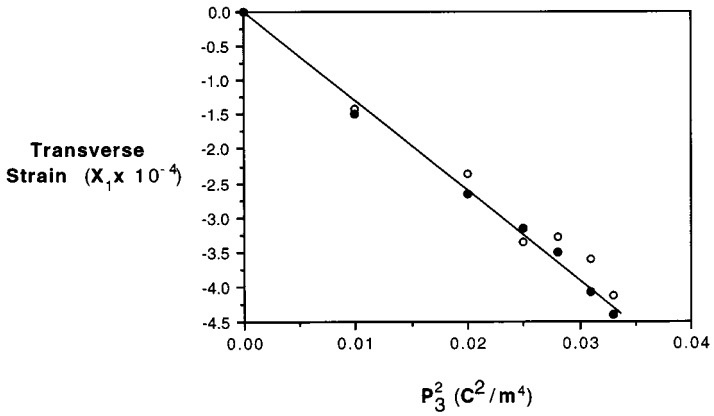

FIGURE 50.2 Transverse strain as a function of the square of the polarization in ceramic 0.9PMN–0.1PT, at RT. The quadratic ($x = QP^2$) nature of electrostriction is illustrated. Shaded circles indicate strain measured while increasing polarization and unshaded circles indicate decreasing polarization.

Based on dielectric constant vs. temperature plots, the electromechanical behavior of a relaxor ferroelectric may divided into three regimes (Fig. 50.1). At temperatures less than T_d, the depolarization temperature, the relaxor material is macropolar, exhibits a stable remanent polarization, and behaves as a piezoelectric. T_{max} is the temperature at which the maximum dielectric constant is observed. Between T_d and T_{max}, the material possesses nanometer-scale microdomains that strongly influence the electromechanical behavior. Large dielectric permittivities and large electrostrictive strains arising from micro–macrodomain reorientation are observed. Above T_{max}, the material is a "true electrostrictor" in that it is paraelectric and exhibits nonhysteretic, quadratic strain-field behavior. Since macroscale domains are absent, no remanent strain is observed. Improved reproducibility in strain and low-loss behavior are achieved.

Figure 50.2 illustrates the quadratic dependence of the transverse strain on the induced polarization for ceramic 0.9PMN–0.1PT. Figure 50.3a and b show the longitudinal strain as a function of the applied electric field for the same composition. The strain-field plots are not quadratic, and illustrate essentially anhysteretic nature of electrostrictive strain. The transverse strain is negative, as expected.

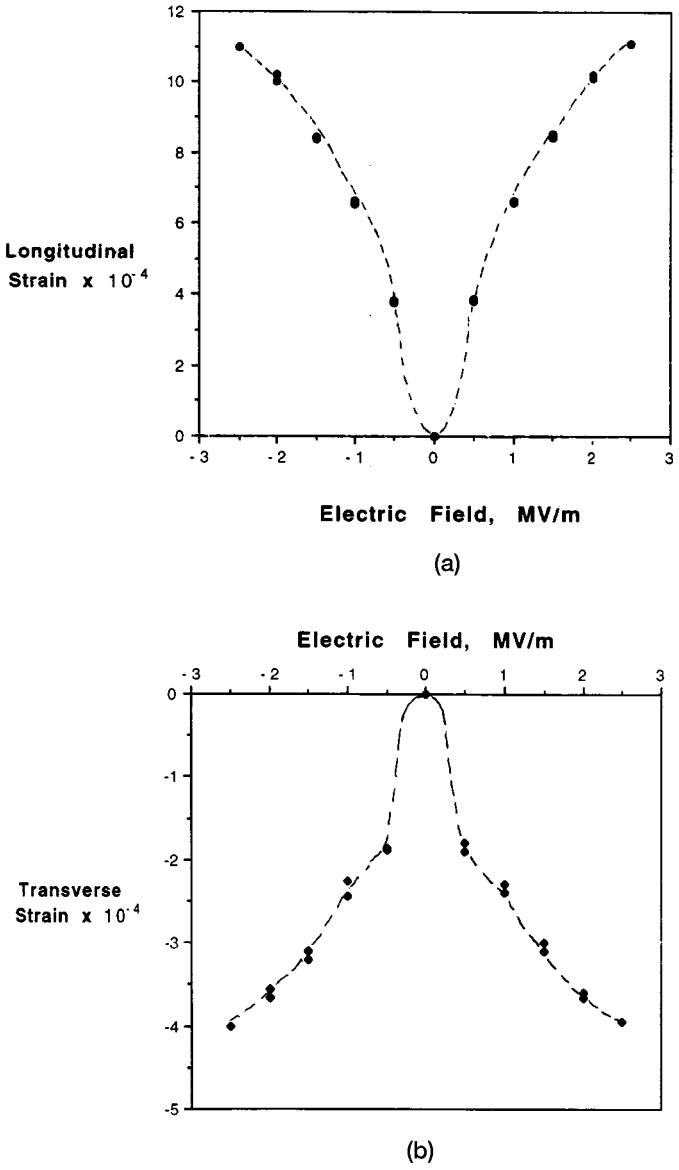

FIGURE 50.3 Longitudinal (a) and transverse (b) strains as a function of applied electric field in 0.9PMN–0.1PT, at RT. x is not quadratic with E except at low fields.

The averaged longitudinal and transverse electrostriction coefficients have been measured for poled ceramic PMN to be $Q_{33} \sim 2.3 \times 10^{-2}$ m^4/C^2, $Q_{13} \sim -0.64 \times 10^{-2}$ m^4/C^2. The corresponding field-related coefficients are $M_{33} \sim 1.50 \times 10^{-16}$ m^2/V^2 and $M_{13} \sim -4.19 \times 10^{-17}$ m^2/V^2. Induced strains of the order of 10^{-4} may be achieved with moderate electric fields of ~40 kV/cm. These strains are much larger than thermal expansion strains, and are in fact equivalent to thermal expansion strains induced by a temperature change of ~1000°C. M_{33} values for some other common ferroelectrics and a PVDF copolymer are listed in Table 50.1.

The mechanical quality factor Q_M for PMN is 8100 (at a field of ~200 kV/m) compared with 300 for poled barium titanate or 75 for poled PZT 5-A [Nomura and Uchino, 1981]. The induced piezoelectric coefficients d_{33} and d_{31} can vary with field (Fig. 50.4). The maxima in the induced piezoelectric coefficients for PMN as a function of biasing electric field are at E ~ 1.2 MV/m, with $d_{33} = 240$ pC/N and $-d_{31} = 72$ pC/N. $Pb(Mg_{0.3}Nb_{0.6}Ti_{0.1})O_3$ is a very active composition, with a maximum $d_{33} = 1300$ pC/N at a biasing field of 3.7 kV/cm.

50.4 Applications

The advantages that electrostrictors have over other actuator materials include low hysteresis of the strain-field response, no remanent strain (walk off), reduced aging and creep effects, a high response speed (<10 ms), and strain values (>0.03%) achievable at realizable electric fields. Displacement ranges of several tens of microns may be achieved with ±0.01μ reproducibility. Most actuator applications of electrostrictors as servotransducers and micropositioning devices take advantage of these characteristics.

Mechanical applications range from stacked actuators through inchworms, microangle adjusting devices, and oil pressure servovalves. Multilayer actuators produce large displacements and high forces at low drive voltages. The linear change in capacitance with applied stress of an electrostrictor can be used as a capacitive stress gauge [Sundar and Newnham, 1992]. Electrostrictors may also be used as used in field-tunable piezoelectric transducers. Recently, electrostrictive materials have been integrated into ultrasonic motors and novel flextensional transducers.

Electrostrictors have also been integrated into **"smart"** optical systems such as bistable optical devices, interferometric dilatometers, and deformable mirrors. Electrostrictive correction of optical aberrations is a significant tool in active optics. Electrostrictors also find applications in **"very smart" systems** such as sensor–actuator active vibration-suppression elements. A shape memory effect arising from inverse hysteretic behavior and electrostriction in PZT family antiferroelectrics is also of interest. A recent survey [Uchino, 1993] predicts that the market share of piezoelectric and electrostrictive transducers is expected to increase to more than $10 billion by 1998.

TABLE 50.2 Selection Critera for Relaxor Ferroelectrics for Electrostrictive Devices

Desirable Properties	Material Behavior
• Large strain, induced polarization, and induced piezoelectricity	• Large dielectric constants
• Large operating temperature range	• $T_{max} - T_d$ is large • Broad dielectric transition
• Low-loss, low-joule heating, minimal hysteresis, no remanent polarization	• Operation in paraelectric regime ($T > T_{max}$)

In selecting electrostrictive relaxor ferroelectrics for actuator and sensor applications, the following criteria are commonly used. A large dielectric constant and field stability in the K vs. E relations are useful in achieving large electrostrictive strains. These criteria also lead to large induced polarizations and large induced piezoelectric coefficients through the second converse effect.

Broad dielectric transitions allow for a large operating temperature range. In the case of relaxors, this implies a large difference between T_{max} and T_d. Minimal E–P hysteresis and no remanent polarization are useful in achieving a low-loss material that is not susceptible to joule heating effects. These factors are listed in Table 50.2.

50.5 Summary

Electrostriction is a fundamental electromechanical coupling effect. In ceramics with large dielectric constants and in some polymers, large electrostrictive strains may be induced that are comparable in magnitude with piezoelectric strains in actuator materials such as PZT. The converse electrostrictive effect, which is the change in dielectric susceptibility with applied stress, facilitates the use of the electrostrictor as a stress gauge. The second converse effect may be used to tune the piezoelectric coefficients of the material as a function of the applied field. Electrostrictive materials offer tunable nonlinear properties that are suitable for application in very smart systems.

Defining Terms

Elastic compliance: A fourth-rank tensor (s_{ijkl}) relating the stress (X) applied on a material and the strain (x) developed in it, $x_{ij} = s_{ijkl}X_{kl}$. Its inverse is the elastic stiffness tensor (c_{ijkl}).

Electrostriction: The quadratic coupling between strain and applied field or induced polarization. Conversely, it is the linear coupling between dielectric susceptibility and applied stress. It is present in all insulating materials.

Ferroelectricity: The phenomenon by which a material exhibits a permanent spontaneous polarization that can be reoriented (switched) between two or more equilibrium positions by the application of a realistic electric field (i.e., less than the breakdown field of the material).

Perovskite: A crystal structure with the formula ABO_3, with A atoms at the corners of a cubic unit cell, B atoms at the body-center position, and O atoms at the centers of the faces. Many oxide perovskites are used as transducers, capacitors, and thermistors.

Piezoelectricity: The linear coupling between applied electric field and induced strain in acentric materials. The converse effect is the induction of polarization when stress is applied.

Relaxor ferroelectric: Relaxor ferroelectric materials exhibit a diffuse phase transition between paraelectric and ferroelectric phases, and a frequency dependence of the dielectric properties.

Smart and very smart systems: A system that can sense a change in its environment, and tune its response suitably to the stimulus. A system that is only smart can sense a change in its environment and react to it.

51.1 Introduction

Piezoresistivity is a linear coupling between mechanical stress X_{kl} and electrical resistivity ρ_{ij}. Hence, it is represented by a fourth rank polar tensor $\prod_{ijkl}$. The piezoresistance properties of semiconducting silicon and germanium were discovered by Smith [1953] when he was verifying the form of their energy surfaces. Piezoresistance measurements can provide valuable insights concerning the conduction mechanisms in solids such as strain-induced carrier repopulation and intervalley scattering in multivalley semiconductors [Herring and Vogt, 1956], barrier tunneling in thick film resistors [Canali et al., 1980] and barrier raising in semiconducting positive temperature coefficient of resistivity (PTCR) perovskites [Amin, 1989]. Piezoresistivity has also been investigated in compound semiconductors, thin metal films [Rajanna et al., 1990], polycrystalline silicon and germanium thin films [Onuma and Kamimura, 1988], heterogeneous solids [Carmona et al., 1987], and high T_c superconductors [Kennedy et al., 1989]. Several sensors that utilize this phenomenon are commercially available.

51.2 Equation of State

The equation of state of a crystal subjected to a stress X_{kl} and an electric field E_i is conveniently formulated in the isothermal representation. The difference between isothermal and adiabatic changes, however, is negligible [Keyes, 1960]. Considering only infinitesimal deformations, where the linear theory of elasticity is valid, the electric field E_i is expressed in terms of the current density I_j and applied stress X_{kl} as [Mason and Thurston, 1957].

$$E_i = E_i\,(I_j,\ X_{kl}) \qquad i,j,k,l = 1,2,3 \tag{51.1}$$

In what follows the summation convention over repeated indices in the same term is implied, and the letter subscripts assume the values 1, 2, and 3 unless stated otherwise. Expanding in a McLaurin's series about the origin (state of zero current and stress)

$$dE_i = (\partial E_i/\partial I_j)\ dI_j + (\partial E_i/\partial X_{kl})\ dX_{kl}$$
$$+ (1/2!)\ [(\partial^2 E_i/\partial I_j \partial I_m)\ dI_j\ dI_m$$
$$+ (\partial^2 E_i/\partial X_{kl}\partial X_{no})\ dX_{kl}\ dX_{no}$$
$$+ 2\ (\partial^2 E_i/\partial X_{kl}\partial I_j)\ dX_{kl}\ dI_j] + \ldots \text{H.O.T} \tag{51.2}$$

The partial derivatives in the expansion Eq. (51.2) have the following meanings: $(\partial E_i/\partial I_j) = \rho_{ij}$(electric resistivity tensor); $(\partial E_i/\partial X_{kl}) = d_{ikl}$(converse piezoelectric tensor); $(\partial^2 E_i/\partial X_{kl}\partial I_j) = (\partial/\partial X_{kl})\ (\partial E_i/\partial I_j) = \Pi_{ijkl}$(piezoresistivity tensor); $(\partial^2 E_i/\partial I_j \partial I_m) = \rho_{ijm}$(nonlinear resistivity tensor); $(\partial^2 E_i/\partial X_{kl}\partial X_{no}) = \delta_{iklno}$(nonlinear piezoelectric tensor).

Replacing the differentials in Eq. (51.2) by the components themselves, we get

$$E_i = \rho_{ij} I_j + d_{ikl}\ X_{kl} + 1/2\ \rho_{ijm}\ I_j I_m + 1/2\ \delta_{iklno}\ X_{kl}\ X_{no} + \prod_{ijkl}\ X_{kl}\ I_j \tag{51.3}$$

Most of the technologically important piezoresistive materials, e.g., silicon, germanium, and polycrystalline films, are centrosymmetric. The effect of center of symmetry (i.e., the inversion operator) on Eq. (51.3) is to force all odd rank tensor coefficients to zero; hence, the only contribution to the resistivity change under stress will result from the piezoresistive term. Therefore, Eq. (51.3) takes the form

$$E_i = \Sigma_j \rho_{ij}\ I_j + \Sigma_j \Sigma_k \Sigma_l \Pi_{ijkl}\ X_{kl}\ I_j \tag{51.4}$$

taking the partial derivatives of Eq. (51.4) with respect to the current density I_j and rearranging

$$\partial E_i/\partial I_j = \rho_{ij}(X)\ 2\ \rho_{ij}(0) = \Sigma_k \Sigma_l \Pi_{ijkl}\ X_{kl}$$

Thus, the specific change in resistivity with stress is given by

$$(\delta\rho_{ij}/\rho_0) = \Pi_{ijkl}\ X_{kl} \tag{51.5}$$

the piezoresistivity tensor Π_{ijkl} in Eq. (51.5) has the dimensions of reciprocal stress (square meters per newton in the MKS system of units). The effects of the intrinsic symmetry of the piezoresistivity tensor and the crystal point group are discussed next.

51.3 Effect of Crystal Point Group on Π_{ijkl}

The transformation law of Π_{ijkl} (a fourth rank polar tensor) is as follows:

$$\Pi'_{ijkl} = (\partial x'_i/\partial x_m)(\partial x'_j/\partial x_n)(\partial x'_k/\partial x_o)(\partial x'_l/\partial x_p)\Pi_{mnop} \tag{51.6}$$

where the primed and unprimed components refer to the new and old coordinate systems, respectively, and the determinants of the form $\|\partial x'_i/\partial x_m\|$, . . . etc. are the Jacobian of the transformation. A general fourth rank tensor has 81 independent components. The piezoresistivity tensor Π_{ijkl} has the following internal symmetry:

$$\Pi_{ijkl} = \Pi_{ijlk} = \Pi_{jilk} = \Pi_{jikl} \tag{51.7}$$

which reduces the number of independent tensor components from 81 to 36 for the most general triclinic point group $C_1(1)$. It is convenient to use the reduced (two subscript) matrix notation

$$\Pi_{ijkl} = \Pi_{mn} \tag{51.8}$$

where $m,n = 1, 2, 3, \ldots, 6$. The relation between the subscripts in both notations is

Tensor:	11	22	33	23, 32	13, 31	12, 21
Matrix:	1	2	3	4	5	6

and

$$\Pi_{mn} = 2\Pi_{ijkl}, \text{ for } m \text{ and/or } n = 4, 5, 6$$

Thus, for example, $\Pi_{1111} = \Pi_{11}$, $\Pi_{1122} = \Pi_{12}$, $2\Pi_{2323} = \Pi_{44}$, $2\Pi_{1212} = \Pi_{66}$, and $2\Pi_{1112} = \Pi_{16}$. Hence, Eq. (51.5) takes the form

$$(\delta\rho_i/\rho_0) = \Pi_{ij} X_j, \qquad (i, j = 1, 2, \ldots, 6) \tag{51.9}$$

Further reduction of the remaining 36 piezoresistivity tensor components is obtained by applying the generating elements of the point group to the piezoresistivity tensor transformation law Eq. (51.6) and demanding invariance. The following are two commonly encountered piezoresistivity matrices:

1. Cubic $O_h(m3m)$: single crystal silicon and germanium

$$\begin{matrix} \Pi_{11} & \Pi_{12} & \Pi_{12} & 0 & 0 & 0 \\ & \Pi_{11} & \Pi_{12} & 0 & 0 & 0 \\ & & \Pi_{11} & 0 & 0 & 0 \\ & & & \Pi_{44} & 0 & 0 \\ & & & & \Pi_{44} & 0 \\ & & & & & \Pi'_{44} \end{matrix}$$

2. Spherical ($\infty \infty mmm$): polycrystalline silicon and germanium and films

$$\begin{matrix} \Pi_{11} & \Pi_{12} & \Pi_{12} & 0 & 0 & 0 \\ & \Pi_{11} & \Pi_{12} & 0 & 0 & 0 \\ & & \Pi_{11} & 0 & 0 & 0 \\ & & & \Pi_{44} & 0 & 0 \\ & & & & \Pi_{44} & 0 \\ & & & & & \Pi_{44} \end{matrix}$$

where $\Pi_{44} = 2(\Pi_{11} - \Pi_{12})$. Thus, three coefficients Π_{11}, Π_{12}, and Π_{44} are required to completely specify the piezoresistivity tensor for silicon and germanium single crystals, and only two, Π_{11} and Π_{12}, for polycrystalline films. Under hydrostatic pressure conditions, the piezoresistivity coefficient Π_h for the preceding two symmetry groups is a linear combination of the longitudinal Π_{11} and transverse Π_{12} components, $\Pi_h = \Pi_{11} + 2\Pi_{12}$. Unlike the elastic stiffness c_{ij} (a fourth rank polar tensor), the piezoresistivity tensor Π_{mn} is not symmetric, i.e., $\Pi_{mn} \neq \Pi_{nm}$, except for the following point groups, $C_{\infty v}(\infty \infty mmm)$, $O_h(m3m)$, $T_d(\overline{4}3m)$, and $O(432)$.

51.4 Geometric Corrections and Elastoresistance Tensor

The experimentally derived quantity is the piezoresistance coefficient $1/R_0(\partial R/\partial X)$. This must be corrected for the dimensional changes to obtain the piezoresistivity coefficient $1/\rho_0(\partial\rho/\partial X)$ as follows:

1. Uniaxial tensile stress parallel to current flow

$$1/R_0(\partial R/\partial X) - (s_{11} - 2s_{12}) = 1/\rho_0(\partial\rho/\partial x) = \Pi_{11} \tag{51.10}$$

TABLE 51.1 Numerical Values of Π_{ij} and M_{ij} for Selected Materials

Material	Resistivity (Unstrained and RT)	(10^{-11} m²/N) Π_{11}	Π_{12}	Π_{44}	Dimensionless M_{11}	M_{12}	M_{44}
Silicon							
n-type	11.7 (Ω-cm)	–102.2	53.4	–13.6	–72.6	86.4	–10.8

	100 ($K\Omega/\square$)				13.5		
ESL 2900	100 (KΩ/□)				13.8	11.6	

2. Uniaxial tensile stress perpendicular to current flow

$$1/R_0(\partial R/\partial X) + s_{11} = 1/\rho_0(\partial\rho/\partial X) = \Pi_{12} \tag{51.11}$$

3. Hydrostatic pressure

$$1/R_0(\partial R/\partial p) - (s_{11} + 2s_{12}) = 1/\rho_0(\partial\rho/\partial p) = \Pi_h \tag{51.12}$$

where s_{11} and s_{12} are the elastic compliances that appear in the linear elasticity equation $x_{ij} = s_{ijkl}\, X_{kl}$, with x_{ij} the infinitesimal strain components. Details on the different geometries and methods of measuring the piezoresistance effect can be found in the References. Equation (51.9) could be written in terms of the strain conjugate x_o as follows

$$(\delta\rho/\rho_0) = M_{io}\, x_o \tag{51.13}$$

the dimensionless quantity M_{io} is the elastoresistance tensor (known as the gage factor in the sensors literature). It is related to the piezoresistivity Π_{ik} and the elastic stiffness c_{ko} tensors by

$$M_{io} = \Pi_{ik}\, c_{ko} \tag{51.14}$$

thus, the 3 independent elastoresistance components (gauge factors) can be expressed as follows

$$M_{11} = \Pi_{11}\, c_{11} + 2\,\Pi_{12}\, c_{12}$$
$$M_{12} = \Pi_{11}\, c_{12} + \Pi_{12}\,(c_{11} + c_{12})$$
$$M_{44} = \Pi_{44}\, c_{44}$$

51.5 Multivalley Semiconductors

For a multivalley semiconductor, e.g., *n*-type silicon, the energy minima (ellipsoids of revolutions) of the unstrained state in momentum space are along the six <100> cubic symmetry directions; they possess the symmetry group $O_h(m3m)$. A tensile stress in the *x*-direction, for example, will strain the lattice in the *xy*-plane and destroy the three-fold symmetry, thereby lifting the degeneracy of the energy minima. However, the four-fold symmetry along the *x*-direction will be preserved. Thus, the two valleys along the direction of stress will be shifted relative to the four valleys in the perpendicular directions.

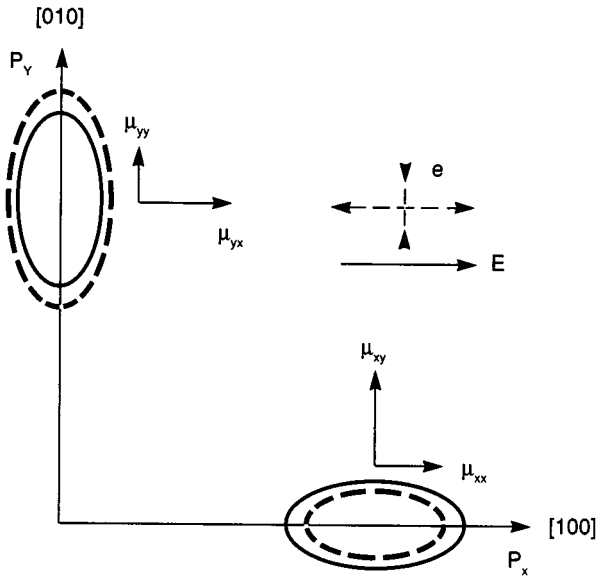

FIGURE 51.1 Two-dimensional representation of the constant energy surfaces in momentum space of a multivalley semiconductor (e.g., *n*-type silicon) showing only one quadrant, point group symmetry $C_{4v}(4mm)$. (*Source:* C.S. Smith, Piezoresistance effect in germanium and silicon, *Phys. Rev.,* vol. 94, p. 42, 1953. With permission.)

According to the deformation potential theory, the strain will shift the energy of all the states in a given band extremum by the same amount, i.e., the valley moves along the energy scale as a whole by an amount (the deformation potential constant) which is linearly proportional to the strain. Let's assume that the energy of those on the *y*- and *z*-axes are lowered with respect to those on the *x*-axis. This effect is represented by dashed lines in Fig. 51.1. As a result, there will be electron transfer from the high to low energy valleys. The components of the mobility tensor μ_{xy} ($= e\,\tau/m_{xy}$, where e is the electron charge, τ is the relaxation time, and m_{xy} is the effective mass) are illustrated by arrows in Fig. 51.1. The mobility anisotropy is due to the curvature of the conduction band near the bottom. The effective mass is inversely proportional to this curvature ($1/m_{xy} = (h/2\pi)^{-2}(\partial^2 E/\partial k_x \partial k_y)$), which is larger for a direction perpendicular to the valley. For an applied E field parallel to the stress, the conductivity will increase (i.e., the resistivity decreases) relative to the unstressed state because of the increase in the number of electrons in the four valleys (*yz*-plane) for which the mobility is large in the field direction. If the field is perpendicular to the stress, the conductivity will decrease (i.e., the resistivity increases) with stress. Therefore, the piezoresistivity components Π_{11} and Π_{12} have opposite signs.

A shear stress about the crystallographic axes will not lift the degeneracy; hence, $\Pi_{44} = 0$. Similarly, a tensile stress along the <111> does not destroy the three-fold symmetry, and the degeneracy will not be lifted; thus, no piezoresistance should be there. Calculations based on the deformation potential model show that $\Pi_{11} = 22\,\Pi_{12}$, and $\Pi_{44} = 0$.

Information concerning the symmetry properties of the valleys can be derived from the representation surface of the longitudinal Π_{11} piezoresistance component. This surface can be constructed by measuring the dependence of Π_{11} on the crystallographic direction. Smith showed that Π_{11} is maximum in the <001> directions of *n*-type silicon and not quite zero in the <111> directions. Reasons for the deviation from the deformation potential model of piezoresistivity in multivalley semiconductors are discussed in Keyes [1960]. For *n*-type germanium Π_{11} is maximum in the <111> directions. This is consistent with the loci of the valleys in these two materials. Qualitatively, a piezoresistance effect is produced whenever the stress destroys the symmetry elements that are responsible for the degeneracy of the valleys.

Intervalley scattering contribution to the piezoresistance of multivalley semiconductors may be comparable to that of the strain-induced electron repopulation. In this scattering process, the initial and final electron states are in different valleys. The effect of intervalley scattering can be deduced from the T^{-1} dependence of the elastoresistance tensor.

The influence of hydrostatic pressure on the electrical resistivity can provide additional insights on the transport properties. Some of the noted features include (1) high pressures (in the GPa range, versus MPa for tensile stresses) can be applied without destroying the crystal; (2) it does not destroy the symmetry, provided no phase transition is involved; hence, the symmetry degeneracies in the band structure are not lifted; (3) band edges which are not degenerate for symmetry reasons will be shifted; and (4) nonlinear effects could be discerned.

51.6 Longitudinal Piezoresistivity Π_l and Maximum Sensitivity Directions

Consider a long thin bar "strain gauge" cut from a piezoresistive crystal with the bar length parallel to an arbitrary direction in the crystal. Let Π_l, θ, and φ be the spherical coordinates of the longitudinal piezoresistivity tensor measured along the length of the bar. For the cubic symmetry group O_h ($m3m$) of Si and Ge, Π_l is given by (Mason et al. 1957)

$$\Pi_l = \Pi_{11} + 2(\Pi_{44} + \Pi_{12} - \Pi_{11})\ [\sin^2\theta \cos^2\theta + \cos^4\theta \cos^2\varphi \sin^2\varphi].$$

$$= \Pi_{11} + 2(\Pi_{44} + \Pi_{12} - \Pi_{11})\ F[\theta,\varphi]$$

The variation of Π_l with direction may be considered as a property surface. The distance from the center to any point in the surface is equal to the magnitude of Π_l. The function $F[\theta,\varphi]$ has a maximum for $\theta = 54° 40`$ and $\varphi = 45°$ which is the <111> family of directions, for which Π_l takes the following form,

$$\Pi_l = \Pi_{11} + 2/3\ (\Pi_{44} + \Pi_{12} - \Pi_{11})$$

If $(\Pi_{44} + \Pi_{12} - \Pi_{11})$ and Π_{11} have the same sign or $2/3 \left| (\Pi_{44} + \Pi_{12} - \Pi_{11}) \right| > \Pi_{11}$ then the maximum sensitivity direction occurs along <111>. If $(\Pi_{44} + \Pi_{12} - \Pi_{11}) = 0$ the longitudinal effect is isotropic and equal to Π_{11} in all directions, otherwise it occurs along a crystal axis. The maximum sensitivity directions are shown in Fig. 51.2 for Si and Ge.

51.7 Semiconducting (PTCR) Perovskites

Large hydrostatic piezoresistance Π_h coefficients (two orders of magnitude larger than those of silicon and germanium) have been observed in this class of polycrystalline semiconductors [Sauer et al., 1959]. PTCR compositions are synthesized by donor doping ferroelectric barium titanate $BaTiO_3$, $(Ba,Sr)TiO_3$, or $(Ba,Pb)TiO_3$ with a trivalent element (e.g., yttrium) or a pentavalent element (e.g., niobium). Below the ferroelectric transition temperature T_c, Schottky barriers between the conductive ceramic grains are neutralized by the spontaneous polarization P_s associated with the ferroelectric phase transition. Above T_c the barrier height increases rapidly with temperature (hence the electrical resistivity) because of the disappearance of P_s and the decrease of the paraelectric state dielectric constant. Analytic expressions that permit the computation of barrier heights under different elastic and thermal boundary conditions have been developed [Amin, 1989].

51.8 Thick Film Resistors

Thick film resistors consist of a conductive phase, e.g., rutile (RuO_2), perovskite ($BaRuO_3$), or pyrochlore ($Pb_2Ru_2O_{7-x}$), and an insulating phase (e.g., lead borosilicate) dispersed in an organic vehicle. They are formed by screen printing on a substrate, usually alumina, followed by sintering at ≈850°C for 10 min.

The increase of the piezoresistance properties of a commercial thick film resistor (ESL 2900 series) with sheet resistivity is illustrated in Fig. 51.3. The experimentally observed properties such as the resistance increase and decrease with tensile and compressive strains, respectively, and the increase of the elastoresistance tensor with sheet resistivity seem to support a barrier tunneling model [Canali et al., 1980].

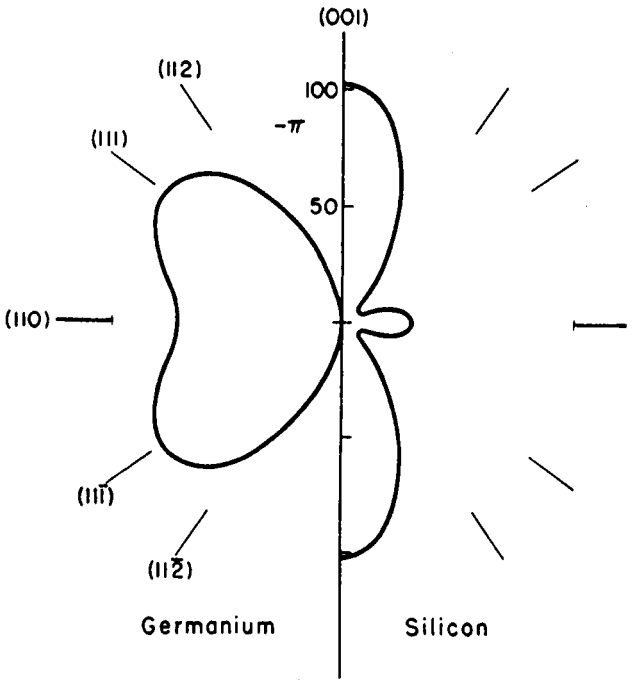

FIGURE 51.2 Section of the longitudinal piezoresistivity surface, the maximum sensitivity directions in Si and Ge are shown [Keys, 1960].

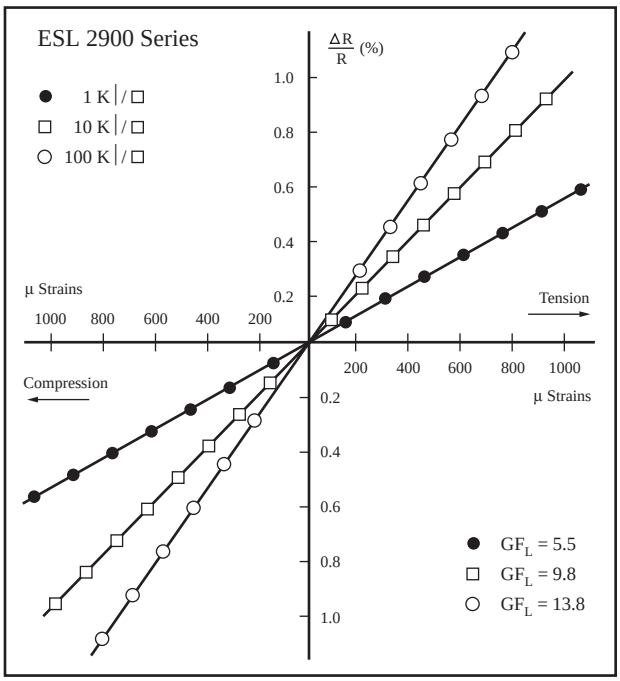

FIGURE 51.3 Relative changes of resistance for compressive and tensile strain applied parallel to the current direction. Note the increase of gage factor with sheet resistivity.

51.9 Design Considerations

Many commercially available sensors (pressure, acceleration, vibration,… etc.) are fabricated from piezoresistive materials (see for example, Chapter 56 in this handbook.) The most commonly used geometry for pressure sensors is the edge clamped diaphragm. Four resistors are usually deposited on the diaphragm and connected to form a Wheatstone bridge. The deposition technique varies depending upon the piezoresistive material: standard IC technology and micro-machining for Si type diaphragms; sputtering for thin film metal strain gauges; bonding for wire strain gauges, and screen printing for thick film resistors. Different types of diaphragms (sapphire, metallic, ceramic,… etc.) have been reported in the literature for hybrid sensors.

To design a highly accurate and sensitive sensor, it is necessary to analyze the stress–strain response of the diaphragm using plate theory and finite element techniques to take into account: (1) elastic anisotropy of the diaphragm, (2) large deflections of plate (elastic non linearities), and (3) maximum sensitivity directions of the piezoresistivity coefficient. Signal conditioning must be provided to compensate for temperature drifts of the gauge offset and sensitivity.

Defining Terms

$\boldsymbol{\rho}_{ij}$: Electric resistivity tensor
$\boldsymbol{d}_{ikl}$: Converse piezoelectric tensor
$\boldsymbol{\Pi}_{ijkl}$: Piezoresistivity tensor
$\boldsymbol{\rho}_{ijm}$: Nonlinear resistivity tensor
$\boldsymbol{\delta}_{iklno}$: Nonlinear piezoelectric tensor

The Hall Effect

Alexander C. Ehrlich
U.S. Naval Research Laboratory

52.1 Introduction
52.2 Theoretical Background
52.3 Relation to the Electronic Structure—(i) $\omega_c\tau << 1$
52.4 Relation to the Electronic Structure—(ii) $\omega_c\tau >> 1$

52.1 Introduction

The Hall effect is a phenomenon that arises when an electric current and magnetic field are simultaneously imposed on a conducting material. Specifically, in a flat plate conductor, if a current density, J_x, is applied in the x direction and (a component of) a magnetic field, B_z, in the z direction, then the resulting electric field, E_y, transverse to J_x and B_z is known as the Hall electric field E_H (see Fig. 52.1) and is given by

$$E_y = RJ_xB_z \tag{52.1}$$

where R is known as the Hall coefficient. The Hall coefficient can be related to the electronic structure and properties of the **conduction bands** in metals and semiconductors and historically has probably been the most important single parameter in the characterization of the latter. Some authors choose to discuss the Hall effect in terms of the Hall angle, ϕ, shown in Fig. 52.1, which is the angle between the net electric field and the imposed current. Thus,

$$\tan\phi = E_H/E_x \tag{52.2}$$

For the vast majority of Hall effect studies that have been carried out, the origin of E_H is the Lorentz force, F_L, that is exerted on a charged particle as it moves in a magnetic field. For an electron of charge e with velocity v, F_L is proportional to the vector product of **v** and **B**; that is,

$$F_L = e\mathbf{vxB} \tag{52.3}$$

In these circumstances a semiclassical description of the phenomenon is usually adequate. This description combines the classical Boltzmann transport equation with the Fermi–Dirac distribution function for the charge carriers (electrons or holes) [Ziman, 1960], and this is the point of view that will be taken in this chapter. Examples of Hall effect that cannot be treated semiclassically are the spontaneous (or extraordinary) Hall effect that occurs in ferromagnetic conductors [Berger and Bergmann, 1980], the quantum Hall effect [Prange and Girvin, 1990], and the Hall effect that arises in conjuction with hopping conductivity [Emin, 1977].

In addition to its use as an important tool in the study of the nature of electrically conducting materials, the Hall effect has a number of direct practical applications. For example, the sensor in some commercial devices for measuring the magnitude and orientation of magnetic fields is a Hall sensor. The spontaneous Hall effect has been used as a nondestructive method for exploring the presence of defects in steel structures. The quantum Hall effect has been used to refine our knowledge of the magnitudes of certain fundamental constants such as the ratio of e^2/h where h is Planck's constant.

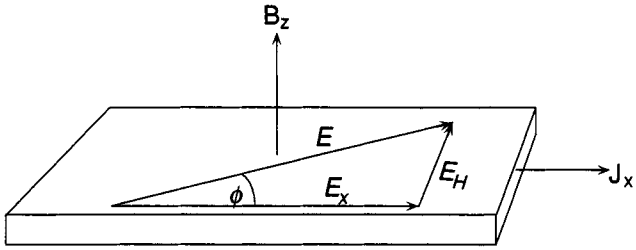

FIGURE 52.1 Typical Hall effect experimental arrangement in a flat plate conductor with current J_x and magnetic field B_z. The Hall electric field $E_H = E_y$ in this geometry arises because of the Lorentz force on the conducting charges and is of just such a magnitude that in combination with the Lorentz force there is no net current in the y direction. The angle ϕ between the current and net electric field is called the Hall angle.

52.2 Theoretical Background

The Boltzmann equation for an electron gas in a homogeneous, isothermal material that is subject to constant electric and magnetic fields is [Ziman, 1960]

$$e[\mathbf{E}+\mathbf{vXB}]\left(\frac{1}{\hbar}\right)\nabla_{\mathbf{k}} f(\mathbf{k})-\left(\frac{\partial f}{\partial t}\right)_s = 0 \tag{52.4}$$

Here $\mathbf{k}$ is the quantum mechanical wave vector, $\hbar$ is Planck's constant divided by 2π, t is the time, f is the electron distribution function, and "s" is meant to indicate that the time derivative of f is a consequence of scattering of the electrons. In static equilibrium (E = 0, B = 0) f is equal to f_0 and f_0 is the Fermi–Dirac distribution function

$$f_0 = \frac{1}{e^{\left(\mathscr{E}(\mathbf{k})-\zeta\right)/KT}+1} \tag{52.5}$$

where $\mathscr{E}(\mathbf{k})$ is the energy, ζ is the chemical potential, K is Boltzmann's constant, and T is the temperature. Each term in Eq. (52.4) represents a time rate of change of f and in dynamic equilibrium their sum has to be zero. The last term represents the effect of collisions of the electrons with any obstructions to their free movement such as lattice vibrations, crystallographic imperfections, and impurities. These collisions are usually assumed to be representable by a relaxation time, $\tau(\mathbf{k})$, that is

$$\left(\frac{\partial f}{\partial t}\right)_c = \frac{-\left(f - f_0\right)}{\tau(\mathbf{k})} = \frac{(\partial f_0 / \partial \mathscr{E})\, g(\mathbf{k})}{\tau(\mathbf{k})} \tag{52.6}$$

where $f - f_0$ is written as $(\partial f_0/\partial\varepsilon)g(\mathbf{k})$, which is essentially the first term in an expansion of the deviation of f from its equilibrium value, f_0. Eqs. (52.6) and (52.4) can be combined to give

$$e[\mathbf{E} + \mathbf{vXB}]\,\frac{1}{\hbar}\,\nabla_{\mathbf{k}} f(\mathbf{k}) = \frac{(\partial f_0/\partial \mathscr{E})\, g(\mathbf{k})}{\tau(\mathbf{k})} \tag{52.7}$$

If Eq. (52.7) can be solved for $g(\mathbf{k})$, then expressions can be obtained for both the E_H and the magnetoresistance (the electrical resistance in the presence of a magnetic field). Solutions can in fact be developed that are linear

in the applied electric field (the regime where Ohm's law holds) for two physical situations: (i) when $\omega_c\tau << 1$ [Hurd, 1972, p. 69] and (ii) when $\omega_c\tau >> 1$ [Hurd, 1972; Lifshitz et al., 1956] where $\omega_c = Be/m$ is the cyclotron frequency. Situation (ii) means the electron is able to complete many cyclotron orbits under the influence of **B** in the time between scatterings and is called the high (magnetic) field limit. Conversely, situation (i) is obtained when the electron is scattered in a short time compared to the time necessary to complete one cyclotron orbit and is known as the low field limit. In effect, the solution to Eq. (52.7) is obtained by expanding $g(\boldsymbol{k})$ in a power series in $\omega_c\tau$ or $1/\omega_c\tau$ for (i) and (ii), respectively. Given $g(\mathbf{k})$ the current vector, J_l ($l = x,y,z$) can be calculated from [Blatt, 1957]

$$J_l = \left(\frac{e}{4\pi^3}\right)\int v_l(\mathbf{k})\,g(\mathbf{k})\,(\partial f_0/\partial \mathscr{E})\,d^3k \tag{52.8}$$

where $v_l(\mathbf{k})$ is the velocity of the electron with wave vector **k.** Every term in the series defining J_l is linear in the applied electric field, **E,** so that the conductivity tensor σ_{lm} is readily obtained from $J_l = \sigma_{lm}E_m$ [Hurd, 1972, p. 9] This matrix equation can be inverted to give $E_l = \rho_{lm}J_m$. For the same geometry used in defining Eq. (52.1)

$$E_y = E_H = \rho_{yx}J_x \tag{52.9}$$

where ρ_{21} is a component of the resistivity tensor sometimes called the Hall resistivity. Comparing Eqs. (52.1) and (52.9) it is clear that the B dependence of E_H is contained in ρ_{12}. However, nothing in the derivation of ρ_{12} excludes the possibility of terms to the second or higher powers in B. Although these are usually small, this is one of the reasons that experimentally one usually obtains R from the measured transverse voltage by reversing magnetic fields and averaging the measured E_H by calculating $(1/2)[E_H(\mathbf{B}) - E_H(-\mathbf{B})]$. This eliminates the second-order term in B and in fact all even power terms contributing to the E_H. Using the Onsager relation [Smith and Jensen, 1989, p. 60] $\rho_{12}(\mathbf{B}) = \rho_{21}(-\mathbf{B})$, it is also easy to show that in terms of the Hall resistivity

$$R = \frac{1}{2}\frac{1}{B}[\rho_{12}(\mathbf{B}) + \rho_{21}(\mathbf{B})] \tag{52.10}$$

Strictly speaking, in a single crystal the electric field resulting from an applied electric current and magnetic field, both of arbitrary direction relative to crystal axes and each other, cannot be fully described in terms of a second-order resistivity tensor. [Hurd, 1972, p. 71] On the other hand, Eqs. (52.1), (52.9), and (52.10) do define the Hall coefficient in terms of a second-order resistivity tensor for a polycrystalline (assumed isotropic) sample or for a cubic single crystal or for a lower symmetry crystal when the applied fields are oriented along major symmetry directions. In real world applications the Hall effect is always treated in this manner.

52.3 Relation to the Electronic Structure — (i) $\omega_c\tau << 1$

General expressions for R in terms of the parameters that describe the electronic structure can be obtained using Eqs. (52.7)–(52.10) and have been given by Blatt [Blatt, 1957] for the case of crystals having cubic symmetry. An even more general treatment has been given by McClure [McClure, 1956]. Here the discussion of specific results will be restricted to the free electron model wherein the material is assumed to have one or more conducting bands, each of which has a quadratic dispersion relationship connecting $\mathscr{E}$ and **k;** that is

$$\mathscr{E}_i = \frac{\hbar^2 k_i^2}{2m_i} \tag{52.11}$$

where the subscript specifies the band number and m_i, the **effective mass** for each band. These masses need not be equal nor the same as the free electron mass. In effect, some of the features lost in the free electron

approximation are recovered by allowing the masses to vary. The **relaxation times**, τ_i, will also be taken to be isotropic (not **k** dependent) within each band but can be different from band to band. Although extreme, these approximations are often qualitatively correct, particularly in polycrystalline materials, which are macroscopically isotropic. Further, in semiconductors these results will be strictly applicable only if τ_i is energy independent as well as isotropic.

For a single spherical band, R_H is a direct measure of the number of current carriers and turns out to be given by [Blatt, 1957]

$$R_H = \frac{1}{ne} \tag{52.12}$$

where n is the number of conduction carriers/volume. R_H depends on the sign of the charge of the current carriers being negative for electrons and positive for **holes**. This identification of the carrier sign is itself a matter of great importance, particularly in semiconductor physics. If more than one band is involved in electrical conduction, then by imposing the boundary condition required for the geometry of Fig. 52.1 that the total current in the y direction from all bands must vanish, $J_y = 0$, it is easy to show that [Wilson, 1958]

$$R_H = (1/\sigma)^2 \Sigma[\sigma_i^2 R_i] \tag{52.13}$$

where R_i and σ_i are the Hall coefficient and electrical conductivity, respectively, for the ith band ($\sigma_i = n_i e^2 \tau_i / m_i$), $\sigma = \Sigma\sigma_i$ is the total conductivity of the material, and the summation is taken over all bands. Using Eq. (52.12), Eq. (52.13) can also be written

$$R_H = \frac{1}{en_{\text{eff}}} = \frac{1}{e} \sum \left[\frac{1}{n_i} \left(\frac{\sigma_i}{\sigma} \right)^2 \right] \tag{52.14}$$

where n_{eff} is the effective or apparent number of electrons determined by a Hall effect experiment. (Note that some workers prefer representing Eqs. (52.13) and (52.14) in terms of the current carrier mobility for each band, μ_i, defined by $\sigma_i = n_i e \mu_i$.)

The most commonly used version of Eq. (52.14) is the so-called two-band model, which assumes that there are two spherical bands with one composed of electrons and the other of holes. Eq. (52.14) then takes the form

$$R_H = \frac{1}{e} \left[\frac{1}{n_e} \left(\frac{\sigma_e}{\sigma} \right)^2 - \frac{1}{n_h} \left(\frac{\sigma_h}{\sigma} \right)^2 \right] \tag{52.15}$$

From Eq. (52.14) or (52.15) it is clear that the Hall effect is dominated by the most highly conducting band. Although for fundamental reasons it is often the case that $n_e = n_h$ (a so-called compensated material), R_H would rarely vanish since the conductivities of the two bands would rarely be identical. It is also clear from any of Eqs. (52.12), (52.14), or (52.15) that, in general, the Hall effect in semiconductors will be orders of magnitude larger than that in metals.

52.4 Relation to the Electronic Structure — (ii) $\omega_c\tau >> 1$

The high field limit can be achieved in metals only in pure, crystalographically well-ordered materials and at low temperatures, which circumstances limit the electron scattering rate from impurities, crystallographic

imperfections, and lattice vibrations, respectively. In semiconductors, the much longer relaxation time and smaller effective mass of the electrons makes it much easier to achieve the high field limit. In this limit the result analogous to Eq. (52.15) is [Blatt, 1968, p. 290]

$$R_H = \frac{1}{e}\frac{1}{n_e - n_h} \tag{52.16}$$

Note that the individual band conductivities do not enter in Eq. (52.16). Eq. (52.16) is valid provided the cyclotron orbits of the electrons are closed for the particular direction of **B** used. It is not necessary that the bands be spherical or the τ's isotropic. Also, for more than two bands R_H depends only on the net difference between the number of electrons and the number of holes. For the case where $n_e = n_h$, in general, the lowest order dependence of the Hall electric field on B is B^2 and there is no simple relationship of R_H to the number of current carriers. For the special case of the two-band model, however, R_H is a constant and is of the same form as Eq. (52.15) [Fawcett, 1964].

Metals can have geometrically complicated Fermi surfaces wherein the Fermi surface contacts the Brillouin zone boundary as well as encloses the center of the zone. This leads to the possibility of open electron orbits in place of the closed cyclotron orbits for certain orientations of **B.** In these circumstances R can have a variety of dependencies on the magnitude of B and in single crystals will generally be dependent on the exact orientation of **B** relative to the crystalline axes [Hurd, 1972, p. 51; Fawcett, 1964]. R will not, however, have any simple relationship to the number of current carriers in the material.

Semiconductors have too few electrons to have open orbits but can manifest complicated behavior of their Hall coefficient as a function of the magnitude of B. This occurs because of the relative ease with which one can pass from the low field limit to the high field limit and even on to the so-called quantum limit with currently attainable magnetic fields. (The latter has not been discussed here.) In general, these different regimes of B will not occur at the same magnitude of B for all the bands in a given semiconductor, further complicating the dependence of R on B.

Defining Terms

Conducting band: The band in which the electrons primarily responsible for the electric current are found.

Effective mass: An electron in a lattice responds differently to applied fields than would a free electron or a classical particle. One can, however, often describe a particular response using classical equations by defining an effective mass whose value differs from the actual mass. For the same material the effective mass may be different for different phenomena; e.g., electrical conductivity and cyclotron resonance.

Electron band: A range or band of energies in which there is a continuum (rather than a discrete set as in, for example, the hydrogen atom) of allowed quantum mechanical states partially or fully occupied by electrons. It is the continuous nature of these states that permits them to respond almost classically to an applied electric field.

Hole or hole state: When a conducting band, which can hold two electrons/unit cell, is more than half full, the remaining unfilled states are called *holes*. Such a band responds to electric and magnetic fields as if it contained positively charged carriers equal in number to the number of holes in the band.

Relaxation time: The time for a distribution of particles, out of equilibrium by a measure Φ, to return exponentially toward equilibrium to a measure Φ/e out of equilibrium when the disequilibrating fields are removed (e is the natural logarithm base).

53.4 Types of Superconductors

53.1 Introduction

The fundamental idea behind all of a superconductor's unique properties is that **superconductivity** is a quantum mechanical phenomenon on a macroscopic scale created when the motions of individual electrons are correlated. According to the theory developed by John Bardeen, Leon Cooper, and Robert Schrieffer (BCS theory), this correlation takes place when two electrons couple to form a Cooper pair. For our purposes, we may therefore consider the electrical charge carriers in a superconductor to be Cooper pairs (or more colloquially, superelectrons) with a mass m^* and charge q^* twice those of normal electrons. The average distance between the two electrons in a Cooper pair is known as the coherence length, ξ. Both the coherence length and the binding energy of two electrons in a Cooper pair, 2Δ, depend upon the particular superconducting material. Typically, the coherence length is many times larger than the interatomic spacing of a solid, and so we should not think of Cooper pairs as tightly bound electron molecules. Instead, there are many other electrons between those of a specific Cooper pair allowing for the paired electrons to change partners on a time scale of $h/(2\Delta)$ where h is Planck's constant.

If we prevent the Cooper pairs from forming by ensuring that all the electrons are at an energy greater than the binding energy, we can destroy the superconducting phenomenon. This can be accomplished, for example, with thermal energy. In fact, according to the BCS theory, the critical temperature, T_c, associated with this energy is

$$\frac{2\Delta}{k_B T_c} \approx 3.5 \tag{53.1}$$

where k_B is Boltzmann's constant. For low critical temperature (conventional) superconductors, 2Δ is typically on the order of 1 meV, and we see that these materials must be kept below temperatures of about 10 K to exhibit their unique behavior. High critical temperature superconductors, in contrast, will superconduct up to temperatures of about 100 K, which is attractive from a practical view because the materials can be cooled cheaply using liquid nitrogen. Other types of depairing energy are kinetic, resulting in a critical current density J_c, and magnetic, resulting in a critical field H_c. To summarize, a superconductor must be maintained under the appropriate temperature, electrical current density, and magnetic field conditions to exhibit its special properties. An example of this phase space is shown in Fig. 53.1.

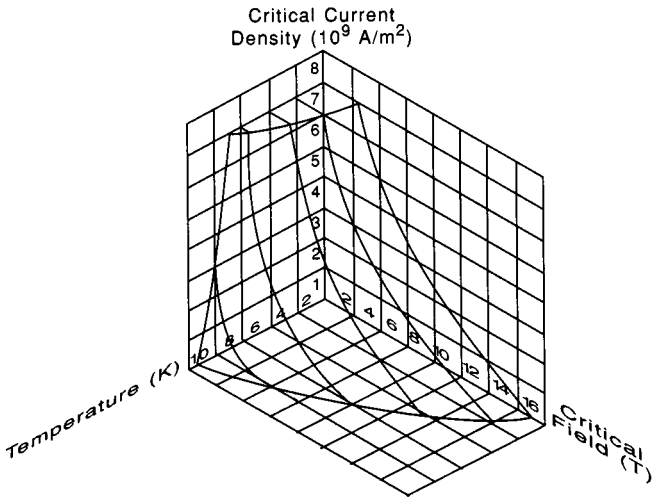

FIGURE 53.1 The phase space for the superconducting alloy niobium–titanium. The material is superconducting inside the volume of phase space indicated.

53.2 General Electromagnetic Properties

The hallmark electromagnetic properties of a superconductor are its ability to carry a static current without any resistance and its ability to exclude a static magnetic flux from its interior. It is this second property, known as the Meissner effect, that distinguishes a superconductor from merely being a perfect conductor (which conserves the magnetic flux in its interior). Although superconductivity is a manifestly quantum mechanical phenomenon, a useful classical model can be constructed around these two properties. In this section, we will outline the rationale for this classical model, which is useful in engineering applications such as waveguides and high-field magnets.

The zero dc resistance criterion implies that the superelectrons move unimpeded. The electromagnetic energy density, w, stored in a superconductor is therefore

$$w = \frac{1}{2}\varepsilon \mathrm{E}^2 + \frac{1}{2}\mu_o \mathrm{H}^2 + \frac{n^\star}{2} m^\star v_s^2 \tag{53.2}$$

where the first two terms are the familiar electric and magnetic energy densities, respectively. (Our electromagnetic notation is standard: ε is the permittivity, μ_o is the permeability, E is the electric field, and the magnetic flux density, B, is related to the magnetic field, H, via the constitutive law $\mathrm{B} = \mu_o \mathrm{H}$.) The last term represents the kinetic energy associated with the undamped superelectrons' motion ($n^\star$ and v_s are the superelectrons' density and velocity, respectively). Because the supercurrent density, J_s, is related to the superelectron velocity by $\mathrm{J}_s = n^\star q^\star \mathrm{v}_s$, the kinetic energy term can be rewritten

$$n^\star \left(\frac{1}{2} m^\star \mathrm{v}_s^2 \right) = \frac{1}{2} \Lambda \mathrm{J}_s^2 \tag{53.3}$$

where Λ is defined as

$$\Lambda = \frac{m^\star}{n^\star \left(q^\star \right)^2} \tag{53.4}$$

Assuming that all the charge carriers are superelectrons, there is no power dissipation inside the superconductor, and so Poynting's theorem over a volume V may be written

$$-\int_V \nabla \cdot \left(\mathbf{E} \times \mathbf{H}\right) dv = \int_V \frac{\partial w}{\partial t}\, dv \tag{53.5}$$

where the left side of the expression is the power flowing into the region. By taking the time derivative of the energy density and appealing to Faraday's and Ampère's laws to find the time derivatives of the field quantities, we find that the only way for Poynting's theorem to be satisfied is if

$$\mathbf{E} = \frac{\partial}{\partial t}\left(\Lambda \mathbf{J}_s\right) \tag{53.6}$$

This relation, known as the first London equation (after the London brothers, Heinz and Fritz), is thus necessary if the superelectrons have no resistance to their motion.

Equation (53.6) reveals that the superelectrons' inertia creates a lag between their motion and that of an applied electric field. As a result, a superconductor will support a time-varying voltage drop. The impedance associated with the supercurrent is therefore inductive and it will be useful to think of Λ as a kinetic inductance created by the correlated motion of the Cooper pairs.

If the first London equation is substituted into Faraday's law, $\nabla \times \mathrm{E} = -(\partial \mathrm{B}/\partial t)$, and integrated with respect to time, the second London equation results:

$$\nabla \times \left(\Lambda \mathbf{J}_s\right) = -\mathbf{B} \tag{53.7}$$

where the constant of integration has been defined to be zero. This choice is made so that the second London equation is consistent with the Meissner effect as we now demonstrate. Taking the curl of the quasi-static form of Ampère's law, $\nabla \times \mathrm{H} = \mathrm{J}_s$, results in the expression $\nabla^2 \mathrm{B} = -\mu_o \nabla \times \mathrm{J}_s$, where a vector identity, $\nabla \times \nabla \times \mathrm{C} = \nabla(\nabla \cdot \mathrm{C}) - \nabla^2 \mathrm{C}$; the constitutive relation, $\mathrm{B} = \mu_o \mathrm{H}$; and Gauss's law, $\nabla \cdot \mathrm{B} = 0$, have been used. By now appealing to the second London equation, we obtain the vector Helmholtz equation

$$\nabla^2 \mathbf{B} - \frac{1}{\lambda^2}\mathbf{B} = 0 \tag{53.8}$$

where the penetration depth is defined

$$\lambda \equiv \sqrt{\frac{\Lambda}{\mu_o}} = \sqrt{\frac{m^\star}{n^\star \left(q^\star\right)^2 \mu_o}} \tag{53.9}$$

From Eq. (53.8), we find that a flux density applied parallel to the surface of a semi-infinite superconductor will decay away exponentially from the surface on a spatial length scale of order λ. In other words, a bulk superconductor will exclude an applied flux as predicted by the Meissner effect.

The London equations reveal that there is a characteristic length λ over which electromagnetic fields can change inside a superconductor. This penetration depth is different from the more familiar skin depth of electromagnetic theory, the latter being a frequency-dependent quantity. Indeed, the penetration depth at zero temperature is a distinct material property of a particular superconductor.

Notice that λ is sensitive to the number of correlated electrons (the superelectrons) in the material. As previously discussed, this number is a function of temperature and so only at $T = 0$ do *all* the electrons that usually conduct ohmically participate in the Cooper pairing. For intermediate temperatures, $0 < T < T_c$, there

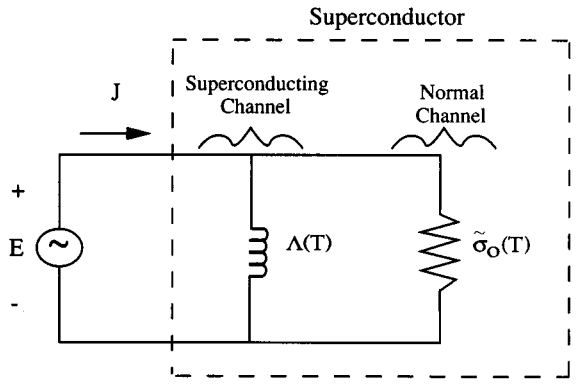

FIGURE 53.2 A lumped element model of a superconductor.

are actually two sets of interpenetrating electron fluids: the uncorrelated electrons providing ohmic conduction and the correlated ones creating supercurrents. This two-fluid model is a useful way to build temperature effects into the London relations.

Under the two-fluid model, the electrical current density, **J**, is carried by both the uncorrelated (normal) electrons and the superelectrons: $\mathbf{J} = \mathbf{J}_n + \mathbf{J}_s$ where $\mathbf{J}_n$ is the normal current density. The two channels are modeled in a circuit as shown in Fig. 53.2 by a parallel combination of a resistor (representing the ohmic channel) and an inductor (representing the superconducting channel). To a good approximation, the respective temperature dependences of the conductor and inductor are

$$\tilde{\sigma}_o(T) = \sigma_o(T_c)\left(\frac{T}{T_c}\right)^4 \quad \text{for } T \leq T_c \tag{53.10}$$

and

$$\Lambda(T) = \Lambda(0)\left(\frac{1}{1-(T/T_c)^4}\right) \quad \text{for } T \leq T_c \tag{53.11}$$

where σ_o is the dc conductance of the normal channel. (Strictly speaking, the normal channel should also contain an inductance representing the inertia of the normal electrons, but typically such an inductor contributes negligibly to the overall electrical response.) Since the temperature-dependent penetration depth is defined as $\lambda(T) = \sqrt{\Lambda(T)/\mu_o}$, the effective conductance of a superconductor in the sinusoidal steady state is

$$\sigma = \tilde{\sigma}_o + \frac{1}{j\omega\mu_o\lambda^2} \tag{53.12}$$

where the explicit temperature dependence notation has been suppressed.

It should be noted that the temperature dependencies given in Equations (53.10) and (53.11) are not precisely correct for the high-T_c materials. It has been suggested that this is because the angular momentum of the electrons forming a Cooper pair in high-T_c materials is different from that in low-T_c ones. Nevertheless, the two-fluid picture of transport and its associated constitutive law, Eq. (53.12), are still valid for high-T_c superconductors.

Most of the important physics associated with the classical model is embedded in Eq. (53.12). As is clear from the lumped element model, the relative importance of the normal and superconducting channels is a

function not only of temperature but also of frequency. The familiar *L/R* time constant, here equal to $\Lambda\tilde{\sigma}_o$, delineates the frequency regimes where most of the total current is carried by J_n (if $\omega\Lambda\tilde{\sigma}_o >> 1$) or J_s (if $\omega\Lambda\tilde{\sigma}_o << 1$). This same result can also be obtained by comparing the skin depth associated with the normal channel, $\delta = \sqrt{2/(\omega\mu_o\tilde{\sigma}_o)}$, to the penetration depth to see which channel provides more field screening. In addition, it is straightforward to use Eq. (53.12) to rederive Poynting's theorem for systems that involve superconducting materials:

$$-\int_V \nabla \cdot \left(\mathbf{E} \times \mathbf{H}\right) dv = \frac{d}{dt}\int_V \left(\frac{1}{2}\varepsilon \mathbf{E}^2 + \frac{1}{2}\mu_o \mathbf{H}^2 + \frac{1}{2}\Lambda(T)\mathbf{J}_s^2\right) dv + \int_V \frac{1}{\tilde{\sigma}_o(T)}\mathbf{J}_n^2\, dv \tag{53.13}$$

Using this expression, it is possible to apply the usual electromagnetic analysis to find the inductance (L_o), capacitance (C_o), and resistance (R_o) per unit length along a parallel plate transmission line. The results of such analysis for typical cases are summarized in Table 53.1.

53.3 Superconducting Electronics

The macroscopic quantum nature of superconductivity can be usefully exploited to create a new type of electronic device. Because all the superelectrons exhibit correlated motion, the usual wave–particle duality normally associated with a single quantum particle can now be applied to the entire ensemble of superelectrons. Thus, there is a spatiotemporal phase associated with the ensemble that characterizes the supercurrent flowing in the material.

If the overall electron correlation is broken, this phase is lost and the material is no longer a superconductor. There is a broad class of structures, however, known as weak links, where the correlation is merely perturbed locally in space rather than outright destroyed. Coloquially, we say that the phase "slips" across the weak link to acknowledge the perturbation.

The unusual properties of this phase slippage were first investigated by Brian Josephson and constitute the central principles behind superconducting electronics. Josephson found that the phase slippage could be defined as the difference between the macroscopic phases on either side of the weak link. This phase difference, denoted as ϕ, determined the supercurrent, i_s, through and voltage, v, across the weak link according to the Josephson equations,

$$i_s = I_c \sin\phi \tag{53.14}$$

and

$$v = \frac{\Phi_o}{2\pi}\frac{d\phi}{dt} \tag{53.15}$$

where I_c is the critical (maximum) current of the junction and Φ_o is the quantum unit of flux. (The flux quantum has a precise definition in terms of Planck's constant, h, and the electron charge, e: $\Phi_o \equiv h/(2e) \approx 2.068 \times 10^{-15}$ Wb). As in the previous section, the correlated motion of the electrons, here represented by the superelectron phase, manifests itself through an inductance. This is straightforwardly demonstrated by taking the time derivative of Eq. (53.14) and combining this expression with Eq. (53.15). Although the resulting inductance is nonlinear (it depends on $\cos\phi$), its relative scale is determined by

$$L_j = \frac{\Phi_o}{2\pi I_c} \tag{53.16}$$

TABLE 53.1 Lumped Circuit Element Parameters Per Unit Length for Typical Transverse Electromagnetic Parallel Plate Waveguides*

Transmission Line Geometry	*Lo*	*Co*	*Ro*
 Two identical, thin ($\lambda \gg b$) superconducting plates	$\frac{\mu_t h}{d} + \frac{2\mu_o \lambda^2}{db}$	$\frac{\varepsilon_t d}{h}$	$\frac{8}{db\tilde{\sigma}_o}\left(\frac{\lambda}{\delta}\right)^4$
 Two identical, thick ($\lambda \ll b$) superconducting plates	$\frac{\mu_t h}{d} + \frac{2\mu_o \lambda}{d}$	$\frac{\varepsilon_t d}{h}$	$\frac{4}{d\delta\tilde{\sigma}_o}\left(\frac{\lambda}{\delta}\right)^3$
 One thick ($\lambda \ll b$) superconducting plate and one thick ($\lambda \ll b$) ohmic plate	$\frac{\mu_t h}{d} + \frac{\mu_o \lambda}{d} + \frac{\mu_n \delta_n}{2d}$	$\frac{\varepsilon_t d}{h}$	$\frac{1}{d\delta_n \sigma_{o,n}}$

*The subscript *n* refers to parameters associated with a normal (ohmic) plate. Using these expressions, line input impedance, attenuation, and wave velocity can be calculated.

a useful quantity for making engineering estimates. For example, the energy scale associated with Josephson coupling is $L_j I_c^2 = (I_c \Phi_o)/2\pi$.

A common weak link, known as the Josephson tunnel junction, is made by separating two superconducting films with a very thin (typically 20 Å) insulating layer. Such a structure is conveniently analyzed using the resistively and capacitively shunted junction (RCSJ) model shown in Fig. 53.3. Under the RCSJ model an ideal lumped junction [described by Eqs. (53.14) and (53.15)] and a resistor R_j represent how the weak link structure influences the respective phases of the super and normal electrons. A capacitor C_j represents the physical capacitance of the sandwich structure. Parasitic capacitance created by the fields around a device interacting with a dielectric substrate is also included in this lumped element. If the ideal lumped junction portion of the circuit is treated as an inductor-like element, many Josephson tunnel junction properties can be calculated with the familiar circuit time constants associated with the model. For example, the quality factor Q of the RCSJ circuit can be expressed as

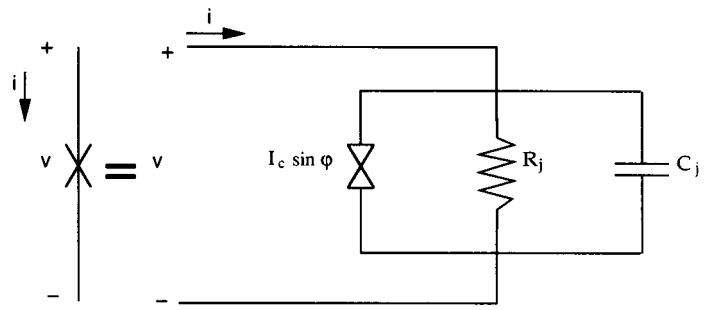

FIGURE 53.3 A real Josephson tunnel junction can be modeled using ideal lumped circuit elements.

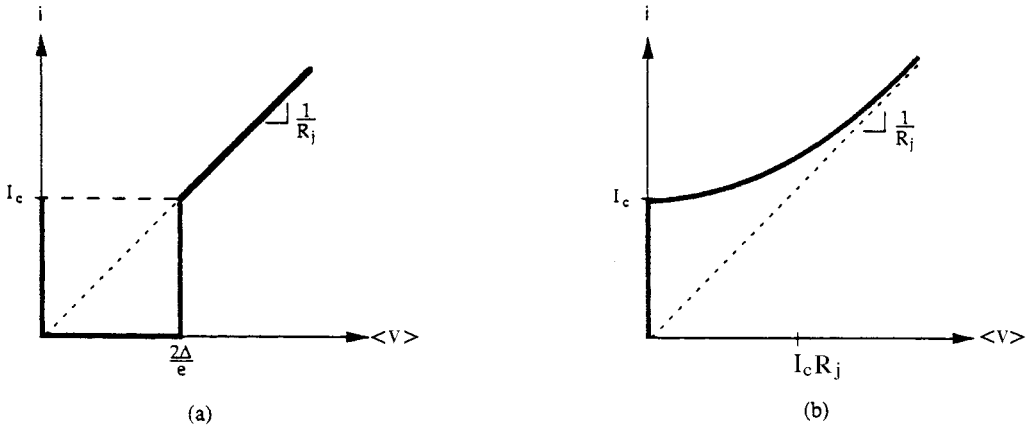

FIGURE 53.4 The *i-v* curves for a Josephson junction: (a) $\beta >> 1$, and (b) $\beta << 1$.

$$Q^2 = \frac{R_j C_j}{L_j / R_j} = \frac{2\pi I_c R_j^2 C_j}{\Phi_o} \equiv \beta \tag{53.17}$$

where β is known as the Stewart-McCumber parameter. Clearly, if $\beta >> 1$, the capacitive time constant R_jC_j dominates the dynamics of the circuit. Thus, as the bias current is raised from zero, no time-average voltage is created until the critical current I_c is exceeded. At this point, the junciton switches to a voltage consistent with the breaking of the Cooper pairs, $2\Delta/e$, with a time constant $\sqrt{L_jC_j}$. Once the junction has latched in the voltage state, however, the capacitor has charged up and the only way for it to discharge is to lower the bias current to zero again. As a result, a device with $\beta >>1$ will have a hysteretic current-voltage curve as shown in Fig. 53.4a. Conversely, $\beta << 1$ implies that the capacitance of the device is unimportant and so the current-voltage curve is not hysteretic (see Fig. 53.4b). In fact, the time-averaged voltage $\langle v \rangle$ for such an RSJ device is

$$\langle v \rangle = iR_j \sqrt{1 - \left(\frac{I_c}{i}\right)^2} \qquad \text{for } |i| > I_c. \tag{53.18}$$

In other words, once the supercurrent channel carries its maximum amount of current, the rest of the current is carried through the normal channel.

Just as the correlated motion of the superelectrons creates the frequency-independent Meissner effect in a bulk superconductor through Faraday's law, so too the macroscopic quantum nature of superconductivity

allows the possibility of a device whose output voltage is a function of a static magnetic field. If two weak links are connected in parallel, the lumped version of Faraday's law gives the voltage across the second weak link as $v_2 = v_1 + (d\Phi/dt)$, where Φ is the total flux threading the loop between the links. Substituting Eq. (53.15), integrating with respect to time, and again setting the integration constant to zero yields

$$\phi_2 - \phi_1 = \left(2\pi\Phi\right)/\Phi_o \tag{53.19}$$

showing that the spatial change in the phase of the macroscopic wavefunction is proportional to the local magnetic flux. The structure described is known as a *superconducting quantum interference device (SQUID)* and can be used as a highly sensitive magnetometer by biasing it with current and measuring the resulting voltage as a function of magnetic flux. From this discussion, it is apparent that a duality exists in how fields interact with the macroscopic phase: electric fields are coupled to its rate of change in time and magnetic fields are coupled to its rate of change in space.

53.4 Types of Superconductors

The macroscopic quantum nature of superconductivity also affects the general electromagnetic properties previously discussed. This is most clearly illustrated by the interplay of the characteristic lengths ξ, representing the scale of quantum correlations, and λ, representing the scale of electromagnetic screening. Consider the scenario where a magnetic field, H, is applied parallel to the surface of a semi-infinite superconductor. The correlations of the electrons in the superconductor must lower the overall energy of the system or else the material would not be superconducting in the first place. Because the critical magnetic field H_c destroys all the correlations, it is convenient to define the energy density gained by the system in the superconducting state as $(1/2)\mu_o H_c^2$. The electrons in a Cooper pair are separated on a length scale of ξ, however, and so the correlations cannot be fully achieved until a distance roughly ξ from the boundary of the superconductor. There is thus an energy per unit area, $(1/2)\mu_o H_c^2 \xi$, that is lost because of the presence of the boundary. Now consider the effects of the applied magnetic field on this system. It costs the superconductor energy to maintain the Meissner effect, $B = 0$, in its bulk; in fact the energy density required is $(1/2)\mu_o H^2$. However, since the field can penetrate the superconductor a distance roughly λ, the system need not expend an energy per unit area of $(1/2)\mu_o H^2 \lambda$ to screen over this volume. To summarize, more than a distance ξ from the boundary, the energy of the material is lowered (because it is superconducting), and more than a distance λ from the boundary the energy of the material is raised (to shield the applied field).

Now, if $\lambda < \xi$, the region of superconducting material greater than λ from the boundary but less than ξ will be higher in energy than that in the bulk of the material. Thus, the surface energy of the boundary is positive and so costs the total system some energy. This class of superconductors is known as type I. Most elemental superconductors, such as aluminum, tin, and lead, are type I. In addition to having $\lambda < \xi$, type I superconductors are generally characterized by low critical temperatures ($\sim$5 K) and critical fields ($\sim$0.05 T). Typical type I superconductors and their properties are listed in Table 53.2.

TABLE 53.2 Material Parameters for Type I Superconductors*

Material	T_c (K)	λ_o (nm)	ξ_o (nm)	Δ_o (meV)	$\mu_0 H_{co}$ (mT)
Al	1.18	50	1600	0.18	110.5
In	3.41	65	360	0.54	123.0
Sn	3.72	50	230	0.59	130.5
Pb	7.20	40	90	1.35	180.0
Nb	9.25	85	40	1.50	198.0

*The penetration depth λ_o is given at zero temperature, as are the coherence length ξ_o, the thermodynamic critical field H_{co}, and the energy gap Δ_o.

Conversely, if $\lambda > \xi$, the surface energy associated with the boundary is negative and lowers the total system energy. It is therefore thermodynamically favorable for a normal–superconducting interface to form inside these type II materials. Consequently, this class of superconductors does not exhibit the simple Meissner effect as do type I materials. Instead, there are now two critical fields: for applied fields below the lower critical field, H_{c1}, a type II superconductor is in the Meissner state, and for applied fields greater than the upper critical field, H_{c2}, superconductivity is destroyed. The three critical field are related to each other by $H_c \approx \sqrt{H_{c1}H_{c2}}$.

In the range $H_{c1} < H < H_{c2}$, a type II superconductor is said to be in the vortex state because now the applied field can enter the bulk superconductor. Because flux exists in the material, however, the superconductivity is destroyed locally, creating normal regions. Recall that for type II materials the boundary between the normal and superconducting regions lowers the overall energy of the system. Therefore, the flux in the superconductor creates as many normal–superconducting interfaces as possible without violating quantum criteria. The net result is that flux enters a type II superconductor in quantized bundles of magnitude Φ_o known as vortices or fluxons (the former name derives from the fact that current flows around each quantized bundle in the same manner as a fluid vortex circulates around a drain). The central portion of a vortex, known as the core, is a normal region with an approximate radius of ξ. If a defect-free superconductor is placed in a magnetic field, the individual vortices, whose cores essentially follow the local average field lines, form an ordered triangular array, or flux lattice. As the applied field is raised beyond H_{c1} (where the first vortex enters the superconductor), the distance between adjacent vortex cores decreases to maintain the appropriate flux density in the material. Finally, the upper critical field is reached when the normal cores overlap and the material is no longer superconducting. Indeed, a precise calculation of H_{c2} using the phenomenological theory developed by Vitaly Ginzburg and Lev Landau yields

$$H_{c2} = \frac{\Phi_o}{2\pi\mu_o\xi^2} \tag{53.20}$$

which verifies our simple picture. The values of typical type II material parameters are listed in Tables 53.3 and 53.4.

Type II superconductors are of great technical importance because typical H_{c2} values are at least an order of magnitude greater than the typical H_c values of type I materials. It is therefore possible to use type II materials to make high-field magnet wire. Unfortunately, when current is applied to the wire, there is a Lorentz-like force on the vortices, causing them to move. Because the moving vortices carry flux, their motion creates a static voltage drop along the superconducting wire by Faraday's law. As a result, the wire no longer has a zero dc

TABLE 53.3 Material Parameters for Conventional Type II Superconductors*

Material	T_c (K)	$\lambda_{GL}(0)$ (nm)	$\xi_{GL}(0)$ (nm)	Δ_o (meV)	$\mu_0 H_{c2,o}$ (T)
Pb-In	7.0	150	30	1.2	0.2
Pb-Bi	8.3	200	20	1.7	0.5
Nb-Ti	9.5	300	4	1.5	13.0
Nb-N	16.0	200	5	2.4	15.0
$PbMo_6S_8$	15.0	200	2	2.4	60.0
V_3Ga	15.0	90	2–3	2.3	23.0
V_3Si	16.0	60	3	2.3	20.0
Nb_3Sn	18.0	65	3	3.4	23.0
Nb_3Ge	23.0	90	3	3.7	38.0

*The values are only representative because the parameters for alloys and compounds depend on how the material is fabricated. The penetration depth $\lambda_{GL}(0)$ is given as the coefficient of the Ginzburg–Landau temperature dependence as $\lambda_{GL}(T) = \lambda_{GL}(0)(1 - T/T_c)^{-1/2}$; likewise for the coherence length where $\xi_{GL}(T) = \xi_{GL}(0)(1 - T/T_c)^{-1/2}$. The upper critical field $H_{c2,o}$ is given at zero temperature as well as the energy gap Δ_o.

$HgBaCaCu_2O_6$	115	150		2.5	
$HgBa_2Ca_2Cu_3O_8$	135				

resistance, even though the material is still superconducting. To fix this problem, type II superconductors are usually fabricated with intentional defects, such as impurities or grain boundaries, in their crystalline structure to pin the vortices and prevent vortex motion. The pinning is created because the defect locally weakens the superconductivity in the material, and it is thus energetically favorable for the normal core of the vortex to overlap the nonsuperconducting region in the material. Critical current densities usually quoted for practical type II materials, therefore, really represent the depinning critical current density where the Lorentz-like force can overcome the pinning force. (The depinning critical current density should not be confused with the depairing critical current density, which represents the current when the Cooper pairs have enough kinetic energy to overcome their correlation. The depinning critical current density is typically an order of magnitude less than the depairing critical current density, the latter of which represents the theoretical maximum for J_c.)

By careful manufacturing, it is possible to make superconducting wire with tremendous amounts of current-carrying capacity. For example, standard copper wire used in homes will carry about 10^7 A/m^2, whereas a practical type II superconductor like niobium–titanium can carry current densities of 10^{10} A/m^2 or higher even in fields of several teslas. This property, more than a zero dc resistance, is what makes superconducting wire so desirable.

Defining Terms

Superconductivity: A state of matter whereby the correlation of conduction electrons allows a static current to pass without resistance and a static magnetic flux to be excluded from the bulk of the material.

Further Information

Every two years an Applied Superconductivity Conference is held devoted to practical technological issues. The proceedings of these conferences have been published every other year from 1977 to 1991 in the *IEEE Transactions on Magnetics.*

In 1991, the *IEEE Transactions on Applied Superconductivity* began publication. This quarterly journal focuses on both the science and the technology of superconductors and their applications, including materials issues, analog and digital circuits, and power systems. The proceedings of the Applied Superconductivity Conference now appear in this journal.

Pyroelectric Materials and Devices

54.1 Introduction
54.2 Polar Dielectrics
54.3 The Pyroelectric Effect
54.4 Pyroelectric Materials and Their Selection

Roger W. Whatmore
Cranfield University

54.1 Introduction

It was known over 2000 years ago that certain minerals such as tourmaline would attract small objects when heated. It was understood over 200 years ago that this attraction was a manifestation of the appearance of electrical charges on the surface as a consequence of the temperature change. This is called the **pyroelectric** effect and over the last 15 years has become the basis of a major worldwide industry manufacturing detectors of infrared radiation. These are exploited in such devices as "people detectors" for intruder alarms and energy conservation systems, fire and flame detectors, spectroscopic gas analyzers—especially looking for pollutants from car exhausts—and, more recently, devices for thermal imaging. Such thermal imagers can be used for night vision and, by exploiting the smoke-penetrating properties of long-wavelength infrared radiation, in devices to assist firefighters in smoke-filled spaces. The major advantages of the devices in comparison with the competing infrared detectors that exploit narrow bandgap semiconductors are that no cooling is necessary and that they are cheap and consume little power.

The pyroelectric effect appears in any material which possesses a polar symmetry axis. This chapter describes the basic effect, gives a brief account of how it can be used in radiation detection, and discusses the criteria by which materials can be selected for use in this application, concluding with a comparison of the properties of several of the most commonly used materials.

54.2 Polar Dielectrics

A polar material is one whose crystal structure contains a unique axis, along which an electric dipole moment will exist. There are 10 polar crystal classes:

• Triclinic	1	• Monoclinic	2, m
• Tetragonal	4, 4mm	• Orthorhombic	mm2
• Hexagonal	6, 6mm	• Trigonal	3, 3m

All crystals whose structures possess one of these symmetry groups will exhibit both pyroelectric and **piezoelectric** characteristics. In **ferroelectrics,** which are a subset of the set of pyroelectrics, the orientation of the polar axis can be changed by application of an electric field of sufficient magnitude. The original and final states of the crystal are symmetrically related. It is important to note that

TABLE 54.1 Spontaneous Polarizations and Curie Temperatures for a Range of Ferroelectrics

Material	T_c(k)	P_s(cm-2)	T(k)
KH_2PO_4 (KDP)	123	0.053	96
Triglycine sulphate	322	0.028	293
Polyvinylidene fluoride (PVDF)	>453	0.060	293
DOBAMBC (liquid crystal)	359	$\sim 3 \times 10^{-5}$	354
$PbTiO_3$	763	0.760	293
$BaTiO_3$	393	0.260	296

1. Not all polar materials are ferroelectric.
2. There is a set of point groups which lack a center of symmetry, without possessing a polar axis. The crystals belonging to these groups (222, $\bar{4}$, 422, $\bar{4}2$m, 32, $\bar{6}$, $\bar{6}$m2, 23, and $\bar{4}3$m) are piezoelectric without being pyroelectric. (432 is a noncentrosymmetric, nonpiezoelectric class.)

Typical values of spontaneous polarizations (P_s) and Curie temperatures (T_c) for a range of ferroelectrics are given in Table 54.1.

A very wide range of materials exhibit ferroelectric, and thus pyroelectric, behavior. These range from crystals, such as potassium dihydrogen phosphate and triglycine sulphate, to polymers, such as polyvinylidene fluoride, and liquid crystals such as DOBAMBC and ceramics, such as barium titanate and lead zirconate titanate.

Most ferroelectrics exhibit a Curie temperature (T_c) at which the spontaneous plarization goes to zero. (A few ferroelectrics, such as the polymer polyvinylidene fluoride [PVDF] melt before this temperature is reached.)

The fact that the orientation of the polar axis in ferroelectrics can be changed by the application of a field has a very important consequence for ceramic materials. If a polycrystalline body is made of a polar material, then the crystal axes will, in general, be randomly oriented. It cannot therefore show pyroelectricity. However, if an electric field greater than the **coercive field** (E_c) is applied to a ferroelectric ceramic, then the polar axes within the grains will tend to be reoriented so that they each give a component along the direction of the applied field. This process is called "poling." The resulting ceramic is polar (with a point symmetry ∞m) and will show both piezoelectricity and pyroelectricity.

54.3 The Pyroelectric Effect

The pyroelectric effect is described by:

$$P_i = p_i \Delta T \tag{54.1}$$

where P_i is the change in the coefficient of the polarization vector due to a change in temperature ΔT and p_i is the pyroelectric coefficient, which is a vector. The effect and its applications have been extensively reviewed in Whatmore [1986]. The effect of a temperature change on a pyroelectric material is to cause a current, i_p, to flow in an external circuit, such that

$$i_p = ApdT/dt \tag{54.2}$$

where A is the electroded area of the material, p the component of the pyroelectric coefficient normal to the electrodes, and dT/dt the rate of change of temperature with time.

Pyroelectric devices detect changes in temperature in the sensitive material and as such are detectors of supplied energy. It can be seen that the pyroelectric current is proportional to the rate of change of the material with time and that in order to obtain a measurable signal, it is necessary to modulate the source of energy. As energy detectors, they are most frequently applied to the detection of incident electromagnetic energy, particularly in the infrared wavebands.

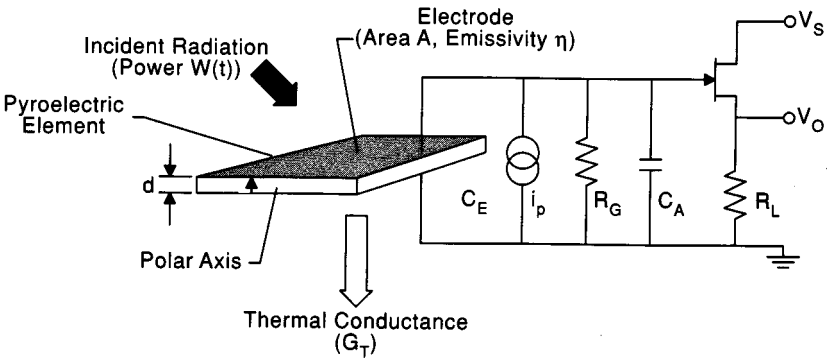

FIGURE 54.1 Pyroelectric detector with FET amplifier.

Typically, a pyroelectric detector element will consist of a thin chip of the pyroelectric material cut perpendicular to the polar axis of the material, electroded with a conducting material such as an evaporated metal and connected to a low-noise, high-input impedance amplifier—for example, a junction field-effect transistor (JFET) or metal-oxide gate transistor (MOSFET)—as shown in Fig. 54.1. In some devices, the radiation is absorbed directly in the element. In this case the front electrode will be a thin metal layer matched to the permittivity of free space with an electrical surface resistivity of 367 Ω/square. However, in most high-performance devices, the element is coated with a layer designed to absorb the radiation of interest. The element itself must be thin to minimize the thermal mass and, in most cases, well isolated thermally from its environment. These measures are designed to increase the temperature change for a given amount of energy absorbed and thus the electrical signal generated. The necessary modulation of the radiation flux can be achieved either by deliberately only "looking" for moving objects or other radiation sources (e.g., flickering flames for a flame detector) or by interposing a mechanical radiation "chopper" such as a rotating blade.

The voltage responsivity of a device such as this is defined as $R_v = V_o/W$, where V_o is the output voltage and W is the input radiation power. For radiation sinusoidally modulated at a frequency ω, R_v is given by

$$R_v = \frac{R_G \eta p A \omega}{G_T (1 + \omega^2 \tau_T^2)^{1/2} (1 + \omega^2 \tau_E^2)^{1/2}} \tag{54.3}$$

where G_T is the thermal conductance from the element to the environment, τ_T is the thermal time constant of the element, τ_E is the electrical time constant of the element, R_G is the electrical resistance across the element, η is the emissivity of the element for the radiation being detected, and A is the sensitive area of the element.

It is easy to show that the response of a pyroelectric device maximizes at a frequency equal to the inverse of the geometric mean of the two time constants and that above and below the two frequencies given by τ_T^{-1} and τ_E^{-1}, R_v falls as ω^{-1}. The consequence of this is that pyroelectric detectors have their sensitivities maximized by having fairly long electrical time constants (0.1 to 10 s) and that such detectors thus work best at low frequencies (0.1 to 100 Hz). However, if high sensitivity is not required, extremely large bandwidths with little sensitivity variation can be obtained by shortening these time constants (making R_G and C_E low and G_T high). In this way, detectors have been made which give picosecond time responses for tracking fast laser pulses.

There are several noise sources in a pyroelectric device. These are discussed in detail in Whatmore [1986]. In many cases of interest, the dominant noise source is the Johnson noise generated by the ac conductance in the capacitance of the detector element. This noise is given by ΔV_j, where

$$\Delta V_j = \left\{ 4kT \frac{\tan\delta}{C_E} \right\}^{1/2} \omega^{-1/2} \qquad \text{for } C_E >> C_A \tag{54.4}$$

where k is Boltzmann's constant, T is the absolute temperature, tanδ is the dielectric loss tangent of the detector material, C_E is the electrical capacitance of the element, and C_A is the input capacitance of the detector element amplifier.

The input radiation power required to give an output equal to the noise at a given frequency in unity bandwidth is known as the noise equivalent power (NEP). This is given by

$$NEP = V_n / R_v \tag{54.5}$$

where V_n is the total RMS voltage noise from all sources.

A performance figure of merit frequently used when discussing infrared detectors is the detectivity, usually designated as D^*. This is given by

$$D^* = A^{1/2}/NEP \tag{54.6}$$

Thus, the detectivity of a pyroelectric detector can be derived from Eqs. (54.3) to (54.6) and is given by

$$D^* = \frac{\eta d}{(4kT)^{1/2}} \cdot \frac{p}{c'(\epsilon\epsilon_o \tan\delta)^{1/2}} \cdot \frac{1}{\omega^{1/2}} \tag{54.7}$$

where c' is the volume specific heat, ϵ is the dielectric constant of the pyroelectric, and d is the thickness of the pyroelectric element. The roll-off in D^* at high frequencies is thus $1/\omega^{1/2}$.

Pyroelectric single-element IR detectors come in many different varieties. A typical commercial device will have the sensitive element made from a material of the type discussed in the next section, such as a piece of lithium tantalate crystal or a ferroelectric ceramic. The element size will be a few millimeters square. Typical performance figures at about 10 Hz would be a responsivity of a few hundred volts per watt of input radiation, a noise equivalent power of about 8×10^{-9} W/Hz$^{1/2}$, and a detectivity of about 2×10^8 cm Hz$^{1/2}$ W^{-1} for unity bandwidth. The detector can be fitted with a wide variety of windows, depending upon the wavelength of the radiation to be detected.

As noted above, pyroelectric devices have also been used for thermal imaging. In this application, their main advantage when compared with photon detector materials such as mercury cadmium telluride (CMT) (which are more sensitive) is that they can be used at room temperature. All the photon detectors require cooling, typically to 77 K. A very successful device for pyroelectric thermal imaging is the pyroelectric vidicon which uses a thin plate of pyroelectric material contained in a vacuum tube. The thermal image is focused onto the surface of the material using a germanium lens. This causes the formation of a pattern of pyroelectric charges, which are "read" by means of an electron beam. Typical sensitivities for such devices are between 0.50 and 1 K temperature differences in the scene for an f/1 lens. This compares with <0.10 K for a cooled CMT detector-based imager. Recently, a solid-state approach to pyroelectric thermal imaging has been developed. In this, an array of many thousands of very small identical detectors, each between 50 and 100 μm square, depending on the array design, are linked to a silicon amplifier/multiplexer circuit which allows the signals from all the elements to be read onto a single output line. These devices have been primarily developed for thermal imaging applications and excellent sensitivities (close to those achieved by many cooled systems) have been demonstrated.

54.4 Pyroelectric Materials and Their Selection

There are many different types of pyroelectrics and the selection of a material depends strongly upon the application. It is possible to formulate from the given equations a number of figures of merit which describe the contribution of the physical properties of a material to the performance of a device. For example, the current responsivity is proportional to F_i:

$$F_i = p/c' \tag{54.8}$$

TABLE 54.2 Pyroelectric Properties of Selected Materials

Material (Temperature)	Pyroelectric Coefficient P 10^{-4} cm^{-2} K^{-1}	Dielectric Properties (1 kHz) ϵ	tanδ	Volume-Specific Heat c' 10^{6} Jm^{-3} K^{-1}	Thermal Conductivity K 10^{-7} m^{2} s^{-1}	F_v m^{2} C^{-1}	F_D 10^{-5} Pa$^{-1/2}$	F_{vid} 10^{6} sC^{-1}
TGS (35°C)	5.5	55	0.025	2.6	3.3	0.43	6.1	1.3
DTGS (40°C)	5.5	43	0.020	2.4	3.3	0.60	8.3	1.8
PVDF polymer	0.27	12	0.015	2.43	0.62	0.10	0.88	1.6
$LiTaO_3$ crystal	2.3	47	0.005	3.2	13.0	0.17	4.9	0.13
Modified PZ ceramic	3.8	290	0.003	2.5		0.06	5.8	
Modified PT ceramic	3.8	220	0.011	2.5		0.08	3.3	

PZ = $PbZrO_3$, PT = $PbTiO_3$.

The voltage response for a pyroelectric element feeding into a high-input impedance, unity gain amplifier (such as a source follower FET) as shown in Fig. 54.1 is proportional to F_v:

$$F_v = p/c'\epsilon\epsilon_o \tag{54.9}$$

The detectivity is proportional to F_D:

$$F_D = p/\{c'(\epsilon\epsilon_o \tan\delta)^{1/2}\} \tag{54.10}$$

For the pyroelectric vidicon, thermal spreading of the pattern on the target is important and the relevant figure of merit is F_{vid}:

$$F_{vid} = F_v/K \tag{54.11}$$

where K is the thermal conductivity of the pyroelectric. It should be noted that the use of these merit figures must be tempered with a knowledge of the type of detector the material is to be used in. It is necessary, if possible, to match the capacitance of the detector to the input capacitance of the amplifier. Hence, low-permittivity materials are better suited to large-area detectors, and conversely arrays of small-area detectors are better served by materials with high permittivities.

Table 54.2 lists the pyroelectric properties of several different materials, single crystals, ceramics, and polymers. It can be seen that triglycine sulphate (TGS) and its deuterated isomorph (DTGS) exhibit the highest value of F_v and are frequently used for high-performance single-element detectors. These are the preferred materials for pyroelectric vidicon targets. However, they are water soluble, difficult to handle, and show poor long-term stability, both chemically and electrically, because of their low **Curie temperatures.** Furthermore, their dielectric loss is rather high, so that the F_D figures are not so favorable. Lithium tantalate, on the other hand, is an oxide single-crystal material which possesses a relatively low value of F_v but a very low loss so that F_D is favorable. The material is very stable and is now widely used for single-element detectors. Its thermal conductivity is quite high so that it is not a good material for the pyroelectric vidicon. The ferroelectric polymers possess relatively low pyroelectric coefficients and low dielectric constants with high losses, so that their figures of merit are also quite low. Their low thermal conductivities make them quite favorable for use in the pyroelectric vidicon and the fact that they are commercially available in thin sections (down to 6 μm) at low cost, removing any requirement for expensive lapping and polishing, makes them attractive for some low-cost detectors. Their low permittivities make them particularly well suited to large-area detectors.

The ceramic materials modified lead zirconate and modified lead titanate are interesting in that they possess high pyroelectric coefficients with relatively high permittivities and low losses. The modified lead zirconate is a solid solution of lead zirconate with lead iron niobate and lead titanate, with small additions of uranium as a stabilizing dopant. The use of uranium in this material minimizes the dielectric constant and loss (thus maximizing F_D) while also permitting control over the electrical resistivity, allowing the gate bias resistor in

Fig. 54.1 to be designed into the sensor element. The modified lead titanate is doped with calcium titanate and lead cobalt tungstate. The use of hot pressing in ceramic manufacture permits the fabrication of very low porosity material, which can be lapped and polished to very thin sections (as low as 20 μm) while being mechanically strong enough to be placed on a mount which provides support only over a small area, permitting the fabrication of detectors with maximum sensitivity. While the F_v values are relatively small in these materials, the F_D values are as good as most of the single-crystal materials. They are very well suited to small-area detectors because their high dielectric constants enable the element capacitance to be matched to that of the amplifier. Pyroelectric ceramics are now finding use in a wide range of the infrared detector market, from low-cost intruder alarms to high-value imaging arrays.

Recently, a new class of pyroelectric materials which use the effect in the region of T_c have been developed [Whatmore, 1991]. In these materials a bias field must be applied to stabilize the effect, but F_D values as high as 10 to 15 $\times$ 10^{-5} $Pa^{-1/2}$ have been recorded in such materials as barium strontium titanate or lead scandium tantalate, both perovskite ceramics. This mode of operation is usually called "dielectric bolometer."

Defining Terms

Coercive field (E_c): The field required to invert a sufficient proportion of the polarization of a body of a poled ferroelectric such that the net measurable external dipole moment is zero.

Curie temperature (T_c): The temperature at which the spontaneous polarization of a ferroelectric goes to zero.

Ferroelectric: A polar dielectric in which the crystallographic orientation of the internal dipole moment can be changed by the application of an electric field.

Paraelectric: The nonpolar phase into which the ferroelectric transforms above T_c, frequently called the paraelectric phase.

Piezoelectric: A material which possesses a noncentrosymmetric crystal structure which will generate charge on the application of a mechanical stress. As in the case of a pyroelectric, this can be detected as either a potential difference or as a charge flowing in an external circuit.

Pyroelectric: A polar dielectric material in which the internal dipole moment is temperature dependent. This leads to a change in the charge balance at the surface of the material which can be detected as either a potential difference or as a charge flowing in an external circuit.

Remanent polarization: The value to which the externally measured polarization of a ferroelectric body relaxes after it has been subjected to an electric field much greater than the coercive field, which is then removed.

Saturation polarization: The value to which the externally measured electrical dipole moment of a ferroelectric body tends when subjected to an external electrical field greater than the coercive field.

Spontaneous polarization: The value of the electrical dipole moment of a ferroelectric crystal due to the separation of positive and negative charges within the unit cell.

55.1 Introduction

Dielectrics are materials that are used primarily to isolate components electrically from each other or ground or to act as capacitive elements in devices, circuits, and systems. Their insulating properties are directly attributable to their large energy gap between the highest filled valence band and the conduction band. The number of electrons in the conduction band is extremely low, because the energy gap of a dielectric (5 to 7 eV) is sufficiently large to maintain most of the electrons trapped in the lower band. As a consequence, a dielectric, subjected to an electric field, will evince only an extremely small conduction or loss current; this current will be caused by the finite number of free electrons available in addition to other free charge carriers (ions) associated usually with contamination by electrolytic impurities as well as dipole orientation losses arising with polar molecules under ac conditions. Often the two latter effects will tend to obscure the miniscule contribution of the relatively few free electrons available. Unlike solids and liquids, vacuum and gases (in their nonionized state) approach the conditions of a perfect insulator—i.e., they exhibit virtually no detectable loss or leakage current.

Two fundamental parameters that characterize a dielectric material are its **conductivity** σ and the value of the real permittivity or dielectric constant ε'. By definition, σ is equal to the ratio of the leakage current density J_l to the applied electric field E,

$$\sigma = \frac{J_l}{E} \tag{55.1}$$

Since J_l is in A cm^{-2} and E in V cm^{-1}, the corresponding units of σ are in S cm^{-1} or Ω^{-1} cm^{-1}. Alternatively, when only mobile charge carriers of charge e and mobility μ, in cm^2 V^{-1} s^{-1}, with a concentration of n per cm^3 are involved, the conductivity may be expressed as

$$\sigma = e\mu n \tag{55.2}$$

The conductivity is usually determined in terms of the measured insulation resistance R in Ω; it is then given by $\sigma = d/RA$, where d is the insulation thickness in cm and A the surface area in cm^2. Most practical insulating materials have conductivities ranging from 10^{-6} to 10^{-20} S cm^{-1}. Often dielectrics may be classified in terms of their resistivity value ρ, which by definition is equal to the reciprocal of σ.

The real value of the permittivity or dielectric constant ε' is determined from the ratio

$$\varepsilon' = \frac{C}{C_o} \tag{55.3}$$

where C represents the measured capacitance in F and C_o is the equivalent capacitance *in vacuo,* which is calculated for the same specimen geometry from $C_o = \varepsilon_o A/d$; here ε_o denotes the permittivity *in vacuo* and is equal to 8.854×10^{-14} F cm^{-1} (8.854×10^{-12} F m^{-1} in SI units) or more conveniently to unity in the Gaussian CGS system. In practice, the value of ε_o in free space is essentially the same as that for a gas (e.g., for air, ε_o = 1.000536). The majority of liquid and solid dielectric materials, presently in use, have dielectric constants extending from approximately 2 to 10.

55.2 Dielectric Losses

Under ac conditions **dielectric losses** arise mainly from the movement of free charge carriers (electrons and ions), space charge polarization, and dipole orientation [Bartnikas and Eichhorn, 1983]. Ionic, space charge, and dipole losses are temperature- and frequency-dependent, a dependency which is reflected in the measured values of σ and ε'. This necessitates the introduction of a complex permittivity ε defined by

$$\varepsilon = \varepsilon' - j\varepsilon'' \tag{55.4}$$

where ε'' is the imaginary value of the permittivity, which is equal to σ/ω. Note that the conductivity σ determined under ac conditions may include the contributions of the dipole orientation, space charge, and ionic polarization losses in addition to that of the drift of free charge carriers (ions and electrons) which determine its dc value.

The complex permittivity, ε, is equal to the ratio of the dielectric displacement vector $\overline{D}$ to the electric field vector $\overline{E}$, i.e., $\varepsilon = \overline{D}/\overline{E}$. Since under ac conditions the appearance of a loss or leakage current is manifest as a phase angle difference δ between the $\overline{D}$ and $\overline{E}$ vectors, then in complex notation $\overline{D}$ and $\overline{E}$ may be expressed as $D_o \exp\,[j(\omega t - \delta)]$ and $E_o \exp[j\omega t]$, respectively, where ω is the radial frequency term, t the time, and D_o and E_o the respective magnitudes of the two vectors. From the relationship between $\overline{D}$ and $\overline{E}$, it follows that

$$\varepsilon' = \frac{D_o}{E_o} \cos\delta \tag{55.5}$$

and

$$\varepsilon'' = \frac{D_o}{E_o} \sin\delta \tag{55.6}$$

It is customary under ac conditions to assess the magnitude of loss of a given material in terms of the value of its **dissipation factor,** tanδ; it is apparent from Eqs. (55.5) and (55.6), that

$$\tan\delta = \frac{\varepsilon''}{\varepsilon'} = \frac{\sigma}{\omega\varepsilon'} \tag{55.7}$$

Examination of Eq. (55.7) suggests that the behavior of a dielectric material may also be described by means of an equivalent electrical circuit. It is most commonplace and expedient to use a parallel circuit representation, consisting of a capacitance C in parallel with a large resistance R as delineated in Fig. 55.1. Here C represents

the capacitance and R the resistance of the dielectric. For an applied voltage V across the dielectric, the leakage current is $I_l = V/R$ and the displacement current is $I_C = j\omega CV$; since $\tan\delta = I_l/I_C$, then

$$\tan\delta = \frac{1}{\omega RC} \tag{55.8}$$

It is to be emphasized that in Eq. (55.8), the quantities R and C are functions of temperature, frequency, and voltage. The equivalence between Eqs. (55.7) and (55.8) becomes more palpable if I_l and I_C are expressed as $\omega\varepsilon'' C_o V$ and $j\omega\varepsilon' C_o V$, respectively.

Every loss mechanism will exhibit its own characteristic $\tan\delta$ loss peak, centered at a particular absorption frequency, ω_o for a given test temperature. The loss behavior will be contingent upon the molecular structure of the material, its thickness, and homogeneity, and the temperature, frequency, and electric field range over which the measurements are performed [Bartnikas and Eichhorn, 1983]. For example, dipole orientation losses will be manifested only if the material contains permanent molecular or side-link dipoles; a considerable overlap may occur between the permanent dipole and ionic relaxation regions. Ionic relaxation losses occur in dielectric structures where ions are able to execute short-range jumps between two or more equilibrium positions. Interfacial or space charge polarization will arise with insulations of multilayered structures where the conductivity and permittivity is different for the individual strata or where one dielectric phase is interspersed in the matrix of another dielectric. Space charge traps also occur at crystalline-amorphous interfaces, crystal defects, and oxidation and localized C-H dipole sites in polymers. Alternatively, space charge losses will occur with mobile charge carriers whose movement becomes limited at the electrodes. This type of mechanism takes place often in thin-film dielectrics and exhibits a pronounced thickness effect. If the various losses are considered schematically on a logarithmic frequency scale at a given temperature, then the $\tan\delta$ and ε' values will appear as functions of frequency as delineated schematically in Fig. 55.2. For many materials the dipole and ionic relaxation losses tend to predominate over the frequency range extending from about 0.5 to 300 MHz, depending upon the molecular structure of the dielectric and temperature. For example, the absorption peak of an oil may occur at 1 MHz, while that of a much lower viscosity fluid such as water may appear at approximately 100 MHz. There is considerable overlap between the dipole and ionic relaxation loses, because the ionic jump distances are ordinarily of the same order of magnitude as the radii of the permanent dipoles. Space charge polarization losses manifest themselves normally over the low-frequency region extending from 10^{-6} Hz to 1 MHz and are characterized by very broad and intense peaks; this behavior is apparent from Eq. (55.7), which indicates that even small conductivities may lead to very large $\tan\delta$ values at very low frequencies. The nonrelaxation-type electronic conduction losses are readily perceptible over the low-frequency spectrum and decrease monotonically with frequency.

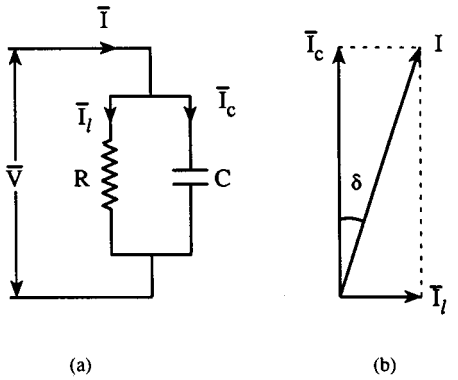

FIGURE 55.1 (a) Parallel equivalent RC circuit and (b) corresponding phasor diagram.

The dielectric loss behavior may be phenomenologically described by the Pellat-Debye equations, relating the imaginary and real values of the permittivity to the relaxation time, τ, of the loss process (i.e., the frequency at which the ε'' peak appears: $f_o = 1/2\ \pi\tau$), the low-frequency or static value of the real permittivity, ε_s, and the high- or optical-frequency value of the real permittivity, ε_∞. Thus, for a loss process characterized by a single relaxation time

$$\varepsilon' = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + \omega^2\tau^2} \tag{55.9}$$

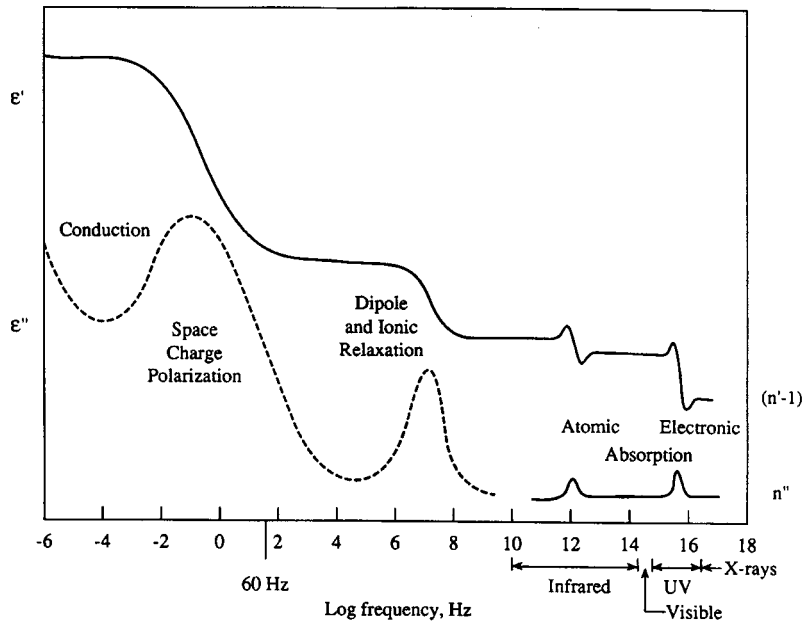

FIGURE 55.2 Schematic representation of different absorption regions [Bartnikas, 1987].

and

$$\varepsilon'' = \frac{(\varepsilon_s - \varepsilon_\infty)\omega\tau}{1 + \omega^2\tau^2} \tag{55.10}$$

In practice Eqs. (55.9) and (55.10) are modified due to a distribution in the relaxation times either because several different loss processes are involved or as a result of interaction or cooperative movement between the discrete dipoles or the trapped and detrapped charge carriers in their own particular environment. Since the relaxation processes are thermally activated, an increase in temperature will cause a displacement of the loss peak to higher frequencies. In the case of ionic and dipole relaxation, the relaxation time may be described by the relation

$$\tau = \frac{h}{kT}\exp\left[\frac{\Delta H}{RT}\right]\exp\left[-\frac{\Delta S}{R}\right] \tag{55.11}$$

where h is the Planck constant (6.624×10^{-34} J s^{-1}), k the Boltzmann constant (1.38×10^{-23} J K^{-1}), ΔH the activation energy of the relaxation process, R the universal gas constant (8.314×10^3 J K^{-1} kmol^{-1}), and ΔS the entropy of activation. For the ionic relaxation process, τ may alternatively be taken as equal to $1/2\Gamma$, where Γ denotes the ion jump probability between two equilibrium positions. Also for dipole orientation in liquids, τ may be approximately equated to the Debye term $\eta/4\pi r^3$T, where η represents the macroscopic viscosity of the liquid and r is the dipole radius [Bartnikas, 1994]. With interfacial or space charge polarization, which may arise due to a pile-up of charges at the interface of two contiguous dielectrics of different conductivity and permittivity, Eq. (55.10) must be rewritten as [von Hippel, 1956]

$$\varepsilon'' = \varepsilon_\infty\left(\frac{\tau}{\omega\tau_1\tau_2} + \frac{K\omega\tau}{1 + \omega^2\tau^2}\right) \tag{55.12}$$

where the Wagner absorption factor K is given by

$$K = \frac{(\tau_1 + \tau_2 - \tau)\tau - \tau_1\tau_2}{\tau_1\tau_2} \tag{55.13}$$

where τ_1 and τ_2 are the relaxation times of the two contiguous layers or strata of respective thicknesses d_1 and d_2; τ is the overall relaxation time of the two-layer combination and is defined by $\tau = (\varepsilon'_1\ d_2 + \varepsilon'_2\ d_1)/(\sigma_1 d_2 + \sigma_2 d_1)$, where ε'_1, ε'_2, σ_1, and σ_2 are the respective real permittivity and conductivity parameters of the two discrete layers. Note that since ε'_1 and ε'_2 are temperature- and frequency-dependent and σ_1 and σ_2 are, in addition, also voltage-dependent, the values of τ and ε'' will in turn also be influenced by these three variables. Space charge processes involving electrons are more effectively analyzed, using dc measurement techniques. If retrapping of electrons in polymers is neglected, then the decay current as a function of time t, arising from detrapped electrons, assumes the form [Watson, 1995]

$$i(t) = \frac{kT}{\nu t} n(E) \tag{55.14}$$

where n(E) is the trap density and ν is the attempt jump frequency of the electrons. The electron current displays the usual t^{-1} dependence and the plot of i(t)t versus kTln(νt) yields the distribution of trap depths. Eq. (55.14) represents an approximation, which underestimates the current associated with the shallow traps and overcompensates for the current due to the deep traps. The mobility of the free charge carriers is determined by the depth of the traps, the field resulting from the trapped charges, and the temperature. As elevated temperatures and low space charge fields, the mobility is proportional to exp[–ΔH/kT] and at low temperatures to $(T)^{1/4}$ [LeGressus and Blaise, 1992]. A high trapped charge density will create intense fields, which will in turn exert a controlling influence on the mobility and the charge distribution profile. In polymers, shallow traps are of the order of 0.5 to 0.9 eV and deep traps are ca. 1.0 to 1.5 eV, while the activation energies of dipole orientation and ionic conduction in solid and liquid dielectrics fall within the same range. It has been known that most charge trapping in the volume occurs in the vicinity of the electrodes; this can now be confirmed by measurement, using thermal and electrically stimulated acoustical pulse methods [Bernstein, 1992]. In the latter method this involves the application of a rapid voltage pulse across a dielectric specimen. The resulting stress wave propagates at the velocity of sound and is detected by a piezoelectric transducer. This wave is assumed not to disturb the trapped charge; the received electrical signal is then correlated with the acoustical wave to determine the profile of the trapped charge. Errors in the measurement would appear to be principally caused by the electrode surface charge effects and the inability to distinguish between the polarization of polar dipoles and that of the trapped charges [Wintle, 1990].

Temperature influences the real value of the permittivity or dielectric constant ε' insofar as it affects the density of the dielectric material. As the density diminishes with temperature, ε' falls with temperature in accordance with the Clausius-Mossotti equation

$$[P] = \frac{(\varepsilon' - 1)}{(\varepsilon' + 2)} \frac{M}{d_o} \tag{55.15}$$

where $[P]$ represents the polarization per mole, M the molar mass, d_o the density at a given temperature, and $\varepsilon' = \varepsilon_s$. Equation (55.14) is equally valid, if the substitution $\varepsilon' = (n')^2$ is made; here n' is the real value of the index of refraction. In fact, the latter provides a direct connection with the dielectric behavior at optical frequencies. In analogy with the complex permittivity, the index of refraction is also a complex quantity, and its imaginary value n'' exhibits a loss peak at the absorption frequencies; in contrast with the ε' value which can only fall with frequency, the real index of refraction n' exhibits an inflection-like behavior at the absorption frequency. This is illustrated schematically in Fig. 55.2, which depicts the kn' or n'' and $n' - 1$ values as a function of frequency over the optical frequency regime. The absorption in the infrared results from atomic

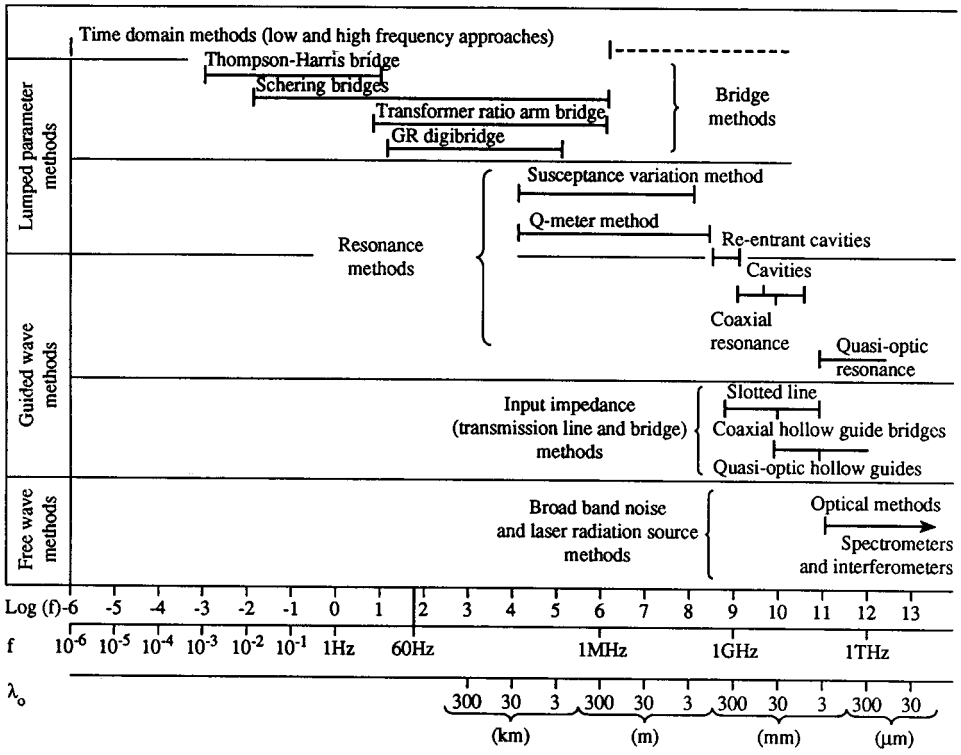

FIGURE 55.3 Frequency rangse of various dielectric test methods [Bartnikas, 1987].

resonance that arises from a displacement and vibration of atoms relative to each other, while an electronic resonance absorption effect occurs over the ultraviolet frequencies as a consequence of the electrons being forced to execute vibrations at the frequency of the external field.

The characterization of dielectric materials must be carried out in order to determine their properties for various applications over different parts of the electromagnetic frequency spectrum. There are many techniques and methods available for this purpose that are too numerous and detailed to attempt to present here even in a cursory manner. However, Fig. 55.3 portrays schematically the different test methods that are commonly used to carry out the characterization over the different frequencies up to and including the optical regime. A direct relationship exists between the time and frequency domain test methods via the Laplace transforms.

The frequency response of dielectrics at the more elevated frequencies is primarily of interest in the electrical communications field. In contradistinction for electrical power generation, transmission, and distribution, it is the low-frequency spectrum that constitutes the area of application. Also, the use of higher voltages in the electrical power area necessarily requires detailed knowledge of how the electrical losses vary as a function of the electrical field. Since most electrical power apparatus operates at a fixed frequency of 50 or 60 Hz, the main variable apart from the temperature is the applied or operating voltage. At power frequencies the dipole losses are generally very small and invariant with voltage up to the saturation fields which exceed substantially the operating fields, being in the order of 10^7 kV cm^{-1} or more. However, both the space charge polarization and ionic losses are highly field-dependent. As the electrical field is increased, ions of opposite sign are increasingly segregated; this hinders their recombination and, in effect, enhances the ion charge carrier concentration. As the dissociation rate of the ionic impurities is further augmented by temperature increases, combined rises in temperature and field may lead to appreciable dielectric loss. Thus, for example, for a thin liquid film bounded by two solids, tanδ increases with voltage until at some upper voltage value the physical boundaries begin to finally limit the amplitude of the ion excursions, at which point tanδ commences a downward trend with voltage (Böning–Garton effect). The interfacial or space charge polarization losses may evince a rather intricate field dependence, depending upon the manner in which the discrete conductivities of the contiguous media change

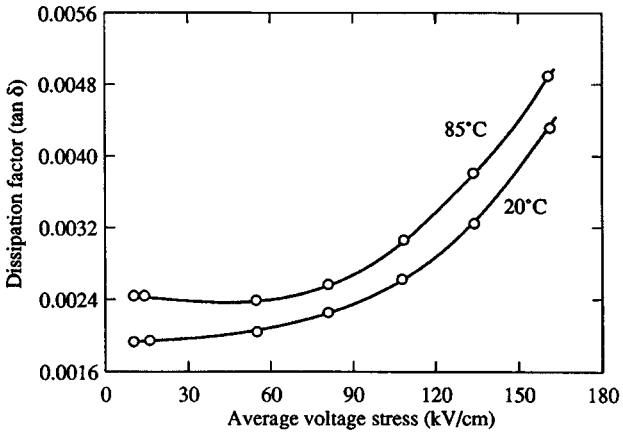

FIGURE 55.4 Loss characteristics of mineral oil-impregnated paper.

with applied voltage and temperature [as is apparent from the nature of Eqs. (55.12) and (55.13)]. The exact frequency value at which the space charge loss exhibits its maximum is contingent upon the value of the relaxation time τ. Figure 55.4 depicts typical tanδ versus applied voltage characteristics for an oil-impregnated paper-insulated cable model at two different temperatures, in which the loss behavior is primarily governed by ionic conduction and space charge effects. The monotonically rising dissipation factor with increasing applied voltage at room temperature is indicative of the predominating ionic loss mechanism, while at 85°C, an incipient decrease in tanδ is suggestive of space charge effects.

55.3 Dielectric Breakdown

As the voltage is increased across a dielectric material, a point is ultimately reached beyond which the insulation will no longer be capable of sustaining any further rise in voltage and breakdown will ensue, causing a short to develop between the electrodes. If the dielectric consists of a gas or liquid medium, the breakdown will be self-healing in the sense that the gas or liquid will support anew a reapplication of voltage until another breakdown recurs. In a solid dielectric, however, the initial breakdown will result in a formation of a permanent conductive channel, which cannot support a reapplication of voltage. The dielectric breakdown processes are distinctly different for the three states of matter.

In the case of solid dielectrics the breakdown is dependent not only upon the molecular structure and morphology of the solid but also upon extraneous variables such as the geometry of the material, the temperature, and the ambient environment. Since breakdown often occurs along some fault of the material, the breakdown voltage displays a readily perceptible decrease with area and thickness of the specimen due to increased incidence of faults over larger volumes. This is indeed part of the reason why thin-film inorganic dielectrics, which are normally evaluated using small-diameter dot counter electrodes, exhibit exceptionally high **dielectric strengths.** With large organic dielectric specimens, recessed electrodes are used to minimize electrode edge effects, leading to greatly elevated breakdown strengths in the order of 10^6 to 10^7 kV cm^{-1}, a range of values which is considered to represent the ultimate breakdown strength of the material or its intrinsic breakdown strength; as the intrinsic breakdown occurs in approximately 10^{-8} to 10^{-6} s, an electronic mechanism is implicated.

The breakdown strength under dc and impulse conditions tends to exceed that at ac fields, thereby suggesting the ac breakdown process may be partially of a thermal nature. An additional factor, which may lower the ac breakdown strength, is that associated with the occurrence of partial discharges either in void inclusions or at the electrode edges; this leads to breakdown values very much less than the intrinsic value. In practice, the breakdowns are generally of an extrinsic nature, and the intrinsic values are useful conceptually insofar as they provide an idea of an upper value that can be attained only under ideal conditions. The intrinsic breakdown theories were essentially developed for crystalline dielectrics, for which it was assumed that a very small number

of thermally activated electrons can be thermally excited to move from the valence to the conduction band and that under the influence of an external field they will be impelled to move in the direction of the field, colliding with the lattice of the crystalline dielectric and dissipating their energy by phonon interactions [Bartnikas and Eichhorn, 1983]. Accordingly, breakdown is said to occur when the average rate of energy gain by the electrons, $A(E, T, T_e, \xi)$, exceeds that lost in collisions with the lattice, $B(T, T_e, \xi)$. Hence, the breakdown criterion can be stated as

$$A(E, T, T_e, \xi) = B(T, T_e, \xi) \tag{55.16}$$

where E is the applied field, T the lattice temperature, T_e the electron temperature, and ξ an energy distribution constant. Thus in qualitative terms as the temperature is increased gradually, the breakdown voltage rises because the interaction between the electrons and the lattice is enhanced as a result of the increased thermal vibrations of the lattice. Ultimately, a critical temperature is attained where the electron–electron interactions surpass in importance those between the electrons and the lattice, and the breakdown strength commences a monotonic decline with temperature; this behavior is borne out in NaCl crystals, as is apparent from Fig. 55.5 [von Hippel and Lee, 1941]. However, with amorphous or partially crystalline polymers, as for example with polyethylene, the maximum in breakdown strength is seen to be absent and only a decrease is observed [Oakes, 1949]; as the crystalline content is increased in amorphous-crystalline solids, the breakdown strength is reduced.

The electron avalanche concept has also been applied to explain breakdown in solids, in particular to account for the observed decrease in breakdown strength with insulation thickness. Since breakdown due to electron avalanches involves the formation of space charge, space charges will tend to modify the conditions for breakdown. Any destabilization of the trapping and detrapping process, such as may be caused by a perturbation of the electrical field, will initiate the breakdown event [LeGressus and Blaise, 1992]. The detrapping of mobile charge carriers will be accompanied by photon emission and formation of the plasma breakdown channel, resulting in the dissipation of polarization energy. If dipole interaction is neglected, the polarization energy due to a trapped charge is of the order of 5χ eV, where χ is the dielectric susceptibility. The release of the polarization energy will be accompanied by electrical tree growth in and melting of the polymer.

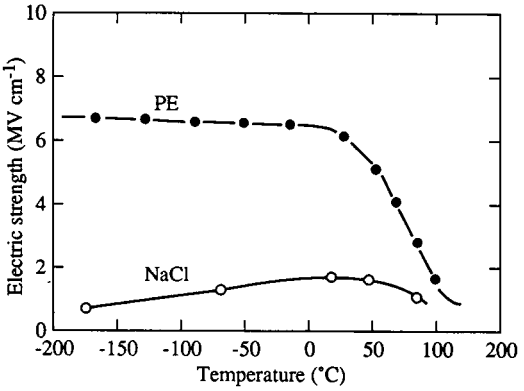

FIGURE 55.5 Dielectric breakdown characteristics of sodium chloride [von Hippel and Lee, 1941] and polyethylene [Oakes, 1949].

The breakdown process in gases is relatively well understood and is explained in terms of the avalanche theory. A free electron, occurring in a gas due to cosmic radiation, will be accelerated in a field and upon collision with neutral molecules in its trajectory will eject, if its energy is sufficient, other electrons that will in turn undergo additional collisions resulting in a production of more free electrons. If the electric field is sufficiently high, the number of free electrons will increase exponentially along the collision route until ultimately an electron avalanche will form. As the fast-moving electrons in the gap disappear into the anode, they leave behind the slower-moving ions, which gradually drift to the cathode where they liberate further electrons with a probability γ. When the height of the positive ion avalanche becomes sufficiently large to lead to a regeneration of a starting electron, the discharge mechanism becomes self-sustaining and a spark bridges the two electrodes. The condition for the Townsend breakdown in a short gap is given by

$$\gamma[\exp(\alpha d) - 1] = 1 \tag{55.17}$$

where d is the distance between the electrodes and α represents the number of ionizing impacts per electron per unit distance. The value of γ is also enhanced by photoemission at the cathode and photon radiation in

the gas volume by the metastable and excited gas atoms or molecules. In fact, in large gaps the breakdown is governed by steamer formation in which photon emission from the avalanches plays a dominant role. Breakdown characteristics of gases are represented graphically in terms of the Paschen curves, which are plots of the breakdown voltage as a function of the product of gas pressure p and the electrode separation d. Each gas is characterized by a well-defined minimum breakdown voltage at one particular value of the pd product.

The breakdown process in liquids is perhaps the least understood due to a lack of a satisfactory theory on the liquid state. The avalanche theory has been applied with limited success to explain the breakdown in liquids, by assuming that electrons injected from an electrode surface exchange energy with the atoms or molecules of the liquid, ultimately causing the atoms and molecules to ionize and thus precipitating breakdown. Recent investigations, utilizing electro-optical techniques, have demonstrated that breakdown involves steamers with tree- or bushlike structures that propagate from the electrodes [Bartnikas, 1994]. The negative streamers emerging from the cathode form due to electron emission, while positive steamers originating at the anode are due to free electrons in the liquid itself. The breakdown of liquids is noticeably affected by electrolytic impurities as well as water and oxygen content; also, macroscopic particles may form bridges between the electrodes along which electrons may hop with relative ease, resulting in a lower breakdown. As in solids, there is a volume effect and breakdown strength decreases with thickness; a slight increase in breakdown voltage is also observed with viscosity.

In both solid and liquid dielectrics, the breakdown strength under dc and impulse fields is markedly greater than that obtained under ac fields, thus suggesting that under ac conditions the breakdown may be partially thermal in nature. Thermal breakdown occurs at localized hot spots where the rate of heat generated exceeds that dissipated by the surrounding medium. The temperature at such hot spots continues to rise until it becomes sufficiently high to induce fusion and vaporization, causing eventually the development of a channel along which breakdown ensues between the opposite electrodes. Since a finite amount of time is required for the heat buildup to occur to lead to the thermal instability, thermally induced breakdown is contingent upon the time of the alternating voltage application and is thus implicated as the leading cause of breakdown in many dielectrics under long-term operating conditions. However, under some circumstances thermal instability may develop over a very short time; for example, some materials have been found to undergo thermal breakdown when subjected to very short repetitive voltage pulses. In low-loss dielectrics, such as polyethylene, the occurrence of thermal breakdown is highly improbable under low operating temperatures, while glasses with significant ionic content are more likely to fail thermally, particularly at higher frequencies.

The condition for thermal breakdown may be stated as

$$KA\,\Delta T/l = \omega\varepsilon' E^2 \tan\delta \tag{55.18}$$

where the left-hand side represents the heat transfer in J s^{-1} along a length l (cm) of sectional area A (cm^2) of the dielectric surface in the direction of the temperature gradient due to the temperature difference ΔT, in °C, such that the units of the thermal conductivity constant K are in J $°C^{-1}$ cm^{-1} s^{-1}. The right-hand side of Eq. (55.18) is equal to the dielectric loss dissipated in the dielectric in J s^{-1}, where E is the external field, ε' the real value of the permittivity, and $\tan\delta$ the dissipation factor at the radial frequency ω.

Other causes of extrinsic breakdown are associated with particular defects in the dielectric or with the environmental conditions under which the dielectric material is employed. For example, some dielectrics may contain gas-filled cavities that are inherent with the porous structure of the dielectric or that may be inadvertently introduced either during the manufacturing process or created under load cycling. If the operating electrical field is sufficiently elevated to cause the gas within the cavities to undergo discharge, the dielectric will be subjected to both physical and chemical degradation by the partial discharges; should the discharge process be sustained over a sufficiently long period, breakdown will eventually ensue.

With overhead line insulators or bushings of electrical equipment, breakdown may occur along the surface rather than in the bulk of the material. Insulator surfaces consisting of porcelain, glass, or polymeric materials (usually elastomers), may become contaminated by either industrial pollutants or salt spray near coastal areas, leading to surface tracking and breakdown below the normal flashover voltage. Surface tracking is enhanced in the presence of moisture, which increases the surface conductivity, particularly in the presence of ionic contaminants [Bartnikas, 1987]. The latter is measured in S or Ω^{-1} and must be distinguished from the volume

conductivity whose units are stated in S cm^{-1} or Ω^{-1} cm^{-1}. Surface tracking may be prevented by cleaning the surface and by applying silicone greases. When insulators are employed under a vacuum environment, charge accumulation will occur in the surface because the charged surface will no longer be able to discharge due to the finite breakdown strength of an ambient gas. Space charge will thus play a dominant role in the surface breakdown mechanism [Miller, 1993].

55.4 Insulation Aging

All insulating materials will undergo varying degrees of aging or deteriorating under normal operating conditions. The rate of aging will be contingent upon the magnitude of the electrical, thermal, and mechanical stresses to which the material is subjected; it will also be influenced by the composition and molecular structure of the material itself as well as the chemical, physical, and radiation environment under which the material must perform. The useful life of an insulating system will thus be determined by a given set and subset of aging variables. For example, the subset of variables in the voltage stress variable are the average and maximum values of the applied voltage, its frequency, and the recurrence rate of superposed impulse or transient voltage surges. For the thermal stress, the upper and lower ambient temperatures, the temperature gradient in the insulation, and the maximum permissible operating temperature constitute the subvariable set. Also, the character of the mechanical stress will differ, depending upon whether torsion, compression, or tension and bending are involved. Furthermore, the aging rate will be differently affected if all stresses (electrical, thermal, and mechanical) act simultaneously, separately, or in some predetermined sequence. The influence exerted on the aging rate by the environment will depend on whether the insulation system will be subjected to corrosive chemicals, petroleum fluids, water or high humidity, air or oxygen, ultraviolet radiation from the sun, and nuclear radiation. Organic insulations, in particular, may experience chemical degradation in the presence of oxygen. For example, polyethylene under temperature cycle will undergo both physical and chemical changes. These effects will be particularly acute at the emergency operating temperatures (90–130°C); at these temperatures partial or complete melting of the polymer will occur and the increased diffusion rate will permit the oxygen to migrate to a greater depth into the polymer. Ultimately the antioxidant will be consumed, resulting in an embrittlement of polymer and in extreme cases in the formation of macroscopic cracks. Subjection of the polymer to many repeated overload cycles will be accompanied by repeated melting and recrystallization of the polymer—a process that will inevitably cause the formation of cavities, which, when subjected to sufficiently high voltages, will undergo discharge, leading eventually to electrical breakdown.

There is a general consensus that electrically induced aging involves the mechanisms of treeing, partial discharge, and dielectric heating. Dielectric heating failures are more characteristic of lossy insulations or when highly conductive contaminants are involved. In the treeing mechanism, a distinction must be made between electrical and water trees [Bartnikas and Eichhorn, 1983]. The former refers to growth, resembling a tree, that occurs under dry conditions in the presence of an electric field; its branches or channels are hollow. In contrast, water trees require the presence of moisture, and their branches consist of fine filamentary channels, joining small cavities, all of which contain water; when placed in a dry environment, they eventually disappear. In a translucent dielectric, water trees are invisible and are rendered visible only when stained with a die, whereas electrical trees once formed remain readily discernible. Water trees are intrinsic to solid polymeric insulation, while electrical trees may occur in both solid and impregnated insulating systems. The actual failure path, when the breakdown current is limited to prevent destruction of evidence, invariably, even in liquids, consists of an electrical treelike structure.

Both electrical and water trees tend to propagate from electrical stress enhancement points, with water trees requiring appreciably lower stresses for their inception (ca. 2 kV/mm). Whereas the electrical tree mechanism usually involves partial discharges, the occurrence of the latter is conspicuously absent in water trees. The fact that water trees may bridge the opposite electrodes without precipitating failure infers a nonconductive nature of the filamentary channels or branches. Yet water trees are implicated in the overall degradation and aging process of the dielectric because of their presence in areas of failure as well as because of the often-observed phenomenon of an electrical tree emerging from some point along a water tree and causing abrupt failure.

The presence of voids or cavities within a solid or solid-liquid insulating system will almost invariably lead to eventual failure, with the proviso that the electrical field is sufficiently elevated to induce them to undergo

either continuous or regularly recurring, though at times intermittent, discharge. Electrical trees may readily ensue from charge injection sites adjacent to discharging cavity inclusions. The time required for electrical tree initiation may be defined quasi-empirically as [Fothergill et al., 1994],

$$t = \frac{N_c}{2bfn_o\left[\exp\left(\alpha l - 1\right)\right]} \tag{55.19}$$

where N_c denotes the critical number of impact ionizations necessary for tree channel formation, l is the avalanche or newly formed tree length, n_o is the number of initiating electrons and b is a constant dependent on the frequency, f. The deterioration rate due to partial discharges is proportional to the power dissipated P by the discharges, which may be expressed as [Bartnikas and McMahon, 1979]

$$P = \sum_{i=1}^{l} \sum_{j=1}^{m} n_{ij}\, \Delta Q_{ij}\, V_{ij} \tag{55.20}$$

where n_{ij} is the recurrence rate of the jth discharge in the ith cavity and ΔQ_{ij} is its corresponding charge release at an applied voltage V_{ij}. Under ac conditions the discharges will tend to recur regularly in each cycle due to the capacitative voltage division across the void. Under dc conditions the discharge rate will be controlled by the time constant required to recharge the cavity following a discharge. The physical damage arising from discharges consists of surface erosion and pitting and is caused by the ion and electron bombardment incident on the void's walls at a given discharge site. Chemical degradation results from molecular chain scission due to particle bombardment of the surface and the reactions between the ambient ionized gases and the gases released due to the molecular chain scission processes. The final chemical composition of the reaction product is generally varied, depending primarily on the molecular structure of the dielectric materials involved and the composition of the ambient ionized gases; one discharge degradation product common to many polymers exposed to discharges in air is that of oxalic acid. Oxalic acid, as a result of its elevated conductivity, when deposited upon the cavity's walls may change the nature of the discharge (e.g., from a spark to a glow type) or may even ultimately extinguish the discharge (i.e., replace the discharge loss by an I^2R-type loss along the cavity's walls).

A number of aging models have been propounded to predict insulation aging under different types of stress. However, there are essentially only two models whose usefulness has been substantiated in practice and which have, therefore, gained wide acceptance. One of these is Dakin's classical thermal degradation model, which is based upon the approach used in chemical reaction rate theory [Bartnikas, 1987],

$$t = A \exp[\Delta H/kT] \tag{55.21}$$

where t represents the time to breakdown, A is a constant, ΔH is the activation energy of the aging process, T is the absolute temperature, and k is the Boltzmann constant (1.38×10^{-23} J K^{-1}). If the log t versus $1/T$ plot represents a straight line that is obtained when the insulation aging is accelerated at various temperatures above the operating temperature, extrapolation of the line to the operating temperature may yield a rudimentary estimate of the aging time or the service life that can be anticipated from the insulation system when operated under normal temperature and load conditions. Deviations from straight-line behavior are indicative of more than one thermal aging mechanism; for example, a polymeric insulation will exhibit such behavior when thermally stressed beyond its melting or phase transition temperature.

Another extremely useful model, applicable to accelerated aging studies under electrical stress, is the so-called inverse power law relationship given by [Bartnikas, 1987]

$$t = BE^{-n} \tag{55.22}$$

where t is the time to breakdown under an electric stress E, B is a constant, and n is an exponent parameter. The relationship is essentially empirical in nature, and its proof of validity rests primarily on experiment and observation. It is found that a single type of electrically induced aging process will generally result in a straight-line relationship between log t and log E. Consequently, aging data obtained at higher electrical stresses with correspondingly shorter times to breakdown when extrapolated to longer times at stresses in the vicinity of the operating stress should yield the value of the effective service life under the operating stress. The slope of the line determines the exponent n, which constitutes an approximate indicator of the type of aging involved. For example, with polymer insulation water treeing ordinarily results in n values less than 4, while under conditions that may involve discharges and electrical trees, the n values may approach 10 or greater.

55.5 Dielectric Materials

Dielectric materials comprise a variety of solids, liquids, and gases. The breakdown strength generally increases with the density of the material so that dielectric solids tend to have higher dielectric strengths than gases. The same tendency is observed also with the dielectric loss and permittivity; for example, the dielectric losses in gases are virtually too small to be measurable and their dielectric constant in most practical applications can be considered as unity. In this section we will describe a number of the more common insulating materials in use.

Gases

The 60-Hz breakdown strength of a 1-cm gap of air at 25°C at atmospheric pressure is 31.7 kV cm^{-1}. Although this is a relatively low value, air is a most useful insulating medium for large electrode separations as is the case for overhead transmission lines. The only dielectric losses in the overhead lines are those due to corona discharges at the line conductor surfaces and leakage losses over the insulator surfaces. In addition, the highly reduced capacitance between the conductors of the lines ensures a small capacitance per unit length, thus rendering overhead lines an efficient means for transmitting large amounts of power over long distances. Nitrogen, which has a slightly higher breakdown strength (33.4 kV cm^{-1}) than air, has been used when compressed in low-loss gas-insulated capacitors. However, as air, which was also used in its compressed form in circuit breakers, it has been replaced by sulfur hexafluoride, SF_6. The breakdown strength of SF_6 is ca. 79.3 kV cm^{-1}. Since the outside metal casing of metal-clad circuit breakers is ordinarily grounded, it has become common practice to have much of the substation interconnected bus and interrupting switching equipment insulated with SF_6. To achieve higher breakdown strengths, the SF_6 gas is compressed at pressures on the order of 6 atm. The use of SF_6 in substation equipment has resulted in the saving of space and the elimination of line insulator pollution problems; however, its extensive usage has also posed some environmental concerns in regard to its flourine content.

The breakdown strength of gases is little affected with increasing frequency until the period of the wave becomes comparable to the transit time of the ions and, finally, electrons across the gap. At this point a substantial reduction in the breakdown strength is observed.

Insulating Liquids

Insulating liquids are rarely used by themselves and are intended for use mainly as impregnants with cellulose or synthetic papers. The 60-Hz breakdown strength of practical insulating liquids exceeds that of gases and for a 1-cm gap separation it is of the order of about 100 kV cm^{-1}. However, since the breakdown strength increases with decreasing gap length and as the oils are normally evaluated using a gap separation of 0.254 cm, the breakdown strengths normally cited range from approximately 138 to 240 kV cm^{-1}. The breakdown values are more influenced by the moisture and particle contents of the fluids than by their molecular structure (cf. Table 55.1).

Mineral oils have been extensively used in high-voltage electrical apparatus since the turn of the century. They constitute a category of hydrocarbon liquids that are obtained by refining petroleum crudes. Their composition consists of paraffinic, naphthenic, and aromatic constituents and is dependent upon the source of the crude as well as the refining procedure followed. The inclusion of the aromatic constituents is desirable

TABLE 55.1 Electrical Properties of a Number of Representative Insulating Liquids [Bartnikas, 1994; Encyclopedia Issue, 1972]

Liquid	Viscosity cSt (37.8°C)	Dielectric Constant (at 60 Hz, 25°C)	Dissipation Factor (at 60 Hz, 100°C)	Breakdown Strength, (kV cm–1)
Capacitor oil	21	2.2	0.001	>118
Pipe cable oil	170	2.15	0.001	>118
Self-contained cable oil	49.7	2.3	0.001	>118
Heavy cable oil	2365	2.23	0.001	>118
Transformer oil	9.75	2.25	0.001	>128
Alkyl benzene	6.0	2.1	0.0004	>138
Polybutene pipe cable oil	110 (SUS)	2.14 (at 1 MHz)	0.0003	>138
Polybutene capacitor oil	2200 (SUS at 100°C)	2.22 (at 1 MHz)	0.0005	>138
Silicone fluid	50	2.7	0.00015	>138
Castor oil	98 (100°C)	3.74	0.06	>138
$C_8F_{16}O$ fluorocarbon	0.64	1.86	<0.0005	>138

because of their gas absorption and oxidation characteristics. Mineral oils used for cable and transformer applications have low polar molecule contents and are characterized by dielectric constants extending from about 2.10 to 2.25 with dissipation factors generally between 2×10^{-5} and 6×10^{-5} at room temperature, depending upon their viscosity and molecular weight. Their dissipation factors increase appreciably at higher temperatures when the viscosities are reduced. Oils may deteriorate in service due to oxidation and moisture absorption. Filtering and treatment with Fullers' earth may improve their properties, but special care must be taken to ensure that the treatment process does not remove the aromatic constituents which are essential to maintaining the gas-absorption characteristics of the oil.

Alkyl benzenes are used as impregnants in high-voltage cables, often as substitutes of the low-viscosity mineral oils in self-contained oil-filled cables. They consist of alkyl chains attached to a benzene ring having the general formula $C_6H_5(CH_2)_nCH_3$; however, branched alkyl benzenes are also employed. Their electrical properties are comparable to those of mineral oils, and they exhibit good gas inhibition characteristics. Due to their detergent character, alkyl benzenes tend to be more susceptible to contamination than mineral oils.

Polybutenes are synthetic oils that are derived from the polymerization of olefins. Their long chains, with isobutene as the base unit, have methyl group side chains with molecular weights in the range from 300 to 1350. Their electrical properties are comparable to those of mineral oils; due to their low cost, they have been used as pipe cable filling oils. Higher viscosity polybutenes have been used as capacitor impregnants. Mixtures of polybutenes and alkyl benzenes have been used to obtain higher ac breakdown strength with impregnated paper systems. They are also compatible and miscible with mineral oils.

Since the discontinued use of the nonflammable polychlorinated biphenyls (PCBs), a number of unsaturated synthetic liquids have been developed for application to capacitors, where due to high stresses evolved gases may readily undergo partial discharge. Most of these new synthetic capacitor fluids are thus gas-absorbing low-molecular-weight derivatives of benzene, with permittivities ranging from 2.66 to 5.25 at room temperature (compared to 3.5 for PCBs). None of these fluids have the nonflammable characteristics of the PCBs; however, they do have high boiling points [Bartnikas, 1994].

Halogenated aliphatic hydrocarbons are derived by replacing the hydrogens by either chlorine or fluorine or both; they may also contain nitrogen and oxygen in their molecular structure. Their dielectric constants range from 1.8 to 3.0, the higher value reflecting some polarity due to molecular asymmetry as a result of branching. They have superior thermal properties to mineral oils and are highly flame-resistant. Fluorocarbons have been used in large power transformers, where both flammability and heat removal are of prime concern.

Silicone liquids consist of polymeric chains of silicon atoms alternating with oxygen atoms, with methyl side groups. For electrical applications, polydimethylsiloxane fluids are used, primarily for transformers as substitutes for the PCBs due to their inherently high flash and flammability points and reduced environmental concerns. They have lower tanδ values than mineral oils but somewhat higher dielectric constants because of their moderately polar nature. The viscosity of silicone fluids exhibits relatively little change with temperature, which is attributed to the ease of rotation about the Si–O–Si bond, thereby overcoming close packing of molecules and reducing intermolecular forces.

There are a large number of organic esters, but only a few are suitable for electrical applications. Their properties are adversely affected by hydrolysis, oxidation, and water content. Due to their reduced dielectric losses at elevated frequencies, they have been used in high-frequency capacitors. Castor oil has found specialized application in energy storage capacitors due to its exceptional resistance to partial discharges. The dielectric constants of esters are substantially higher than those for mineral oils.

Solid Insulating Materials

Solid insulating materials may be classified into two main categories, organic and inorganic. There are an extremely large number of solid insulants available, but in this section only the more commonly representative solid insulants will be considered.

Inorganic Solids

Below are described a number of the more prevalent inorganic dielectrics in use; their electrical and physical properties are listed in Table 55.2.

Alumina (Al_2O_3) is produced by heating aluminum hydroxide or oxyhydroxide; it is widely used as a filler for ceramic insulators. Further heating yields the corundum structure, which in its sapphire form is used for dielectric substrates in microcircuit applications.

Barium titanate ($BaTiO_3$) is an extraordinary dielectric in that below 120°C it behaves as a ferroelectric. That is, the electric displacement is both a function of the field as well as its previous history. Due to spontaneous polarization of the crystal, a dielectric hysteresis loop is generated. The dielectric constant is different in the x and z axis of the crystal (e.g., at 20°C, $\varepsilon' > 4000$ perpendicular to the z axis and $\varepsilon' < 300$ in the x-axis direction.

Porcelain is a multiphase ceramic material that is obtained by heating aluminum silicates until a mullite ($3Al_2O_3 \cdot 2SiO_2$) phase is formed. Since mullite is porous, its surface must be glazed with a high-melting-point glass to render it smooth and impervious and thus applicable for use in overhead line insulators. For high-frequency applications, low-loss single-phase ceramics, such as steatite ($3MgO \cdot 4SiO_2 \cdot H_2O$), are preferred.

Magnesium oxide (MgO) is a common inorganic insulating material, which due to its relatively high thermal conductivity is utilized for insulating heating elements in ovens. The resistance wire elements are placed concentrically within stainless steel tubes, with magnesium oxide packed around them to provide the insulation.

Electrical-grade glasses consist principally of SiO_2, B_2O_3, and P_2O_5 structures that are relatively open to permit ionic diffusion and migration. Consequently, glasses tend to be relatively lossy at high temperatures, though at low temperatures they are suitable for use in overhead line insulators and in transformer, capacitor, and circuit breaker bushings. At high temperatures, their main application lies with incandescent and fluorescent lamps as well as electronic tube envelopes.

Most of the mica used in electrical applications is of the muscovite [$KAl_2(OH)_2Si_3AlO_{10}$] type. Mica is a layer-type dielectric, and mica films are obtained by the splitting of mica blocks. The extended two-dimensionally layered strata of mica prevent the formation of conductive pathways across the mica, resulting in a high dielectric strength. It has excellent thermal stability and due to its inorganic nature is highly resistant to partial discharges. It is used in sheet, plate, and tape form in rotating machines and transformer coils. For example, a mica-epoxy composite is employed in stator bar insulation of rotating machines.

In metal-oxide-silicon (MOS) devices, the semiconductor surface is passivated by thermally growing a silicon dioxide, SiO_2, film (about 5000 Å) with the semiconductor silicon wafer exposed to an oxygen ambient at 1200°C. The resulting SiO_2 dielectric film has good adhesion properties, but due to its open glassy structure is not impervious to ionic impurities (primarily sodium). Accordingly, a denser film structure of silicon nitride, Si_3N_4, is formed in a reaction between silane and ammonia and is pyrolytically deposited on the SiO_2 layer.

TABLE 55.2 Electrical and Physical Properties of Some Common Solid Insulating Materials [Bartnikas and Eichhorn, 1983; Insulation Circuits, 1972]

Material	Specific Gravity	Maximum Operating Temperature (°C)	Dielectric Constant 20°C 60 Hz	Dielectric Constant 20°C 1 kHz	Dielectric Constant 20°C 1 MHz	Dissipation Factor 20°C 60 Hz	Dissipation Factor 20°C 1 kHz	Dissipation Factor 20°C 1 MHz	AC Dielectric Strength (kV cm–1)
Alumina (Al_2O_3)	3.1–3.9	1950	8.5	8.5	8.5	1×10^{-3}	1×10^{-3}	1×10^{-3}	98–157
Porcelain (mullite)	2.3–2.5	1000	8.2	8.2	8.2	1.4×10^{-3}	5.7×10^{-4}	2×10^{-4}	94–157

Glass-reinforced polyester premix	1.8–2.3	265	5.3–7.3		5.0−6.4	$1–4 \times 10^{-2}$		$0.8–2.2 \times 10^{-2}$	90.6–158
Thermoplastic polyester	1.31–1.58	250	3.3–3.8 (100 Hz)			$1.5–2.0 \times 10^{-3}$			232–295
Polyimide polyester	1.43–1.49	480°F		3.4 (100 kHz)			$1–5 \times 10^{-3}$ (100 kHz)		220
Polycarbonate	1.20	215	3.17		2.96	9×10^{-4}		1×10^{-2}	157
Epoxy (with mineral filler)	1.6–1.9	200 (decomposition temperature)	4.4–5.6	4.2–4.9	4.1–4.6	$1.1–8.3 \times 10^{-2}$	$0.19–1.4 \times 10^{-1}$	$0.13–1.4 \times 10^{-1}$	98.4–158
Epoxy (with silica filler)	1.6–2.0	200 (decomposition temperature)	3.2–4.5	3.2–4.0	3.0–3.8	$0.8–3.0 \times 10^{-2}$	$0.8–3.0 \times 10^{-2}$	$2–4 \times 10^{-2}$	158–217
Silicone rubber	1.1–1.5	700°F	3.3–4.0		3.1–3.7	$1.5–3.0 \times 10^{-2}$		$3.0–5.0 \times 10^{-3}$	158–197

The thin film of Si_3N_4 is characterized by extremely low losses, and its relatively closed structure does not provide any latitude for free sodium movement, thereby providing complete passivation of the semiconductor device. The high dielectric strength of the double film layer of SiO_2 and Si_3N_4 renders it dielectrically effective in field-effect transistor (FET) applications.

In integrated circuit devices, a number of materials are suitable for thin-film capacitor applications. In addition to Al_2O_3, tantalum pentoxide, Ta_2O_5, has been extensively utilized. It is characterized by high-temperature stability and is resistant to acids with the exception of hydrofluoric acid (HF). The high dielectric constant material hafnia (HfO_2) has also been used in thin-film capacitors.

Organic Solids

Solid organic dielectrics consist of large polymer molecules, which generally have molecular weights in excess of 600. Primarily, with the exception of paper, which consists of cellulose that is comprised of a series of glucose units, organic dielectric materials are synthetically derived.

Polyethylene (PE) is perhaps one of the most common solid dielectrics, which is extensively used as a solid dielectric extruded insulant in power and communication cables. Linear PE is classified as a low- (0.910–0.925), medium- (0.926–0.940), or high- (0.941–0.965) density polymer (cf. Table 55.2). Since PE is essentially a long-chain hydrocarbon material in which the repeat unit is $–CH_2–CH_2–$, a low-density PE necessarily implies a high degree of branching. Decreased branching increases the crystallinity as molecules undergo internal folding, which leads to improved stiffness, tear strength, hardness, and chemical resistance. Cross linking of PE produces a thermosetting polymer with a superior temperature rating, improved tensile strength, and an enhanced resistance to partial discharges. Most of the PE used on extruded cables is of the cross-linked polyethylene (XLPE) type.

Ethylene-propylene rubber (EPR) is an amorphous elastomer, which is synthesized from ethylene and propylene. As an extrudent on cables its composition has filler contents up to 50%, comprising primarily clay, with smaller amounts of added silicate and carbon black. The dielectric losses are appreciably enhanced by the fillers, and, consequently, EPR is not suitable for extra-high-voltage applications, with its use being usually confined to lower and intermediate voltages (≤138 kV) and also where high cable flexibility due to its rubber properties may be additionally desired.

Polypropylene has a structure related to that of ethylene with one added methyl group. It is a thermoplastic material having properties similar to high-density PE, though due to its lower density it has also a lower dielectric constant. It has many electrical applications both in bulk form as in molded and extruded insulations as well as in film form in taped capacitor, transformer, and cable insulations.

Polytetrafluoroethylene (PTFE) or Teflon is a fully fluorinated version of PE, having a repeat unit of $[–CF_2–CF_2–]$. It is characterized by a low dielectric constant, extremely low losses, and has excellent temperature stability and is resistive to chemical degradation. It has been extensively used in specialized applications on insulators, wires and cables, transformers, motors, and generators. Its relatively high cost is attributable to both the higher cost of the fluorinated monomers as well as the specialized fabrication techniques required.

Polyesters are obtained most commonly by reacting a dialcohol with a diester; they may be either thermosetting or thermoplastic. The former are usually employed in glass laminates and glass-fiber-reinforced moldings, while thermoplastic polyesters are used for injection-molding applications. They are used in small and large electrical apparatus as well as in electronic applications.

Polyimides (kaptons), as nylons (polyamides), have nitrogen in their molecular structure. They constitute a class of high-temperature thermoplastics that may be exposed to continuous operation at 480°F. When glass-reinforced, they may be exposed to temperatures as high as 700°F; they are used in molded, extruded wire, and film form.

Polycarbonates are thermoplastics that are closely related to polyesters. They are primarily employed in the insulation of electrically powered tools and in the casings of electrical appliances. Polycarbonates may be either compression- or injection-molded and extruded as films or sheets.

Epoxy resins are prepared from an epoxide monomer. The first step involves a reaction between two comonomers, and in the subsequent step the prepolymer is cured by means of a cross-linking agent. Epoxy resins are characterized by low shrinkage and high mechanical strength; they may be reinforced with glass fibers and mixed with mica flakes. Epoxy resins have many applications such as, for example, for insulation of bars in the stators of rotating machines, solid-type transformers, and spacers for compressed-gas-insulated busbars and cables.

TABLE 55.3 Electrical Properties of Taped Solid-Liquid Insulations

Tape	Impregnating Liquid	Average Voltage Stress (kV cm^{-1})	tanδ at Room Temperature	tanδ at Operating Temperature
Kraft paper	Mineral oil	180	3.8×10^{-3} at 23°C	5.7×10^{-3} at 85°C
Kraft paper	Silicone liquid	180	2.7×10^{-3} at 23°C	3.1×10^{-3} at 85°C
Paper-polypropylene-paper (PPP)	Dodecyl benzene	180	9.8×10^{-4} at 18°C	9.9×10^{-4} at 100°C
Kraft paper	Polybutene	180	2.0×10^{-3} at 25°C	2.0×10^{-3} at 85°C

Silicone rubber is classified as an organic-inorganic elastomer, which is obtained from the polymerization of organic siloxanes. They are composed of dimethyl-siloxane repeat units, $(CH_3)_2SiO$–, with the side groups being methyl units. Fillers are added to obtain the desired silicone rubber compounds; cross linking is carried out with peroxides. Since no softeners and plasticizers are required, silicone rubbers are resistant to embrittlement and may be employed for low- temperature applications down to –120°F. Continuous operation is possible up to 500°F, with intermittent usage as high as 700°F.

Solid-Liquid Insulating Systems

Impregnated-paper insulation constitutes one of the earliest insulating systems employed in electrical power apparatus and cables. Although in some applications alternate solid- or compressed-gas insulating systems are now being used, the impregnated-paper system still constitutes one of the most reliable insulating systems available. Proper impregnation of the paper results in a cavity-free insulating system, thereby eliminating the occurrence of partial discharges that inevitably lead to deterioration and breakdown of the insulating system. The cellulose structure of paper has a finite acidity content as well as a residual colloidal or bound water, which is held by hydrogen bonds. Consequently, impregnated cellulose base papers are characterized by somewhat more elevated tanδ values in the order of 2×10^{-3} at 30 kV cm^{-1}. The liquid impregnants employed are either mineral oils or synthetic fluids. Since the dielectric constant of these fluids is normally about 2.2 and that of dried cellulose about 6.5–10, the resulting dielectric constant of the impregnated paper is approximately 3.1–3.5.

Lower-density cellulose papers have slightly lower dielectric losses, but the dielectric breakdown strength is also reduced. The converse is true for impregnated systems utilizing higher-density papers. The general chemical formula of cellulose paper is $C_{12}H_{20}O_{10}$. If the paper is heated beyond 200°C, the chemical structure of the paper breaks down even in the absence of external oxygen, since the latter is readily available from within the cellulose molecule. To avert this process from occurring, cellulose papers are ordinarily not used beyond 100°C.

In an attempt to reduce the dielectric losses in solid-liquid systems, cellulose papers have been substituted in some applications by synthetic papers (cf. Table 55.3). For example in extra-high-voltage cables, cellulose paper–polypropylene composite tapes have been employed. A partial paper content in the composite tapes is necessary both to retain some of the impregnation capability of a porous cellulose paper medium and to maintain the relative ease of cellulose-to-cellulose tape sliding capability upon bending. In transformers the synthetic nylon or polyamide paper (nomex) has been used both in film and board form. It may be continuously operated at temperatures up to 220°C.

Defining Terms

Conductivity σ: Represents the ratio of the leakage current density to the applied electric field density. In general its ac and dc values differ because the mechanisms for establishing the leakage current in the two cases are not necessarily identical.

Dielectric: A material in which nearly all or a large portion of the energy required for its charging can be recovered when the external electric field is removed.

Dielectric constant ε': A quantity that determines the amount of electrostatic energy which can be stored per unit volume per unit potential gradient. It is a real quantity and in Gaussian–CGS units is numerically equal to the ratio of the measured capacitance of the specimen, C, to the equivalent geometrical capacitance *in vacuo,* C_o. It is also commonly referred to as the real value of the permittivity. Note that when the SI system of units is employed, the ratio C/C_o defines the real value of the *relative permittivity* ε'_r.

Dielectric loss: The rate at which the electrical energy supplied to a dielectric material by an alternating electrical field is changed to heat.

Dielectric strength: Represents the value of the externally applied electric field at which breakdown or failure of the dielectric takes place. Unless a completely uniform field gradient can be assured across the dielectric specimen, the resulting breakdown value will be a function of the specimen thickness and the test electrode geometry; this value will be substantially below that of the intrinsic breakdown strength.

Dissipation factor (**tanδ**): Equal to the tangent of the loss angle δ, which is the phase angle between the external electric field vector $\overline{E}$ and the resulting displacement vector $\overline{D}$. It is numerically equal to the ratio of the imaginary permittivity ε'' to the real permittivity, ε'; alternatively, it is defined by the ratio of the leakage current to the displacement (charging or capacitive) current.

56.1 Introduction

Sensors are critical components in all measurement and control systems. The need for computer-compatible sensors closely followed the advent of the microprocessor. Together with the always-present need for sensors in science and medicine, the demand for sensors in automated manufacturing and processing is rapidly growing. In addition, small, inexpensive sensors are finding their way into all sorts of consumer products, from childrens' toys to dishwashers to automobiles. Because of the vast variety of useful things to be sensed and sensor applications, sensor engineering is a multidisciplinary and interdisciplinary field of endeavor. This chapter introduces some basic definitions, concepts, and features of sensors and illustrates them with several examples. The reader is directed to the references and the sources listed under "Further Information" for more details and examples.

There are many terms which are often used synonymously for sensor, including transducer, meter, detector, and gage. Defining the term sensor is not an easy task; however the most widely used definition is that which has been applied to electrical transducers by the Instrument Society of America (ANSI MC6.1, 1975): *Transducer—A device which provides a usable output in response to a specified measurand.* A transducer is more generally defined as a device which converts energy from one form to another. A usable ouput refers to an optical, electrical, or mechanical signal. In the context of electrical engineering, however, a usable output refers to an electrical output signal. The measurand can be a physical, chemical, or biological property or condition to be measured.

Most, but not all, sensors are transducers, employing one or more transduction mechanisms to produce an electrical output signal. Sometimes sensors are classified as direct and indirect sensors according to how many transduction mechanisms are used. For example, a mercury thermometer produces a change in volume of mercury in response to a temperature change via thermal expansion, but the output is a mechanical displacement and not an electrical signal. Another transduction mechanism is required. A thermometer is still a useful sensor since humans can read the change in mercury height using their eyes as the second transducing element. However, in order to produce an electrical output for use in a control loop, the height of the mercury would have to be converted to an electrical signal. This could be accomplished using capacitive effects. However, there are more direct temperature sensing methods, i.e., one where an electrical output is produced in response to a change in temperature. An example is given in the next section on physical sensors. Figure 56.1 depicts a

sensor block diagram identifying the measurand and associated input signal, the primary and intermediate transduction mechanisms, and the electronic output signal. Active sensors require an external power source in order to produce a usable output signal, e.g., the piezoresistor. Table 56.1 is a 6×6 matrix of the more commonly employed physical and chemical transduction mechanisms. Many of the effects listed are described in more detail in this handbook (see Chapters 53–58).

In choosing a particular sensor for a given application, there are many factors to be considered. These deciding factors or specifications can be divided into three major categories: environmental factors, economic factors, and the sensor characteristics. The most commonly encountered factors are listed in Table 56.2, although not all of these factors may be pertinent to a particular application. Most of the environmental factors determine the packaging of the sensor, with packaging meaning the encapsulation or insulation which provides protection and isolation and the input/output leads or connections and cabling. The economic factors determine the type of manufacturing and materials used in the sensor and to some extent the quality of the materials (with respect to lifetime). For example, a very expensive sensor may be cost effective if it is used repeatedly or for very long periods of time. On the other hand, a disposable sensor, such as is desired in many medical applications, should be inexpensive. The sensor characteristics of the sensor are usually the specifications of primary concern. The most important parameters are **sensitivity, stability,** and **repeatability.** Normally, a sensor is only useful if all three of these parameters are tightly specified for a given range of measurand and time of operation. For example, a highly sensitive device is not useful if its output signal drifts greatly during the measurement time and the data obtained is not reliable if the measurement is not repeatable. Other output characteristics, such as selectivity and linearity, can often be compensated for by using additional, independent sensor input or with signal conditioning circuits. In fact, most sensors have a response to temperature, since most tranducing effects are temperature dependent.

Sensors are most often classified by the type of measurand, i.e., physical, chemical, or biological. This is a much simpler means of classification than by transduction mechanism or output signal (e.g., digital or analog), since many sensors use multiple transduction mechanisms and the output signal can always be processed, conditioned, or converted by a circuit so as to cloud the definition of output. A description of each class and examples are given in the following sections. The last section introduces microsensors and gives some examples.

TABLE 56.2

Environmental Factors	Economic Factors	Sensor Characteristics
Temperature range	Cost	Sensitivity
Humidity effects	Availability	Range
Corrosion	Lifetime	Stability
Size		Repeatability

Susceptibility to EM interferences		Error
Ruggedness		Response time
Power consumption		Frequency response
Self-test capability		

56.2 Physical Sensors

Physical measurands include temperature, strain, force, pressure, displacement, position, velocity, acceleration, optical radiation, sound, flow rate, viscosity, and electromagnetic fields. Referring to Table 56.1, all but those transduction mechanisms listed in the chemical column are used in the design of physical sensors. Clearly, they comprise a very large proportion of all sensors. It is impossible to illustrate all of them, but three measurands stand out in terms of their widespread application: temperature, displacement (or associated force), and optical radiation.

Temperature Sensors

Temperature is an important parameter in many control systems, most familiarly in environmental control systems. Several distinctly different transduction mechanisms have been employed. The mercury thermometer was mentioned in the Introduction as a nonelectrical sensor. The most commonly used electrical temperature sensors are thermocouples, thermistors, and resistance thermometers. Thermocouples employ the Seebeck effect, which occurs at the junction of two dissimilar metal wires. A voltage difference is generated at the hot junction due to the difference in the energy distribution of thermally energized electrons in each metal. This voltage is measured across the cool ends of the two wires and changes linearly with temperature over a given range, depending on the choice of metals. To minimize measurement error the cool end of the couple must be kept at a constant temperature, and the voltmeter must have a high input impedance.

The resistance thermometer relies on the increase in resistance of a metal wire with increasing temperature. As the electrons in the metal gain thermal energy, they move about more rapidly and undergo more frequent collisions with each other and the atomic nuclei. These scattering events reduce the mobility of the electrons, and since resistance is inversely proportional to mobility, the resistance increases. Resistance thermometers consist of a coil of fine metal wire. Platinum wire gives the largest linear range of operation. To determine the resistance indirectly, a constant current is supplied and the voltage is measured. A direct measurement can be made by placing the resistor in the sensing arm of a Wheatstone bridge and adjusting the opposing resistor to "balance" the bridge, which produces a null output. A measure of the sensitivity of a resistance thermometer is its temperature coefficient of resistance: TCR = $(\Delta R/R)(1/\Delta T)$ in units of % resistance per degree of temperature.

Thermistors are resistive elements made of semiconductor materials and have a negative coefficient of resistance. The mechanism governing the resistance change of a thermistor is the increase in the number of conducting electrons with an increase in temperature due to thermal generation, i.e., the electrons which are the least tightly bound to the nucleus (valence electrons) gain sufficient thermal energy to break away and become influenced by external fields. Thermistors can be measured in the same manner as resistance thermometers, but thermistors have up to 100 times higher TCR values.

Displacement and Force

Many types of forces are sensed by the displacements they create. For example, the force due to acceleration of a mass at the end of a spring will cause the spring to stretch and the mass to move. Its displacement from the zero acceleration position is governed by the force generated by the acceleration ($F = m \cdot a$) and the restoring force of the spring. Another example is the displacement of the center of a deformable membrane due to a difference in pressure across it. Both of these examples use multiple transduction mechanisms to produce an electronic output: a primary mechanism which converts force to displacement (mechanical to mechanical) and then an intermediate mechanism to convert displacement to an electrical signal (mechanical to electrical).

Displacement can be measured by an associated capacitance. For example, the capacitance associated with a gap which is changing in length is given by C = area × dielectric constant/gap length. The gap must be very small compared to the surface area of the capacitor, since most dielectric constants are of the order of 1×10^{-13} farads/cm and with present methods, capacitance is readily resolvable to only about 10^{-12} farads. This is because measurement leads and contacts create parasitic capacitances the same order of magnitude. If the capacitance is measured at the generated site by an integrated circuit (see Section III), capacitances as small as 10^{-15} farads

can be measured. Displacement is also commonly measured by the movement of a ferromagnetic core inside of an inductor coil. The displacement produces a change in inductance which can be measured by placing the inductor in an oscillator circuit and measuring the change in frequency of oscillation.

The most commonly used force sensor is the strain gage. It consists of metal wires which are stretched in response to a force. The resistance of the wire changes as it undergoes strain, i.e., a change in length, since the resistance of a wire is R = resistivity × length/cross-sectional area. The wire's resistivity is a bulk property of the metal which is a constant for constant temperature. For example, a strain gage can be used to measure acceleration by attaching both ends of the wire to a cantilever beam, with one end of the wire at the attached beam end and the other at the free end. The cantilever beam free end moves in response to an applied force, such as the force due to acceleration which produces strain in the wire and a subsequent change in resistance. The sensitivity of a strain gage is described by the unitless gage factor, $G = (\Delta R/R)/(\Delta L/L)$. For metal wires, gage factors typically range from 2 to 3. Semiconductors are known to exhibit piezoresistivity, which is a change in resistance in response to strain which involves a large change in resistivity in addition to the change in linear dimension. Piezoresistors have gage factors as high as 130. Piezoresistive strain gages are frequently used in **microsensors,** described in Section 56.5.

Optical Radiation

The intensity and frequency of optical radiation are parameters of growing interest and utility in consumer products such as the video camera and home security systems and in optical communications systems. The conversion of optical energy to electronic signals can be accomplished by several mechanisms (see radiant to electronic transduction in Table 56.1); however, the most commonly used is the photogeneration of carriers in semiconductors. The most often-used device is the *p-n* junction photodiode (Section III). The construction of this device is very similar to the diodes used in electronic circuits as rectifiers. The diode is operated in reverse bias, where very little current normally flows. When light is incident on the structure and is absorbed in the semiconductor, energetic electrons are produced. These electrons flow in response to the electric field sustained internally across the junction, producing an externally measurable current. The current magnitude is proportional to the light intensity and also depends on the frequency of the light. Figure 56.2 shows the effects of varying incident optical intensity on the terminal current versus voltage behavior of a *p-n* junction. Note that for zero applied voltage, a net negative current flows when the junction is illuminated. This device can therefore also be a source of power (a solar cell).

56.3 Chemical Sensors

Chemical measurands include ion concentration, chemical composition, rate of reactions, reduction-oxidation potentials, and gas concentration. The last column of Table 56.1 lists some of the transduction mechanisms that have been, or could be, employed in chemical sensing. Two examples of chemical sensors are described

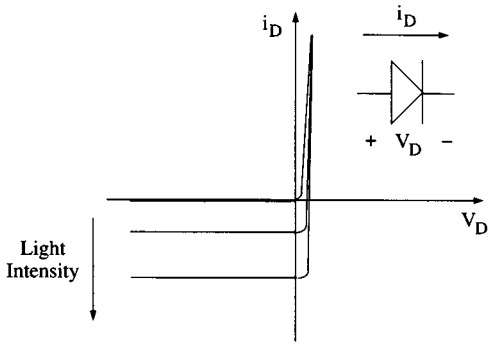

FIGURE 56.2 Sketch of the variation of current versus voltage characteristics of a *p-n* photodiode with incident light intensity.

here: the ion-selective electrode (ISE) and the gas chromatograph. They were chosen because of their general use and availability and because they illustrate the use of a primary (ISE) versus a primary plus intermediate (gas chromatograph) transduction mechanism.

Ion-Selective Electrode (ISE)

As the name implies, ISEs are used to measure the concentration of a specific ion concentration in a solution of many ions. To accomplish this, a membrane which selectively generates a potential which is dependent on the concentration of the ion of interest is used. The generated potential is usually an equilibrium potential, called the Nernst potential, and develops across the interface of the membrane with the solution. This potential is generated by the initial net flow of ions (charge) across the membrane in response to a concentration gradient, and from thence forth the diffusional force is balanced by the generated electric force and equilibrium is established. This is very similar to the so-called built-in potential of a *p-n* junction diode. The ion-selective membrane acts in such a way as to ensure that the generated potential is dependent mostly on the ion of interest and negligibly on any other ions in solution. This is done by enhancing the exchange rate of the ion of interest across the membrane, so it is the fastest moving and, therefore, the species which generates and maintains the potential.

The most familiar ISE is the pH electrode. In this device the membrane is a sodium glass which possesses a high exchange rate for H^+. The generated Nernst potential, E, is given by the expression: $E = E_0 + (RT/F) \ln[H^+]$, where E_0 is a constant for constant temperature, R is the gas constant, and F is the Faraday constant. pH is defined as the negative of the $\log[H^+]$; therefore $\text{pH} = (E_0 - E)(\log e)F/RT$. One pH unit change corresponds to a tenfold change in the molar concentration of H^+ and a 59 mV change in the Nernst potential at room temperature. Other ISEs have the same type of response, but specific to a different ion, depending on the choice of membrane. Many ISEs employ ionophores trapped inside of a polymeric membrane. An ionophore is a molecule which selectively and reversibly binds with an ion and thereby creates a high exchange rate for that particular ion.

The ISE consists of a glass tube with the ion-selective membrane closing that end of the tube which is immersed into the test solution. The Nernst potential is measured by making electrical contact to each side of the membrane. This is done by placing a fixed concentration of conductive filling solution inside of the tube and placing a wire into the solution. The other side of the membrane is contacted by a reference electrode placed inside of the same solution under test. The reference electrode is constructed in the same manner as the ISE but it has a porous membrane which creates a liquid junction between its inner filling solution and the test solution. That junction is designed to have a potential which is invariant with changes in concentration of any ion in the test solution. The reference electrode, solution under test, and the ISE form an electrochemical cell. The reference electrode potential acts like the ground reference in electric circuits, and the ISE potential is measured between the two wires emerging from the respective two electrodes. The details of the mechanisms of transduction in ISEs are beyond the scope of this chapter. The reader is referred to Bard and Faulkner [1980] and Janata [1989].

Gas Chromatograph

Molecules in gases have thermal conductivities which are dependent on their masses; therefore, a pure gas can be identified by its thermal conductivity. One way to determine the composition of a gas is to first separate it into its components and then measure the thermal conductivity of each. A gas chromatograph does exactly that. The gas flows through a long narrow column, which is packed with an adsorbant solid (for gas–solid chromatography) wherein the gases are separated according to the retentive properties of the packing material for each gas. As the individual gases exit the end of the tube one at a time, they flow over a heated wire. The amount of heat transferred to the gas depends on its thermal conductivity. The gas temperature is measured a short distance downstream and compared to a known gas flowing in a separate sensing tube. The temperature is related to the amount of heat transferred and can be used to derive the thermal conductivity according to thermodynamic theory and empirical data. This sensor required two transductions: a chemical to thermal energy transduction followed by a thermal to electrical transduction.

56.4 Biosensors

Biological measurands are biologically produced substances, such as antibodies, glucose, hormones, and enzymes. Biosensors are not the same as biomedical sensors, which are any sensors used in biomedical applications, such as blood pressure sensors, or electrocardiogram electrodes. Many biosensors are biomedical sensors; however, they are also used in industrial applications, e.g., the monitoring and control of fermentation reactions. Table 56.1 does not include biological signals as a primary signal because they can be classified as either chemical or physical in nature. Biosensors are of special interest because of the very high selectivity of biological reactions and binding. However, the detection of that reaction or binding is often elusive. A very familiar commercial biosensor is the in-home pregnancy test sensor, which detects the presence of human growth factor in urine. That device is a nonelectrical sensor since the output is a color change which the eye senses. In fact, most biosensors require multiple transduction mechanisms to arrive at an electrical output signal. Two examples are given below: an immunosensor and an enzyme sensor. Rather than examine a specific species, the examples describe a general type of sensor and transduction mechanism, since the same principles can be applied to a very large number of biological species of the same type.

Immunosensor

Commercial techniques for detecting antibody-antigen binding utilize optical or x-radiation detection. An optically fluorescent molecule or radioisotope is nonspecifically attached to the species of interest in solution. The complementary binding species is chemically attached to a glass substrate or glass beads which are packed into a column. The tagged solution containing the species of interest, say the antibody, is passed over the antigen-coated surface, where the two selectively bind. After the specific binding occurs, the nonbound fluorescent molecules or radioisotopes are washed away, and the antibody concentration is determined by fluorescence spectroscopy or with a scintillation counter, respectively. These sensing techniques are quite costly and bulky, and therefore other biosensing mechanisms are rapidly being developed. One experimental technique uses the change in the mechanical properties of the bound antibody-antigen complex in comparison to an unbound surface layer of antigen. It uses a shear mode, surface acoustic wave (SAW) device (see Chapter 51 and [Ballentine et al., 1997]) to sense this change as a change in the propagation time of the wave between the generating electrodes and the pick-up electrodes some distance away on the same piezoelectric substrate. The substrate surface is coated with the antigen and it is theorized that upon selectively binding with the antibody, this layer stiffens, changing the mechanical properties of the interface and therefore the velocity of the wave. The advantages of this device are that the SAW device produces an electrical signal (a change in oscillation frequency when the device is used in the feedback loop of an oscillator circuit) which is dependent on the amount of bound antibody; it requires only a very small amount of the antigen which can be very costly; the entire device is small, robust and portable; and the detection and readout method is inexpensive. However, there are numerous problems which currently preclude its commercial use, specifically a large temperature sensitivity and responses to nonspecific adsorption, i.e., by species other than the desired antibody.

Enzyme Sensor

Enzymes selectively react with a chemical substance to modify it, usually as the first step in a chain of reactions to release energy (metabolism). A well-known example is the selective reaction of glucose oxidase (enzyme) with glucose to produce gluconic acid and peroxide, according to

$$C_6H_{12}O_6 + O_2 \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + H_2O_2 + 80 \text{ kilojoules heat}$$

An enzymatic reaction can be sensed by measuring the rise in temperature associated with the heat of reaction or by the detection and measurement of byproducts. In the glucose example, the reaction can be sensed by measuring the local dissolved peroxide concentration. This is done via an electrochemical analysis technique called amperometry [Bard and Faulkner, 1980]. In this method, a potential is placed across two inert metal

wire electrodes immersed in the test solution and the current which is generated by the reduction/oxidation reaction of the species of interest is measured. The current is proportional to the concentration of the reducing/oxidizing species. A selective response is obtained if no other available species has a lower redox potential. Because the selectivity of peroxide over oxygen is poor, some glucose sensing schemes employ a second enzyme called catalase which converts peroxide to oxygen and hydroxyl ions. The latter produces a change in the local pH. As described earlier, an ISE can then be used to convert the pH to a measurable voltage. In this latter example, glucose sensing involves two chemical-to-chemical transductions followed by a chemical-to-electrical transduction mechanism.

56.5 Microsensors

Microsensors are sensors that are manufactured using integrated circuit fabrication technologies and/or **micromachining.** Integrated circuits are fabricated using a series of process steps which are done in batch fashion, meaning that thousands of circuits are processed together at the same time in the same way. The patterns which define the components of the circuit are photolithographically transferred from a template to a semiconducting substrate using a photosensitive organic coating. The coating pattern is then transferred into the substrate or into a solid-state thin film coating through an etching or deposition process. Each template, called a mask, can contain thousands of identical sets of patterns, with each set representing a circuit. This "batch" method of manufacturing is what makes integrated circuits so reproducible and inexpensive. In addition, photoreduction enables one to make extremely small features, on the order of microns, which is why this collection of process steps is referred to as microfabrication. The resulting integrated circuit is contained in only the top few microns of the semiconductor substrate and the submicron thin films on its surface. Hence, integrated circuit technology is said to consist of a set of planar, microfabrication processes. Micromachining refers to the set of processes which produce three-dimensional microstructures using the same photolithographic techniques and batch processing as for integrated circuits. Here, the third dimension refers to the height above the substrate of the deposited layer or the depth into the substrate of an etched structure. Micromachining produces third dimensions in the range of 1–500 μm (typically). The use of microfabrication to manufacture sensors produces the same benefits as it does for circuits: low cost per sensor, small size, and highly reproducible behavior. It also enables the integration of signal conditioning, compensation circuits and actuators, i.e., entire sensing and control systems, which can dramatically improve sensor performance for very little increase in cost. For these reasons, there is a great deal of research and development activity in microsensors.

The first microsensors were integrated circuit components, such as semiconductor resistors and *p-n* junction diodes. The piezoresistivity of semiconductors and optical sensing by the photodiode were already discussed. Diodes are also used as temperature-sensing devices. When forward-biased with a constant diode current, the resulting diode voltage increases approximately linearly with increasing temperature. The first micromachined microsensor to be commercially produced was the silicon pressure sensor. It was invented in the mid-to-late 1950s at Bell Labs and commercialized in the 1960s. This device contains a thin silicon diaphragm (≈10 μm) which is produced by chemical etching. The diaphragm deforms in response to a pressure difference across it (Fig. 56.3). The deformation produces two effects: a position-dependent displacement which is maximum at the diaphragm center and position-dependent strain which is maximum near the diaphragm edge. Both of these effects have been used in microsensors to produce an electrical output which is proportional to differential pressure. The membrane displacement is sensed capacitively as previously described in one type of pressure sensor. The strain is sensed in another by placing a piezoresistor, fabricated in the same silicon substrate, along one edge of the diaphragm. The two leads of the piezoresistor are connected to a Wheatstone bridge. The latter type of sensor is called a piezoresistive pressure sensor and is the commercially more common type of pressure microsensor. Pressure microsensors constituted about 5% of the total U.S. consumption of pressure sensors in 1991. Most of them are used in the medical industry as disposables due to their low cost and small, rugged construction. Many other types of microsensors are commercially under development, including accelerometers, mass flow rate sensors, and biosensors.

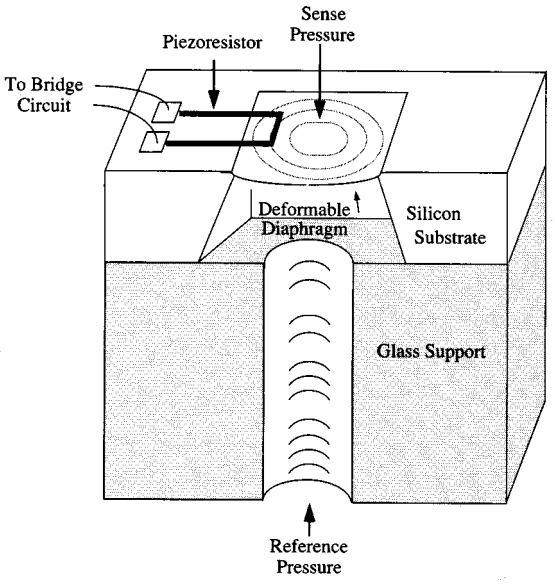

FIGURE 56.3 Schematic cross section of a silicon piezoresistive pressure sensor. A differential pressure deforms the silicon diaphragm, producing strain in the integrated piezoresistor. The change in resistance is measured via a Wheatstone bridge.

Defining Terms

Micromachining: The set of processes which produce three-dimensional microstructures using sequential photolithographic pattern transfer and etching or deposition in a batch processing method.

Microsensor: A sensor which is fabricated using integrated circuit and micromachining technologies.

Repeatability: The ability of a sensor to reproduce output readings for the same value of measurand, when applied consecutively and under the same conditions.

Sensitivity: The ratio of the change in sensor output to a change in the value of the measurand.

Sensor: A device which produces a usable output in response to a specified measurand.

Stability: The ability of a sensor to retain its characterisctics over a relatively long period of time.

57.1 Introduction

When a magnetic field **H** is applied to a magnetic medium (crystal), a change in the magnetization **M** within the medium will occur as described by the constitution relation of the Maxwell equations $\mathbf{M} = \overleftrightarrow{\chi} \cdot \mathbf{H}$ where $\overleftrightarrow{\chi}$ is the magnetic susceptibility tensor of the medium. The change in magnetization can in turn induce a perturbation in the complex optical permittivity tensor $\overleftrightarrow{\varepsilon}$. This phenomenon is called the magnetooptic effect. Mathematically, the magnetooptic effect can be described by expanding the permittivity tensor as a series in increasing powers of the magnetization [Torfeh et al., 1977] as follows:

$$\overleftrightarrow{\varepsilon} = \varepsilon_0[\varepsilon_{ij}] \tag{57.1}$$

where

$$\varepsilon_{ij}(\mathbf{M}) = \varepsilon_r\delta_{ij} + jf_1\ e_{ijk}M_k + f_{ijkl}M_kM_l$$

Here j is the imaginary number. M_1, M_2, and M_3 are the magnetization components along the principal crystal axes X, Y, and Z, respectively. ε_0 is the permittivity of free space. ε_r is the relative permittivity of the medium in the paramagnetic state (i.e., $\mathbf{M} = 0$), f_1 is the first-order magnetooptic scalar factor, $f_{ijk\ l}$ is the second-order magnetooptic tensor factor, δ_{ij} is the Kronecker delta, and e_{ijk} is the antisymmetric alternate index of the third order. Here we have used Einstein notation of repeated indices and have assumed that the medium is quasi-transparent so that $\overleftrightarrow{\varepsilon}$ is a Hermitian tensor. Moreover, we have also invoked the Onsager relation in thermodynamical statistics, i.e., $\varepsilon_{ij}(\mathbf{M}) = \varepsilon_{ji}(-\mathbf{M})$. The consequences of Hermiticity and Onsager relation are that the real part of the permittivity tensor is an even function of **M** whereas the imaginary part is an odd function of **M**. For a cubic crystal, such as YIG (yttrium-iron-garnet), the tensor f_{ijkl} reduces to only three independent terms. In terms of Voigt notation, they are f_{11}, f_{12}, and f_{44}. In a principal coordinate system, the tensor can be expressed as

$$f_{ijkl} = f_{12}\delta_{ij}\delta_{kl} + f_{44}\ (\delta_{il}\delta_{kj} + \delta_{ik}\delta_{lj}) + \Delta f\,\delta_{kl}\delta_{ij}\delta_{jk} \tag{57.2}$$

where $\Delta f = f_{11} - f_{12} - 2f_{44}$.

In the principal crystal axes [100] coordinate system, the magnetooptic permittivity reduces to the following forms:

$$\overleftrightarrow{\varepsilon} = \varepsilon_0 \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{12}^{\star} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{13}^{\star} & \varepsilon_{23}^{\star} & \varepsilon_{33} \end{bmatrix}$$

where * denotes complex conjugate operation. The elements are given by

paramagnetic state

$$\overleftrightarrow{\varepsilon} = \varepsilon_0 \begin{bmatrix} \varepsilon_r & 0 & 0 \\ 0 & \varepsilon_r & 0 \\ 0 & 0 & \varepsilon_r \end{bmatrix}$$

Faraday rotation

$$+ \quad \varepsilon_0 \begin{bmatrix} 0 & +jf_1M_3 & -jf_1M_2 \\ -jf_1M_3 & 0 & +jf_1M_1 \\ +jf_1M_2 & -jf_1M_1 & 0 \end{bmatrix}$$

Cotton-Mouton effect

$$+ \quad \varepsilon_0 \begin{bmatrix} f_{11}M_1^2 + f_{12}M_2^2 + f_{12}M_3^2 & 2f_{44}M_1M_2 & 2f_{44}M_1M_3 \\ 2f_{44}M_1M_2 & f_{12}M_1^2 + f_{11}M_2^2 + f_{12}M_3^2 & 2f_{44}M_2M_3 \\ 2f_{44}M_1M_3 & 2f_{44}M_2M_3 & f_{12}M_1^2 + f_{12}M_2^2 + f_{11}M_3^2 \end{bmatrix} \tag{57.3}$$

In order to keep the discussion simple, analytic complexities due to optical absorption of the magnetic medium have been ignored. Such absorption can give rise to magnetic circular dichroism (MCD) and magnetic linear dichroism (MLD). Interested readers can refer to Hellwege [1978] and Arecchi and Schulz-DuBois [1972] for more in-depth discussions on MCD and MLD.

57.2 Classification of Magnetooptic Effects

Faraday Rotation or Magnetic Circular Birefringence

The classic Faraday rotation takes place in a cubic or isotropic transparent medium where the propagation direction of transmitted light is parallel to the direction of applied magnetization within the medium. For example, if the direction of magnetization and the propagation of light is taken as *Z*, the permittivity tensor becomes (assuming second-order effect is insignificantly small):

$$\overleftrightarrow{\varepsilon} \cong \varepsilon_0 \begin{bmatrix} \varepsilon_r & jf_1M_3 & 0 \\ -jf_1M_3 & \varepsilon_r & 0 \\ 0 & 0 & \varepsilon_r \end{bmatrix} \tag{57.4}$$

The two eigenmodes of light propagation through the magnetooptic medium can be expressed as a right circular polarized (RCP) light wave

$$\tilde{E}_1(Z) = \begin{bmatrix} 1 \\ j \\ 0 \end{bmatrix} \exp\left[j\left(\omega t - \frac{2\pi n_+}{\lambda_0} Z \right)\right] \tag{57.5a}$$

and a left circular polarized (LCP) light wave

$$\tilde{E}_2(Z) = \begin{bmatrix} 1 \\ -j \\ 0 \end{bmatrix} \exp\left[j\left(\omega t - \frac{2\pi n_-}{\lambda_0} Z \right)\right] \tag{57.5b}$$

where $n_\pm^2 \cong \varepsilon_r \pm f_1 M_3$; ω and λ_0 are the angular frequency and the wavelength of the incident light, respectively. n_+ and n_- are the refractive indices of the RCP and LCP modes, respectively. These modes correspond to two counterrotating circularly polarized light waves. The superposition of these two waves produces a linearly polarized wave. The plane of polarization of the resultant wave rotates as one circular wave overtakes the other. The rate of rotation is given by

$$\begin{aligned} \theta_F &\cong \frac{\pi f_1 M_3}{\lambda_0 \sqrt{\varepsilon_r}} \quad \text{rad/m} \\ &= \frac{1.8 f_1 M_3}{\lambda_0 \sqrt{\varepsilon_r}} \quad \text{degree/cm} \end{aligned} \tag{57.6}$$

θ_F is known as the Faraday rotation (FR) coefficient. When the direction of the magnetization is reversed, the angle of rotation changes its sign. Since two counterrotating circular polarized optical waves are used to explain FR, the effect is thus also known as optical magnetic circular birefringence (MCB). Furthermore, since the senses of polarization rotation of forward traveling and backward traveling light waves are opposite, FR is a nonreciprocal optical effect. Optical devices such as **optical isolators** and **optical circulators** use the Faraday effect to achieve their nonreciprocal functions. For ferromagnetic and ferrimagnetic media, the FR is characterized under a magnetically saturated condition, i.e., $M_3 = M_S$, the saturation magnetization of the medium. For paramagnetic or diamagnetic materials, the magnetization is proportional to the external applied magnetic field H_0. Therefore, the FR is proportional to the external field or $\theta_F = VH_0$ where $V = \chi_0 f_1 \pi/(\lambda_0 \sqrt{\varepsilon_r})$ is called the Verdet constant and χ_0 is the magnetic susceptibility of free space.

Cotton-Mouton Effect or Magnetic Linear Birefringence

When transmitted light is propagating perpendicular to the magnetization direction, the first-order isotropic FR effect will vanish and the second-order anisotropic Cotton-Mouton (CM) effect will dominate. For example, if the direction of magnetization is along the Z axis and the light wave is propagating along the X axis, the permittivity tensor becomes

$$\overleftrightarrow{\varepsilon} = \varepsilon_0 \begin{bmatrix} \varepsilon_r + f_{12} M_3^2 & 0 & 0 \\ 0 & \varepsilon_r + f_{12} M_3^2 & 0 \\ 0 & 0 & \varepsilon_r + f_{11} M_3^2 \end{bmatrix} \tag{57.7}$$

The eigenmodes are two linearly polarized light waves polarized along and perpendicular to the magnetization direction:

$$\tilde{E}_{//}(x) = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \exp\left[j\left(\omega t - \frac{2\pi}{\lambda_0} n_{//} x \right) \right] \tag{57.8a}$$

$$\tilde{E}_{\perp}(x) = \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} \exp\left[j\left(\omega t - \frac{2\pi}{\lambda_0} n_{\perp} x \right) \right] \tag{57.8b}$$

with $n_{//}^2 = \varepsilon_r + f_{11}M_3^2$ and $n_{\perp}^2 = \varepsilon_r + f_{12}M_3^2$; $n_{//}$ and $n_{\perp}$ are the refractive indices of the parallel and perpendicular linearly polarized modes, respectively. The difference in phase velocities between these two waves gives rise to a magnetic linear birefringence (MLB) of light which is also known as the CM or Voigt effect. In this case, the light transmitted through the crystal has elliptic polarization. The degree of ellipticity depends on the difference $n_{//} - n_{\perp}$. The phase shift or retardation can be found by the following expression:

$$\psi_{cm} \cong \frac{\pi(f_{11} - f_{12})M_3^2}{\lambda_0\sqrt{\varepsilon_r}} \quad \text{rad/m}$$

or

$$\frac{1.8(f_{11} - f_{12})M_3^2}{\lambda_0\sqrt{\varepsilon_r}} \quad \text{degree/cm} \tag{57.9}$$

Since the sense of this phase shift is unchanged when the direction of light propagation is reversed, the CM effect is a reciprocal effect.

Kerr Effects

Kerr effects occur when a light beam is reflected from a magnetooptic medium. There are three distinct types of Kerr effects, namely, polar, longitudinal (or meridional), and transverse (or equatorial). Figure 57.1 shows the configurations of these Kerr effects. A reflectivity tensor relation between the incident light and the reflected light can be used to describe the phenomena as follows:

$$\begin{bmatrix} E_{r\perp} \\ E_{r//} \end{bmatrix} = \begin{bmatrix} r_{11} & r_{12} \\ r_{21} & r_{22} \end{bmatrix} \begin{bmatrix} E_{i\perp} \\ E_{i//} \end{bmatrix} \tag{57.10}$$

where r_{ij} is the reflectance matrix. $E_{i\perp}$ and $E_{i//}$ are, respectively, the perpendicular (TE) and parallel (TM) electric field components of the incident light waves (with respect to the plane of incidence). $E_{r\perp}$ and $E_{r//}$ are, respectively, the perpendicular and parallel electric field components of the reflected light waves.

The diagonal elements r_{11} and r_{22} can be calculated by Fresnel reflection coefficients and Snell's law. The off-diagonal elements r_{12} and r_{21} can be derived from the magnetooptic permittivity tensor, the applied magnetization and Maxwell equations with the use of appropriate boundary conditions [Arecchi and Schulz-DuBois, 1972]. It is important to note that all the elements of the reflectance matrix r_{ij} are dependent on the angle of incidence between the incident light and the magnetooptic film surface.

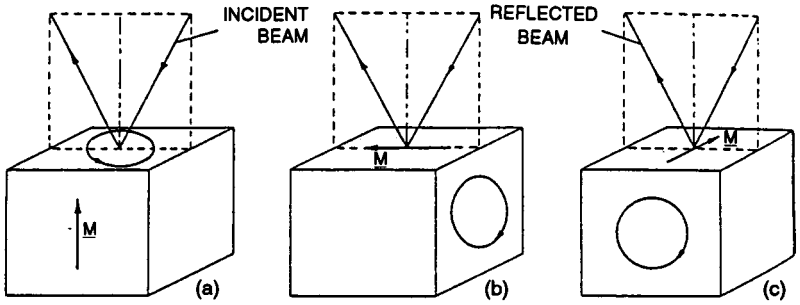

FIGURE 57.1 Kerr magnetooptic effect. The magnetization vector is represented by M while the plane of incidence is shown dotted. (a) Polar; (b) longitudinal; (c) transverse. (*Source:* A.V. Sokolov, *Optical Properties of Metals*, London: Blackie, 1967. With permission.)

Polar Kerr Effect

The polar Kerr effect takes place when the magnetization is perpendicular to the plane of the material. A pair of orthogonal linearly polarized reflected light modes will be induced and the total reflected light becomes elliptically polarized. The orientation of the major axis of the elliptic polarization of the reflected light is the same for both TE ($E_{i\perp}$) or TM ($E_{i//}$) linearly polarized incident lights since $r_{12} = r_{21}$.

Longitudinal or Meridional Kerr Effect

The longitudinal Kerr effect takes place when the magnetization is in the plane of the material and parallel to the plane of incidence. Again, an elliptically polarized reflected light beam will be induced, but the orientation of the major axis of the elliptic polarization of the reflected light is opposite to each other for TE ($E_{i\perp}$) and TM ($E_{i//}$) linearly polarized incident lights since $r_{12} = -r_{21}$.

Transverse or Equatorial Kerr Effect

This effect is also known as the equatorial Kerr effect. The magnetization in this case is in the plane of the material and perpendicular to the plane of incidence. The reflected light does not undergo a change in its polarization since $r_{12} = r_{21} = 0$. However, the intensity of the TM ($E_{r//}$) reflected light will be changed if the direction of the magnetic field is suddenly reversed. For TE ($E_{r\perp}$) reflected light, this modulation effect is at least two orders of magnitude smaller and is usually ignored.

57.3 Applications of Magnetooptic Effects

Optical Isolator and Circulator

In fiber-optic-based communication systems with gigahertz bandwidth or coherent detection, it is often essential to eliminate back reflections from the fiber ends and other surfaces or discontinuities because they can cause amplitude fluctuations, frequency instabilities, limitation on modulation bandwidth, noise or even damage to the lasers. An optical isolator permits the forward transmission of light while simultaneously preventing reverse transmission with a high degree of extinction. The schematic configuration of a conventional optical isolator utilizing bulk rotator and permanent magnet [Johnson, 1966] is shown in Fig. 57.2. It consists of a 45-degree polarization rotator which is nonreciprocal so that back-reflected light is rotated by exactly 90 degrees and can therefore be excluded from the laser. The nonreciprocity is furnished by the Faraday effect. The basic operation principle is as follows: A Faraday isolator consists of rotator material immersed in a longitudinal magnetic field between two polarizers. Light emitted by the laser passes through the second polarizer being oriented at 45 degrees relative to the transmission axis of the first polarizer. Any subsequently reflected light is then returned through the second polarizer, rotated by another 45 degrees before being extinguished by the first polarizer—thus optical isolation is achieved.

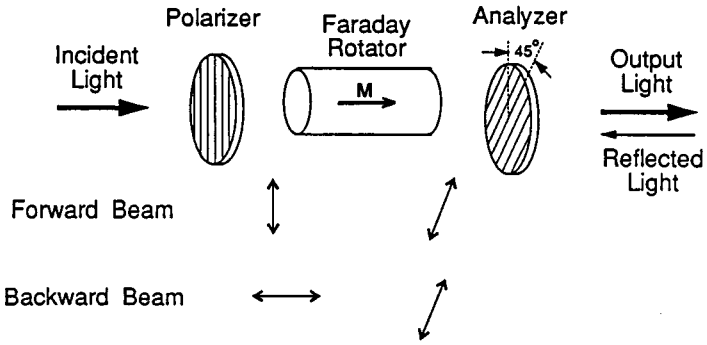

FIGURE 57.2 Schematic of an optical isolator. The polarization directions of forward and backward beams are shown below the schematic.

TABLE 57.1 Characteristics of YIG and BIG Faraday Rotators

	YIG	BIG
Verdet constant (min/cm-Gauss)		
1300 nm	10.5[a]	–806
1550 nm	9.2	–600
Saturated magnetooptic rotation (degree/mm)

The major characteristics of an optical isolator include isolation level, insertion loss, temperature dependence, and size of the device. These characteristics are mainly determined by the material used in the rotator. Rotating materials generally fall into three categories: the paramagnetics (such as terbium-doped borosilicate glass), the diamagnetic (such as zinc selenide), and the ferromagnetic (such as rare-earth garnets). The first two kinds have small Verdet constants and mostly work in the visible or shorter optical wavelength range. Isolators for use with the InGaAsP semiconductor diode lasers ($\lambda_0 = 1100$–1600 nm), which serve as the essential light source in optical communication, utilize the third kind, especially the yttrium-iron-garnet (YIG) crystal. A newly available ferromagnetic crystal, epitaxially grown bismuth-substituted yttrium-iron-garnet (BIG), has an order-of-magnitude stronger Faraday rotation than pure YIG, and its magnetic saturation occurs at a smaller field [Matsuda et al., 1987]. The typical parameters with YIG and BIG are shown in Table 57.1. As the major user of optical isolators, fiber optic communication systems require different input-output packaging for the isolators. Table 57.2 lists the characteristics of the isolators according to specific applications [Wilson, 1991].

For the purpose of integrating the optical isolator component into the same substrate with the semiconductor laser to facilitate monolithic fabrication, integrated waveguide optical isolators become one of the most exciting areas for research and development. In a waveguide isolator, the rotation of the polarization is accomplished in a planar or channel waveguide. The waveguide is usually made of a magnetooptic thin film, such as YIG or BIG film, liquid phase epitaxially grown on a substrate, typically gadolinium-gallium-garnet (GGG) crystals. Among the many approaches in achieving the polarization rotation, such as the 45-degree rotation type or the

TABLE 57.2 Applications of Optical Isolators

Application	Type	Wavelength Tunable	Isolation (dB)	Insertion Loss (dB)	Return Loss (dB)
Fiber to fiber	PI	Yes/no	30–40	1.0–2.0	> 60
Fiber to fiber	PS	Normally no	33–42	1.0–2.0	> 60

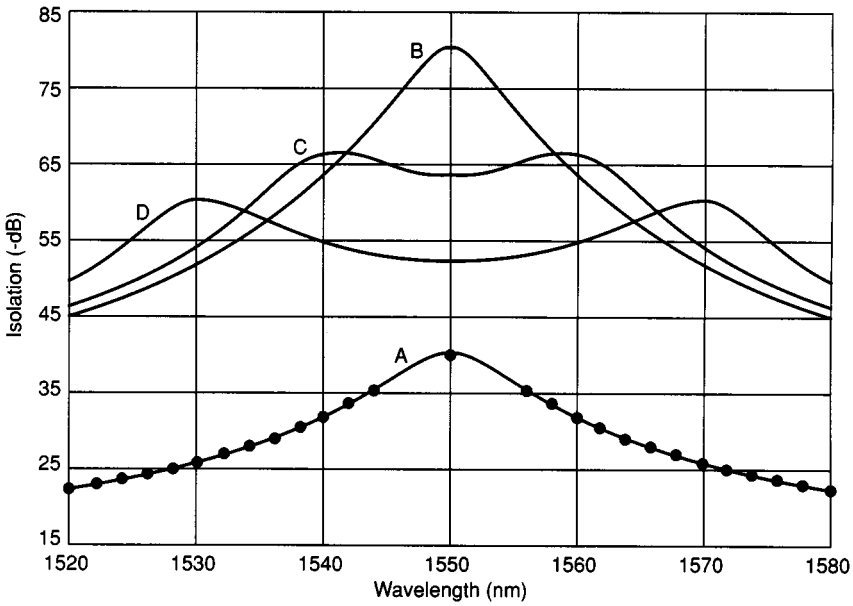

FIGURE 57.3 Isolation performance of four isolators centered around 1550 nm shows the effects of different configurations. A single-stage isolator (curve A) reaches about –40 dB isolation, and two cascaded single-wavelength isolators (curve B) hit –80 dB. Wavelength broadening (curves C and D) can be tailored by cascading isolators tuned to different wavelengths. (*Source:* D.K. Wilson, "Optical isolators adapt to communication needs," *Laser Focus World*, April 1991. With permission.)

unidirectional TE-TM mode converter type, the common point is the conversion or coupling process between the TE and TM modes of the waveguide. Although very good results have been obtained in some specific characteristics, for example, 60-dB isolation [Wolfe et al., 1990], the waveguide optical isolator is still very much in the research and development stage.

Usually, the precise wavelength of any given semiconductor diode is uncertain. Deviation from a specified wavelength could degrade isolator performance by 1 dB/nm, and an uncertainty of 10 nm can reduce isolation by 10 dB. Therefore, a tunable optical isolator is highly desirable. A typical approach is to simply place two isolators, tuned to different wavelengths, in tandem to provide a broadband response. Curves C and D of Fig. 57.3 show that isolation and bandwidth are a function of the proximity of the wavelength peak positions. This combination of nontunable isolators has sufficiently wide spectral bandwidth to accommodate normal wavelength variations found in typical diode lasers. In addition, because the laser wavelength depends on its operating temperature, this broadened spectral bandwidth widens the operating temperature range without decreasing isolation.

The factors that limit isolation are found in both the polarizers and the Faraday rotator materials. Intrinsic strain, inclusions, and surface reflections contribute to a reduction in the purity of polarization which affects

isolation. About 40 dB is the average isolation for today's materials in a single-isolator stage. If two isolators are cascaded in tandem, it is possible to double the isolation value.

Finally, an optical circulator [Fletcher and Weisman, 1965] can be designed by replacing the polarizers in a conventional isolator configuration with a pair of calcite polarizing prisms. A laser beam is directed through a calcite prism, then through a Faraday rotator material which rotates the polarization plane by 45 degrees, then through a second calcite prism set to pass polarization at 45 degrees. Any reflection beyond this second calcite prism returns through the second prism, is rotated by another 45 degrees through the Faraday material, and, because its polarization is now 90 degrees from the incident beam, is deflected by the first calcite prism. The four ports of the circulator then are found as follows: (1) the incident beam, (2) the exit beam, (3) the deflected beam from the first calcite prism, and (4) the deflected beam from the second calcite prism.

MSW-Based Guided-Wave Magnetooptic Bragg Cell

When a ferrimagnet is placed in a sufficiently large externally applied dc magnetic field, H_0, the ferrimagnetic materials become magnetically saturated to produce a saturation magnetization $4\pi M_S$. Under this condition, each individual magnetic dipole will precess in resonance with frequency $f_{res} = \gamma H_0$ where γ is the gyromagnetic ratio (γ = 2.8 MHz/Oe). However, due to the dipole–dipole coupling and quantum mechanical exchange coupling, the collective interactions among neighboring magnetic dipole moments produce a continuum spectrum of precession modes or spin waves at frequency bands near f_{res}. Exchange-free spin wave spectra obtained under the magnetostatic approximation are known as magnetostatic waves (MSWs) [Ishak, 1988]. In essence, MSWs are relatively slow propagating, dispersive, magnetically dominated electromagnetic (EM) waves which exist in biased ferrites at microwave frequencies (2–20 GHz). In a ferrimagnetic film with a finite thickness, such as a YIG thin film epitaxially grown on a nonmagnetic substrate such as GGG, MSW modes are classified into three types: magnetostatic surface wave (MSSW), magnetostatic forward volume wave (MSFVW), and magnetostatic backward volume wave (MSBVW), depending on the orientation of the dc magnetic field with respect to the film plane and the propagation direction of the MSW. At a constant dc magnetic field, each type of mode only exists in a certain frequency band. An important feature of MSW is that these frequency bands can be simply tuned by changing the dc magnetic field.

As a result of the Faraday rotation effect and Cotton-Mouton effect, the magnetization associated with MSWs will induce a perturbation in the dielectric tensor. When MSW propagates in the YIG film, it induces a moving optical grating which facilitates the diffraction of an incident guided light beam. If the so-called Bragg condition is satisfied between the incident guided light and the MSW-induced optical grating, Bragg diffraction takes place. An optical device built based on this principle is called the **magnetooptic Bragg cell** [Tsai and Young, 1990].

A typical MSFVW-based noncollinear coplanar guided-wave magnetooptic Bragg cell is schematically shown in Fig. 57.4. Here a homogeneous dc bias magnetic field is applied along the Z axis to excite a Y-propagating MSFVW generated by a microstrip line transducer. With a guided lightwave coupled into the YIG waveguide and propagating along the X axis, a portion of the lightwave is Bragg-diffracted and mode-converted (TE to TM mode and vice versa). The Bragg-diffracted light is scanned in the waveguide plane as the frequency of the MSFVW is tuned. Figure 57.5 shows the scanned light spots by tuning the frequency at a constant dc magnetic field.

MSW-based guided-wave magnetooptic Bragg cell is analogous to surface acoustic wave (SAW)-based guided-wave acoustooptic (AO) Bragg cell and has the potential to significantly enhance a wide variety of integrated optical applications which had previously been implemented with SAW. These include TE-TM mode converter, spectrum analyzer, convolvers/correlators, optical frequency shifters, tunable narrowband optical filters, and optical beam scanners/switches [Young, 1989]. In comparison to their AO counterparts, the MSW-based magnetooptic Bragg cell modules may possess the following unique advantages: (1) A much larger range of tunable carrier frequencies (2–20 GHz, for example) may be readily obtained by varying a dc magnetic field. Such high and tunable carrier frequencies with the magnetooptic device modules allow direct processing at the carrier frequency of wide-band RF signals rather than indirect processing via frequency down-conversion, as is required with the AO device modules. (2) A large magnetooptic bandwidth may be realized by means of a simpler transducer geometry. (3) Much higher and electronically tunable modulation/switching and scanning speeds are possible as the velocity of propagation for the MSW is higher than that of SAW by one to two orders of magnitude, depending upon the dc magnetic field and the carrier frequency.

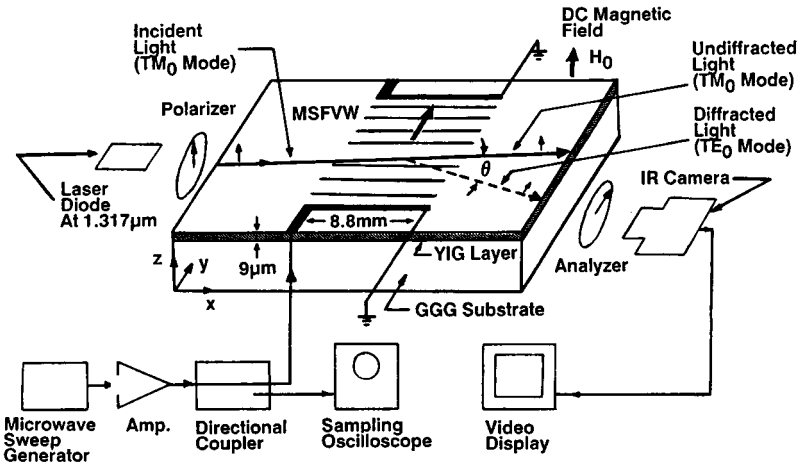

FIGURE 57.4 Experimental arrangement for scanning of guided-light beam in YIG-GGG waveguide using magnetostatic forward waves.

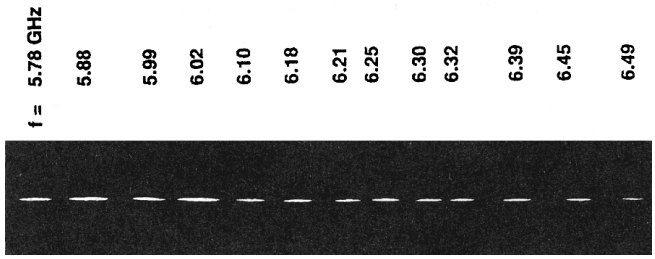

FIGURE 57.5 Deflected light spots obtained by varying the carrier frequency of MSFVW around 6 GHz.

Magnetooptic Recording

The write/erase mechanism of the **magnetooptical (MO) recording system** is based on a thermomagnetic process in a perpendicularly magnetized magnetooptic film. A high-power pulsed laser is focused to heat up a small area on the magnetooptic medium. The coercive force of the MO layer at room temperature is much greater than that of a conventional non-MO magnetic recording medium. However, this coercive force is greatly reduced when the heated spot is raised to a critical temperature. Application of a bias magnetic field can then easily reverse the polarization direction of the MO layer within the heated spot. As a result, a very small magnetic domain with magnetization opposite to that of the surrounding area is generated. This opposite magnetic domain will persist when the temperature of the medium is lowered. The magnetization-reversed spot represents one bit of stored data. To erase data, the same thermal process can be applied while reversing the direction of the bias magnetic field.

To read the stored information optically, the Kerr effect is used to detect the presence of these very small magnetic domains within the MO layer. When a low-power polarized laser beam is reflected by the perpendicularly oriented MO medium, the polarization angle is twisted through a small angle θ_k, the Kerr rotation. Furthermore, the direction of this twist is either clockwise or counterclockwise, depending on the orientation of the perpendicular magnetic moment, which is either upward or downward. Therefore, as the read beam scans across an oppositely magnetized domain from the surrounding medium, there is a total change of $2\theta_k$ in the polarization directions from the reflected beam coming from the two distinct regions. Reading is done by detecting this phase difference.

The MO recording medium is one of the most important elements in a high-performance MO data-storage system. In order to achieve fast writing and erasing functions, a large Kerr rotation is required to produce an

acceptable carrier-to-noise (C/N) ratio. In general, a high-speed MO layer has a read signal with a poor C/N ratio, while a good read-performance MO layer is slow in write/erase sensitivity.

Defining Terms

Cotton-Mouton effect: Second-order anisotropic reciprocal magnetooptic effect which causes a linearly polarized incident light to transmit through as an elliptically polarized output light wave when the propagation direction of the incident light is perpendicular to the direction of the applied magnetization of the magnetooptic medium. It is also known as magnetic linear birefringence (MLB).

Faraday rotation: First-order isotropic nonreciprocal magnetooptic effect which causes the polarization direction of a linearly polarized transmitted light to rotate when the propagation direction of the incident light wave is parallel to the direction of the applied magnetization of the magnetooptic medium. It is also known as magnetic circular birefringence (MCB).

Kerr effects: Reflected light from a magnetooptic medium can be described by the optical Kerr effects. There are three types of Kerr effects: polar, longitudinal, and transverse, depending on the directions of the magnetization with respect to the plane of incidence and the reflecting film surface.

Magnetooptic Bragg cell: A magnetically tunable microwave signal processing device which uses optical Bragg diffraction of light from a moving magnetooptic grating generated by the propagation of magnetostatic waves within the magnetic medium.

Magnetooptic recording system: A read/write data recording system based on a thermomagnetic process to write oppositely magnetized domains onto a magnetooptic medium by means of high-power laser heating. Magnetooptic Kerr effect is then employed to read the data by using a low-power laser as a probe beam to sense the presence of these domains.

Optical circulator: A four-port optical device that can be used to monitor or sample incident light (input port) as well as reflected light (output port) with the two other unidirectional coupling ports.

Optical isolator: A unidirectional optical device which only permits the transmission of light in the forward direction. Any reflected light from the output port is blocked by the device from returning to the input port with a very high extinction ratio.

58.1 Introduction

Smart materials are a class of materials and/or composite media having inherent intelligence together with self-adaptive capabilities to external stimuli. Also known as **intelligent materials,** they constitute a few subsets of the material family that "manifest their own functions intelligently depending on environmental changes" [Rogers and Rogers, 1992].

Classically, such intelligent material systems have been conceived in the development of mechanical structures that contain their own sensors, actuators and self-assessing computational feasibilities in order to modify their structural (elastic) behavior via feedback control capabilities. The relevant concepts have stemmed from intelligent forms of natural (material) systems, namely, living organisms; hence, in modern concepts smart or

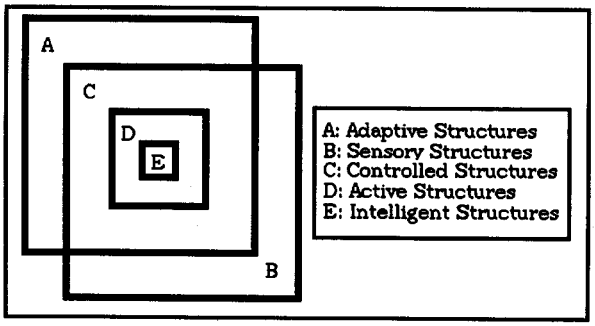

FIGURE 58.1 Set of structures. (Adapted from B. K. Wada, J. L. Fanson, and E.F. Crawley, "Adaptive structures," *J. Intell. Mat. Syst. Struct.*, 1, 1990.)

intelligent materials and systems are conceived as those that mimic the life functions of sensing, actuation, control, and intelligence.

The inherent intelligence and self-adaptable control of artificial smart materials should be programmable in terms of the constituent processing, microstructural characteristics, and defects to permit the self-conditionings to adapt in a controlled manner to various types of stimuli. The dividing line between smart materials and the so-called **intelligent structures** is not, however, distinct. In simple terms, intelligent material systems are constructed of smart materials with a dedicated, discrete set of integrated actuators, sensors, and so on, and smart materials contain largely a built-in or embedded set of distributed sensors. In general, the term *smart materials* usually connotes the structural constituent in which the discrete functions of sensing, actuation, signal processing and control are tangibly integrated. Intelligent structures, as an extension, are constructed with smart materials to respond to the environment around them in a predetermined, desired manner.

Intelligent or smart materials that manifest their own functions intelligently vis-à-vis the changes in their surroundings are capable of performing, in general (Chong et al., 1990):

- Primary functions specifying the adaptive roles of the sensor, the effector and processor capabilities (including the memory functions)
- Macroscopic functions that enclave the extensive or global aspects of the intelligence inherent in the materials
- Built-in social utility aspects with an instilled human-like intelligence with hyper-performance capabilities

58.2 Smart/Intelligent Structures

The framework of intelligent structures as a subset in the gamut of conventional material-based systems is illustrated in Fig. 58.1. This general classification of material structures refer to [Chong et al., 1990]:

- Sensory structures, "which possess sensors that enable the determination or monitoring of system states or characteristics" [Chong et al., 1990]
- Adaptive structures, which possess actuators that facilitate the alteration of system-states or characteristics in a controlled manner
- Sensory systems, which may contain sensors, but no actuators
- Adaptive systems, which contain actuators, but no sensors

Referring to Fig. 58.1, the intersection of sensory versus adaptive structures depicts the controlled structures with a feedback architecture. That is, the active structure has an integrated controlled unit with sensors and/or actuators that have structural as well as control functionality. Hence, the logical subset that defines an intelligent structure is a highly integrated unit (with controlled logic, electronics, etc.) that provides the cognitive element of a distributed or a hierarchic controlled structure.

58.3 Objective-Based Classification of Smart/Intelligent Materials

Smart Structural Materials

Intelligent structural engineering materials are the classical versions of smart systems in which the mechanical (elastic) properties of a structure can be modified adaptively by means of an imbedded distribution of smart material(s), and an associated (integral) set of sensors and actuators together with an external control system to facilitate adaptive changes in the elastic behavior of structures so that motion, vibration, strength, stiffness, redistribution of load path in response to damage, etc. are controlled.

Smart Thermal Materials

A **smart thermal material,** in response to environmental demands, can self-adaptively influence its thermal states (temperature or such thermal properties as conductivity, diffusivity, absorptivity), by means of an integrated conglomeration of thermal sensors, heaters, or actuators with an associated control system.

Smart Acoustical Materials

Smart acoustical materials can be classified as those that have self-adaptive characteristics on their acoustical behavior (such as transmission, reflection, and absorption of acoustical energy) by means of sensors that assess the acoustical states (intensity, frequency, response, etc.), along with a set of actuators (dampers, exciters) with an associated control system. Again, the self-adaptive behavior of these materials is in response to ambient acoustical changes.

Smart Electromagnetic Materials

Smart Magnetic Shielding Materials

As warranted by the surroundings, the self-adaptive shielding effectiveness to magnetic fields at low frequencies (power frequencies such as 60 or 50 Hz) can be achieved by means of an integrated set of magnetic field sensors and actuators (magnetic biasing, current elements, etc.) plus a control system arrangement [Neelakanta and Subramaniam, 1992].

High-Frequency Smart Shielding Materials

Corresponding to radio and higher frequency environments, the shielding requirement warrants curtailing both electric and magnetic fields. Hence, the relevant self-adaptive intelligent shielding system would consist of an array of distributed electromagnetic sensors with appropriate elements (actuators) and a control system.

Smart Radar-Absorbing Materials

Absorption of microwave/millimeter wave energy at radar frequency is useful in radar stealth applications. Adaptively controllable smart radar-absorbing materials (smart RAMs) can be synthesized with integrated distribution of electromagnetic detectors (sensors) with appropriate actuators and control system [Neelakanta et al., 1992].

Smart Optical Surface Materials

Smart optical surface materials can be envisioned as those in which the surface optical properties (hue, intensity, etc.) can be adaptively controlled by means of an intelligent sensor/actuator combinational control system.

Pyrosensitive Smart Materials

Electromagnetic active surfaces constituted by pyrosensitive inclusions have been successfully developed to manage the electromagnetic reflection and/or absorption characteristics from the active surface by means of thermal actuation of the pyrosensitive nodes imbedded in the medium [Neelakanta et al., 1992]. With the inclusion of a feedback systems, smart operation in adaptively manipulating the active surface characteristics can be achieved.

58.4 Material Properties Conducive for Smart Material Applications

Certain specific characteristics of materials make them suitable for smart material applications. These properties are:

1. Piezoelectric effect
2. Magnetostrictive effect
3. Electroplastic effect
4. Shape-memory effects
5. Electrorheological properties
6. Nonlinear electro-optic properties
7. Nonlinear electroacoustic properties
8. Nonlinear electromagnetic properties
9. Pyrosensitive properties

Piezoelectric Effect

Piezoelectric property of a material refers to the ability to induce opposite charges at two faces (correspondingly, to exhibit a voltage difference between the faces) of the material as a result of the strain due to mechanical force (either tension or compression) applied across the surfaces. This process is also reversible in the sense that a mechanical strain would be experienced in the material when subjected to opposite electric charging at the two faces by means of an applied potential.

In the event of such an applied voltage being alternating, the material specimen will experience vibrations. Likewise, an applied vibration on the specimen would induce an alternating potential change between the two faces. The most commonly known materials that exhibit piezoelectric properties are natural materials like quartz and a number of crystalline and polycrystalline compounds.

The strain versus the electric phenomenon perceived in piezoelectric materials is dictated by a coefficient that has components referred to a set of orthogonal coordinate axes (which are correlated to standard crystallographic axes). For example, denoting the piezoelectric coefficient (ratio between piezoelectric strain component to applied electric field component at a constant mechanical stress or vice versa) as d_{mn}, the subscript n (1 to 3) refers to the three euclidian orthogonal axes, and $m = 1$ to 6 specifies the mechanical stress-strain components. The unit for d_{mn} is meter/volt which is the same as coulomb/newton.

In the piezoelectric phenomenon, there is an electromechanical synergism expressed as a coupling factor K defined by K^2, which quantifies the ratio of mechanical energy converted into electric charges to the mechanical energy impressed on the material. Being a reversible process, a relevant inverse ratio is also applicable.

Magnetostrictive Effect

Magnetostrictive effect refers to the structural strain experienced in a material subjected to a polarizing magnetic flux. A static strain of $\Delta l/l$ is produced by a dc polarizing magnetic flux density B_o such that $\Delta l/l = CB_o^2$, where C is a material constant expressed in (meter^4/weber^2) taking the units for B_o as weber/meter^2.

The magnetic stress constant (Λ) in (newton/weber) is given by $\Lambda = 2CB_oY_o$ where Y_o refers to the Young's modulus of a linearly strained free bar. The coefficient (Λ) could be both positive or negative. For example, nickel contracts with increasing B_o, whereas magnetic alloys such as 45 Permalloy (45% Ni + 55% Fe), Alfer (13% Al, 87% Fe) exhibit positive magnetostrictive coefficient [Reed, 1988].

Electroplastic Effect

The **electroplastic effect** (EPE) refers to the plastic deformation of metals with the application of high-density electric current with an enhanced deformation rate (that persists in addition to that caused by the side effects of the current such as joule-heating and the magnetic pinch effect). The plastic strain rate resulting from a current pulse is given by $\varepsilon_I/\varepsilon_A = \alpha J^2 \exp(\beta J)$ where ε_I is the strain rate occurring during the current pulse, ε_A is the strain rate in the absence of the current pulse, J is the current density and α and β are material constants. Typically the EPE has been observed in zinc, niobium, titanium, etc.

Shape-Memory Effects

The mechanism by which a plastically deformed object in the low-temperature martensitic condition regains its original shape when the external stress is removed and heat is applied is referred to as the shape-memory

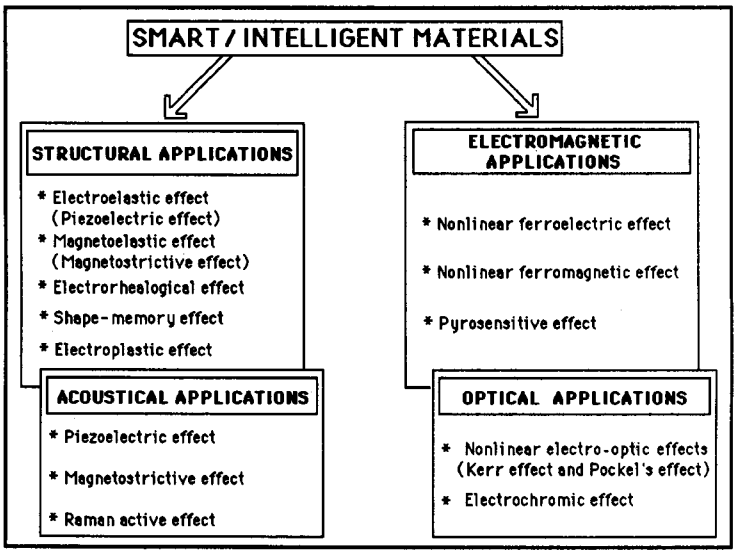

FIGURE 58.2 Application-specific classification of smart/intelligent materials.

effect (SME) [Jackson et al., 1972]. It is a memory mechanism that is the result of a martensitic transformation taking place during heating.

Alhough the exact mechanism by which the shape-memory effect occurs is still under study, the process by which the original shape is regained is associated with a reverse transformation of the deformed martensitic phase to the higher temperature austenite phase. A group of nickel-titanium alloys (referred to as Nitinol) of proper composition exhibit the shape-memory property and are widely used in smart material applications [Jackson et al., 1972].

Electrorheological Property

Electrorheological property is the property exhibited by certain fluids that are capable of altering their flow characteristics depending on an external applied electric field. These fluids have a fast response time, only a few milliseconds. Once the external field is applied, there is a form of progressive gelling of the fluid proportional to the applied field strength. Without the applied field, the fluid flows freely. If the electrified electrorheological (ER) fluid is sheared by an applied force larger than a certain critical value, it flows. Below this critical value of applied shear force, the electrified fluid remains in the gel phase [Gandhi and Thompson, 1989].

An electrorheological fluid requires particles (1 to 100 mm in diameter) dispersed in a carrier fluid. Sometimes a surfactant is also added to help the dispersion of particles in the fluid. The surfactant is used to prevent particle interaction that could otherwise result in a tendency for the particulates to clump together when the fluid is allowed to stand still over a stretch of time. The tendency of the particles to clump together is referred to as settling.

The applied electric field to perceive the electrorheological phenomenon is usually in the order of 4 kV/mm. When the electric field is applied, the positive and negative charges on the suspended particles are separated, forming a dipole of charges. These dipoles then align (polarize) themselves by mutual forces of attraction and repulsion to other similar dipoles, resulting in unique flow characteristics. In the absence of an electric field, there is no dipole separation of charges, and hence the fluid returns to its normal flow.

An ideal electrorheological fluid is one that has a low viscosity in the absence of an applied field and that which transforms into a high-viscosity gel capable of withstanding high shear stresses when the field is on. Further, it must also have a low power consumption. The first reported ER fluid consisted of finely dispersed suspensions of starch or silica gel in mineral oil nearly 40 years ago.

Nonlinear Electro-optic Properties

In certain materials that are optically transparent when subjected to an external electric field, the refractive index of the material changes. Invariably the electric field versus optical effect thus experienced is nonlinear,

with the result that a time-varying electric field will modulate the refractive index, and hence a phase shift is experienced by the light passing through the medium. In materials that have a central symmetry, this phenomenon is called the Kerr effect; in noncentrosymmetric materials, it is referred to as Pockel's effect [Kaminow, 1965].

Nonlinear Electroacoustic Properties

Electroacoustic synergism is experienced in certain classes of materials in which the mechanical atomic vibrations are influenced by the electronic polarizability, with the result that nonlinear interaction between the atomic displacements versus the electric field causes modulation effects resulting in the generation of new sideband frequencies. Such sidebands (labeled Raman frequencies) and the response function of a Raman active medium have the form

$$H(\omega) = A_1E(\omega) + A_2E^2(\omega) + A_3E^3(\omega) + \cdots$$

Pyrosensitive Properties

The **pyrosensitive property** is governed by a class of materials known as solid electrolytes. On thermally energizing such materials, they exhibit superionic electric conduction (also known as fast ion conduction), with the result that the medium, which is dielectric under cold conditions, becomes conducting at elevated temperatures. Correspondingly, the media that are embedded with solid electrolytes show different extents of electromagnetic reflection/transmission characteristics at low and high temperatures and hence can be manipulated thermally [Neelakanta et al., 1992].

Typical solid electrolytes that can be adopted for such pyrosensitive applications are, for example, AgI and $RbAg_4I_5$. The materials like β-AgI and β-alumina show increasing conductivity with increasing temperature. The compound β-AgI exhibits superionic conductivity, with an abrupt transition at a temperature close to 147°C. This transition is known as the β- to α-phase transition, and there are a host of other materials that exhibit this phenomenon. For example, the material $RbAg_4I_5$ has a high electrical conductivity even at room temperature. It has also been observed that solid electrolytes provide sufficiently high electrical conductivity in the α-phase even when included in low volume fractions in a mixture with a nonsolid-electrolyte host [Neelakanta et al., 1992].

Nonlinear Electromagnetic Properties

Basically, the nonlinear electromagnetic properties can manifest as two subsets of material characteristics, namely, **nonlinear dielectric properties** and **nonlinear magnetic properties.**

Nonlinear Dielectric Properties

Dielectric materials whose permittivity has a distinct dependence on the intensity of the applied electric field are referred to as active or nonlinear dielectrics. Such materials demonstrate very high values of permittivity (in the order of several thousand), pronounced dependence of dielectric parameters on the temperature, and a loop of electric hysteresis under the action of an alternating voltage.

Ferroelectrics are the most typical example of nonlinear dielectrics. Rochelle's salt (potassium sodium tartrate) was the first substance in which nonlinearity was discovered. All ferroelectrics, however, possess nonlinear properties only within a definite temperature range. The temperature transition points over which the ferroelectric materials gain or lose their ferroelectric properties are referred to as Curie points. The arsenates and dihydrogen phosphates of alkali metals are also examples of ferroelectric materials.

Piezoelectrics also fall under the category of active dielectrics. Electrets, which are capable of preserving an electric charge for a long period of time (hence regarded analogous to permanent magnets), exhibit highly nonlinear dielectric properties.

Nonlinear Magnetic Properties

Ferromagnetic materials are materials in which the permanent magnetic dipoles align themselves parallel to each other. These materials have a characteristic temperature below and above which their properties differ greatly. This temperature is referred to as the Curie temperature. Above the Curie temperature they behave as paramagnetic materials, while below it they exhibit the well known hysteresis B versus H curves. Examples of such ferromagnetic materials are iron, Mu-metal, and Supermalloy. Ferrimagnetic materials are similar in their hysteresis properties to ferromagnetic materials but differ from them in that their magnetic dipoles align

themselves antiparallel to each other. Ferrites are the most popular ferrimagnetic materials, and they are of the greatest interest in electrical engineering applications.

58.5 State-of-the-Art Smart Materials

Piezoelectric Smart Materials

Piezoelectric smart materials find applications primarily in intelligent structures deploying electroelastic synergism, and a class of ceramics (popularly known as ferroelectric ceramics) have emerged in recent times for such applications. Typically, such ceramics include the base polycrystalline piezoelectrics such as $BaTiO_3$, $CdTiO_3$, $PbZrO_3$, and $PbTiO_3$, formulated with various stoichiometric proportions. Another class of piezoelectric flexible composite that has the potential for smart applications is a compound consisting of $PbTiO_3$ and chloroprene rubber. A set of glass ceramic composites containing the crystalline phases of Li_2SiO_3, $Li_2Si_2O_5$, $Ba_2TiSi_2O_8$, $Ba_2TiGe_2O_8$, $Li_2B_4O_7$, etc. are also emerging samples in smart material engineering [Chong et al., 1990].

Piezoelectric smart materials can also be made from the family of polymers, namely, polyvinylidene fluoride (PVDF). The main advantages of using this polymer are that it can be formed into very thin sheets and has excellent mechanical strength combined with high sensitivity to pressure changes.

Another piezoelectric material recently developed in the NTK Research facility in Japan is a kind of rubber-based material referred to as piezoelectric rubber. This material is composed of a base material of synthetic rubber, namely, chloroben, dispersed with fine particles of a popular piezoelectric ceramic, called PZT (lead zirconium titanate). Piezoelectric rubber combines the favorable properties of PZT, namely, high sensitivity, chemical inertness, linearity, and simplicity, with that of the rubber base, namely, flexibility. The main drawback with the piezoelectric rubber is in making an electrical contact with it. This problem has been circumvented by the development of a coaxial cable connection that is easier to use [Ting, 1990].

Magnetostrictive Smart Materials

Materials with a high degree of magnetostriction are deployed in modern intelligent structures. Typically, the amount of strain inducible with intelligent materials in the current state of the art is 2000 ppm. These are alloys made with iron and rare earth materials such as terbium (Te), dysprosium (Dy), and niobium (Nb). A commercially known material of this category is Terfenol [Reed, 1988]. Magnetostrictive transducers for smart applications have also been developed with a certain class of metallic glass materials.

Electroplastic Smart Materials

Electroplastic materials are useful as smart elastic media inasmuch as the stimulus that modifies the elastic deformation is the electric current that can be controlled externally. The usefulness of these materials for smart systems under room temperature conditions is still under investigation.

Shape-Memory Smart Materials

Shape-memory smart materials include three categories, namely shape-memory alloys (SMA), shape-memory hybrid composites (SMHC), and shape-memory polymers (SMP).

Nickel–titanium (Nitinol) alloys of proper composition exhibit unique memory, or shape-restoration force characteristics, and are the most popular shape-memory alloys. When the material is plastically deformed in its low-temperature phase and then heated above its characteristic transition temperature, the original configuration or shape is restored. Deformations up to 6–8% can be completely restored by heating the material. It is this property that is used in smart electromechanical actuations.

Shape-memory hybrid composites are composite materials that contain SMA fibers or films in such a way that they can be mechanically controlled by heat. These materials can be heated by passing a current through the fibers. SMHCs offer a wide scope of applications in material–structure interaction. The fibers used in these composites are also made of Nitinol alloys.

The third form of shape-memory materials are the shape-memory polymers. These materials have an elastic memory, meaning that a large reversible change in the elastic modulus exists across the glass-transition

temperature. In other words, across the glass-transition temperature, the material can change from a glass to rubbery state, allowing significant deformation in response to temperature changes. Shape-memory polymers, in general, are durable, lightweight, and transparent. Nippon Zeon Company and Mitsubishi Company have developed high-performance SMPs in the recent past [Chong et al., 1990]. While the SMP of Nippon Zeon Company is polynorborene based, Mitsubishi's SMP is polyurethane based, which overcomes crucial weaknesses such as poor processability and limited-temperature operating range. In their applications SMPs can be used either as an elastic memory material or a shape-memory material. Depending on which of these possibilities are used, the range of applications differs.

Electrorheological Smart Fluids

Current research on electrorheological fluids is focused toward development of carrier–particle combinations that result in the desirable characteristics to achieve smart elastic behavior [Gandhi and Thompson, 1989]. The earlier versions of electrorheological fluids contained adsorbed water, which limited their operating temperature change (up to 80°C). Particles in the newer electrorheological fluids are, however, based on polymers, minerals, and ceramics, which have a higher operating range (200°C). Also, the increase in power consumption is less with temperature increments in the recent anhydrous systems. The most commonly used carrier fluids are silicone oil, mineral oil, and chlorinated paraffin, which offer good insulation and compatibility for particulate dispersion.

Electro-optic Smart Materials

Typically potassium dihydrogen phosphate (KDP) exhibits electro-optic behavior. Synthetic materials that have the ability to alter their refractive index (and hence the optical transmission and reflection characteristics) in the presence of an electric stimulus can be comprehended as viable **smart sensor** applications.

Electroacoustic Smart Materials

Although classically the nonlinear interaction of a vibrational (acoustic) wave and an electromagnetic wave has been studied in reference to Raman active media, relevant concepts can be exercised for smart engineering applications using those materials that exhibit strong vibrational versus piezoelectric characteristics. The NTK piezorubber, PZT ceramics, $LiNBO_3$, PZT with donor additives, insolvent additives, etc. are viable candidates for smart applications in addition to piezoelectric polymers.

Electromagnetic Smart Materials

In recent times a number of materials that possess ferroelectric properties have been discovered, the most popular of which is barium titanate ($BaTiO_3$). Barium titanate has an excellent prospect as a smart material because of the several advantages it offers, such as high mechanical strength, resistance to heat and moisture, and ease of manufacturing. $BaTiO_3$ and other similar materials are frequently referred to as ferroelectric ceramics. Also, electrets such as polymethylmethacrylate offer promise for smart applications.

Among the nonlinear magnetic materials, ferromagnetic materials such as Alnico V, platinum– cobalt, and a variety of ferrites are possible smart materials.

Pyrosensitive Smart Materials

Pyrosensitive smart materials are useful in realizing intelligent electromagnetic active surfaces, radar-absorbing materials, electromagnetic shielding, and so on. For example, it has been demonstrated [Neelakanta et al., 1992] that the microwave reflection characteristics at a surface of a composite medium comprised of thermally controllable, solid-electrolytic zones (made of AgI pellets) show broadband microwave absorption/reflection characteristics under elevated temperatures. This principle can be adopted in conjunction with an electromagnetic sensor to provide a controllable feedback for thermal activation of fast-ion zones reconfigurably in order to acheive smart active-surface characteristics. Exclusive for this application, depending on the temperature limited conditions, the solid electrolyte can be chosen on the basis of its α- to β-phase transition characteristics. In order to keep the cost of the system low, a mixture phase can also be adopted, in which, commensurate with the elevated temperature operation, the host medium of the mixture could be a ceramic (dielectric).

58.6 Smart Sensors

Fiber-Optic-Based Sensors

The field of sensing technology has been revolutionized in the past decade by the entry of fiber optics. The properties of fiber optics that have made the technology suitable for communications are responsible for it being successful as a sensor as well. Fiber-optic sensors are of two types, namely, extrinsic and intrinsic. In the extrinsic type, the fiber itself acts only as a transmitter and does no part of the sensing. In an intrinsic type, however, the fiber acts as a sensor by using one of its intrinsic properties, such as induced birefringence or electrochromatism, to detect a phenomenon or quantify a measurement. Relevant to smart systems, the use of fiber optics in conjunction with optical (sensors) is based on changes in optical effects such as refractive index, optical absorption, luminescence, and chromic properties due to alterations in the environment in which the fiber is imbedded. Such alterations refer to strain or other elastic characteristics and thermal and/or electromagnetic properties [Claus, 1991]. Surfaces located with smart fiber sensors are known as smart skins.

Piezoelectric-Based Sensors

The most conventional form of sensing technology is that of piezoelectric materials, which generate an electrical response to a stimulus. In recent times piezoelectric materials have been greatly improved in mechanical strength and sensitivity. Pressure and vibration can be directly sensed as a one-to-one transduction effect resulting from the elastic-to-piezoelectric effect. Bending, on the other hand, can be sensed via piezoabsorption characteristics.

Magnetostriction-Based Sensors

The use of metallic glass as a distributive magnetostrictive sensor has been studied. Typically, in the imbedded smart sensing applications using the magnetostrictive property, the magnetic field is in the submicrogauss regime, and the nonlinearity associated with the hysteresis of magnetostriction provides a detectable sensor signal. Pressure and force, which cause static or quasi-static magnetic fields, as well as vibrations, which induce alternating magnetic fields, can be regarded as direct magnetostrictive sensor responses. In the bending mode, corresponding magnetostrictive absorption can also be sensed via reduction in the Q-factor due to absorption losses in a magnetostrictively tunable system.

Shape-Memory Effects-Based Sensors

The latest form of sensing technology utilizes shape-memory materials, namely, Nitinol alloys. The Nitinol sensors are used to measure strain and consist of superelastic Nitinol wires. The basic concept is to measure the change in resistance of a Nitinol wire used as an unbalanced arm of a Wheatstone bridge as a function of the strain. The desirable properties of Nitinol in such a sensing application are its high sensitivity and superelastic nature (which permits strains up to 6% to be accurately and repeatedly measured). The piezoelectric and Nitinol sensing materials can also be used for actuation applications.

Electromagnetics-Based Sensors

Smart electromagnetic sensors are simple deviations of classic electric/magnetic probes, more properly known as antennas or pickups. Depending on changes in the surroundings vis-à-vis the electromagnetic characteristics, these sensors respond and yield a corresponding signal. Again, the environmental changes refer to possible alterations caused by elastic, thermal, optical, magnetic, electric, and/or chemical influences.

Electroacoustic Smart Sensors

Electroacoustic smart sensors are embedded acoustic (vibration) sensors (similiar to a microphone) that adaptively yield a signal proportional to the acoustic input. Such inputs could result from changes in the alterations in the surroundings caused by elastic or thermal effects.

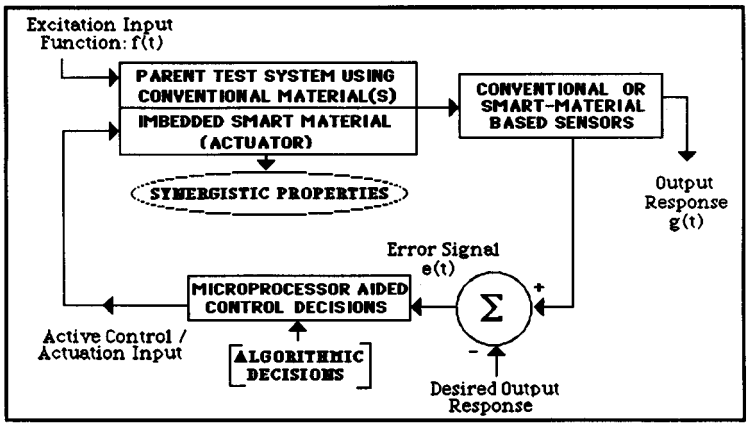

FIGURE 58.3 Schematic of a smart system.

As far as smart sensor technology is concerned, in fact, all the synergistic responses and effects between the electric and nonelectric phenomena just discussed can be judiciously adopted. Considering the state-of-the-art technology and practical considerations, however, the existing smart sensors are limited to the aforesaid versions. Future trends could, however, include other possible electric to nonelectric synergistic responses.

58.7 Examples of Smart/Intelligent Systems

The method of synthesizing a smart/intelligent system is illustrated in Fig. 58.3. The output response under a given set of input condition(s) of a parent test system is normally decided by the properties of the constituent (conventional) materials. If the system-states (changes) under the influence of external inputs are sensed, however, an appropriate feedback control can be used to actuate an imbedded smart material in the parent unit, so that output will track adaptively a desired response. The feedback path may include relevant electronic hardware (such as microprocessors) for on-line processing of the feedback signal to optimize the system performance.

Essentially, the smart materials can be adopted in two regimes of the system shown in Fig. 58.3. The *sensing unit* can be zones of an integrated set of smart material that senses the response of the parent system on a real time basis. (Sometimes, conventional sensors/tranducers can serve this purpose, as well.) The *actuating unit,* built-in as a part of the parent structure, consists of a smart material, which upon receiving the electric signal from the feedback loop modifies the response of the parent system, as dictated by the input signal. Thus, the actuation is based on the synergism between the electric input to the corresponding material property of the parent structure being altered.

The feedback control unit may consist of decision logic, which can relatively modify the error signal being fed to the actuator. The decision logic refers to, for example, response linearization, time-averaged smoothing, amplitude-limiting, and bandwidth control. On the basis of the general schematic depicted in Fig. 58.3, the following discusses a few examples of application-specific intelligent systems using smart materials.

Structural Engineering Applications

Figure 58.4 illustrates a smart vibration control strategy in structural beams. Normally, the parent beam is made of conventional materials, and its vibrational characteristics are decided by the elastic behavior of the constituent materials. Suppose a smart material is imbedded in the test beam. This material could be one of the types indicated in Fig. 58.2. A vibration sensor yields an electric output proportional to the vibration. Suppose the dynamic response of the beam (as observed at the output of the sensor) deviates from the desired characteristics. Then an error signal can be generated, which in turn can be used to develop an optimal control signal and this control signal can be fed back to the smart material whose elastic behavior is then altered as a function of the control input. As a result, the vibration characteristics of the entire (parent) structure are modified, or the system is dynamically tuned in an adaptive manner.

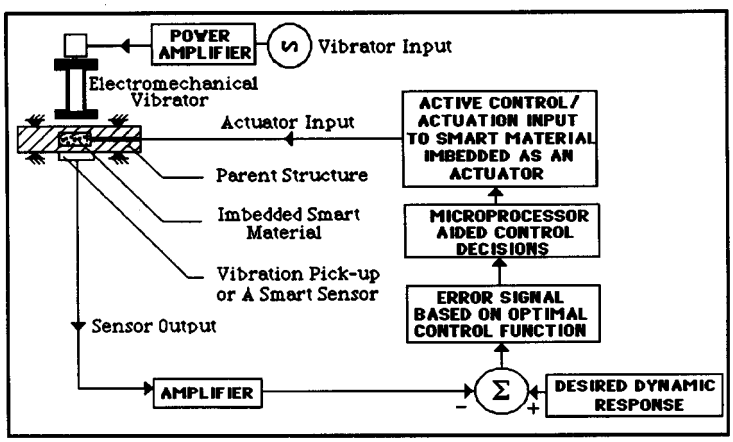

FIGURE 58.4 Active control of vibrating beams.

The vibration sensor used can be either a conventional transducer (such as resistive, capacitive, inductive, or optical displacement versions) or it can be a smart sensor by itself. For example, an optical fiber with a leaky sheath (which permits the light energy to leak from the core to the outside surface) can be imbedded in the parent structure. When the structure is deformed, the extent of light leakage from the fiber to the surrounding material will modify proportionately. Hence, the detected light signal from the fiber optics, when detected, delivers information on the deformation or the dynamic structural characteristics of the test beam. This sensor can be made smart by integrating a distributed set of fibers that can sense strain, vibration, temperature, if needed, and so on, so that the network implemented with appropriate algorithms will provide exhaustive data for a comprehensive adaptive feedback control strategy.

Although the scheme illustrated in Fig. 58.4 refers to vibration control (or damping) in structures, judicious choice of subsystems and materials will permit adaptive control over other structural aspects also, namely, strain, bending moment, and redistribution of load path in response to failures.

Electromagnetic Applications

Smart material/structural techniques can be adopted in electromagnetic systems. The following are possible applications:

- Smart low-frequency magnetic shields
- Smart high-frequency electromagnetic shields
- Smart electrostatic dissipative/conductive surfaces
- Smart radar-absorbing materials (smart RAMs)
- Smart linear and aperture antennas

In all the preceding applications, the basic consideration is that the relevant structure can smartly and adaptively change its electromagnetic properties (normally specified via dielectric permittivity, magnetic permeability, and electrical conductivity parameters) so that the desired electromagnetic performance is acheived. Two typical systems are detailed next.

Electromagnetic Active Surface Embedded with Ferroelectric Inclusions

Figure 58.5 illustrates the concept of a smart electromagnetic active surface. The surface is made of a mixture of polyacrylamide, ferrite, and barium titanate on a ceramic substrate. This skin material, which represents a lossy, nonlinear electromagnetic medium with anisotropic ferroelectric and ferromagnetic properties, offers different extents of surface impedence, in the presence and absence of an electric voltage stimulus applied to

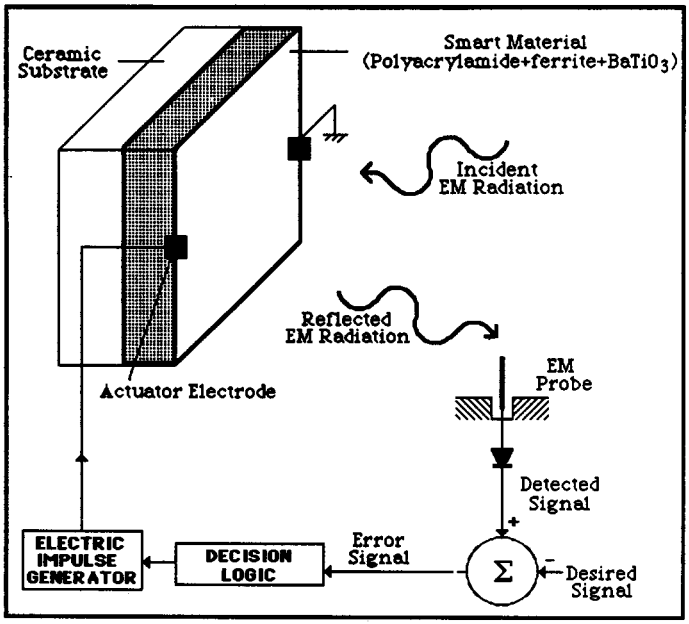

FIGURE 58.5 Smart electromagnetic active surface.

it. Hence, the reflection coefficient of this material to electromagnetic energy can be altered via electric stimulus. Relevant feedback can facilitate adaptive smart responsiveness of the system as illustrated [Neelakanta et al., 1992].

Smart Electromagnetic Aperture

The aperture-radiation of microwaves can be smartly controlled by using a pyrosensitive material as illustrated in Fig. 58.6. A set of solid-electrolyte (AgI) pellets interconnected via nichrome heating elements is placed at the aperture of a microwave horn. At room temperature, the pellets behave as dielectrics (β-phase AgI). When heated, however, the β-phase AgI changes to a highly conducting medium (α-phase), which would mask a part of the aperture, thus modifying the radiation pattern of the horn antenna. Again, an appropriate feedback loop would render the functioning of this system intelligent [Neelakanta et al., 1992].

58.8 High-Tech Application Potentials

Although smart material technology is in its infancy pending significant efforts to make it usable on a wide scale, the existing results and ongoing research have confirmed the usability of these materials in several avenues of modern high-technology systems.

Currently imaginable enclaves for the use of intelligent materials not only include structural engineering but also such areas as electromagnetics and biomedical, optical, and biological techniques. Relevant research has also been focused heavily in aerospace, aeronautics, marine vessel, and robotic applications.

Adaptive, self-monitoring of well-being by a system that has an integrated set of smart devices to self-assess its performance, diagnosing any malfunctions and failures and able to change its system characteristics vis-à-vis the environment, has been the objective of the relevant seed research pursued until now. For example, self-health checks by aircraft via a network of smart-skin sensors offer real-time monitoring of the structural well-being of tomorrow's aircraft [Claus, 1991]. The protocols in such efforts include self-diagnosis, prediction and notification, and self-repair strategies relevant to mechanical structures (such as aircraft bodies).

Another domain of smart material application is in self-induced morphologies in the infrastructure of the material with self-adaptive adjustments to the surroundings. Examples of this category include materials usable over a wide range of temperatures (as in space shuttles), with a smart adaptibility to transform according to the environment. Similarly, in radar stealth applications, the target skin could offer variable electromagnetic absorption over a broad band of radar frequencies.

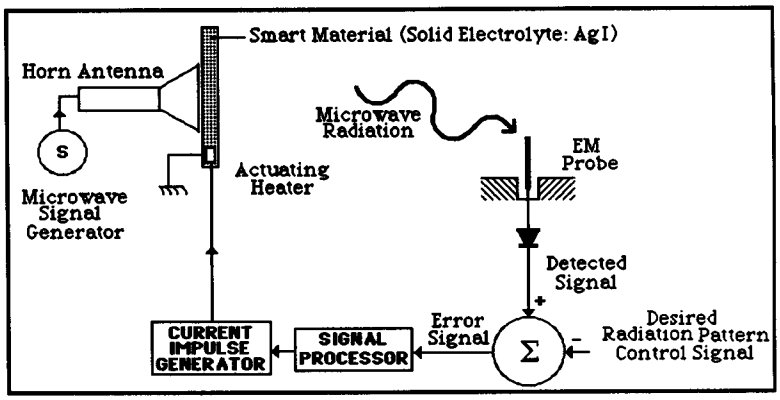

FIGURE 58.6 Smart electromagnetic aperture radiation control.

Extensions of smart material concepts can cover selective acoustical absorptions and adaptive chromic controls in glasses, mirrors, etc. In short, viable smart systems can be conceived with various combinations of material characteristics discussed earlier together with the advent of new conventional materials, innovative sensors, advances in microcomputers, artificial intelligence, neural networking, and other upcoming technologies. Currently imaginable outlets for smart materials are summarized in the following list.

1. Structural/mechanical engineering
   - Airborne/space-borne systems with smart skins for adaptive self-health check feasibilities
   - Earthquake-resistant intelligent buildings
   - Large deployable space structures
   - Nondestructive evaluation of large structures
2. Thermal engineering
   - Adaptive heat transfer and heat-resistant structures (space shuttles, etc.)
3. Optical engineering
   - Adaptive hue, optical transparency, reflection, opaqueness control in glasses and mirrors
4. Electromagnetic engineering
   - Magnetic and electrostatic shielding
   - High-frequency shielding
   - Radar-absorbing materials
   - Active surfaces
   - Adaptive scattering/radiation control
5. Acoustical engineering
   - Active absorption/reflection of sonar radiation
   - Adaptive anechoic chambers
6. Chemical engineering
   - Materials with adaptive adsorption characteristics
   - Adaptive corrosion-resistant materials
7. Biomedical engineering
   - Materials with smart structural properties usable as artificial limbs
   - Materials with adaptive biochemical properties
8. Warfare systems
   - Smart shelters
   - Shock-resistant structures

58.9 Conclusions

The quest for new materials in scientific endeavors and engineering applications is everlasting. The emergence of the smart material concept has set a trend that science and technology in the coming years will rely to a large extent on the development of exotic materials, with intelligent materials being the leading candidates. Such materials will be hyper-functional with unstereotyped purposiveness responses to novel and changing situations.

Defining Terms

Electroacoustic smart materials: Materials that have self-adaptive characteristics in their acoustical behavior (such as transmission, reflection, and absorption of acoustical energy) in response to an external stimulus applied as a function of the sensed acoustical response.

Electromagnetic smart materials: Materials such as shielding materials, radar-absorbing materials (RAMs), and electromagnetic surface materials, in all of which some electromagnetic properties can be adaptively controlled by means of an external stimulus dictated by the sensed electromagnetic response.

Electro-optic smart materials: Materials in which optical properties are changed self-adaptively with an external electric stimulus proportional to the sensed optical characteristics.

Electroplastic effect: Plastic deformation of metals with the application of high-density electric current.

Electroplastic smart materials: Materials with smart properties of elastic deformation changes proportional to a controlled electric current applied in proportion to the sensed deformation.

Electrorheological property: Property exhibited by some fluids that are capable of altering their flow characteristics depending on an externally applied electric field.

Electrorheological smart fluids: Fluids with smart flow characteristics dictated to change self-adaptively by means of an electric field applied in proportion to the sensed flow parameters.

Intelligent structures: Structures constructed of smart materials with a dedicated, discrete set of integrated actuators, sensors, etc., in order to respond to the environment around them in a predetermined (desired) manner.

Magnetostrictive effect: Structural strain experienced in a material subjected to a polarizing magnetic flux, or reversibly, experiencing magnetic property changes to external mechanical stresses.

Magnetostrictive smart materials: A class of materials with self-adaptively modifiable elastic properties in response to a magnetic field applied in proportion to sensed stress–strain information.

Nonlinear dielectric property: The distinct dependence of the electric permittivity of certain dielectric materials on the intensity of an applied electric field.

Nonlinear electroacoustic property: Nonlinear interaction between the atomic displacement and the electric field experienced in certain materials that would cause modulation effects resulting in the generation of new sideband frequencies (called Raman frequencies).

Nonlinear electro-optic property: Nonlinear changes in the refractive index of certain optically transparent materials with change(s) in the externally applied electric field.

Nonlinear magnetic property: Nonlinear dependence of the magnetic susceptibility of certain materials on the intensity of an applied magnetic field.

Piezoelectric property: Ability of a material to induce opposite charges at two faces (correspondingly to exhibit a voltage difference between the faces) of the material as a result of the strain due to a mechanical force applied across the faces; reversibly, application of a potential across the faces would induce a mechanical strain.

Piezoelectric smart materials: Materials capable of changing their elastic characteristics (by virtue of their piezoelectric property) self-adaptively in response to an externally applied electric potential proportional to the observed elastic behavior.

Pyrosensitive properties: Exhibited by materials known as solid electrolytes whose electromagnetic properties can be altered by temperature.

Pyrosensitive smart materials: Materials that self-adaptively (smartly) manage the electromagnetic surface characteristics of active surfaces constituted by pyrosensitive inclusions, in response to an external temperature-inducing stimulus applied per the feedback information on electromagnetic characteristics.

Shape-memory effects: Mechanism by which a plastically deformed object in the low-temperature martensitic condition regains its original shape when the external stress is removed and heat is applied.

Shape-memory smart materials: Materials that smartly change their elastic characteristics by virtue of their shape-restoration characteristics achieved by means of an external stimulus in proportion to the magnitude of sensed shape changes.

Smart, or intelligent, materials: A class of materials and/or composite media having inherent intelligence together with self-adaptive capabilities to external stimuli applied in proportion to a sensed material response.

Smart sensors: Sensors with inherent intelligence via bulit-in electronics.

Smart structural materials: Materials in which the mechanical (elastic) properties can be modified adaptively through the application of external stimuli.

Smart thermal materials: Materials that can influence their thermal states (temperature or thermal properties such as conductivity) self-adaptively by means of an external control in response to environmental demands.

California's Mojave Desert is the site of Solar Two, the world's most technically advanced solar power plant. Solar Two uses an innovative molten salt technology to capture and store the sun's energy. This technology vastly differs from other solar technologies because, for the first time, it allows the practical storage of solar energy during the day to generate electricity at night.

Solar Two uses 1,926 heliostats (mirrors) located on a field in circular formation around a 300-ft tower to focus sunlight on a central receiver which generates a clean, inexhaustible supply of energy. The heliostats are equipped with two dual-axis electrical motors that position the mirrors to reflect the most sunlight onto the receiver via a computerized program.

Scheduled for testing until 1998, Solar Two will demonstrate the technical and economical viability of an emission-free solar thermal power plant to produce virtually unlimited supplies of electricity. (Photo courtesy of Southern California Edison.)

THE GENERATION, TRANSMISSION, AND DISTRIBUTION of electrical energy remains one of the most exciting and challenging areas of electrical engineering. Without a safe, reliable, and economic supply of electrical energy, all industry would come to a grinding halt.

This section will present chapters discussing the theory and methods for the generation, transmission, and distribution of electrical energy. While the fundamentals have been around a long time, the application of the fundamentals will continue to take on many new forms.

The great majority of electrical energy continues to be generated by large conventional power plants, which are discussed in Chapter 61. As Chapter 62 will explain, fuel cells, wind, and solar are becoming important components of the overall generation picture.

The transmission of electrical energy over long distances and at increasingly higher voltages has become an ever more important component as "open access" of these facilities becomes a reality. Chapter 63 will present the theory of transmission, including alternating current and direct current transmission, both overhead and underground. In addition, the discussion will include the protection of these facilities, transient operation, and planning.

A modern power system operates at many different voltage levels. Because of this, transformers play a key role. The theory is the same for all voltage levels and will be presented in Chapter 66. The chapter will also discuss application of the theory for different types of transformers commonly used.

The final component in bringing electrical energy to the ultimate user is the distribution system. For many years the stepchild to the more costly generation and transmission components, distribution systems are now playing an important role in increasing reliability and service at a reduced cost. Chapter 67 presents an overview of this key component.

Generators and motors are still the primary devices for converting energy from mechanical to electrical and vice versa. Chapter 68 is devoted to the theory of ac/dc motors and generators.

The automatic control of the total power system is presented in Chapter 69. This is one area of power systems that has changed dramatically and continues to change on almost a daily basis. In many ways, the total field of electrical engineering is applied in the control of a modern power system.

Nomenclature

Symbol	Quantity	Unit
D	damping coefficient	
DF	demand factor	
δ	power angle	degree
δ	torque angle	degree
f_s	slip frequency	Hz
ϕ	core flux	Wb
ϕ_f	magnetic field flux	Wb
I_{ac}	rms ac current	A
I_f	field current	A
I_r	rotor current	A
J	moment of inertia of rotor	kg-m^2/rad
K_a	armature constant of a dc machine	
K_t	torque constant of a dc machine	
LSF	loss factor	
λ	magnetic flux linkages	Wb/m
n	rotor speed	rpm
n	Steinmetz constant	
N	number of turns	
N_p	number of stator pole pairs	
ω_s	slip frequency radian	
P	real power	W
P_e	eddy current loss	W
P_h	hysteresis power loss	W
Q	reactive power	
r	radius of conductor	m
ρ	resistivity of conductor	Ωm
s	slip of an induction motor	
$\overline{S}$	complex power	
T	shaft torque	N-m
θ	rotor angle	degree
θ	power factor angle	degree
V_a	armature back emf	V
w	shaft speed	rad/s

59.1 Introduction

The electric energy demand of the world is continuously increasing, and most of the energy is generated by conventional power plants, which remain the only cost-effective method for generating large quantities of energy.

Power plants utilize energy stored in the earth and convert it to electrical energy that is distributed and used by customers. This process converts most of the energy into heat, which increases the entropy of the earth. In this sense, power plants deplete the earth's energy supply. Efficient operation becomes increasingly important to conserve energy.

Typical energy sources used by power plants include fossil fuel (gas, oil, and coal), nuclear fuel (uranium), geothermal energy (hot water, steam), and hydro energy (water falling through a head).

Around the turn of the century, the first fossil power plants used steam engines as the prime mover. These plants were evolved to an 8- to 10-MW capacity, but increasing power demands resulted in the replacement by a more efficient steam boiler–turbine arrangement. The first commercial steam turbine was introduced by DeLaval in 1882. The boilers were developed from heating furnaces. Oil was the preferred and most widely used fuel in the beginning. The oil shortage promoted coal-fired plants, but the adverse environmental effects (sulfur dioxide generation, acid rain, dust pollution, etc.) curtailed their use in the late seventies. Presently the most acceptable fuel is natural gas, which minimizes pollution and is available in large quantities. During the next two decades, gas-fired power plants will dominate the electric industry.

The hydro plants' ancestors are water wheels used for pumping stations, mill driving, etc. Water-driven turbines were developed in the last century and used for generation of electricity since the beginning of their commercial use. However, most of the sites that can be developed economically are currently being utilized. No significant new development is expected in the United States in the near future.

Nuclear power plants appeared after the Second World War. The major development occurred during the sixties; however, by the eighties environmental considerations stopped plant development in the United States and slowed it down all over the world. Presently, the future of nuclear power generation is unclear, but the abundance of nuclear fuel and the expected energy shortage in the early part of the next century may rejuvenate nuclear development if safety issues can be resolved.

Geothermal power plants are the product of the clean energy concept, although the small-scale, local application of geothermal energy has a long history. Presently only a few plants are in operation. The potential for further development is limited because of the unavailability of geothermal energy sites that can be developed economically.

Typical technical data for different power plants is shown in Table 59.1.

59.2 Fossil Power Plants

The operational concept and major components of a fossil power plant are shown in Fig. 59.1.

Fuel Handling

The most frequently used **fuels** are oil, natural gas, and coal. Oil and gas are transported by rail, on ships, or through pipelines. In the former case the gas is liquefied. Coal is transported by rail or ships if the plant is near a river or the sea. The power plant requires several days of fuel reserve. Oil and gas are stored in large metal tanks, and coal is kept in open yards. The temperature of the coal layer must be monitored to avoid self-ignition.

Oil is pumped and gas is fed to the burners of the **boiler.** Coal is pulverized in large mills, and the powder is mixed with air and transported by air pressure, through pipes, to the burners. The coal transport from the yard to the mills requires automated transporter belts, hoppers, and sometimes manually operated bulldozers.

Boiler

Two types of boilers are used in modern power plants: subcritical water-tube drum-type and supercritical once-through type. The former operates around 2500 psi, which is under the water critical pressure of 3208.2 psi. The latter operates above that pressure, at around 3500 psi. The superheated steam temperature is about 1000°F (540°C) because of turbine temperature limitations.

A typical subcritical water-tube drum-type boiler has an inverted-U shape. On the bottom of the rising part is the furnace where the fuel is burned. The walls of the furnace are covered by water pipes. The drum and the **superheater** are at the top of the boiler. The falling part of the U houses the reheaters, **economizer** (water heater), and air preheater, which is supplied by the forced-draft fan. The induced-draft fan forces the flue gases out of the system and sends them up the stack, which is located behind the boiler. A flow diagram of the drum-type boiler is shown in Fig. 59.2. The steam generator has three major systems: fuel, air-flue gas, and water-steam.

Fuel System. Fuel is mixed with air and injected into the furnace through burners. The burners are equipped with nozzles, which are supplied by preheated air and carefully designed to assure the optimum air-fuel mix. The fuel mix is ignited by oil or gas torches. The furnace temperature is around 3000°F.

Air-Flue Gas System. Ambient air is driven by the forced-draft fan through the air preheater, which is heated by the high-temperature (600°F) flue gases. The air is mixed with fuel in the burners and enters into the furnace, where it supports the fuel burning. The hot combustion flue gas generates steam and flows through the boiler

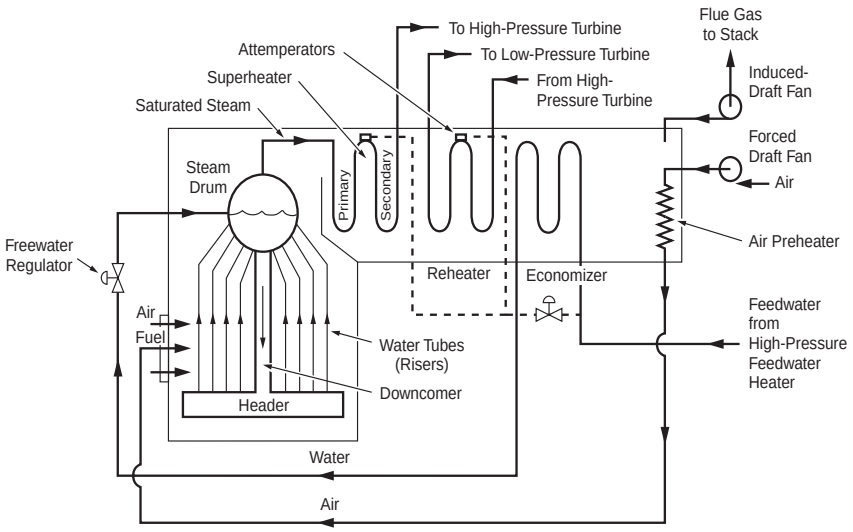

FIGURE 59.2 Flow diagram of a typical drum-type steam boiler.

to heat the superheater, reheaters, economizer, etc. Induced-draft fans, located between the boiler and the stack, increase the flow and send the 300°F flue gases to the atmosphere through the stack.

Water-Steam System. Large pumps drive the feedwater through the high-pressure heaters and the economizer, which further increases the water temperature (400–500°F). The former is heated by steam removed from the turbine; the latter is heated by the flue gases. The preheated water is fed to the steam drum. Insulated tubes, called downcomers, are located outside the furnace and lead the water to a header. The header distributes the hot water among the risers. These are water tubes that line the furnace walls. The water tubes are heated by the combustion gases through both convection and radiation. The steam generated in these tubes flows to the drum, where it is separated from the water. Circulation is maintained by the density difference between the water in the downcomer and the water tubes. Saturated steam, collected in the drum, flows through the superheater. The superheater increases the steam temperature to about 1000°F. Dry superheated steam drives the high-pressure turbine. The exhaust from the high-pressure turbine goes to the reheater, which again increases the steam temperature. The reheated steam drives the low-pressure turbine.

The typical supercritical once-through-type boiler concept is shown in Fig. 59.3.

The feedwater enters through the economizer to the boiler, which consists of riser tubes that line the furnace wall. All the water is converted to steam and fed directly to the superheater. The latter increases the steam temperature above the critical temperature of the water and drives the turbine. The construction of these steam generators is more expensive than the drum-type units but has a higher operating efficiency.

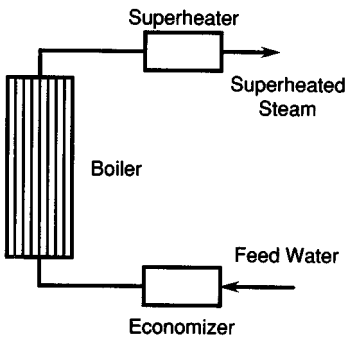

FIGURE 59.3 Concept of once-through-type steam generator.

Turbine

The turbine converts the heat energy of the steam into mechanical energy. Modern power plants usually use one high-pressure and one or two lower-pressure turbines. A typical turbine arrangement is shown in Fig. 59.4.

The figure shows that only one bearing is between each of the machines. The shafts are connected to form a tandem compound steam turbine unit. High-pressure steam enters the high-pressure turbine to flow through and drive the turbine. The exhaust is reheated in the boiler and returned to the lower-pressure units. Both the rotor and the stationary part of the turbine have blades. The length of the blades increases from the steam entrance to the exhaust.

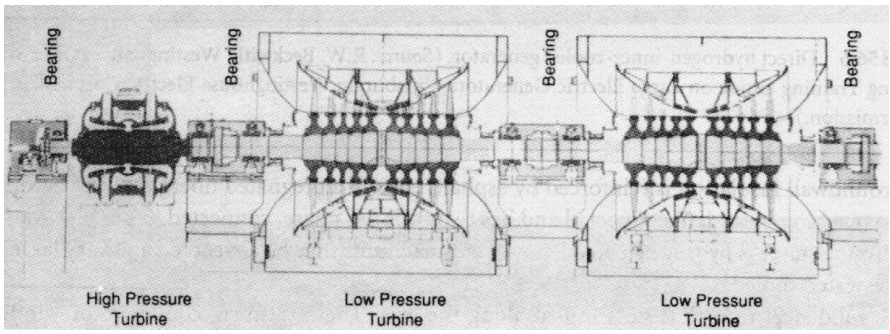

FIGURE 59.4 Large tandem compound steam turbine. (*Source:* M.M. El-Wakil, *Power Plant Technology,* New York: McGraw-Hill, 1984, p. 210. With permission.)

Figure 59.5 shows the blade arrangement of an *impulse*-type turbine. Steam enters through nozzles and flows through the first set of moving rotor blades. The following stationary blades change the direction of the flow and direct the steam into the next set of moving blades. The nozzles increase the steam speed and reduce pressure, as shown in the figure. The impact of the high-speed steam, generated by the change of direction and speed in the moving blades, drives the turbine.

The *reaction*-type turbine has nonsymmetrical blades arranged like those shown in Fig. 59.5. The blade shape assures that the pressure continually drops through all rows of blades, but steam velocity decreases in the moving blades and increases in the stationary blades.

Generator

The generator converts mechanical energy from the turbines into electrical energy. The major components of the generator are the frame, stator core and winding, rotor and winding, bearings, and cooling system. Figure 59.6 shows the cross section of a modern hydrogen-cooled generator.

The stator has a laminated and slotted silicon steel iron core. The stacked core is clamped and held together by insulated axial through bolts. The stator winding is placed in the slots and consists of a copper-strand configuration with woven glass insulation between the strands and mica flakes, mica mat, or mica paper ground-wall insulation. To avoid insulation damage caused by vibration, the groundwall insulation is reinforced by asphalt, epoxy-impregnated fiberglass, or Dacron. The largest machine stator is Y-connected and has two coils per phase, connected in parallel. Most frequently, the stator is hydrogen-cooled; however, small units may be air-cooled and very large units may be water-cooled.

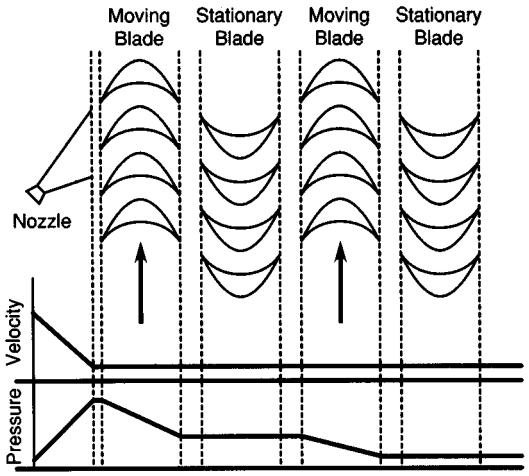

FIGURE 59.5 Velocity and pressure variation in an impulse turbine.

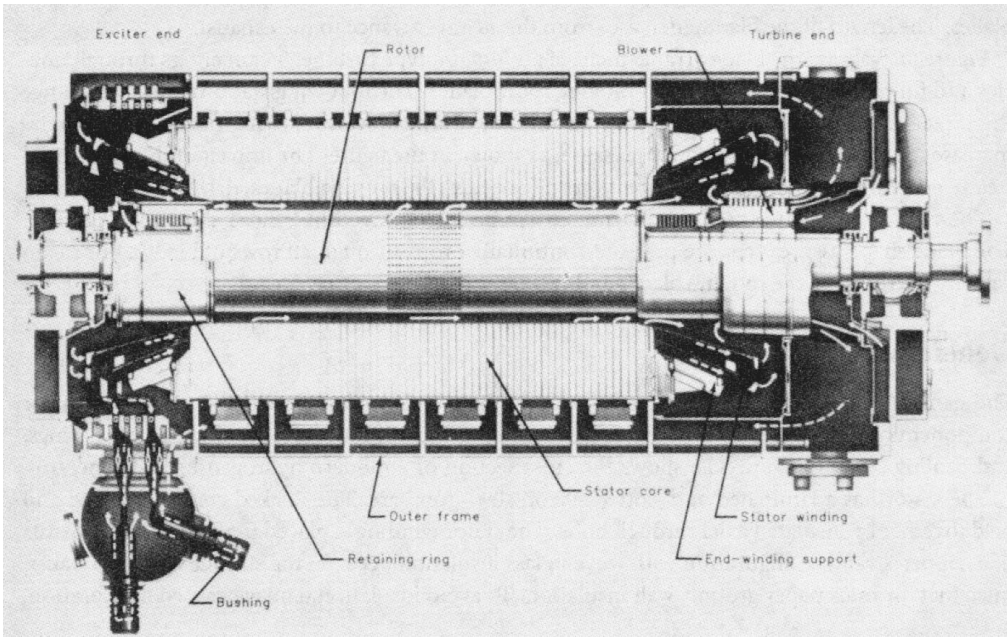

FIGURE 59.6 Direct hydrogen-inner-cooled generator. (*Source:* R.W. Beckwith, Westinghouse Power Systems Marketing Training Guide on Large Electric Generators, Pittsburgh: Westinghouse Electric Corp. 1979, p. 54. With permission.)

The solid steel rotor has slots milled along the axis. The multiturn, copper rotor winding is placed in the slots and cooled by hydrogen. Cooling is enhanced by subslots and axial cooling passages. The rotor winding is restrained by wedges inserted in the slots.

The rotor winding is supplied by dc current, either directly by a brushless excitation system or through collector rings. The rotor is supported by bearings at both ends. The non-drive-end bearing is insulated to avoid shaft current generated by stray magnetic fields. The hydrogen is cooled by a hydrogen-to-water heat exchanger mounted on the generator or installed in a closed-loop cooling system.

The dc current of the rotor generates a rotating magnetic field that induces an ac voltage in the stator winding. This voltage drives current through the load and supplies the electrical energy.

Electric System

Energy generated by the power plant supplies the electric network through transmission lines. The power plant operation requires auxiliary power to operate mills, pumps, etc. The auxiliary power requirement is approximately 10 to 15%.

Smaller generators are directly connected in parallel using a busbar. Each generator is protected by a circuit breaker. The power plant auxiliary system is supplied from the same busbar. The transmission lines are connected to the generator bus, either directly or through a transformer.

The larger generators are unit-connected. In this arrangement the generator is directly connected, without a circuit breaker, to the main transformer. A conceptual one-line diagram is shown in Fig. 59.7. The generator supplies main and auxiliary transformers without circuit breakers. The units are connected in parallel at the high-voltage side of the main transformers by a busbar. The transmission lines are also supplied from this bus. Circuit breakers are installed at the secondary side of the main and auxiliary transformer. The application of generator circuit breaker is not economical in the case of large generators. Because of the generator's large short-circuit current, special expensive circuit breakers are required. However, the transformers reduce the short-circuit current and permit the use of standard circuit breakers at the secondary side. The disconnect switches permit visual observation of the off state and are needed for maintenance of the circuit breakers.

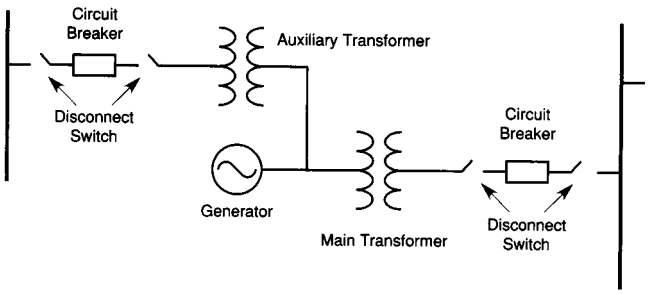

FIGURE 59.7 Conceptual one-line diagram for a unit-connected generator.

Condenser

The condenser condenses turbine exhaust steam to water, which is pumped back to the steam generator through various water heaters. The condensation produces a vacuum, which is necessary to exhaust the steam from the turbine. The condenser is a shell-and-tube heat exchanger, where steam condenses on water-cooled tubes. Cold water is obtained from the cooling towers or other cooling systems. The condensed water is fed through a deaerator, which removes absorbed gases from the water. Next, the gas-free water is mixed with the feedwater and returned to the boiler. The gases absorbed in the water may cause corrosion (oxygen) and increase condenser pressure, adversely affecting efficiency. Older plants use a separate deaerator heater, while deaerators in modern plants are usually integrated in the condensor, where injected steam jets produce pressure drop and remove absorbed gases.

Stack and Ash Handling

The stack is designed to disperse gases into the atmosphere without disturbing the environment. This requires sufficient stack height, which assists the fans in removing gases from the boiler through natural convection. The gases contain both solid particles and harmful chemicals. Solid particles, like dust, are removed from the flue gas by electrostatic precipitators or bag-house filters. Harmful sulfur dioxide is eliminated by scrubbers. The most common is the lime/limestone scrubbing process.

Coal-fired power plants generate a significant amount of ash. The disposition of the ash causes environmental problems. Several systems have been developed in past decades. Large ash particles are collected by a water-filled ash hopper, located at the bottom of the furnace. Fly ash is removed by filters, then mixed with water. Both systems produce sludge that is pumped to a clay-lined pond where water evaporates and the ash fills disposal sites. The clay lining prevents intrusion of groundwater into the pond.

Cooling and Feedwater System

The condenser is cooled by cold water. The open-loop system obtains the water from a river or sea, if the power plant location permits it. The closed-loop system utilizes cooling towers, spray ponds, or spray canals. In the case of spray ponds or canals, the water is pumped through nozzles, which generate fine sprays. Evaporation cools the water sprays as they fall back into the pond. Several different types of cooling towers have been developed. The most frequently used is the wet cooling tower, where the hot water is sprayed on top of a latticework of horizontal bars. The water drifts downward and is cooled, through evaporation, by the air, which is forced by fans or natural draft upward.

The power plant loses a small fraction of the water through leakage. The feedwater system replaces this lost water. Replacement water has to be free from absorbed gases, chemicals, etc., because the impurities cause severe corrosion in the turbines and boiler. The water treatment system purifies replacement water by pretreatment, which includes filtering, chlorination, demineralization, condensation, polishing. These complicated chemical processes result in a corrosion-free high-quality feedwater.

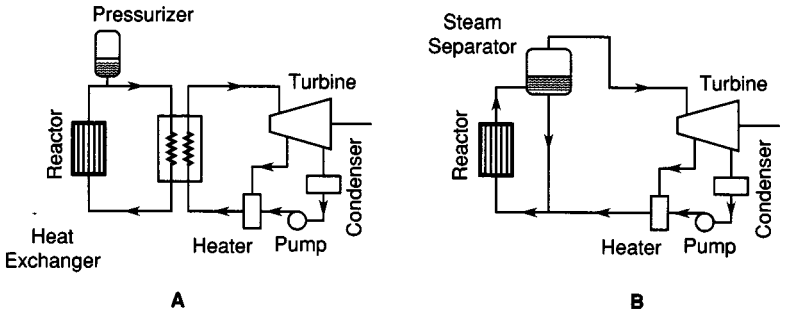

FIGURE 59.8 (A) Power plant with PWR; (B) power plant with BWR.

59.3 Nuclear Power Plants

More than 500 nuclear power plants operate around the world. Close to 300 operate pressurized water reactors (PWRs), more than 100 are built with boiling-water reactors (BWRs), about 50 use gas-cooled reactors, and the rest are heavy-water reactors. In addition a few fast breeder reactors are in operation. These reactors are built for better utilization of uranium fuel. The modern nuclear plant size varies from 100 to 1200 MW.

Pressurized Water Reactor

The general arrangement of a power plant with a PWR is shown in Fig. 59.8(A).

The **reactor** heats the water from about 550 to about 650°F. High pressure, at about 2235 psi, prevents boiling. Pressure is maintained by a pressurizer, and the water is circulated by a pump through a heat exchanger. The heat exchanger evaporates the feedwater and generates steam, which supplies a system similar to a conventional power plant. The advantage of this two-loop system is the separation of the potentially radioactive reactor cooling fluid from the water-steam system.

The reactor core consists of fuel and control rods. Grids hold both the control and fuel rods. The fuel rods are inserted in the grid following a predetermined pattern. The fuel elements are Zircaloy-clad rods filled with UO_2 pellets. The control rods are made of a silver (80%), cadmium (5%), and indium (15%) alloy protected by stainless steel. The reactor operation is controlled by the position of the rods. In addition, control rods are used to shut down the reactor. The rods are released and fall in the core when emergency shutdown is required. Cooling water enters the reactor from the bottom, flows through the core, and is heated by nuclear fission.

Boiling-Water Reactor

In the BWR shown in Fig. 59.8(B), the pressure is low, about 1000 psi. The nuclear reaction heats the water directly to evaporate it and produce wet steam at about 545°F. The remaining water is recirculated and mixed with feedwater. The steam drives a turbine that typically rotates at 1800 rpm. The rest of the plant is similar to a conventional power plant. A typical reactor arrangement is shown in Fig. 59.9. The figure shows all the major components of a reactor. The fuel and control rod assembly is located in the lower part. The steam separators are above the core, and the steam dryers are at the top of the reactor. The reactor is enclosed by a concrete dome.

59.4 Geothermal Power Plants

The solid crust of the earth is an average of 20 mil (32 km) deep. Under the solid crust is the molten mass, the magma. The heat stored in the magma is the source of geothermal energy. The hot molten magma comes close to the surface at certain points in the earth and produces volcanoes, hot springs, and geysers. These are the signs of a possible geothermal site. Three forms of geothermal energy are considered for development.

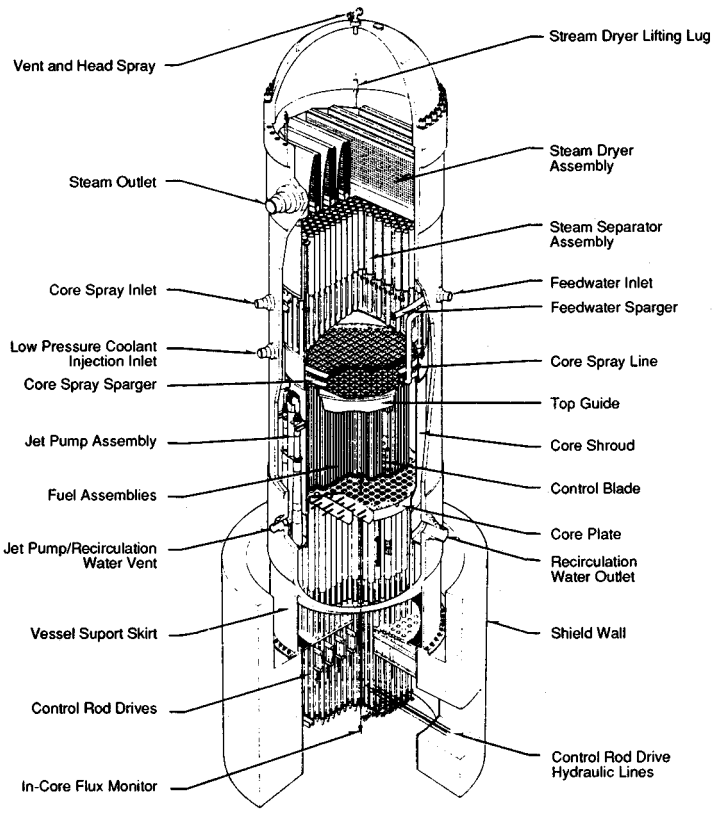

FIGURE 59.9 Typical BWR reactor arrangement. (*Source:* Courtesy of General Electric Company.)

Hydrothermal Source. This is the most developed source. Power plants, up to a capacity of 2000 MW, are in operation worldwide. Heat from the magma is conducted upward by the rocks. The groundwater drifts down through the cracks and fissures to form reservoirs when water-impermeable solid rock bed is present. The water in this reservoir is heated by the heat from the magma. Depending on the distance from the magma and rock configuration, steam, hot pressurized water, or the mixture of the two are generated. Signs of these underwater reservoirs include hot springs and geysers. The reservoir is tapped by a well, which brings the steam-water mixture to the surface to produce energy. The geothermal power plant concept is illustrated in Fig. 59.10.

The hot water and steam mixture is fed into a separator. If the steam content is high, a centrifugal separator is used to remove the water and other particles. The obtained steam drives a turbine. The typical pressure is

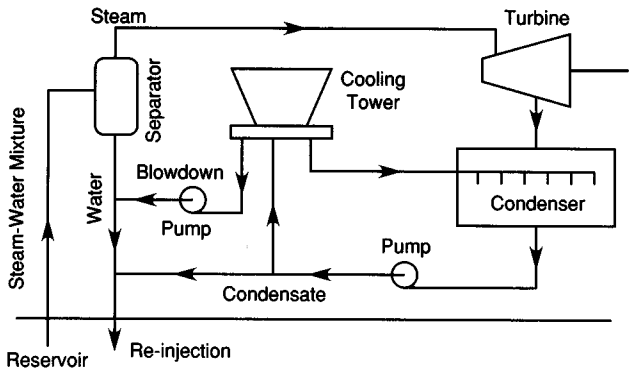

FIGURE 59.10 Concept of a geothermal power plant.

around 100 psi and the temperature is around 400°F (200°C). If the water content is high, the water-steam mixture is led through a flashed-steam system where the expansion generates a better quality of steam and separates the steam from the water. The water is returned to the ground, the steam drives the turbine. Typically the steam entering the turbine has a temperature of 120 to 150°C and a pressure of 30 to 40 psi.

The turbine drives a conventional generator. The typical rating is in the 20- to 100-MW range. The exhaust steam is condensed in a direct-contact condenser. A part of the obtained water is reinjected into the ground. The rest of the water is fed into a cooling tower to provide cold water to the condenser.

Major problems with geothermal power plants are the minerals and noncondensable gases in the water. The minerals make the water highly corrosive, and the separated gases cause air pollution. An additional problem is noise pollution. The centrifugal separator and blowdowns require noise dampers and silencers.

Petrothermal Source. Some fields have only hot rocks under the surface. Utilization of this petrothermal source requires pumping surface water through a well in a constructed hole to a reservoir. The hot water is then recovered through another well. The problem is the formation of a reservoir. The U.S. government is studying practical uses of petrothermal sources.

Geopressured Source. In deep underground holes (8000 to 30,000 ft) a mixture of pressurized water and natural gas, like methane, may sometimes be found. These geopressured sources promise power generation through the combustion of methane and the direct recovery of heat from the water. The geopressured method is currently in an experimental stage, with operating pilot plants.

59.5 Hydroelectric Power Plants

Hydroelectric power plants convert energy produced by a water head into electric energy. A typical hydroelectric power plant arrangement is shown in Fig. 59.11.

The head is produced by building a dam across a river, which forms the upper-level reservoir. In the case of low head, the water forming the reservoir is fed to the turbine through the intake channel or the turbine is integrated in the dam. The latter arrangement is shown in Fig. 59.11(A). **Penstock** tubes or tunnels are used for medium- [Fig. 59.11(B)] and high-head plants (Fig. 59.12). The spillway regulates the excess water by opening gates at the bottom of the dam or permitting overflow on the spillway section of the dam. The water discharged from the turbine flows to the lower or tail water reservoir, which is usually a continuation of the original water channel.

High-Head Plants. High-head plants (Fig. 59.12) are built with impulse turbines, where the head-generated water pressure is converted into velocity by nozzles and the high-velocity water jets drive the turbine runner.

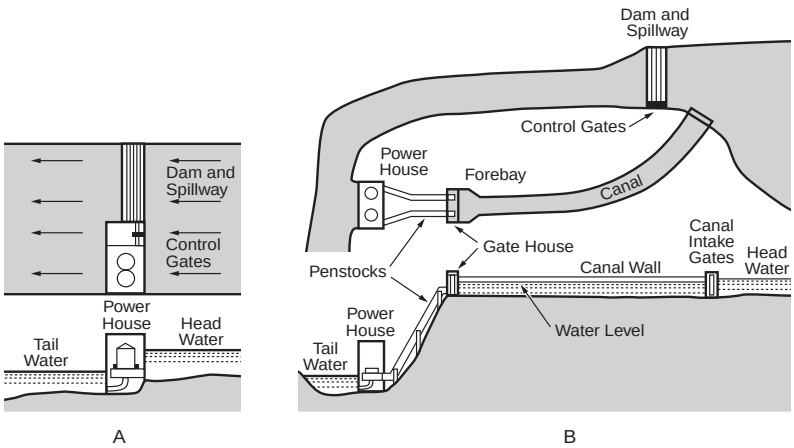

FIGURE 59.11 Hydroelectric power plant arrangement. (A) Low-head plant, (B) medium-head plant.

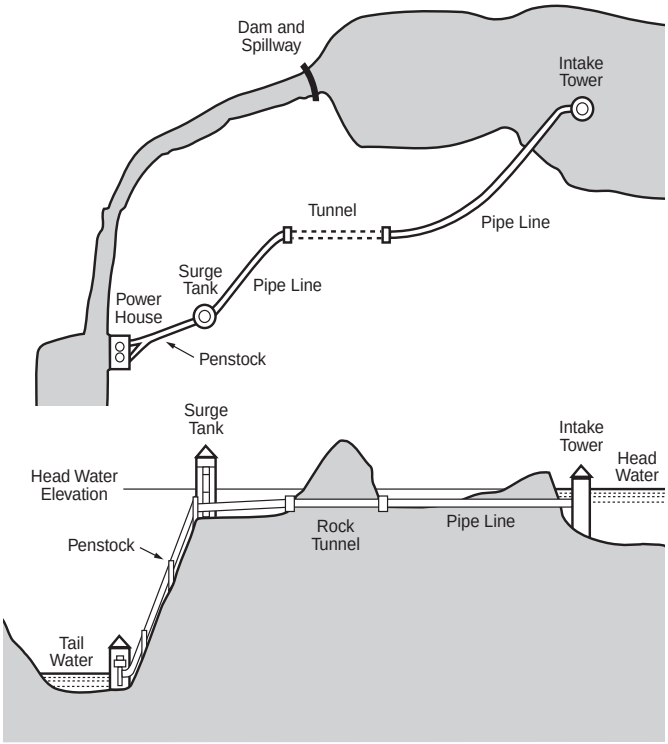

FIGURE 59.12 Hydroelectric power plant arrangement, high-head plant.

Low- and Medium-Head Plants. Low- and medium-head installations (Fig. 59.11) are built with reaction-type turbines, where the water pressure is mostly converted to velocity in the turbine. The two basic classes of reaction turbines are the propeller or Kaplan type, mostly used for low-head plants, and the Francis type, mostly used for medium-head plants. The cross section of a typical low-head Kaplan turbine is shown in Fig. 59.13.

The vertical shaft turbine and generator are supported by a thrust bearing immersed in oil. The generator is in the upper, watertight chamber. The turbine runner has 4 to 10 propeller types, and adjustable pitch blades. The blades are regulated from 5 to 35 degrees by an oil-pressure-operated servo mechanism. The water is evenly distributed along the periphery of the runner by a concrete spiral case and regulated by adjustable wicket blades. The water is discharged from the turbine through an elbow-shaped draft tube. The conical profile of the tube reduces the water speed from the discharge speed of 10–30 ft/s to 1 ft/s to increase turbine efficiency.

Hydrogenerators. The hydrogenerator is a low-speed (100 to 360 rpm) salient-pole machine with a vertical shaft. A typical number of poles is from 20 to 72. They are mounted on a pole spider, which is a welded, spoked wheel. The spider is mounted on the forged steel shaft. The poles are built with a laminated iron core and stranded copper winding. Damper bars are built in the pole faces. The stator is built with slotted, laminated iron core that is supported by a welded steel frame. Windings are made of stranded conductors insulated between the turns by fiberglass or Dacron-glass. The ground insulation is multiple layers of mica tape impregnated by epoxy or polyester resins. The older machines use asphalt and mica tape insulation, which is sensitive to corona-discharge-caused insulation deterioration. Direct water cooling is used for very large machines, while the smaller ones are air- or hydrogen-cooled. Some machines use forced-air cooling with an air-to-water heat exchanger. A braking system is installed in larger machines to stop the generator rapidly and to avoid damage to the thrust.

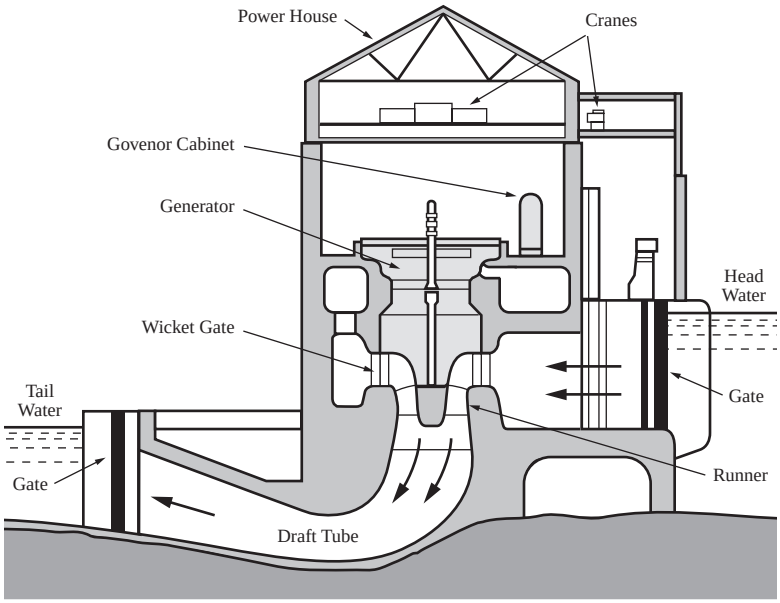

FIGURE 59.13 Typical low-head hydroplant with Kaplan turbine.

Defining Terms

Boiler: A steam generator which converts the chemical energy stored in the fuel (coal, gas, etc.) to thermal energy by burning. The heat evaporates the feedwater and generates high-pressure steam.

Economizer: A heat exchanger which increases the feedwater temperature. It is heated by the flue gases.

Fuel: Thermal power plants use coal, natural gas, and oil as a fuel, which is burned in the boiler. Nuclear power plants use uranium as a fuel.

Penstock: A water tube which feeds the turbine. It is used when the slope is too steep for using an open canal.

Reactor: A container where the nuclear reaction takes place. The reactor converts the nuclear energy to heat.

Superheater: A heat exchanger which increases the steam temperature to about 1000°F. It is heated by the flue gases.

Surge tank: An empty vessel which is located at the top of the penstock. It is used to store water surge when the turbine valve is suddenly closed.

60.1 Distributed Power Generation

Distributed generation (DG) refers to small (a few watts up to 1 MW) power plants at or near the loads, operating in a stand-alone mode or connected to a grid at the distribution or subtransmission level, and geographically scattered throughout the service area. Typically they harness unconventional energy resources such as **insolation,** wind, **biomass,** tides and waves, and **geothermal.** Small plants powered by site-specific conventional energy resources such as low-head and small hydro and natural gas are also included in this general group.

Interest in DG has been growing steadily since the dramatic oil embargo of 1973. In addition to the obvious advantages realized by the development of renewable energy sources, DG is ideally suited to power small remote loads, located far from the grid. An entire family of small power sources has been developed and employed for space, underwater, and biomedical applications. Another niche for these systems is in energizing remote rural areas of developing countries. It is estimated that there are more than one million remote villages in the world with no grid connection and minimally sustained by locally available energy sources. Integrated renewable energy systems (**IRES**), a special subset of DG, are ideally suited for these situations.

General Features

DG will have one or more of the following features:

- Small size
- Intermittent input resource
- Stand-alone or interface at the distribution or subtransmission level
- Extremely site-specific inputs
- Located near the loads

- Remoteness from conventional grid supply
- Availability of energy storage and reconversion for later use

Potential and Future

Globally, the potential for DG is vast. Even extremely site-specific resources such as tides, geothermal, and small hydro are available in significant quantities. Assessments of the future for various DG technologies vary, depending on the enthusiasm of the estimator. However, in almost all cases, the limitations are economic rather than technical. Concerns over the unrestricted use of depletable energy resources and the ensuing environmental problems such as the greenhouse effect and global warming are providing the impetus necessary for the continued development of technologies for DG.

Motivation

Among the powerful motivations for the entry of DG are:

- Less capital investment and less capital at risk in the case of smaller installations
- Easier to site smaller plants under the ever-increasing restrictions
- Likely to result in improved reliability and availability
- Location near load centers decreases delivery costs and lowers transmission and distribution losses
- In terms of the cost of power *delivered,* DG is becoming competitive with large central-station plants, especially with the advent of open access and competition in the electric utility industry

DG Technologies

Many technologies have been proposed and employed for DG. Power ratings of DG systems vary from milliwatts to megawatts, depending on the application. A listing of the technologies is given below.

- **Photovoltaics** (PV)
- **Wind-electric conversion** systems
- Mini and micro hydro
- Geothermal plants
- Tidal and wave energy conversion
- **Fuel cells**
- **Solar-thermal-electric conversion**
- Biomass utilization
- **Thermoelectrics**
- **Thermionics**
- Small cogeneration plants powered by natural gas and supplying electrical and thermal energies

The technology involved in the last item above is mature and very similar to that of conventional thermal power plants and therefore will not be considered in this section.

Photovoltaics

PV refers to the direct conversion of insolation (incident solar radiation) to electricity. A PV cell (also known as a solar cell) is simply a large-area semiconductor *pn* junction diode with the junction positioned very close to the top surface. Typically, a metallic grid structure on the top and a sheet structure in the bottom collect the minority carriers crossing the junction and serve as terminals. The minority carriers are generated by the incident photons with energies greater than or equal to the energy gap of the semiconductor material.

Since the output of an individual cell is rather low (1 or 2 W at a fraction of a volt), several (30 to 60) cells are combined to form a module. Typical module ratings range from 40 to 50 W at 15 to 17 V. PV modules are progressively put together to form panels, arrays (strings or trackers), groups, segments (subfields), and ultimately a PV plant consisting of several segments. Plants rated at several MW have been built and operated successfully.

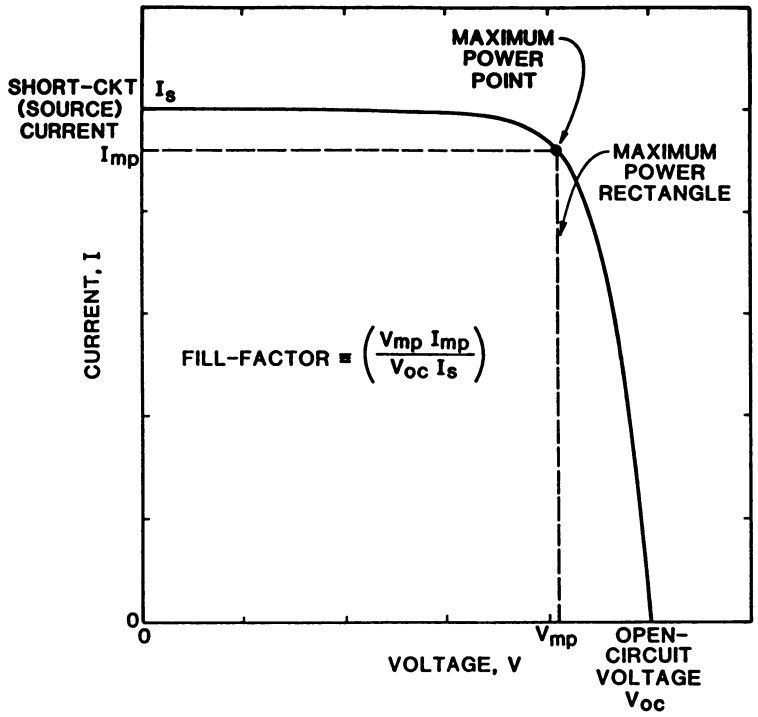

FIGURE 60.1 Typical current-voltage characteristic of an illuminated solar cell.

Advantages of PV include demonstrated low operation and maintenance costs, no moving parts, silent and simple operation, almost unlimited lifetime if properly cared for, no recurring fuel costs, modularity, and minimal environmental effects. The disadvantages are its cost, need for large collector areas due to the diluteness of insolation, and the diurnal and seasonal variability of the output.

PV systems can be flat-plate or concentrating type. While flat-plate systems utilize the global (direct and diffuse) radiation, concentrator systems harness only the direct or beam radiation. As such, concentrating systems must track (one axis or two axis) the sun. Flat-plate systems may or may not be mounted on trackers.

By 1990, efficiencies of flat-plate crystalline and thin-film cells had reached 23 and 15%, respectively. Efficiencies as high as 34% were recorded for concentrator cells. Single-crystal and amorphous PV module efficiencies of 12 and 5% were achieved by the early '90s. For an average module efficiency of 10% and an insolation of 1 kW/m^2 on a clear afternoon, 10 m^2 of collector area is required for each kW of output.

The output of a PV system is dc and inversion is required for supplying ac loads or for utility-interactive operation. While the required fuel input to a conventional power plant depends on its output, the input to a PV system is determined by external factors such as cloud cover, time of day, season of the year, geographic location, orientation, and geometry of the collector. Therefore, PV systems are operated, as far as possible, at or near their maximum outputs. Also, PV plants have inertialess generation and are subject to rapid changes in their outputs due to moving clouds.

The current-voltage (*IV*) characteristic of an illuminated solar cell is shown in Figure 60.1. It is given as

$$I = I_s - I_o\left[\exp\left(\frac{eV}{kT}\right) - 1\right]$$

where I_o and I_s are the dark and source currents, respectively, k is the Boltzmann constant (1.38×10^{-23} J/K), T is the temperature in K, and e is the electronic charge. Under ideal conditions (identical cells), for a PV module with a series-parallel arrangement of cells, the *IV* characteristic will be similar, except that the current scale should be multiplied by the number of parallel branches and the voltage scale by the number of cells in series in the module. The source current varies linearly with insolation. The dark current increases as the cell

operating temperature increases. Also, the larger the energy gap of the material, the smaller the dark current. The ratio of source current to dark current should be made as large as possible for improved operation.

Single-crystal silicon is still the dominant technology for fabricating PV devices. Polycrystalline, semicrystalline, and amorphous silicon technologies are developing rapidly to challenge this. Highly innovative technologies such as spheral cells are being introduced to reduce costs. Concentrator systems typically employ gallium arsenide or multiple junction cells. Many other materials and thin-film technologies are under investigation as potential candidates.

PV applications range from milliwatts (consumer electronics) to megawatts (central station plants). They are suitable for portable, remote, stand-alone, and utility-interactive applications. PV systems should be considered as energy sources and their design should maximize the conversion of insolation into useable electrical form. Power requirements of practical loads are met using an energy storage and reconversion system or utility interconnection. Concentrating systems have been designed and operated to provide both electrical and low-grade thermal outputs with combined peak utilization efficiencies approaching 60%.

The vigorous growth of PV technology is manifested by a doubling of world PV module shipments in six years — from 42 MW in 1989 to 84 MW in 1995. Tens of thousands of small (<1 kW) systems are in operation around the world. Thousands of kilowatt-size systems (1 to 10s of kW) also have been installed and are in operation. Many intermediate-scale systems (10 to 100s of kW) and large-scale systems (1 MW or larger) are being installed by utility- and government-sponsored programs as proof-of-concept experiments and to glean valuable operational data.

By 1988, nearly 11 MW of PV was interconnected to the utility system in the United States alone. Most were in the 1- to 5-kW range. The two major exceptions are the 1-MW Hesperia-Lugo project installed in 1982 and the 6.5-MW Carrisa Plains project installed in 1984, both in California. In Germany, a 340-kW system began operation in 1988 as part of a large program. Switzerland had a plan to install 1 MW of PV in 333 roof-mounted units of 3 kW each. By 1990, the installed capacity of PV in Italy exceeded 3 MW. Many nations have recognized the vast potential of PV and have established their own PV programs within the past decade. A view of the 300 kW flat-plate grid-connected PV system installed and operated by the city of Austin electric utility department in Austin, Texas is shown in Figure 60.2.

From a capital cost of $7000/kW in 1988 with an associated levelized energy cost of 32¢/kWh, even with a business-as-usual scenario, a twofold reduction to $3500/kW by 2000 and an additional 3-to-1 reduction to $1175/kW by 2030 are being projected. The corresponding energy costs are 15 and 5¢/kWh, respectively. These

FIGURE 60.2 A view of the city of Austin PV-300 flat-plate grid-connected photovoltaic system. (Courtesy of the city of Austin electric utility department.)

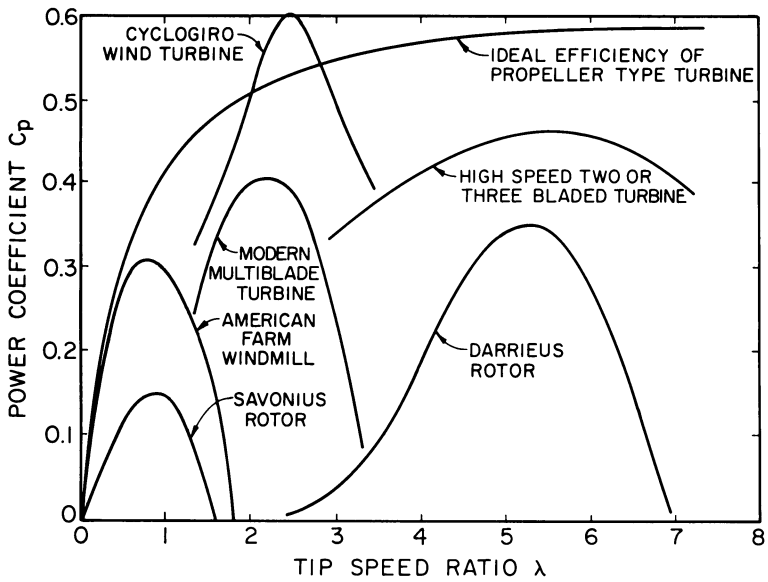

FIGURE 60.3 Typical aeroturbine characteristics.

estimates put the cost of energy from PV in par with the cost of energy from conventional plants in the early part of the twenty-first century.

Wind-Electric Conversion

Wind energy is intermittent, highly variable, and site-specific, exists in three dimensions, and is the least dependent upon latitude among all renewable resources. The power density (in W/unit area) in moving air (wind) is a cubic function of wind speed and therefore even small increases in average wind speeds can lead to significant increases in the capturable energy. Wind sites are typically classified as good, excellent, or outstanding, with associated mean wind speeds of 13, 16, and 19 mph, respectively.

Aeroturbines employ lift and/or drag forces to convert wind energy to rotary mechanical energy, which is then converted to electrical energy by coupling a suitable generator. The power coefficient C_p of an aeroturbine is the fraction of the incident power converted to mechanical shaft power, and it is a function of the tip speed-to-wind speed ratio λ as shown in Figure 60.3. For a given propeller configuration, at any given wind speed, there is an optimum tip speed that maximizes C_p.

Several types of aeroturbines are available. They can have horizontal or vertical axes, number of blades ranging from one to several, mounted upwind or downwind, and fixed- or variable-pitch blades with full blade control or tip control. Vertical-axis (Darrieus) turbines are not self-starting and require a starting mechanism. Today, horizontal-axis turbines with two or more blades are the most prevalent, and considerable work is underway to develop advanced versions of these.

The electrical output P_e of a wind-electric conversion system (WECS) is given as

$$P_e = \eta_g \eta_m A C_p K v^3$$

where η_g and η_m are the efficiencies of the electrical generator and mechanical interface, respectively, A is the swept area, K is a constant, and v is the wind speed incident on the aeroturbine.

There are two basic options for wind-electric conversion. With varying wind speeds, the aeroturbine can be operated at a constant speed by blade-pitch control, and a conventional synchronous machine is then employed to generate constant-frequency ac. More commonly, an induction generator is used with or without an adjustable var supply. In this case, the aeroturbine will operate at a nearly constant speed. Alternatively, the aeroturbine rotational speed can be allowed to vary with wind to maintain a constant and optimum tip speed ratio, and then a combination of special energy converters and power electronics is employed to obtain utility-grade ac.

The variable-speed option allows optimum efficiency operation of the turbine over a wide range of wind speeds, resulting in increased outputs with lower structural loads and stresses. All future utility-grade advanced turbines are expected to operate in the variable-speed mode and use power electronics to convert the variable-frequency output to constant frequency with minimal harmonic distortion.

Large-scale harnessing of wind energy will require hundreds or even thousands of WECS arranged in a wind farm with spacings of about 2 to 3 diameters crosswind and about 10 diameters apart downwind. The power output of an individual WECS will fluctuate over a wide range, and its statistics strongly depend on the wind statistics. When many WECS are used in a wind farm, some smoothing of the total power output will result, depending on the statistical independence of the outputs of individual WECS. This is desirable, especially with high (>20%) penetration of WECS in the generation mix. While the output of WECS is not dispatchable, with large wind farms the possibility of assigning some capacity credit to the overall output significantly improves.

Although wind-electric conversion has overall minimum environmental impacts, the large rotating structures involved do generate some noise and introduce visual aesthetics problems. By locating wind energy systems sufficiently far from centers of population, these effects can be minimized. The envisaged potential for bird kills turned out to be not a serious problem. Wind energy systems occupy only a very small fraction of the land. However, the area surrounding them can be used only for activities such as farming and livestock grazing. Thus, there is some negative impact on land use.

Today, the cost of energy delivered by wind plants rivals those obtained from some nonrenewable sources. By 1990, wind became the most utilized and competitive option among all the solar energy technologies for the bulk power market at a cost of generation of about 8¢/kWh (or roughly 7¢/kWh in 1987 dollars). Ongoing research and development work in new design tools, advanced airfoils, site tailoring, operating strategies, array spacing, and improved reliability and manufacturability is expected to bring the cost of energy further down by a factor of 2 to 3.

At around 1600 MW, nearly 90% of all the WECS installed in the world are in California. They are expected to generate nearly 3 billion kWh of electricity per year to the state's utilities to which they are interconnected. Although their lack of control and the intermittent nature of wind-derived energy are not embraced enthusiastically by electric utilities, this gap is expected to be bridged very soon with appropriate computer controls and operating strategies. Wind energy is already an economical option for remote areas endowed with good wind regimes. The modularity of WECS, coupled with the associated environmental benefits, potential for providing jobs, and economic viability point to a major role for wind energy in the generation mix of the world in the decades to come.

Hydro

Hydropower is a mature but neglected and one of the most promising renewable energy technologies. In the context of DG, small (less than 15 MW), mini (less than 1 MW), and micro (less than 100 kW) hydroelectric plants are of interest. The source of hydropower is the hydrologic cycle driven by the energy from the sun. Most of the sites for DG hydro are either low-head (2 to 20 m) or medium-head (20 to 150 m). The global hydroelectric potential is vast. One estimate puts it at 31 GW for Indonesia alone! The installed capacity of small hydro in the People's Republic of China was exceeding 7 GW by 1980.

Both impulse and reaction turbines have been employed for small-scale hydro for DG. Several standardized units are available in the market. Most of the units are operated at constant speed with governor control and are coupled to synchronous machines to generate utility-grade ac. If the water source is highly variable, it may be necessary to employ variable-speed operation. If the speed variations are not large, induction generators can be used. Special variable-speed constant-frequency (VSCF) generation schemes may be needed if the range of speed variations is large ($> \pm 10\%$). Permanent magnet generators provide another alternative, especially if the output is to be rectified and stored for later use in the case of very small units.

Geothermal

Geothermal plants exploit the heat stored in the form of hot water and steam in the earth's crust at depths of 2000 to 8000 ft. By nature, these resources are extremely site-specific and slowly run down (depletable) over a period of years. For electric power generation, the resource should be at least around 250°C. Depending on the temperature and makeup, dry steam, flash steam, or binary technology can be employed. Of these, dry natural steam is the best since it eliminates the need for a boiler.

The three basic components of a geothermal plant are (1) a production well to bring the resource to the surface, (2) a turbine generator system for energy conversion, and (3) an injection well to recycle the spent geothermal fluids back into the reservoir.

Worldwide deployment of geothermal plants reached 5000 MW by 1987 in 17 countries. Nearly one-half of this was in the United States. The Geysers plant north of San Francisco is the largest in the world with an installed capacity of 516 MW. In some developing countries, the Philippines for example, geothermal plants supply nearly 20% of their electrical needs.

Tidal Energy

The origin of **tidal energy** is the upward-acting gravitational force of the moon, which results in a cyclic variation in the potential energy of water at a point on the earth's surface. These variations are amplified by topographical features such as the shape and size of estuaries. The ratio between maximum spring tide and minimum at neap can be as much as 3 to 1. In estuaries, the tidal range can be as large as 10 to 15 m.

Power can be generated from a tidal estuary in two basic ways. A single basin can be used with a barrage at a strategic point along the estuary. By installing turbines at this point, electricity can be generated both when the tide is ebbing or flooding. In the two-basin scheme, generation can be time-shifted to coincide with hours of peak demand by using the basins alternately.

As can be expected, tidal energy conversion is very site-specific. The largest tidal power plant is the single-basin scheme at La Rance in Brittany, France. It is rated at 240 MW and employs 24 vane-type horizontal turbines and alternator motors, each rated at 10 MVA. The plant has been in operation since 1966 with good technical and economic results. It has generated, on the average, around 500 GWh of net energy per year. The Severn estuary in the southwest of England and the Bay of Fundy in the border between the United States and Canada with the highest known tidal range of 17 m have been extensively studied for tidal power generation. There are several other possible sites around the world, but the massive capital costs required have delayed their exploitation.

Fuel Cells

A fuel cell is a simple static device that converts the chemical energy in a fuel directly, isothermally, and continuously into electrical energy. Fuel and oxidant (typically oxygen in air) are fed to the device in which an electrochemical reaction takes place that oxidizes the fuel, reduces the oxidant, and releases energy. The energy released is in both electrical and thermal forms. The electrical part provides the required output. Since a fuel cell completely bypasses the thermal-to-mechanical conversion involved in a conventional power plant and since its operation is isothermal, fuel cells are not Carnot-limited. Efficiencies in the range of 43 to 55% are forecasted for modular dispersed generators featuring fuel cells.

The low (< 0.05 lb/MWh) airborne emissions of fuel cell plants make them prime candidates for siting in urban areas. The possibility of using fuel cells in combined heat and power (CHP) units provides the cleanest and most efficient energy system option utilizing valuable (or imported) natural gas resources.

Hydrocarbon fuel (natural gas or LNG) or gasified coal is reformed first to produce hydrogen-rich (and sulphur-free) gas that enters the fuel cell stack where it is electrochemically "burned" to produce electrical and thermal outputs. The electrical output of a fuel cell is low-voltage high-current dc. By utilizing a properly organized stack of cells and an inverter, utility-grade ac output is obtained.

Early MW-scale demonstration plants employed phosphoric acid fuel cells. Molten carbonate fuel cell systems have shown considerable promise in recent years with demonstrated efficiencies in the 50 to 55% range based on the higher heating value. Another competitor in the long range is the solid oxide fuel cell that can be intergrated with a coal gasifier and a steam bottoming cycle.

Solar-Thermal-Electric Conversion

The quality of thermal energy needed for DG employing solar-thermal-electric conversion necessitates concentrated sunlight. Parabolic troughs, parabolic dishes, and central receivers are used to generate temperatures in the range of 400 to 500, 800 to 900, and >500°C, respectively.

Technical feasibility of the central receiver system was demonstrated in the early '80s by the 10-MWe Solar One system in Barstow, California. Over a six-year period, this system delivered 37 GWh of net energy to the

Southern California Edison's grid with an overall system efficiency in the range of 7 to 8%. With improvements in heliostat and receiver technologies, annual system efficiencies of 14 to 15% and generation cost of 8 to 12¢/kWh have been projected.

Parabolic-dish electric-transport technology for DG was under active development at the Jet Propulsion Laboratory (JPL) in Pasadena, California, in the late '70s and early '80s. Prototype modules with Stirling engines reached a record 29% overall efficiency of conversion from insolation to electrical output. Earlier parabolic-dish designs collected and transported thermal energy to a central location for conversion to electricity. Advanced designs such as the one developed at JPL employed engine driven generators at the focal points of the dishes, and energy was collected and transported in electrical form.

By far the largest installed capacity (nearly 400 MW) of solar-thermal-electric DG employs parabolic-trough collectors and oil to transport the thermal energy to a central location for conversion to electricity via a steam-Rankine cycle. With the addition of a natural gas burner for hybrid operation, this technology, developed by LUZ under the code name SEGS (solar electric generating system), accounts for more than 90% of the world's solar electric capacity, all located in Daggett, Kramer Junction, and Harper Lake in California. Generation costs of around 8 to 9¢/kWh have been realized with SEGS. This technology uses natural gas to compensate for the temporal variations of insolation and firms up the power delivered by the system. This compensation may come during 7 to 11 P.M. in summer and during 8 A.M. to 5 P.M. in winter. SEGS will require about 5 acres/MW or can deliver 130 MW/mi^2 of land area.

Biomass Energy

Biological sources provide a wide array of materials that have been and continue to be used as energy sources. Wood, wood wastes, and residue from wood processing industries, sewage or municipal solid waste, cultivated herbaceous and other energy crops, waste from food processing industries, and animal wastes are lumped together by the term ***biomass.*** The most compelling argument for the use of biomass technologies is the inherent recycling of the carbon by photosynthesis. In addition to the obvious method of burning biomass, conversion to liquid and gaseous fuels is possible, thus expanding the application possibilities.

In the context of electric power generation, the role of biomass is expected to be for repowering old units and for use in small (20 to 50 MW) new plants. Several new high-efficiency conversion technologies are either already available or under development for the utilization of biomass. The technologies and their overall conversion efficiencies are listed below.

- FBC (fluidized-bed combustor), 36–38%
- EPS (energy performance system) combustor, 34–36%
- BIG/STIG (biomass-integrated gasifier/steam-injected gas turbine), 38–47%

Acid or enzymatic hydrolysis, gasification, and aqueous pyrolysis are some of the other technology options available for biomass utilization.

Anaerobic digestion of animal wastes is being used extensively in developing countries to produce biogas, which is utilized directly as a fuel in burners and for lighting. An 80–20 mixture of biogas and diesel has been used effectively in biogas engines to generate electricity in small quantities.

Biomass-fueled power plants are best suited in small (<100 MW) sizes for DG to serve base load and intermediate loads in the eastern United States and in many other parts of the world. This contribution is clean, renewable, and reduces CO_2 emissions. Since biomass fuels are sulphur-free, these plants can be used to offset CO_2 and SO_2 emissions from new fossil power plants. Ash from biomass plants can be recycled and used as fertilizer. A carefully planned and well-managed SRWC (short-rotation woody crop) plantation program with yields in the range of 6 to 12 dry tons/acre/year can be effectively used to mitigate greenhouse gases and contribute thousands of MW of DG to the U.S. grid by the turn of the century.

Thermoelectrics

Thermal energy can be directly converted to electrical energy by using the thermoelectric effects in materials. Semiconductors offer the best option as thermocouples since thermojunctions can be constructed using a *p*-type

and an *n*-type material to cumulate the effects around a thermoelectric circuit. Moreover, by using solid solutions of tellurides and selenides doped to result in a low density of charge carriers, relatively moderate thermal conductivities and reasonably good electrical conductivities can be achieved.

In a thermoelectric generator, the Seebeck voltage generated under a temperature difference drives a dc current through the load circuit. Even though there is no mechanical conversion, the process is still Carnot-limited since it operates over a temperature difference. In practice, several couples are assembled in a series-parallel configuration to provide dc output power at the required voltage.

Typical thermoelectric generators employ radioisotope or nuclear reactor or hydrocarbon burner as the heat source. They are custom-made for space missions as exemplified by the SNAP (systems for nuclear auxiliary power) series and the RTG (radioisotope thermoelectric generator) used by the Apollo astronauts. Maximum performance over a large temperature range is achieved by cascading stages. Each stage consists of thermocouples electrically in series and thermally in parallel. The stages themselves are thermally in series and electrically in parallel.

Tellurides and selenides are used for power generation up to 600°C. Silicon germanium alloys turn out better performance above this up to 1000°C. With the materials available at present, conversion efficiencies in the 5 to 10% range can be expected. Whenever small amounts of silent reliable power is needed for long periods of time, thermoelectrics offer a viable option. Space, underwater, biomedical, and remote terrestrial power such as cathodic protection of pipelines fall into this category.

Thermionics

Direct conversion of thermal energy into electrical energy can be achieved by employing the Edison effect—the release of electrons from a hot body, also known as thermionic emission. The thermal input imparts sufficient energy (≥ work function) to a few electrons in the emitter (cathode), which helps them escape. If these electrons are collected using a collector (anode) and a closed path through a load is established for them to complete the circuit back to the cathode, then electrical output is obtained. Thermionic converters are heat engines with electrons as the working fluid and, as such, are subject to Carnot limitations.

Converters filled with ionizable gases such as cesium vapor in the interelectrode space yield higher power densities due to space charge neutralization. Barrier index is a parameter that signifies the closeness to ideal performance with no space charge effects. As this index is reduced, more applications become feasible.

A typical example of developments in thermionics is the TFE (thermionic fuel element) that integrates the converter and nuclear fuel for space nuclear power in the kW to MW level for very long (7 to 10 years) duration missions. Another niche is the thermionic cogeneration burner module, a high-temperature burner equipped with thermionic converters. Electrical outputs of 50 kW/MW of thermal output have been achieved. High (600 to 650°C) heat rejection temperatures of thermionic converters are ideally suited for producing flue gas in the 500 to 550°C range for industrial processes. A long-range goal is to use thermionic converters as toppers for conventional power plants. Such concepts are not economical at present.

Integrated System Concepts

DG technologies offer many possibilities for integrated operation. Integrated systems may be stand-alone with energy storage and reconversion or include grid connection. Also, both renewable and conventional systems can be integrated to achieve the required operational characteristics. Integrated renewable energy systems (**IRES**) that harness several manifestations of solar energy to supply a variety of energy and other needs have many advantages and applications worldwide. The complementary nature of some of the resources (insolation and wind, for example) over the annual cycle can be exploited by IRES to decrease the amount of energy storage necessary and lower the overall cost of energy.

System Impacts

Response of distribution systems to high penetrations of DG is not yet fully understood. Also, the nature of the response will depend on the DG technology involved. However, there are some general areas of potential impacts common to most of the technologies: (i) voltage flicker, imbalance, regulation, etc.; (ii) power quality;

(iii) real and reactive power flow modifications; (iv) islanding; (v) synchronization during system restoration; (vi) transients; (vii) protection issues; (viii) load following capability; and (ix) dynamic interation with the rest of the system. Since there are very few systems with high penetration of DG, studies based on detailed models should be undertaken to forecast potential problems and arrive at suitable solutions.

Defining Terms

Biomass: General term used for wood, wood wastes, sewage, cultivated herbaceous and other energy crops, and animal wastes.

Distributed generation: Small power plants at or near loads and scattered throughout the service area.

Fuel cell: Device that converts the chemical energy in a fuel directly and isothermally into electrical energy.

Geothermal energy: Thermal energy in the form of hot water and steam in the earth's crust.

Hydropower: Conversion of potential energy of water into electricity using generators coupled to impulse or reaction water turbines.

Insolation: Incident solar radiation.

IRES: Acronym for integrated renewable energy system, a collection of devices that harness several manifestations of solar energy to supply a variety of energy and other needs.

Photovoltaics: Conversion of insolation into dc electricity by means of solid state *pn* junction diodes.

Solar-thermal-electric conversion: Collection of solar energy in thermal form using flat-plate or concentrating collectors and its conversion to electrical form.

Thermionics: Direct conversion of thermal energy into electrical energy by using the Edison effect (thermionic emission).

Thermoelectrics: Direct conversion of thermal energy into electrical energy using the thermoelectric effects in materials, typically semiconductors.

Tidal energy: The energy contained in the varying water level in oceans and estuaries, originated by lunar gravitational force.

Wind-electric conversion: The generation of electrical energy using electromechanical energy converters driven by aeroturbines.

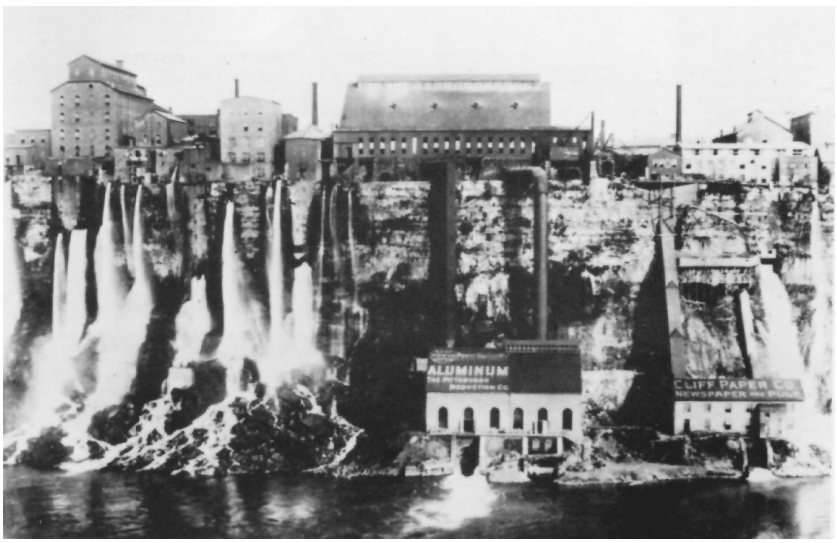
Niagara Falls Electrical Technology Showplace

At the close of the 19th century, Niagara Falls, New York, represented a showplace for displaying how far the electrical engineering profession had come in one short decade. Here, electrical engineers were confronted with one of the great technical challenges of the age — how to harness the enormous power latent in Niagara's thundering waters and make it available for useful work.

Years of study and heated debate preceded the start-up of the first Niagara Falls Power Station in the summer of 1895, as engineers and financiers argued about whether electricity could be relied on to transmit large amounts of power the 20 miles to Buffalo and, if so, whether it should be direct or alternating current. The success of the giant polyphase alternating current generators made clear the directions that electric power technology would take in the new century, and the attraction of novel industries that consumed great amounts of electricity, such as aluminum and other electrochemical manufacturers, showed the vast potential for growth and change that electricity held for the future. (Courtesy of IEEE Center for the History of Electrical Engineering.)



The discovery of how to use electricity to make aluminum in 1886 gave Niagara Falls its first major consumer of power — the Pittsburgh Reduction Company, known today as the Aluminum Company of America (ALCOA). (Photo courtesy of IEEE Center for the History of Electrical Engineering.)

60.2 Photovoltaic Solar Cells

Allen M. Barnett and Lawrence L. Kazmerski

Photovoltaic solar cells are semiconductor diodes that are designed to absorb sunlight and convert it into electricity. The absorption of sunlight creates free minority carriers, which determine the solar cell current. These carriers are collected and separated by the junction of the diode, which determines the voltage. Photovoltaic solar cells have been the power supply of choice for satellites since 1958; 350 kilowatts of solar cells were sold for space applications in 1998. The widespread use of photovoltaic solar cells for terrestrial applications began during the oil crisis of 1973. The market for these solar cells has grown from 240 kilowatts in 1976 to 160 megawatts in 1998. Space solar cells cost approximately 100 times as much as terrestrial solar cells, so the revenue difference between the two markets is not as great as the power generation difference.

Solar Cell Operation and Characteristics

The basic operation of a **solar cell** is shown in Fig. 60.4. Photons of light are absorbed by the semiconductor material and each photon that is absorbed generates an electron-hole pair. The generated minority carriers diffuse to the junction where they are collected. The number of collected carriers determines the current. The voltage is determined by the junction characteristics. The equivalent circuit is shown in Fig. 60.5. The characteristic curve of the photovoltaic solar cell can be determined by first calculating the collected minority carriers and then separately calculating the current–voltage characteristic of the diode. Superposition can be used to combine them.

The maximum current for any solar cell is dependent on the bandgap of the absorbing semiconductor and the solar spectrum. Any photon with an energy greater than the bandgap can be expected to generate one electron-hole pair, which will lead to one collectable minority carrier. The absorption coefficient of the semiconductor material determines the thickness required to absorb the sunlight with energies greater than the bandgap. As examples, a silicon thickness of 0.5 mm will absorb 93% of the sunlight with an energy above its

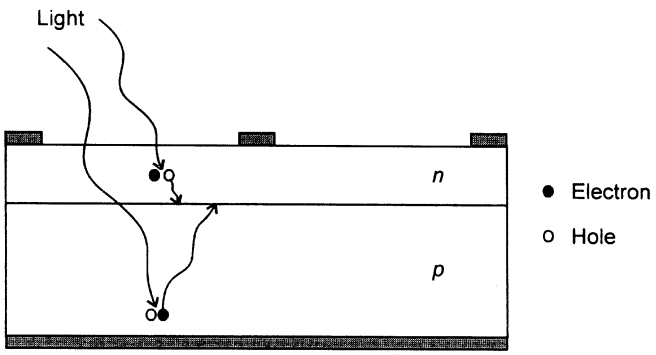


FIGURE 60.4 Operation of a solar cell.

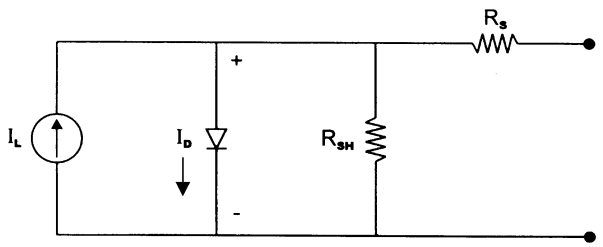

FIGURE 60.5 Equivalent circuit of a solar cell.

bandgap, while a gallium arsenide thickness of 5 μm will absorb 96% of the sunlight with an energy above it bandgap.

The photogenerated minority carriers must diffuse to the junction to be collected. These carriers will recombine as a function of the distance that they travel in accordance with the following formula $n = n_0 e^{x/L}$, where x is the distance traveled and L is the diffusion length for the minority carrier.

$$L = \sqrt{kT\mu\tau/q} = \sqrt{D\tau} \tag{60.1}$$

The other determinant of current is the spectrum of the light. The two most commonly used spectra in modeling are AM1.5 for terrestrial applications and AM0 for space applications. AM1.5 is the spectrum of the sunlight after it has passed through an equivalent thickness of 1.5 atmospheres. The integrated power of this spectrum is 970 W m^{-2}. AM0 is the spectrum of the sunlight before it passes through any of the atmosphere (0 atmospheres) and has an integrated power of 1353 W m^{-2}. AM1.5D is used to describe direct sunlight for applications that use optics to focus the sunlight onto the solar cell, these solar cells are called concentrators and the available power to the optical surface is 752 W m^{-2}.

The solar cell voltage is determined by the diode junction. The most common and most efficient junction is the *pn* junction. The diode characteristic is determined by $J = J_0(e^{qV/kT} - 1)$. J_0 is the reverse saturation current of the solar cell and is most commonly described as

$$J_0 = q\frac{D_p}{L_p}\frac{n_1^2}{N_D} + q\frac{D_n}{L_n}\frac{n_1^2}{N_A} \tag{60.2}$$

This is the case where surface recombination can be ignored and the device thickness is much greater than the minority carrier diffusion length. Unfortunately, surface recombination is an important factor in a number of semiconductor materials, including silicon. Also, the minority carrier diffusion length can be greater than the solar cell thickness. The equation for J_0 then becomes the more formidable (see [Hovel, 1976] or [Fahrenbruch and Bube, 1983]).

Superposition of the theoretical maximum generated current as a function of energy gap and the diode characteristic leads to the solar cell curve shown in Fig. 60.6. This is the diode curve offset by the light-generated current (I_L). The maximum current is called the short circuit current, I_{sc}, while the maximum voltage is called the open circuit voltage, V_{oc}. The maximum power point is shown in Fig. 60.6 as the product of V_{mp} and I_{mp} as the IV curve is traced by varying the load.

The maximum power is often described by $V_{oc} \times I_{sc} \times FF$, where FF is called the **fill factor** and is defined as $V_{mp} \times I_{mp}/V_{oc} \times I_{sc}$.

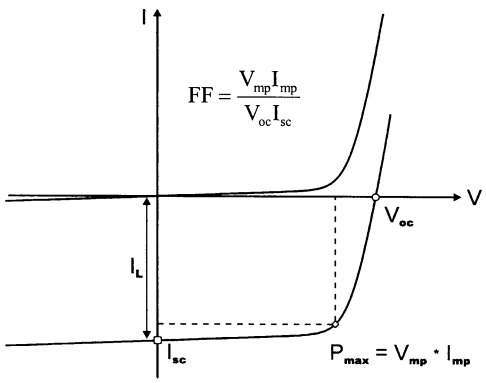

FIGURE 60.6 Current voltage characteristic of solar cell showing superposition.

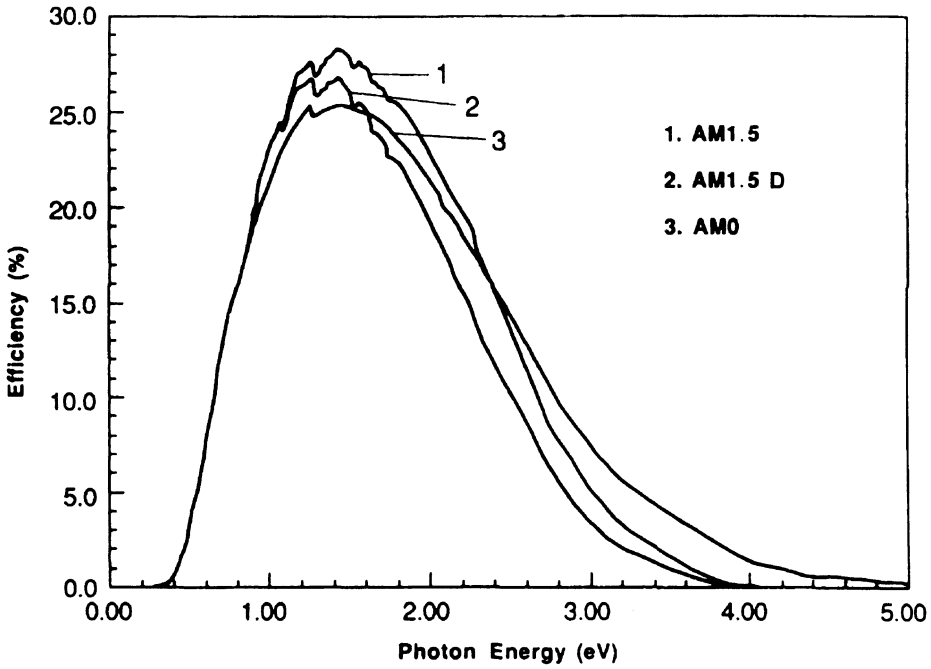

FIGURE 60.7 Single-junction solar cell efficiencies for the standard spectra.

Efficiency is defined as the maximum power divided by the power in the solar spectrum (for the solar cell area). The theoretical maximum efficiency as a function of photon energy and solar spectrum can be calculated and is shown in Fig. 60.7. The effect of energy gap is embedded in term n_i in the equation for J_0.

Solar Cell Types and Their Optimization

When one reviews the defining equation for an ideal solar cell,

$$I = I_0 \left[e^{(qV/kT)} - 1 \right] - I_L \tag{60.3}$$

it becomes apparent that there are two types of solar cell design improvements:

1. Those that improve the light-generated current, I_L
2. Those that improve the open-circuit voltage by decreasing the diode saturation current, I_0

The full impact of new solar cell designs is often hard to separate from the three parameters used to characterize the performance of any solar cell: short-circuit current, open-circuit voltage, fill factor and their product, P_{max}. However, these parameters merely summarize, and often obscure, the potential performance of any particular design. Light-generated current, together with all the various recombination processes, are the fundamental determinants of solar cell performance. A high efficiency solar cell design must maximize light-generated current and minimize losses in the bulk base and emitter, within the collecting junction, and at the surfaces. Because of these requirements, a particular device design for any material is typically optimized to obtain, first, light-generated current, then open-circuit voltage, and finally fill factor. Many examples of this approach can be found for a variety of solar cell materials, including silicon, GaAs, amorphous silicon, $CuInSe_2$, $CuInGaSe_2$, CdTe, and InP.

More recently, however, an approach that emphasizes open-circuit voltage, rather than short-circuit current, has been followed. Notable examples are present high-efficiency crystalline silicon and GaAs solar cells. This

philosophy is due, in part, to the fact that for any photovoltaic material, optimizing the light-generated current is, in general, an easier task to accomplish than optimizing the voltage-sensitive parameters. Therefore, a better measure of the potential performance of a material or design is the actual achieved open-circuit voltage, relative to the theoretical open-circuit voltage, rather than short-circuit current, which often has a value approaching the theoretically expected current.

Although the open-circuit voltage of a *pn* junction solar cell is influenced by the operating temperature, the light-generated current and the minority carrier losses**,** the minority carrier loss term visually dominates since it can change by orders of magnitude for different solar cell designs, materials, and fabrication processes. Minority carriers can recombine in each of the various regions of the solar cell — in the base, within the junction depletion region, in the emitter, and at either the front or the rear surface. For completeness, it should be mentioned that recombination at each surface consists of two parts: recombination at the ohmic contact and recombination at the free surface (if the metallization does not cover the whole surface, such as the front of the solar cell). In the limiting thick-base case, recombination at the surfaces and within the junction and emitter of the solar cell will be minimized in comparison to the base recombination term, and minority carrier losses will be controlled solely by the minority carrier lifetime in the base "bulk" region. For the thin-base device, however, base recombination will be reduced with volume, and minority carrier losses will be increasingly influenced by the surfaces and contacts.

Solar cell design innovations that significantly impact high-efficiency performance include:

1. Increased photon absorption with surface texturing and antireflection coatings to reduce top surface reflection
2. Surface passivation and low-recombination emitters that decrease both bulk and surface recombination near the top surface
3. High-low junctions and heterojunctions for reducing surface recombination, particularly at the back surface
4. Reduced-area and heterojunction contacts to reduce contact recombination losses
5. High-injection conditions that can lead to reduced J_0
6. And for polycrystalline materials, grain-boundary passivation to reduce recombination at the defects at the grain boundaries

The first design innovation contributes to improved performance primarily by increasing the light-generated current. The second innovation leads to increases in light-generated current for a direct bandgap material and to increased voltage in all materials. The next four lead to decreases in minority carrier recombination, and increased open-circuit voltage.

In addition to the *pn* junction, there are a number of other ways to make semiconductor diode junctions. These approaches, in addition to the *pn* or homojunction, are heterojunction, metal/semiconductor junction, metal/insulator/semiconductor (MIS), semiconductor/insulator/semiconductor (SIS), and electrolyte/semiconductor.

Band diagrams for these six structures are shown on Fig. 60.8.
For a detailed discussion of the physics of these junction types, see [Fonash, 1981; Green, 1982; and Hovel, 1976]. The junction is designed to maximize the voltage at any current; accordingly the objective is to minimize J_0. The *pn* junction leads to the minimum values for I_0, in part due to the lack of interface states and the ability to tune the doping. Other junction types can approximate, but usually fall short of the values achieved by the *pn* junction.

The status of the technologies — including an examination of the problems, opportunities, and issues with the various technical approaches — is summarized in this chapter. Bulk crystalline (Si, GaAs) and thin-film Cu-ternaries and multinaries, CdTe, hydrogenated amorphous silicon and dye-sensitized, $CuInSe_2$, CdTe technologies are reviewed. Applications for flat-plate and concentrator modes of operation are considered. This chapter can only present a brief overview, and the reader is directed to several other sources for more detailed evaluations and technical discussions [Kazmerski, 1997]. It can also only provide a "snapshot" of technologies that are changing with advancing R&D and manufacturing.

Following is a discussion of specific solar cells.

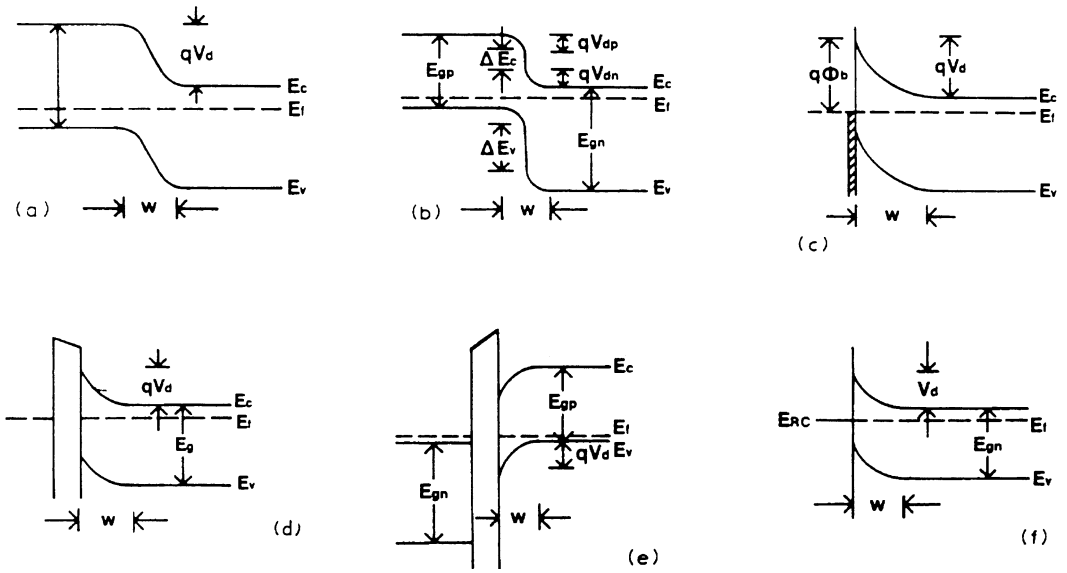

FIGURE 60.8 Band diagrams for various solar cell junctions: (a) homojunction; (b) heterojunction; (c) metal/semiconductor; (d) metal/insulator/semiconductor (MIS); (e) semiconductor/insulator/semiconductor (SIS); and, (f) electrolyte/semiconductor.

Crystalline Silicon

Silicon continues to be the foundation of the PV industry. The material is abundant, and Si solar cells have demonstrated reliability in both space and terrestrial environments [Green, 1996]. Although the properties of this semiconductor might make it non-ideal from a theoretical view, Si solar cells have reached among the highest efficiencies among the PV material options. The evolution of the high-efficiency Si solar cell is illustrated in the device cross sections shown in Fig. 60.9. The relatively simple, conventional *p-n* junction has given way to more complicated designs and structures — all aimed at capturing every incident photon, maximizing electron-hole generation, and generating maximum currents. This has called for improving antireflection approaches on the front surfaces, providing for multiple passes for the light, incorporating back surface electric field to reflect noncollected carriers, and minimizing obscuration of the incident light on the front surfaces. The evolution of these designs has included metal/insulator/*n*-type/*p*-type (MINP), passivated-emitter solar cells (PESC), single-sided and doubled-sided buried contact (SSBC and DSBC), point contact, and bifacial cells (see [Green, 1996]). Efficiencies up to 24% have been verified with monocrystalline Si cells. It should be noted that although performance enhancement is attained through these more complex designs, there is also a potentially significant increase in manufacturing cost.

A major cost factor for the Si solar cell is that associated with a high-perfection wafer. This has directed attention toward less energy-intensive process, which sacrifice the crystalline order and higher device efficiency for the benefits of lower energy production and perhaps the utilization of lower purity feedstock Si. Casting (and some sister technologies) has become conventional in the current Si manufacturing industry. Bulk and ribbon approaches for sheet-Si material have undergone extensive investigations and development over the past 20 years. Among the more developed technologies is the Edge Film-Fed Growth (EFG) process, which involves the shaping of Si through a special die and forming a connected octagon of flat sheets. The cells are cut from the connected structure by lasers, and large area solar cells (100 cm^2) with efficiencies exceeding 14% have been produced.

Treatments of the multi- and polycrystalline Si with hydrogen, lithium, aluminum, arsenic, and phosphorus have been used with varying degrees of success to minimize the effects of active defects and boundary surfaces. There is considerable effort on identifying treatment processes that benefit commercially produced polycrystalline Si products and to implement them into manufacturing. The best bulk multicrystalline Si cells have reported 18.6% efficiency.

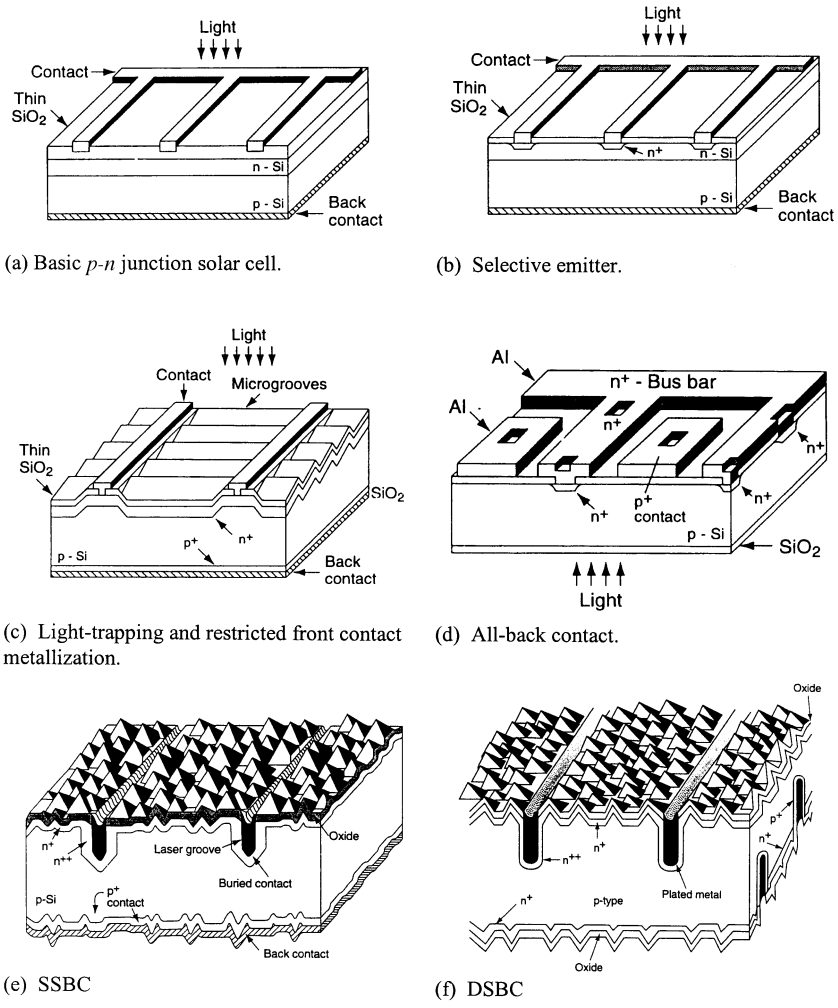

FIGURE 60.9 Evolution of silicon solar cell designs.

For better materials utilization, thin-film Si has always been of keen interest to the photovoltaics community. Early work in this area was limited to cells having efficiencies in the 5% regime, much below expectations. With the evolution of better cell engineering and understanding of Si deposition, higher efficiencies have been realized. Among these are a 20.6% (CVD of Si on Si) 47 μm thick active layer, a 47 μm thinned Si cell (CVD of Si on Si) with efficiency of 21.5%, and a PERL structure. However, the economy of these cells is not expected to meet large-scale production requirements in their current technologies. (Figure 60.10 presents some structures of advanced thin-film Si designs.) They serve as indicators that high efficiencies can be reached with thin-Si layers. The economy of films of Si requires high-performance and low-cost materials, process, and production methods. AstroPower Silicon-Film™ solar cells have reached 16.6%. This thin-Si solar cell represents a first-phase commercial design. Other more advanced designs are also illustrated in Fig. 60.10.

Si-based solar cells continue to lead the industry in performance, reliability, and availability. Major issues and concerns for Si include:

- Silicon feedstock (materials availability, solar-grade Si, competitiveness with electronic technologies)
- Manufacturing costs (yields, complexity)
- Manufacturing capacity (current output, demands, plans for increased capacity)
- Research (materials production, processing, solar cell design, thin films)

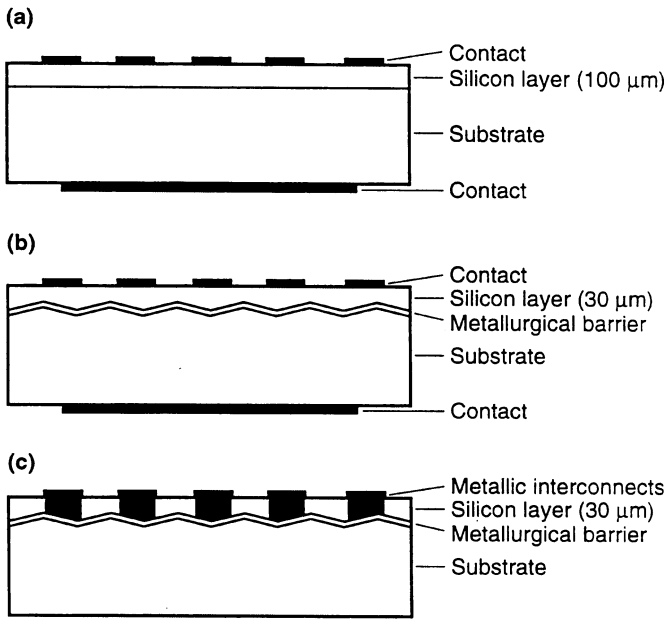

FIGURE 60.10 Silicon-Film™ products: (a) current design; (b) thinner solar cell design; and (c) thin, interconnected solar cell design.

III-V Semiconductors

Semiconductors such as GaAs, GaAlAs, GaInAsP, InSb, and InP have been receiving attention for photovoltaics because they have exceptional characteristics that offer energy conversions exceeding one third of the sun's energy. Although cost is the overriding consideration for terrestrial applications, some compelling arguments can be made for their use in concentrators. Space markets have expanded for these materials, since solar cell cost has been less a factor compared to performance. Because of the ability to adjust the electro-optical properties (e.g., bandgap), these materials lend themselves extremely well to multiple bandgap cell designs. Fig. 60.11 presents structures for two-, three-, and four-terminal approaches. Solar cells in the 30 to 34% efficiency range have been realized for these structures, and research continues in order to bring about better performances with lower complexities [Friedman, 1998]. There has been some recent attention directed toward the two-terminal, two-junction tandem — with the best efficiency of 30.3% under non-concentrator conditions. While these robust performing solar cells boast the highest efficiencies, the cost demands for terrestrial markets are still impeding their acceptance in competition with other approaches. Dominant issues include:

- Cost (materials, manufacturing, and processing)
- Industry (primarily directed toward space applications currently)
- Research (materials, processing, cell engineering)

Emerging from the development of lower-bandgap III-V cells is the resurgent *thermophotovoltaic* (TPV) technology [Coutts and Ward, 1998]. These are photovoltaic devices designed to work with infrared or thermal sources rather than sunlight. Early considerations of this technology used semiconductors with bandgaps in the range of 0.9 to 1.1 eV (primarily Ge and Si), that are matched to black-body temperatures above 2000K, which is difficult to engineer real systems. The development of devices in the 0.5 eV range correspond to temperatures of approximately 1500K, more suitable for system realization.

The complete TPV system includes: (1) a fuel and a burner that is non-direct solar, (2) a radiator using either selective or broadband emitters, (3) a long-wave photon recovery mechanism, (4) a PV cell or converter, and (5) a waste-heat recuperation system. TPV represents a growing and intensive research area for photovoltaics.

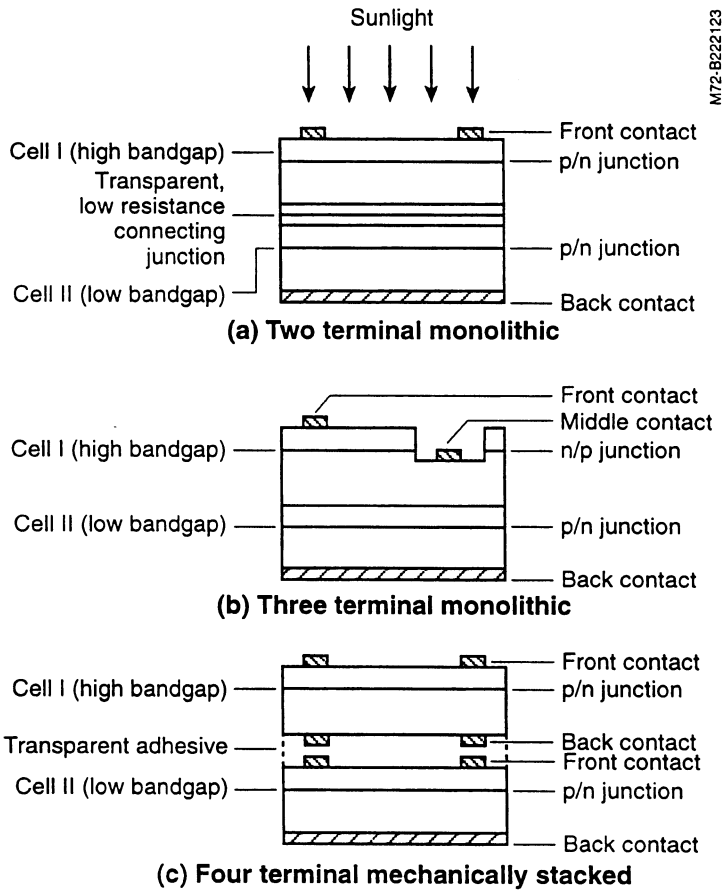

FIGURE 60.11 Multijunction structures for high-efficiency cells: (a) two terminal; (b) three terminal; and, (c) four terminal.

System efficiencies have promise of better than 40%. Certainly, an attractive system quality is that it offers "24-hour power" potential, directly from a fueled burner. Selective emitters, primarily rare-earth oxides (e.g., Yb_2O_3 for Si, Ho_2O_3 for III-V alloys) and broadband emitters, black and gray-body types (e.g., SiC-based for 1300 to 1700K), are under consideration. The TPV cells are central to the system, and include InGaAs, GaSb, and InGaAsSb. The GaSb cells have been introduced into commercial products. Thin-film semiconductor cells based on Ge and chalcopyrites are research projects. The radiation sources for terrestrial applications remain the most intriguing. These vary from biomass related (e.g., burning of wood-powder) to industrial waste heat (e.g., large furnaces used in float-glass production). In any case, TPV is in the area of next-generation technologies that could make a very large contribution to energy generation.

Thin-Film Solar Cells

The arguments for thin-film solar cells for terrestrial PV applications are primarily based on materials utilization, large-scale manufacturing potential, and better energy economy for production. The focus of this section is on the major approaches based on copper indium selenide, cadmium telluride, hydrogenated amorphous silicon (α Si:H), and dye-sensitized cells (see [Kazmerski, 1997]). Solar cells made from these materials generally have lower voltages than predicted by the energy gap because the diode technology is not an ideal *pn* junction. Additionally, there may be grain boundary losses due to additional minority carrier recombination, parallel diodes, and parasitic resistance, as shown in Fig. 60.12.

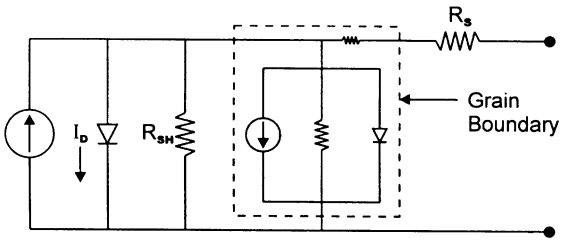

FIGURE 60.12 Equivalent circuit of a solar cell with grain boundaries.

Cu-Ternaries and Multinaries

Interest in Cu-ternary semiconductors began in the early 1970s for solar cells. $CuInSe_2$ and $CuInS_2$ (and their various alloys) have dominated R&D. Advantageous properties include: (1) suitable bandgaps for homojunctions or heterojunctions; (2) direct bandgap transitions minimizing requirements for absorber-layer thickness; (3) *n*- and *p*-type semiconductor types achievable; (4) lattice and electron affinity matches with window layer partners; (5) high optical absorption coefficients; and (6) stable electro-optical properties.

Most of the emphasis has been on modifications of CdS/Cu(In,Ga)Se_2 (or CIGS) heterojunction devices. The cross-sectional representations in Fig. 60.13 indicate the relative complexity in structure. Each of the layers, thicknesses, interfaces, and compositions are ascribed to the engineering of the cell for optimal performance and reliability. The best research cells have been demonstrated as high as a remarkable 18.8% for these true, polycrystalline thin films. Certainly, the positive and perhaps unique factors that favor this thin-film technology are stability and large-area production potential — with performance characteristics similar to those for laboratory devices. (Commercial modules with better than 12% efficiency and 4 ft^2 areas are available, using Cu(In,Ga)$(S,Se)_2$ active layers.) The variety of techniques (vacuum and non-vacuum deposition) used to make the cells speaks to the potential of low-cost manufacturing. Recently, a 15% "Cd-free" ZnO/CIGS research device has been reported. This and other Cu ternaries are undergoing research: $CuGaSe_2$ and $CuInS_2$ are prime contenders. The issues and concerns with $CuInSe_2$ and alloys include:

- Research (chemical paths to materials realization, window heteropartner, process development, minority carrier properties, contacts, role of sodium, alloy compositions)
- Complexity (manufacturing costs, control)
- Stability (increase in efficiency with light exposure)
- Device issues (low open-circuit voltage, high short-circuit current)
- Scale-up
- Manufacturing base (enhancing the current embryonic commercial base and products)

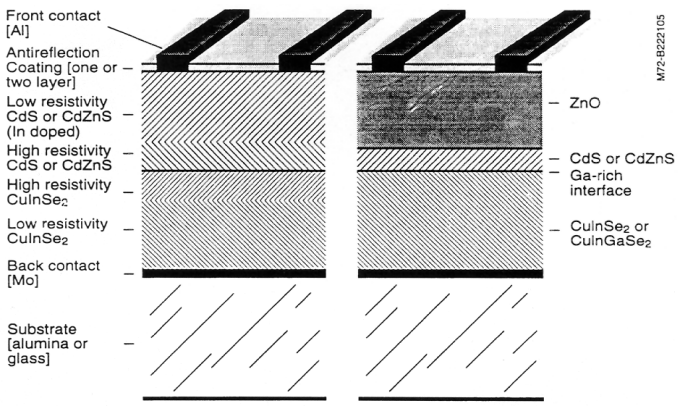

FIGURE 60.13 Device cross sections for Cu(In,Ga)Se_2 solar cell designs.

Cadmium Telluride

Since the 1960s, CdTe has been a candidate photovoltaic material. Evaporation, spraying, screen printing/sintering, and electrodeposition have been used to produce efficient solar cells. Inherent to most solar cell processing is a chemical treatment in $CdCl_2$: methanol solutions at high temperature (~400°C). The beneficial effects of this process have been attributed to enhanced grain size, identification, evolution of a *p*-i-*n* or heterojunction, surface alteration/passivation, alteration of shallow and/or deep electronic levels, improvement in morphology, and the formation of an interfacial CdSTe layer. The best solar cell efficiency has been measured at 15.8%. There is some concern that this record efficiency has not been exceeded since its report more than 6 years ago.

There is a small manufacturing base. Modules in excess of 9% have been confirmed. The devices are relatively stable, although there are concerns with humidity. Concerns for the environmental effects of Cd surround this (and other technologies). A great deal of validation (fire testing, leaching) testing has been undertaken by the industry and research laboratories. The reader is directed to the literature about this sensitive area for Cd-based cells. Issues and concern for CdTe include:

- Research (process development, modeling, interface optimization, contacts, chemical treatments, role of oxygen)
- Substrates (cost of borosilicate glass and use of sodium glasses)
- Cadmium (environmental concerns and availability)
- Stability (Cu diffusion, contact oxidation, contact degradation, humidity)
- Scale-up (cell vs. module performance levels)
- Manufacturing base

Hydrogenated-Amorphous Silicon

In contrast to more perfect crystalline materials, amorphous semiconductors have neither short- nor long-range structural order. At its introduction, a-Si:H seemed to be the ideal photovoltaic candidate. Its bandgap can be varied over tenths of eVs by changing the hydrogen content. Because its physics are considerably different from its single-crystal relative, its absorption characteristics make it about 100 times more effective in absorbing the sun's irradiance. It also has benefited technologically because there are other electronic technologies (transistors, flat-panel displays) that have enhanced knowledge and understanding of its properties.

The evolution of the a-Si:H cell is illustrated in Fig. 60.14. The development of various device structures has been an integral part of improving solar cell performance. The inherent light instabilities [Staebler and Wronski, 1977] have been minimized by engineering of the layer thicknesses, and by the use of multiple or tandem structures. The origins and cure for the light instabilities have not been completely identified, but "stabilized" cells and modules having less than 10% change in output characteristics have been produced. Many solar cells and modules with efficiencies exceeding 10% have been reported and confirmed.

Amorphous silicon-based solar cells and modules have serious problems with several stability mechanisms. The stabilized efficiencies of research solar cells are about 33% less than other thin-film options (i.e., 12% vs. 18%). Although solar cell and module engineering have minimized the Staebler-Wronski effect, the stability issue remains a major research, manufacturing, and consumer acceptance issue. Module design has requirements beyond those for crystalline Si and the ingress of any environmental entity has major influence because of the large surface-to-volume ratios involved. Stability and reliability of a device is the major issue relating to amorphous Si technology.

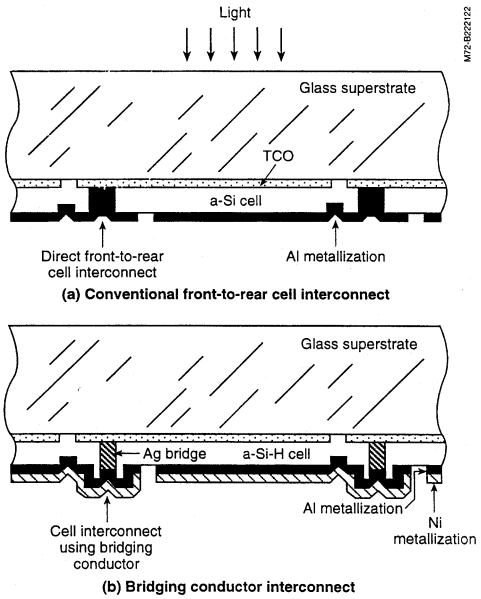

FIGURE 60.14 Amorphous Si:H module designs, showing interconnections.

These issues may require the development of new methods of producing the films, new film structures (e.g., nanocrystalline Si or multilayers), or a new a-Si technology.

Issues and concerns with the amorphous silicon technology primarily relate to the overriding stability issues. However, a variety of other concerns do accompany this technology:

- Stability and reliability
- Research (modeling, characterization, analysis, deposition research)
- Production costs (capital costs)
- Manufacturing capacity (vacuum based costs, yields, production volume)

Dye-Sensitized Cells

Among the thin-film technologies on the near horizon is the dye-sensitized solar cell. The device, illustrated in Fig. 60.15, utilizes an oxide semiconductor (TiO_2) having a bandgap in the 3-eV range that is insensitive to the solar spectrum. The extension of the photoresponse across the visible portion of the spectrum is achieved by separation of the two steps of the photovoltaic process. The oxide semiconductor in the electrochemical system is sensitized by a monolayer of an electroactive dye having an optical absorption band extending across the width of the visible spectrum. Charge separation occurs by electron loss from the photoexcited dye to the semiconductor substrate. Following absorption of a photon, the excited state of the dye is such that relaxation

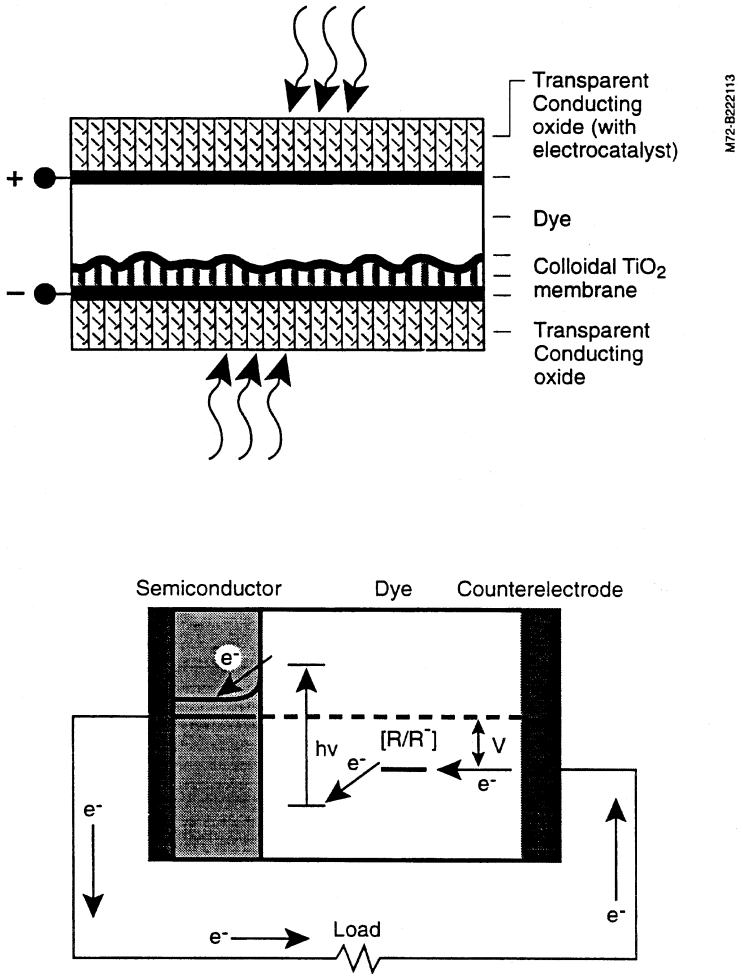

FIGURE 60.15 Device cross section for dye-sensitized solar cell.

by electron loss to the semiconductor substrate is possible, leaving the dye molecule as an oxidized species. The original ground state of the dye is restored by charge transfer reactions with the redox electrolyte. The solar cell circuit is completed by a metallized counterelectrode at which a reduction reaction with a redox system takes place. Research cells with better than 10% efficiency have been confirmed. Such cells have substantially better conversion efficiencies at lower light intensity levels. The technology is promising because it involves a low-cost processing of large areas. The solar cell continues to show growth in performance and in stability, a parameter that has been of concern to research and manufacturing groups. This technology is still in its infancy, and represents one area of thin films that is an alternative to conventional junction solar cell approaches.

Module Technologies

Solar cells are typically electrically connected into series and parallel strings to deliver a desired voltage and current and encapsulated into a supporting structure for environmental protection and strength. The module is a composite structure involving mechanical, optical, and electrical optimization that has required the collaborating and overlapping knowledge of physics, chemistry, materials science, and engineering to ensure viability [Lasnier and Ang, 1990]. The materials used for support and encapsulation depend on both the solar cell type and the application/installation. The module construction determines not only its cost, but also its lifetime. Module design has occupied a significant portion of the development efforts in photovoltaics, and the complexities and details for all photovoltaic materials are beyond the scope of this review. However, module issues are almost as important as solar cell issues because they directly impact the performance, lifetime, and cost of the photovoltaic technology [Wohlgemuth, 1995]. The module is central to meeting not only the efficiency goals (e.g., 15 to 25% for modules), but also the system cost (e.g., $1.00 to $1.50/W) and system lifetime (e.g., >30 years) in the 2010 to 2030 timeframe. (See Fig. 60.16.)

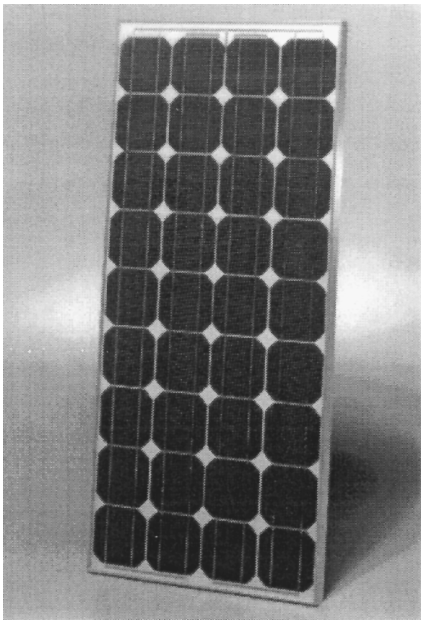

FIGURE 60.16 75 W, 36 solar cell module.

Even the most developed and commercialized of the photovoltaics approaches, crystalline Si, has required many redirections of its module construction to meet either operational or cost limitations over the past 25 years. Two examples highlight this ability and necessity for change. First, the module has been redesigned to eliminate framing to decrease materials cost, and improve loading (weight) and aerodynamics when configured into the array. In this same area, some modules, traditionally only the DC delivery system, have integrated the inverter into its construction to meet AC energy requirements. The second example has to do with the encapsulation of the Si cells in a polymer — commonly ethylene vinyl acetate (EVA). This encapsulant was identified through several development programs as a cost-effective and environment-resistant material for PV modules in the late 1970s. In the mid-1980s, the EVA in some modules was observed to turn yellow and brown. Subsequently, new and improved polymer encapsulants have also been developed to replace the original EVA formulations and UV-absorption glass has been implemented.

The evolving thin-film and concentrator technologies have additional complexities and, likely, as yet unknown problems. These advanced technologies are much different from their flat-plate silicon cousins. Consider the thin-film solar cells. Because the surface-to-volume ratios in these solar cell types are extremely high compared with bulk counterparts, materials and environmental interactions are not only enhanced, but affect relatively larger portions of the structures. These structures are also more complex, beyond the numerous interfaces that are inherent to the device itself. The cross sections for a-Si:H integrated module designs, shown in Fig. 60.14, illustrate areas of concern for shunting (bridges), contact openings, electromigration, interdiffusion, delamination, and microdefects that affect macroscale electrical behavior. Moreover, concentrators present module designs and complexities that have little relationship to their "one-sun" relatives.

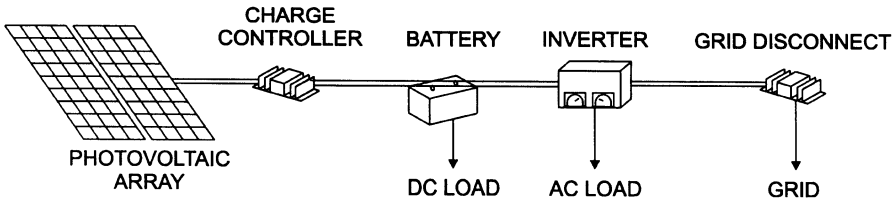

FIGURE 60.17 Grid-connected photovoltaic system.

Photovoltaic Power Systems

The photovoltaic module is the power generating component of a power system. Systems can be generically divided into stand-alone and grid-connected. A stand-alone system provides power directly to a load and usually includes storage. Stand-alone systems can vary greatly in complexity. A relatively simple system is a lighting system that includes a battery, battery charge regulator, the photovoltaic module(s), and the lights. More complex stand-alone systems include a range of battery charging systems, provide power for a whole house, provide power to a telecommunications repeater, or provide power to a satellite. All of these systems have battery and the battery charge control electronics in common. The simplest stand-alone system is a water pump that can be directly connected to the photovoltaic module. In this case, no electricity storage is required because the pumped water can be stored if it is not immediately used.

Electricity grid-connected systems generally exist in two basic forms. Systems that immediately convert the generated electricity from direct current (dc) to alternating current (ac) and synchronize this power with the electricity grid are the most fundamental for safety reasons. These systems are designed to not supply electricity to the grid when there is a grid power outage. The most complex photovoltaic systems are grid-connected systems with storage — sometimes called uninterruptible power supplies. These systems disconnect from the utility grid when there is a power outage but continue to provide electricity to the load. The load can often be a home, commercial building, or a sensitive load, such as a computer. The systems include the ability to synchronize with the grid, the ability to provide electricity to the grid when the amount generated is greater than the load, battery charging, and the conversion of dc to ac. A schematic of one of these systems is shown in Fig. 60.17. All other systems can be derived from this complex system by removing components.

Defining Terms

Photovoltaic effect: Conversion of photons to electricity.
Solar cell: Diode that converts sunlight to electricity using photovoltaic effect.
Fill factor: A measure of the relative squareness of the solar cell diode curve.
Electricity grid: Transmission and distribution system for centrally generated electricity.

60.3 Thermophotovoltaics

John P. Benner and Timothy J. Coutts

Thermophotovoltaic (TPV) is the title given to a process of generating electric power by photovoltaic conversion of the energy radiated from a thermal source. The source of energy can be a hydrocarbon or hydrogen burner, concentrated solar energy, radioisotope or nuclear reactor heating the emitter to an operating temperature in the range of 1000°C to 1800°C. Two significant attributes of TPV systems, relative to photovoltaic solar energy conversion, are that the source is in close proximity to the cell and thus delivers a high power density and that the emission spectrum lies in the infrared. TPV cells share many design features with concentrator solar cells, but are generally made from semiconductors with smaller bandgaps in order to achieve peak response better matched to the spectrum of the emitter. Silicon devices, however, are still viable for systems with emitter temperatures in the upper end of the above range. The final component essential for high conversion efficiency is some mechanism for controlling the flux of sub-bandgap photons such that their energy is not lost. This can be achieved with either selective emission or optical systems to return unused energy to the emitter. Theoretically, TPV systems could achieve conversion efficiencies approaching 30%, far higher than any other candidates for energy conversion in this temperature range. In the near term, a system efficiency of 10% is a practical goal. System design must balance the conversion efficiency and power density from the PV converter. This important trade-off will be described later.

TPV systems are now commercially available operating at power levels in the range of several tens of watts to about 500 W. Market analyses indicate that TPV may be competitive for a variety of distributed generation applications of up to about 100 kW. In addition, many industrial processes operate in a range of temperatures suitable for TPV conversion. As the technology matures, these may provide the opportunity for co-generation of heat, as well as electricity. In this type of application, TPV units of several megawatt electric generating capacity would be reached to correspond with the scale of the waste heat from associated manufacturing processes.

Background

The first reference to the concept of TPV appeared in 1961 and attributes the original idea to Professor Pierre Agrain [1]. In a series of lectures at MIT in the early 1960s, Agrain assumed that radiation from the emitter that is not useful for conversion in the photocell could be returned to the emitter. Photocells were available in several materials systems, but only silicon had reached conversion efficiencies of a level for consideration in power conversion. Silicon's limited utilization of the emission spectrum from early systems was addressed in

1964 with proposed use of selective emitters, development of rare-earth oxide systems for selective emission, and with use of germanium photocells [2–4]. By the mid-1970s, system designs of up to 1 kW with projected efficiencies of 6 to 7% were brought to the stage of working prototypes [5]. Interest waned as the benefits did not appear to outweigh the challenges in thermal management and structural stability through thermal cycling to the required emitter temperatures.

More than a decade later, the advances in high-efficiency solar photovoltaics and innovations in selective emitter development prompted renewed interest in TPV systems. Solar-to-electric energy conversion efficiencies greater than 30% were achieved in multiple-junction structures. These devices exploit the range of properties that can be obtained from III–V semiconductors. The ability to tune the photocell to a desired response characteristic provided the degree of freedom necessary to address the remaining system design issues effectively.

Design Considerations of a TPV System

Figure 60.18 is a cross-sectional drawing of a prototype TPV unit under development by McDermott Technologies for use as a portable power source and battery charger [6]. One of the major advantages of TPV is the wide variety of fuels that can be selected for powering the system. This system will use diesel fuel, greatly simplifying logistics for the planned use by the Army. The combination of burner, radiator, gas flow channels, and emitter is designed to optimize the temperature uniformity over the emitter surface and also to isolate the PV cells from any of the hot combustion products. At a flame temperature of 1700K, the TPV system can be designed for very low NO_x emission. The steady burn contributes to quiet and reliable operation. Burner efficiency is improved by thermal **recuperation.** This consists of a heat exchanger that recirculates a high percentage of the heat of the combustion products to raise the temperature of the incoming combustion air and fuel. Note that the exhaust is mixed with the air flowing over the cooling fins for the PV cells, dropping the final outlet temperature to only 30 to 50°C over ambient.

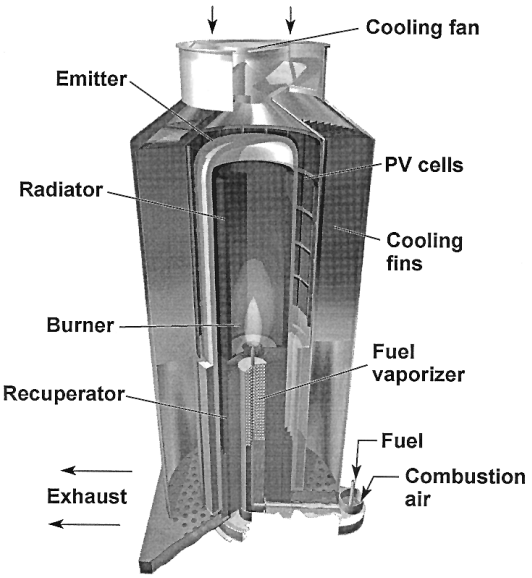

FIGURE 60.18 Schematic of the McDermott Technologies portable TPV generator. (Used with permission of the American Institute of Physics.)

The cylindrical geometry and flow from the burner, up through the radiator, then down through the channel between the radiator and the emitter, are key features in the thermal design. The energy emitted depends on emitter temperature in proportion to T^4. System performance will clearly require a high degree of uniformity of emitter surface temperature. In this particular system, the emitter produces a black-body spectrum. The front surface of the cell is coated with a selective filter that reflects long-wavelength light back to the emitter. This not only minimizes the cooling load on the PV array, but also returns useful energy to the emitter, maintaining more efficient energy conversion. The solar cells are made of GaSb. These usefully absorb energies to a maximum wavelength of about 1.8 μ.

Figure 60.19 shows the emission spectrum for several temperatures, overlaid by the cut-off energies for silicon and GaSb. For an emitter temperature of 1700K, the silicon device is able to use only about 5% of the available flux, while the device with a bandgap at about 0.7 eV can use 30%. When corrected for obscuration of the front contact grid, this portion of the available spectrum that the cell can use is called the **spectral utilization factor.** A silicon photovoltaic cell can achieve efficiencies of about 25% under illumination by the solar spectrum. The major losses are in relaxation of carriers generated by high-energy photons back to the bandgap and nonabsorbing sub-bandgap energies. The photovoltaic cell in a TPV system can be quite efficient — 40 to 50% — in converting the usable energy into electricity, since most of this energy arrives at close to the bandgap energy for a selective radiator. For this reason, the silicon device will be more efficient than the 0.7 eV device.

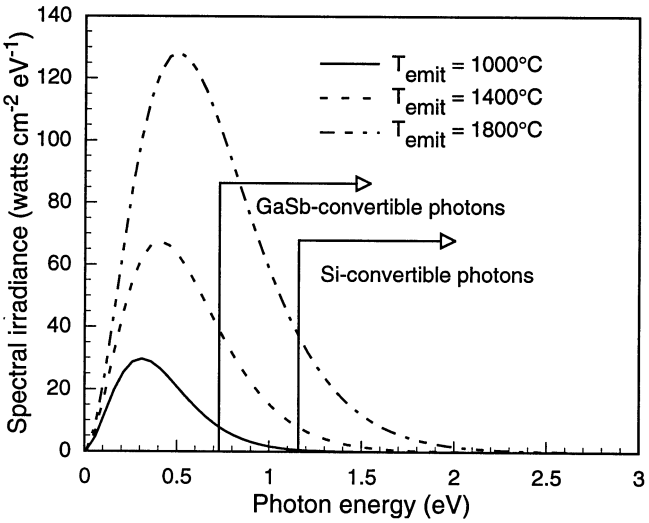

FIGURE 60.19 Black-body emission spectrum and spectral utilization for GaSb and Si photovoltaic cells.

And, as mentioned, some proportion of the sub-bandgap photons are not lost, but recirculated. However, the power density produced by the silicon-based system will be quite small. The overall system efficiency is more critically dependent on the efficiency of the spectral control components — the efficiency of recirculating the unused energy. This challenge is further compounded by the broad bandwidth needed for spectral control. Figure 60.20 plots the trade-off between conversion efficiency and power density for PV cells of various cut-off wavelengths and a black-body emitter at 1700K. The calculations assume that 100% of the sub-bandgap energy is usefully returned to the emitter. If this figure is reduced to 50%, the theoretical silicon-based system efficiency will drop to under 10%, while the 0.7 eV system efficiency will fall to 25%. The power density is, however, unaffected. The practical challenges in efficiently recirculating the sub-bandgap energies highlight the importance of the development of low-bandgap TPV cells.

For high-efficiency III-V-based PV cells, such as the GaSb device, economic considerations demand that TPV systems operate a PV cell at power densities of about 1 W cm^{-2}. The geometry of the TPV system also has a major impact on power density for the converter. For example, it would be technically desirable to evacuate the region between the emitter and cell to reduce convection losses or to place a filter in this region, but economic considerations may render these improvements impracticable. In the cylindrical geometry, if the

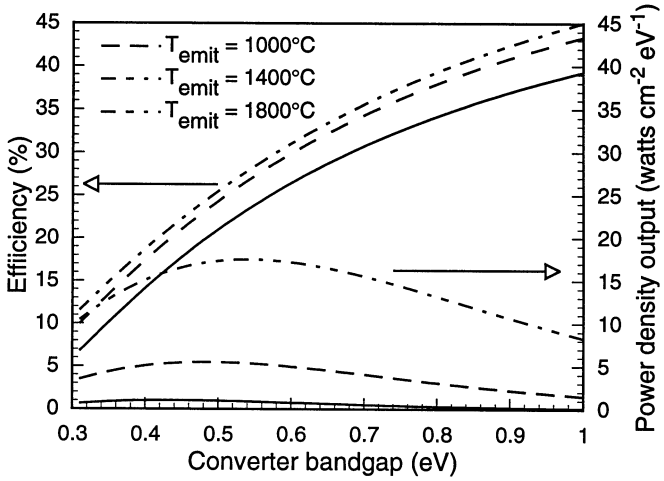

FIGURE 60.20 Calculated power density and converter efficiency for TPV operating at three different emitter temperatures.

converter array is separated far from the emitter, then the **view factor** is reduced. The view factor is the ratio of the photon flux per unit area impinging on the converter to that emanating from the emitter.

The TPV system has several potential advantages, including:

- Versatile fuel usage
- High efficiency
- High power density
- Quiet
- Clean, low NO_x emission
- No moving parts

Optical Control of Sub-bandgap Energies

Advances in selective emitters provided a major influence in rekindling interest in TPV development. Several investigators have shown the utility of rare-earth oxides such at holmia, ytterbia, erbia in modifying the emission spectrum from a broad band to one that selectively emits a substantial portion of the energy in a narrow band around a characteristic resonant frequency. Ytterbia emits with good selectivity at a peak wavelength of 980 nm — close to the bandgap of silicon (1070 nm). Given the relative maturity, efficiency, and low cost of silicon solar cells, development of an effective ytterbia emitter and surrounding system for use of silicon converters presents a pathway with potential for good performance and quick development for TPV. Unfortunately, the bulk properties of the substrate for these materials also contribute to the total radiation. Even a very low value of out-of-band emissivity integrated over a broad spectrum presents unacceptable losses. Mantles, similar to those used in camping lanterns, alleviate this loss by eliminating most of the bulk of the support structure. Nelson was the first to observe that fibrous emitters for TPV systems yield the same improvement [7]. However, it is difficult to scale the mantle structure to larger sizes and maintain acceptable mechanical performance. Several solutions for design of mechanically robust emitters are in development. One example uses selectively emitting fibers embedded in a ported ceramic block that allows the radiating fibers to work within the flame while the ceramic substrate remains relatively cool.

The alternative to selective emission is to reflect sub-bandgap energy back to the emitter. Several types of filters show potential for this task, including dielectric layers, plasma filters, metallic reflectors on the back surface of the cell, or some combination of these. An ideal filter will have 100% transmission up to the band edge of the semiconductor and 100% reflection for lower energies. Even very small absorption losses in the filter system can produce unacceptable cooling loads at typical TPV system power densities.

A new class of systems for **optical control** is under development using geometrical feature sizes on the order of the wavelength of the light. Patterning a metal film to produce a high-density array of antenna elements can achieve an inductive resonance that produces a bandpass filter. In a somewhat similar way, producing a fine periodic surface structure on the emitter material can produce wavelength-selective behavior.

Development of PV Cells

High-performance silicon solar cells are more widely available and lower in cost than other types of photovoltaic devices. For this reason, they remain in consideration for a number of TPV prototype systems. As discussed, choosing silicon for the PV converter places stringent requirements on other subsystems. TPV system design can take one of two paths to improve on Si-based converters; namely, either raise the emitter temperature (which will worsen thermal management problems) or seek PV devices with smaller bandgaps and commensurately longer wavelength response. During the early phase of TPV research, only Ge cells offered a longer wavelength response. However, the intrinsic carrier concentration of germanium is too high for this device technology ever to reach a high efficiency [8].

Development of very high efficiency tandem PV cells for use with concentrated solar power provided the other major stimulus for renewed interest in TPV. Two designs were particularly important in that they took the approach of developing low bandgap booster cells of GaSb or $Ga_xIn_{1-x}As$ for use under existing high-performance devices [9–11]. Both GaSb and $Ga_{0.47}In_{0.53}As$ have bandgaps of about 0.7 eV, corresponding to a

cut-off wavelength near 1.8 μm. This response enabled new designs and applications for TPV using lower emitter temperatures and less-demanding photon recuperation.

Ongoing research in TPV converters is advancing on two fronts. First, materials are in development with even lower bandgaps in the $Ga_xIn_{1-x}As_ySb_{1-y}$ system and in $Ga_xIn_{1-x}As$. As shown in Figure 60.20, maximum power densities should be achieved for devices at about 0.5 eV or less. The availability of devices over a narrow range of bandgaps opens the possibility of further system efficiency gains through use of cascade multiple-junction converters. A two-cell stack with bandgaps of 0.7 eV and 0.53 eV should be current-matched for a black-body emitter operating at about 1500°C. The use of such tandem cells will likely place an even greater premium on achieving exceedingly uniform temperature profile over the emitter area.

The other avenue of converter development is in the creation of monolithic interconnected modules. These devices are fabricated in semiconductor layers grown on semi-insulating substrates (or an isolation layer on a conducting substrate), using processing to isolate mesas into individual cells and then to connect the cells in series to produce a higher-voltage, lower-current circuit. This greatly simplifies the balance-of-system design and assembly because the converter size is limited only by dimensions of available substrates rather than current handling capability for the single high-flux device. The use of a semi-insulating substrate in the design may also provide the simplest method for optical and thermal control by incorporating a back surface reflector. This option is essentially precluded in other converter designs because of excessive free-carrier absorption losses in the relatively thick substrate.

All of the TPV converters described above present some challenge in reaching a cost target of about $1 per watt. In the case of silicon, the power densities are quite small. For the GaSb or GaInAs devices, the cost of the substrate (GaSb or InP) and device processing leaves little margin. Thus, as in solar photovoltaics, there is growing research interest in thin-film technologies and in low-cost substrate alternatives.

Status of System Development

Despite the elegance of the physics of the emitters, optical control, and PV converters, the engineering of components and system designs to minimize optical and thermal losses is probably the major near-term barrier. Monte Carlo analyses of photon paths have provided insights into the mechanisms of photon loss for characteristic Lambertian emission profiles. These analyses yield some surprising results. Off-normal angle of incidence and internal reflection can multiply the effective cross section of absorbing or reflecting materials. As mentioned, the emitter operates at relatively high temperatures and must maintain a highly uniform temperature profile. Considerations of **view factor** and power density require close spacing between hot and cool components. Thus, some designs include evacuation of the region between emitter and converter. Small oversights in estimating conductive losses have also broadened the gap between predicted and achieved performance.

Systems and Applications

One class of systems, used for explanation here, is intended for military use. The Army consumes large quantities of batteries for communications and a range of other applications. In these kinds of applications, systems of less than 5% conversion efficiency using diesel fuel compare favorably to batteries.

Remote communication systems also benefit from new approaches for power delivery. For example, many are currently powered by hybrid systems that may contain combinations of small diesel engines, photovoltaics, thermoelectrics, and batteries. In many remote applications, risk of environmental damage from spilled liquid fuels limits choices for power generation. TPV systems offer efficient conversion of energy from gaseous sources. This offers greatly reduced maintenance, reduced delivery cost of maintaining the fuel supply, and improved environmental acceptance.

In the commercial sector, one of the early applications might well be for recreational vehicles and boats. Quiet operation carries premium value. One of the next early opportunities may well be for self-powered appliances. A furnace can be designed to extract the electricity needed to power the blower motor by TPV conversion of radiant emission from the burner. More than a million households in the U.S. experience power outages annually, leaving their homes without electric power to drive circulation circuits on heating units. The

Gas Research Institute estimates that a unit costing about $500 added to furnaces could capture much of this market to make furnaces self-powered units. The power demands for these will be in the range of 200 to 500 W. This path leads to larger energy units that could provide electricity, heat, and hot water for a home.

The PV cell array for TPV systems are likely to represent about half of the system cost for units using crystalline silicon or III–V devices. How might the applications for TPV systems change if thin-film photovoltaics or other advances significantly drop projected system costs? One possibility may be in co-generation in industrial processes. For example, float-glass manufacturing processes 600 tons of material each day for a typical line. These factories melt feedstock in crucibles 100 ft long by 30 ft wide operating at 1500°C. Projected technology advances both in improving energy efficiency of glass manufacturing as well as in TPV create the potential for covering the top of this melt unit with an umbrella of TPV converters. A large part of the electric demand for the factory might be met by the co-generation unit. The engineering problems may be challenging, however, even if the benefits are potentially great.

Defining Terms

Recuperator: A heat exchanger that extracts energy from the combustion products to heat the incoming fuel and air. In TPV systems, optical control is sometimes called photon recuperation.

Optical control: Technology such as a selective emitter or filter used to minimize loss of unusable sub-bandgap photons by the photovoltaic converter.

View factor: Ratio of the photon flux per unit area impinging on the converter to that emanating from the emitter.

Spectral utilization factor: The fraction of the incident energy that the photovoltaic converter can use to generate electricity.

61.1 Alternating Current Overhead: Line Parameters, Models, Standard Voltages, Insulators

Mo-Shing Chen

The most common element of a three-phase power system is the overhead transmission line. The interconnection of these elements forms the major part of the power system network. The basic overhead transmission lines consist of a group of phase conductors that transmit the electrical energy, the earth return, and usually one or more neutral conductors (Fig. 61.1).

Line Parameters

The transmission line parameters can be divided into two parts: series impedance and shunt admittance. Since these values are subject to installation and utilization, e.g., operation frequency and distance between cables, the manufacturers are often unable to provide these data. The most accurate values are obtained through measuring in the field, but it has been done only occasionally.

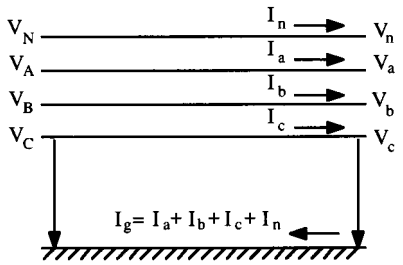

FIGURE 61.1 A three-phase transmission line with one neutral wire.

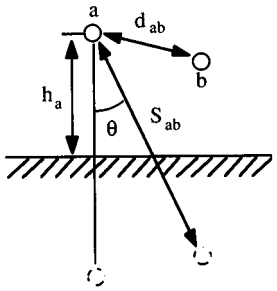

FIGURE 61.2 Geometric diagram of conductors *a* and *b*.

Though the symmetrical component method has been used to simplify many of the problems in power system analysis, the following paragraphs, which describe the formulas in the calculation of the line parameters, are much more general and are not limited to the application of symmetrical components. The sequence impedances and admittances used in the symmetrical components method can be easily calculated by a matrix transformation [Chen and Dillon, 1974]. A detailed discussion of symmetrical components can be found in Clarke [1943].

Series Impedance

The network equation of a three-phase transmission line with one neutral wire (as given in Fig. 61.1) in which only series impedances are considered is given as follows:

$$\begin{bmatrix} V_A \\ V_B \\ V_C \\ V_N \end{bmatrix} = \begin{bmatrix} Z_{aa-g} & Z_{ab-g} & Z_{ac-g} & Z_{an-g} \\ Z_{ba-g} & Z_{bb-g} & Z_{bc-g} & Z_{bn-g} \\ Z_{ca-g} & Z_{cb-g} & Z_{cc-g} & Z_{cn-g} \\ Z_{na-g} & Z_{nb-g} & Z_{nc-g} & Z_{nn-g} \end{bmatrix} \begin{bmatrix} I_a \\ I_b \\ I_c \\ I_n \end{bmatrix} + \begin{bmatrix} V_a \\ V_b \\ V_c \\ V_n \end{bmatrix} \tag{61.1}$$

where Z_{ii-g} = self-impedance of phase *i* conductor and Z_{ij-g} = mutual impedance between phase *i* conductor and phase *j* conductor.

The subscript *g* indicates a ground return. Formulas for calculating Z_{ii-g} and Z_{ij-g} were developed by J. R. Carson based on an earth of uniform conductivity and semi-infinite in extent [Carson, 1926]. For two conductors *a* and *b* with earth return, as shown in Fig. 61.2, the self- and mutual impedances in ohms per mile are

$$Z'_{aa-g} = z_a + j\omega \frac{\mu_0}{2\pi} \ln \frac{2h_a}{r_a} + \omega \frac{\mu_0}{\pi} (p + jq) \tag{61.2}$$

$$Z'_{ab-g} = j\omega \frac{\mu_0}{2\pi} \ln \frac{S_{ab}}{d_{ab}} + \omega \frac{\mu_0}{\pi} (p + jq) \tag{61.3}$$

where the "prime" is used to indicate distributed parameters in per-unit length; $z_a = r_c + jx_i$ = conductor *a* internal impedance, Ω/mi; h_a = height of conductor *a*, ft; r_a = radius of conductor *a*, ft; d_{ab} = distance between conductors *a* and *b*, ft; S_{ab} = distance from one conductor to image of other, ft; $\omega = 2\pi f$; *f* = frequency, cycles/s; μ_0 = the magnetic permeability of free space, $\mu_0 = 4\pi \times 10^{-7} \times 1609.34$ H/mi; and *p, q* are the correction terms for earth return effect and are given later.

The conductor internal impedance consists of the effective resistance and the internal reactance. The effective resistance is affected by three factors: temperature, frequency, and current density. In coping with the temperature effect on the resistance, a correction can be applied.

TABLE 61.1 Electrical Properties of Metals Used in Transmission Lines

Metal	Relative Conductivity (Copper = 100)	Electrical Resistivity at 20°C, Ω · m (10^{-8})	Temperature Coefficient of Resistance (per °C)
Copper (HC, annealed)	100	1.724	0.0039
Copper (HC, hard-drawn)	97	1.777	0.0039
Aluminum (EC grade, 1/2 H-H)	61	2.826	0.0040
Mild steel	12	13.80	0.0045
Lead	8	21.4	0.0040

$$R_{\text{new}} = R_{20^\circ}[1 + \alpha\ (T_{\text{new}} - 20)] \tag{61.4}$$

where R_{new} = resistance at new temperature, T_{new} = new temperature in °C, R_{20° = resistance at 20°C (Table 61.1), and α = temperature coefficient of resistance (Table 61.1).

An increase in frequency causes nonuniform current density. This phenomenon is called *skin effect*. Skin effect increases the effective ac resistance of a conductor and decreases its internal inductance. The internal impedance of a solid round conductor in ohms per meter considering the skin effect is calculated by

$$z = \frac{\rho m}{2\pi r}\frac{I_0(mr)}{I_1(mr)} \tag{61.5}$$

where ρ = resistivity of conductor, Ω · m; r = radius of conductor, m; I_0 = modified Bessel function of the first kind of order 0; I_1 = modified Bessel function of the first kind of order 1; and $m = \sqrt{j\omega\mu/\rho}$ = reciprocal of complex depth of penetration.

The ratios of effective ac resistance to dc resistance for commonly used conductors are given in many handbooks [such as *Electrical Transmission and Distribution Reference Book* and *Aluminum Electrical Conductor Handbook*]. A simplified formula is also given in Clarke [1943].

p and q are the correction terms for earth return effect. For perfectly conducting ground, they are zero. The determination of p and q requires the evaluation of an infinite integral. Since the series converge fast at power frequency or less, they can be calculated by the following equations:

$$p = \frac{\pi}{8} - \frac{1}{3\sqrt{2}}k\cos\theta + \frac{k^2}{16}\left[\left(0.6728 + \ln\frac{2}{k}\right)\cos 2\theta + \theta\sin 2\theta\right] + \frac{k^3\cos 3\theta}{45\sqrt{2}} - \frac{\pi k^4\cos 4\theta}{1536} \tag{61.6}$$

$$q = -0.0386 + \frac{1}{2}\ln\frac{2}{k} + \frac{1}{3\sqrt{2}}k\cos\theta - \frac{\pi k^2\cos 2\theta}{64} + \frac{k^3\cos 3\theta}{45\sqrt{2}} - \frac{k^4}{384}\left[\left(\ln\frac{2}{k} + 1.0895\right)\cos 4\theta + \theta\sin 4\theta\right] \tag{61.7}$$

with

$$k = 8.565 \times 10^{-4} D\sqrt{\frac{f}{\rho}}$$

where $D = 2h_i$ (ft), $\theta = 0$, for self-impedance; $D = S_{ij}$ (ft), for mutual impedance (see Fig. 61.2 for θ); and ρ = earth resistivity, Ω/m^3.

Shunt Admittance

The shunt admittance consists of the conductance and the capacitive susceptance. The conductance of a transmission line is usually very small and is neglected in steady-state studies. A capacitance matrix related to phase voltages and charges of a three-phase transmission line is

$$Qabc = Cabc \cdot Vabc \quad \text{or} \quad \begin{bmatrix} Q_a \\ Q_b \\ Q_c \end{bmatrix} = \begin{bmatrix} C_{aa} & -C_{ab} & -C_{ac} \\ -C_{ba} & C_{bb} & -C_{bc} \\ -C_{ca} & -C_{cb} & C_{cc} \end{bmatrix} \begin{bmatrix} V_a \\ V_b \\ V_c \end{bmatrix} \tag{61.8}$$

The capacitance matrix can be calculated by inverting a potential coefficient matrix.

$$Qabc = Pabc^{-1} \cdot Vabc \quad \text{or} \quad Vabc = Pabc \cdot Qabc$$

or

$$\begin{bmatrix} V_a \\ V_b \\ V_c \end{bmatrix} = \begin{bmatrix} P_{aa} & P_{ab} & P_{ac} \\ P_{ba} & P_{bb} & P_{bc} \\ P_{ca} & P_{cb} & P_{cc} \end{bmatrix} \begin{bmatrix} Q_a \\ Q_b \\ Q_c \end{bmatrix} \tag{61.9}$$

$$P_{ii} = \frac{l}{2\pi\varepsilon} \ln \frac{2h_i}{r_i} \tag{61.10}$$

$$P_{ij} = \frac{l}{2\pi\varepsilon} \ln \frac{S_{ij}}{d_{ij}} \tag{61.11}$$

where d_{ij} = distance between conductors i and j, h_i = height of conductor i, S_{ij} = distance from one conductor to the image of the other, r_i = radius of conductor i, ε = permittivity of the medium surrounding the conductor, and l = length of conductor.

Though most of the overhead lines are bare conductors, aerial cables may consist of cable with shielding tape or sheath. For a single-core conductor with its sheath grounded, the capacitance C_{ii} in per-unit length can be easily calculated by Eq. (61.12), and all C_{ij}'s are equal to zero.

$$C = \frac{2\pi\varepsilon_0\varepsilon_r}{\ln(r_2/r_1)} \tag{61.12}$$

where ε_0 = absolute permittivity (dielectric constant of free space), ε_r = relative permittivity of cable insulation, r_1 = outside radius of conductor core, and r_2 = inside radius of conductor sheath.

Models

In steady-state problems, three-phase transmission lines are represented by lumped-π equivalent networks, series resistances and inductances between buses are lumped in the middle, and shunt capacitances of the

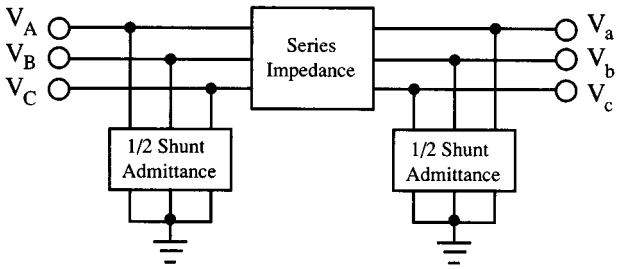

FIGURE 61.3 Generalized conductor model.

TABLE 61.2 Standard System Voltage, kV

	Rating	
Category	Nominal	Maximum
	34.5	36.5
	46	48.3
	69	72.5
	115	121
	138	145
	161	169
	230	242
Extra-high voltage (EHV)	345	362
	400 (principally in Europe)	
	500	550
	765	800
Ultra-high voltage (UHV)	1100	1200

transmission lines are divided into two halves and lumped at buses connecting the lines (Fig. 61.3). More discussion on the transmission line models can be found in El-Hawary [1995].

Standard Voltages

Standard transmission voltages are established in the United States by the American National Standards Institute (ANSI). There is no clear delineation between distribution, subtransmission, and transmission voltage levels. Table 61.2 shows the standard voltages listed in ANSI Standard C84 and C92.2, all of which are in use at present.

Insulators

The electrical operating performance of a transmission line depends primarily on the insulation. Insulators not only must have sufficient mechanical strength to support the greatest loads of ice and wind that may be reasonably expected, with an ample margin, but must be so designed to withstand severe mechanical abuse, lightning, and power arcs without mechanically failing. They must prevent a flashover for practically any power-frequency operation condition and many transient voltage conditions, under any conditions of humidity, temperature, rain, or snow, and with accumulations of dirt, salt, and other contaminants which are not periodically washed off by rains.

The majority of present insulators are made of glazed porcelain. Porcelain is a ceramic product obtained by the high-temperature vitrification of clay, finely ground feldspar, and silica. Porcelain insulators for transmission may be disks, posts, or long-rod types. Glass insulators have been used on a significant proportion of transmission lines. These are made from toughened glass and are usually clear and colorless or light green. For transmission voltages they are available only as disk types. Synthetic insulators are usually manufactured as long-rod or post types. Use of synthetic insulators on transmission lines is relatively recent, and a few questions

TABLE 61.3 Typical Line Insulation

Line Voltage, kV	No. of Standard Disks	Controlling Parameter (Typical)
115	7–9	Lightning or contamination
138	7–10	Lightning or contamination
230	11–12	Lightning or contamination
345	16–18	Lightning, switching surge, or contamination
500	24–26	Switching surge or contamination
765	30–37	Switching surge or contamination

about their use are still under study. Improvements in design and manufacture in recent years have made synthetic insulators increasingly attractive since the strength-to-weight ratio is significantly higher than that of porcelain and can result in reduced tower costs, especially on EHV and UHV transmission lines.

NEMA Publication "High Voltage Insulator Standard" and AIEE Standard 41 have been combined in ANSI Standards C29.1 through C29.9. Standard C29.1 covers all electrical and mechanical tests for all types of insulators. The standards for the various insulators covering flashover voltages (wet, dry, and impulse; radio influence; leakage distance; standard dimensions; and mechanical-strength characteristics) are addressed. These standards should be consulted when specifying or purchasing insulators.

The electrical strength of line insulation may be determined by power frequency, switching surge, or lightning performance requirements. At different line voltages, different parameters tend to dominate. Table 61.3 shows typical line insulation levels and the controlling parameter.

Defining Term

Surge impedance loading (SIL): The surge impedance of a transmission line is the characteristic impedance with resistance set to zero (resistance is assumed small compared to reactance). The power that flows in a lossless transmission line terminated in a resistive load equal to the line's surge impedance is denoted as the surge impedance loading of the line.

Further Information

Other recommended publications regarding EHV transmission lines include *Transmission Line Reference Book, 345 kV and Above,* 2nd ed., 1982, from Electric Power Research Institute, Palo Alto, Calif., and the IEEE Working Group on Insulator Contamination publication "Application guide for insulators in a contaminated environment," *IEEE Trans. Power Appar. Syst.,* September/October 1979.

Research on higher voltage levels has been conducted by several organizations: Electric Power Research Institute, Bonneville Power Administration, and others. The use of more than three phases for electric power transmission has been studied intensively by sponsors such as the U.S. Department of Energy.

61.2 Alternating Current Underground: Line Parameters, Models, Standard Voltages, Cables

Mo-Shing Chen and K.C. Lai

Although the capital costs of an underground power cable are usually several times those of an overhead line of equal capacity, installation of underground cable is continuously increasing for reasons of safety, security, reliability, aesthetics, or availability of right-of-way. In heavily populated urban areas, underground cable systems are mostly preferred.

Two types of cables are commonly used at the transmission voltage level: pipe-type cables and self-contained oil-filled cables. The selection depends on voltage, power requirements, length, cost, and reliability. In the United States, over 90% of underground cables are pipe-type design.

Cable Parameters

A general formulation of impedance and admittance of single-core coaxial and pipe-type cables was proposed by Prof. Akihiro Ametani of Doshisha University in Kyoto, Japan [Ametani, 1980]. The impedance and admittance of a cable system are defined in the two matrix equations

$$\frac{d(V)}{dx} = -[Z] \cdot (I) \tag{61.13}$$

$$\frac{d(I)}{dx} = -[Y] \cdot (V) \tag{61.14}$$

where (V) and (I) are vectors of the voltages and currents at a distance x along the cable and $[Z]$ and $[Y]$ are square matrices of the impedance and admittance. For a pipe-type cable, shown in Fig. 61.4, the impedance and admittance matrices can be written as Eqs. (61.15) and (61.16) by assuming:

1. The displacement currents and dielectric losses are negligible.
2. Each conducting medium of a cable has constant permeability.
3. The pipe thickness is greater than the penetration depth of the pipe wall.

$$[Z] = [Z_i] + [Z_p] \tag{61.15}$$

$$[Y] = j\omega[P]^{-1} \tag{61.16}$$

$$[P] = [P_i] + [P_p]$$

where $[P]$ is a potential coefficient matrix.

$$[Z_i] = \text{single-core cable internal impedance matrix}$$

$$= \begin{bmatrix} [Z_{i1}] & [0] & \cdots & [0] \\ [0] & [Z_{i2}] & \cdots & [0] \\ \vdots & \vdots & \ddots & \vdots \\ [0] & [0] & \cdots & [Z_{in}] \end{bmatrix} \tag{61.17}$$

$$[Z_p] = \text{pipe internal impedance matrix}$$

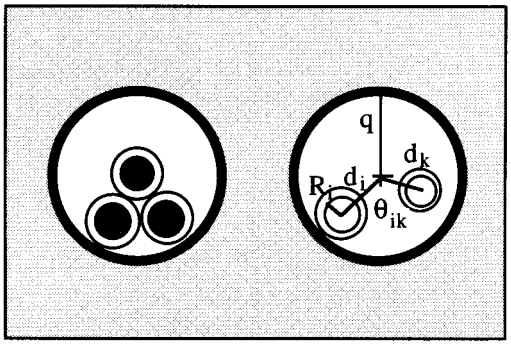

FIGURE 61.4 A pipe-type cable system.

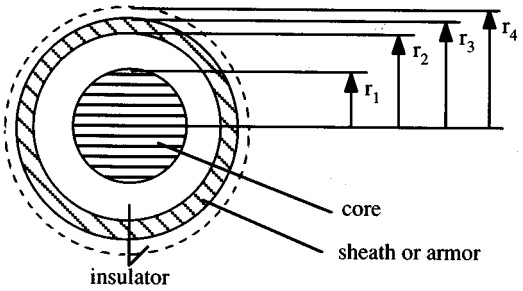

FIGURE 61.5 A single-core cable cross section.

$$= \begin{bmatrix} [Z_{p11}] & [Z_{p12}] & \cdots & [Z_{p1n}] \\ [Z_{p12}] & [Z_{p22}] & \cdots & [Z_{p2n}] \\ \vdots & \vdots & \ddots & \vdots \\ [Z_{p1n}] & [Z_{p2n}] & \cdots & [Z_{pnn}] \end{bmatrix} \tag{61.18}$$

The diagonal submatrix in $[Z_i]$ expresses the self-impedance matrix of a single-core cable. When a single-core cable consists of a core and sheath (Fig. 61.5), the self-impedance matrix is given by

$$[Z_{ij}] = \begin{bmatrix} Z_{ccj} & Z_{csj} \\ Z_{csj} & Z_{ssj} \end{bmatrix} \tag{61.19}$$

where

$$Z_{ssj} = \text{sheath self-impedance}$$

$$= Z_{\text{sheath-out}} + Z_{\text{sheath/pipe-insulation}} \tag{61.20}$$

$$Z_{csj} = \text{mutual impedance between the core and sheath}$$

$$= Z_{ssj} - Z_{\text{sheath-mutual}} \tag{61.21}$$

$$Z_{ccj} = \text{core self-impedance}$$

$$= (Z_{\text{core}} + Z_{\text{core/sheath-insulation}} + Z_{\text{sheath-in}}) + Z_{csj} - Z_{\text{sheath-mutual}} \tag{61.22}$$

where

$$Z_{\text{core}} = \frac{\rho m}{2\pi r_1} \frac{I_0(mr_1)}{I_1(mr_1)} \tag{61.23}$$

$$Z_{\text{core/sheath-insulation}} = \frac{j\omega\mu_1}{2\pi} \ln \frac{r_2}{r_1} \tag{61.24}$$

$$Z_{\text{sheath-in}} = \frac{\rho m}{2\pi r_2 D}\left[I_0(mr_2)K_1(mr_3) + K_0(mr_2)I_1(mr_3)\right] \tag{61.25}$$

$$Z_{\text{sheath-mutual}} = \frac{\rho}{2\pi r_2 r_3 D} \tag{61.26}$$

$$Z_{\text{sheath-out}} = \frac{\rho m}{2\pi r_3 D}\left[I_0(mr_3)K_1(mr_2) + K_0(mr_3)I_1(mr_2)\right] \tag{61.27}$$

$$Z_{\text{sheath/pipe-insulation}} = \frac{j\omega\mu_0}{2\pi}\cosh^{-1}\left(\frac{q^2 + R_i^2 - d_i^2}{2qR_i}\right) \tag{61.28}$$

where ρ = resistivity of conductor, $D = I_1(mr_3)K_1(mr_2) - I_1(mr_2)K_1(mr_3)$, γ = Euler's constant = 1.7811, I_i = modified Bessel function of the first kind of order i, K_i = modified Bessel function of the second kind of order i, and $m = \sqrt{j\omega\mu/\rho}$ = reciprocal of the complex depth of penetration.

A submatrix of $[Z_p]$ is given in the following form:

$$[Z_{pjk}] = \begin{bmatrix} Z_{pjk} & Z_{pjk} \\ Z_{pjk} & Z_{pjk} \end{bmatrix} \tag{61.29}$$

Z_{pjk} in Eq. (61.29) is the impedance between the jth and kth inner conductors with respect to the pipe inner surface. When $j = k$, $Z_{pjk} = Z_{\text{pipe-in}}$; otherwise Z_{pjk} is given in Eq. (61.31).

$$Z_{\text{pipe-in}} = \frac{\rho m}{2\pi q}\frac{K_0(mq)}{K_1(mq)} + \frac{j\omega\mu}{\pi}\sum_{n=1}^{\infty}\left[\left(\frac{d_i}{q}\right)^{2n}\frac{K_n(mq)}{n\mu_r K_n(mq) - mqK_n'(mq)}\right] \tag{61.30}$$

$$Z_{pjk} = \frac{j\omega\mu_0}{2\pi}\left\{\begin{aligned}&\ln\frac{q}{S_{jk}} + \frac{\mu_r}{mq}\frac{K_0(mq)}{K_1(mq)} \\ &+\sum_{n=1}^{\infty}\left(\frac{d_j d_k}{q^2}\right)^n \cos(n\theta_{jk})\left[2\mu_r\frac{K_n(mq)}{n\mu_r K_n(mq) - mqK_n'(mq)} - \frac{1}{n}\right]\end{aligned}\right\} \tag{61.31}$$

where q is the inside radius of the pipe (Fig. 61.4).

The formulation of the potential coefficient matrix of a pipe-type cable is similar to the impedance matrix.

$$[P_i] = \begin{bmatrix} [P_{i1}] & [0] & \cdots & [0] \\ [0] & [P_{i2}] & \cdots & [0] \\ \vdots & \vdots & \ddots & \vdots \\ [0] & [0] & \cdots & [P_{in}] \end{bmatrix} \tag{61.32}$$

$$[P_p] = \begin{bmatrix} [P_{p11}] & [P_{p12}] & \cdots & [P_{p1n}] \\ [P_{p12}] & [P_{p22}] & \cdots & [P_{p2n}] \\ \vdots & \vdots & \ddots & \vdots \\ [P_{p1n}] & [P_{p2n}] & \cdots & [P_{pnn}] \end{bmatrix} \tag{61.33}$$

The diagonal submatrix in $[P_i]$ expresses the potential coefficient matrix of a single-core cable. When a single-core cable consists of a core and sheath (Fig. 61.5), the submatrix is given by

$$[P_{ij}] = \begin{bmatrix} P_{cj} + P_{sj} & P_{sj} \\ P_{sj} & P_{sj} \end{bmatrix} \tag{61.34}$$

where

$$P_{sj} = \left(\frac{1}{2}\pi\varepsilon_0\varepsilon_{sj}\right) \ln\frac{r_4}{r_3} \tag{61.35}$$

$$P_{cj} = \left(\frac{1}{2}\pi\varepsilon_0\varepsilon_{cj}\right) \ln\frac{r_2}{r_1} \tag{61.36}$$

ε_0 = absolute permittivity of free space, ε_{sj} = relative permittivity of insulation outside sheath, and ε_{cj} = relative permittivity of insulation outside core.

Submatrix $[P_{pjk}]$ of $[P_p]$ is given by

$$[P_{pjk}] = \begin{bmatrix} P_{pjk} & P_{pjk} \\ P_{pjk} & P_{pjk} \end{bmatrix} \tag{61.37}$$

P_{pjk} in Eq. (61.37) is the potential coefficient between the jth and kth inner conductors with respect to the pipe inner surface. When $j = k$, $P_{pjk} = P_{\text{pipe-in}}$; otherwise P_{pjk} is given in Eq. (61.39).

$$P_{\text{pipe-in}} = \frac{\ln\left\{\dfrac{q}{R_i}\left[1 - \left(\dfrac{d_i}{q}\right)^2\right]\right\}}{2\pi\varepsilon_p\varepsilon_0} \tag{61.38}$$

$$p_{pjk} = \frac{1}{2\pi\varepsilon_p\varepsilon_0}\left[\ln\frac{q}{S_{jk}} - \sum_{n=1}^{\infty}\left(\frac{d_j d_k}{q^2}\right)^n \cdot \frac{\cos(n\theta_{jk})}{n}\right] \tag{61.39}$$

where ε_p is the relative permittivity of insulation inside the pipe; R_i is the outer radius of cable i; and d_i, d_j, and d_k are the inner radii of cables i, j, and k.

Models

Refer to "Models" in Section 61.1.

Standard Voltages

In the United States, the underground transmission cables are rated 69 to 345 kV (refer to Table 61.2 in Section 61.1). Cables rated 550 kV are used commercially in Japan. In the United States, cables installed at the 550-kV level are used in relatively short distances, for example, at the Grand Coulee Dam.

Cable Standards

The most universal standardizing authority for cables is the International Electrotechnical Commission (IEC). The IEC standards cater to a large variety of permissible options and serve mainly as a basis for the preparation of national standards. In the United States, in addition to national standards for materials and components, there are cable standards in widespread use by industry issued by four bodies: Underwriter's Laboratories (UL), Association of Edison Illuminating Companies (AEIC), and jointly by the Insulated Power Cables Engineers Association and the National Electrical Manufacturers' Association (IPCEA/NEMA).

Further Information

The development of advanced cable systems is continuously supported by government and utilities. Information and reports regarding these activities are available from two principal funding agencies, the Electric Power Research Institute (EPRI) and the U.S. Department of Energy.

61.3 High-Voltage Direct-Current Transmission

Rao S. Thallam

The first commercial high-voltage direct-current (HVDC) power transmission system was commissioned in 1954, with an interconnection between the island of Gotland and the Swedish mainland. It was an undersea cable, 96 km long, with ratings of 100 kV and 20 MW. There are now more than 50 systems operating throughout the world, and several more are in the planning, design, and construction stages. HVDC transmission has become acceptable as an economical and reliable method of power transmission and interconnection. It offers advantages over alternating current (ac) for long-distance power transmission and as asynchronous interconnection between two ac systems and offers the ability to precisely control the power flow without inadvertent loop flows in an interconnected ac system. Table 61.4 lists the HVDC projects to date (1995), their ratings, year commissioned (or the expected year of commissioning), and other details. The largest system in operation, Itaipu HVDC transmission, consists of two ±600-kV, 3150-MW-rated bipoles, transmitting a total of 6300 MW power from the Itaipu generating station to the Ibiuna (formerly Sao Roque) converter station in southeastern Brazil over a distance of 800 km.

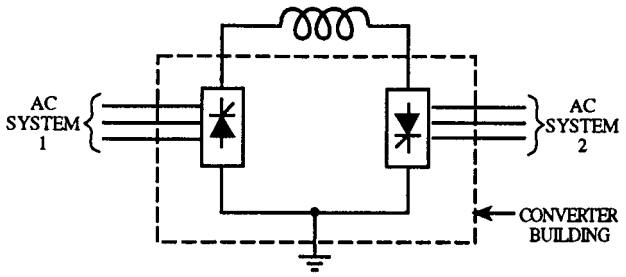

FIGURE 61.6 Back-to-back dc system.

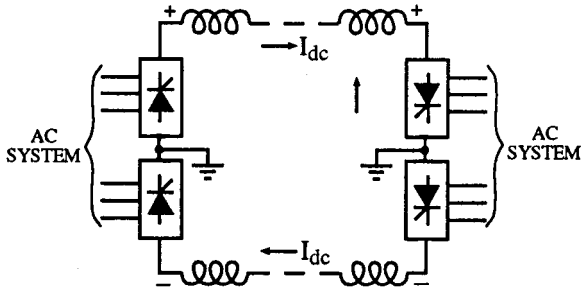

FIGURE 61.7 Bipolar dc system.

Configurations of DC Transmission

HVDC transmission systems can be classified into three categories:

1. Back-to-back systems
2. Two-terminal, or point-to-point, systems
3. Multiterminal systems

These will be briefly described here.

Back-to-Back DC System

In a back-to-back dc system (Fig. 61.6), both rectifier and inverter are located in the same station, usually in the same building. The rectifier and inverter are usually tied with a reactor, which is generally of outdoor, air-core design. A back-to-back dc system is used to tie two **asynchronous ac systems** (systems that are not in synchronism). The two ac systems can be of different operating frequencies, for example, one 50 Hz and the other 60 Hz. Examples are the Sakuma and Shin-Shinano converter stations in Japan. Both are used to link the 50- and 60-Hz ac systems. The Acaray station in Paraguay links the Paraguay system (50 Hz) with the Brazilian system, which is 60 Hz. Back-to-back dc links are also used to interconnect two ac systems that are of the same frequency but are not operating in synchronism. In North America, eastern and western systems are not synchronized, and Quebec and Texas are not synchronized with their neighboring systems. A dc link offers a practical solution as a tie between nonsynchronous systems. Thus to date, there are 10 back-to-back dc links in operation interconnecting such systems in North America. Similarly, in Europe, eastern and western systems are not synchronized, and dc offers the practical choice for interconnection between them.

Two-Terminal, or Point-to-Point, DC Transmission

Two-terminal dc systems can be either **bipolar** or monopolar. Bipolar configuration, shown in Fig. 61.7, is the commonly used arrangement for systems with overhead lines. In this system, there will be two conductors, one for each polarity (positive and negative) carrying nearly equal currents. Only the difference of these currents, which is usually small, flows through ground return.

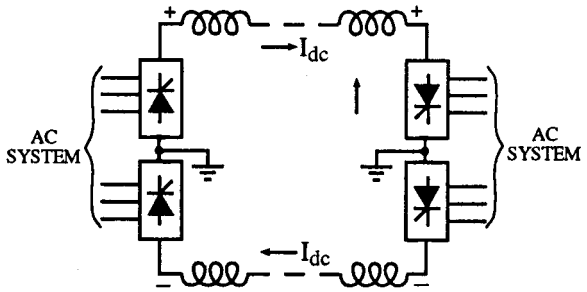

FIGURE 61.8 Monopolar ground return dc system.

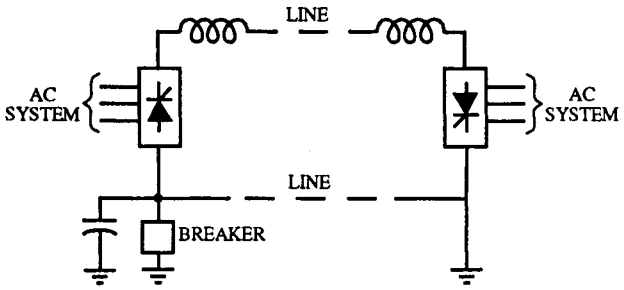

FIGURE 61.9 Monopolar metallic return dc system.

A monopolar system will have one conductor, either positive or negative polarity with current returning through either ground or another metallic return conductor. The monopolar ground return current configuration, shown in Fig. 61.8, has been used for undersea cable systems, where current returns through the sea. This configuration can also be used for short-term emergency operation for a two-terminal dc line system in the event of a pole outage. However, concerns for corrosion of underground metallic structures and interference with telephone and other utilities will restrict the duration of such operation. The total ampere-hour operation per year is usually the restricting criterion.

In a monopolar metallic return system, shown in Fig. 61.9, return current flows through a conductor, thus avoiding problems associated with ground return current. This method is generally used as a contingency mode of operation for a normal bipolar transmission system in the event of a partial converter (one-pole equipment) outage. In the case of outage of a one-pole converter, the conductor of the affected pole will be used as the returning conductor. A metallic return transfer breaker will be opened, diverting the return current from the ground path and into the pole conductor. This conductor will be grounded at one end and will be insulated at the other end. This system can transmit half the power of the normal bipolar system capacity (and can be increased if overload capacity is available). However, the line losses will be doubled compared to the normal bipolar operation for the same power transmitted.

Multiterminal DC Systems

There are two basic configurations in which the dc systems can be operated as multiterminal systems:

1. Parallel configuration
2. Series configuration

Parallel configuration can be either radial-connected [Fig. 61.10(a)] or mesh-connected [Fig. 61.10(b)]. In a parallel-connected multiterminal dc system, all converters operate at the same nominal dc voltage, similar to ac system interconnections. In this operation, one converter determines the operating voltage, and all other terminals operate in a current-controlling mode.

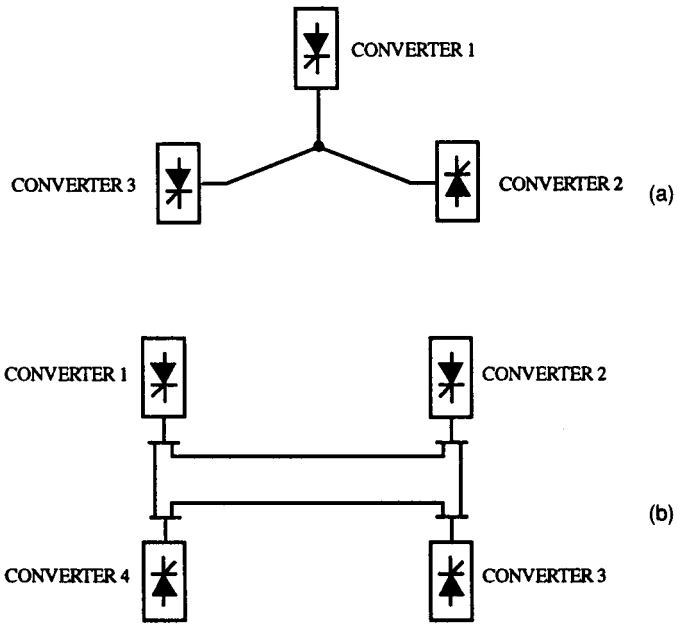

FIGURE 61.10 (a) Parallel-connected radial MTDC system; (b) parallel-connected mesh-type MTDC system.

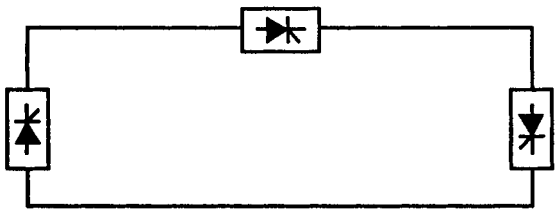

FIGURE 61.11 Series-connected MTDC system.

In a series-connected multiterminal dc system (Fig. 61.11), all converters operate at the same current. One converter sets the current that will be common to all converters in the system. Except for the converter that sets the current, the remaining converters operate in voltage control mode (constant **firing angle** or constant **extinction angle**). The converters operate almost independently without requirement for high-speed communication between them. The power output of a non-current-controlling converter is varied by varying its voltage. At all times, the sum of the voltages across the rectifier stations must be larger than the sum of voltages across the inverter stations. Disadvantages of a series-connected system are (1) reduced efficiency because full line insulation is not used at all times and (2) operation at higher firing angles will lead to high converter losses and higher reactive power requirements from the ac system.

There are now two truly multiterminal dc systems in operation. The Sardinia–Corsica–Italy three-terminal dc system was originally commissioned as a two-terminal (Sardinia–Italy) system in 1967 with a 200-MW rating. In 1986, the Corsica tap was added and the system was upgraded to a 300-MW rating. The two-terminal Hydro Quebec–New England HVDC interconnection (commissioned in 1985) was extended to a five-terminal system and commissioned in 1990 (see Table 61.4). The largest terminal of this system at Radisson station in Quebec is rated at 2250 MW. Two more systems, the Nelson River system in Canada and the Pacific NW-SW Intertie in the United States, also operate as multiterminal systems. Each of these systems has two converters at each end of the line, but the converters at each end are constrained to operate in the same mode, either rectifier or inverter.

Economic Comparison of AC and DC Transmission

In cases where HVDC is selected on technical considerations, it may be the only practical option, as in the case of an asynchronous interconnection. However, for long-distance power transmission, where both ac and HVDC are practical, the final decision is dependent on total costs of each alternative. Total cost of a transmission system includes the line costs (conductors, insulators, and towers) plus the right-of-way (R-o-W) costs. A dc line with two conductors can carry almost the same amount of power as the three-phase ac line with the same size of line conductors. However, dc towers with only two conductors are simpler and cheaper than three-phase ac towers. Hence the per-mile costs of line and R-o-W will be lower for a dc line. Power losses in the dc line are also lower than for ac for the same power transmitted. However, the HVDC system requires converters at the two ends of the line; hence the terminal costs for dc are higher than for ac. Variation of total costs for ac and dc as a function of line length are shown in Fig. 61.12. There is a break-even distance above which the total costs of dc option will be lower than the ac transmission option. This is in the range of 500 to 800 km for overhead lines but much shorter for cables. It is between 20 and 50 km for submarine cables and twice as far for underground cables.

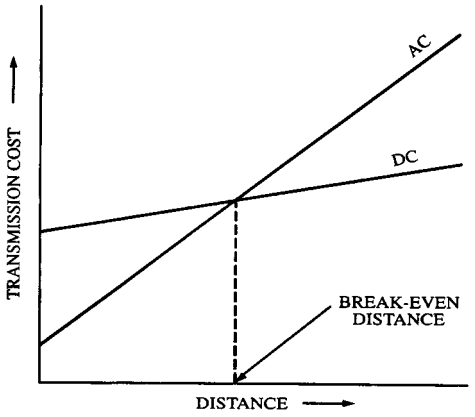

FIGURE 61.12 Transmission cost as function of line length.

Principles of Converter Operation

Converter Circuit

Since the generation and most of the transmission and utilization is alternating current, HVDC transmission requires conversion from ac to dc (called rectification) at the sending end and conversion back from dc to ac (called inversion) at the receiving end. In HVDC transmission, the basic device used for conversion from ac to dc and from dc to ac is a three-phase full-wave bridge converter, which is also known as a Graetz circuit. This is a three-phase six-pulse converter. A three-phase twelve-pulse converter will be composed of two three-phase six-pulse converters, supplied with voltages differing in phase by 30 degrees (Fig. 61.13). The phase difference of 30 degrees is obtained by supplying one six-pulse bridge with a Y/Y transformer and the other by Y/Δ transformer.

Relationships between AC and DC Quantities

Voltages and currents on ac and dc sides of the converter are related and are functions of several converter parameters including the converter transformer. The following equations are provided here for easy reference. Detailed derivations are given in Kimbark [1971].

E_{LL} = rms line-to-line voltage of the converter ac bus
I_1 = rms value of fundamental frequency component of the converter ac current
h = harmonic number
α = valve firing delay angle (from the instant the valve voltage is positive)
u = **overlap angle** (also called **commutation angle**)
ϕ = phase angle between voltage and current
$\cos\phi$ = displacement power factor
V_{d0} = ideal no-load dc voltage (at $\alpha = 0$ and $u = 0$)
L_c = commutating circuit inductance
$\beta = 180 - \alpha$ = angle of advance for inverter
$\gamma = 180 - (\alpha + u)$ = margin angle for inverter

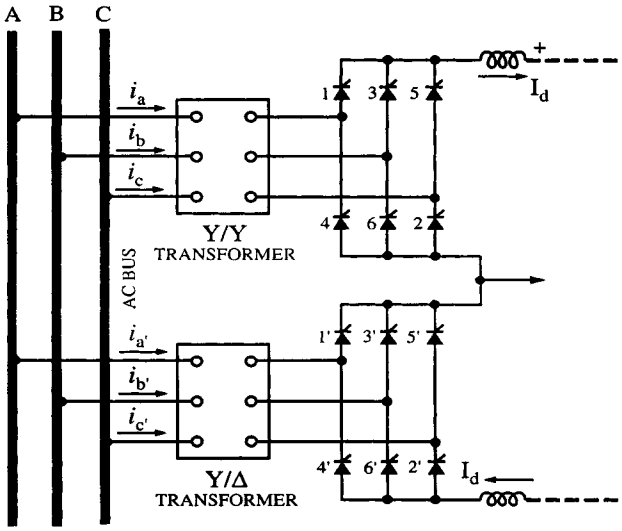

FIGURE 61.13 Basic circuit of a 12-pulse HVDC converter.

with $\alpha = 0$, $u = 0$,

$$V_{d0} = \frac{3\sqrt{2}}{\pi} E_{LL} = 1.35E_{LL} \tag{61.40}$$

With $\alpha > 0$, and $u = 0$

$$V_d = V_{d0} \cos \alpha \tag{61.41}$$

Theoretically α can vary from 0 to 180 degrees (with $u = 0$); hence V_d can vary from $+V_{d0}$ to $-V_{d0}$. Since the valves conduct current in only one direction, variation of dc voltage from V_{d0} to $-V_{d0}$ means reversal of power flow direction and the converter mode of operation changing from rectifier to inverter.

$$I_1 = \frac{\sqrt{6}}{\pi} I_d = 0.78I_d \tag{61.42}$$

$$\cos \phi = \cos \alpha = \frac{V_d}{V_{d0}} \tag{61.43}$$

With $\alpha > 0$ and $0 < u > 60°$,

$$V_d = V_{d0} \frac{\cos \alpha + \cos(\alpha + u)}{2} \tag{61.44}$$

$$V_d = \frac{3\sqrt{2}}{\pi} E_{LL} \frac{\cos \alpha + \cos(\alpha + u)}{2} \tag{61.45}$$

$$I_1 \approx \frac{\sqrt{6}}{\pi} I_d \tag{61.46}$$

The error in Eq. (61.46) is only 4.3% at $u = 60$ degrees (maximum overlap angle for normal steady-state operation), and it will be even lower (1.1%) for most practical cases when u is 30 degrees or less. It can be seen from Eqs. (61.45) and (61.46) that the ratio between ac and dc currents is almost fixed, but the ratio between ac and dc voltages varies as a function of α and u. Hence the HVDC converter can be viewed as a variable-ratio voltage transformer, with almost fixed current ratio.

$$P_{\text{dc}} = V_d I_d \tag{61.47}$$

$$P_{\text{ac}} = \sqrt{-3} E_{LL} I_1 \cos \phi \tag{61.48}$$

Substituting for V_d and I_d in (61.47) and comparing with (61.48),

$$\cos \phi \approx \frac{\cos \alpha + \cos(\alpha + u)}{2} \tag{61.49}$$

From Eqs. (61.44) and (61.49),

$$\cos \phi \approx \frac{V_d}{V_{d0}} \tag{61.50}$$

From Eqs. (61.40), (61.44), and (61.49),

$$V_d \approx 1.35 E_{LL} \cos \phi \tag{61.51}$$

AC Current Harmonics

The HVDC converter is a harmonic current source on the ac side. Fourier analysis of an ac current waveform, shown in Fig. 61.14, shows that it contains the fundamental and harmonics of the order 5, 7, 11, 13, 17, 19, etc. The current for zero degree overlap angle can be expressed as

$$i(t) = \frac{2\sqrt{3}}{\pi} I_d \left(\begin{array}{l} \cos\ \omega t - \frac{1}{5} \cos\ 5\omega t + \frac{1}{7} \cos\ 7\omega t \\ - \frac{1}{11} \cos\ 11\omega t + \frac{1}{13} \cos\ 13\omega t + \cdots \end{array} \right) \tag{61.52}$$

and

$$I_{h0} = \frac{I_{10}}{h} \tag{61.53}$$

where I_{10} and I_{h0} are the fundamental and harmonic currents, respectively, at $\alpha = 0$ and $u = 0$.

Equation (61.53) indicates that the magnitudes of harmonics are inversely proportional to their order.

Converter ac current waveform $i_{a'}$ for phase a with a Y/Δ transformer is also shown in Fig. 61.14. Fourier analysis of this current shows that the fundamental and harmonic components will have the same magnitude

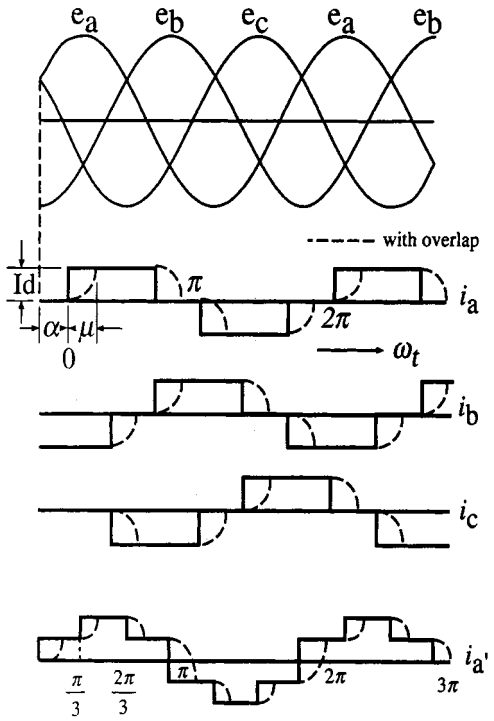

FIGURE 61.14 AC line current waveforms, i_a, i_b, i_c with Y/Y transformer and $i_{a'}$ with Y/Δ transformer.

as in the case of the Y/Y transformer. However, harmonics of order 5, 7, 17, 19, etc. are in phase opposition, whereas harmonics of order 11, 13, 23, 25, etc. are in phase with the Y/Y transformer case. Hence harmonics of order 5, 7, 17, 19, etc. will be canceled in a 12-pulse converter and do not appear in the ac system. In practice they will not be canceled completely because of imbalances in converter and transformer parameters.

Effect of Overlap. The effect of overlap due to commutation angle is to decrease the amplitude of harmonics from the case with zero overlap. Magnitudes of harmonics for a general case with finite firing angle (α) and overlap angle (u) are given by

$$\frac{I_h}{I_{h0}} = \frac{1}{x}\left[A^2 + B^2 - 2AB\cos(2\alpha + u)\right]^{1/2} \tag{61.54}$$

where

$$A = \frac{\sin(h+1)\dfrac{u}{2}}{h+1} \qquad B = \frac{\sin(h-1)\dfrac{u}{2}}{h-1}$$
$$x = \cos\alpha - \cos(\alpha + u)$$

Noncharacteristic Harmonics. In addition to the harmonics described above, converters also generate other harmonics due to "nonideal" conditions of converter operation. Examples of the nonideal conditions are converter ac bus voltage imbalance, perturbation of valve firing pulses, distortion of ac bus voltages, and unbalanced converter transformer impedances. Harmonics generated due to these causes are called *noncharacteristic* harmonics. These are usually smaller in magnitude compared to characteristic harmonics but can create problems if resonances exist in the ac system at these frequencies. In several instances additional filters were installed at the converter ac bus to reduce levels of these harmonics flowing into the ac system.

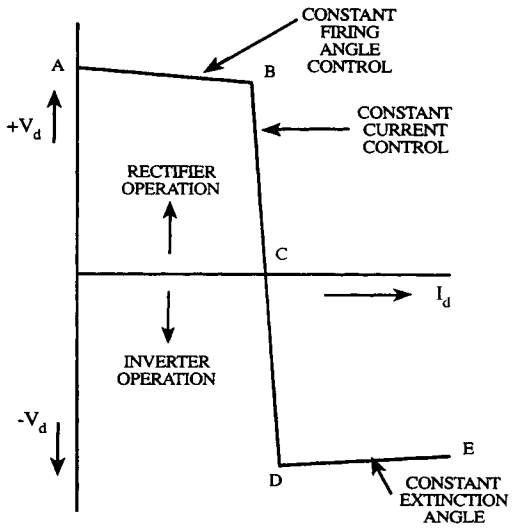

FIGURE 61.15 HVDC converter static characteristic.

Converter Control

The static characteristic of a HVDC converter is shown in Fig. 61.15. There are three distinct features of this characteristic.

***Constant Firing Angle Characteristic* (A–B).** If the converter is operating under constant firing angle control, the converter characteristic can be described by the equation

$$V_d = V_{d0} \cos \alpha - \frac{3\omega L_c}{\pi} I_d \tag{61.55}$$

When the ordered current is too high for the converter to deliver, it will operate at the minimum firing angle (usually 5 degrees). Then the current will be determined by the voltage V_d and the load. This is also referred to as the natural voltage characteristic. The converter in this mode is equivalent to a dc voltage source with internal resistance R_c, where

$$R_c = \frac{3\omega L_c}{\pi} \tag{61.56}$$

Constant Current Control. This is the usual mode of operation of the rectifier. When the converter is operating in constant current control mode, the firing angle is adjusted to maintain dc current at the ordered value. If the load current goes higher than the ordered current for any reason, control increases the firing angle to reduce dc voltage and the converter operation moves in the direction from *B* to *C*. At point *C*, the firing angle reaches 90 degrees (neglecting overlap angle), the voltage changes polarity, and the converter becomes an inverter. From *C* to *D*, the converter works as an inverter.

Constant Extinction Angle Control. At point *D*, the inverter firing angle has increased to a point where further increase can cause commutation failure. The inverter for its safe operation must be operated with sufficient angle of advance β, such that under all operating conditions the extinction angle γ is greater than the valve deionization angle. The deionization angle is defined as the time in electrical degrees from the instant current reaches zero in a particular valve to the time the valve can withstand the application of positive voltage.

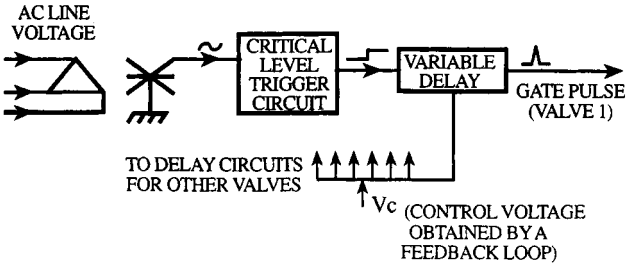

FIGURE 61.16 Constant α control.

Typical minimum values of γ are 15 to 20 degrees for mercury arc valves and slightly less for thyristor valves. During the range *D* to *E*, the increase of load current increases the overlap angle, which reduces the dc voltage. This is the negative resistance characteristic of the inverter.

The functional requirements for HVDC converter control are:

1. Minimize the generation of noncharacteristic harmonics.
2. Safe inverter operation with fewest possible commutation failures even with distorted ac voltages.
3. Lowest possible consumption of reactive power. This requires operation with smallest possible delay angle α and extinction angle γ without increased risk of commutation failures.
4. Smooth transition from current control to extinction angle control.
5. Sufficient stability margins and response time when the ratio of the ac system short-circuit strength and the rated dc power (short-circuit ratio) is low.

Individual Phase Control

In the early HVDC systems individual phase control systems were used. The firing angle of each valve is calculated individually and operated either as constant α or constant γ control.

A schematic of the individual phase control system is shown in Fig. 61.16. Six timing voltages are derived from the ac bus voltage, and the six grid pulses are generated at nominally identical delay times subsequent to the respective voltage-zero crossings. The delays are produced by independent delay circuits and controlled by a common direct voltage V_c, which is derived through a feedback loop to control constant dc line current or constant power. Several variations of this control were used until the late 1960s.

Disadvantages of Individual Phase Control. With distorted ac bus voltages, the firing pulses will be unequally spaced, thus generating noncharacteristic harmonics in ac current. This in turn will further distort the ac bus voltage. This process could lead to harmonic instability, particularly with ac systems of low short-circuit capacity (high-impedance system). Control system filters were tried to solve this problem. However, the filters could increase the potential for commutation failures and also reduce the speed of control system response for faults or disturbances in the ac system.

Equal Pulse Spacing Control

A control system based on the principle of equal spacing of firing pulses at intervals of 60 degrees (electrical) independent of ac bus voltages was developed in the late 1960s. The basic components of this system, shown in Fig. 61.17, consist of a voltage-controlled oscillator and ring counter. The frequency of the oscillator is directly proportional to the dc control voltage V_c. Under steady-state conditions, pulse frequency is precisely 6*f*, where *f* is the ac system frequency. The phase of each grid pulse will have some arbitrary value relative to the ac bus voltage. If the three-phase ac bus voltages are symmetrical sine waves with no distortion, then α is the same for all valves. The oscillator will be phase-locked with the ac system frequency to avoid drifting. The dc control voltage V_c is derived from a feedback loop for constant current, constant power, or constant extinction angle γ.

The control systems used in recent projects are digital-based and much more sophisticated than the earlier versions.

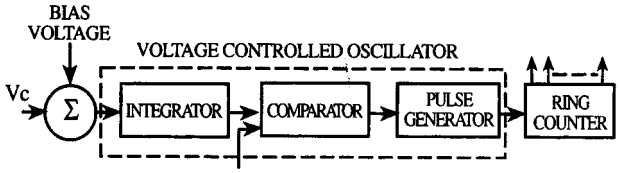

FIGURE 61.17 Equal pulse spacing control.

Developments

During the last two or three decades, several developments in HVDC technology have taken place that improved viability of the HVDC transmission. Prior to 1970 mercury arc valves were used for converting from ac to dc and dc to ac. They had several operational problems including frequent arcbacks. Arcback is a random phenomenon that results in failure of a valve to block conduction in the reverse direction. This is most common in the rectifier mode of operation. In rectifier operation, the valve is exposed to inverse voltage for approximately two-thirds of each cycle. Arcbacks result in line-to-line short circuits, and sometimes in three-phase short circuits, which subject the converter transformer and valves to severe stresses.

Thyristors

Thyristor valves were first used for HVDC transmission in the early 1970s, and since then have completely replaced mercury arc valves. The term thyristor valve, carried over from mercury arc valve, is used to refer to an assembly of series and parallel connection of several thyristors to make up the required voltage and current ratings of one arm of the converter. The first test thyristor valve in a HVDC converter station was installed in 1967, replacing a mercury arc valve in the Ygne converter station on the island of Gotland (see Gotland I in Table 61.4). The Eel River back-to-back station in New Brunswick, Canada, commissioned in 1972, was the first all-thyristor HVDC converter station. The voltage and current ratings of thyristors have increased steadily over the last two decades. Figure 61.18 shows the maximum blocking voltage of thyristors from the late 1960s to date. The current ratings have also increased in this period from 1 to 4 kA. Some of the increased current ratings were achieved with large-diameter silicon wafers (presently 100-mm diameter) and with improved cooling systems. Earlier projects used air-cooled thyristors. Water-cooled thyristors are used for all the recent projects.

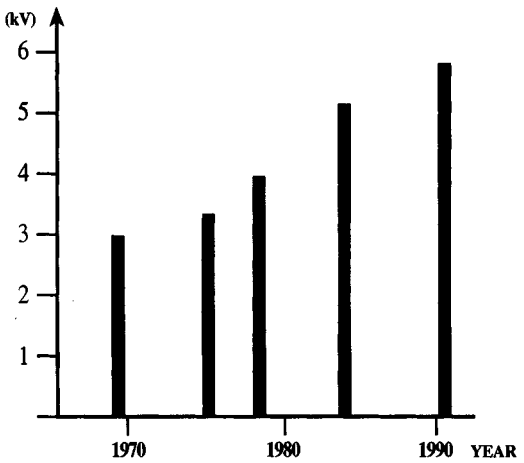

FIGURE 61.18 Maximum blocking voltage development.

Other recent developments include direct light-triggered thyristors and gate turn-off (GTO) thyristors. GTO thyristors have some advantages for HVDC converters connected to weak ac systems. They are now available in ratings up to 4.5 kV and 4 kA but have not yet been applied in HVDC systems.

DC Circuit Breakers

Interrupting the current in ac systems is aided by the fact that ac current goes through zero every half-cycle or approximately every 8 ms in a 60-Hz system. The absence of natural current zero in dc makes it difficult to develop a dc circuit breaker. There are three principal problems in designing a dc circuit breaker:

1. Forcing current zero in the interrupting element
2. Controlling the overvoltages caused by large di/dt in a highly inductive circuit
3. Dissipating large amounts of energy (tens of megajoules)

The second and third problems are solved by the application of zinc oxide varistors connected line to ground and across the breaking element. The first is the major problem, and several different solutions are adopted by different manufacturers. Basically, current zero is achieved by inserting a counter voltage into the circuit.

In the circuit shown in Fig. 61.19, opening CB (air-blast circuit breaker) causes current to be commutated to the parallel LC circuit. The commutating circuit will be oscillatory, which creates current zero in the circuit breaker. The opening of CB increases the voltage across the commutating circuit, which will be limited by the zinc oxide varistor ZnO_1 by entering into conduction. The resistance *R* is the closing resistor in series with switch *S*.

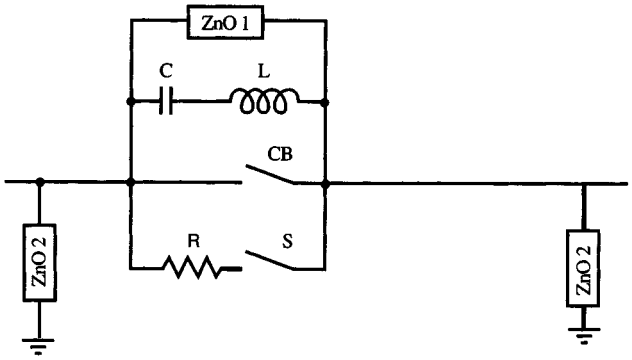

FIGURE 61.19 DC circuit breaker (one module).

It should be noted that a two-terminal dc system does not need a dc breaker since the fast converter control response can bring the current quickly to zero. In multiterminal systems, dc breakers can provide additional flexibility of operation. The multiterminal dc systems commissioned so far have not employed dc breakers.

Defining Terms

Asynchronous ac systems: AC systems with either different operating frequencies or that are not in synchronism.

Bipole: DC system with two conductors, one positive and the other negative polarity. Rated voltage of a bipole is expressed as ±100 kV, for example.

Commutation: Process of transferring current from one valve to another.

Commutation angle (overlap angle): Time in electrical degrees from the start to the completion of the commutation process.

Extinction angle: Time in electrical degrees from the instant the current in a valve reaches zero (end of conduction) to the time the valve voltage changes sign and becomes positive.

Firing angle (delay angle): Time in electrical degrees from the instant the valve voltage is positive to the application of firing pulse to the valve (start of conduction).

Pulse number of a converter: Number of ripples in dc voltage per cycle of ac voltage. A three-phase two-way bridge is a six-pulse converter.

Thyristor valve: Assembly of series and parallel connection of several thyristors to make up the required current and voltage ratings of one arm of the converter.

Further Information

The three textbooks cited under References are excellent for further reading. The IEEE (USA) and IEE (UK) periodically hold conferences on "DC Transmission." The last IEEE conference was held in 1984 in Montreal, and the IEE conference was held in 1991 (conf. publ. no. 345) in London. Proceedings can be ordered from these organizations.

61.4 Compensation

Mohamed E. El-Hawary

The term *compensation* is used to describe the intentional insertion of reactive power-producing devices, either capacitive or inductive, to achieve a desired effect in the electric power system. The effects include improved voltage profiles, enhanced stability performance, and improved transmission capacity. The devices are connected either in series or in **shunt** (parallel) at a particular point in the power circuit.

For illustration purposes, we consider the circuit of Fig. 61.20, where the link has an impedance of $R + jX$, and it is assumed that $V_1 > V_2$ and V_1 leads V_2. The corresponding phasor diagram for zero R and lagging load current I is shown in Fig. 61.21. The approximate relationship between the scalar voltage difference between two nodes in a network and the flow of reactive power Q can be shown to be [Weedy, 1972]

$$\Delta V = \frac{RP_2 + XQ_2}{V_2} \tag{61.57}$$

In most power circuits, $X >> R$ and the voltage difference ΔV determines Q.

The flow of power and reactive power is from A to B when $V_1 > V_2$ and V_1 leads V_2. Q is determined mainly by $V_1 - V_2$. The direction of reactive power can be reversed by making $V_2 > V_1$. It can thus be seen that if a scalar voltage difference exists across a largely reactive link, the reactive power flows toward the node of lower voltage. Looked at from an alternative point of view, if there is a reactive power deficit at a point in an electric network, this deficit has to be supplied from the rest of the circuit and hence the voltage at that point falls. Of course, a surplus of reactive power generated will cause a voltage rise. This can be interpreted as providing voltage support by supplying reactive power at that point.

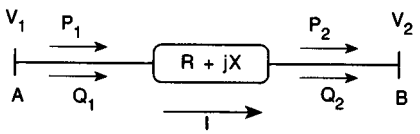

FIGURE 61.20 Two nodes connected by a link.

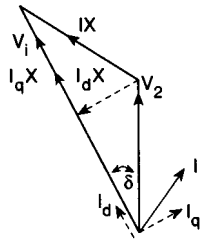

FIGURE 61.21 Phasor diagram for system shown in Fig. 61.20.

Assuming that the link is reactive, i.e., with $R = 0$, then $P_1 = P_2 = P$. In this case, the active power transferred from point A to point B can be shown to be given by [El-Hawary, 1995]

$$P = P_{\max} \sin \delta \tag{61.58}$$

The maximum power transfer $P_{\max}$ is given by

$$P_{\max} = \frac{V_1 V_2}{X} \tag{61.59}$$

It is clear that the power transfer capacity defined by Eq. (61.59) is improved if V_2 is increased.

Series Capacitors

Series capacitors are employed to neutralize part of the inductive reactance of a power circuit, as shown in Fig. 61.22. From the phasor diagram of Fig. 61.23 we see that the load voltage is higher with the capacitor inserted than without the capacitor.

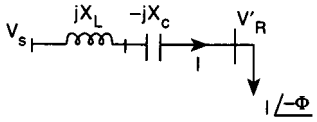

FIGURE 61.22 Line with series capacitor.

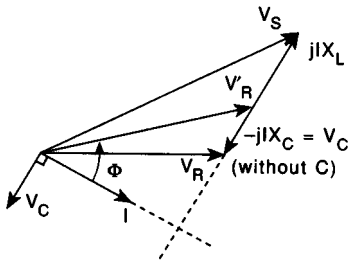

FIGURE 61.23 Phasor diagram corresponding to Fig. 61.22.

Introducing series capacitors is associated with an increase in the circuit's transmission capacity [from (61.59) with a net reduction in X] and enhanced stability performance as well as improved voltage conditions on the circuit. They are also valuable in other aspects such as:

- Controlling reactive power balance
- Load distribution and control of overall transmission losses

Series-capacitor compensation delays investments in additional overhead lines for added transmission capacity, which is advantageous from an environmental point of view.

The first worldwide series-capacitor installation was a 33-kV 1.25-MVAR bank on the New York Power & Light system, which was put in service in 1928. Since then, many higher-capacity, higher-voltage installations have been installed in the United States, Canada, Sweden, Brazil, and other countries.

The reduction in a circuit's inductive reactance increases the short-circuit current levels over those for the noncompensated circuit. Care must be taken to avoid exposing series capacitors to such large short-circuit currents, since this causes excessive voltage rise as well as heating that can damage the capacitors. Specially calibrated spark gaps and short-circuiting switches are deployed within a predetermined time interval to avoid damage to the capacitors.

The interaction between a series-capacitor-compensated ac transmission system in electrical **resonance** and a turbine-generator mechanical system in torsional mechanical resonance results in the phenomenon of **sub-synchronous resonance** (SSR). Energy is exchanged between the electrical and mechanical systems at one or more natural frequencies of the combined system below the synchronous frequency of the system. The resulting mechanical oscillations can increase until mechanical failure takes place.

Techniques to counteract SSR include the following:

- *Supplementary excitation control:* The subsynchronous current and/or voltage is detected and the excitation current is modulated using high-gain feedback to vary the generator output voltage, which counters the subsynchronous oscillations [see El-Serafi and Shaltout, 1979].
- *Static filters:* These are connected in series with each phase of each main generator. Step-up transformers are employed. The filters are tuned to frequencies that correspond to the power system frequency and the troublesome machine natural modes of oscillations [see Tice and Bowler, 1975].
- *Dynamic filters:* In a manner similar to that of excitation control, the subsynchronous oscillation is detected, and a counter emf is generated by a thyristor cycloconverter or a similar device and injected in the power line through a series transformer [see Kilgore et al., 1975].
- *Bypassing series capacitors:* To limit transient torque buildup, complete or partial bypass with the aid of low set gaps.
- Amortisseur windings on the pole faces of the generator rotors can be employed to improve damping.
- A more recent damping scheme [see Hingorani, 1981] is based on measuring the half-cycle period of the series-capacitor voltage, and if this period exceeds a preset value, the capacitor's charge is dissipated into a resistor shunting the capacitor through two antiparallel thyristors.
- A passive SSR countermeasure scheme [see Edris, 1990] involves using three different combinations of inductive and capacitive elements on the three phases. The combinations will exhibit the required equal degree of capacitive compensation in the three phases at power frequency. At any other frequency, the three combinations will appear as unequal reactances in the three phases. In this manner, asynchronous oscillations will drive unsymmetrical three-phase currents in the generator's armature windings. This creates an mmf with a circular component of a lower magnitude, compared with the corresponding component if the currents were symmetrical. The developed interacting electromagnetic torque will be lower.

Synchronous Compensators

A synchronous compensator is a synchronous motor running without a mechanical load. Depending on the value of excitation, it can absorb or generate reactive power. The losses are considerable compared with static capacitors. When used with a voltage regulator, the compensator can run automatically overexcited at high-load current and underexcited at low-load current. The cost of installation of synchronous compensators is high relative to capacitors.

Shunt Capacitors

Shunt capacitors are used to supply capacitive kVAR to the system at the point where they are connected, with the same effect as an overexcited synchronous condenser, generator, or motor. Shunt capacitors supply reactive power to counteract the out-of-phase component of current required by an inductive load. They are either energized continuously or switched on and off during load cycles.

Figure 61.24(a) displays a simple circuit with shunt capacitor compensation applied at the load side. The line current I_L is the sum of the motor load current I_M and the capacitor current I_c. From the current phasor diagram of Fig. 61.24(b), it is clear that the line current is decreased with the insertion of the shunt capacitor. Figure 61.24(c) displays the corresponding voltage phasors. The effect of the shunt capacitor is to reduce the source voltage to V_{s1} from V_{s0}.

From the above considerations, it is clear that shunt capacitors applied at a point in a circuit supplying a load of lagging power factor have the following effects:

- Increase voltage level at the load
- Improve voltage regulation if the capacitor units are properly switched
- Reduce I^2R power loss and I^2X kVAR loss in the system because of reduction in current
- Increase power factor of the source generators

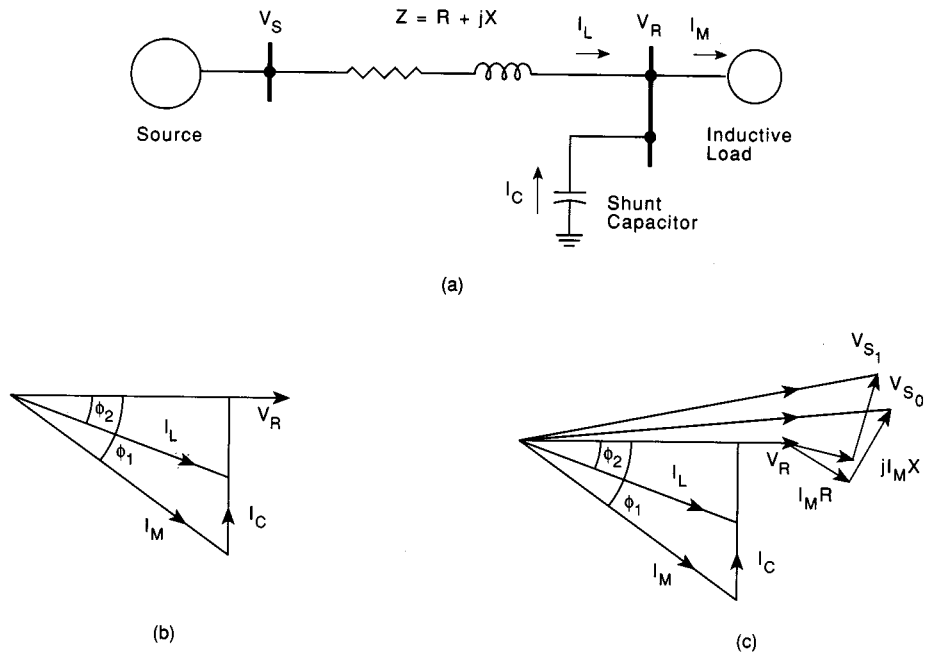

FIGURE 61.24 (a) Shunt-capacitor-compensated load; (b) current phasor diagram; (c) voltage phasor diagram.

- Decrease kVA loading on the source generators and circuits to relieve an overloaded condition or release capacity for additional load growth
- By reducing kVA load on the source generators, additional active power loading may be placed on the generators if turbine capacity is available
- Reduce demand kVA where power is purchased
- Reduce investment in system facilities per kW of load supplied

To reduce high inrush currents in starting large motors, a capacitor starting system is employed. This maintains acceptable voltage levels throughout the system. The high inductive component of normal reactive starting current is offset by the addition, during the starting period only, of capacitors to the motor bus. This differs from applying capacitors for motor power factor correction.

When used for voltage control, the action of shunt capacitors is different from that of synchronous condensers, since their reactive power varies as the square of the voltage, whereas the synchronous machine maintains approximately constant kVA for sudden voltage changes. The synchronous condenser has a greater stabilizing effect upon system voltages. The losses of the synchronous condenser are much greater than those of capacitors.

Note that in determining the amount of shunt capacitor kVAR required, since a voltage rise increases the lagging kVAR in the exciting currents of transformer and motors, some additional capacitor kVAR above that based on initial conditions without capacitors may be required to get the desired correction. If the load includes synchronous motors, it may be desirable, if possible, to increase the field currents to these motors.

The following are the relative merits of shunt and series capacitors:

- If the total line reactance is high, series capacitors are very effective.
- If the voltage drop is the limiting factor, series capacitors are effective; also, voltage fluctuations are evened out.
- If the reactive power requirements of the load are small, the series capacitor is of little value.
- If thermal considerations limit the current, then series capacitors are of little value since the reduction in line current associated with them is small.

Applying capacitors with harmonic-generating apparatus on a power system requires considering the potential of an excited harmonic resonance condition. Either a series or a shunt resonance condition may take place. In

actual electrical systems utilizing compensating capacitors, either type of resonance or a combination of both can occur if the resonant point happens to be close to one of the frequencies generated by harmonic sources in the system. The outcome can be the flow of excessive amounts of harmonic current or the appearance of excessive harmonic overvoltages, or both. Possible effects of this are excessive capacitor fuse operation, capacitor failure, overheating of other electrical equipment, or telephone interference.

Shunt Reactors

Shunt reactor compensation is usually required under conditions that are the opposite of those requiring shunt capacitor compensation (see Fig. 61.25). Shunt reactors are installed to remedy the following situations:

- Overvoltages that occur during low load periods at stations served by long lines as a result of the line's capacitance (Ferranti effect).
- Leading power factors at generating plants resulting in lower transient and steady-state stability limits, caused by reduced field current and the machine's internal voltage. In this case, shunt reactors are usually installed at either side of the generator's step-up transformers.
- Open-circuit line charging kVA requirements in extra-high-voltage systems that exceed the available generation capabilities.

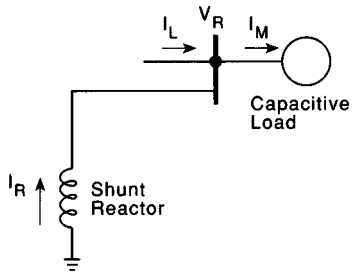

FIGURE 61.25 Shunt-reactor-compensated load.

Coupling from nearby energized lines can cause severe resonant overvoltages across the shunt reactors of unenergized compensated lines.

Static VAR Compensators (SVC)

Advances in **thyristor** technology for power systems applications have lead to the development of the static VAR compensators (SVC). These devices contain standard shunt elements (**reactors**, capacitors) but are controlled by thyristors [El-Hawary, 1995].
